uniquely associated with the parasite (e.g., beta-giardin (*bg*); Lalle et al. 2005). These markers are still widely used for genotyping parasite isolates (Feng and Xiao 2011). In particular, a multi-locus typing scheme based on the *gdh*, *tpi*, and *bg* markers has been consistently used (Cacciò et al. 2008; Lebbad et al. 2010). Nevertheless, the limited genetic variation found in these markers is not sufficient for a full discrimination of isolates. A recent study has demonstrated the potential of a new multi-locus typing scheme, based on six highly variable genes, to distinguish isolates of sub-assemblages AI and AII, trace zoonotic infection, and identity outbreak samples (Ankarklev et al. 2018). Similarly, a new typing scheme with high resolution has been proposed for assemblage B. This scheme is based on sequence analysis of only three markers, but result in clustering the isolates with a resolution similar to that obtained by whole genome comparison (Seabolt et al. 2021). The limitations of the currently available markers and the need for new genotyping tools have been recently reviewed (Capewell et al. 2021).

41.2.2 The Complex Genetics of *Giardia duodenalis*

Giardia is a tetraploid organism (it has two diploid nuclei) and has been considered as an asexually replicating organism (Adam 2021). Replication is equational rather than reductional, which means that nuclear asymmetry is maintained throughout the replication cycle (Yu et al. 2002). Therefore, mutations are expected to be fixed independently in each nucleus and, if genetic exchanges do not occur, allelic heterozygosity should accumulate, as observed in other asexual organisms (Gladyshev and Arkhipova 2010).

Opposite to this prediction, an extremely low level (0.002%) of allelic sequence heterozygosity (ASH) was detected in the genome of an assemblage A isolate (WB isolate, sub-assemblage AI) (Morrison et al. 2007). While this was a surprising finding, whole genome sequencing (WGS) of sub-assemblage AII isolates showed a heterozygosity level of 0.25–0.35% (Ankarklev et al. 2015), and an even higher level (0.43%) was found in the genome of an assemblage B (GS isolate) (Franzén et al. 2009). Additional WGS confirmed variable levels of ASH in *G. duodenalis* assemblages, from 0.89% in assemblage C to 0.74% in assemblage D (Kooyman et al. 2019), and to 0.037% in assemblage E (Jerlström-Hultqvist et al. 2010).

ASH is often visualized as "double peaks" in chromatograms obtained from direct sequencing of PCR products. The majority of the heterozygous sites contain two different bases but some feature three or four, capturing the diversity from all of the copies of the genome. Formally, these sequencing profiles can be generated by the presence of genetically different parasites (i.e., a mixed infection) and/or by ASH in a single population of parasites. Using micromanipulation to isolate single trophozoites from in vitro culture and single cysts from human stools, Ankarklev et al. (2012) showed that ASH is present in both single trophozoites and single cysts. Additionally, different sequence patterns were observed in different cysts originated from the same human patient, thus suggesting the presence of multiple sub-assemblage infections

(Ankarklev et al. 2012). Unfortunately, this elegant approach is unsuitable for multi-locus sequence typing scheme, and difficult to apply routinely.

Certainly, mixed infections with genetically different isolates are common, as demonstrated by the use of assemblage-specific PCR assays (Almeida et al. 2010; Vanni et al. 2012). More recently, Woschke et al. (2021) analyzed longitudinal samples collected from patients in Germany, and demonstrated that reproducible pattern of ASH are discernable and of epidemiologic value.

The reliability of any typing scheme is influenced by the occurrence and extent of genetic exchanges. As mentioned above, the range of allelic heterozygosity observed in *G. duodenalis* (<0.001 to 0.89) is similar to that expected in sexually reproducing organisms (Adam 2021), and this has raised the question of whether canonical meiotic sexual reproduction, or another form of sexuality, is occurring in this parasite. Two lines of experimental evidences are pertinent to that question. First, recombination has been inferred from genotyping data of sub-assemblage AII field isolates in an endemic setting (Cooper et al. 2010), but also between sub-assemblages AI and AII in Europe (Ankarklev et al. 2018), and even between assemblages A and E (Ankarklev et al. 2018).

Second, electron microscopy studies revealed fused nuclei in forming cysts while fluorescent in situ hybridization allowed visualization of plasmid transfer between nuclei (Poxleitner et al. 2008). Based on these observations, a model in which homologous recombination occurs after nuclear envelope fusion was proposed. However, more recently it has been shown that the two nuclei of *Giardia* possess different numbers of chromosomes (aneuploidy, or near tetraploidy) with unequal distribution of individual chromosomes and genes between the two nuclei (Tůmová et al. 2019). This indicates that nuclear differentiation provides opportunities for generation of novel genetic variability.

Clearly, a better understanding of the genetics of *G. duodenalis* remains essential to improve genotyping schemes.

41.3 Epidemiology and Molecular Epidemiology of Giardiasis in Humans

Giardiasis is a very common gastrointestinal infection of humans; it has been estimated that every year about 184 million people in Asia, Africa, and Latin America have symptomatic infections (WHO 1996; Pires et al. 2015). The parasite has a global distribution, but the prevalence of infection is clearly higher in developing regions of the world, where *Giardia* is common in both children and adults (Cacciò and Sprong 2011; Pires et al. 2015).

Infection rates have been reported in both low-income countries (range 8–30%) and high-income countries (range 1–8%) (Feng and Xiao 2011). Those rates are probably higher in individuals with diarrhea, but the current epidemiological scenario is largely influenced by the fact that many countries did not report any data, by the lack of monitoring programs, and by the high rate of asymptomatic carriage of

Giardia in humans (Cacciò and Sprong 2011). This suggests that giardiasis is strongly underdiagnosed and underreported.

In humans, giardiasis is mainly a pediatric infection, with the highest prevalence observed in children aged 0–4 years. This pattern is found in both high- and low-income countries, and is thought to be due to lower hygiene and higher susceptibility of children at the first exposure to the parasite (Cacciò and Sprong 2011). A secondary peak is observed in adults aged 30–40; in this case, women represent the risk category, likely because of direct transmission of *Giardia* from children to their mothers. Other risk groups include institutionalized and adopted children, returning travelers, immigrant/refugees, and in men who have sex with men (Cacciò and Sprong 2011; Escobedo et al. 2010).

Seasonality has been observed in high-income countries. In the USA, a twofold increase in transmission of giardiasis occurs during the summer, and coincides with increased outdoor activities (e.g., swimming and camping) (Yoder et al. 2012). Similarly, a study in New Zealand (period 1997–2006) showed peaks in the late summer and early autumn (Snel et al. 2009). In Europe, higher number of cases was reported from August to October with a peak in September (European Centre for Disease Prevention and Control. Giardiasis (lambliasis). In: ECDC. Annual epidemiological report for 2017. Stockholm: ECDC 2019). Bearing in mind the delay between infection, onset of symptoms, and diagnosis (up to 5 weeks), the late summer/early autumn peak probably represents an increase in infection during late summer months, resulting from travel and outdoor recreational activities.

The routes of transmission for sporadic cases are only partially known, but studies in the USA and the UK have identified international travel, male-male sexual behavior, having contact with children in diapers, and exposure to drinking and recreational water as the most important risk factors (Reses et al. 2018; Horton et al. 2019). These studies therefore suggest that prevention measures should focus on reducing risks associated with diaper handling, sexual contact, swimming in untreated water, and drinking untreated water.

As mentioned above, humans are mostly infected by assemblages A and B, although a small number of individuals have been found infected with assemblage C, E, and F (Ryan and Zahedi 2019; Cai et al. 2021). The geographical distribution of assemblages largely overlaps, but globally assemblage B is more prevalent than assemblage A.

Genetic characterization of isolates of assemblage A is relatively straightforward, also because of the low level of ASH. Phylogenetic analysis of multiple markers (Cacciò et al. 2008; Lebbad et al. 2010; Ankarklev et al. 2018) showed three strongly supported groups, namely, sub-assemblages AI, AII, and AIII. Clearly, animal-derived isolates are grouped in sub-assemblages AI and AIII, but never in sub-assemblage AII. On the other hand, most human-derived isolates belong to sub-assemblage AII, but a few are grouped in sub-assemblage AI. The latter may represent cases of zoonotic transmission, and, when available, data on exposure substantiated contact with animals as a risk (Ankarklev et al. 2018). Of note, the high genetic variability of the markers allowed distinguishing isolates from outbreaks, which shared a specific multi-locus genotype not observed in unrelated, sporadic

cases from the same country (Ankarklev et al. 2018). The good discriminatory power of this scheme has been recently confirmed by another study (Woschke et al. 2021).

The situation is less clear for assemblage B. Indeed, while more genetic variability is present in the genotyping markers, the high level of ASH complicate the assignment of isolates to specific genotypes or multi-locus genotypes (Woschke et al. 2021).

41.4 Epidemiology and Molecular Epidemiology of Giardiasis in Animals

This section will only provide a concise account of the many studies published in recent years. Interested readers can find additional details in exhaustive review articles (Ryan and Zahedi 2019; Cai et al. 2021). As a general comment, is may be useful to recall that the current knowledge on the prevalence and distribution of genotypes of *Giardia* in animals is still incomplete, as data from many areas of the word are scanty, particularly from Central and South American countries, where giardiasis is endemic in humans (Coelho et al. 2017; Rivero et al. 2020).

41.4.1 Farm Animals

The prevalence of *Giardia* in farm animals is clearly influenced by the age of the animals tested, the study design, the sensitivity of the diagnostic methods, the geographical and climatological parameters, and management practices (Ryan and Zahedi 2019).

In cattle, the infection has a global distribution, with animal prevalence ranging from 1% to 74%, and farm prevalence from 45% to 100%. In general, the prevalence is higher in young animals compared to adults, and in dairy cattle compared to beef cattle (Ryan and Zahedi 2019).

In sheep, the animal prevalence ranges from 1.5% to 89% and the farm prevalence from 10% to 100% (Feng and Xiao 2011; Ryan and Zahedi 2019). As for cattle, the prevalence is higher in lambs than in adult sheep. In goats, the animal prevalence ranges from 4% to 43% and the farm prevalence from 66% to 95%. In pigs, the animal prevalence ranges from 0.6% to 26.9% and the farm prevalence from 10% to 84% (Feng and Xiao 2011, Ryan and Zahedi 2019). The data at the farm level, although variable, indicate that a large proportion of animals will become infected at a time (Xiao and Herd 1994).

From a public health perspective, identification of the assemblage, sub-assemblage, and genotype from animal samples is essential to infer zoonotic potential (Ryan and Cacciò 2013; Cai et al. 2021). Molecular surveys have shown that assemblage E largely predominates (prevalence >90%) in cattle, globally. In a recent review that examined studies published since 2012 (Ryan and Zahedi 2019), typing data from 2672 cattle showed assemblage E in 2426 animals, assemblage A in 207 animals, assemblage B in 29 animals, and mixed assemblages in 37 animals.

A similar distribution was found in yaks from China and in water buffaloes, with dominance of assemblage E (Ryan and Zahedi 2019; Cai et al. 2021). Importantly, the main sub-assemblage in assemblage A in cattle is AI, which is uncommon in humans, thus suggesting a minor role of cattle as zoonotic reservoir.

In sheep and goats, assemblage E clearly predominates, followed by assemblage A (Ryan and Zahedi 2019, Cai et al. 2021). Like for cattle, sub-assemblage AI is the most common variant, although sub-assemblage AII was reported in some studies (see Cai et al. 2021).

In pigs, Assemblage E is the most commonly found, and among isolates belonging to assemblage A, sub-assemblage AI was found.

In horses, the prevalence ranges from 1.5% to 17.4%, being usually higher in foals than in adults (Cai et al. 2021). Contrary to what is reported above for other farm animals, surveys conducted in Europe, South America, and Asia showed that most positive samples from horses had assemblages A and B, with identification of sub-assemblage AI.

41.4.2 Companion Animals

Giardiasis is a common infection of dogs and cats, with prevalence ranging from1.1% to 45.9% (Bouzid et al. 2015; Ryan and Zahedi 2019; Cai et al. 2021). This wide range of prevalence can be attributed to the use of diagnostic techniques with different sensitivity (microscopy, ELISA, and PCR), but also to the nature of the population studied (household, shelter, stray), the animal age, breed, spay/neuter status, and geographic location (Ryan and Zahedi 2019; Cai et al. 2021). In general, the highest prevalence is observed in younger animals and in kennel or shelter populations.

Molecular analysis of dog isolates showed that the host-specific assemblages C and D are more prevalent than the zoonotic assemblages A and B, although a remarkable number mixed infections was found (Ryan and Zahedi 2019; Cai et al. 2021).

Among cats, the host-specific assemblage F is the most prevalent, followed by assemblage A, with less frequent reports of assemblage B, C, D, and E (Ryan and Zahedi 2019).

41.4.3 Wild Animals

As mentioned above, a number of host-adapted species (*G. muris*, *G. microti*, *G. peramelis*, *G. agilis*, *G. cricetidarum*, *G. ardeae*, and *G. psittaci*; Table 1) are known to infect a wide range of wild animals. However, the zoonotic assemblages A and B are also commonly found in wild animals.

In non-human primates (NHP), data from chimpanzees, gibbons, gorillas, macaques, monkeys, and lemurs indicate a prevalence ranging from 4.8% to 57.8% (Ryan and Zahedi 2019; Cai et al. 2021). In many cases, surveys have

concerned captive animals, where transmission of *Giardia* may differ from that occurring in the natural environment. However, genotyping data have shown a similar distribution of assemblages in captive and wild NHPs, with assemblages A and B present, and the latter being more prevalent. Thus, NHP and humans share similar distribution and relative proportion of *G. duodenalis* assemblages.

In rodents, the prevalence of *G. duodenalis* infection is high, ranging from 6% to 66.3% (Cai et al. 2021). The host-specific assemblage G and the zoonotic assemblage B have been commonly found in species such as chinchillas, bamboo rats, and beavers. Beavers are of particular interest, since it was association between infection in these animals and waterborne outbreaks of human giardiasis that led the World Health Organization to classify *Giardia* as a zoonotic parasite (WHO 1979). In Canada and North America, giardiasis is also known as "beaver fever" and the role of these animals as source of human infection through contamination of drinking source water has been argued since many years, but proved difficult to confirm. Recently, a retrospective comparative genomics analysis of *Giardia* isolates following various waterborne outbreaks have shown clustering of human isolates with isolates from surface water and beavers implicated to be sources by public health (Prystajecky et al. 2015; Tsui et al. 2018). Thus, beavers can act as an amplification host or reservoir host for *G. duodenalis* in watersheds.

In wild hoofed animals, assemblage E is rare, while it is highly prevalent in livestock. Interestingly, sub-assemblage AIII appears to be largely restricted to this group of animals, albeit it has been found in a cat (Lebbad et al. 2010), but never in humans.

In wild carnivores, molecular analyses have shown that the host-adapted assemblage D is prevalent in coyotes, raccoon dogs, foxes, and wolves, but assemblages A and B have been found in most wild carnivores tested (Cai et al. 2021). The most common sub-assemblage found in these hosts is AI.

In marsupials, one of the dominant mammalian groups within watersheds in Australia, data from 31 species belonging to 9 families have indicated a prevalence ranging between 1.3% and 24.1% (Ryan and Zahedi 2019). Molecular typing has detected assemblages A and B with higher frequency compared to the host adapted species, *G. peramelis* (Ryan and Zahedi 2019). Although sporadically, assemblages C, D, and E have also been reported in marsupials, suggesting transmission between multiple hosts.

In marine mammals, including seals, dolphins, whales, and porpoise, all *G. duodenalis* assemblages, except assemblage E, have been found. These animals often harbor the host-specific assemblage H, which has never been detected in humans (Ryan and Zahedi 2019).

41.5 Remarks on Zoonotic Transmission

With the increased application of molecular typing techniques, it is becoming clear that most animal species do not act as reservoirs of *Giardia* cysts infectious to humans. This is based on the higher occurrence of host-adapted assemblages (C to H)

in animals, which are rarely described in humans (Cacciò et al. 2018; Cai et al. 2021). Moreover, the identification of sub-assemblages AI and AII in animals, and the lack of sub-assemblage AII, which seems to be largely adapted to humans, suggest that zoonotic transmission of assemblage A is limited, although possible.

The situation is less clear for assemblage B, also due to difficulties in genotyping isolates caused by high ASH, but future efforts should focus on this assemblage. High-resolution typing of isolates using whole genome data, although technically demanding, can generate relevant data, as already shown (Tsui et al. 2018). Well-designed studies that include evaluation of risk factors and consider cross-species transmission in endemic settings, such as rural areas where people, domesticated animals, and wildlife overlap (e.g., Kuthyar et al. 2021), remain important to assess zoonotic transmission.

41.6 Waterborne and Foodborne Giardiasis

Although the importance of zoonotic transmission is still to be understood, there is little doubt that a large number of different hosts can shed *Giardia* cysts in the environment, thus potentially contribute to contamination of water and food. Not surprisingly, a plethora of studies have demonstrated the ubiquitous presence of *Giardia* cysts in all water samples tested, including raw and treated wastewater, surface water, ground water, and drinking water (reviewed by Hamilton et al. 2018).

Quite logically, contamination is highest in untreated wastewater samples, and, indeed, up to 77% of the samples from published studies (1543 of 2010) were positive, with concentrations of up to 1,200,000 cysts per liter (Hamilton et al. 2018). In treated wastewater samples, the maximum concentration reported was of 51,333 cysts per liter. The number of positive samples, and the concentration in *Giardia* cysts, decreases in surface water samples, yet the reported levels range from 0.01 to 1000 cysts per liter in river water samples, from 0.004 to 16.2 cysts per liter in samples from lakes and dams, and from 0.3 to 33 cysts per liter in beach waters (Hamilton et al. 2018). Since these water sources are used for recreational activities or for the production of drinking water, contamination with *Giardia* cysts is of particular relevance for public health.

The ability of the *Giardia* cyst stage to withstand chlorine disinfection of water and to persist for long periods in the environment while maintaining viability, coupled with the low infective dose, clearly enhances its transmission (Boarato-David et al. 2017).

A recent review examined waterborne protozoan outbreaks during the period from 2017 to 2020, and found that *Giardia* has been responsible for 48 of the 251 outbreaks (Ma et al. 2022). Almost all outbreaks were reported in the USA, UK, and New Zealand, a finding most likely explained by more advanced diagnostic capabilities and existence of surveillance programs to monitor water contamination in high-income countries. Large outbreaks linked to contaminated drinking water have been reported in Portland (USA) with about 50,000 infected individuals, and in Bergen (Norway) with about 2500 infected individuals.

Food can also be a vehicle of *Giardia* transmission. The detection of parasite cysts in food is difficult, because contamination levels are expected to be low and available detection methods have sub-optimal performance (e.g., microscopy), or are costly (e.g., immunomagnetic separation). Moreover, specific characteristics of food may interfere with extraction/elution of cysts, therefore influencing recovery and leading to an underestimation of the contamination.

Nevertheless, cysts have been detected on dairy products, meat, shellfish, fruit, and vegetables (Ryan et al. 2019). Fresh produce, which are often consumed raw, is thought to represent the high-risk food.

Few outbreaks of foodborne giardiasis have been identified and investigated, all in the USA, and have been linked to various foods, with fresh produce being the most common food type. Investigations have indicated infected food handlers as the most common source of contamination (Ryan et al. 2019).

41.7 Giardiasis in Humans

Human giardiasis occurs with heterogeneous clinical manifestations and high variability in the severity of disease, ranging from the lack of apparent symptoms (subclinical or asymptomatic giardiasis) to acute or chronic illness (Farthing 1997). Symptoms usually appear within 2 weeks after ingestion of cysts and last for up to 6 weeks. Diarrhea is the commonest symptom of the acute phase accompanied by greasy stools, flatulence, abdominal discomfort, fatigue, and weight loss. Fever, nausea, vomiting, itch, and urticaria are far less common (Farthing 1997). Acute symptoms are generally self-limiting and resolve following clearance of the parasite. Although recurrent infection can be frequent in poor-hygiene settings, persistent (chronic) infection, with intermittent or no symptoms, has been observed worldwide in some patients to last far more than 2 months, up to years (Escobedo et al. 2014). Low production of specific anti-*Giardia* antibodies, malnutrition, immunosuppression, and co-infection with other pathogens have been associated with the development of chronic giardiasis (Fink and Singer 2017; Escobedo et al. 2018). Extraintestinal manifestations have been reported in up to 30% of infected patients, and include ocular pathologies, reactive and post-infectious arthritis, IgE-mediated allergies, and muscular complication due a decrease in potassium level following diarrhea (Halliez and Buret 2013). Long-term sequelae are well documented too, in both adults and children. In low-income countries and poor-hygiene settings, where giardiasis is endemic and highly prevalent in children below 2 years of age, worsening of symptoms has been reported (Platts-Mills et al. 2015). A prospective longitudinal studies on a large children cohort clearly identified giardiasis, independently of diarrheal disease (Muhsen and Levine 2012), as a risk factor to develop failure-to-thrive syndrome, malnutrition, malabsorption, retarded growth and development, and poor cognitive functions (Donowitz et al. 2016; Rogawski et al. 2017). In high-income countries, patients who experienced symptomatic giardiasis are at high risk to develop long-term post-infectious sequelae, such as post-infectious irritable bowel syndrome (PI-IBS) and chronic fatigue (CF),

with a higher provability compared to other gastrointestinal infections (Litleskare et al. 2018; Halliez and Buret 2013; Nakao et al. 2017; Dormond et al. 2016). The prevalence of PI-IBS in patients infected with *Giardia* is significantly higher compared to control groups, even 10 years after infection (Litleskare et al. 2018). Delays in diagnosis and treatment of giardiasis might cause/increase the risk of chronic infection and the development of PI-IBS and CF (Mørch et al. 2009). The complex interplay between host factors (immunological response, gut microbiota) and parasite factors (e.g., genotype/assemblage-specific pathogenic mechanisms) accounts for the extreme variability in clinical manifestations, although our understanding of this complexity is still incomplete (Fig. 2) (Allain and Buret 2020). Acute symptomatology (i.e., diarrheal disease), and also malabsorption, are the result of an alteration of the intestinal barrier function induced by the parasite, which occurs via enterocyte apoptosis, increased intestinal permeability, and disruption of microvillous brush border and villus shortening (Allain and Buret 2020). To resist peristaltic flow, *G. duodenalis* trophozoites tightly adhere to the surface of enterocytes of the small intestine epithelium, without invading the intestinal tissue. Attachment occurs mechanically via the ventral disc, a microtubule-based suckling structure, and via chemical binding mediated by specific proteins, such as giardins and lectins (Müller and von Allmen 2005). Although mechanical damages (i.e., ventral disc imprint) were observed in vivo on mouse enterocytes infected by *G. muris* (Erlandsen and

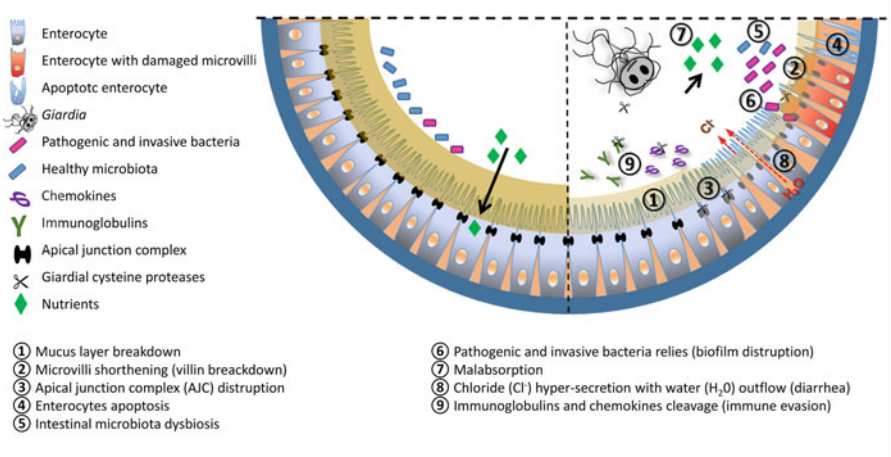

Fig. 2 *Giardia* pathogenic mechanisms. *Giardia* adheres to the mucosa of small intestine (by ventral disk and adhesive proteins) and induces disruption of the epithelial barrier via: (1) mucus layer breakdown, (2) shortening of microvilli, (3) disruption and alteration of apical junctional complexes, (4) enterocyte apoptosis. *Giardia* (5) alters the relative composition of intestinal microbiota, and (6) promotes disruption of biofilms of pathobionts. Impairment of intestinal function by Giardia leads to (7) malabsorption of water, glucose, nutrients, and electrolytes, (8) leading to chlorine hypersecretion water outflow into the intestinal lumen and diarrhea. *Giardia* survives host immune system and modulate inflammatory response by (9) cysteine protease-mediated cleavage of immunoglobulin and chemokines/cytokines

Chase 1974) or *G. duodenalis* (Khanna et al. 1990), and in vitro on MDCK cell lines incubated with different *G. duodenalis* isolates (Chávez et al. 1995), a similar damage was not observed when examining human biopsies. Nevertheless, duodenal biopsies of patients with chronic giardiasis showed villus shortening, decreased transepithelial electrical resistance (TEER) and increased paracellular permeability, altered ion and glucose transport, downregulation of tight junction proteins (i.e., claudin 1), and increased apoptosis of enterocytes (Troeger et al. 2007). Since epithelial microvilli are responsible for nutrient-coupled absorption of electrolytes (particularly Na and D-glucose), their shortening impairs the absorption of water, glucose, and electrolytes. This imbalance causes chloride hyper-secretion with water outflow into the intestinal lumen, resulting in distension, rapid peristalsis, and diarrhea (Maàyeh and Svärd 2017). *Giardia* can compromise the intestinal barrier function in several ways, particularly via the activity of excretory/secretory products (ESPs). Damaging of brush-border microvilli occurs at the expense of cytoskeleton both directly, via degradation of the key actin-binding protein villin by *Giardia* secreted cysteine proteases (CPs), and indirectly, via modulation of phosphorylation level and degradation of villin and ezrin by T-lymphocyte CD4+/CD8 + -mediated immune responses (Solaymani-Mohammadi and Singer 2013; Bhargava et al. 2015). Additionally, the agglutination properties of *Giardia* lectins on enterocyte membrane, to which the parasite adheres, might contribute to microvillus shortening (Farthing et al. 1986).

The intestinal barrier integrity can also be compromised by depletion of the mucus barrier, breakdown of apical junctional complexes (AJCs), and apoptosis of enterocytes in an ESP-mediated manner. *Giardia* can thin the mucus layer, coating the enterocytes surface, by CP-mediated cleavage of mucin-2, and can further deplete the mucin stock by triggering mucus hypersecretion from goblet cells via cleavage and activation of protease-activated receptor 2 (Amat et al. 2017; Fekete et al. 2022). The lack of the mucus barrier indeed promotes parasitic colonization and access of the trophozoites to enterocyte cell membrane. Proteins from AJCs, particularly those in tight and adherent junctions (claudins, occludins, ZO proteins, E-cadherin, β-cathenin), are targeted and degraded by *Giardia* CPs (Ma'ayeh et al. 2017; Liu et al. 2018; Ortega-Pierres and Argüello-García 2019). In a human organoid-derived in vitro model of giardiasis, disruption of tight junctions and loss of epithelial barrier function with decrease in TEER activation was observed early in response to Giardia infection, and associated to the activation of enterocytes cAMP/PKA signaling pathways (Holthaus et al. 2021). Giardia also induces enterocyte apoptosis mediated by activation of pro-apoptotic caspase-3 and -9, increased expression of pro-apoptotic Bax, decreased expression of anti-apoptotic Bcl-2, and induced proteolytic cleavage of poly(-ADP-ribose) polymerase (PARP). Impaired glucose uptake by Giardia through SGLT1 inhibition is another mechanism associated with activation of the apoptotic pathway in enterocytes (Maàyeh and Svärd 2017). However, the identity of *Giardia* molecules responsible for the activation of these different pathways is still unknown.

Pathogenesis and outcomes of giardiasis, and the composition of gut microbiota, are strictly correlated, as mainly observed in animal models. Colonization of the host

gut can be controlled by commensal microbiota that prevent establishment of the parasite (Fekete et al. 2021). In turn, during the acute phase of infection, the parasite can induce alteration in the microbiota, both at the site of infection and beyond (Fekete et al. 2021). This alteration results in an enrichment of bacterial taxa showing high metabolic flexibility and better oxygen tolerance, with lipids and arginine as energy source (Fink and Singer 2017). Moreover, the breakdown of the mucus layer induced by *Giardia* can also promote disruption of microbiota biofilms, leading to the release of pathobionts that in turn triggers an inflammatory response eventually responsible for the development of post-infection inflammatory diseases (Fekete et al. 2021). Further evidences also indicate that the microbiota may play an important role in the development of stunting associated with giardiasis (Singer et al. 2020).

Giardia infection is characterized by an absence of overt inflammatory cell infiltration, thus with a low inflammatory response of the mucosal layer (Oberhuber et al. 1997). Giardia takes advantage of multiple strategies to evade the host's immune system and modulate local inflammatory responses. The parasite possess a mechanism of antigenic variation that relies on the exposure of variant surface proteins (VSPs), which form a dense coat on the surface of the trophozoite (Gargantini et al. 2016). The VSPs repertoire is large, with up to 300 different members, and highly variable between assemblages and even among isolates (Franzén et al. 2009). Only one VSP is predominantly expressed at any time by the parasite, and its replacement during infection allows the parasite to escape the immune response (Gargantini et al. 2016). Sera from *Giardia*-infected individuals recognize VSPs, as well as other *Giardia* secreted proteins, indicating their importance in antibody-mediated immunity (Moss et al. 2014). Indeed, a significantly lower anti-VSP IgG/M response is associated with chronic infections (Hjøllo et al. 2018). Simultaneous exposure of the immune system to multiple VSPs represents a promising vaccine strategy (Serradell et al. 2016). *Giardia* is also able to neutralize antimicrobial molecules produced by the host. Secretion in the gut lumen of parasite enzymes able to metabolize arginine (i.e., arginine deiminase [ADI], ornithine carbamoyl transferase [OCT)], and of CPs result in the inhibition of nitric oxide production, by arginine consumption, and cleavage of antimicrobial defensins, respectively (Liu et al. 2019; Eckmann et al. 2000). Giardia CPs also degrade host immunoglobulins (IgG, IgA1, and IgA2) and pro-inflammatory chemokines/cytokines (CXCL1–3, CXCL8, CCL2, and CCL20) (Ortega-Pierres and Argüello-García 2019). Evidences from in vitro long-term exposure of human enterocytes to *Giardia* trophozoites and from duodenal biopsies of children (<2 years) suffering from environmental enteric dysfunction (EED), a subclinical disorder of intestinal function common in tropical countries and in settings of poverty and economic disadvantage, and giardiasis indicate that *Giardia* also induces downregulation of genes associated with host inflammatory response pathways (Roxstrom-Lindquist et al. 2005; Haberman et al. 2021). In the gerbil model of giardiasis, a switch from an initial Th1/proinflammatory response to a marked Th2 response was observed during late infection (Serradell et al. 2018).

The host immune response can control primary *G. duodenalis* infection by multiple immunological factors. Increasing evidences indicate that CD4+ T cells

are essential for parasite clearance, since T cell-deficient mice fail to control infection. In particular, a prominent role is played by the Th17 cell population, which produces IL-17 in IL-6-dependent manner. Upregulation of IL-17 during murine or bovine infections was reported, whereas IL-17 deficiency in mice results in a delay in parasite clearance (Singer et al. 2019). The complement system is also involved in activating and mediating downstream immune responses during infection. Mice deficient for the complement receptor C3aR displays a reduced T-cell response against parasite antigens following infection (Singer et al. 2019).

The role of secretory IgA in parasite clearance and in protection against reinfection is controversial. IgA are produced in response to intestinal infections by B-cells within the intestinal lamina propria, and then transported in the gut lumen by the enterocytes (Fink and Singer 2017). An increased risk of giardiasis with chronic diarrhea, malabsorption, and even lymphoid hyperplasia has been observed in patients with IgA immunodeficiency, and patients with symptomatic giardiasis had significantly lower secretory IgA levels in fecal samples (Swain et al. 2019). Evidence from the murine model of infection with *G. muris* suggested that IgA antibodies contribute to protective immunity (Fink and Singer 2017). However, while *G. muris* infection can persist in pIgR-deficient or B cell-deficient mice (with impaired IgA production), no difference in parasite clearance were observed in mice infected with *G. duodenalis*, irrespective of IgA deficiency (Fink and Singer 2017). In gerbils infected with *G. duodenalis*, the amount of fecal IgA was directly proportional to the inoculum (dose) of trophozoites, while the elimination of cysts was inversely proportional to the dose and to fecal IgA levels (Amorim et al. 2010). Mast cells (MCs) also play a role in the immune response against *Giardia*. As shown in the murine infection model, MCs are massively recruited to the small intestine during infection and are linked to IgA production, as mice deficient in the receptor protein kinase c-kit, a weak activator of MCs, failed to produce parasite-specific IgA (Fink and Singer 2017).

41.8 Giardiasis in Other Mammals

Clinical signs of giardiasis has been documented in both livestock and companion animals, although less extensively than in humans. On the other hand, and despite the availability of the murine and gerbil models, information on Giardia-induced pathogenesis in animals is fragmentary.

Infection in dogs and cats is mostly asymptomatic. When present, clinical signs in dogs range from slight abdominal discomfort to severe abdominal pain, cramps, and soft to watery diarrhea, whereas acute diarrhea and weight loss are more commonly reported in cats (Tangtrongsup and Scorza 2010; Janeczko and Griffin 2010). As observed in humans, infection is more common in puppies and in kittens than in adults, likely as the result of an immature immune system (Dixon 2021). For both animal species, shedding of cysts is similar in healthy and in symptomatic animals (Thompson et al. 2008; Tangtrongsup and Scorza 2010; Tysnes et al. 2014). As for humans, the clinical presentation of giardiasis in animals is likely influenced by strain variability, genetic predisposition, presence of other pathogens, gut microbiota

composition, nutritional status, stress, and immunosuppression (Uiterwijk et al. 2019). Noteworthy, chronic giardiasis is also observed in dogs. Study on puppies naturally infected with G. duodenalis (assemblages C and/or D) lead to the conclusion that the disease is not self-limiting and can last for over 5 months, in the absence of any treatment (Boucard et al. 2021). Moreover, a marked alteration of the gut microbiota was observed in puppies shedding high number of cysts compared to those that shed low numbers, suggesting microbiota-mediated impaired intestinal function (Boucard et al. 2021).

Infection with *Giardia* is very common in ruminants, and can be associated with diarrhea, weight loss, and malabsorption; however, asymptomatic infections are also common (Thompson et al. 2008; Geurden et al. 2010). Malabsorption has been reported in infected calves and goat kids, and related to an increased number of intraepithelial lymphocytes, suggestive of epithelial permeability, and a decreased villus to crypt ratio (Ruest et al. 1997; Koudela and Vítovec 1998). The relevance of Giardia as a causative agent of diarrhea in ruminants is still unclear, as diarrheal disease is influenced by other factors, such as co-infections with other pathogens and husbandry practices. Nevertheless, even asymptomatic infections can have a negative impact in production and growth performance in livestock. Indeed, pre-weaned dairy calves positive for Giardia showed a reduced daily gain compared to Giardia-negative calves (Santin 2020).

In sheep and goats, Giardia can cause severe diarrhea, depression, weight loss, and mortality, and infection has been associated with poor feed efficiency and decreased weight gain (Thompson et al. 2008; Geurden et al. 2010). In an outbreak caused by Giardia Assemblage B in a sheep farm, malabsorption, decreased weight gain, and impairment in feed efficiency was associated with excretion of malodorous and poorly formed feces, but not with diarrhea. A mild to severe infiltrative enteritis with eosinophils, lymphocytes, and plasma cells was detected in histological sections of the gut (Aloisio et al. 2006). Giardiasis in sheep was associated with a reduced carcass weight (Jacobson et al. 2016). In pigs, Giardia has been associated with diarrhea; however high rates of infection have also been reported in asymptomatic pigs (Armson et al. 2009; Akinkuotu et al. 2019). Characterization of the assemblage is important, since pigs infected with assemblage E showed soft/diarrheic feces, whereas those infected with assemblage A did not (Armson et al. 2009). Giardiasis has been reported also in horses but clinical signs of infection are rarely observed. When present, particularly in young and aged or immunologically suppressed horses, symptoms include mild/self-limiting diarrhea, severe in case of heavy infections, poor hair coat, and weight loss (Siwila 2017).

41.9 Treatment of Giardiasis in Human and Animals

Currently, no vaccine is available to protect humans from *Giardia* infection. Treatment options then rely on a limited pool of effective molecules, with metronidazole (MTZ) and other long acting 5-nitroimidazoles (tinidazole, secnidazole, and ornidazole) being the first-line drugs (Lalle 2010). Treatment of symptomatic cases

of giardiasis is always recommended, particularly in low-endemic areas, to alleviate disease's severity, prevent chronic infection, and reduce the risk of spreading the infection (Lalle and Hanevik 2018). The 5-nitroimidazoles are pro-drugs that can exert their toxic effects only after reduction of the nitro group into reactive nitroimidazole intermediates. As this happens in a strongly reductive environment, only anaerobic/microaerophilic organisms are targeted by the drugs (Lalle 2010; Lalle and Hanevik 2018). Standard MTZ regimen in adults consists of three doses/day of 250 mg or 500 mg of drugs for 7 or 5 days, respectively. For children, 5–7 mg of MTZ is administered three times/day for 5–7 days (Mørch and Hanevik 2020). Tinidazole, secnidazole, and ornidazole are commonly administered in a single-dose regimen of 1–2 g in adults and 20–50 mg/kg in children (Mørch and Hanevik 2020). Unpleasant side effects and an increase of cases that are refractory to MTZ treatment, particularly among returning travelers from Asia, are posing new challenges for the management of giardiasis (Lalle and Hanevik 2018). To treat cases of refractory giardiasis, different regimens of MTZ and of second-line drugs, such as albendazole and cloroquine, either individually or in combination, have been used successfully (Lalle and Hanevik 2018).

An inactivated veterinary vaccine (GiardiaVax), composed of killed trophozoites isolated from a sheep (unknown assemblage), was licensed to prevent disease and reduce cyst shedding in dogs (Siwila 2017). As the efficacy of this vaccine is contradictory in calves and cats, and even in dogs, it has been withdrawn from several markets, worldwide (Siwila 2017; Geurden et al. 2014). An oral vaccine formulation comprising VSPs immunopurified from trophozoites of the *Giardia* WB isolate expressing full VSP repertoire has proven effective to reduce clinical signs and to prevent new infections in experimentally infected gerbils, puppies, and kittens (Serradell et al. 2016). Noteworthy, immunization of dogs with this vaccine in an endemic area resulted in a decrease of *Giardia* infection among children living in the same area (Serradell et al. 2016).

Pharmacological treatment of symptomatic companion animals is widely used to reduce the potential zoonotic transmission to human. Treatment approval varies between countries. Fenbendazole is widely registered in EU countries for the treatment of dogs, and it is also recommended for cats. A combination tablet containing febantel/pyrantel/praziquantel is licensed for dogs in European countries and countries outside the EU (ESSCAP 2018). Metronidazole is also licensed in most European countries for dogs and cats, but onset of serious adverse effects of the CNS in dogs treated recurrently or with high dose might discourage its use (Robertson 2021). Currently, no drugs are approved for treatment of giardiasis in pets in USA, but fenbendazole and metronidazole are commonly used as well (Siwila 2017). No drug is licensed for treatment of giardiasis in ruminants or other livestock. Treatment with fenbendazole, albendazole, and the broad-spectrum antibiotic paromomycin is effective in improving clinical conditions (decreased diarrhea and increase weight gain) and in reducing cyst shedding. However, drug treatment of ruminants might be of limited significance, due to the high risk of reinfection associated to high environmental contamination of farm and high costs for producers (Siwila 2017; Robertson 2021).

41.10 Conclusions

The issue of zoonotic transmission has dominated the debate around *Giardia* for about 30 years, since the WHO recognized giardiasis as a zoonosis. In recent years, there have been substantial advances in our understanding of the biology, genetics, and taxonomy of *Giardia*, and a wealth of data has been generated through the molecular characterization of isolates from many hosts and from the environment. We now understand that the genetics of *Giardia* is complex, and that more complexity is found among isolates of assemblage B, possibly due to more frequent genetic exchanges. Molecular epidemiologic surveys have demonstrated that animals are more commonly infected with assemblage-specific *Giardia* parasites that are not infectious to humans. However, animals are also infected with assemblage A and B, which are zoonotic. Sub-assemblages AI and AII are found in both humans and animals, but sub-assemblage AI is preferentially found in livestock and pets whereas sub-assemblage AII is predominantly found in humans. Sub-assemblage AIII is almost exclusively found in wild hoofed animals, and is likely to be non-zoonotic. The host distribution of assemblage B is predominantly human and non-human primates, but many other mammals are also infected. Therefore, while the potential for zoonotic transmission exists, studies in well-defined epidemiologic settings are needed to confirm which animal can act as reservoir and under which conditions zoonotic transmission can occur. Further, the extent of reverse zoonotic transmission (i.e., from humans to animals) should also be evaluated in view of its importance for conservation management.

Concerning the pathology of giardiasis, current knowledge on disease outcomes in animals is limited and not linked to the different Assemblages potentially infecting both human and animal. Zoonotic transmission and differences in symptomatology are questions that certainly need to be further investigated. Some evidences suggest that vaccination of companion animals can be a valuable strategy to prevent human giardiasis, particularly in poor-hygiene settings where anthropozoonotic transmission is likely to occur and the zoonotic Assemblages A and B are mainly present. The possible role of animal reservoirs in the onset of parasite resistance to drugs (e.g., nitroimidazoles) should also receive attention.

Future studies, in particular, those aimed at further comparative genomics of assemblages, should lead to a more comprehensive understanding of the host-specificity and transmission cycles of *Giardia*.

Abstract

Leptospirosis is a biphasic febrile illness common in tropical and subtropical regions. Clinically, patients may present with a mild, influenza-like illness through to syndromes revealing multiorgan failure. The aim of the current review is to focus on the rare neurological and psychiatric complexities of leptospirosis. A review of neuroleptospirosis and psychosis in leptospirosis will precede a review of the extant literature concerning acute disseminated encephalomyelitis following a leptospiral infection. Physicians working in areas where the incidence of leptospirosis is high should remain cognizant of patients with leptospirosis presenting primarily with a neurological syndrome. Such awareness will ensure a diagnosis of leptospirosis is not delayed and appropriate treatment strategies implemented.

Keywords

Infectious disease · Leptospirosis · Neuroleptospirosis · Psychosis · Acute disseminated encephalomyelitis · Neurology · Psychiatry · Psychology · Neuroscience

42.1 Introduction

Since the previous edition of this body of work, there have been advances in molecular biology that reveal that the genus *Leptospira* consists of 66 species that can be classified across four subclades. Pathogenic leptospires belong primarily in the P1 subclade of the new classification (Casanovas-Massana et al. 2020; Vincent et al. 2019). Serologically, there are more than 300 distinct leptospiral serovars arranged across 30 serogroups (World Organization for Animal Health 2022). The current chapter in this second edition of Zoonoses – Infecting Humans and Animals, is not aiming to provide an all-encompassing review of the extant leptospirosis literature. There is a plethora of excellent reviews in the medical and scientific literature reviewing leptospirosis and those looking for extensive reviews of great breadth and depth in the area are directed to the work of Ellis (1990), Levett (2001), Adler and de la Peña Moctezuma (2010), Levett and Haake (2010), Adler (2015), the first addition of this series (Craig et al. 2015), and of course the seminal review of the topic by Faine et al. (1999). The aim of the current review is to focus on the rare neurological and psychiatric complexities of leptospirosis. This will manifest itself with a review of neuroleptospirosis, which in isolation of other symptomology is a rare presentation of leptospirosis. The chapter will also offer a review of psychosis in leptospirosis and a review of the extant literature concerning acute disseminated encephalomyelitis

(ADEM) following a leptospiral infection. In discussing ADEM, Hill's (1965) perspectives of causation will be considered in assessing if ADEM following an episode of leptospirosis is a coincidence. Such a review is timely given the emergence of these neurological and psychiatric manifestations in the course of leptospirosis, and, secondly, given that altered mental status is a poor prognostic indictor.

42.2 Leptospira

In their reviews Reik (1987) and Levett (2001) describe leptospires, the causative infectious agent of leptospirosis, as 6–20 μm in length with a diameter of 0.1–0.2 μm and may consist of 30–50 closely wound spirals. Leptospires morphologically resemble a corkscrew when they are observed in scanning electron micrographs (Tulsiani et al. 2011; Willcox 1976). Leptospirosis has been reported in over 150 mammalian species (Picardeau 2013; Ko et al. 2009). The main animal reservoirs include rodents, dogs, cattle, horses, and pigs. These animals may act as maintenance hosts for adapted serovars such as serovar Canicola in dogs or serovars Ballum, Icterohaemorrhagiae, or Copenhageni in rodents. Renal colonization and shedding of leptospires in the urine of infected animals engenders the transmission of the organism to infect humans and other animals who are incidental hosts (Adler and de la Peña Moctezuma 2010; Faine et al. 1999).

42.3 Human Epidemiology

The global burden of human leptospirosis is currently unknown; however, estimates of the annual incidence range from 0.1–1 case/100,000 people in temperate areas to 100 cases/100,000 during epidemics in tropical regions (Everard and Everard 1993; Levett 2001). In addition, the incidence of leptospirosios is also higher in those environments prone to flooding (Lau et al. 2010a). An estimated 300,000–500,000 severe cases occur each year, with case fatality reports of up to 30% (WHO 2003; Hartskeerl 2006). In an attempt to develop a better understanding of the burden of leptospiral disease, the WHO (2011) estimates that the global incidence in endemic areas exceeds five severe cases per 100,000. Across Europe as a whole, the overall incidence rate in 2010 was 0.13 per 100,000 inhabitants (Dupouey et al. 2014). The Asia Pacific region has some of the highest incidence rates for leptospirosis since high population densities are potentially a risk factor for leptospirosis (Victoriano et al. 2009). This is not surprising given the frequent climatic calamities, overcrowding, poor sanitation, proximity of domestic and wild animals, and occupational risks. In Sri Lanka the annual incidence is reported as 54 per million, in Thailand the annual incidence is estimated to be 48.9 per million, and Taiwan the incidence has been reported at 4.1 per million (Pappas et al. 2008). In French Polynesia, the average incidence is 39 per 100,000 and in New Caledonia, the average incidence is 45 per 100,000 (Picardeau 2013). In Australia, the annual

incidence is 8.9 cases per million. Leptospirosis is endemic in the Caribbean islands and in many parts of Central and Southern America. Pappas et al. (2008) reported that the incidence in Trinidad and Tobago is 120.4 per million, Barbados 100.3 per million, and Jamaica 78 per million. In El Salvador, Brazil, and Argentina the incidence is 35.8, 12.8, and 9.5 per million, respectively. Given the lack of reporting in many developing areas, misdiagnosis, lack of awareness, patients failing to present for treatment, and those with subclinical infections, it is almost impossible to determine the true incidence. The source of infection in humans is usually through either direct or indirect contact with the urine of an infected animal. Further, the usual portal of entry is via compromised cutaneous or mucosal membranes (Levett 2001). Occupation is a significant risk factor as dairy and cattle farmers, veterinarians, abattoir workers, meat inspectors, rodent control workers, and other occupations where intermit contact with animals is required, all have a greater chance of direct contact with the urine of infected animals. Occupations that bring humans into indirect contact with animal urine are also at risk of infection, e.g., sewer workers, miners, soldiers, septic tank cleaners, fish farmers, gamekeepers, canal workers, rice field workers, taro farmers, banana farmers, and sugar cane workers (Faine et al. 1999; Levett 2001; Tulsiani et al. 2011). Recreational activities while traveling are also considered a risk factor for the disease (Lau et al. 2010b).

42.4 Evidence of Human-to-Human Transmission

Currently, reported evidence of human-to-human transmission is scarce. Adler and de la Peña Moctezuma (2010), p. 289) submit that "human to human transmission for practical purposes is non-existent and that leptospirosis is recognised globally as a zoonosis." However, diagnosis of such transmission has been suggested serologically. Bolin and Koellner (1988) reported the case of a 29-year-old breastfeeding mother who worked as a veterinarian and had a confirmed *L. interrogans* serovar Hardjo infection. The mother continued to breastfeed during her illness and 21 days post-onset of symptoms, the infant displayed clinical signs consistent with leptospirosis. A positive result was confirmed by the microscopic agglutination test (MAT). In another report detailing possible human-to-human transmission, Harrison and Fitzgerald (1988) discussed the possible sexual transmission of *L. interrogans* serovar Icterohaemorrhagie. The diagnosis of this condition was also confirmed serologically by MAT.

42.5 Pathogenesis

The minimum infecting dose leading to leptospirosis is elusive; however, the incubation period is assumed to be inversely correlated with the size of the inoculum. For example, a high infecting dose may engender a short incubation period when compared to a low infecting dose. Conversely, small doses may result in prolonged

incubation times which may extend into the immune phase. It is anticipated that these small infecting doses might be responsible for mild or even subclinical infection (Faine et al. 1999). Once in the blood, leptospires are capable of circulating to all tissues. Leptospires that evade phagocytic cells of the recticuloendothelial system grow in an exponential manner doubling every eight hours (Faine et al. 1999). There is evidence to suggest that phagocytosed leptospires do not survive long within the interior of the phagocyte (Tu et al. 1982; Wang et al. 1984). Virulent strains have the ability to attenuate phagocytic responses by activating apoptosis in the macrophage (Merien et al. 1998). Moreover, Adler and de la Peña Moctezuma (2010) write that the ability to resist complement and death by neutrophilic destruction may be a feature of virulent leptospires in nonimmune hosts. A number of leptospiral virulence factors such as hemolysins, fibronectin binding proteins, and numerous surface proteins such as LipL32, Lig A, Lig B, lipoprotein Loa22, and the 6 Len proteins (LenABCDEF) are postulated to play a role in pathogenesis (Adler and de la Peña Moctezuma 2010; Bulach et al. 2006; Hoke et al. 2008; Matsunaga et al. 2003; Merien et al. 2000; Picardeau et al. 2008; Ristow et al. 2007; Stevenson et al. 2007). *L. interrogans* catalase KatE and HtpG (high-temperature protein G is the bacterial homolog to the highly conserved molecular chaperone Hsp90) and CLpB, an ATP-dependent disaggregase (Lourdault et al. 2011; Kędzierska-Mieszkowska and Arent 2020), have also been shown to be virulence factors in leptospires (Eshghi et al. 2012; King et al. 2014) as have several flagellar components (Lambert et al. 2012; Wunder et al. 2016), phospholipase C (Zhao et al. 2013) and collenganse A (Kassegne et al. 2014).

42.6 Clinical Presentation

Following the initial incubation period which can be as short as 3 days or as long as one month (Haake and Levett 2015), the infection enters the acute phase of the disease which can last up to 10 days (Tulsiani et al. 2011). Clinically, during the acute phase, patients typically present with headache, fever, excruciating myalgia, and arthralgia and sometimes rigors, vomiting, photophobia, and a mucosal rash (Faine et al. 1999). Conjunctival suffusion has utility as a diagnostic indicator as it is commonly reported in leptospirosis (Haake and Levett 2015). Hemoptysis, hypotension, and bradycardia are also common presentations. These symptoms are considered nonspecific, thereby making the diagnosis of leptospirosis difficult. Hepatosplenomegaly, jaundice, liver failure, renal failure, and acute respiratory distress are common features of the more acute form of the disease (Sutliff et al. 1953; Solbrig et al. 1987; Faine et al. 1999; Levett 2001). Central to the pathology observed in leptospirosis is the damage caused to the endothelium of small blood vessels. This engenders ischemia in target organs, thus resulting in renal, hepatic, and pulmonary damage and thrombocytopenia. Levett (2001) posits that many of the clinical complications occur during the immune phase when the patient produces immunoglobulins, specific for the destruction of leptospires and the leptospires localize within tissues.

42.7 CNS Involvement

Before the central tenants of this chapter are explored it is appropriate to orientate the reader to the subject matter with a brief overview of CNS involvement in leptospirosis. In their review of 483 cases of leptospirosis, Heath et al. (1965) reported that of all the organ systems, the CNS was the most frequent system involved in leptospirosis. Heath et al. (1965) observed CNS complications such as CSF pleocytosis, meningismus, CSF protein elevation, or mental disturbance in 235 (68%) of their 483 cases. Leptospires reach the CNS rapidly and Mumford et al. (1990) posit that the neurological derangements may be due to the effects of the organism and the hosts immune reaction to the leptospires. Here Mumford et al. (1990) are noting that CNS pathology may occur in the acute and immune phases of leptospirosis. During the acute/leptospiremic phase, patients may endure an intense, analgesic-resistant headache. While the pain is mostly frontal, bitemporal or occipital pain may be reported and may persist into the immune phase (Reik 1987). Leptospires may be isolated in CSF during the acute phase, in which the CSF will usually be otherwise unremarkable and any signs of meningeal irritation are the exception rather than the norm. Reik (1987) posits that while 25% of cases may exhibit cerebral symptoms in the acute phase, these symptoms are mild and transient as are cranial nerve and peripheral nerve neuropathies experienced during this time.

The CNS derangements observed in the immune phase add to the rich tapestry in the fabric of the pathology observed in leptospirosis. Faine et al. (1999) posits that aseptic meningitis is a common complication in the immune phase. Headaches, vomiting, photophobia, neck stiffness, confusion, and delirium may emerge during this time. The CSF in the immune phase reveals a pleocytosis in 80–90% of cases with a transient granulocytosis giving way to a lymphocyte predominance. Hemorrhagic CNS complications may be diverse and multifocal with bleeding in cerebral subarachnoid, subdural, intraparenchymal, and spinal extradural regions (Reik 1987). Cranial nerve neuropathies with optic, oculomotor, glossopharyngeal, facial, or auditory nerve involvement have been reported (Gsell 1978) as have peripheral nerve abnormalities engendering brachial and lumbosacral plexitis and Guillain-Barré syndrome (Faine et al. 1999; Reik 1987). Recovery from these cranial and peripheral neuropathies may take weeks or months and in some instances recovery may be incomplete (Gsell 1978).

At autopsy there are diverse pathologic changes observed both macroscopically and microscopically in those who have succumbed to leptospirosis. While Edwards and Domm (1960) suggest that changes in the brain and meninges are minimal and nonspecific, Koppisch and Bond (1953, as cited in Gsell 1978) reported that macroscopically, narrow sulci, flattened gyri, and a yellow or greenish subarachnoid fluid and choroid plexis can be observed in some but not all instances. Arean (1962) examined the brains of 13 leptospirosis patients and posited the brain was slightly green and the convolutions were edematous and the sulci narrow. Reik (1987) posits that pathological changes in the CNS during leptospirosis include perivascular lymphocytic infiltration in the brain and spinal cord, loss of cerebellar granular cells, patchy demyelination in the cortex and pons as well as gliosis. Moreover,

Gsell (1978) posits glial cell proliferation, variable perivasal lymphocytic inflammation, and purpural hemorrhages may underpin the encephalitic process.

42.8 Neurological Presentation in Leptospirosis (Neuroleptospirosis)

The World Health Organization (2003) confirms that the clinical manifestations of leptospirosis are highly variable and the disease may present as either a mild, influenza-like illness; Weil's syndrome characterized by jaundice and renal failure; hemorrhage and myocarditis with arrhythmias; meningitis/meningoencephalitis, or pulmonary hemorrhage with respiratory failure. Panicker et al. (2001) reported on 40 patients who were admitted to hospital with an acute neurological disease, and who were subsequently found to have leptospirosis. While 13 of these 40 patients presented with headache, fever, neck stiffness, and a CSF consistent with an aseptic meningitis, 17 of the 40 patients presented with a primary paraparesis. Recent reports of patients presenting with a primary acute neurological disease with an absence of, or very few leptospiral symptoms are presented in Table 1. Inspection of Table 1 shows that the neurological presentation of the six patients is quite variable. Headache, stiff neck, and vomiting are consistent with an aseptic meningitis seen in the CSF as an elevated white blood cell count with elevated protein and glucose. In the peripheral blood a neutrophilic leucocytosis may be observed with elevated liver function tests and serum creatinine in some instances. Radiologically, X-ray and ultrasound appear to be of limited utility as they present normal findings. T2-weighted MRI showing hyperintense signals in different CNS regions may be clinically useful, however this technology may not have the specificity to differentiate CNS pathology due to a leptospiral etiology from other microbial etiologies. Physicians working in areas where the incidence of leptospirosis is high should remain cognizant of primary neuroleptospirosis as this initial presentation is uncommon. Further, in the absence of hepatic or renal involvement, a diagnosis of leptospirosis is likely to be delayed. This delay may prevent the most appropriate treatment, therefore reducing positive outcomes.

42.9 Psychosis During Leptospirosis

Watson et al. (2021, p. 1) succinctly summarize psychosis as "a highly disruptive syndrome with many aetiologies characterised primarily by delusions, hallucinations, and disorganised thought, speech and behaviour." Psychosis during an episode of leptospirosis was reported in the work of early pioneers in leptospirology (Hecker and Otto 1911, as cited in Gsell 1978; Trembur and Schallert 1916, as cited in Gsell 1978). Recent accounts of psychosis during an episode of leptospirosis are presented in Table 2. Inspection of Table 2 reveals that most case studies have reported psychosis in the immune phase of leptospirosis. The one exception was the latest case series by Semiz et al. (2005); however, while leptospires were identified in their

Table 1 Recent reports of neuroleptospirosis

Publication	Neurological symptoms	CSF	Other pathology (Blood) Radiology	Outcome
Mumford et al. (1990)	Increasing leg weakness and pain in lower limbs. Flaccid paraplegia and areflexia	Not Reported	Neutrophilic leucocytosis, thrombocytopenia, deranged LFTs Abdominal/Liver ultrasound normal Chest, abdominal, and spinal X-ray normal Nerve conduction studies normal	Succumbed
Wang et al. (2016)[a]	Neck stiffness, vomiting, and headache	WBC of 254 cells/μL 91% lymho/ mononuclear Protein = 91 mg/dl Glucose = 64 mg/dl	Hemoglobin 15.7 g/ dL Platelet count was 338,000 cells/μL WBC count was 18,670 cells/μL 81.2% segmented neutrophils creatinine 1.03 mg/ dl, AST 34 IU/L	Recovered
Bhatt et al. (2018)	Diffuse headache, decreased responsiveness to commands with decreased verbal output and inability to move limbs. Constricted pupils, nonreactive to light, neck rigidity, positive Brudzinski and Kernig's signs	WBC = 115/mm^3 Lymphocytic predominance Glucose = 60 mg/dL Protein = 53 mg/dL	MRI hyperintensity in dorsal midbrain and area surrounding the anterior commissure	Recovered
Tomacruz et al. (2019)	Altered sensorium, behavioral changes, agitated and disoriented to person, time, and place, and seizures	WBC = 5 cells/μL lymphocytic predominance Protein = 60 mg/dL Glucose = 74.55 mg/ dL	WBC = 16×10^9/L Elevated LFTs and serum creatinine Hyperintense signals located at the bilateral, frontal subcortical white matter and left external capsule	Recovered
Bandara et al. (2021)[b]	Patient 1 Headache, photophobia, and	WBC = 166 cells/μL Polymorphs 96% Protein = 52.4 mg/dL	WBC = 14×10^3/μ L (Neutrophilia) CRP = 238 mg/dL	Recovered

patients' blood cultures, they were also IgM reactive. Therefore, it is likely these patients were in the late acute/early immune phase. This would also be consistent with the mixed microscopic agglutination test results. Table 2 also reveals that there is no specific serovar engendering the observed psychosis, as psychosis was observed in patients infected with different serovars. Unfortunately, the majority of reported cases do not mention the infecting serovar.

While psychiatric symptoms may result from direct invasion of the central nervous system by an infectious agent, a number of lines of evidence point toward an immune-based response providing the genesis for psychosis in leptospirosis. Firstly, there is a greater risk of developing systemic autoimmune diseases following an episode of leptospirosis (Teh et al. 2020). Moreover, recently, a 13-year-old female developed neuropsychiatric and extrapyramidal features and sleep disturbances (but no definite hallucinations, illusion, or delusion) following an episode of leptospirosis. The patient was shown to produce anti-N-methyl-D-aspartate receptor (anti-NMDAR) auto-antibodies and was started on intravenous methylprednisolone and intravenous immunoglobulin. The patient showed gradual improvement over one week following immunotherapy. Furthermore, the extrapyramidal and neuropsychiatric features completely resolved within 2 weeks. Interestingly, Pollak et al. (2020) delineate numerous CNS auto-antibodies that may provide the genesis for numerous psychiatric states and report that the main psychiatric symptoms associated with anti-NMDAR antibodies include anxiety, agitation, bizarre behavior, catatonia, delusional or paranoid thoughts, visual or auditory hallucinations,

Table 2 Reports of psychosis during an episode of leptospirosis

Author	N	Phase	Serovar	Titre	Presentation/Symptoms
Bouman (1935)	2	Immune	Not reported	Patient 1. 1:3000	Agitated and walked atactically, constantly moving arms, stealing, had visual disturbances, and acts of violence. Scared and thought people were threatening him and his condition would not improve. Though he was a sexual deviant. Later believed that people had negative thoughts of him. Believed his illness was due to a political and medical conspiracy
		Immune	Not reported	Patient 2. 1: 100000	Restless, conversant but disorientated and though people were talking about him. Believed he was bad for his wife, and people wanted to kill him. He was mute, anxious, and had eating disturbances. Could be easily agitated and was at times aggressive
Edwards and Domm (1960)	1	Late acute early immune	Canicola	Patient. 1: 3200	Refused to take medication, ran down hallway screaming, escaped from the hospital, and assaulted a restaurant attendant
Avery (1976a)*	1	Late acute	Hardjo (prijitno/ bovis?)	1:12800	Paranoia, believed a bad spirit had entered him. Hebephrenic though disorder with poor association of though, Communication, and staturing. Had bodily hallucinations
Avery (1976b)* same patient	1	Immune	Not reported	Not reported	Psychotic symptoms – no further delineation of the symptoms
Marshall and Scrimgeour (1978)	1	Immune	Tarassovi	1:1500	Schizophreniform psychosis – limited delineation of symptoms auditory hallucinations, confused meaningless speech, and disorientated in time and space
Ram and Karim (1981)	2	Indeterminable	Pomona	Patient 1 not reported	Patient 1: Numerous visual hallucinations and delusions of people wanting to harm him
		Indeterminable	Not reported	Patient 2 not reported but reactive	Patient 2: Numerous visual hallucinations and delusions of people wanting to harm him, labile mood, apprehensive, and disorientated in time and space
Semiz et al. (2005)	4	Late acute/ (blood culture +)	Not reported	Patient 1 not reported	Patient 1: Increased psychomotor activity, concentration difficulties, insomnia, grandiosity, and flight of ideas.

(continued)

Table 2 (continued)

Author	N	Phase	Serovar	Titre	Presentation/Symptoms
		Early immune (IgM reactive)			EEG. Abnormalities from right temporal lobe. MRI revealed gliosis in bilateral thalamus and brachium pontis. Brief Psychiatric Rating Scale (BPRS) score of 20 and Young Mania Rating Scale (YMRS) score of 35
		Late acute/ (blood culture +) Early immune (IgM reactive)	Not reported	Patient 2 not reported	Patient 2: Aggressive behavior, nihilistic delusions, lack of insight, slowing of though and psychomotor abilities Scale for the Assessment of Negative Symptoms (SANS) = 59 Scale for the Assessment of Positive Symptoms (SAPS) = 41 BPRS = 32
		Late acute/ (blood culture +) Early immune (IgM reactive)	Not reported	Patient 3 not reported	Patient 3: Insomnia, agitated, and aggressive behavior Persecutory and grandiose delusions, flight of ideas, euphoria Distractibility, and increased psychomotor activity SANS = 22, SAPS = 43, BPRS = 35, and YMRS = 40
		Late acute/ (blood culture +) Early immune (IgM reactive)	Not reported	Patient 4 not reported	Patient 4: referential, persecutory, and influence delusions affective blunting, decreased psychomotor activity, flow of thought, and self-care. SANS = 107, SAPS = 15, and BPRS = 44

movement disorder, and seizures. Moreover, recent animal studies using a mouse model have reported that mice infused with CSF from patients with anti-NMDAR encephalitis displayed reversible psychotic-like features and dopamine receptor changes in cell surface dopamine receptors (Carceles-Cordon et al. 2020). In total the evidence presented here suggests the generation of anti-NMDAR auto-antibodies may be germane to psychiatric disturbance in leptospirosis.

Pollak et al. (2020) delineate further immune mechanisms that may be associated with psychosis. For example, Pollak et al. (2020) postulate that raised CRP, IL-6, TNF-α, and several other cytokines are increased in patients with psychosis compared with healthy controls and may qualify as biomarkers for psychosis. This is of interest to the association of leptospirosis and psychosis as IL-6 and TNF-α may be elevated in leptospirosis (Levett 2001; Haake and Levett 2015). Pollak et al. (2020) provide further avenues of immunological underpinnings associated with psychosis when they posit that there is evidence of increased microglial density and activation

as well as lymphocyte infiltration occurring in approximately 20% of brains of individuals who had schizophrenia. This latter point is of interest given psychosis is common in schizophrenia and the observed CNS pathology outlined in the previous section reporting glial cell proliferation (Gsell 1978) and perivascular lymphocytic infiltration in the brain and spinal cord are pathological features of leptospirosis.

42.10 Acute Disseminated Encephalomyelitis (ADEM) Following a Leptospiral Infection

Tenembaum (2013) posits that acute disseminated encephalomyelitis (ADEM) is an immune-mediated inflammatory demyelinating disease effecting the brain and spinal cord that can follow vaccination or systematic infection. Fever, malaise, headache, nausea, and vomiting may precede the altered consciousness and neurological symptoms. ADEM is rapidly progressive and while a full recovery is observed in most of patients, a minority of patients show residual neurological deficits even after 6 months. Tenembaum (2013) also highlights how life-threating ADEM can be with reports of respiratory failure secondary to brainstem involvement or severe impaired consciousness occurring in 11–16% of cases. Moreover, a case control study revealed neurocognitive deficits in attention, executive function, IQ, and educational achievement in children following an ADEM diagnosis before five years of age (Jacobs et al. 2004). ADEM may also be a risk for a future diagnosis of multiple sclerosis in a minority of patients (Hintzen et al. 2016). A complete understanding of the pathogenesis underpinning ADEM eludes the literature; however, an autoimmune etiology predominates with molecular mimicry, inflammatory cascades, and associations with some major histocompatibility complex (MHC) class II alleles all being postulated in the etiology (Tenembaum 2013). Treatment regimens consists of corticosteroids, intravenous immunoglobulin, and plasmapheresis (Pohl and Tenembaum 2012). Diagnosis may require MRI imaging. MRI T2-weighted images typically reveal multiple hyperintense bilateral, asymmetric patchy and poorly marginated lesions. ADEM lesions are typically observed in the subcortical and central white matter, cortical gray-white matter junctions, thalamus, basal ganglia, cerebellum, and brainstem. Spinal cord involvement may also be observed in patients with large spinal cord lesions extending over multiple segments (Pohl et al. 2016). The cerebrospinal fluid (CSF) findings of patients with ADEM are unremarkable. If a pleocytosis is observed it is usually a mild lymphomonocytic pleocytosis, with increased protein and normal glucose levels. Oligoclonal IgG bands are considered transient and a rare phenomenon (Tenembaum 2013).

The clinical presentation, CSF results, and MRI T2 observations of the extant case reports of ADEM following a leptospiral infection are presented in Table 3. Strikingly, there is consistent clinical presentation with all five patients with ADEM following leptospirosis presenting with some form of altered consciousness. The CSF results were consistent across the five case reports. CSF white cell counts were similar in four of the five patients with lymphocytes, the predominate cells, observed

Table 3 Acute disseminated encephalomyelitis (ADEM) following a leptospiral infection

Publication	Neurological symptoms	CSF	MRI	Follow-up
Alonso-Valle et al. (2001)	Confusion and left hemiparesis with facial central palsy	11 cells/mm^3 (90% Lymphocytes) Protein 168 mg/dL Glucose Normal	T2 hyperintense bilateral sub cortical matter lesions and T2 hyperintense unilateral lesion in the left cerebellum	MRI at 1 month resolution
Chandra et al. (2004)	Stuporous, responding only to painful stimuli	10 cells/mm^3 (100% lymphocytes)	T2 hyperintense lesions in the subcortical white matter, corpus callosum, thalamus, basal ganglia, and upper brainstem	MRI at 6 months resolution
Lelis et al. (2009)	Fever, fatigue, seizures, and reduced consciousness	Normal	T2 hyperintense lesions near lateral ventricles, cerebellar peduncle, and left cerebellar lobe	Sequalae at 1 month
Singh et al. (2011)	Altered sensorium, drowsy	10 cells/mm^3 (70% lymphocytes) Protein 81 mg/dL Glucose normal	T2 hyperintense lesions involving subcortical white matter, bilateral internal and external capsules, basal ganglia, corpus callosum, cerebellar hemispheres, pons, and bilateral middle cerebellar peduncles	MRI at 1.5 months resolution
Özbay et al. (2021)	Severe confusion	WBC 20 $\times$ 10^6/L Protein 1620 mg/L Glucose normal	T2 hyperintense lesions involving the thalamus, periventricular white matter, and the corpus callosum and regions distal to the internal capsule	Nil. Patient succumbed

in most instances. Similarly, while CSF protein was elevated, CSF glucose was normal. T2 MRI results also revealed all patients demonstrating hyperintense lesions throughout the CNS. Combined these results are congruent with ADEM (Tenembaum 2013). Complete resolution however was not observed in all the patients. One patient succumbed to the disease and one patient had sequalae after 1-month follow-up. It is uncertain if this patient achieved full resolution.

While randomized controlled studies may not be possible to prove pathogenic leptospires causing ADEM, it is germane to consider if leptospires are causing the immune-mediated manifestations of ADEM or is the development of ADEM following an episode of leptospirosis simply coincidental. This is a reasonable consideration and one analyzed by Ellul et al. (2020) who used Hill's (1965) nine pillars of

causation in their consideration of SARS-Cov2 and the development of neurological disorders. In applying Hill's (1965) criteria to determine causative links between leptospirosis and ADEM it can be argued that six of the nine pillars of causation are supported. Firstly, although case reports are low there is *consistency* with the link in regard to presentation and clinical accounts from different locations around the world (Asia and Europe). The relationship appears *specific* in regard to the pathology observed and neurological manifestations. *Temporality* is observed with the ADEM postinfectious syndrome, due to an adaptive immune response, proceeding not preceding leptospirosis. *Biological plausibility* is supported by the recent observation of CNS-targeted auto-antibodies such as anti-NMDAR antibodies in leptospirosis in addition to the reports of Guillain-Barre syndrome and an increased risk of systemic autoimmune rheumatic diseases following leptospirosis (Levett 2001; Panda et al. 2021; Teh et al. 2020). *Coherence* is perhaps supported by the vast CNS, PNS, cranial nerve and peripheral nerve, and CNS hemorrhagic complications observed in leptospirosis. The development of ADEM does not, in the words of Hill (1965, p. 289), "seriously conflict with the generally known facts of the natural history and biology of the disease" (leptospirosis). Further, *analogy* is supported by the finding that ADEM has been reported following infection with other bacteria such as *Mycoplasma pneumoniae*, *Borrelia burgdorferi*, and beta-hemolytic *Streptococcus* and vaccination against pertussis (Tenembaum,2013). Unequivocally, the limited number of reports (N = 5) of ADEM relative to incidence of leptospirosis in the tropics, estimated to be 10–100 per 100,000 (WHO 2003), undermines Hill's (1965) *experimental*, *strength, and biological gradient* aspects of causation. It should be noted that Hill (1965, p. 299) states that, "none of my nine viewpoints can bring indisputable evidence for or against the cause and-effect hypothesis and none can be required as a *sine qua non*." Evidence in support of *experimental*, *strength, and biological gradient* aspects of causation may change, however, as more cases of ADEM following leptospirosis come to light and/or *in vitro* or animal models are developed.

42.11 Conclusion

Understanding the pathology underpinning the neurological and psychiatric symptoms observed during an episode of leptospirosis is pivotal given that altered mental status is a poor prognostic indictor. The pathology observed in the CNS and PNS are extensive and much of the pathology may be driven by immune-mediated factors. Further case reports and investigations focusing on immune-mediated factors such as anti-NMDAR auto-antibodies are necessary to advance our understanding of the underlying pathological process in leptospirosis.

Acknowledgements We extend our thanks to the dedicated efforts of Sonia Johnson, Carol Church, and Trish Murphy and the rest of the Public and Environmental Health library staff, who were able to source the many obscure, dated journal articles reviewed in this work. We cannot express how thankful we are to you for the highest level of librarianship you provided.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_35

Abstract

Glanders, caused by infection with *Burkholderia mallei*, primarily causes infection in equines, but may be transmitted to humans, and thus qualifies as a true zoonosis. Melioidosis is caused by *B. pseudomallei*, genetically very similar to *B. mallei*, but which is an environmental saprophyte capable of infecting humans and a wide range of other animals. Good evidence of animal-to-human, or even human-to-human, transmission of melioidosis is lacking, and so it is most appropriately referred to as a sapronosis, or at most a sapro-zoonosis. Although rare in Western countries, both microorganisms have recently gained much interest because of their potential use as bioterrorism agents and widening geographic footprint. The increasing recognition of melioidosis in humans and recent outbreaks of glanders in animals have led to their description as emerging or reemerging diseases, and melioidosis as a neglected tropical disease. Laboratory-associated infections with both organisms have also occurred, resulting in their categorization as Hazard Group 3 pathogens. In this chapter we review the epidemiology of animal and human cases of glanders and melioidosis, the evidence for different modes of transmission, pathogenesis and clinical features, diagnosis and treatment, as well as public health and disease control issues.

43.1 Introduction

Glanders, caused by infection with *Burkholderia mallei*, primarily causes infection in equines, but may be transmitted to humans, and thus qualifies as a true zoonosis. Melioidosis is caused by *B. pseudomallei*, genetically very similar to *B. mallei*, but

which is an environmental saprophyte capable of infecting humans and a wide range of other animals. Good evidence of animal-to-human, or even human-to-human, transmission of melioidosis is lacking, and so it is most appropriately referred to as a sapronosis, or at most a sapro-zoonosis. Although rare in Western countries, both microorganisms have recently gained much interest because of their potential use as bioterrorism agents and widening geographic footprint. The increasing recognition of melioidosis in humans and recent outbreaks of glanders in animals have led to their description as emerging or reemerging diseases, and melioidosis as a neglected tropical disease. Laboratory-associated infections with both organisms have also occurred, resulting in their categorization as Hazard Group 3 pathogens. In this chapter we review the epidemiology of animal and human cases of glanders and melioidosis, the evidence for different modes of transmission, pathogenesis and clinical features, diagnosis and treatment, as well as public health and disease control issues.

43.2 Glanders

43.2.1 History and Epidemiology

Symptoms of glanders in equines were reported as early as 425 BC by Hippocrates; however it was Aristotle who first described it as "μηλις" (malis in Latin, from which *B. mallei* takes its name) in approximately 350 BC (Sharrer 1995). *B. mallei* was first isolated from the liver of an infected horse in 1882 (Boerner 1882). Infection resulted in significant morbidity and mortality in equines worldwide, and was occasionally transmitted to humans in prolonged close contact with horses, such as grooms, coachmen, veterinarians, and butchers, or to other animals through direct or indirect contact.

Glanders has since been eradicated from Western Europe, the USA, and Canada due mainly to the reduction in the use of horses in everyday life, but also to improved animal husbandry and hygiene and strict programs enforcing statutory testing and slaughter of infected animals (Blancou 1994; Derbyshire 2002); however the disease persists in the Middle-East, parts of Asia, and South America. A possible reintroduction occurred in Germany in 2014, which was identified on routine pre-export serological tests despite a lack of epidemiological evidence of contact with *B. mallei* infected horses (Kettle and Wernery 2016). This possibly represented latent disease, which was not detected by standard diagnostics (Kettle and Wernery 2016). Within the last 20 years, increasing numbers of equine cases have been reported from countries including Pakistan, India, Bangladesh, Brazil, Turkey, Iran, Iraq, Afghanistan, Kuwait, Bahrain, UAE, Lebanon, Latvia, Belarus, Mongolia, and China (Rahman et al. 2018; Health 2013; Khan et al. 2013). These are usually sporadic involving single or small numbers of animals, although occasionally larger outbreaks have occurred, such as that in India between 2006 and 2010 involving 8 states and 164 equines (Malik et al. 2012). Sporadic human cases have also been reported from Cameroon, Curaçao, Sri Lanka, and Turkey (Office

International des Épizooties 2011). Laboratory-associated human cases, such as that which occurred in a military research microbiologist in the USA in 2000 (Srinivasan et al. 2001), the first case in the USA for over 50 years, have also been reported occasionally.

Due to its high fatality rates and transmissibility of the disease in animals and humans, glanders has long been considered as a potential biological weapon. When horses were widely used for military purposes, devastating natural outbreaks occurred, for example, during the American Civil War (Sharrer 1995). *B. mallei* was actually used by the Germans in sabotage attempts during World War I (Christopher et al. 1997), and in human experiments by the notorious Japanese Unit 731 in Manchuria in the period leading up to World War II (Darling and Woods 2004). It is reported to have been weaponized by the Soviet Union, and used against the Mujaheddin in Afghanistan in the 1980s (Alibek and Handelman 1999). With resurgent bioterrorism concerns, *B. mallei*, listed as a category B bioterrorism agent and Tier 1 Select Agent by the Centers for Disease Control and Prevention and the US Department of Agriculture, is now being studied in many laboratories throughout the world.

43.2.2 Modes of Transmission

It was initially thought that glanders was transmitted through the air; however in the early eighteenth century it was proposed that transmission took place through direct contact with infected horses, or indirectly through contaminated harnesses and water troughs (Khan et al. 2013; Kinsley 1911). Inoculation or ingestion of infected clinical material was demonstrated to cause infection in horses and other animals in experiments conducted in the late nineteenth and early twentieth centuries, which also confirmed that "glanders" and "farcy" were different manifestations of the same disease (O'Leary 1908; Schutz 1898). Later, nasal discharge and skin exudate from infected animals was shown to contain large numbers of bacteria that could be readily cultured, and it was shown that viable bacteria could survive for at least 4 weeks suspended in water (Miller et al. 1948).

Once it has contaminated harnesses, grooming tools, hoof trimming equipment, water troughs, or hands, *B. mallei* may transmit to new hosts through skin abrasions, mucous membranes, ingestion of water containing infective material, or inhalation of dried infected particles (Carr Gregory 2007). The disease spreads quickly in overcrowded, poorly hygienic, and humid environments (Khan et al. 2013). Occasional cases have been reported in carnivores fed on infected meat (Alibasoglu et al. 1986; Khaki et al. 2012). Vertical transmission has occurred naturally from mare to foal, and from laboratory infected guinea pig sows to their offspring (Loeffler 1886; Rutherford 1906).

Zoonotic transmission to humans appears to be relatively uncommon. During World War II, human infections were rare despite a 30% prevalence in horses in China (Darling and Woods 2004). Disease has occurred almost exclusively in individuals whose occupation involves close and prolonged contact with horses,

but there is often no history or clinical evidence of inoculation or path of infection (Bernstein and Carling 1909). Lethal human glanders has also been documented to occur following a bite by an infected horse (Pilcher 1907). As is the case for melioidosis, diabetes may place humans at greater risk of infection after exposure, although reports of this are remarkably rare, perhaps because of the rarity of human glanders since diabetes became readily treatable (Srinivasan et al. 2001). Human infection by ingestion has not been definitively reported, although it has been seen in carnivores (Alibasoglu et al. 1986; Khaki et al. 2012). In fact even where there is known to have been consumption of glanderous meat, human infection has not occurred (Loeffler 1886). Human-to-human transmission is also rare, but has been reported, and has usually involved close contact with the infected individual either as a family member, a carer, during medical procedures, or postmortem examination (Loeffler 1886; Robins 1906). In a review of 156 reported cases at the turn of the last century, around 10% were believed to have been acquired from human contact (Robins 1906). In the present day, improved living conditions, universal precautions, disinfection, and available treatment make human-to-human transmission much less likely to occur. Recently, a study examining 538 in-contact individuals, including equine handlers, veterinarians/field assistants, and laboratory workers processing *B. mallei* samples, found no seropositive individuals by complement fixation test (CFT) and enzyme-linked immunosorbent assay (ELISA) (Singha et al. 2020a).

In developed countries, laboratory exposure seems to be a greater threat than animal contact, and anecdotal observations suggest that *B. mallei* may be more infectious in this setting than *B. pseudomallei* (Howe and Miller 1947). Some cases have occurred following obvious aerosol exposures during spillage of culture material, or direct inoculation injuries (Howe and Miller 1947) but many did not recall a particular exposure (Srinivasan et al. 2001). It is suspected that most laboratory-acquired cases are a result of inhalation (Carr Gregory 2007).

Although outbreaks continue to occur in the endemic regions listed above, little is known about the ecology and population dynamics of *B. mallei*. A recent study investigated the molecular epidemiology of glanders in Pakistan. Isolates from 15 glanderous horses in the Punjab between 1999 and 2007 underwent variable number of tandem repeat (VNTR) analysis, phylogenetic analysis, and comparison to ten whole-genome-sequenced strains of *B. mallei*. The results confirmed the Punjab strains to be genetically distinct from the sequenced strains, and to form three distinct clades, with the majority belonging to a single clade temporally and geographically spread, suggesting that this is ecologically established in the Punjab region (Hornstra et al. 2009). Together with additional epidemiological data, the authors concluded that human movement of equines contributed to the dispersal of *B. mallei* genotypes and that strains could persist for at least 1.5 years. Similarly, glanders infection in a dromedary in Bahrain was shown to be genetically similar to the Dubai 7 strain, which caused an outbreak in horses in United Arab Emirates in 2004 (Wernery et al. 2011), and it was suggested that the strain was introduced from that region through international horse trade. The first molecular characterization of a Brazilian *B. mallei* strain isolated from a mule in 2016 found that it was most closely related to an Indian strain isolated from a horse in 1932 (Laroucau et al. 2018).

Using 45 *B. mallei* isolates, this study identified three distinct lineages; L1- included only two isolates from Turkey and the United Kingdom, L2- isolates mainly from India, China, and Burma, with some from Hungary, Iran, Pakistan, and the UAE, and L3- mainly Turkish isolates along with some from Brazil, Hungary, India, Iran, Russia, and the USA. Caution is advised due to the paucity of available *B. mallei* genome data, meaning there is likely to be bias in the geographic clustering seen so far (Laroucau et al. 2018). In India, the state of Uttar Pradesh (UP) has become a glanders hotspot. Between 2013 and 2016, ten isolates from horses and mules identified a cluster of five that were linked to UP (Singha et al. 2021). However, further VNTR analysis identified considerable genotypic variability of *B. mallei* isolates from India. These were closely linked to isolates from Pakistan, followed by Turkey, which points to an ancestral clone that disseminated to geographically linked countries via equine movement over time (Singha et al. 2021).

43.2.3 Microbiology

B. mallei is a facultative intracellular, aerobic, nonmotile Gram-negative bacillus. The results of DNA-DNA hybridization (Rogul et al. 1970), multi-locus sequence typing (MLST) (Godoy et al. 2003), and whole genome sequencing (Nierman et al. 2004) have demonstrated unequivocally that *B. mallei* is actually a clone of *B. pseudomallei*, which has undergone a substantial reduction in the size of its genome during the process of adaptation as an equine pathogen (Nierman et al. 2004), differing at only a single nucleotide site in one of seven housekeeping genes studied. Based on these data it should not taxonomically be considered a separate species; however it retains species status due to its specific clinical and epidemiological behavior.

Very few recent clinical isolates are available for study, so knowledge of the characteristics of *B. mallei* is based on historical descriptions and archived strains, which may be laboratory-adapted to varying degrees. The organism often has an irregularly stained appearance on Gram's stain due to the presence of "lipoid granules" (Worley and Young 1945). Miller noted that when the organism was stained in clinical specimens, there was an impression of a capsule; however this is not apparent using common capsule stains (Miller et al. 1948). It is nutritionally versatile, being able to use a wide range of organic compounds as a carbon source, and can oxidize glucose and usually mannitol. It is able to grow on most laboratory media, but requires glycerol for optimum growth (Miller et al. 1948), initially forming shiny and translucent colonies, which tend to become mucoid with age. Selective agars have been developed and may be useful when clinical specimens from non-sterile sites are collected (Kinoshita et al. 2019). Most strains are oxidase positive. The optimal temperature for growth is 37 °C; many strains grow poorly below 25 °C but all will grow at 41 °C. *B. mallei* is unable to survive in dried pus for longer than a few days, or for 24 h when exposed to sunlight, although it can survive in tap water for at least 4 weeks (Miller et al. 1948; Howe and Miller 1947) and for 3–5 weeks in wet, humid, or dark environmental conditions. Following inoculation

onto nonporous laboratory materials (e.g., rubber gloves, glass, and stainless-steel), *B. mallei* China 7 viability decreased to nondetectable levels within 4–7 days. However, it was inactivated on exposure to vapor phase hydrogen peroxide (Rogers et al. 2016).

It grows less luxuriantly on laboratory media than *B. pseudomallei*, from which it may be distinguished by its susceptibility to aminoglycosides and lack of motility. Like *B. pseudomallei*, it is intrinsically resistant to colistin and polymyxin B. *B. mallei* is nonflagellated, despite retaining flagellar genes that are not expressed (Song et al. 2010), whereas *B. pseudomallei* has 2–4 polar flagella per cell.

43.2.4 Pathogenesis

B. mallei has the ability to invade and replicate inside epithelial and phagocytic cells and evade host immune mechanisms, resulting in an acute and fatal course, or a more chronic persistent infection state. In vivo animal models of glanders, in particular hamster and mice models, have provided important data on various pathogenic mechanisms. Nonhuman primate models highlight striking differences in pathological features observed between melioidosis and glanders (Nelson et al. 2014). With *B. pseudomallei* infection, most pathological features were hepato-splenic; multifocal suppurative lesions with areas of variable necrosis, whereas *B. mallei* lesions, although multifocal, were non-necrotic, and more severe in the lungs. All *B. mallei*-challenged animals had multifocal necrotizing pneumonia, but only one-third of *B. pseudomallei*-challenged animals exhibited pneumonia (Nelson et al. 2014).

B. mallei ATCC 23344 genome contains at least two *luxI* and four *luxR* homologues, which are quorum sensing (cell-density)-based regulators of virulence factor expression. When inactivated, reduced bacterial virulence was observed in mice (Ulrich et al. 2004). The genome also encodes a *virAG* two-component regulatory system that is required for virulence in hamsters (Nierman et al. 2004) and overexpression results in transcription of approximately 60 genes (Schell et al. 2007).

Like many pathogenic Gram-negative bacteria, *Burkholderia* spp. use a Type III secretion system (T3SS) to interact with and invade host cells. This system involves secretion of a protein onto the membrane of a host cell, to which the bacteria can subsequently bind, form a pore, and insert effector proteins directly into the host cell cytosol. *B. mallei* contains two T3SS, one of which is the animal pathogen-like Bsa T3SS (T3SSAP), which is required for rupture of endocytic vacuoles, escape into the host cell cytoplasm (Ribot and Ulrich 2006) and actin-based motility to promote spread within and between cells (Ulrich and Deshazer 2004). A type VI secretion system, T6SS-1, part of the *VirAG* regulon, is essential for *B. mallei* virulence in the hamster model of glanders (Schell et al. 2007) and has an important role in growth and actin-based motility following uptake of *B. mallei* by murine macrophages (Burtnick et al. 2010). *B. mallei* also exhibits Bim-A dependent intracellular actin-based motility, similar to that discussed later for *B. pseudomallei*. Multinucleated giant cell (MNGC) formation is characteristic of both organisms and is believed to

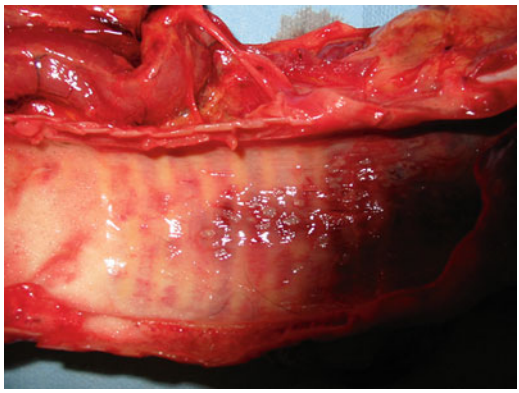

Fig. 1 Tracheal ulcers noted on post-mortem of a glanderous horse. Copyright Prof. D.E. Woods

be involved in establishing persistent infection by facilitating intercellular spread and immune evasion (Duval and White 1907; Burtnick et al. 2011).

In laboratory infected guinea pigs, *B. mallei* has been shown to produce a thick carbohydrate capsule (Popov et al. 1991), the coding sequence of which is 99% identical to that of the *B. pseudomallei* capsule (Deshazer et al. 2001). This enables *B. mallei* to resist macrophage and complement-mediated killing, promoting survival in serum (Burtnick et al. 2002). Furthermore, mutated strains lacking a capsule appear nonpathogenic in mice and hamsters (Deshazer et al. 2001). Lipopolysaccharide has also been shown to be a potent activator of Toll-like receptor-4 in vitro (Brett et al. 2007).

Through the various modes of transmission outlined previously, using these pathogenic mechanisms, *B. mallei* is able to penetrate mucosae, invade lymphatics, and spread hematogenously. Postmortem examinations of glanderous animals have revealed nodules and ulcers of the nasal passages, larynx, lip, and other tissues (Fig. 1); sero-sanguinous fluid in the nasal cavity, paranasal sinuses, and trachea; sub-pleural lung nodules; diffuse, miliary granulomatous nodules with caseo-necrotic centers; pulmonary edema or severe bronchopneumonia; and less frequently, muscle abscesses (Khan et al. 2013). Some ulcerating lesions are believed to be endotoxin mediated (Carr Gregory 2007).

43.2.5 Clinical Presentation in Animals

In addition to the normal equine hosts, glanders has been confirmed in camels, bears, wolves, dogs, and felines (Health 2013; Wernery et al. 2011), and in laboratory experiments guinea-pigs and hamsters appear to be susceptible, whereas cattle, fowl, rats, and pigs appear to be more resistant (Hu et al. 1958, Minnet 1959). Donkeys are particularly susceptible and develop an acute fatal form of infection, whereas horses tend to develop a chronic, more insidious, yet eventually fatal illness. The clinical presentation of equine glanders may be acute or chronic, and it typically manifests as a respiratory illness with pulmonary and nasal

Fig. 2 Typical purulent nasal exudate due to glanders infection in horses. Copyright Prof. D.E. Woods

involvement ("glanders"; Fig. 2) or with cutaneous nodules and lymphangitis ("farcy"; Fig. 3a, b), although these forms often coexist, and pulmonary involvement is almost invariably found at postmortem. The incubation period varies from a few days to several months (Health 2013). The clinical presentation in other susceptible animals appears similar to that in equines. General clinical signs noted may include fever, rough hair coat, breathing difficulty, joint and limb swelling, inappetence, and gradual emaciation (Singha et al. 2020b).

Acute infection in donkeys begins with fever, anorexia, loss of stamina, and respiratory symptoms such as nasal discharge and cough. This is shortly followed by swelling of the nostrils, nodules, and ulceration of the nasal septum, mucopurulent nasal discharge, submaxillary lymphadenopathy (often with suppuration), and increasing shortness of breath (Health 2013; Wernery et al. 2011; Minnet 1959). Death occurs within a few days to weeks as a result of respiratory failure and sepsis.

In horses, glanders generally follows a more chronic course with episodic exacerbations followed by improvement in symptoms. The animal may have intermittent, low-grade fever, and mild respiratory symptoms; however the disease may remain latent for months to years without significant symptoms or signs. As disease progresses, cough, weakness, and signs of wasting develop, and nasal and cutaneous forms ensue with inflammatory nodules and ulceration of the nasal cavity and upper respiratory tract (see Fig. 1), yellow-green purulent nasal discharge (see Fig. 2), and lymphangitis or nodular lymphadenitis particularly affecting the limbs (Fig. 3b). The skin nodules may also ulcerate, and deep lesions are often associated with joint swelling and edema of the hind quarters resulting in lameness. Shortness of breath progresses as lung nodules and abscesses develop, and nodules are often found in the liver and spleen. Neurological involvement has been noted but is rare (Dobberstein 1935). Although chronic cases may survive for many years, the animal will usually become increasingly debilitated and eventually die (Health 2013; Khan et al. 2013; Minnet 1959; Saqib et al. 2012). Chronic and subclinical cases are potential sources of transmission to other animals or humans through shedding of bacteria in respiratory secretions and skin exudate (Wittig et al. 2006). Increased incidence of glanders

has been recorded during the seasonal transition from spring to summer followed by the humid rainy season, with working stress also playing an important role (Singha et al. 2020b; Fonseca-Rodriguez et al. 2019; Ghori et al. 2017).

43.2.6 Clinical Presentation in Humans

Knowledge of the clinical features of glanders in humans is based on a relatively narrow window in the literature of just over 100 years between the early nineteenth and the early twentieth centuries, and a few more recently published

laboratory-acquired cases (Srinivasan et al. 2001; Robins 1906; Howe and Miller 1947). The clinical manifestations appear to relate to the route of infection, and whether the disease remains localized or disseminates, which probably accounts for the relative frequency of involvement of the head, neck, and upper limbs. Typically, it results in pneumonia, septicemia, and chronic suppurative skin infection. Average incubation is 1–14 days (Nelson et al. 2014). Localized infection typically produces pus-forming, ulcerating nodules and abscesses of the skin, subcutaneous tissues, or mucous membranes, with associated lymphangitis or regional lymphadenopathy. Depending on the site affected, there may be swelling and increased discharge from nasal, ocular, or respiratory mucous membranes. Fever, malaise, headache, myalgia, and gastrointestinal upset are common accompanying features.

Cutaneous inoculation or entry of *B. mallei* via mucous membranes typically results in a localized infection at the site of entry within 1–5 days. Although involvement of the nasal or oral mucosa has been well described, this is by no means invariable and certainly not as prominent as it is in horses, but pustular lesions around the face appear to be common. If untreated, lymphatic or hematogenous spread takes place after 1–4 weeks, resulting in pulmonary, septicemic, or disseminated infection with abscesses in many organs, but particularly the spleen, liver, and lungs (Carr Gregory and D. 2007). Multiple, painful skin and soft tissue nodules and abscesses may be a particularly prominent feature, and these often contain a characteristic oily pus ("farcy oil"). Pulmonary involvement, secondary to aerosol inhalation or as part of disseminated infection, may present with cough, purulent sputum, shortness of breath, and chest pain as a result of pneumonia, lung abscess, or pleural effusion. Pneumonia, abscesses with cavitation, and miliary nodules have been seen on chest radiographs (Carr Gregory 2007). Septicemia may develop immediately or up to 2 weeks after initial exposure or recurrence, and has a poor prognosis. The most recent reported case of human glanders occurred in Brazil in 2020, when an 11-year-old child, who was known to be in constant close contact with families who owned horses, presented with fever, chest pain, and breathing difficulty, going on to develop septic shock. Chest X-rays identified pericardial and pleural effusions with pneumonia. *B. mallei* was subsequently cultured from abscesses, which appeared on his trunk. An abrasion on his left knee was presumed to be the portal of infection (Santos Junior et al. 2020).

Although human glanders was generally fatal over days to weeks before antibiotics were available, a more protracted course of disseminated infection interrupted by latent periods has also been described (Bartlett 1988), as well as cases of localized abscesses, which responded to incision and drainage only (Bernstein 1909). Recent naturally occurring and laboratory-acquired cases have survived with antibiotic treatment similar to that used for melioidosis despite delays in making the diagnosis.

43.2.7 Diagnosis

A definitive diagnosis of glanders, in animals or humans, generally requires isolation and identification of *B. mallei* from clinical samples, although seroconversion following known exposure would also be highly suggestive of infection.

Specimens from suspected or confirmed cases should be handled with appropriate laboratory containment. All suspected cases should have blood and urine culture, together with sputum, pus, exudate from superficial lesions and other samples as available or appropriate. Guidelines for culture and identification of *B. mallei* have been developed (Microbiology 2008). Gram's stain of clinical samples may demonstrate the irregularly stained Gram-negative bacilli. The organisms are difficult to demonstrate in tissue sections where they may have a beaded or encapsulated appearance (Miller et al. 1948). Isolation from non-sterile sites may be optimized by using a selective medium such as *Burkholderia cepacia* agar, although selective media containing aminoglycosides designed for *B. pseudomallei*, such as Ashdown's agar, are inhibitory to the aminoglycoside-susceptible *B. mallei* (Glass et al. 2009). *B. mallei* is often not correctly identified by API 20NE (Amornchai et al. 2007) and other commercial identification systems (Glass and Popovic 2005). Well-resourced laboratories are now using matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry for bacterial identification. However, accurate results require good sample preparation and a well-developed database. To ensure highly pathogenic organisms are nonviable and safe for handling, the American Society for Microbiology document "Sentinel Level Clinical Laboratory Protocols for Suspected Biological Threat Agents and Emerging Infectious Diseases" recommends that laboratories use the tube extraction method followed by filtration through a ≤ 2 μm pore size filter for suspected biothreat agents (Rudrik et al. 2017). Caution is advised with a genus-level identification of *Burkholderia* species by MALDI-TOF MS. All suspected *B. mallei* isolates should be referred to the relevant national reference laboratory for molecular confirmation.

Molecular techniques have been developed to identify *B. mallei* in laboratory culture (Lee et al. 2005; Thibault et al. 2004b; U'ren et al. 2005) and although their use is currently restricted to research and reference laboratories, they could potentially be used to detect the organism in clinical specimens. PCR targeting the flagellin gene of *B. mallei* (fli-P) was used successfully to detect the organism in clinical samples taken during a glanders outbreak in horses (Scholz et al. 2006).

In suspected cases of glanders in animals, the mallein skin test was historically used for diagnostic purposes. The test is based on a hypersensitivity reaction to a protein fraction (mallein) of *B. mallei* following intrapalpebral or subcutaneous injection or administration in eyedrops, leading to marked eyelid swelling, a painful raised lesion, or conjunctivitis, respectively, after 1–2 days, often accompanied by fever (Health 2013). Mallein testing can, however, lead to subsequent false positive results in other serological tests (Hagebock et al. 1993), and may be falsely negative in animals with acute glanders or in the late stages of chronic disease (Neubauer et al. 2005). It is no longer recommended due to animal welfare concerns, but may be used in remote endemic regions where storage and transport of samples for serological testing is problematic (Health 2013).

Numerous serological tests for the diagnosis of glanders in horses exist including complement fixation test (CFT), various enzyme-linked

immunosorbent assay (ELISA), immunoblot (IB), Rose Bengal Test (RBT), indirect hemagglutination assay (IHA), agar-gel immunodiffusion (AGID), indirect fluorescent assay test (IFAT), counter immunoelectrophoresis (CIE), and dot ELISA. Many of these methods are not widely validated, cross-react with other *Burkholderia* species, and, like the mallein test, may give false negative results in acute cases or very debilitated animals. CFT represents the current method of choice for the diagnosis of glanders and is required before international horse trade by the World Organization for Animal Health (OIE) (Health 2013). It is 90–98% sensitive, becoming positive within 1 week of infection, and remaining positive in chronic cases and exacerbations of latent cases (Health 2013). A cELISA has been developed using an uncharacterized anti-lipopolysaccharide monoclonal antibody, and shown to have similar performance characteristics to the CFT (Katz et al. 2000). However, both methods have suboptimal specificity (Neubauer et al. 2005), particularly when testing serum samples from animals in glanders-endemic areas (Khan et al. 2012). A recently optimized BimA protein-based indirect enzyme-linked immunosorbent assay (iELISA) exhibited 96% sensitivity and 91% specificity, with 100% repeatability and minimal decrease in diagnostic efficacy after storage of ELISA plates at room temperature or 37 °C for 90 days (Singh et al. 2018). ELISAs based on recombinant antigens (TssA, TssB, and Hcp1) and semi-purified fractions of *B. mallei* (IDVet) have been shown to have significantly higher specificity, offering a suitable alternative for serological testing of equids (Elschner et al. 2019; Elschner et al. 2021). CFT performance is also significantly affected by the availability of quality reagents and specifically by the *B. mallei* antigen applied. False positive tests can have serious consequences in terms of animal slaughter and financial losses. Performing an immunoblot as a confirmatory test for all positive CFT results has been suggested as a means of overcoming the sensitivity issues (Khan et al. 2012). The serodiagnosis of glanders in animals should only be undertaken and interpreted by specialists with relevant expertise. Ideally, the diagnosis should be confirmed by culture if possible. The European Union Reference Laboratory (EURL) for glanders, nominated in 2008, found good intra-laboratory repeatability of CFT testing; however, a risk of inter-laboratory inconsistency was highlighted, which may misclassify positive samples with low CFT titers (Laroucau et al. 2016). A field deployable recombinase polymerase amplification-lateral flow (RPA-LF) assay, which is highly sensitive (down to 10 fg of *B. mallei* genomic DNA) and specific, shows promise as a tool for use in endemic areas with limited laboratory resources (Saxena et al. 2019).

No validated serological test is currently available for the diagnosis of human glanders, although numerous melioidosis serodiagnostic tests are in use around the world and, given the serological cross-reactivity between *B. mallei* and *B. pseudomallei*, it is likely that these would become positive in many cases of human glanders. Recent molecular and immunological research is leading to the identification of more specific and immunogenic *B. mallei* antigens to optimize serological diagnosis.

43.2.8 Treatment

B. mallei is intrinsically resistant to a range of antimicrobial agents, including early beta-lactams, but unlike *B. pseudomallei*, *B. mallei* remains susceptible to aminoglycosides and macrolides (Kenny et al. 1999; Thibault et al. 2004a). Most strains are susceptible to carbapenems, ceftazidime, amoxycillin–clavulanic acid, piperacillin, doxycycline, and trimethoprim-sulfamethoxazole (Thibault et al. 2004a; Kenny et al. 1999; Al-Izzi and Al-Bassam 1989; Heine et al. 2001). Despite low mean inhibitory concentrations in vitro, certain antimicrobials, including aminoglycosides, may not be effective in vivo due to the intracellular nature of the infection. Doxycycline and fluoroquinolones, such as ciprofloxacin and ofloxacin, with good intracellular and tissue penetration, have demonstrated efficacy when used to treat experimental infection in animals (Batmanov 1991; Iliukhin et al. 1994; Russell et al. 2000); however, in one study relapse occurred in some doxycycline treated animals (Russell et al. 2000). Doxycycline has also been shown to have some efficacy as post-exposure prophylaxis following aerosol and intraperitoneal challenge in animals (Russell et al. 2000; Iliukhin et al. 1994).

Trials to determine optimal treatment for animal and human glanders are lacking. Until recently, glanderous animals, including those that are asymptomatic with positive serological tests, have been euthanized according to strict veterinary public health policies to prevent spread to other domestic animals or humans. In the case of high value animals, such as those in equestrian sports, an expensive treatment regimen may be justified. During an outbreak of culture confirmed glanders in 23 horses at the Lahore Polo Club in Pakistan, a combination of intravenous enrofloxacin and trimethoprim-sulfadiazine for 3 weeks, followed by oral doxycycline for a total of 12 weeks, successfully treated all infections (Saqib et al. 2012).

Recommendations for treatment of human glanders adopt the same antimicrobial regimens as those validated for melioidosis, which are based on clinical trial evidence. This consists of an intensive phase of intravenous antimicrobial therapy (ceftazidime or a carbapenem) for a minimum of 10–14 days, followed by an eradication phase of oral antimicrobial (trimethoprim-sulfamethoxazole) for 12–20 weeks, or longer if there is widespread visceral disease (Lipsitz et al. 2012). Without the latter phase, there is likely to be a high risk of relapse, particularly in those with disseminated infection. Drainage of abscesses where possible is an important adjunct to antimicrobial therapy.

43.2.9 Prevention and Control

Control and eradication of glanders has to date depended on the detection and elimination of infected animals to prevent onward transmission. A requirement for serological testing of animals prior to international transport in order to prevent the introduction of glanders into glanders-free regions, has been recommended by the World Organization for Animal Health (Health 2003).

Attempts to develop vaccines against *B. mallei* have so far been experimental and no vaccine against glanders is yet available for either human or animal use. Intranasally vaccinated BALB/c mice using an iron-acquisition-deficient *B. mallei*$_{\text{tonB}}$ strain had 100% survival on subsequent challenge. However, necropsy and organ colony-forming units (CFU) enumeration showed splenomegaly and abscess formation with persistence of the attenuated *B. mallei,* which poses a significant safety concern (Hatcher et al. 2016). In contrast, a recombinant Parainfluenza virus 5 expressing BatA (autotransporter protein) resulted in 74% survival, with complete bacterial clearance from the lungs and spleen in 78% (Lafontaine et al. 2019). Interestingly, using a double mutant by deletion of tonB and hcp1 genes produced clearance from all organs by 21 days post inoculation, with unremarkable histopathology. Furthermore, serum from these mice was able to inhibit bacterial growth when co-cultured with *B. mallei*. Greatest protection was observed in mice with the highest total IgG titers and IgG2a/IgG1 ratios (markers of Th1-driven immune response and protection). Together, these studies demonstrate that live-attenuated vaccines can elicit a strong humoral response that contributes toward protection (Hatcher et al. 2016). The addition of the Toll-like receptor 9 (TLR9) agonist CpG oligodeoxynucleotide (activating B and NK cells, antibody production, and Th1 cell development) as an adjuvant may yet provide better protection and reduce the number of vaccine doses required (Hatcher et al. 2016). More recent work is taking advantage of genome-wide bio- and immune-informatic analysis to predict highly immunogenic antigens. This led to the development of a nano-glycoconjugate vaccine (containing OmpW, OpcP, and Hemagglutinin protein antigens alongside LPS), which offered complete protection in an inhalational glanders mouse model (Tapia et al. 2020). Vaccine development is gaining momentum and much progress has also been made with melioidosis vaccines (*see below*), which may offer cross-protection.

If animal or human glanders is suspected, the case should be isolated, and personal protective equipment (PPE) worn by any person who must come into contact with the patient or samples. Local and national public health and veterinary authorities must be notified immediately and confirmed cases in animals reported to the World Organization for Animal Health. Any confirmed human glanders case occurring without equine exposure should prompt consideration of a deliberate release of the organism. In human cases, isolation and appropriate infection control precautions (according to the site of infection) should be taken until the patient is culture negative.

Confirmed animal cases and serologically positive animal contacts should be destroyed humanely, with the provision of adequate compensation to owners. Reasonable compensation schemes helped to eradicate glanders in Canada (Derbyshire 2002). In contrast, in some developing countries as little as $1.1 US dollars is paid in compensation for slaughter of a glanderous animal, which may be the basis of the owner's livelihood, thus forcing them to sell the animal and risk onward transmission to other animals and regions (Khan et al. 2013; Saqib et al. 2012). Premises and facilities of infected animals should be quarantined, cleaned, and disinfected. Carcases as well as contaminated bedding, feed, manure, and equipment in the vicinity should be buried or incinerated.

Prevention of laboratory-acquired human infection depends on a full risk assessment, appropriate containment and practices, the use of personal protective equipment, and the institution of appropriate guidelines in the event of accidental laboratory exposure (Lipsitz et al. 2012).

43.3 Melioidosis

43.3.1 History and Epidemiology

Melioidosis was first described by Whitmore and Krishnaswami as a "glanders-like. . . .pyaemic or septicaemic" illness occurring in morphia addicts in Rangoon in 1911 (Whitmore and Krishnaswami 1912) and was documented in 5% of postmortem examinations in Myanmar around this time (Cheng and Currie 2005). Fulminant presentations at autopsy were characterized by widespread caseous consolidation of the lungs and typically abscesses in the liver, spleen, or other organs (Whitmore 1913). The name originates from the Greek "μηλις" (distemper of asses) and "ειδος" (resemblance), and the name was suggested by Stanton and Fletcher in 1921 (Stanton and Fletcher 1921), who went on to report a number of human and animal cases around Kuala Lumpur (Stanton and Fletcher 1932). It was later demonstrated that the causative bacterium, now known as *B. pseudomallei*, was saprophytic and could be cultured from soil and surface water in Vietnam (Chambon 1955) and subsequently from many other parts of Southeast Asia and northern Australia. In Australia, *B. pseudomallei* was first identified in sheep in 1949 (Cottew 1952) and the first human case occurred in a diabetic patient who died of septicemic melioidosis in north Queensland in 1950 (Rimington 1962). Using MLST (Currie et al. 2007), and more recently whole-genome sequencing (Chewapreecha et al. 2017), phylogenetic analysis has suggested that Australian isolates, which demonstrate greater genetic diversity, are ancestral to those found in Southeast Asia (Pearson et al. 2009). This supports the present hypothesis that Australia was the original reservoir for the current *B. pseudomallei* population, which expanded to Southeast Asia, where the Mekong subregion has emerged as a hotspot for *B. pseudomallei* evolution (Chewapreecha et al. 2017). Further dissemination to Africa and Central and South America is thought to have occurred between the seventeenth and nineteenth centuries (Chewapreecha et al. 2017). Gee et al. used a typing scheme for length polymorphisms in the 16S–23S internal transcribed spacer (ITS) of *Burkholderia* spp. and identified ITS type G isolates (containing the *Yersinia*-like fimbrial (YLF) gene) as associated with the Western Hemisphere (Gee et al. 2014). Analysis of single-nucleotide polymorphisms (SNPs) from whole genome sequencing is proving valuable in linking clinical isolates with geographic provenance. For example, a US military veteran who had spent time in Southeast Asia during World War II was initially reported as having the longest latency period (62 years) before developing melioidosis (Ngauy et al. 2005). There was no history of travel to other known endemic regions. However, WGS found the isolate to belong to the Western Hemisphere clade and grouped with genomes from

patient isolates with a travel history to Guatemala, Panama, and Peru. This isolate also belongs to the ITS type G cluster, which suggests that his exposure to *B. pseudomallei* may not actually have occurred during his internment in World War II (Gee et al. 2017). In the Darwin cohort periods of latency were thought to have occurred in 3% of melioidosis cases (Currie et al. 2021).

Melioidosis is endemic in many tropical regions, mainly between latitudes 20°N and 20°S, although *B. pseudomallei* is unevenly distributed in the environment in these areas and the true distribution has not been accurately defined (Dance 2000a). The highest isolation rates have been found in rice paddies, rubber plantations, and other cleared and cultivated areas (Nachiangmai et al. 1985; Strauss et al. 1969) but high rates have also been seen in urban sports fields in Singapore (Thin et al. 1971), and grazing sites of animals with melioidosis in Australia (Thomas et al. 1979). Factors that may influence environmental distribution include temperature, humidity, rainfall, ultra-violet exposure, soil composition, vegetation, fertilizers, and soil disturbance such as excavation or ploughing (Inglis et al. 2001). Recent modeling and epidemiological studies highlighted the underdiagnosis and underreporting of melioidosis, which was estimated to have infected 165,000 people (95% credible interval 68,000–412,000) and caused 89,000 deaths (36,000–227,000) worldwide in 2015 (Limmathurotsakul et al. 2016). This equates to 4.6 million disability adjusted life-years (DALYs), a greater burden than those for dengue and leptospirosis, and suggests that melioidosis should be formally categorized as a reemerging neglected tropical disease (Limmathurotsakul et al. 2016; Birnie et al. 2019; Savelkoel et al. 2021). India, Bangladesh, Vietnam, Nigeria, and Indonesia are predicted to contribute almost three-quarters of the total global disease burden (Birnie et al. 2019). Despite this, only ~1300 cases were reported annually worldwide in 2010, less than 1% of the estimated incidence (Limmathurotsakul et al. 2016). Whether this reflects the inadequacy of current surveillance systems or the inaccuracy of the modeling remains to be determined.

The relatively small numbers of cases reported in endemic areas during the latter half of the twentieth century probably reflects the limited culture facilities in many rural, high risk regions (Dance 1991). This is supported by the fact that western armed forces, with access to high quality laboratory diagnostics, reported at least 100 confirmed cases of melioidosis among French (Rubin et al. 1963) and American (Sanford 1985) soldiers, respectively, during the conflicts in Vietnam in contrast to the numbers of cases identified among the indigenous population. In Thailand, very few cases were reported until the improvement of district microbiology laboratories and increased clinical awareness in the 1980s, which led to in around 800 case reports by 1986 (Leelarasamee and Bovornkitti 1989) and an average of nearly 1800 culture-positive cases annually between 2012 and 2015 (Hantrakun et al. 2019). Sri Lanka has become a case study for uncovering the hidden burden using enhanced surveillance, awareness, and WHO's laboratory capacity building program (Corea et al. 2016). Despite only a handful of cases identified since 1927, and at times even being considered non-endemic for melioidosis (Cheng and Currie 2005), rising annual cases have been identified there since 2006, totaling 250 cases over 10 years in 8 out of 9 provinces (Corea et al. 2018).

Warm climates favor the persistence of *B. pseudomallei* in the environment; however when introduced to a non-endemic area the organism may persist for several years in soil. This apparently occurred during a prolonged outbreak in France in the 1970s, which was thought to have followed the importation of an infected panda (Mollaret 1988). More recently, cases occurring in the USA have been linked to imported tropical fish (see below) and an aromatherapy spray (Dawson et al. 2020; CDC 2021). With increasing movement of humans, animals, and goods around the world, new endemic foci may become established. Sporadic cases have been reported in the Americas, the Caribbean, and sub-Saharan Africa (Cheng and Currie 2005; Dance 1991) although the true incidence in these areas is unclear because of a lack of laboratory facilities and clinical awareness. Ongoing mapping of the distribution of *B. pseudomallei* and melioidosis is available at https://www.melioidosis.info/map.aspx.

Molecular tools have demonstrated that environmental isolates are often identical to epidemiologically related human or animal strains, that there is considerable diversity among isolates persisting in a particular region, and that clonal outbreaks have occurred when the organism is introduced to a non-endemic region (Gee et al. 2017; Cheng and Currie 2005; Currie et al. 1994).

By the year 2000, melioidosis was regarded as an emerging infection due to increasing reports of confirmed cases in endemic regions, particularly Thailand, where it is estimated that more than 2500 culture-positive cases of human melioidosis occur annually, increasing reports of cases from regions where the disease was not known to be endemic (e.g., the Americas and the Caribbean) (Cossaboom et al. 2020; Sanchez-Villamil and Torres 2018), and concerns that it could be spread to non-endemic regions by infected animals (Dance 2000b). Much of the increase has been due to improved diagnostics and clinical awareness, but the increasing prevalence of predisposing medical conditions such as diabetes in populations of endemic areas (Dance 2000b) and possibly climate change and increasing travel and migration have also impacted on melioidosis epidemiology. Analysis of melioidosis among returned travelers in Europe identified Thailand as the main source of infection (53%), with one-fifth of patients being misdiagnosed (Le Tohic et al. 2019). However, even in countries where notification is mandatory, such as the UK, many cases are still going unreported (O'connor et al. 2020).

Currently, the greatest burden of melioidosis is reported in Thailand (especially the northeast) and Northern Australia where annual incidence rates vary between 4 and 50/100,000/year (Parameswaran et al. 2012; Hantrakun et al. 2018). Melioidosis is now the third most common cause of death from infectious disease in northeast Thailand,(Limmathurotsakul et al. 2010) although this has been underrecognized through routine surveillance systems (Hantrakun et al. 2019) and is the commonest cause of fatal community-acquired bacteremic pneumonia in the Northern Territory of Australia (Currie et al. 2000b). The disease is highly seasonal, with 75–85% of cases presenting during the rainy season (Suputtamongkol et al. 1994; Currie et al. 2010), and incidence rates as high as 102.4/100,000 have been recorded in the indigenous Australian population during severe rains (Parameswaran et al. 2012; Currie et al. 2004). Large case series have identified diabetes mellitus as by far

the most important risk factor for infection, with occupational exposure to soil and water, male sex, Aboriginal Australians, alcoholism, chronic lung disease, chronic renal disease, thalassemia, and kava and steroid use all additional risk factors for melioidosis (Cheng and Currie 2005; Suputtamongkol et al. 1994; Currie et al. 2010). The majority of cases have a predisposition, but in around 20% none is identified (Currie et al. 2010). Presence of a single risk factor increases the risk of death from melioidosis by 8.4 times (95% CI 2.7–26.0) (Currie et al. 2021).

With respect to animal infection, *B. pseudomallei* appears to affect a broader range of animal hosts than glanders, with infection in equines being relatively rare, although it may occasionally cause severe infections in horses. Species that have been infected include terrestrial and aquatic mammals, birds, and fish. Goats, sheep, pigs, and camels appear particularly susceptible, whereas dogs, cats, and cattle appear more resistant, but these may develop disease if they become immunocompromised (Choy et al. 2000). Sporadic cases or small outbreaks have been reported in various primates, marsupials, deer, buffalo, camels, llamas, zebras, horses, mules, rabbits, meerkats, rodents, iguanas, parrots, crocodiles, dolphins, and seals (Elschner et al. 2014; Sprague and Neubauer 2004). Animal cases have also been reported in other regions, such as southern and western Australia(Currie et al. 1994; Ketterer et al. 1986), China(Li et al. 1994), Iran (Baharsefat and Amjadi 1970), Saudi Arabia (Barbour et al. 1997), United Arab Emirates (Wernery et al. 1997), South Africa (Van Der Lugt and Henton 1995), and the Americas (Zehnder et al. 2014; Galimand and Dodin 1982). Epizootics have been reported after importation of animals from areas of endemicity. This was believed to be the source of a cluster of infections in sheep, goats, and pigs in Aruba in 1957 (Fournier 1965), an outbreak in a Paris zoo, which spread to other zoos and equestrian clubs in France in the 1970s (Mollaret 1988), and an outbreak in primates in the UK in the 1990s (Dance et al. 1992). More detail on confirmed cases of melioidosis in different animal species worldwide can be found in a review by Sprague and Neubauer (Sprague and Neubauer 2004).

43.3.2 Modes of Transmission

Whitmore's early observations of melioidosis in guinea pigs led him to believe that the infection was transmitted by consumption of food and drink contaminated by urine, sputum, or other secretions containing viable bacteria, from infected persons or animals (Whitmore 1913). In the 1930s, Stanton and Fletcher also proposed that infection occurred by ingestion, although they believed that rodents were a zoonotic reservoir (Stanton and Fletcher 1932). It was subsequently observed that human infections commonly followed exposure to mud and water, and that *B. pseudomallei* could be isolated from mud and surface water (Chambon 1955), leading to the current knowledge that it is an environmental saprophyte. Well-documented modes of transmission include inoculation and aspiration of water during near drowning (such as during the Asian tsunami in 2004), and laboratory-acquired infection (although only two such instances have been reported in the literature). Epidemiological evidence and animal studies also suggest a role for inhalation and ingestion,

although it is often impossible to define precisely how and when infection occurred. Although sporadic cases have been anecdotally associated with infection in animals, there is limited evidence for zoonotic or person-to-person spread (Dance 2000a), and it is equally likely that both humans and animals have acquired infection from the same environmental source. The few suspected human-to-human *B. pseudomallei* transmissions have been in siblings with cystic fibrosis (Holland et al. 2002) and diabetes (Arauz et al. 2020), an American Vietnam veteran diagnosed with *B. pseudomallei*-associated prostatitis and his spouse (Mccormick et al. 1975), and cases of mother-to-child transmission via transplacental, breast, or perinatal routes (Aziz et al. 2020; Rodriguez et al. 2020; Ralph et al. 2004; Kunakorn et al. 1991). Recently, a case of transmission from a breastfeeding mother with mastitis was confirmed using WGS (Aziz et al. 2020).

Inoculation of organisms through penetrating injuries or preexisting skin lesions appears to be the major mode of acquisition, particularly in farmers who are continually exposed while working in the mud and surface water of paddy fields (Suputtamongkol et al. 1994). Twenty five percent of patients in one case series recalled a previous inoculation injury, but often there is no such history (Currie et al. 2000b). *B. pseudomallei* is most abundant in soil depths of >10 cm; however during the rainy season it can rise and concentrate at the surface (Limmathurotsakul et al. 2013a). Inoculation is the method most frequently used to induce infection in animal models, and natural infection in animals occurs in this way by entry of bacteria through minor skin trauma, bite wounds, and scratch injuries. This was the likely mode of infection in a patient from Maryland, USA with no travel history who developed melioidosis in 2019. Isolates of *B. pseudomallei* that were indistinguishable by WGS and clustered with isolates from Southeast Asia were obtained from both the patient and a freshwater aquarium in which all the fish had died. The patient recalled reaching into the aquarium with bare hands and arms a month prior to onset of illness (Dawson et al. 2020). Nosocomial infections have also occasionally been reported, mainly through use of contaminated medical supplies and solutions (Merritt et al. 2016).

Infection after inhalation has been repeatedly demonstrated in laboratory animals (Jeddeloh et al. 2003), and this may be an important and underestimated mode of acquisition in humans. In Australia, *B. pseudomallei* recovered from an air sample was linked to a clinical isolate from a patient with mediastinal melioidosis by WGS (Currie et al. 2015), and the north-easterly winds during the typhoon season in Taiwan were associated with detection of *B. pseudomallei*-specific DNA in aerosols and a hot spot of transmission (Hsueh et al. 2018). It is now established that during periods of very heavy rainfall, increases in pneumonic cases of melioidosis occur, probably as a result of aerosolization of the bacteria (Currie and Jacups 2003). Inhalation was previously thought to be the primary mode of transmission due to the high incidence of melioidosis in US military helicopter crews during and after the Vietnam War.

Ingestion has also been proposed as a mode of infection in both humans and animals. Contaminated water supplies have been implicated by PFGE as the point source of melioidosis outbreaks in Australia (Currie et al. 2001; Inglis et al. 1999).

Suppurative parotitis, a common presentation in children with melioidosis in Southeast Asia, is believed to be due to the ingestion of contaminated water or soil, resulting in the ascent of bacteria from the mouth to the parotid gland (Stoesser et al. 2012). Although not confirmed, an untreated river water supply was implicated in melioidosis outbreaks occurring in intensive piggeries (Ketterer et al. 1986). In these outbreaks, an oral mode of transmission was suspected due to the common finding of infected gastro-hepatic nodes. Feco-oral transmission was felt to be unlikely due to the fact that *B. pseudomallei* was infrequently isolated from fecal samples of infected pigs. However, fecal shedding has been detected from wallabies and wild stock, suggesting it may be a means of expanding the geographical distribution of *B. pseudomallei* (Höger et al. 2016). Recent nonhuman primate models showed that ingestion of $>6 \times 10^6$ cfu resulted in acute-febrile, lethal disease (Nelson et al. 2021). Enteritis was observed in fatal disease with the lungs being the first organ colonized outside of the gastro-intestinal tract. Severe pathological feature in the mesenteric lymph nodes suggests that lymphatic drainage maybe an important route of dissemination post ingestion (Nelson et al. 2021).

Despite early theories, there is relatively little evidence for melioidosis being a true zoonosis. In addition to the aquarium-associated case described above, three anecdotal cases of possible zoonotic infection in Australia were described by Choy et al. (Choy et al. 2000). In one case, *B. pseudomallei* was cultured from a wrist lesion of a meat worker in Darwin; secondly, a vet in rural Queensland developed abscesses on the arm, but this does not appear to have been confirmed as melioidosis by culture; and similarly, a goat farmer had a lesion on his hand resembling a "milker's lesion" for 2 months preceding a diagnosis of melioidosis, which again does not appear to have been culture-confirmed. In Malaysia, a case of suspected sheep-to-human-transmission was reported in a 10-year-old boy (Idris et al. 1998). The evidence for this was entirely circumstantial, and it is more likely that he contracted the illness from soil and water in the environment (from which *B. pseudomallei* was also isolated). Earlier anecdotal evidence of animal-to-human transmission of melioidosis was reported during "L'affaire du Jardin des Plantes," an outbreak of melioidosis that started in a Paris zoo and spread to other zoos and equestrian clubs in France through transport of infected animals and contaminated manure. At least two fatal human cases were said to have occurred during this outbreak, although details were never published (Dodin and Galimand 1986). In none of these cases has there ever been genotypic evidence of the relationship between the human and animal isolates, and so the case for animal-to-human transmission remains unproven. Nonetheless, the potential for zoonotic transmission can lead to significant public health concerns and responses, such as those that occurred following the importation into the USA of a rescue dog from Thailand that was subsequently found to have *B. pseudomallei* urinary tract infection. Fortunately, there were no resultant human infections (Ryan et al. 2018).

There have been concerns that goats, which appear to be particularly susceptible to melioidosis and often develop mastitis as a manifestation of the infection (Fig. 4), could transmit the disease via infected milk. However, small studies of infected goats have found that the organism is only isolated from body fluids in a minority of cases

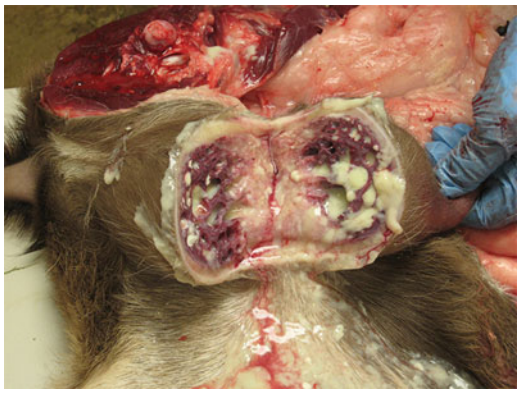

Fig. 4 Mastitis found on post-mortem of a goat who died of melioidosis. Copyright Dr Carl Soffler

(Thomas et al. 1988a). Furthermore, a recent literature review of bacterial infections following animal bites worldwide did not identify any cases of melioidosis, supporting the fact that transmission from body fluids is unlikely (Abrahamian and Goldstein 2011). However, clearly it makes sense in public health terms to avoid drinking milk or eating meat from infected animals.

43.3.3 Microbiology

B. pseudomallei is an irregularly staining, oxidase-positive, motile Gram-negative bacillus, which sometimes exhibits marked bipolarity microscopically. It can be distinguished from *B. mallei* by its motility and usually its resistance to aminoglycosides. It grows readily on most routine culture media, initially forming smooth creamy, nonhemolytic colonies (Day 2), which may become dry and wrinkled (Day 4) with a metallic sheen on prolonged incubation (Fig. 5), sometimes with a zone of hemolysis surrounding confluent growth. Considerable variability in colonial morphology may be seen between, and even within, strains. It is often dismissed as a contaminant or misidentified (e.g., as *Acinetobacter* spp. *Pseudomonas* spp. or *Bacillus* spp.), especially on nonselective agars, where it may be outgrown by other microbial flora. Ideally, selective media (e.g., Ashdown's agar) should be used, particularly where laboratory staff are unfamiliar with its characteristics or when polymicrobial growth is expected, with daily examination of plates for up to 4 days in suspected cases. In respiratory samples from low-incidence settings, this approach improved sensitivity (87.5%) and allowed for quicker identification than routine media (50%) (Subakir et al. 2020). Important characteristics include arginine dihydrolase and gelatinase activity, the inability to assimilate arabinose (distinguishing *B. pseudomallei* from the closely related avirulent *B. thailandensis*), and growth at 42 °C. Its intrinsic resistance to aminoglycosides (although clonal isolates susceptible to gentamicin are common in Sarawak, Malaysia) (Podin et al. 2014), polymyxins and the early beta-lactams, but susceptibility to co-amoxiclav, is

Fig. 5 Typical dry, wrinkled colonies of Burkholderia pseudomallei after 48 hours culture on Ashdown's media

particularly characteristic, and any oxidase positive Gram-negative bacillus with these characteristics should be assumed to be *B. pseudomallei* until proved otherwise (Trinh et al. 2018). The species is antigenically homogeneous, but a number of molecular techniques, most usefully MLST and WGS, can distinguish between isolates.

43.3.4 Pathogenesis

A range of bacterial factors have been associated with virulence, but the relative contributions of individual virulence factors to the disease process have not been fully characterized. A variety of adhesins, in particular type 4 pili, appear to be involved in attachment of bacteria to different eukaryotic cell types, and expression is regulated by the *pilA* gene (Allwood et al. 2011). Capsular polysaccharides also act to inhibit opsonophagocytosis and complement-mediated killing (Egan and Gordon 1996). Like *B. mallei, B. pseudomallei* utilizes up to three T3SS, including Bsa T3SS. In vitro experiments have demonstrated the importance of this system, and its individual components, in host cell invasion, escape from endosomes and intracytoplasmic survival (Stevens et al. 2002). Mutations in components of the T3SS in *B. pseudomallei* have reduced ability to cause disease in animal models (Stevens et al. 2004). Cell-to-cell spread takes place by actin-based motility, which is dependent on the BimA protein (Stevens et al. 2005) (mutations of which have been linked to central nervous system diseases, especially in Australia) and the cluster 1 type VI secretion system (T6SS-1), which mediates endocyte escape and membrane fusion during intracellular spread via VgrG5 spike protein (Toesca et al. 2014). The antiphagocytic polysaccharide capsule, quorum sensing mechanisms, and bacterial components such as lipopolysaccharide, flagella, secreted products (protease, lipase, lecithinase, various toxins), and a siderophore ("malleobactin") also have important roles in environmental protection and adaptation, and host immune system

evasion (Wiersinga et al. 2018; Cheng and Currie 2005). The ability of the organism to survive and grow intracellularly or become metabolically inactive within granulomas probably contributes to the persistent nature of the infection and the risk of relapse.

The clinical outcome after exposure to *B. pseudomallei* in the environment varies from person to person, ranging from asymptomatic seroconversion (the commonest outcome) or localized infection to fulminant sepsis and death, and is dependent on the size and route of the inoculum, the virulence of the infecting strain, and host immune factors. On the host side, innate immune mechanisms, macrophage, and neutrophil function, and both cellular and humoral responses all play a role in defense against the organism, hence the strong associations with immune-suppressing conditions such as diabetes (12-fold increased risk compared with the normal population) (Limmathurotsakul et al. 2010), thalassemia, renal impairment (associated with disease severity in India) (Shaw et al. 2019), and alcohol excess (Cheng and Currie 2005; Currie et al. 2004). In a prospective study of over 1000 patients with melioidosis, a third of whom had diabetes, there was a statistically significant survival advantage in diabetics compared with nondiabetics. However, this was confined only to patients taking glyburide (a second generation sulfonylurea, which acts as K_{ATP}-channel blocker and broad-spectrum ATP-binding cassette (ABC) transporter inhibitor used in treating type 2 diabetes mellitus) (Koh et al. 2011). Subsequent diabetic mice models demonstrated an anti-inflammatory effect of glyburide by reducing IL-1b, diminished cellular influx, and reduced bacterial dissemination to distant organs (Koh et al. 2013).

Interestingly, HIV does not appear to be a risk factor despite murine studies showing a role for the adaptive immune system in control of infection, with increased survival correlated to CD8+ T cell responses in humans (Jenjaroen et al. 2015). An exaggerated host response with high levels of pro-inflammatory cytokines such as TNF-alpha may also have a pathogenic role (Nuntayanuwat et al. 1999), whereas hypofunctional TLR5 has been associated with decreased organ failure, improved survival, and functional cytokine response (Chantratita et al. 2014; West et al. 2014). Antigens and epitopes (e.g., BopE – Type III secreted protein, AhpC – alkyl hydroperoxide reductase, PilO – Type IV pilus biosynthesis protein), immunodominant in survivors, have been identified as immune correlates of protection (Dunachie et al. 2017). Diabetic patients were noted for their impaired response to GroEL proteins (chaperonins that assist in protein folding) during acute infection (Dunachie et al. 2017).

43.3.5 Clinical Presentation in Humans

The majority of infections appear to be subclinical with 60–70% of populations in endemic areas acquiring antibodies to *B. pseudomallei* by the age of 4 years without clinically apparent disease (Wuthiekanun et al. 2006). When disease manifests, it may be localized or disseminated with septicemia. The incubation period varies depending on the mode of acquisition and infecting dose, with most cases occurring

within 3 weeks after an inoculation injury (median 4 days, IQR 3–7 days), (Currie et al. 2021) and as soon as 24 h after a near-drowning event (Currie et al. 2000b; Suputtamongkol et al. 1994). The median age at presentation with melioidosis is 50 years, with 4–10% of patients under 16 years of age (Currie et al. 2010; Mcleod et al. 2015). Pneumonia is the commonest presentation, and is evident in around half of all cases (Currie et al. 2010). Cavitation may occur in the upper zones mimicking tuberculosis. Localized abscesses may occur in any other organ including the skin and soft tissues, lymph nodes, liver, spleen, genitourinary tract (especially the prostate gland in males), parotid gland, bone or joint, and nervous system. Localized disease without bacteremia generally has a good outcome and low mortality. However, in 50–75% of cases the patient is bacteremic, although this is lower in pediatric populations (Turner et al. 2016; Currie et al. 2021), and just over one-fifth of these are in septic shock at presentation, which has a mortality approaching 50% despite optimal treatment (Birnie et al. 2019; Currie et al. 2010; Suputtamongkol et al. 1994). There appear to be geographical variations in manifestations, with hepatosplenic abscesses more common in Asian populations and suppurative parotitis in Asian children, and higher rates of prostatic and neurological melioidosis seen in Australia (Cheng and Currie 2005), although this could be biased by better access to imaging. Recrudescent melioidosis after treatment occurs in up to 5% of cases (Currie et al. 2021). This is due to reactivation of the original strain (relapse) in approximately 75% of cases, which is usually associated with a failure to sterilize deep-seated foci of infection in disseminated disease, but may also be associated with poor adherence to therapy or an insufficient duration of eradication therapy (Currie et al. 2000a). Reinfection with a different strain accounts for ~25% of recurrent infections (Currie et al. 2021).

43.3.6 Clinical Presentation in Animals

As outlined above, a wide range of animal species may be affected by melioidosis, with a range of clinical manifestations and severity. In fact, the disease in animals is usually similar to that in humans, with subclinical infections common and abscesses occurring in any organ, particularly lungs, liver, spleen, and associated lymphatics. The acute form presents as fulminant sepsis with hematogenous dissemination and high mortality, often associated with respiratory distress and diarrhea, and tends to occur in younger animals of susceptible species. The chronic form presents as a more non-specific illness in older animals, with low-grade fever, anorexia, cough, progressive emaciation, and lameness (Choy et al. 2000). In sheep, goats, and horses, nasal, and ocular discharge (similar to that seen in glanders) is common, and central nervous system involvement may contribute to paralysis, convulsions, nystagmus, and blindness (Sprague and Neubauer 2004). Mastitis appears to be a particular feature in goats (Fig. 4), orchitis has been described in rams and boars, and skin lesions, limb edema, lymphangitis, and meningoencephalitis in horses (Sprague and Neubauer 2004). Monkeys are affected in a similar way to horses, but neurological involvement is more unusual (Sprague and Neubauer 2004).

43.3.7 Diagnosis

Melioidosis should be considered in any person or animal who has visited or migrated from an endemic area presenting with septicemia and/or abscesses, especially if they have a predisposing condition such as diabetes. Confirmation of the diagnosis relies on culture of the organism from blood, sputum, pus, or other body fluid indicated by the clinical presentation. Liaison with the microbiology laboratory is of utmost importance if melioidosis is suspected. Firstly, the organism is a hazard group 3 pathogen and must be handled in appropriate laboratory containment in case of transmission to laboratory staff. Secondly, selective media such as Ashdown's or *B. cepacia* media may be used to optimize the isolation of the organism from sites with a normal flora. And thirdly, if not aware of the clinical context, growth in cultures may be dismissed as a contaminant by the unwary.

Culture may take several days, and meanwhile microscopy of pus, sputum, or urine may reveal bipolar or unevenly staining Gram-negative rods, although this appearance is not specific. Immunofluorescent staining of such samples is a useful rapid diagnostic tool but is not widely available (Wuthiekanun et al. 2005). Once cultured, commercial identification kits such as the API 20NE usually identify the organism correctly but may give misleading results (Amornchai et al. 2007), so presumptive isolates should be sent to a Reference Laboratory if in doubt as to the identity. Well-equipped laboratories are increasingly using matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry for bacterial identification, provided an appropriate database including hazardous pathogens is available as discussed above (Lasch et al. 2016). A latex agglutination test using a monoclonal antibody to the 200 kDa extracellular polysaccharide is also useful for screening suspect colonies or positive blood culture fluid, with 95% sensitivity and 99.7% specificity (Anuntagool et al. 2000). In low-resource or -incidence settings, selective media followed by real-time PCR has been shown to improve diagnosis of melioidosis at a reasonable cost (Subakir et al. 2020).

Direct detection of *B. pseudomallei* antigens in clinical samples is another approach that might be particularly useful in areas where culture is not available. A lateral flow test using a monoclonal antibody specific for capsular polysaccharide (CPS), with a limit of detection of ~0.2 ng/ml, the Active Melioidosis Detect Lateral Flow Immunoassay (AMD LFI; InBios, USA), is not yet on the market but has undergone evaluation in several settings. Testing against a large panel of *B. pseudomallei* isolates showed an analytical reactivity of 98.7%, with cross-reactivity in only 2.8% of near neighbor species (Houghton et al. 2014). The AMD-LFI was 99% sensitive and 100% specific on turbid blood culture bottles. The high specificity was maintained across all sample types, with relatively high sensitivity in pus and sputum samples but poor sensitivity on serum. In this cohort from Laos, urine samples had a positive predictive value of 94% for diagnosing melioidosis; a potential game changer for diagnostics in resource limited settings (Woods et al. 2018). Similar findings were reproduced from prospective cohorts in India, although highest discordance was demonstrated from serum – 34.1%. This was corroborated in Thailand where sensitivity in serum was 31.3% (Wongsuvan et al. 2018).

There is no standard serological test for melioidosis. An indirect hemagglutination (IHA) test, using a crude mixture of poorly characterized antigens, is most widely used, but it lacks sensitivity and specificity in humans, particularly in endemic areas where background seropositivity rates are high (e.g., 29%, 38%, and 12.8% in studies in India, Thailand, and Australia, respectively) (Vandana et al. 2016; Chaichana et al. 2018; Smith et al. 2018). A rapid immunochromatographic test for IgG appeared to be more sensitive and specific than IHA in populations of endemic areas but is no longer commercially available (Wuthiekanun et al. 2004). Recently, ELISAs employing better characterized antigens such as purified O-polysaccharide (OPS) and hemolysin co-regulated protein (Hcp-1) have been shown to have better performance than the IHA for serodiagnosis of melioidosis in endemic areas (Pumpuang et al. 2017), with IgG antibody levels for both antigens raised from an early stage (Pumpuang et al. 2019). A rapid immunochromatography test (ICT) using Hcp-1 was evaluated in cohorts of melioidosis patients, healthy controls, and patients with other infections, demonstrating an overall sensitivity of 88.3% (Phokrai et al. 2018). However, until kits using more refined, standardized antigens are available, the utility of serological tests is largely limited to non-endemic regions. Despite the limitations, serology continues to be used in veterinary medicine, and a two-step method by screening with IHA followed by confirmation with a complement fixation test was shown to be sensitive and specific in caprine melioidosis (Thomas et al. 1988b). Molecular methods have also been developed but are not yet used for routine diagnostic purposes.

Radiology is an important adjunct to microbiological diagnosis, and may demonstrate diffuse nodular infiltrates, abscess, or cavitating pneumonia on chest radiograph. Liver, splenic, prostatic, or other intra-abdominal abscesses on ultrasound or CT may be suggestive of the diagnosis (Huson et al. 2020).

43.3.8 Treatment

B. pseudomallei is intrinsically resistant to many classes of antibiotics, including some third generation cephalosporins, early penicillins, aminoglycosides, colistin, and polymyxin, and exhibits relative resistance to quinolones and macrolides (Cheng and Currie 2005). Acquired resistance may occur but rarely compromises the choice of antibiotic treatment (Wuthiekanun et al. 2011; Fen et al. 2021), although one recent paper from China reported nearly 13% of isolates as resistant to ceftazidime (Rao et al. 2019).

The treatment of melioidosis may be classified into acute and eradication phases. In the acute phase the aim is to kill bacteria in the circulation and prevent patients dying of overwhelming sepsis, and in the eradication phase the aim is to kill any residual bacteria in abscesses or tissues and prevent relapse of infection. Currently, ceftazidime or a carbapenem for 2 weeks is the treatment of choice for the acute phase, and co-trimoxazole for 12–20 weeks for eradication (Anunnatsiri et al. 2020). Recent updates to Australian guidelines recommend a minimum of 3 weeks intravenous therapy for multi-lobar pneumonia without bacteremia, 4 weeks if

bacteremic, and minimum 3 weeks for those with only single lobar pneumonia with concomitant bacteremia. Even longer courses of treatment (up to 8 weeks intravenously and 6 months orally) are recommended for those with deep-seated foci of infection, including bone and joint, central nervous system, and intravascular involvement (Sullivan et al. 2020).

In a trial of 161 patients in Thailand (65 with confirmed melioidosis, 54 of these septicemic), ceftazidime (120 mg/kg/day) in the acute phase reduced mortality from 74% to 37%, compared with the conventional combination regimen of chloramphenicol, doxycycline, and co-trimoxazole (White et al. 1989). Other cephalosporins, such as cefotaxime and ceftriaxone, were associated with significantly greater mortality compared with ceftazidime in retrospective analyses (Chaowagul et al. 1999). Subsequent trials assessed ceftazidime with and without the addition of co-trimoxazole in the acute phase of melioidosis, and failed to demonstrate any difference in mortality between the monotherapy and combination groups (Chierakul et al. 2005). Median time to defervescence of fever was 9 days (Simpson et al. 1999b). In the Darwin cohort, extending the acute intensive phase to 4 weeks, resulted in a relapse rate of only 1.2% (Pitman et al. 2015).

Carbapenems are the most active drugs in vitro against *B. pseudomallei*, and are more rapidly bactericidal (Smith et al. 1996). A randomized trial comparing ceftazidime (120 mg/kg/day) with imipenem/cilastatin (50 mg/kg/day) for a minimum of 10 days was unfortunately terminated early and therefore underpowered. It showed no difference in mortality between the two groups, but higher rates of treatment failure in the ceftazidime group (41.3% versus 20.3%) (Simpson et al. 1999a). Co-amoxiclav is considered second-line therapy for the acute phase. One study from Malaysia has suggested veterinary cases, especially those involving novel ST 1130 isolates show significantly higher likelihood of resistance to meropenem (Sadiq et al. 2018). *B. pseudomallei* isolates carrying the carbapenemase blaOXA-57 have also been identified, although, >90% of blaOXA-57 carrying isolates were phenotypically susceptible to imipenem (Amladi et al. 2019). The concern is however that IS (insertion sequences) family transposases (carried by these isolates), which facilitate mobilization of extended-spectrum -lactamase (ESBL) and carbapenemase genes, would have been missed had hybrid genome assembly not been performed (Amladi et al. 2019). This highlights the wider threat of AMR and virulence gene acquisition and need for robust surveillance systems globally.

The conventional combination of chloramphenicol, doxycycline, and co-trimoxazole for eradication therapy was extremely poorly tolerated leading to reduced compliance and increased rates of relapse. Omitting chloramphenicol was shown to be beneficial in terms of side effect profile, with no adverse treatment outcomes (Chaowagul et al. 2005). Years of clinical experience in Australia,(Currie et al. 2021) however, suggest that co-trimoxazole monotherapy for 12–20 weeks is probably adequate to prevent relapse. The MERTH trial conducted in Thailand, also supported the use of co-trimoxazole monotherapy on the basis of efficacy, safety, and tolerance by patients (Chetchotisakd et al. 2014). Another recent RCT,which did not meet the primary end point (culture-confirmed recurrent melioidosis), found that

all-cause mortality was significantly lower with a 12-week regimen (0.3%) compared to 20 weeks (3%), meeting the criteria for non-inferiority for the secondary composite end-point (overall recurrent melioidosis and mortality) (Anunnatsiri et al. 2020). In the rare cases of co-trimoxazole resistance (determined by MIC), and where co-trimoxazole is contraindicated, co-amoxiclav is the preferred choice for eradication therapy, although this is associated with increased rates of relapse (Rajchanuvong et al. 1995). In a cohort of >3000 patient isolates, only 0.33% were resistant to co-trimoxazole. Encouragingly, all resistant isolates were susceptible to co-amoxiclav, but only 91% to doxycycline (Saiprom et al. 2015). As mentioned previously, poor compliance also contributes to relapse, and so it is crucial that each patient is counseled in the importance of completing the full treatment course regardless of symptomatic improvement.

Novel agents such as cefiderocol, a siderophore cephalosporin, which inhibits peptidoglycan synthesis and is described as universally stable against β-lactamases (providing greater efficacy than carbapenems, cephalosporins, and other inhibitor combinations), shows promise as it is highly active in vitro against *B. pseudomallei* (Burnard et al. 2021).

Apart from appropriate antibiotic therapy, the management of melioidosis must also incorporate optimal supportive treatment for sepsis, including maintenance of blood pressure, adequate glycemic control, and management of respiratory and acute renal failure. Around one quarter of cases require admission to intensive care (Currie et al. 2021). The drainage of abscesses should also take place where possible. Adjunctive granulocyte colony-stimulating factor (G-CSF) has been used to boost host neutrophils in an attempt to control infection, but despite promising outcomes in a retrospective study, G-CSF did not significantly reduce mortality in a randomized controlled trial (Cheng et al. 2004; Cheng et al. 2007).

Even with appropriate antimicrobial and supportive therapy, mortality remains high for septicemic cases. Poor prognostic factors include shock, absence of fever, leucopenia, abnormal liver function, renal impairment, high level or persistent bacteremia, hypoglycemia, and acidosis (Currie et al. 2021; Limmathurotsakul et al. 2011). However, over the past 5 years, a combination of optimal sepsis management and antibiotic therapy has reduced the overall mortality from melioidosis in Darwin, Australia, to only 6% (Currie et al. 2021).

The efficacy of post-exposure prophylaxis (PEP) in protection against developing melioidosis remains unknown. Animal models show that PEP simply delays the onset of disease, rather than preventing it (Dance et al. 2017). In over 70-years of combined experience in diagnostic laboratories from endemic regions, which handle thousands of *B. pseudomallei* samples at containment levels less stringent than US biosafety level 3, leaders in the melioidosis field have not once been consulted about a case of laboratory-acquired infection (Dance et al. 2017). Exposure of 30 healthcare workers (HCWs) in South Korea, including five high risk exposures to pus/blood through non-intact skin and 25 low risk contacts with blood through intact skin, along with two laboratory staff who opened the lid of an agar plate growing *B. pseudomallei* outside a biological safety cabinet, resulted in no seroconversion or symptoms of melioidosis. The only two well-described laboratory-acquired cases

to date involved sonication outside a safety cabinet and cleaning up a spillage of *B. pseudomallei* culture with bare hands while having an ulcerative lesion on a finger (Jun et al. 2017). A recent study in Queensland (Australia) identified no infections or seroconversions following 1267 instances when *B. pseudomallei* was handled outside a safety cabinet (Gassiep et al. 2021). Using bioaerosol sampling and *B. thailandensis,* as a bioequivalent surrogate in handling experiments, the authors found no evidence of environmental contamination. This suggests the risk of laboratory-acquired melioidosis may be lower than that for glanders or some other hazard group 3 agents. In the rare occasion where a high-risk exposure or low risk exposure in a lab worker with underlying risk factors has occurred, PEP with co-trimoxazole may be considered following a careful discussion of risks and benefits (Peacock et al. 2008). As a caution, of two lab technicians who were exposed to aerosolized *B. pseudomallei* while manipulating cultures outside a biosafety cabinet, neither of whom developed melioidosis or seroconverted, one had to take time off work due to adverse drug reaction (fever, cough, and rash) to co-trimoxazole, so the decision to offer PEP should not be taken lightly (Mitchell et al. 2017).

As is the case for glanders, the long duration of treatment of melioidosis in animals can be expensive and ineffective. In cases where treatment is deemed necessary, such as in animals of economic value, treatment regimens are as for human cases.

43.3.9 Prevention and Control

A cost-benefit analysis has suggested that immunization against melioidosis would be worthwhile if used in high-risk populations, even when only partial protection is assumed (Luangasanatip et al. 2019). A Steering Group on Melioidosis Vaccine Development (SGMVD) was created to advise the scientific community in 2015 (Limmathurotsakul et al. 2015). A key recommendation was that vaccine candidates should also be tested in diabetic animal models. The Defense Threat Reduction Agency (DTRA) recently funded the United States Army Medical Research Institute of Infectious Diseases (USAMRIID) to conduct head-to-head comparisons of promising vaccine candidates in 2020. As recommended by SGMVD, this study should provide concrete evidence for antibody- and cytokine-mediated responses that confer protection and preferably sterilizing immunity (Khakhum et al. 2020). However, although potential candidates are under investigation, as yet there is no licensed human or animal vaccine for melioidosis.

Due to the complex pathogenicity of *B. pseudomallei* and strain heterogeneity, it has become evident that a multicomponent vaccine using a combination of protective antigens will be required for complete protection. Thankfully, intense research has resulted in several multivalent platforms such as glycoconjugates, multivalent subunit preparations, live-attenuated bacteria, nanoparticle platforms, and outer membrane vesicles (OMV) that have proven highly effective in experimental animal models of melioidosis, conferring 40–100% efficacy (Morici et al. 2019). OMVs hold particular promise as they lack any observable toxicity, are self-adjuvanting

(driving dendritic cell maturation), and can contain intracellular stage-specific proteins such as T3SS-3 or T6SS-1 (Baker et al. 2021). A recent study using purified *B. pseudomallei* CPS covalently linked to recombinant CRM197 (a nontoxic mutant of diphtheria toxin) produced opsonizing antibody responses with high IgG titers. Mice vaccinated with a combination of CPS-CRM197 and recombinant Hcp1 showed 100% survival in a lethal inhalational challenge model, with 70% sterilizing immunity (Burtnick et al. 2018). This candidate is planned to be the first melioidosis vaccine used in a human phase 1 clinical trial in diabetic and nondiabetic volunteers.

In the absence of a licensed vaccine, preventive measures must focus on avoidance of contact with *B. pseudomallei* in the environment. A matched case-control study carried out in northeast Thailand found that working in rice fields, walking barefoot, bathing in pond water, exposure to rain, water inhalation, and having an open wound all significantly increased the odds of acquiring melioidosis (Limmathurotsakul et al. 2013b). A lower risk of melioidosis was associated with wearing protective clothing such as long trousers and rubber boots, and washing with clean water after working in the fields. The authors, therefore, recommended avoidance of direct contact with soil and environmental water whenever possible, but wearing protective clothing and washing after exposure if this is unavoidable. Wounds should be kept covered until they have completely healed, and the application of herbal remedies to wounds should be avoided, as this was also associated with an increased risk of melioidosis. Since there was a small but significant risk observed with drinking untreated water, and since *B. pseudomallei* was found in water drunk by 7% of cases and 3% of controls, including borehole, wells, and piped supplies, it was also recommended that only treated water should be drunk in endemic areas (Limmathurotsakul et al. 2013b). It has also been recommended that goat's milk be pasteurized to avoid potential zoonotic transmission by ingestion (Choy et al. 2000), although this has never been reported, but this makes sense in general public health terms.

Very recently, the results of PREMEL, a stepped-wedge cluster-RCT on the effectiveness of a multifaceted prevention program for melioidosis in diabetics from 116 primary care units in northeast Thailand, have been published (Suntornsut et al. 2021). Although rates of culture-confirmed melioidosis were not decreased in participants who had received an intervention in the form of a behavioral support group session, they had a lower incidence of hospital admissions involving infectious diseases and of all-cause mortality. Proposals for modification/addition of behavioral techniques and need for more frequent intervention have been suggested (Suntornsut et al. 2021).

Due to the low but theoretical risk of person-to-person transmission, human cases should be nursed in isolation with contact precautions and care taken when handling any body fluids. People with strongly associated predisposing conditions, such as diabetes, should be informed of their increased risk of melioidosis, and advised to avoid the above high-risk activities. Unfortunately, in rural areas, and during heavy rain and winds, exposure may be unavoidable for many.

It has been recommended that animals be removed from contaminated sources, such as soil or water in endemic regions, to prevent melioidosis outbreaks in herds

(Choy et al. 2000); however infections have still occurred when pigs were reared on artificial, hard surfaces such as concrete (Thomas et al. 1981). Chlorination of water has been shown to eliminate *B. pseudomallei* (Howard and Inglis 2005), but only if pH and concentrations of organic substrates are carefully controlled, and this could prove difficult in water troughs, which may become highly contaminated (Choy et al. 2000). When an animal becomes infected in an endemic area, it has been suggested that strict maintenance of a hygienic environment may prevent a larger outbreak, although supporting evidence is lacking. Regular disinfection with potassium hypochlorite and cresol (to include all surfaces and the lower limbs of the animal), removal of infected excrement several times per day, and the avoidance of large quantities of water were used in an effort to curtail the outbreak in Paris zoos and equestrian clubs in the 1970s (Sprague and Neubauer 2004). Infected carcasses of animals must be condemned and destroyed. Guidelines for handling and disposal are available in the Manual for Meat Inspection in Developing Countries (http://www.fao.org/docrep/003/t0756e/T0756E05.htm#ch4.2.9). There are no mandatory requirements for serological screening for melioidosis in animals that are transported internationally, although it is possible that such animals might react in serological or skin tests to the closely related *B. mallei*. Serological testing of imported primates for melioidosis was used following an outbreak among Cynomolgus monkeys in the United Kingdom in the 1990s but has never been used routinely (Dance et al. 1992).

43.4 Conclusion

Both glanders and melioidosis may be regarded as reemerging infections with the ability to infect both animals and humans, although only glanders is a true zoonosis. Glanders has been eradicated from many countries, whereas melioidosis is widespread across the tropics, particularly South and Southeast Asia and tropical North Australia. Various factors have contributed to their emergence such as increasing awareness and diagnostic capability, increasing prevalence of underlying predisposing conditions, increased transport of animals (and associated contaminated waste and equipment) and other products internationally, human migration patterns, and adventure travel to tropical regions. Subclinically infected human and animal carriers risk further transmission of infection in the case of glanders, as well as persistence in a new environment under the right physical conditions. Global warming may extend the current geographic limitations of melioidosis and place a greater population at risk of exposure. This is particularly of concern as the prevalence of diabetes and other immunosuppressive states increases in many developing countries. Finally, we must be alert to the possible use of these agents in bioterrorism. Increased awareness of these pathogens is important so that early recognition, treatment, and public health action occurs, and so that organisms are handled at the appropriate level of containment to prevent laboratory-associated cases. Further research is required to develop effective vaccines and optimize prevention strategies.

Control of Zoonotic TB: The Need for Multidisciplinary One Health Framework

44

Adwoa Asante-Poku, Isaac Darko Otchere, Prince Asare, Stephen Osei-Wusu, Eric Koka, and Dorothy Yeboah-Manu

Contents

Abstract

The increasing incidence of human tuberculosis (TB) caused by new mycobacterial strains such as *Mycobacterium orygis* and the syndemic relationship between TB and other endemic diseases have renewed interest in zoonotic TB (zTB) especially in Africa where control strategies and data are very limited. Furthermore, the animal-adapted mycobacterial species are intrinsically resistant to some of the first-line anti-TB medications. The main TB control tool using meat inspection and condemnation of suspected infected meat has not yielded the needed impact to reduce animal-to-human transmissions. There is therefore the need for a renewed energy involving the use of transdisciplinary measures to reduce the risk of the disease in both humans and animals. Such a measure requires scientific, sociocultural, and economic efforts to implement and sustain

effective strategies for prevention and control of zoonotic TB transmission. In this chapter, we have elaborated on the importance of using the "One Health" concept in the control of zTB.

Keywords

Zoonotic TB · One health approach · Control

44.1 Introduction

Tuberculosis (TB) remains one of the world's deadliest infectious diseases ever known. Until the coronavirus disease (COVID-19) pandemic, TB was the leading cause of death from a single infectious agent, killing close to two million people annually across many populations in the world. In 2020, 10 million people (range, 8.9–11.0 million) developed TB disease and approximately 1.2 million people (including 208,000 deaths attributed to the TB-HIV syndemics) died from TB (Global TB report 2021). Of the 10 million people diagnosed with active TB, 140,000 (range, 69,800–235,000), that is, 1.4%, were estimated to be new cases of zoonotic TB (zTB) with 8.1% (11,400; range 4470–21,600) deaths. Although TB cases are globally distributed, the burden is skewed heavily toward areas where poverty and high population density overlap (Kibuuka et al. 2021). The WHO Africa region (home to 11% of human population) accounts for one quarter of the world's TB cases, with highest rates of cases and deaths relative to population.

Tuberculosis-causing pathogens are members of *Mycobacterium tuberculosis* complex (MTBC) (Kanabalan et al. 2021). Although genetically similar, they differ in host specificity with occasional cross-species infections. *M. tuberculosis* (Mtb) and *M. africanum* (Maf) cause the majority of human TB. *M. bovis*, primarily a cattle pathogen with the widest host range, is thought to be the main causative agent of zTB (Yeboah-Manu et al. 2016). However, with new evidence from South Asia and Africa, several other mycobacterial species present in animals and environment are now known to cause zTB; these include *M. caprae*, *M. microti*, *M. mungi*, *M. pinnipedii* (Jagielski et al. 2016), and most recently *M. orygis* (members of the Bovidae family) (Brites et al. 2018). These new potential drivers of zTB warrant the urgent assessment of prevalence in order to develop appropriate control tools.

zTB, an infection directly transmissible from animal reservoirs to humans, is potentiated when there is close contact between humans and infected animals or when humans consume unpasteurized infected animal products (Kock et al. 2021). It is considered a major disease that has direct impact on international trade of live animals and animal products and is on the list of notifiable diseases of the World Organisation for Animal Health (OIE) (WHO-FAO 2017). Although zTB is efficiently controlled from commercial animals in the industrialized countries, it regrettably remains poorly controlled in low-income/middle-income countries (LMICs) encumbered with major diagnostic challenges and poor public health surveillance and reporting structures (de Macedo Coutoet et al. 2022). Unfortunately, in these

countries, nearly 85% of cattle and 82% of the human population share the same microenvironment, thence allowing for continuous transmission of zTB (Ayele et al. 2004).

Importantly, an even more troubling possibility particularly in the endemic areas is the prospect of transmission of drug resistance because of reverse zoonosis at the human-animal interface (Rahman et al. 2020). *M. bovis*, the causative agent, is naturally resistant to pyrazinamide, one of the four medications used in the standard first-line anti-TB treatment regimen (Hannan et al. 2001). The potential for MDR-TB strains to acquire an animal reservoir that could then pose a future risk to human TB control is even more troubling (Seung et al. 2015). As most treatment is initiated without drug susceptibility testing, patients with zTB could receive inadequate treatment leading to poorer treatment outcomes and the development of further resistance to other anti-TB drugs (WHO-FAO 2017). Additionally, zTB in humans is often presented as extrapulmonary disease especially among immunocompromised individuals and may be misdiagnosed, and therefore initiation of treatment can be delayed.

Sadly, sub-Saharan Africa, which is home to more than half of the world's cattle population, has been the hardest hit region for various reasons. Firstly, in most African countries, cattle are used to show economic status in society and secondly serve as the main source of income for many natives (Otte & Chilonda 2002). Moreover, countries in Africa are yet to fully implement the test-and-slaughter (TS) policy due to lack of financial commitment on the part of governments to compensate farmers.

Given the insufficient laboratory facilities, lack of accurate diagnostic tools, poor or no surveillance programs leading to underreporting of cases, and lack of financial commitment on the part of governments to compensate farmers with infected animals, the control of zTB is limited and largely ineffective in endemic regions. There is no reliable data to determine if zTB incidence and prevalence is going up or down in many regions. Furthermore, sociocultural practices such as the use of cattle to depict the economic status in the society particularly in countries where zTB is endemic also impede zTB control (Otte & Chilonda 2002).

Current zTB burden and diagnostics are all based on *M. bovis* (Kock et al. 2021). However, the existence of other causative agents such as *M. caprae* and *M. orygis* calls for new laboratory services for accurate identification and speciation to effectively determine the true burden of zTB. Rapid tests are urgently needed to assist veterinarians and farmers to quickly diagnose TB, so infected animals can be separated from the rest of the herd even if the TST strategy cannot be used due to financial limitations (Duffy et al. 2020).

As the world make strides to control TB in humans, it is important to understand the role zTB plays in the human TB burden, especially in LMICs with poor or no animal TB control programs. The "Roadmap for Zoonotic Tuberculosis," which defines milestones for both human and animal health, requires strengthening transdisciplinary and multisectoral collaboration to fight zTB. The implications of zTB go beyond human health. Therefore, an approach that recognizes the interdependence of the human and animal health, the environment, and engagement of relevant

stakeholders in diverse sectors and disciplines is urgently needed. The time is right for a bold and concerted "One Health" approach to strengthen surveillance systems and expand the availability of "appropriate diagnostic tools" that can identify and characterize zTB at points of care for both humans and animals.

44.2 Burden of zTB in Africa

zTB is present in almost all African countries and affects both domestic and wild animals. Until recently in Africa, only 7 countries (Algeria, Burkina Faso, Cameroon, Morocco, Namibia, South Africa, and Zambia) out of 55 had a zTB control program in cattle herds (Carruth et al. 2016). These countries relied mostly on the tuberculin test and post-mortem inspection for the surveillance of this disease. A large proportion of the countries in Africa, i.e., 48 countries, even to date do not have any effective zTB control measures in place (Meiring et al. 2018). Ghana is among the epizootic countries reporting zTB in Africa but has no concerted effective zTB control program with only a few selected dairy farms in the country employing the test-and-slaughter strategy at the expense and convenience of the farm owners (Bonsu et al. 2000; Asante-Poku et al. 2014). However, there is a strong suspicion of underreporting as most cattle herds are reared on a free-range system under the stewardship of nomadic herdsmen. Such animals are hardly screened and might only be screened post-mortem. Many factors account for the failure of developing countries to control and eradicate zTB but they are mostly associated with unavailability of funds to support the globally tested and proven test-and-slaughter strategy. Nevertheless, the impact of insufficient veterinary expertise and communication networks, ineffective collaboration with bordering countries, and smuggling of live animals across state boundaries cannot be understated and need to be taken seriously for better control of zTB in Africa (Etter et al. 2006). Currently, ineffective control programs are implemented by most African countries, partly because of transhumance from areas where the measures are not properly applied to other areas and lack of synergy between countries involved in the fight against zTB.

In the Sahel where most cattle population are reared, cattle breeding is practiced extensively and depends mostly on the availability of natural grazing and water. Their availability is constantly linked to the annual rainfall, often forcing breeders and their livestock to move from arid regions to more humid ones (Sanou et al. 2021). In addition, the emphasis on common enzootic diseases has led to continuous neglect of zTB disease in Africa. Thus, the only information available often comes from suspicions during routine meat inspection at slaughterhouses and slaughter areas.

44.3 Control Efforts and Associated Challenges

One of the effective ways to achieve control of zTB and eventually eradication is through the implementation of an effective surveillance system (de Macedo Couto et al. 2022). With the reclassification of zTB as list B disease by the World

Organisation for Animal Health (OIE), this is of paramount importance. Low zTB prevalence observed in developed countries has been attributed to effective surveillance activities including detection of zTB in live animals, meat inspection, screening of cattle in infected areas, trace back of carcasses suspected of zTB, movement restriction of infected herds, awareness creation on its economic and health implications, and laboratory testing and confirmation techniques (Asseged et al. 2004; Lopes et al. 2016). These, together with the enforcement of regulations such as condemnation of zTB-infected carcasses or organs, periodic test and slaughter or segregation, pasteurization of milk, and restriction of breeding from infected herds, culminated in the reduction of zTB infections (Robinson et al. 2003). And yet, in Africa with regular reports of zTB, the prevalence or actual burden remains unknown with little to no datasets and disease surveillance programs for zTB (Luciano and Roess 2020). This is largely because zTB remains one of the most difficult pathogens to detect. Additionally, maintenance of surveillance activities is very costly and largely not covered by the national budget. Testing technologies are prohibitively expensive and unreliable without state-of-the-art facilities. Moreover, the existing multiple borders and low cattle populations as well as transhumance of cattle within the region with limited tracking systems further aggravate the situation.

Despite these challenges, detection of TB in animal and animal products as well as people at high risk of zTB infection is essential for TB control. While the most widely used method for animals is the test-and-slaughter method (de la Rua-Domemech et al. 2006; Klepp et al. 2019), this is hardly conducted in LMICs due to financial constraint. The routine methods for humans are microscopy (cheap, but with only low sensitivity) in LMIC, PCR mostly in developed countries, and cultivation of bacteria which is time consuming and requires more sophisticated infrastructure absent in most African countries. There are genotyping tools that explore the genetic diversity within the different members of the MTBC, as well as identify closely related strains (Niemann et al. 2000). Several studies have found the sensitivity and specificity of these assays to be 100% (Portillo-Gómez and Sosa-Iglesias 2011). Other gene targets have been evaluated to identify and differentiate between closely related species such as *M. tuberculosis*, *M. bovis*, and *M. caprae*. The gene targets include *katG*, *pncA*, *hupB*, and *gyrB* (Sreevatsan et al. 1996; Mishra et al. 2005; Scorpio & Zhang 1996). However, the major limitations include lack of technical expertise in the characterization of zTB, the expensive instrumentation required, and the lack of these resources in LMICs (Luciano and Roess 2020; Ramos et al. 2015).

Several rapid and automated diagnostic tools have been developed for rapid identification of members of MTBC with emphasis on zTB. Examples of such tools include GeneLEAD VIII (Diagenode, Belgium), Deeplex Myc-TB assay, and GenoType MTBC (Hain Lifescience, Germany) (Bonnet et al. 2021; Jouet et al. 2021). A combination of GeneLEAD and Deeplex Myc-TB assay (diagnostic tool designed according to a 24-plexed amplicon mix) can detect bTB and resistance to 13 anti-TB drugs including pyrazinamide. These combined methods showed promising features of efficiency with sensitivity and specificity of 79.3% and 100%,

respectively (Bonnet et al. 2021; El Achkar et al. 2020). However, these kits are expensive and limited in detecting novel biovars of the MTBC and/or mutations associated with drug resistance.

44.4 Sociocultural and Economic Drivers and Their Potential Impact on zTB

In Africa, the control of zTB still remains a complex process. Livestock systems in Africa are constantly undergoing rapid transition. Changes in market dynamics, environmental factors, and cultural practices are all changing the way people keep livestock, either for food or as sources of income. However, the consequences of these changes on zoonotic disease risk still remain unknown. These changes, be they ecological, political, economic, social, and cultural forces operating at local, national, and regional levels, provide conditions that allow for a selected number of pathogens to expand and adapt to a new niche.

One of the most important drivers of these changes are social and cultural factors (Patz et al. 2000; Daszak et al. 2001; Macpherson 2005). In sub-Saharan Africa, culture, society, and religion influence the kinds of foods people eat, how foods are prepared, and the demand for foods at certain times (Shanklin 1985). In recent times, globalization of food has fostered the taste for foods from other cultures that contain raw meat or fish (e.g., sushi). For example, in some societies, bushmeat which was previously consumed in low quantity is now consumed in large amounts as an inexpensive source of protein or as a sought-after delicacy. An estimated 90 percent of all bushmeat consumed moves through a distinct and well-organized market chain, with numerous nodes along the supply chain where the meat changes hands multiple times between the animal's death and its presence on the dinner table (de Merode and Cowlishaw 2006). The exchangers in this process include, among others, hunters, porters, bicycle traders, wholesalers, market-stall owners, and food preparers. Each person handling the meat or carcasses is exposed to the normal flora as well as any potential pathogens present the animal might carry. In addition, in some societies, parts of the meat including liver, heart, and brain are consumed raw based on ethnic identity, nostalgia, and social memory (Holtzman 2006).

In parts of Africa, animal products are deemed to have medicinal value and, when consumed, play an important role in ethnomedical systems to increase strength as well as enhance virility (Afolayan and Yakubu 2009) or to treat illness in humans and domestic animals (Martin et al. 2001; Mathias and McCorkle 2004; Kakati et al. 2006; Mahawar and Jaroli 2008; Soewu 2008). All these changes increase the chances of zoonotic infection from several different types of diseases (including TB, salmonellosis, *Giardia*, *Cryptosporidium*, toxoplasmosis, or rabies).

The "One Health" approach will have a positive impact on the economic costs related to the management of zoonotic diseases. These economic burdens fall more heavily on emerging countries than on the developed world. Epizootics of disease that can be controlled by vaccination have serious consequences for livestock industries, both upstream (inputs, genetic resources) and downstream (slaughter,

processing, marketing), jobs, income, or market access, and have serious consequences for food security and food safety (Nara et al. 2008). Zoonotic diseases also have negative consequences for livestock production: decreased milk production, reduced fertility, slower growth, animal mortality, as well as market loss for animals and animal products (Lamy et al. 2012; Zinsstag et al. 2008).

Nevertheless, indirect costs of zoonoses are often overlooked. The impact of zoonoses in terms of disability-adjusted life-years (DALYs) can be quantified by using a "One Health" approach (Grace et al. 2012): a cost-benefit analysis of vaccinating livestock in Mongolia for brucellosis found that the estimated costs for vaccination (US$ 8.3 million) were exceeded by the overall benefit (US$ 26.6 million), with an average benefit-cost ratio of 3.2. Cost-benefit analyses have determined that interventions in animal populations to reduce levels of zoonotic diseases were cost effective: control of the animal diseases was less expensive than the costs of disease in humans (Zinsstag et al. 2008). Given the complex nature of the epidemiology of zoonotic TB and the influences of sociological, economic, and ecological factors, "One Health" provides an excellent economical approach for conducting research, as well as development of effective control and prevention programs for zTB.

zTB causes significant economic losses due to increased production costs of infected animals, carcass confiscation, and international trade restrictions (Canto Alarcon et al. 2013). The disease has an important economic impact through reduced meat and milk production, as well as condemnation of carcasses or affected parts that are unfit for human consumption. The drivers of zoonotic diseases, especially zTB, are quite complex – individually, culturally, and socially. Although some of these drivers may be understood in isolation or in their simpler, temporal interactions with each other (e.g., food insecurity for workers in a logging or mining camp in Africa, leading to increased hunting and consumption of bushmeat), the complex ways in which they change over time and how they interact are not well understood, hence the need for a multidisciplinary "One Health" approach to help unravel the complexities associated with the reemergence of zoonotic TB and deal appropriately with them.

44.5 Vaccines for zTB

For an effective control strategy, vaccination provided a promising option in the prevention of human and animal tuberculosis (TB) in the beginning of the twentieth century. Considerable progress has therefore been made in the past years to develop improved vaccines for both humans and animals. *Mycobacterium bovis* bacille Calmette-Guérin (BCG), an experimental vaccine designed to protect cattle from zTB, was administered for the first time to a newborn baby in Paris in 1921. Over the past century, BCG has saved millions of lives and has been given to humans more than any other vaccine. It remains the sole TB vaccine licensed for use in humans. BCG provides long-lasting strong protection against miliary and meningeal TB in children, but it is less effective for the prevention of pulmonary TB, especially in

adults. The legacy of BCG includes fundamental discoveries about TB-specific and non-specific immunity and the demonstration that TB is a vaccine-preventable disease, providing a foundation for new vaccines to hasten TB elimination (Lange et al. 2022). Therefore, a safer and more effective vaccine than BCG is urgently required.

More than a dozen TB vaccine candidates are under active evaluation in clinical trials aimed to prevent infection, disease, and recurrence (Buddle et al. 2013). Candidate vaccines undergoing testing in humans include live mycobacterial vaccines to replace BCG, subunit vaccines (virus vector or protein) to boost BCG, and therapeutic vaccines used as an adjunct to chemotherapy. Encouraging results have been obtained from field trials in cattle using BCG vaccine to protect against natural exposure to *M. bovis*. To date, no subunit TB vaccines have induced improved protection compared with that of BCG, but prime-boost combinations of BCG with DNA, protein, or virus-vectored vaccines have induced better protection than BCG vaccine alone (Buddle et al. 2006, 2013).

Also, development of an oral bait BCG formulation has demonstrated the practicability of delivering TB vaccines to wildlife. Oral BCG preparations have induced protection against experimental challenge of *M. bovis* in possums, badgers, wild boar, and white-tailed deer and against natural exposure to *M. bovis* in possums. Progress in TB vaccine development has provided much impetus for their future use (Buddle et al. 2013).

Achieving dramatic results and vaccination of cattle was discontinued as it compromised the interpretation of the tuberculin skin test. Renewed interest in the use of TB vaccination of domestic livestock rose from the realization of the financial impact of bovine TB on animal health and trade, and the need to identify a cost-effective control measure where test-and-slaughter control programs are not affordable. Strategic use of TB vaccines for cattle or wildlife maintenance species could be applicable where it is not economically feasible to cull the animal serving as the wildlife reservoir or if they are a protected species. Tests differentiating infected from vaccinated animals (DIVA tests) have now been developed, which can differentiate animals vaccinated with BCG from those infected with *M. bovis*. For these tests, antigens from the *M. tuberculosis* complex which are not expressed by BCG are used instead of bovine PPD in skin test or in the whole-blood interferon-gamma release assay (Whelan et al. 2010).

Use of BCG vaccine in cattle is appealing as the vaccine is safe, inexpensive, and commercially produced for human application and DIVA tests are available, although protection may be incomplete. Many of the parameters that may affect the efficacy of BCG for cattle have now been identified. Relatively low doses of 10^4 to 10^6 CFU Pasteur BCG administered subcutaneously to cattle were shown to be effective in inducing protection against experimental challenge with *M. bovis*. Pasteur and Danish strains of BCG have induced similar levels of protection in cattle, although IFN-gamma levels released in antigen-stimulated blood cultures were higher in the Pasteur BCG-vaccinated groups.

Protection of Eurasian badgers (*Meles meles*) from TB after intramuscular vaccination with different doses of BCG was observed in a study in Great Britain

(Lesellier et al. 2011). Vaccinating badgers with BCG has been shown to be efficacious against experimentally induced TB of badgers when administered subcutaneously and orally. As the subcutaneous route is impractical for vaccinating wild badgers and an oral vaccine bait formulation is currently unavailable, the study evaluated the intramuscular (IM) route of BCG administration. It was demonstrated that the IM route is safe in badgers. IM administration has the practical advantage of being relatively easy to perform on trapped wild badgers without recourse to chemical immobilization. Vaccination using BCG Danish strain 1331 at two different doses (high and low) generated a dose-dependent cell-mediated immune response characterized by the production of interferon-γ (IFNγ) and protection against endobronchial challenge with virulent *M. bovis*. Protection, expressed in terms of a significant reduction in the severity of disease, the number of tissues containing acid-fast bacilli, and reduced bacterial excretion, was statistically significant with higher dose only (Lesellier et al. 2011).

In Ethiopia, bTB is prevalent in intensive dairy farms. Vaccination could be an alternative control approach given the socioeconomic challenges of a test-and-slaughter control strategy. An efficacy study using BCG on calves recruited from single intradermal cervical comparative tuberculin (SICCT) test negative herds was carried out in Ethiopian farms with monitoring of immune responses by interferon gamma (IFN-γ) release assay (IGRA), SICCT test, and antibody assay. Vaccinated calves developed strong responses to the SICCT test at the sixth week post-vaccination but did not respond to ESAT-6/CFP-10 peptide antigen-based IGRA. The direct protective efficacy of BCG in protecting against bovine TB in the calves was observed to be low; it was also demonstrated that BCG vaccination reduced the severity and dissemination of lesions and delayed *M. bovis* infection in the vaccinated calves. These impacts of BCG vaccination could contribute to the containment of onward transmission of *M. bovis* from vaccinated animals to other susceptible animals (Bayissa et al. 2021).

Canto Alarcon et al. (2013) in a study showed that the BCG vaccine, alone or in combination with a culture filtrate protein (CFP) boost, has the potential to reduce TB dissemination in cattle by reducing the number of lesions and the bacterial load per lesion (Canto Alarcon et al. 2013). However, to make definitive conclusions about the usefulness of the vaccine in programs against TB in the field, it is necessary to perform long-term field trials.

Also, the use of polymers such as chitosan and poly-lactic-co-glycolic acid (PLGA) improves the immune response against different diseases by improving the interaction of antigens with the cellular immune system and modulating the host immune response (Contreras-Magallanes et al. 2021). In a study on prime vaccination with chitosan-coated Phipps BCG and boosting with CFP-PLGA against tuberculosis in a goat model, it was demonstrated that the prime BCG vaccination, boosted with a culture filtrate protein (CFP) alone or in combination with chitosan and PLGA, has the potential to reduce TB dissemination by reducing the number of animals with lesions, the number of lesions per animal, and the size of the lesions in vaccinated animals, compared with those not vaccinated or those vaccinated with BCG alone. The vaccinated groups showed significantly higher interferon-γ levels in

the blood compared to the control, non-vaccinated group after vaccination, after boosting, and after the challenge with the wild-type *Mycobacterium bovis* strain (Contreras-Magallanes et al. 2021).

44.6 Conclusion and Outlook

The above discussions underpin the need for a concrete and active plan to tackle TB in animals as it has been implemented in humans. Vaccines will protect livestock against TB; as Africa is in quest of becoming self-sufficient, it also thinks about production of vaccines against animal TB. Furthermore, there is a need to intensify surveillance to reduce animal-to-animal as well as animal-to-human transmission and this requires good detection methods. Such method should be simplified and inexpensive and can be done on the farm. A good example is the need for a rapid method such as Xpert MTB/RIF, but this should be able to differentiate between the MTBC. On the other hand, a simple serological method such as a lateral flow assay is also needed.

To design a strategy to include all stakeholders, we employ for more funding to conduct multisectoral formative studies to understand the burden of the problem. Findings from these studies may provide the true picture of global zoonotic TB for all stakeholders to design acceptable One Health interventions.

Hepatitis E Virus Zoonotic Axis

45

HEV, the Master of Hide and Seek

Kush Kumar Yadav and Scott P. Kenney

Contents

Abstract

Viral hepatitis is primarily caused by five unrelated hepatotropic viruses, hepatitis A, B, C, D, and E. While hepatitis A through C are commonly recognized as causing significant liver disease by many average individuals due to successful public health campaigns, hepatitis E is often completely unknown. Despite being unheard of in the general public, hepatitis E virus (HEV) is the leading cause of acute viral hepatitis worldwide with an estimated 20 million cases annually. Hepatotropic viruses are notoriously tricky, utilizing differing mechanisms to avoid detection and elimination by the host organism. While hepatitis B and C infections often produce few symptoms in the host while becoming chronic and spreading silently to new hosts, HEV utilizes a different strategy to continue circulating in its hosts. HEV's long incubation period and ability to self-resolve in many infected individuals coupled with animal reservoirs that show little disease upon infection allow HEV to transmit to humans through

the food chain. Endemic human strains have similar strategies, circulating at low levels within the populace waiting for conditions associated with socioeconomic turmoil when sanitary conditions decrease allowing for massive outbreaks through contaminated water. This virological game of hide and seek ensures the continued survivability and transmission of the pathogen. While most otherwise healthy individuals will be able to self-resolve HEV infections, people with underlying comorbidities, immunocompromised people, and pregnant women in their third trimester are at much greater risk of succumbing to hepatitis E. There is still much work to be done to unravel the nuances of HEV's deadly hide-and-seek game so that humans may rid themselves of this malady.

45.1 Introduction

Hepatitis E virus (HEV) is the most prevalent cause of acute viral hepatitis, which is mainly transmitted fecal-orally in humans and animals (Meng 2013). In developing countries, the fecal oral route is the predominant route of transmission through contaminated water sources (Khuroo et al. 2016). In developed countries, consumption of contaminated meat, particularly pork products, is known to zoonotically transmit HEV to humans (Capai et al. 2018). While most infections are asymptomatic, they can cause acute hepatitis in patients with preexisting liver disease and in pregnant women, predominantly in developing countries (Wu et al. 2020; Koning et al. 2015). Extra-hepatic manifestations have been described with HEV infection and acute infection can progress to chronicity primarily seen in immunocompromised patients (Horvatits and Pischke 2018).

HEV belongs to the Hepeviridae family, which has two genera: *Piscihepevirus (cutthroat trout virus)* and *Orthohepevirus* (mammalian and avian strains) with four species (pasla-, avi-, roca-, chiro-). *Paslahepevirus* contains HEV variants isolated from human, pig, wild boar, deer, mongoose, rabbit, and camel; *Avihepevirus* from chickens, *Rocahepevirus* from rat, greater bandicoot, Asian musk shrew, ferret, and mink; *Chirohepevirus* from bat (Fig. 1). *Paslahepevirus balayani* is the largest species consisting of at least 8 genotypes (gt) that infect humans (gt1, gt2, gt3,

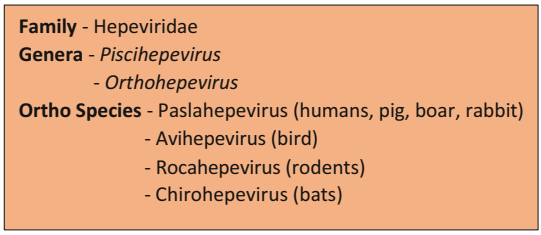

Fig. 1 Taxonomical classification of HEV

gt4, and gt7), pigs (gt3 and gt4), wild boar (gt3, gt4, gt5, and gt6), rabbits (gt3), mongoose (gt3), deer (gt3), yaks (gt4), and camels (gt7 and gt8) (Smith et al. 2014a, 2016). To date, only one serotype has been described (Smith et al. 2014b).

Of the various genotypes infecting humans, gt1 and gt2 are obligate to humans (Meng 2013). Genotype 3 is widely distributed around the world and gt4 is mainly found in Asia. Zoonotic transmission of gt3 and gt4 from pigs, wild boar, deer, and mongoose to humans have been reported (Meng 2013). In addition, rabbit strains that are close to gt3 have been discovered in humans. Camel gt7 was described in a liver transplant recipient who had consumed camel milk and meat (Lee et al. 2016). Recently, *Rocahepevirus ratti* HEV strains have been reported in humans, despite their genetic differences with other human pathogenic strains (Sridhar et al. 2018, 2021; Andonov et al. 2019).

HEV is a single-stranded, positive-sense RNA virus, possessing an ~7.2 kb RNA genome that contains three open reading frames (ORFs), ORF1, ORF2, and ORF3 (Fig. 2). ORF1 encodes a nonstructural protein about 1693 amino acids (aa) long, with several functional domains: methyltransferase, Y domain, cysteine protease, hypervariable region, X domain, helicase, RNA-dependent RNA polymerase (Reyes 1993). It is still unclear whether the ORF1 polyprotein functions as a singular polyprotein or is processed into individual proteins. Recent studies have described the presence of an additional ORF4 in gt1 HEV overlapping with ORF1. Endoplasmic reticulum stress-induced synthesis of ORF4 has been described to play a role on the proper functioning of the HEV RNA polymerase (Nair et al. 2016). Furthermore, ORF2 and ORF3 also partially overlap and are transcribed from the bicistronic subgenomic RNA (Graff et al. 2006). ORF2 protein encodes for 660 aa and is divided into three domains: S (shell), M (middle), and P (protruding) (Yamashita et al. 2009). In addition, ORF2 is known to encode a secreted free form of the capsid protein (ORF2s) that differs from the virion forming capsid protein, ORF2i (for infectious) (Yin et al. 2018). ORF3 encodes for a 113 aa phosphoprotein creating ion channel activity, involved in virus egress from infected cells, and is involved in cell signaling modification (Wang et al. 2014a).

Morphologically, HEV is considered quasi enveloped and presents in two forms: (a) the naked form, excreted in feces where the outer lipid envelope is degraded by the action of bile. (b) enveloped form, circulating in blood (Chapuy-Regaud et al. 2017; Yin et al. 2016) (Fig. 3).

HEV is transmitted mainly by fecal oral route via contaminated water ingestion and the consumption of undercooked pork or wild boar (Geng and Wang 2016). HEV transmission by blood components is becoming more prevalent and has been an increasing concern in European countries and emerging concern in the United States (Ticehurst et al. 2019; Mateos et al. 1998; Harvala et al. 2019). In addition,

Fig. 2 Genomic organization of HEV

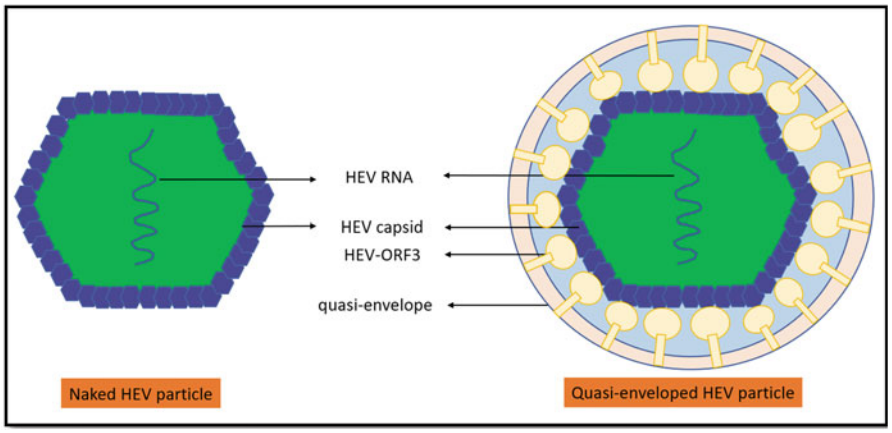

Fig. 3 Morphological forms of HEV

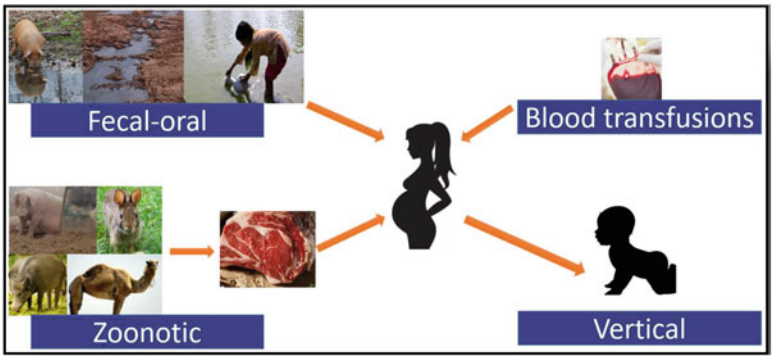

Fig. 4 Transmission route of HEV

vertical transmission from infected mother to fetus has been recognized (Li et al. 2020; Jilani et al. 2007; Gouilly et al. 2018) (Fig. 4). HEV gt1 and gt2 are correlated with poor hygiene and untreated sewage; however, gt3 and gt4 are increasing in the developed countries with high consumption of raw or undercooked pork meat (pig is known as the main reservoir) (Khuroo et al. 2016; King et al. 2018).

45.2 HEV Zoonoses and Cross-Species Infection

HEV is a zoonotic disease capable of transmitting from animals to humans (forward zoonoses) and back to animals from humans (reverse zoonoses). *Paslahepevirus balayani* species are known to infect humans producing severe disease associated with acute liver failure in pregnant women and chronic hepatitis in immunocompromised individuals. gt1 and gt2 HEV within the *Paslahepevirus* species is known to have a limited host range because experimental infection of pigs, rats, and goats was

unsuccessful. However, lambs and Wistar rats were reportedly infected by gt1 human HEV (Usmanov et al. 1994; Maneerat et al. 1996). Although independent confirmation of these reports is still lacking, gt1 and gt2 are considered obligate to humans. Pigs are considered as the major reservoir for HEV and are known to transmit gt3 and gt4 HEV to humans (Kenney and Meng 2019). Pig handlers, farmers, and swine veterinarians in both developing and industrialized countries are at the highest risk for HEV infection. For instance, individuals within the United States from major swine producing states are more likely to be seropositive for HEV antibodies than those from traditionally non-swine states; for example, individuals from Minnesota (major swine state), are approximately five to six times more likely to be seropositive than those from Alabama, which is not a major swine state (Meng et al. 2002). Furthermore, swine veterinarians were 1.9 times more likely to be HEV seropositive than non-swine veterinarians with seroprevalence of 20.8% among Austrian veterinarians (Taus et al. 2019). Interestingly, potential transmission of HEV from a pet cat and a pet pig to human owners were also reported (Renou et al. 2007; Kuno et al. 2003). Recently, *Rocahepevirus* species have been shown to infect humans (Sridhar et al. 2018, 2021; Andonov et al. 2019). Further research is required to understand the cross-species ability of *Rocahepevirus* species in various animals.

The dynamics of HEV spread and adaptation within genotypes allowing for extension of host range are unclear. Since the discovery of the first animal HEV in pigs in 1997, the first avian strain in 1998, and the first rabbit strain in 2009, an abundance of animal species have been identified with distinct circulating HEV strains, many with zoonotic potential. In recent years, it has been demonstrated that several strains causing disease in humans possess a high degree of similarity to strains detected in animals and food products of animal origin. Epidemiological screening studies for HEV via serology demonstrated high (1–53%) antibody prevalence in several countries (high-income and low-income) (Kamar et al. 2012). Furthermore, reports in healthy blood donors suggest that 1 out of 4500 in Germany, and 1 out of 8000 in Sweden, had HEV RNA in their blood at the time of donation (Lapa et al. 2015). Hence, HEV is no longer simply a disease of underdeveloped countries and there are autochthonous sources of HEV present in industrialized countries that cause infections and disease in humans. In addition, some agriculturally important species such as chickens can have reduced productivity due to HEV infection. Infection of poultry with aHEV can display symptoms including hepatitis splenomegaly syndrome, egg drop, regressive ovaries, and acute death reducing the yields of a farmed species that provides the second highest amount of protein to humans globally (Younus et al. 2017). Despite aHEV only infecting poultry, the liver tropism for the disease mimics human HEV infection in some aspects.

(a) **Non-Human Primates (NHPs)**

All four genotypes of HEV can induce infection in rhesus macaques with the development of viremia, fecal shedding, and specific antibody responses. In brief, acute viral hepatitis, viremia, fecal shedding, slight elevation of ALT, and seroconversion was reported in rhesus macaques when infected with gt3 swine HEV and gt4 swine HEV (Meng et al. 1998; Arankalle et al. 2006). Furthermore, rHEV strain developed viremia, fecal shedding along with

jaundice and malaise with elevation of liver enzymes, and seroconversion demonstrating infection in cynomolgus monkeys (Liu et al. 2013). However, avian HEV, rat and ferret strains of HEV could not infect NHPs as evidenced by no detection of viremia, fecal shedding, or seroconversion (Huang et al. 2004; Li et al. 2015a; Purcell et al. 2011). Summarization of the cross-species transmission is described below (Fig. 5).

(b) **Swine**

Specific pathogen-free pigs are susceptible to human HEV gt3 and gt4 but not to gt1 or gt2 as detected via viremia, fecal shedding, and seroconversion (Córdoba et al. 2012; Feagins et al. 2011; Meng 2003). Interestingly, swine can be infected by rabbit HEV demonstrating low levels of viremia, fecal shedding, indicative of active but not robust HEV infection (Cossaboom et al. 2012). Summarization of the cross-species transmission in pigs is described below (Fig. 6).

(c) **Rabbit**

HEV gt3 isolated from rabbit and HEV gt4 isolated from both human and swine origins are infectious to rabbits as indicated by viremia, fecal shedding, elevation of ALT, and histopathologic changes in the liver (Cheng et al. 2012; Han et al. 2014; Ma et al. 2010; Zhang et al. 2015a). Interestingly, even though rHEV strain have been assigned to HEV gt3, human gt3 could not infect SPF rabbits, similar to human gt1 HEV (Cheng et al. 2012; Ma et al. 2010). Summary of the cross-species transmission in rabbits is described below (Fig. 7).

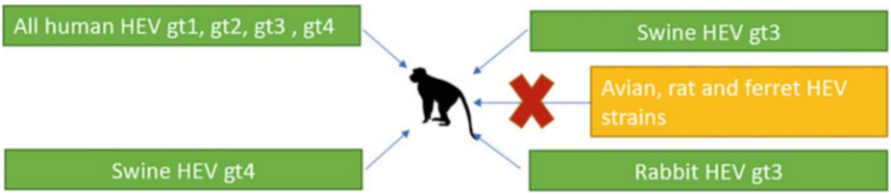

Fig. 5 Cross-species transmission in NHPs

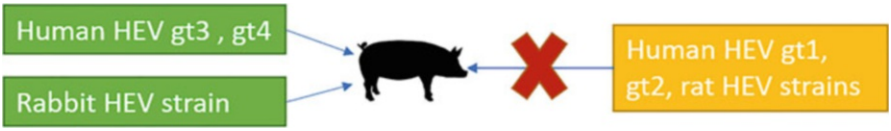

Fig. 6 Cross-species transmission in pigs

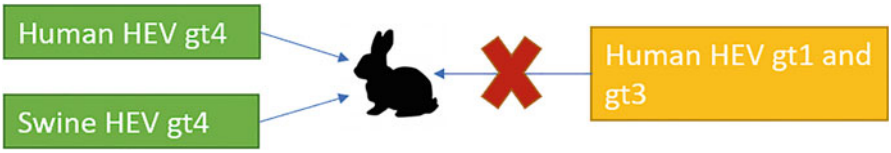

Fig. 7 Cross species transmission in rabbits

45.3 Epidemiology of HEV

HEV is suggested as one of the most common causes of acute hepatitis distributed worldwide (A. R. 2010). Estimated infections around 2.3 million and 70,000 deaths are recognized due to HEV per year (Rein et al. 2012). HEV genotypes, transmission routes, source of virus infection, disease prevalence, clinical characteristics of the disease are known to determine the epidemiological patterns around the globe. However, the HEV epidemiological pattern is mainly based on the predominant genotype in the geographical region and the presence of their respective hosts. Description of these two patterns is summarized in Figs. 8 and 9.

HEV gt1 and gt2 occur as outbreaks and sporadic cases spread via the fecal-oral route through contaminated water in endemic regions (Yugo and Meng 2013). Although sporadic reports of gt1 and gt2 HEV have been observed, circulation of the predominant gt1 and gt2 are primarily seen in Asia and Africa. Furthermore, gt3 and gt4 are frequently reported in Asia (gt4 mainly in China) (WHO 2017; Dai et al. 2013; Minagi et al. 2016). Seroprevalence studies have reported seroconversion for HEV (anti-HEV IgG) between 3% and 27% (Ren et al. 2014; Fierro et al. 2016).

Areas with scarcity of water and compromised sanitary conditions, often seen in low income countries and refugee camps, have been documented with endemic gt1 and gt2 with potential for large-scale outbreaks (A. R. 2010). Africa and Asia are known to be the major geographical regions affected by these two genotypes as reported by the World Health Organization (WHO). Seroprevalence studies have reported seroconversion for HEV (anti-HEV IgG) in Africa between 4.6% and

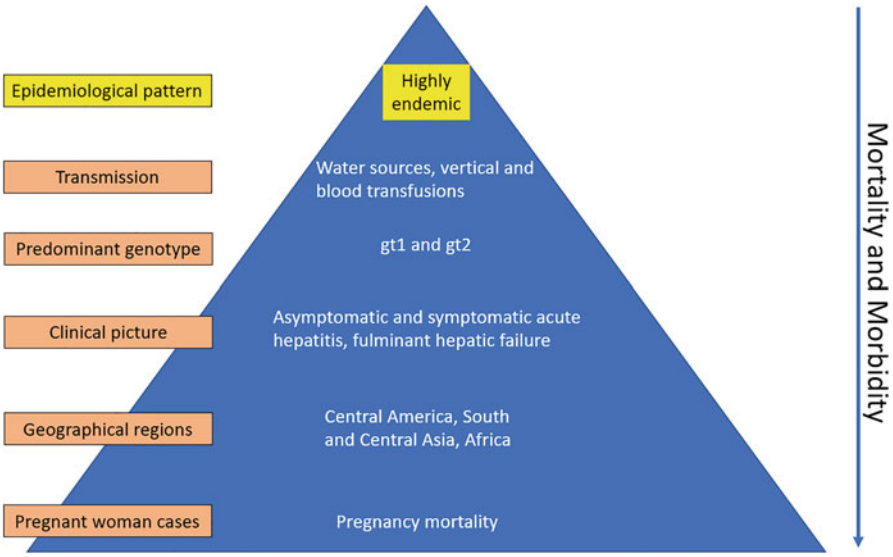

Fig. 8 HEV genotypes, transmission route, and clinical picture in highly endemic region

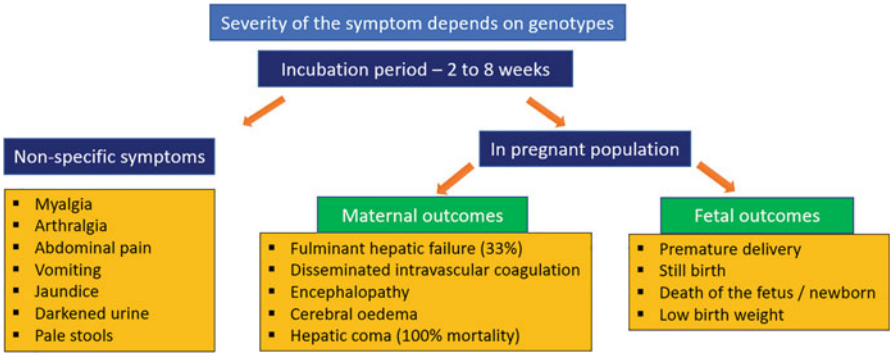

Fig. 9 Symptoms in the HEV infected patient

10.7% and in Asia between 34.8% and 94% (Ren et al. 2014; You et al. 2013; Kang et al. 2017; Korsman et al. 2019; Dagnew et al. 2019).

It has been reported that 15% of the people infected with gt1 and gt2 present signs and symptoms during the HEV gt1 and gt2 outbreaks (Goel and Aggarwal 2016). Infection in children, adolescents, and young adults is often asymptomatic in typical HEV infection. Overall morbidity rates are higher among teenagers and young adults (between 10 and 40 years old) but lower in children and elderly people (A. R. 2017). Infection in men usually outnumbers women, possibly because of greater exposure to contaminated water. However, infection of pregnant woman and patients with preexisting chronic liver disease leads to fulminant hepatitis with higher morbidity and severity of the disease (Kumar Acharya et al. 2007; S. KM 1981). Hepatitis E disease diagnosis is difficult, because clinical and diagnostic enzymatic biochemical panels can be indistinguishable clinically and biochemically from other diseases (Singh et al. 2018).

HEV gt1 and gt2 are also recognized for their ability to transmit via parenteral and vertical routes (Khuroo et al. 1995; Kumar et al. 2001; Arankalle and Chobe 1999). Pregnant women, primarily in the third trimester of pregnancy, demonstrate severe acute liver failure (ALF) with a mortality rate of 15–25% when infected with HEV gt1 (Naidu and Viswanathan 1957; Sharma et al. 2017). Abortion, fetal death, premature delivery, still birth, miscarriage have been reported when infected with HEV gt1 while pregnant (Jilani et al. 2007; Salam et al. 2013) (Fig. 9). Furthermore, anicteric or icteric hepatitis, hypoglycemia, and neonatal death are seen in fetuses and neonates, which is the result of vertical transmission of HEV (Jilani et al. 2007; Sharma et al. 2017). India is reported to have the highest pregnancy mortality cases due to outbreaks of HEV and findings such as HEV viral load, immunological changes, nutrition, and hormonal differences have been correlated with worse outcomes and hence defined as the risk factors associated with HEV in pregnant women (Jilani et al. 2007; Sharma et al. 2017; Salam et al. 2013; Kumar et al. 2014; Bose et al. 2011; Gong et al. 2021).

Low endemic areas for hepatitis E, such as Europe, East Asia (including China), and the Americas are known to have more widespread and better sanitary water processing conditions and well-controlled water supplies ,hence are reported to have

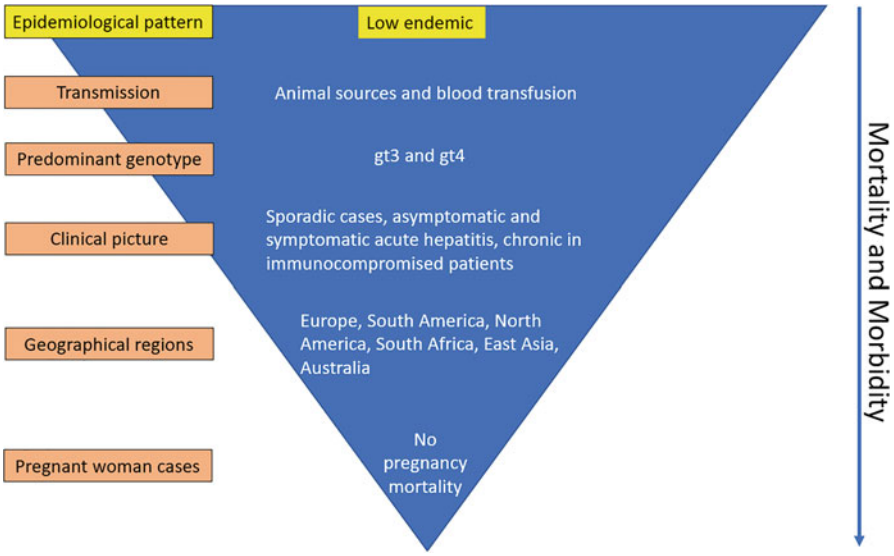

Fig. 10 HEV genotypes, transmission route, and clinical picture in low endemic region

mainly sporadic cases of HEV (Fig. 10) (Fierro et al. 2016; Domanović et al. 2017a; WHO 2017; Panduro et al. 2011).

HEV cases reported in these low endemic regions are autochthonous and are typically zoonotic (forward zoonoses) in nature. The primary infection source is related with the consumption of meat, mainly pork (gt3 and gt4) and its associated products. Hence, ingestion of raw or undercooked meat contaminated with HEV is linked with HEV in low endemic areas (Dalton et al. 2014). For instance, HEV gt3 prevalence in liver samples from France was 2.8% with a level of contamination of up to 1.46×10^8 copies/g (Feurer et al. 2018). Similarly, out of 131 pork products collected from grocery stores and butcher shops between October 2019 and February 2020 in Germany, 10% were positive for HEV RNA. These meats were predominantly pork livers, liver sausage, and liver pates (Pallerla et al. 2021). Similarly, HEV gt3 is present in US swine herds with a small proportion of commercial pork products, such as liver and chitterlings, from US grocery stores contain infectious HEV (Huang et al. 2002; Feagins et al. 2007). Also, in the United States, 15 out of 119 (12.6%) ground pork samples tested positive for HEV RNA and 13 out of 20 packages (65%) contained at least one positive sample. Twenty-five of 56 (45%) of pork liver samples were positive for HEV RNA (Harrison et al. 2021). Two percent of commercial pig livers from local grocery stores in Japan, 4% in Germany, 6.5% in the Netherlands, and 11% in the United States tested positive for zoonotic gt3 HEV RNA. Similarly, 6% of sausages sampled at processing and at the point of sale in Spain were also positive for the zoonotic gt3 HEV RNA (Meng 2016). In France, consumption of pig liver sausage (Figatelli) has been definitively linked to cases of hepatitis E as well and almost 30% of Figatelli in France tested gt3 HEV positive (Colson et al. 2010; Pavio et al. 2014). Beyond the farmed swine industry, cases of HEV have been linked to consumption of wild boar meat, grilled pig

entrails, and raw deer meats in Japan (Takahashi and Okamoto 2014). Hence, prevalence rates of HEV seropositivity in most countries could be explained by pork consumption, as in France and Germany, where the seroprevalence is 17% and 35%, respectively (Lapa et al. 2015), but additional cases may be through other specialty or cultural dishes that are not traditionally pork.

Additionally, iatrogenic transmission of HEV gt3 between humans through infected blood and blood products is reported in Europe. Recently, screening HEV in blood products is gaining importance in developed countries due to transfusion-associated HEV infections reported in Japan (gt3 and gt4), France (gt3), and China (gt1 and gt4) (Domanović et al. 2017b; Satake et al. 2017; Zhang et al. 2017). Such transfusion-transmitted HEV infections occur with red cells, platelets, and fresh-frozen plasma. Currently available inactivation technologies for blood products are unable to prevent transfusion-transmitted HEV infections, which can result in chronic severe hepatitis in immunosuppressed patients (Gallian et al. 2019). For instance, anti-HEV IgG prevalence was reported to be high in blood banks (52%) in France (Bouamra et al. 2014). In American regions, seroprevalence of anti-HEV IgG in United States was found to be 9%, in Brazil 4.2%, and in mixed Caribbean countries 1% (Horvatits et al. 2018). Similarly, gt1, gt2, and gt3 have been reported in humans and animals in Uruguay (gt1 and gt3), Colombia (gt3), Argentina (gt3), Mexico (gt2 and gt3, only humans), Venezuela (gt1 and gt3), Brazil (gt3), and the United States (gt3) (Oxford et al. 2016; Rendon et al. 2016; Lopes Dos Santos et al. 2010; Mirazo et al. 2011; García et al. 2012; Martínez Wassaf et al. 2014; Passos-Castilho et al. 2016; Viera-Segura et al. 2019).

Previously, gt3 and gt4 infection was thought to be self-limiting in humans. However, recent updates have shown chronic infection caused by gt3 in immunosuppressed patients, especially post organ transplant patients (Gérolami et al. 2008). For illustration, a recipient of an HEV-infected liver from a donor with occult HEV infection rapidly developed graft cirrhosis and died from decompensated liver disease (Schlosser et al. 2012). Furthermore, HEV infections were also transmitted via renal grafts given to two recipients (Pourbaix et al. 2017). In addition, preexisting chronic liver patients who acquire HEV gt3 may progress to fulminant hepatitis, as seen in gt1 infected individuals (Dalton et al. 2007). Although nosocomial transmission of HEV infection is unusual, there has been a report of this rare event in the hematology ward in France (Mansuy et al. 2009). In brief, a 33-year-old man receiving treatment for leukemia in a hematological ward developed acute hepatitis. All donor samples were tested and had negative results plus he had no travel history in the HEV endemic areas and had not eaten raw meat or shellfish. Thus, it was demonstrated that his stay in the ward overlapped with that of the other patient with hepatitis E shedding HEV in both blood and stool for a year. Therefore, based on the HEV nucleotide sequence identity between the two patients (97.8–98.6%) and because of the identical insertion in the ORF1 hypervariable region between the strains, it was referred as patient to patient transmission of HEV (Mansuy et al. 2009). Hence, transfusion of blood products, solid organ transplantation, stem cells, and pork-derived products constitute the principal sources of infection, especially for immunosuppressed individuals.

Table 1 Species, host tropism, geographical distribution of zoonotic HEV

Paslahepevirus balayani Genotypes	Host species	Geographical distribution	References
1	Human	Asia, Africa, Central America	Nelson et al. (2016) Kamar et al. (2012, 2014)
2	Human	West Africa, Mexico	Nelson et al. (2016) Kamar et al. (2012, 2014)
3	Human, pig, wild boar, red deer, mongoose, rabbit	Europe, South Africa, East Asia, and Americas	Oxford et al. (2016) Nelson et al. (2016) Kamar et al. (2012, 2014)
4	Human, pig, sheep, cattle	Asia, Europe	Oxford et al. (2016) Nelson et al. (2016) Wang and Ma (2010)
7	Dromedary camel, human	Asia	Sridhar et al. (2017)
Rocahepevirus	Rat, ferret, greater bandicoot, asian musk, shrew, mink, human	Asia, North America	Sridhar et al. (2018, 2021) Andonov et al. (2019)

Interestingly, only *Paslahepevirus* species were thought to infect humans. However, recent reports have suggested that *Rocahepevirus* strains have gained zoonotic potential and is described in two clinical cases: persistent hepatitis in a liver transplant patient in Hongkong and severe acute hepatitis in an immunocompetent patient in Canada (Sridhar et al. 2018; Andonov et al. 2019). Seven additional rat HEV infections have been confirmed recently in Hong Kong (Sridhar et al. 2021) (Table 1).

Disease severity resulting from HEV infection is thought to be dose dependent with higher starting doses leading to more severe disease manifestation. HEV superinfection is known to accelerate disease progression in patients with chronic HBV infection and increases mortality in those with cirrhosis (Tseng et al. 2020). Extrahepatic manifestations including neurological disorders, kidney injury, acute pancreatitis, and hematological abnormalities have been related with acute or chronic HEV infection caused by gt1-gt4. Several neurological disorders such as Guillain-Barre syndrome, brachial neuritis, and meningoencephalitis are known to be rarely seen during viral hepatitis, however, have been noted during HEV infection (Kamar et al. 2016; McLean et al. 2017).

45.4 Epidemiological Information of HEV Pregnancy Mortality

Mortality due to fulminant hepatitis in pregnant women has been reported from developing countries during HEV infection (Fig. 11) (Kar and Sengupta 2019). Underlying mechanisms demonstrating the virulent characteristics of the virus in

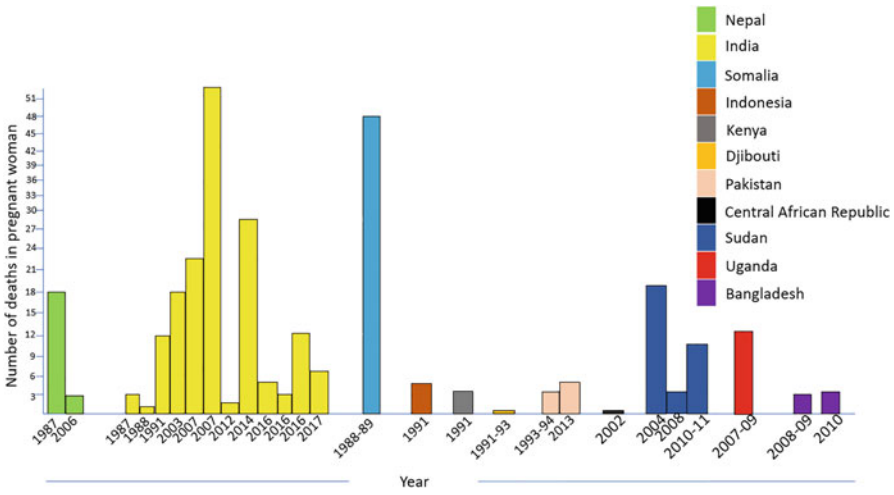

Fig. 11 HEV reported pregnancy mortality in different countries. Numerator = the number of deaths due to HEV during pregnancy. Denominator = the number of infected individuals. 1987, Nepal (18/73); 2006, Nepal (3/19); 1987, India (3/19); 1988, India (2/30); 1991, India (12/48); 2003, India (18/24); 2007, India (23/42); 2007, India (54/132); 2012, India (2/220); 2014, India (29/148); 2016, India (5/36); 2016, India (3/30); 2016, India (10/25); 2017, India (7/32); 1988–1989, Somalia (48/346); 1991, Indonesia (5/19); 1991, Kenya (4/28); 1991–1993, Djibouti (1/3); 1993–1994, Pakistan (4/35); 2013, Pakistan (5/25); 2002, Central African Republic (1/7); 2004, Sudan (19/61); 2008, Sudan (4/6); 2010–2011, Sudan (11/39); 2007–2009, Uganda (13/189); 2008–2009, Bangladesh (4/21); 2010, Bangladesh (3/12)

the pregnant woman is still lacking. Although we have multiple reports of pregnancy-associated deaths in various countries, reasons behind the severity of the disease only in pregnant women is deficient due to inappropriate cell culture model and insufficient animal models (Nimgaonkar et al. 2018).

45.5 Animal Models Demonstrating HEV-Induced Pregnancy Mortality

Various animals naturally susceptible to HEV or experimentally infected with HEV were studied to dissect the mechanism behind HEV-related pregnancy outcomes in humans. However, only few of them somewhat recapitulated the scenario of HEV-induced pregnancy mortality in humans.

(a) **Non-Human Primates**

Chimpanzees, pig-tailed macaques, vervets, owl monkeys, squirrel monkeys, and patas monkeys are known to be susceptible to experimental HEV infection (Yugo et al. 2014; Ticehurst et al. 1992; Tsarev et al. 1993a; Arankalle et al. 1988). However, based on the transmission studies, chimpanzees, rhesus

monkeys, and cynomolgus monkeys were the most susceptible to both human strains of HEV (gt1 to gt4) and animal strains of HEV (gt3 and gt4) (Kenney and Meng 2019; Yugo et al. 2014; Purcell and Emerson 2001). Experimental infection of cynomolgus and rhesus macaques induced clinical signs, coinciding with acute viral hepatitis with occasional excretion of virus like particles (VLPs) in the stool, and detection of antiviral antibodies (Tsarev et al. 1993a, b; Arankalle et al. 1995; Bradley et al. 1987). Previously, infection in pregnant rhesus macaques failed to recapitulate any severe pregnancy outcomes or fulminant hepatitis E observed in pregnant women (Tsarev et al. 1995). However, recently in a study targeted to demonstrate the vertical transmission of HEV gt4, premature delivery and fetal death occurred in one of the HEV-infected pregnant rhesus macaques (Yu et al. 2020).

(b) **Rabbits**

Rabbits are naturally infected with the rabbit strain of HEV (rHEV) (Zhao et al. 2009; Cossaboom et al. 2011; Caruso et al. 2015). In a pathogenesis study, similar clinical manifestations of acute hepatitis E are seen with fecal shedding, viremia, seroconversion, and elevated ALT levels with IV administration of rHEV (Cheng et al. 2012; Ma et al. 2010). In addition, rHEV isolate CHN-BJ-R14 produced infection in six pregnant rabbits with two demonstrating miscarriage and three deaths among the pregnant rabbits. Both positive and negative strands of HEV RNA were detected in the placental tissues of the infected pregnant rabbits, and positive staining for the HEV antigen was observed in placental tissue by immunohistochemistry (Xia et al. 2015). Furthermore, vertical transmission of HEV was also reported with the fecal detection of HEV in the first defecation of the newborn offspring. Seroconversion in the offspring was seen at 3 months of age (Xia et al. 2015). Also, pregnant rabbits administered HEV 239 vaccine and later challenged by rHEV (CHN-BJ-R14) demonstrated prevention against HEV-related adverse outcomes (Li et al. 2019). Furthermore, adverse fetal outcomes with 67–80% fetal mortality in pregnant rabbits experimentally infected with rHEV KOR-Rb-1 was reported (Ahn et al. 2017).

(c) **Mouse**

Pregnant BALB/c mice were experimentally infected in their early, middle, and late stages of pregnancy with genotype 4 swine HEV (KMO1). Miscarriages (7/8, 87.5%) reported in pregnant mice infected with HEV in the middle of pregnancy although no maternal death reported. Vertical transmission was confirmed by the HEV replication in the uterus, placenta, and fetal livers of the newborn mice (Yang et al. 2019) (Fig. 12).

45.6 Cell Culture Propagation Ability of HEV

In vitro studies are the foundation for understanding infectious diseases. Cell culture is utilized to study entry, replication, and pathogenesis mechanism. Due to a history of lacking the ability to cell culture HEV, research has been hindered

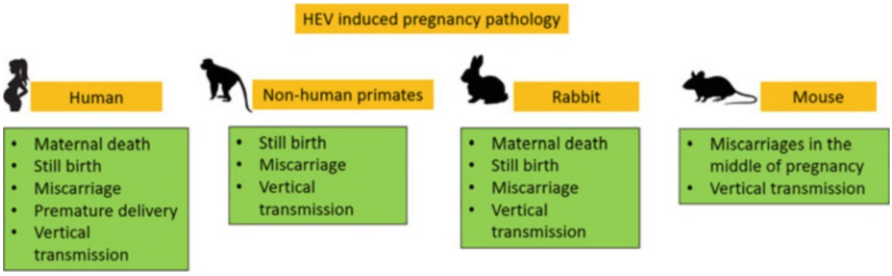

Fig. 12 Summarization of HEV induced pregnancy outcomes in human verses animal models

and focused on screening various cell types for increased HEV replication. Recent improvements in cell culture systems have significantly advanced HEV research. Several years of research led to the development of HEV infectious clones, identification of permissive cells, and optimization of HEV growth because of which the molecular studies of HEV have progressed. These are complemented by efforts in improving not only the hepatocyte systems that are physiologically more important but also differing cell lines origin pertaining to the extra-hepatic manifestations related to HEV. Furthermore, an ideal cell system would recapitulate cell polarity, co-secrete bile acids, and/or other host factors helping to fully mature HEV particles into their non-enveloped form, support virus spread and full lifecycle of HEV, and support infection with the clinical isolates of HEV. Here are some cell lines that are susceptible and permissive to HEV (Table 2).

45.7 Vaccination, Prevention, and Treatment of Zoonotic HEV

(a) **Vaccination**

Public health surveillance in pregnant and non-pregnant women is of utmost importance for limiting the number of sporadic outbreaks, in line with sanitation improvements in endemic countries (Fierro et al. 2016; Domanović et al. 2017a; Clemente-Casares et al. 2009). Due to the lack of in vitro cell culture replication, development of live attenuated or inactivated vaccines for HEV is ceased (Kamili 2011). Recombinant vaccines have been a focus for HEV as active immunization has been found to be effective in experimental animal models and because of the failure of passive immunoprophylaxis (Tsarev et al. 1994).

HEV 239 vaccine (Hecolin, Xiamen Innovax Biotech, China) is the only commercially available vaccine, which has been registered in China since 2011 (Park 2012; Riedmann 2012). However, yet to be approved by the FDA. A special feature of this recombinant vaccine is that it contains 26 aa and is an extension from the N terminal of another peptide, E2, from the HEV capsid protein, which is

Table 2 Different cell lines used for the study of various HEV genotypes

Cell line	HEV genotype	Reference
Hepatoma cell lines

		Okamoto (2011)
	gt4	Tanaka et al. (2009)
	gt1	Takahashi et al. (2010)
	gt3	Shukla et al. (2012)
LLC-PK1 (Pig kidney cells) LLC-PK1A (Pig kidney cells) SK-RST (Pig kidney cells)	gt3 Kernow-C1	Shukla et al. (2011)
MDCK (Dog kidney cells)	gt3 Kernow-C1	Shukla et al. (2011)
CRFK (Cat kidney cells)	gt3 Kernow-C1	Shukla et al. (2011)
LLC-RK1 (Rabbit kidney)	gt3 Kernow-C1	Shukla et al. (2011)
Caco-2 (Colon carcinoma)	gt1 Sar55	Emerson et al. (2004)
JEG-3 (Human placental cells)	gt1 and gt3	Knegendorf et al. (2018)
BeWo (Human placental cells)	gt1 and gt3	Knegendorf et al. (2018)
MO3.13 (Oligodendrocytic cells)	gt3	Drave et al. (2016)
Ex vivo transplants		
Maternal decidua and fetal placenta	gt1 and gt3	Gouilly et al. (2018)
Primary cells		
Primary human hepatocytes (PHHs)	gt3 and gt4	Oshiro et al. (2014)
Immune competent PHHs	gt3 Kernow-C1 P6	Yin et al. (2017)
Human fetal liver cells	gt3 Kernow-C1 P6	Wu et al. (2018)
Primary mouse neurons	gt3 Kernow-C1 P6	Zhou et al. (2017)

the one major structural protein. The approach was successful, because HEV is antigenically conserved, presenting only one identified serotype observed to be protective for all four HEV genotypes (gt1, gt2, gt3 and gt4) (Anonymous 2015; Wu et al. 2016).

HEV 239 vaccine is proven to be effective in Rhesus macaques, rabbits immunized and challenged with infectious virus strains (gt1 and gt4) (Cheng et al. 2012; Zhang et al. 2009; Li et al. 2015b). In mouse models, a strong T cell-dependent antibody response was observed after vaccination, which was partly attributed to two

T cell epitopes located in the portion of aa 533–552 on the HEV capsid peptide (Khateri et al. 2018).

In humans HEV 239 vaccine is administered as mentioned below.

Vaccine	Route	Volume	Number of dose	Composition	Side effects	Efficacy	Safety in pregnant woman
HEV 239 (Hecolin)	IM	0.5 ml	0, 1, and 6 months	30 μg of the purified protein absorbed to 0.8 mg of aluminum hydroxide suspended in 0.5 ml buffered saline	Well tolerated, no vaccination-related serious adverse events (Zhu et al. 2010)	85.1% for those receiving at least one dose, 93.3% after full three doses (Zhu et al. 2010; Zhang et al. 2015b)	Although contraindicated because of safety concern, preliminary data demonstrated safe and immunogenic among 37 pregnant woman receiving vaccine during pregnancy (Wu et al. 2012)

Furthermore, the cost of Hecolin 239 vaccine from Xiamen Innovax Biotech is around USD 17.60–41.70 per dose (Riedmann 2012; Zhao et al. 2016). This is cost efficient for an effective immunization that can reduce the cost of hospitalization and treatment; hence the implementation of the HEV vaccine would be beneficial to the public from a one health perspective.

(b) **Prevention**

Preventative measures for HEV are almost the same as for other infectious diseases (Nelson et al. 2016; Teshale and Hu 2011; Barnaud et al. 2012; Schielke et al. 2011)

Preventive measures	Procedures
Sanitation and hygiene	Government – treat sewage and water supplies Personal – wash hands, wash vegetables, avoid cross contamination while preparing food, use gloves to prepare food
Surveillance	HEV screening for health workers, live animal, carcass handlers, and in the blood bank
Diagnostic test	HEV test included in the diagnostic list for the hepatitis cases
Virus Inactivation	Cooking food above 71 °C for 20 min (Barnaud et al. 2012) and boiling water above 90 °C Wash fruits and vegetables with chlorine solutions
Vaccination	Perform mass vaccination with a safe vaccine in endemic areas

(c) **Treatment**

The population most at risk for HEV are organ transplant patients, HIV patients, and hemodialysis patients, which have the tendency to develop chronic hepatitis E (Kamar et al. 2014). Treatment drugs prescribed or used in the specific cases while diagnosed with HEV are listed below (Kamar et al. 2015; Pischke et al. 2014).

Clinical representation with HEV	Treatment approach
Liver transplant patients with immunosuppression and hemodialysis, and anemic patients with HEV viremia	Pegylated-interferon monotherapy, although reduction in the immunosuppressive regime leads to self-resolution in many cases
Immunocompromised patients with HEV viremia < 6 months	Ribavirin and pegylated-interferon
Immunocompetent patients with acute infection and immunocompromised patients with HEV viremia > 6 months (chronic infection)	Ribavirin monotherapy
Pregnant woman with HEV	Supportive therapy

Inactivation of RNA polymerase function using antiviral drugs such as zinc salt and nucleoside analogue 2'-C-methylcytidine (2CMC) inhibited HEV replication in human cell lines in vitro (Kaushik et al. 2017; Qu et al. 2017). In addition, sofosbuvir, calcineurin inhibitors, and mTOR inhibitors may help in virus clearance as suggested by in vitro assays, however, testing the efficacy and safety in humans would determine the fate of these drugs (Wang et al. 2014b; Netzler et al. 2019).

Similarly, immunocompetent patients return to their normal physiology within 3–4 weeks of ribavirin treatment due to the short duration of viremia (Péron et al. 2016).

45.8 Difference of HEV with Other Hepatitis-Causing Viruses

Viral hepatitis remains a significant public health problem in the United States, despite advances in antiviral therapy and effective vaccines. CDC reports document 20,000 deaths each year attributed to viral hepatitis, and 5 million people are chronically infected and at risk for serious liver disease and hepatocellular cancer (Loader et al. 2019). Clinical feature of viral hepatitis, including risk for progression to chronic infection with development of cirrhosis, vary considerably and are virus-specific. Differences between various hepatitis viruses are listed below to allow the reader to comprehend HEV with other hepatitis-producing viruses.

Variables	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Morphology	RNA virus	DNA virus	RNA virus	RNA virus	RNA virus
Transmission routes	Fecal-oral route	Percutaneous or perinatal exposure with HBV-infected blood or body	Infected blood or blood-containing body fluid	Shared needles among drug abusers, contaminated	Fecal-oral route, contaminated pork meat,

(continued)

Variables	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
		fluid, sexual contact		blood, and by sexual contact	and camel milk products
Clinical effects	Incubation Period (IP) – 28 days	I.P – 28 days to 6 months	Asymptomatic	I.P – 1 to 2 months	I.P – 5 to 6 weeks
	Fatigue, abdominal discomfort, vomiting, pruritus, fever, jaundice, dark-colored urine	Fever, fatigue, loss of appetite, vomiting, abdominal pain, dark colored urine, clay-colored stools, arthralgias, jaundice	Chronic infection is associated with hepatic fibrosis, cirrhosis. Extrahepatic manifestation includes cryoglobulinemia vasculitis, membranoproliferative glomerulonephritis, porphyria cutanea tarda, B-cell non-Hodgkin lymphoma	Jaundice, joint pain, abdominal pain, vomiting, loss of appetite, dark urine, fatigue, chronic cases develop cirrhosis	Fever, fatigue, loss of appetite, nausea, vomiting, abdominal pain, jaundice, dark urine, clay-colored stool, joint pain
	Acute liver Failure (ALF) – 1%	ALF – 1 to 2%	Cirrhosis – 10 to 20%	Cirrhosis – 4%	Fulminant hepatic failure (FHF) – 30%
Treatment	Supportive	Tenofovir and entecavir	Direct acting antiviral medications, ledipasvir-sofosbuvir, sofosbuvir-velpatasvir, elbasvir-grazoprevir	Supportive	Supportive in pregnant woman. No treatment for acute HEV infections
Vaccine	Havrix (two doses 6 months apart for children 1–2-year-old) and Vaqta (two doses 6 months apart for people traveling to endemic areas)	First dose at birth Heplisav-B (for 18 years and older)	No approved vaccine	No approved vaccine	Hecolin (HEV 239)– only approved in China

45.9 Loopholes in HEV Studies

Inefficiency of the cell culture system for the study of HEV hinders research into this important human pathogen. Thus, finding suitable animal model to dissect the pathogenesis and the virulent adaptation of HEV in the pregnant woman is critically important. Although rhesus macaque, rabbits and humanized mouse model have been used to study HEV, absolute recapitulation of clinical signs, lesions as seen in humans is not found. Various aspects of clinical outcomes are not reproduced in the animal models, including the chronic infection seen in immunocompromised patients and extrahepatic manifestations observed in HEV-infected patients, such as neurological disorders and kidney diseases. Furthermore, scarce knowledge is

present on the key aspects of the viral life cycle – for example, the cellular (co-) factors involved in the viral life cycle and prominent receptors mediating viral entry. In addition, several reports suggesting infection of animal species are based on a small number of serologically positive samples and interpretation needs further analysis. Only serological results are difficult to direct the conclusion as confirmatory assay, a gold standard for HEV, is lacking. There are no established guidelines on the management of HEV and other hepatitis-causing viruses in case of dual infection. Although the HEV vaccine is approved and used in China, worldwide approval and availability need to be prioritized.

45.10 Conclusions

Although HEV is considered as an emerging pathogen, it has been known to produce epidemic outbreaks starting from the 1950s. Current findings suggest that although pigs are the major reservoir spreading the disease to humans, the host range appears to be increasing. The zoonotic axis has gained importance due to the continued reemergence of HEV despite advances in hygiene practices. HEV continues to remain relevant producing new pathology manifestations including chronicity, extrahepatic manifestations, and the continued danger to pregnant women. Technological advances in sequencing, coupled with more thorough sampling will inevitably reveal more novel HEV strains. Continued research will continue unlocking novel treatment options. There is still much work to be done to unravel the nuances of HEV's deadly game of hide and seek so that humans may rid themselves of this malady.

Abstract

Since the mid-1990s, West Nile virus (WNV) outbreaks of increased severity first appeared in Africa, then in Europe, and finally in North America. These outbreaks were due to related lineage 1 viruses of apparent increased pathogenicity. More recently lineage 2 strains also of apparent increased pathogenicity have caused outbreaks in Europe. Some of the implicated lineage 1 strains and the lineage 2 strains have a mutation in the NS3 helicase gene, which confers increased viral pathogenesis in birds. The recent pattern of sporadic cases and outbreaks of WNV that has emerged in Europe and North America shows no signs of abating. While broad areas of high risk can be identified, the sporadic, local, and regional outbreaks that occur within these areas remain elusively unpredictable. Fewer than 1% of persons infected develop neuroinvasive disease, characterized by meningitis, encephalitis, or acute flaccid paralysis. Increasing age is a risk factor for neuroinvasive disease, both in humans and horses. Four WNV vaccines are currently marketed for horses in the United States. Although clinical trials have been conducted for six human vaccines, no vaccines are currently approved for human use. Treatment is supportive.

West Nile Virus · West Nile Virus Infection · West Nile Fever · West Nile Virus Transmission · West Nile Virus Strain

46.1 Introduction

The last three decades have witnessed the global emergence or reemergence of the West Nile virus. The virus was introduced to and spread throughout the Americas and outbreaks resulting in significant morbidity are now commonplace in North America and Europe. This chapter discusses the geographic emergence of this virus, the virology and biology behind this emergence, the virus's clinical and diagnostic aspects, and treatment and control measures.

46.2 Virology

West Nile virus (WNV) is one of more than 70 viruses of the family *Flaviviridae* of the genus Flavivirus (Heinz et al. 2000). The flaviviruses comprise some of the most medically important arthropod-borne viruses, including the yellow fever, Japanese

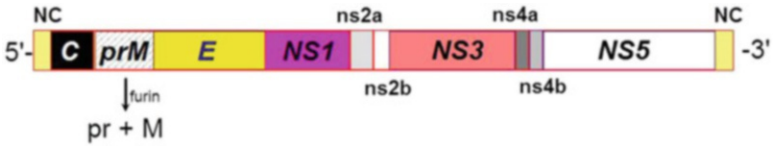

Fig. 1 WNV genome

encephalitis, dengue, and tick-borne encephalitis viruses (Mackenzie and Williams 2009). Like other flaviviruses, WNV is an enveloped spherical-shaped virion encompassing a single-stranded RNA molecule of positive polarity of approximately 11-kb. The genomic RNA of WNV encodes three 5′ structural proteins (C-prM-E) and seven nonstructural proteins (NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5) at the 3′ end, which are flanked by 5′ and 3′ untranslated regions involved in transcription and translation (Fig. 1). Both structural and nonstructural proteins are translated as a single polyprotein that is cleaved into the respective viral proteins by host and viral proteases both co- and post-translationally (Chambers et al. 1990).

Serologically, WNV is a member of the Japanese encephalitis serocomplex, which includes the Japanese encephalitis, Murray Valley encephalitis, and St. Louis encephalitis viruses (Calisher 1988). Sequence analyses suggest that WNVs can be categorized into at least five phylogenetic lineages (May et al. 2011), although up to nine genetic lineages have been suggested (De Filette et al. 2012; Mackenzie and Williams 2009; Pachler et al. 2014; Vazquez et al. 2010). Only lineage 1 and 2 WNVs have been associated with significant disease outbreaks in humans.

The lineage 1 viruses can be further subdivided into three sublineages (a–c): isolates from the Western Hemisphere, Africa, the Middle East, and Europe constitute lineage 1a; Kunjin virus from Australasia represents lineage 1b; and lineage 1c consists of viruses from India (Bondre et al. 2007; May et al. 2011). Distribution of lineage 1 most likely occurred during the past 300 years, possibly resulting from increased trade between Africa and India and Australia. The lineage 1a viruses are the most widely dispersed and epidemiologically important, having caused large outbreaks in Europe, Russia, and North America during the past three decades. Lineage 1a can be further subdivided phylogenetically into several clusters, each with a relatively distinct geographic focus of circulation (May et al. 2011). Nevertheless, all but one cluster contains isolates from Africa, suggesting frequent gene flow from Africa to Europe and Russia, most likely by migrating birds.

WNV was first discovered in the Western Hemisphere during simultaneous human epidemics and avian epizootics in the New York City area in 1999 (Mostashari et al. 2001). The means and origin of the WNV brought into North America are unknown. A Middle Eastern origin was first hypothesized based on the fact that the initial North American isolates (East Coast genotype) from 1999 were most closely related to a lineage 1a WNV isolated from Israel in 1998

(Lanciotti et al. 1999). However, more recent analysis suggests that the Israel outbreak was not the progenitor of the North American outbreak, but rather that both outbreaks were initiated by the introduction of strains from the same independent location, probably Africa (May et al. 2011). The WNV strain imported into North America contains a single nucleotide change in the NS3 gene (T249P), which confers avian virulence in otherwise nonvirulent strains (Brault et al. 2007). Since approximately 2002, the East Coast genotype has largely been displaced by a new genotype (WN02) encompassing several conserved amino acid substitutions (Davis et al. 2005). This displacement may have resulted from a temperature-dependent increased efficiency and rapidity of dissemination and transmission of the WN02 virus in North American mosquito vectors (Ebel et al. 2004; Kilpatrick et al. 2008).

Only lineage 1 and 3 WNV strains had been found in Europe until 2004, when a lineage 2 strain pathogenic to birds of prey was identified in Hungary (Bakonyi et al. 2006). Before then, lineage 2 WNVs were isolated almost exclusively from African transmission cycles and were considered to be of low pathogenicity (Murgue et al. 2002). Subsequently, highly pathogenic lineage 2 WNV strains have caused both human and animal disease in South Africa (Venter 2009; Zaayman and Venter 2012) and Europe (Bakonyi et al. 2013; Papa 2012). Isolates from lineage 2 viruses generally have histidine at the 249 locus of the NS3 gene. While isolates that have caused large outbreaks in Greece since 2010 have contained a proline substitution at this locus (Barzon et al. 2013b; Papa et al. 2011a, 2013), experimental data indicate that this residue does not cause increased viral replication or virulence in European birds (Del Amo et al. 2014; Sotelo et al. 2011a). Like lineage 1 viruses, phylogenetic analysis suggests multiple introductions of lineage 2 viruses into Europe from Africa (Ciccozzi et al. 2013; McMullen et al. 2013). Two subclades of lineage 2 viruses circulate in Europe. The Central European/Hungarian subclade present in central Europe and the eastern Mediterranean region now causes most seasonal outbreaks in Europe (Chaintoutis et al. 2019). The Eastern European/Russian subclade has caused outbreaks in Eastern Europe and Russia.

46.3 Transmission Cycle

WNV exists in a bird-mosquito-bird transmission cycle (Fig. 2). Following mating, female *Culex spp*. mosquitoes obtain a blood meal from a vertebrate host to obtain protein to make eggs. She can become infected from a blood meal from a vertebrate host with sufficient viremia levels to efficiently infect mosquitoes. Viremia in vertebrate hosts generally lasts about 5–7 days (Komar et al. 2003). After depositing her eggs, she seeks another vertebrate host to feed upon. Sufficient time is required after the initial blood meal for the virus to replicate within the mosquito and spread to its salivary glands (extrinsic incubation period), at which time it can transmit the virus to this and subsequent vertebrate hosts during feeding.

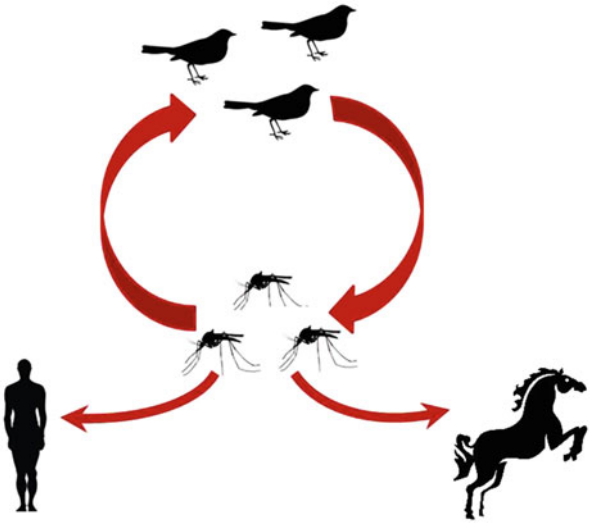

Fig. 2 WNV transmission cycle

46.3.1 Mosquitoes

WNV has been detected in 65 different mosquito species in the United States (Centers for Disease Control and Prevention). However, most of these detections used molecular methods without virus isolation, thus confirming the presence of WNV but not necessarily the ability to transmit the virus (Rochlin et al. 2019). Further, mosquito host preference is complex and driven by multiple intrinsic (e.g., preference for birds) and extrinsic (e.g., host abundance) determinants (Takken and Verhulst 2013). Only a few ornithophilic *Culex* mosquito species drive epizootic and epidemic transmission: *Culex pipiens* in the northern half of the United States; the closely-related species *Culex quinquefasciatus* in the southern and western United States; and *Culex tarsalis* in many areas that overlap with the distribution of *Culex pipiens* and *Culex quinquefasciatus* (Andreadis 2012; Andreadis et al. 2004; Godsey Jr. et al. 2012; Kilpatrick et al. 2006b). *Culex pipiens* and *Culex quinquefasciatus* typically use man-made habitats for laying eggs (oviposition) and larval development, including peridomestic containers and above- and below-ground waste water systems (Reisen 2012; Reisen et al. 1990; Rochlin et al. 2019). *Culex tarsalis* is often associated with irrigated farmland (Reisen 2012), but can use diverse sources for breeding such as abandoned swimming pools (Reisen et al. 2008). The ubiquitous sources for Culex mosquito breeding make larval control a formidable challenge. In Europe, *Culex pipiens* is considered the most important vector (Reiter 2010; Vogels et al. 2017). The major mosquito vector in Africa and the Middle East is *Culex univittatus*, with other Culex species important in some areas (Hubalek and Halouzka 1999; Ochieng et al. 2013; Solomon 2004).

Several other mosquito species can play important roles in certain circumstances. For example, *Culex restuans*, an ornithophilic mosquito present in high numbers early in the transmission season and commonly found infected with WNV, can play an important role in early amplification of enzootic transmission in the northeastern United States (Andreadis and Armstrong 2007). *Culex salinarius*, a mosquito found in high numbers during August and September in coastal areas of the northeastern United States, is frequently found to have high WNV infection rates. Because this mosquito feeds indiscriminantly on both birds and mammals and readily bites humans, it can be an important bridge vector to humans (Andreadis 2012).

In temperate climates, WNV overwinters in hibernating (diapause) adult female Culex mosquitoes, probably in some birds and possibly in rodents (Nasci et al. 2001; Platt et al. 2008; Reisen et al. 2006a). Although the means by which pre-hibernating Culex females become infected is not entirely clear, it has been conclusively demonstrated that vertically infected female *Culex pipiens* that enter diapause in the fall are able to initiate infection in the spring (Anderson and Main 2006). In semi-tropical environments, such as found in the southeastern United States, transmission occurs throughout the year, albeit at a very low level during cooler periods (Tesh et al. 2004).

46.3.2 Vertebrate Hosts

The extensive distribution of WNV throughout Africa, the Middle East, southern Europe, western Russia, southwestern Asia, and Australia (Kunjin subtype) derives in part from its ability to infect numerous bird species. Infection has been documented in at least 326 bird species in the United States alone (Centers for Disease Control and Prevention). Numerous passerine birds develop extremely high viremias and thus are competent amplifier hosts (Komar et al. 2003; Weingartl et al. 2004). Nevertheless, a relatively small subset of the bird community can significantly influence WNV transmission dynamics (McKenzie and Goulet 2010); high avian species diversity, particularly if it is rich in non-passerine species, can dampen WNV transmission (Ezenwa et al. 2006). For example, the American robin (*Turdus migratorius*) can be an important amplifier host despite its low abundance relative to other WNV susceptible birds (Kilpatrick et al. 2006a; Savage et al. 2007). Kilpatrick has hypothesized that WNV outbreaks are promoted by mosquito feeding shifts from American robins to humans coincident with late-season robin dispersal (Kilpatrick et al. 2006b); however, others have failed to demonstrate a shift of feeding preference from robins to mammals (Savage et al. 2007).

WNV transmission might be influenced by the spatial interactions of birds in several ways. One study examining American robins indicated that communal roosts can form important WNV amplification foci (Diuk-Wasser et al. 2010) while another indicated that *Culex quinquefasciatus* more frequently fed on species that roost communally, including the American robin, finch, and sparrow (Hannon et al. 2019). A potential mechanism is the CO_2 generated from many birds congregating at night, which attracts host-seeking mosquitoes (Janousek et al. 2014). In contrast,

one study demonstrated that roosts are not necessarily important for WNV amplification (Benson et al. 2012). Cloacal and oral shedding of WNV is common in infected birds (Komar et al. 2003) and direct bird-to-bird transmission has been documented in birds housed together (Banet-Noach et al. 2003; Komar et al. 2003; Weingartl et al. 2004). The influence of non-mosquito, direct bird-to-bird transmission on the amplification cycle is unknown, although one mathematical model indicated that it can play an important role in some circumstances (Naowarat and Tang 2004).

Other factors can potentially influence avian-related WNV transmission and increase the risk for epidemics. American robins that were food-deprived for 48 h before WNV infection were found to develop higher viral titers and had a longer infectious period compared with robins fed normally (Owen et al. 2021). Another study demonstrated that exposure to artificial light at night increased the duration of potentially infectious titers in house sparrows without greater WNV-induced mortality (Kernbach et al. 2019).

The role of non-avian vertebrate hosts for maintaining or amplifying the virus is unknown. Humans and horses generally develop insufficient WNV titers in the blood to infect mosquitoes, but squirrels, chipmunks, and rabbits, and potentially opossum, can develop sufficiently high viremia to infect mosquitoes, raising the possibility that small mammals might contribute to WNV transmission cycles (Platt et al. 2007, 2008; Reisen and Brault 2007; Root and Bosco-Lauth 2019). Snakes could play a possible role in the WNV transmission cycle (Dahlin et al. 2016). Alligators might also serve as competent reservoirs in the southeastern United States and have been shown experimentally to be capable of WNV amplification and transmission to mosquitoes, thus indicating the potential for maintaining WNV outside of the bird-mosquito transmission cycle (Byas et al. 2022; Klenk et al. 2004).

46.3.3 Determinants of Human Disease Incidence and Outbreaks

As with most mosquito-borne arboviral diseases, WNV incidence in humans exhibits considerable annual and geographic variation. Nevertheless, outbreaks in temperate climates tend to occur during mid- to late summer after sufficient viral amplification in the bird-mosquito-bird transmission cycle has produced enough infected mosquitoes to present a human infection risk (Fig. 3). Certain areas also tend to have consistently higher human disease incidence, indicating an underlying permissive ecology that promotes WNV amplification. Factors such as urban and agricultural land covers (Bowden et al. 2011), rural irrigated landscapes (DeGroote and Sugumaran 2012), orchard habitats (Crowder et al. 2013), farming activities as determined by total crop sales (Miramontes Jr. et al. 2006) and several socioeconomic factors such as housing age and community drainage patterns (Ruiz et al. 2007), per capita income (DeGroote and Sugumaran 2012), and even neglected swimming pool density (Harrigan et al. 2010; Reisen et al. 2008) relate to higher WNV incidence in some locations. Overall, persons living in rural areas in the United States and Canada seem to be at higher risk of acquiring WNV infection

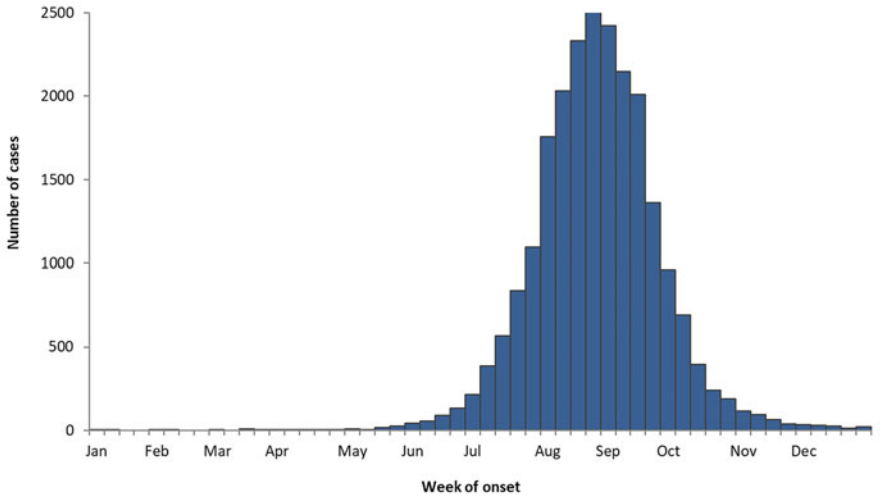

Fig. 3 Cumulative incidence of WNV neuroinvasive disease, by week of symptom onset, United States, 1999–2019. Source: US Centers for Disease Control and Prevention

than those living in urban settings. A United States nationwide study comparing viremic to uninfected blood donors illustrated that residents of rural areas were 3.4 times more likely to be infected than residents of surburban or urban locations (Orton et al. 2006). In Saskatchewan, Canada, residents of rural areas were approximately six times more likely than urban dwellers to have WNV antibodies (Schellenberg et al. 2006).

Weather has an enormous impact on WNV amplification in the bird-mosquito-bird transmission cycle. Increasing ambient temperature shortens the viral extrinsic incubation period and increases viral replication in mosquitoes, both of which greatly increase the probability of viral transmission to susceptible hosts (Cornel et al. 1993; Dohm et al. 2002; Kilpatrick et al. 2008; Reisen et al. 2006b; Richards et al. 2007). However, changes in ambient temperature influence the abundance of vector mosquitoes, host survival and distribution, and human behavior in unpredictable ways differentially influenced by the underlying local ecology. Rainfall and humidity variably influence mosquito abundance and survival, distribution of hosts, and human behavior. Given the infinite possible combinations of temperature and rainfall events and their variable effects on arboviral transmission parameters, combined with other parameters that influence transmission, such as underlying immunity in birds, no models have been able to predict when and where WNV outbreaks will occur nationally (Petersen and Fischer 2012). Nevertheless, human disease incidence over broad areas in temperate climates has correlated with increased temperatures (Hartley et al. 2012; Soverow et al. 2009; Watts et al. 2021; Wimberly et al. 2008) as well as increased (Landesman et al. 2007; Soverow et al. 2009) or decreased rainfall (Landesman et al. 2007; Mavrakis et al. 2021; Wang

et al. 2010). A substantial need exists to develop short-term planning models over small geographic areas that can assist mosquito control districts and public health authorities in surveillance, vector control, and public health messaging (Keyel et al. 2021).

46.4 Transmission to Humans

Nearly all humans acquire WNV infection from mosquito bites. Persons with extensive outdoor exposure are likely at higher risk for infection. One study in the United States found that children were more likely than adults to spend time outdoors and less likely to practice personal protective behaviors (LaBeaud et al. 2007). People of lower socioeconomic status and particularly those experiencing homelessness might be at higher risk of WNV infection (Gujral et al. 2007; Meyer et al. 2007).

Transfusion-associated WNV transmission was first detected during the 2002 WNV epidemic in the United States when 23 transfusion recipients were infected through receipt of platelets, red blood cells, or fresh frozen plasma from 16 viremic blood donors (Pealer et al. 2003). Mathematical models indicated the risk of transfusion-associated WNV transmission during the 2002 epidemic ranged from 2.1 to 4.7 per 10,000 donors in high incidence areas (Biggerstaff and Petersen 2003). These findings prompted screening of the United States and Canadian blood supplies using WNV nucleic acid amplification (NAT) tests since 2003. Blood centers conduct NAT testing on minipools of 6 to 16 specimens, depending on test kit manufacturer. While universal pooled blood donation screening has nearly eliminated WNV transfusion transmission, some "breakthrough" transmissions have occurred from donations with virus levels below the limit of detection by minipool screening (Centers for Disease Control and Prevention 2007; Groves et al. 2017; Petersen and Epstein 2005). To minimize the risk of "breakthrough" transmissions, blood centers switch to individual donation testing in areas experiencing outbreaks; however, one transmission occurred from a donor with viremia below levels detected by individual unit testing (Centers for Disease and Prevention 2013).

In 2002, transmission via donated organs was first documented when four recipients of organs from a common donor developed WNV infection (Iwamoto et al. 2003). Since then, seven additional transmission clusters in the United States (Nett et al. 2012; Soto et al. 2022) and two in Italy (Inojosa et al. 2012; Morelli et al. 2010) have been documented and published. Interestingly, archived serum from the donors of four of these nine clusters had negative NAT results, indicating that viable WNV can be sequestered in organs for a short time after viremia has cleared. The urgency of procuring and transplanting organs has precluded most organ procurement organizations from routinely conducting WNV screening of organ donors (Nett et al. 2012; Theodoropoulos et al. 2021).

Intrauterine transmission of WNV was first documented in 2002 when a woman with WNV encephalitis during the 27th week of pregnancy delivered a term infant with chorioretinitis, cerebral lesions, and laboratory evidence of congenitally

acquired WNV infection (Alpert et al. 2003; Centers for Disease Control and Prevention 2002a). Fortunately, intrauterine transmission appears uncommon. A follow-up study of 71 women infected with WNV during pregnancy demonstrated that none of their 72 live infants had malformations linked to WNV infection or had conclusive laboratory evidence of congenital WNV infection (O'Leary et al. 2006). However, three infants born to women with illness occurring within 3 weeks prepartum had evidence of WNV infection that could have been congenitally acquired or acquired at the time of birth: one had WNV meningitis at 10 days of age, one had a neonatal rash and was positive for anti-WNV IgM at 1 month of age, and one had WNV encephalitis with underlying lissencephaly detected at 17 days of age (O'Leary et al. 2006). A study of 549 infants born to mothers who were pregnant during a community WNV outbreak found evidence of WNV infection in 4% of the mothers and in none of the infants (Paisley et al. 2006). Similar birth outcomes were noted among infants born to mothers with and without evidence of WNV infection during pregnancy (Paisley et al. 2006). A small prospective study that compared 28 pregnant women who had serologically confirmed WNV illness with 26 WNV-uninfected pregnant women found that none of the infants born to the WNV-infected mothers were born with clinical evidence of infection and none had neurologic deficits at birth (Pridjian et al. 2016). Further, infants born to the WNV-infected mothers were no more likely to have congenital malformations or developmental delays.

WNV transmission has also been reported through percutaneous exposure and inhalation in laboratories, conjunctival exposure while handling dead birds, in a dialysis center by unidentified means, and at a turkey farm, possibly by aerosol (Centers for Disease Control and Prevention 2002b, 2003, 2004; Fonseca et al. 2005; Nir et al. 1965). Transmission via breast milk has also been reported, but appears uncommon (Hinckley et al. 2007).

46.5 Global Epidemiology

46.5.1 Africa

WNV lineages 1, 2, 7 (now classified as a separate virus, Koutango virus), and 8 have been identified in Africa (Fall et al. 2017). WNV lineage 1 is mainly found in Central and Northern Africa; whereas, lineage 2 is found in Southern Africa (Mencattelli et al. 2022). Phylogenetic analysis suggests that all European lineage 1 and 2 strains originated from Africa (Bakonyi et al. 2006, 2013; Charrel et al. 2003; May et al. 2011). Consistent with this hypothesis, serological studies in humans and animals conducted in several African countries indicate widespread viral circulation (Mencattelli et al. 2022; Murgue et al. 2002). Seroprevalence ranges markedly by location, even within the same country. For example, a serological study of Egyptian university students showed that WNV antibody prevalence ranged from 28% in Cairo to 74% in Upper Egypt (Darwish and Ibrahim 1971). Similarly, a serological survey of randomly selected household members demonstrated WNV antibody

prevalences ranging from 2% in the Northern Sinai to 35% in Upper Egypt (Soliman et al. 2010). Consistent with an endemic pattern, antibody seroprevalence increased by age. A similar pattern of increasing seroprevalence with age was noted in a serological survey of humans in Kenya (Sutherland et al. 2011). While serological data suggest frequent WNV exposure in Africa, these data must be interpreted cautiously because of differing testing methodologies and the considerable serological cross-reactivity among the flaviviruses.

In contrast to the apparent frequent exposure to WNV throughout much of Africa, human and animal illness has been reported infrequently. Nevertheless, sporadic cases of mild illness undoubtedly occur much more commonly than reports indicate. The virus was first recognized in a febrile woman in Uganda in 1937 (Smithburn et al. 1940). WN viral nucleic acid has confirmed WNV circulation in humans in eight countries between 1983 and 2020 and serological surveys have suggested viral exposure to humans in 23 countries (Mencattelli et al. 2022). The most notable outbreak occurred in South Africa in 1974 following heavy rains and above normal temperatures in early summer. Despite an estimated 18,000 cases, neuroinvasive disease or mortality was not recorded (Jupp 2001). More recently, a new pattern of outbreaks of unusual severity in northern Africa has occurred. An outbreak of approximately 50 human cases with neurological disease occurred in Algeria in 1994 (Le Guenno et al. 1996), which was followed in 1997 by an outbreak involving 173 patients (Triki et al. 2001). An outbreak associated with severe neurological disease in a military camp in the Democratic Republic of Congo was noted in 1998 (Nur et al. 1999). In Sudan in 2002, at least 31 cases of encephalitis occurred during an outbreak in children (Depoortere et al. 2004). In addition, outbreaks of severe neurological disease in equines in Morocco in 1996 and 2003 were associated with 94 and 7 equines, respectively (Schuffenecker et al. 2005). These outbreaks were associated with viral strains of apparent increased virulence and were closely related to the lineage 1 WNV strains that caused large human outbreaks in Romania, Russia, Israel, and the United States (Lanciotti et al. 1999; Schuffenecker et al. 2005). In recent years, sporadic cases of neurologic disease from lineage 2 WNV strains have been identified in South Africa (Venter 2009; Venter and Swanepoel 2010; Zaayman and Venter 2012).

46.5.2 Europe

WNV strains are likely transported between sub-Saharan Africa and Europe by migratory birds. This hypothesis is supported by the relatively high prevalence of WNV antibodies in migratory birds noted in Russia, Israel, and several European countries (Lelli et al. 2012; Valiakos et al. 2012), as well as by phylogenetic analyses of WNV strains suggesting multiple WNV introductions to Europe in recent years (Parreira et al. 2007). Thus, the likely long co-evolution of virus and hosts in Europe may account for the relative paucity of widespread mortality in European birds compared to what has occurred among many North American bird species (Komar et al. 2003; LaDeau et al. 2007). Nevertheless, lineage I WNV strains genetically

related to the strain imported into New York City in 1999 (East Coast strain) resulted in clinical illness in white storks (*Cicona ciconia*) migrating from central Europe through Israel in 1998 (Malkinson et al. 2002) and an epizootic of encephalitis in Hungarian geese (*Anser anser domesticus*) in 2003 (Bakonyi et al. 2006). In 2004 and 2005, several deaths in goshawks (*Accipiter gentilis*) and a sparrow hawk (*Accipiter nisus*) from the same region of Hungary were attributed to a central African lineage 2 virus, which was the first report of a lineage 2 virus outside of Africa (Erdelyi et al. 2007).

From the 1960s through the 1980s, WNV isolates were obtained infrequently in southern and central Europe from mosquitoes, humans, birds, and horses, although serological surveys conducted in humans, birds, and other animals suggested more widespread viral exposure (Hubalek and Halouzka 1999; Linke et al. 2007). Human or equine illness was sporadic, with isolated human cases of WN fever identified in France, Spain, Romania, Belarus, and Czechland (Hubalek and Halouzka 1999). An outbreak in the Camargue region of southern France from 1962 to 1965 resulted in 15 virologically confirmed human cases with 1 death and approximately 80 equine cases with 25–30% mortality (Murgue et al. 2001a).

The first large human outbreak in Europe occurred in Romania with 352 cases of neuroinvasive disease in 1996 (Tsai et al. 1998). An equine outbreak with 14 cases occurred in Italy in 1998 and another with 76 cases in the Camargue region in 2000 (Autorino et al. 2002; Murgue et al. 2001b). Four humans with WNV-related illness were noted in the Camargue region in 2003, which represented the first human WNV-related illnesses documented there since 1965 (Del Giudice et al. 2004).

WNV outbreaks and sporadic cases subsequently have increased in frequency and geographic distribution in Europe. Human cases and dead birds have been associated with both lineage 1 and 2 WNV strains (Barzon et al. 2012a, b, c; Magurano et al. 2012; Savini et al. 2012) and strains from both virus lineages have been identified in *Culex pipiens* mosquitoes (Savini et al. 2012), indicating co-circulation of both viruses. Lineage 2, first detected in Hungary in 2004, subsequently spread across central Europe and the eastern Mediterranean region, causing major outbreaks in Greece in 2010 and the largest outbreak recorded in Europe in 2018. The 2010 Greek outbreak resulted in 262 laboratory-confirmed cases and 35 deaths while the 2018 outbreak involved 1993 cases and 207 deaths mainly in Greece, Hungary, Italy, and Romania (Fig.4) (Young et al. 2021). The totals from 2018 exceeded those of the previous 7 years combined. It is hypothesized that the 2018 outbreak was precipitated by environmental factors including an exceptionally hot summer. In recent years, WNV lineage 2 has extended its northern bounds (Bakonyi and Haussig 2020). The virus was first detected in birds and horses in Germany for the first time in 2018 (Ziegler et al. 2019), which preceded the first human cases in that country in 2019 (Ziegler et al. 2020). In 2020, WNV was reported in birds, mosquitoes, and humans for the first time in the Netherlands (Vlaskamp et al. 2020). In addition, WNV lineage 1 has spread westward, causing an outbreak of 71 humans in Andalusia, Spain in 2020 (Casimiro-Soriguer et al. 2021).

46.5.3 Americas

WNV spread rapidly throughout the Americas following its discovery in the New York City area in 1999 (Nash et al. 2001). It spread across the United States and reached the Pacific Coast by 2003 (Lindsey et al. 2010). The virus was first detected in Canada in 2001. By 2001 WNV had spread south to islands in the Caribbean Sea (Komar and Clark 2006); by 2003 to El Salvador, Guatemala, and Belize; by 2004 to Colombia and Venezuela (Bosch et al. 2007; Mattar et al. 2005); and by 2005 to Argentina (Adrian Diaz et al. 2008). Despite the virus' apparent extensive distribution in Latin America and the Caribbean, only isolated instances of human illness have been reported (Gubler 2007; Hunsperger et al. 2009; Komar and Clark 2006; Pupo et al. 2006). The explanation for this discrepancy is unknown; however, it is noteworthy that this same pattern is observed in tropical Africa. Perhaps the continuous avian host availability for ornithophilic mosquitoes in tropical areas might decrease the likelihood that infected mosquitoes feed on humans.

The virus is now endemic throughout much of the United States and southern Canada (Lindsey et al. 2010; Petersen et al. 2013a). Through 2019, 51,801 persons have been reported with WNV disease in the United States, including 25,290 patients with neuroinvasive disease and 1549 deaths; 6423 patients with WNV disease were reported in Canada. In the United States, sporadic human cases occur each year throughout the country along with focal or regional outbreaks of varying

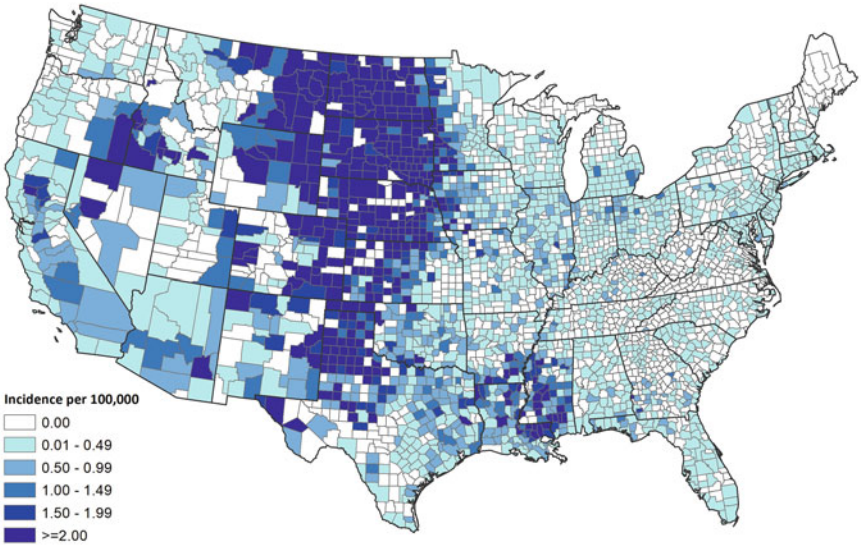

Fig. 5 Average annual incidence of WNV neuroinvasive disease, by county, United States, 1999–2019. Source: US Centers for Disease Control and Prevention

sizes. Large regional outbreaks, each involving nearly 3000 patients with neuroinvasive disease, occurred in 2002, 2003, and 2012. Despite the sporadic nature of outbreaks, certain areas appear to be at higher overall risk than others (Fig. 5). Nearly 90% of cases have onsets from July through September (Fig. 3) (McDonald et al. 2021).

46.5.4 Israel, Asia, Russia

The first reported WNV human epidemic in Israel occurred in 1951–1952 (Bernkopf et al. 1953), and was followed by a series of human outbreaks throughout the 1950s and in 1980. Illnesses were generally mild, although neuroinvasive disease was prominent during an outbreak among the elderly in 1957 (Murgue et al. 2002). Little subsequent WNV activity occurred in Israel until 1997 and 1998 when WNV was identified from dying migrating storks from Europe as well as other bird species, including domestic geese (Malkinson and Banet 2002; Malkinson et al. 2002). Two human fatalities occurred in 1999, followed by an outbreak with 417 cases and 35 deaths the following year (Chowers et al. 2001; Weinberger et al. 2001). Since then, outbreaks have occurred every few years, including a lineage 1 outbreak involving at least 139 cases in 2018 (Lustig et al. 2019).

Since 1963, WNV has been isolated from ticks, birds, and mosquitoes in the southern area of European Russia and western Siberia, and in adjacent republics of the former Soviet Union. Serological surveys of healthy humans indicated up to 8%

anti-WNV IgG antibody seroprevalence (Platonov 2001). Yet outbreaks were uncommon until 1999 when a large outbreak of severe neurological disease involved 318 cases and 40 deaths in Volgograd (Platonov et al. 2001). This outbreak occurred during an unusually hot and dry summer. The lineage 1 virus that caused the 1999 outbreak was genetically related to that which caused the 1996 Romanian outbreak (Lanciotti et al. 2002). Sporadic cases and outbreaks have subsequently occurred from both lineage 1 and 2 viruses, mainly in areas near the Volga River (Fig. 4). Nevertheless, the distribution of the virus may be extensive in Russia, as suggested by a 2004 report of WNV in patients in Novosibirsk in southwestern Siberia and by a serosurvey showing a 15% seroprevalence of WNV neutralizing antibodies in birds in far-Eastern Siberia (Murata et al. 2011).

Although WNV illness is infrequent elsewhere in the Middle East and South Asia, Turkey began experiencing large numbers of human cases throughout the country in 2010 and 2011, concurrent with many cases occurring in Greece, Russia, and Israel (Kalaycioglu et al. 2012). Serological surveys in humans and horses conducted in Iran since 1967 indicate circulation of the virus, although human illness has been uncommonly reported (Chinikar et al. 2012, 2013; Kalantari et al. 2019; Naficy and Saidi 1970). Serological evidence of WNV antibodies in humans in India was first identified in 1952 and the virus was identified since then in mosquitoes and in ill humans in several areas (George et al. 1984; Paul et al. 1970). A study of samples collected throughout India from 1992 to 2001 identified 88 ill persons with WNV-specific antibodies, suggesting that WNV-related illness incidence may be higher than that currently recognized (Thakare et al. 2002). Several recent outbreaks occurring concurrently with other mosquito-borne illness have been noted in India (Khan et al. 2011; Shukla et al. 2012). A WNV outbreak occurred in Xinjiang, China in 2004 (Li et al. 2013).

46.5.5 Australia

Kunjin virus, a lineage I WNV variant (1b) (May et al. 2011), is endemic throughout most of tropical Australia and eastern Queensland. Phylogenetic analysis suggests a single successful introduction of a virus originating from Africa sometime within the last 300 years (May et al. 2011). Documented illness is rare, and cases occur in infrequent small outbreaks or sporadically. Illness is typically mild, non-encephalogenic, and non-life threatening (Knope et al. 2013).

46.6 Clinical Aspects

46.6.1 Humans

Approximately 25% of humans infected with WNV become ill (Zou et al. 2010). The incubation period for clinical illness generally ranges from 2 to 14 days, but immunocompromised patients may experience prolonged incubation periods up to

21 days (Pealer et al. 2003; Rhee et al. 2011). Most of those who become ill develop West Nile fever, characterized by the sudden onset of symptoms such as headache, malaise, fever, myalgia, chills, vomiting, rash, and eye pain (Pacenti et al. 2020; Zou et al. 2010). Fever may be low-grade or absent (Landry et al. 2019). A rash, which often appears around the time of defervescence, tends to be morbilliform, maculopapular, and non-pruritic and predominates over the torso and extremities, sparing the palms and soles (Anderson et al. 2004; Del Giudice et al. 2005; Ferguson et al. 2005; Gorsche and Tilley 2005). Persistent fatigue, headaches, and difficulties concentrating may continue for weeks or months and can be quite debilitating (Patel et al. 2015).

Risk factors for developing West Nile fever are not well defined. A follow-up study of asymptomatic, viremic blood donors indicated that increasing viral load and female gender, but not age, subsequently increased the risk of developing West Nile fever (Zou et al. 2010). A smaller follow-up study of viremic blood donors suggested that younger persons were more likely to develop West Nile fever (Brown et al. 2007).

Approximately one in 150 to 250 persons infected with WNV develop neuroinvasive disease (Mostashari et al. 2001; Petersen et al. 2012), which is manifested by meningitis, encephalitis, or acute flaccid paralysis. Advancing age profoundly increases the risk of neuroinvasive disease, particularly encephalitis (Carson et al. 2012; Lindsey et al. 2010). The risk may approach 1 in 50 among persons aged at least 65 years, a rate 16 times higher than that for persons aged 16–24 years (Carson et al. 2012). In addition, a history of cancer, diabetes, hypertension, alcohol abuse, renal disease, immunosuppressive medications, and *CCR5* deficiency as well as male gender may increase the risk of neuroinvasive disease (Bode et al. 2006; Carson et al. 2012; Cho and Diamond 2012; Lindsey et al. 2010, 2012b; Murray et al. 2006). Persons infected through transplantation of infected organs are at extreme risk of developing neuroinvasive disease (Nett et al. 2012); however, conflicting data exist regarding risk among previous organ recipients infected via a mosquito bite (Freifeld et al. 2010; Kumar et al. 2004).

West Nile meningitis is clinically like that of other viral meningitides with abrupt onset of fever and headache along with meningeal signs and photophobia. Headache may be severe, requiring hospitalization for pain control; associated gastrointestinal disturbance may result in dehydration (Sejvar et al. 2008). West Nile encephalitis ranges in severity from a mild, self-limited confusional state to severe encephalopathy, coma, and death. Extrapyramidal disorders are frequently observed (Burton et al. 2004; Pepperell et al. 2003; Sayao et al. 2004; Sejvar et al. 2003a). Increased intracranial pressure, cerebral edema, and seizures are infrequent (Doron et al. 2003). Patients with West Nile encephalitis frequently develop a coarse tremor, particularly in the upper extremities. The tremor tends to be postural, and may have a kinetic component (Burton et al. 2004; Emig and Apple 2004; Sayao et al. 2004; Sejvar et al. 2003a). Myoclonus, predominantly of the upper extremities and facial muscles, may occur, and may be present during sleep. Features of Parkinsonism may be seen (Robinson et al. 2003; Sejvar et al. 2003a) and cerebellar ataxia has been described (Burton et al. 2004; Kanagarajan et al. 2003; Sayao et al. 2004).

WNV-associated paralysis most commonly results from destruction of the anterior horn cells of the spinal cord (Glass et al. 2002; Jeha et al. 2003; Leis et al. 2002; Li et al. 2003; Sejvar et al. 2003b, 2005). Asymmetric weakness usually develops rapidly within the first 48 h after symptom onset, although patients with extensive spinal cord involvement develop a more symmetric dense quadriplegia. Central facial weakness, frequently bilateral, may occur (Jeha et al. 2003). Respiratory failure requiring emergent endotracheal intubation may result from diaphragmatic and intercostal muscle paralysis (Fan et al. 2004; Sejvar et al. 2005). Sensory loss or numbness is generally absent though some patients experience intense pain in the affected limbs just before or during the onset of weakness (Sejvar et al. 2005). Other causes of weakness associated with WNV infection include Guillian-Barré syndrome and other demyelinating neuropathies, transverse myelitis, motor axonopathy, axonal polyneuropathy, involvement of ventral spinal roots, myasthenia gravis, and brachial plexopathies (Leis and Stokic 2012).

Other manifestations described with WNV infection include myocarditis, pancreatitis, fulminant hepatitis, rhabdomyolysis, stiff-person syndrome, and autonomic instability (Petersen and Hayes 2008). Chorioretinitis is the most common ocular manifestation, occurring in approximately 80% of persons with neuroinvasive disease (Rousseau et al. 2020). Other reported ocular manifestations include anterior uveitis, occlusive retinal vasculitis, and optic neuritis (Rousseau et al. 2020).

Full recovery is the norm for patients with uncomplicated West Nile fever or meningitis; however, initial symptoms, particularly extreme fatigue, may be prolonged (Patel et al. 2015; Watson et al. 2004). West Nile fever may precipitate death among a few persons of advanced age or with underlying medical conditions (Sejvar et al. 2011). Outcomes of West Nile encephalitis are variable and may not correlate with severity of initial illness. Patients hospitalized with WNV encephalitis frequently require assistance with daily activities following acute care discharge (Emig and Apple 2004; Pepperell et al. 2003) and often report substantial functional and cognitive difficulties for up to a year following acute infection (Patel et al. 2015).

While some studies have documented neurocognitive deficits on standardized testing as long as 1 year after acute illness (Haaland et al. 2006; Sadek et al. 2010), others have failed to confirm this finding (Sejvar et al. 2008). Nevertheless, self-reported fatigue, somatic, and cognitive complaints lasting months or years are common among persons recovering from WNV illness (Anastasiadou et al. 2013; Carson et al. 2006; Klee et al. 2004; Patel et al. 2015). Neuropsychiatric symptoms, including depression, anxiety, agitation, and apathy, have been reported (Berg et al. 2010; Loeb et al. 2008; Murray et al. 2007; Patel et al. 2015; Sejvar et al. 2003a). One investigator found WNV RNA in urine in patients up to 7 years following acute illness and implied an association with chronic renal failure (Murray et al. 2010); however, three other studies failed to substantiate persistent WNV RNA in urine (Barzon et al. 2013a; Baty et al. 2012; Gibney et al. 2011). Among patients with acute flaccid paralysis due to poliomyelitis-like syndrome, one-third recover

regarding their strength to near baseline, one-third have some improvement, and one-third have little or no improvement (Sejvar et al. 2006).

Case fatality rates among patients with neuroinvasive disease generally are around 10% (Lindsey et al. 2010), with persons developing encephalitis or acute flaccid paralysis having a higher case fatality rate (14% and 13%, respectively) than persons with meningitis (2%) (McDonald et al. 2021). Advanced age is the most important risk factor for death, ranging from 0.8% among those aged less than 40 years to 17% aged at least 70 years (Lindsey et al. 2010). Encephalitis with severe muscle weakness, change in the level of consciousness, diabetes, cardiovascular disease, hepatitis C virus infection, and immunosuppression are possible risk factors for death (Lindsey et al. 2010; Murray et al. 2006; Nash et al. 2001; Popescu et al. 2020). Long-term, all-cause mortality is two to three times higher among survivors of acute WNV illness (Green et al. 2005; Lindsey et al. 2012a).

46.6.2 Birds

Serologic studies demonstrate that numerous bird species are exposed to WNV during outbreaks, with antibody prevalence as high as 70% noted in some species (Gibbs et al. 2006; Komar et al. 2001a, b; Ringia et al. 2004; Savage et al. 1999; Valiakos et al. 2012). In the United States, avian mortality has been noted in more than 300 species (http://www.cdc.gov/westnile/faq/deadBirds.html), with corvids particularly impacted (Foppa et al. 2011; LaDeau et al. 2007; Nemeth et al. 2007). Consistent with these findings, mortality following experimental infection of eight species of North American birds ranged from 33% to 100% (Komar et al. 2003). However, surveillance in recent years in the United States has recorded fewer WNV-related dead bird reports. Whether this reflects surveillance fatigue, decreases in susceptible populations, or decreased avian mortality following infection is not known. One analysis suggested increasing survival in American crows (*Corvus brachyrhynchos*) following WNV infection (Reed et al. 2009). Fortunately, available data indicates WNV has had low to moderate impact on most avian populations long term (Kilpatrick and Wheeler 2019).

One particular area of concern has been the impact of WNV on raptors (Gancz et al. 2006; Harris and Sleeman 2007; Saito et al. 2007). Experimental infection via the oral route of several raptor species, including great horned owls (*Bubo virginianus*) and American kestrels (*Falco sparverius*), has been recorded (Nemeth et al. 2006), suggesting that oral ingestion in addition to mosquito exposure may be important routes of infection in at least some raptor species.

While considerably less avian mortality has been noted in Europe compared to the United States, avian mortality has been occasionally reported in several species, particularly the Northern goshawk (*Accipiter gentilis*) (Bakonyi et al. 2013; Feyer et al. 2021; Glavits et al. 2005; Hubalek et al. 2019; Malkinson et al. 2002; Ziegler et al. 2019). The reason for this difference is unknown but may be related to the long-standing exposure of European birds to WNV strains imported from Africa. Nevertheless, experimental infection of several European species, including red-legged

partridges (Sotelo et al. 2011a), falcons (Ziegler et al. 2013), and Carrion crows (*Corvus corone*) (Dridi et al. 2013), with WNV strains circulating in Europe in recent years result in considerable mortality.

46.6.3 Equines

Serologic studies demonstrate that a high proportion of horses living in endemic areas may be exposed to WNV (Epp et al. 2007; Gardner et al. 2007; Metz et al. 2021; Olufemi et al. 2021; Schmidt and Elmansoury 1963). However, studies of experimentally infected horses confirm that most infections are clinically unapparent and produce a transient low-level viremia of approximately 1 week in duration (Bunning et al. 2002; Schmidt and Elmansoury 1963). These low-level viremias are inadequate to infect mosquitoes, confirming that horses are incidental hosts (Bunning et al. 2002). Reported symptoms and signs include fever, anorexia, incoordination, weakness or ataxia, muscle rigidity, fasciculations, tremors, and cranial nerve dysfunction, depression, and recumbency (Bertram et al. 2020; Cantile et al. 2000; Porter et al. 2003; Ward et al. 2004). The mean duration of illness is approximately 22 days (Salazar et al. 2004) and reported survival rates are in the range of 20–30% (Porter et al. 2003; Salazar et al. 2004; Ward et al. 2004). Animals that become recumbent and unable to rise are nearly 80 times more likely to die than those able to rise (Salazar et al. 2004). Residual symptoms are common among surviving horses.

46.6.4 Other Animals

Numerous other animals may become infected with WNV, mostly resulting in minimal or no symptoms. Species without reported clinical disease but with WNV antibodies detected during serologic surveys include bats, deer, raccoons, opossums, and small rodents. Experimental infection of several species as diverse as fox squirrels (*Sciurus niger*) (Root et al. 2006), American alligators (*Alligator mississippiensis*) (Klenk et al. 2004), dogs (Blackburn et al. 1989), cats (Austgen et al. 2004), Eastern chipmunks (*Tamias striatus*) (Platt et al. 2007), monkeys (*Macaca mulatta*) (Pogodina et al. 1983), and common garter snakes (*Thamnophis sirtalis*) (Steinman et al. 2006) exhibit transient viremia and some morbidity and mortality. Viremia in some species such as American alligators and Eastern chipmunks was high enough to infect mosquitoes, suggesting a possible role in WNV transmission in some settings. Isolated reports of morbidity and mortality due to WNV in numerous wild or captive animal species exist. These include squirrels, harbor seals, macaques, elk, sheep, crocodiles, and alpacas. Experimental evidence suggests that WNV infection can persist in some species. Virus could be isolated from the organs of rhesus monkeys at least 5 months after inoculation, and interestingly, virus isolates obtained at least 2 months after inoculation were non-pathogenic when inoculated into white mice (Pogodina

et al. 1983). WNV could be cultured from urine in hamsters up to 242 days following inoculation (Tesh et al. 2005).

46.7 Pathogenesis

Mosquito salivary components introduced at the site of infection modulate the initial immune response by target cells including keratinocytes (Lim et al. 2011) and dendritic cells through several mechanisms including focalized suppression of immune effector cell trafficking to the site of inoculation (Schneider and Higgs 2008; Styer et al. 2011). Infected dendritic cells or keratinocytes migrate to the draining lymph node from which a serum viremia is generated that relays infection to visceral organs and potentially to the central nervous system (CNS). Additional mosquitoes that feed on avian amplification hosts exhibiting high-level viremias during this viremic phase become infected. Given the low-level serum viremias observed in humans and horses, they are unlikely to infect probing mosquitoes and as such are considered "dead end" hosts despite the potential for development of severe neurological disease.

West Nile virus is capable of replicating and eliciting pathology in the brain (i.e., neurovirulent); however, a critical perquisite to generate neurological disease manifestations in humans is the virus' capacity to gain access to the CNS (i.e., neuroinvasiveness). Postulated WNV neuroinvasive mechanisms based on small rodent models include: (i) direct viral crossing of the blood–brain barrier due to cytokine-mediated increased vascular permeability (Kong et al. 2008; Wang et al. 2004), (ii) a Trojan horse mechanism in which infected tissue macrophages are trafficked across the blood–brain barrier (Bai et al. 2010; Verma et al. 2009), (iii) direct infection and passage through the endothelium of the blood–brain barrier (Dropulic and Masters 1990), and (iv) retrograde axonal transport of the virus to the CNS via the infection of olfactory or peripheral neurons (Hunsperger and Roehrig 2006; Wang et al. 2009). Regardless of how WNV enters the CNS, additional studies in murine models have indicated that viral replication can persist in various tissues, including the CNS, thus shedding additional light on the potential etiology for long-term neurological sequelae observed in neuroinvasive disease patients (Appler et al. 2010).

Many of the clinical features of CNS infection in both humans and animals are accounted for by the predilection of WNV to certain areas of the CNS, such as the basal ganglia, thalami, brain stem, cerebellum, and anterior horn cells (Cantile et al. 2000, 2001; Guarner et al. 2004; Kelley et al. 2003; Leis et al. 2003; Li et al. 2003). For example, asymmetrical paralysis is associated with destruction of anterior horn cells and Parkinsonian symptoms with involvement of the basal ganglia (Sejvar and Marfin 2006). Histopathologic changes include microglial nodules composed of lymphocytes and histiocytes, perivascular inflammation consisting predominantly of CD8 T-lymphocytes, and leptomeningeal mononuclear inflammatory infiltrates when meningitis is present (Cantile et al. 2000; Sejvar and Marfin 2006).

46.8 Diagnosis

Numerous experimental studies in animals as well as observations in humans indicate that viremia usually develops 1–2 days following infection, which then lasts approximately 1 week. Viremia is cleared about the time WNV-specific IgM antibodies can be detected, with IgG antibodies developing shortly thereafter (Busch et al. 2008). One unusual feature is that IgM antibodies persist in many humans for 1 year or longer (Busch et al. 2008; Murray et al. 2013; Roehrig et al. 2003). WNV can persist in organs and tissues of humans and animals after acute viremia has cleared. Immunocompromised patients can exhibit prolonged viremia with delayed or absent development of IgM and IgG antibodies (Pealer et al. 2003). IgG and neutralizing antibodies probably can be detected for life in immunocompetent individuals following natural infection.

46.8.1 Human Diagnosis

Detection of IgM antibodies in CSF or serum forms the cornerstone of laboratory diagnosis in most clinical settings. Because IgM antibody does not pass the blood–brain barrier, presence of IgM antibodies in CSF is indicative of CNS infection. IgM antibodies are present in at least 90% of patients with encephalitis or meningitis within 8 days of symptom onset. IgM or IgG antibodies may not be present at clinical presentation, particularly among patients with West Nile fever (Anastasiadou et al. 2011; Papa et al. 2011c). One study showed that only 58% of patients with West Nile fever had a positive MAC-ELISA result (Tilley et al. 2006). Nevertheless, IgM antibody testing of acute- and convalescent-phase sera should provide a definitive diagnosis.

Considerable cross-reactivity of serologic tests among the flaviviruses can complicate serological diagnosis. Recent vaccination with yellow fever or Japanese encephalitis vaccines or recent infection with a related flavivirus such as St. Louis encephalitis or dengue viruses can produce a false-positive IgM antibody result. The plaque reduction neutralization test can help distinguish the cross-reactions among the flaviviruses when the infecting flavivirus is the first flavivirus exposure. However, neutralization test results for WNV infected patients with previous flavivirus exposure are usually inconclusive; often the highest neutralizing antibody titer is to the first infecting flavivirus rather than to WNV ("original antigenic sin" phenomenon) (Johnson et al. 2005b). In addition, the persistence of detectable IgM antibodies (Papa et al. 2011b) – in one study in 17% of patients after 1 year (Busch et al. 2008) – means that a positive WNV IgM antibody result may be unrelated to the current illness.

Identification of WNV RNA by RT-PCR in human cerebrospinal fluid, serum, or other tissues has diagnostic utility in certain clinical settings as an adjunct to IgM antibody testing. A combined approach using nucleic acid and IgM antibody testing increased the sensitivity of testing from 58% using serology alone to 94% among patients with West Nile fever (Tilley et al. 2006). IgM antibody development may be

delayed in immunocompromised patients and in these instances RT-PCR testing may be diagnostic (Goates et al. 2017; Pacenti et al. 2020; Pealer et al. 2003). Immunohistochemistry can detect WNV in formalin-fixed tissue.

46.8.2 Diagnosis in Non-Human Vertebrates

The IgM antibody capture ELISA has been developed for use in horses and can be readily adapted to other animal species where anti-IgM antibody reagents are commercially available. Alternatively, seroconversion for IgG, neutralizing antibodies, and hemagglutinin inhibition (HAI) assays in acute- and convalescent-phase serum samples collected 2–3 weeks apart can be used as screening assays. The latter two approaches do not require species-specific reagents and thus have broad applicability. The ELISA format may be used when employed as inhibition or competition ELISAs, which avoid the use of species-specific reagents. Blocking ELISAs have been applied to a variety of vertebrate species with very high specificity and sensitivity (Blitvich et al. 2003; Sotelo et al. 2011b). Similarly, the microsphere immunoassay, when used comparatively with WNV antigen-coated beads and SLEV antigen-coated beads, performs with high specificity and sensitivity (Johnson et al. 2005a). As with human diagnostics, the PRNT is used to confirm serology in non-human vertebrates. The same caveats regarding the "original antigenic sin" phenomenon apply both to human and non-human vertebrate diagnostics. Deceased animals can be tested for viral nucleic acid or antigen (Nemeth et al. 2007).

46.9 Prevention

In the absence of an approved WNV vaccine for humans, preventing human cases of WNV disease is accomplished by preventing infected mosquitoes from biting people. Equine cases of WNV disease can be prevented through vaccination and preventing mosquitoes from biting susceptible horses. Preventing bites from infected mosquitoes is accomplished by reducing mosquito numbers using an integrated mosquito management approach and by use of personal protection measures such as application of mosquito repellents. The integrated mosquito management approach is guided by timely surveillance to monitor the level of risk to humans.

46.9.1 Surveillance

Integrated mosquito management is guided by regular monitoring of vector mosquito populations and WNV activity levels in humans and other vertebrates to determine if, when, and where interventions are needed to keep mosquito numbers below levels that produce risk of human disease. Mosquito surveillance is accomplished by either larval or adult monitoring. Larval surveillance identifies and samples aquatic habitats where vector mosquitoes can breed. Adult mosquito

surveillance identifies the abundance of adult vector mosquitoes and monitors viral infection rates in mosquitoes. Adult mosquito surveillance for WNV is mostly accomplished using CO_2-baited light traps or gravid traps. CO_2-baited light traps monitor host-seeking mosquitoes, whereas gravid traps capture females seeking a location to deposit eggs. *Culex* species are differentially attracted to each of these types of traps. Gravid traps are most likely to capture infected mosquitoes because they have already taken a blood meal. A consistent approach is required from year to year to establish levels of mosquito activity that equate to increased human risk.

Different approaches to assessing human risk from vector mosquitoes have differing sensitivities and specificities, which should be balanced by available resources, including funding, labor, and equipment (Caillouet and Robertson 2016). The vector index is considered the most useful of the available WNV surveillance indicators and is roughly defined as the number of infected vector mosquitoes multiplied by the infection rate in those mosquitoes, and might be the best measure of impending human risk in urban settings (Chung et al. 2013). The vector index requires personnel, facilities, and equipment that allow for species identification, pathogen testing, and statistical analyses (Caillouet and Robertson 2016).

WNV activity in non-human vertebrates can be measured by WNV-related avian mortality, seroconversion to WNV in sentinel chickens or other sentinel animals, seroprevalence in wild birds, and cases of WNV illness in animals, primarily horses. Unfortunately, all of these approaches have significant limitations: there is little avian mortality in Europe and Africa, avian mortality appears to be decreasing in North America, sentinel chickens are expensive to maintain, seroprevalence in wild birds is difficult to monitor consistently and might not correlate highly with future risk of transmission, and mortality in horses has been dramatically reduced because of equine vaccination (Gardner et al. 2007). It is also difficult to correlate activity in non-human vertebrates with human risk.

Monitoring human neuroinvasive disease cases provides the best measure of the overall scope of a WNV outbreak given neuroinvasive disease cases are most consistently recognized and reported because of disease severity (Weber et al. 2011; Zou et al. 2010). It is estimated approximately 30–70 nonneuroinvasive disease cases occur for every case of WNV neuroinvasive disease (Petersen et al. 2013b). The total number of human infections can be estimated by multiplying the number of neuroinvasive disease cases by the ratio of infections to neuroinvasive disease cases. Only a small fraction of West Nile fever cases is captured by surveillance, with estimates varying between 1 neuroinvasive disease case in 140 WNV infections to 1 in 256–353 infections (Busch et al. 2006; Mostashari et al. 2001). However, West Nile fever cases can be the first indication of the occurrence of human infections in an area. Infections in blood donors can be monitored in areas where blood donor screening is conducted. The main limitation of human surveillance is that several weeks can occur between the date of infection and when illness is reported to health authorities (Chung et al. 2013).

46.9.2 Mosquito Control

Community-based mosquito control programs using integrated mosquito management principles include several methods to reduce mosquito populations below levels that increase human risk (Reisen and Brault 2007). These include eliminating mosquito breeding sites (source reduction) and applying larvicides to aquatic habitats where mosquitoes might breed. When adult mosquito density becomes high, adulticides can be applied through ultra-low volume (ULV) spraying applied by ground-based or aerial mounted sprayers. A modeling analysis using mosquito surveillance data collected in Sacramento and Yolo counties in California during 2006–2017 demonstrated reductions in *Cx. pipiens* and *Cx. tarsalis* at 1-week post-insecticide treatments (Holcomb et al. 2021). Although the effectiveness of this approach cannot be readily assessed because of the highly focal and sporadic nature of WNV illness, a few well-controlled studies do exist. In response to surveillance findings indicating increasing human risk, early-season control of adult mosquitoes using ULV applications of insecticides in a populated agricultural area in California decreased subsequent WNV transmission (Lothrop et al. 2008). In addition, ULV pesticide application decreased WNV infected mosquito abundance and reduced human WNV case incidence during a WNV outbreak in another populated area of California (Carney et al. 2008; Macedo et al. 2010).

Human health risks associated with ULV organophosphate or synthetic pyrethroid pesticide use appear to be negligible, largely because the timing of application and low volume of pesticide used result in minimal human exposure (Centers for Disease Control and Prevention 2005; Chung et al. 2013; Duprey et al. 2008). Further, an assessment of the correlation between ULV application of pyrethrin insecticide and emergency department visits in Sacramento, California, demonstrated that ULV pyrethrin applications were not correlated with types of diagnoses known to be associated with pyrethrin exposures (Geraghty et al. 2013).

46.9.3 Personal Protection

Personal protection measures include application of mosquito repellents and wearing permethrin-treated clothing. However, the effectiveness of these measures is difficult to assess. A Canadian study comparing people who practiced at least two personal protective strategies (wearing repellent, wearing protective clothing, or avoiding outdoor exposure to mosquitoes) with those who did not demonstrated that personal protective strategies halved the risk of WNV infection (Loeb et al. 2005). A study comparing two adjacent communities in the United States found that incidence of WNV disease was better correlated ecologically with the practice of personal protection strategies than with the level of local mosquito control efforts (Gujral et al. 2007).

Commercially available insect repellents containing DEET, IR3535, oil of lemon eucalyptus, and picaradin are effective in reducing or preventing mosquito biting (Fradin and Day 2002). Unfortunately, regular repellent use is not widespread even during well-publicized WNV outbreaks (Gibney et al. 2012; McCarthy et al. 2001).

However, a study in Maryland demonstrated that adults aged ≥60 years who expressed worry about WNV disease were over three times more likely to report insect repellent use in the previous 90 days, indicating a potential benefit for using targeted prevention messages for adults at increased risk of severe WNV disease (Mitchell et al. 2018).

46.9.4 Vaccines

The introduction of a vaccine against WNV for use in horses has substantially reduced the incidence of equine WNV disease in the United States (Bosco-Lauth and Bowen 2019; Gardner et al. 2007; Petersen and Roehrig 2007). Two licensed live, attenuated equine vaccines and two licensed inactivated vaccines are available in the United States or the European Union (De Filette et al. 2012; Long et al. 2007a, b; Seino et al. 2007; Siger et al. 2006); a DNA vaccine has also been licensed in the United States, but is not commercially available (Davis et al. 2001) (Table 1). Vaccination of horses with a WNV Lineage 1 vaccine appears to confer protection against WNV Lineage 2 infection (Bowen et al. 2014). Although the routine use of vaccines have reduced the incidence of WNV disease in horses, the available

Table 1 West Nile virus vaccines for horses approved in the United States and the European Union

Vaccine	Viral antigen	Status	Comment
West Nile Innovator® in U.S. and Equip® WNV in E.U. (Zoetis)	Formalin inactivated whole virus	Approved in US/EU	Two doses, booster annually
Vetera® WNV vaccine (Boehringer Ingelheim)	Inactivated virus	Approved in US.	Two doses, booster annually
Recombitek® West Nile Virus and Proteq® West Nile in E.U. (Merial)	prM and E proteins expressed in canarypox virus	Approved in US/EU	Two doses, booster annually
Equi-Nile® (Merck)	Inactivated chimeric virus, WNV prM/E proteins in yellow fever 17D backbone	Approved in US	Two doses, booster annually
PreveNile® (Intervet)	Live chimeric virus, WNV prM/E proteins in yellow fever 17D backbone	Approved in US; recalled in 2010 because of adverse events	
West Nile-Innovator DNA® (Fort Dodge Animal Health)	Plasmid DNA coding for prM and E proteins	Approved in US; currently not commercially available	

vaccines do have limitations, including the need for 2-dose initial series and annual or bi-annual boosters (Bosco-Lauth and Bowen 2019; Saiz 2020).

Several human WNV vaccine constructs employing various strategies have been developed; six have reached human clinical trials, but none have advanced past phase 2 (De Filette et al. 2012; Ulbert 2019). Chimeric vaccines inserting WNV PrM and E protein genes into attenuated yellow fever and dengue 4 virus backbones have undergone successful phase 2 and 1 clinical trials, respectively (Biedenbender et al. 2011; Dayan et al. 2012; Durbin et al. 2013). A successful phase 1 WNV DNA vaccine trial has been completed (Martin et al. 2007). An inactivated whole virus WNV vaccine candidate underwent a phase-1/2 clinical trial and demonstrated an immune response without related serious adverse events (Barrett et al. 2017). Phase-3 efficacy trials have not been attempted because of the unknown market potential of a WNV vaccine and logistical difficulties in conducting phase-3 clinical trials for this sporadic and widely dispersed disease (Barrett et al. 2017; Beasley 2011; Martina et al. 2010).

Initial simulations concluded that a universal WNV vaccine would not result in societal cost savings unless WNV incidence increased substantially or the estimated cost of the vaccination was less than $12 USD per person vaccinated (Zohrabian et al. 2006). A subsequent analysis demonstrated a WNV vaccine strategy targeting older adults would be more cost-effective than a universal program (Shankar et al. 2017). A more recent analysis highlighted that an age-based and incidence-based WNV strategy was more cost-effective than an age-based strategy alone (Curren et al. 2021).

46.10 Treatment

Treatment is supportive. Multiple drug discovery studies have evaluated anti-flaviviral drug candidates, but these studies have not advanced past the preclinical stage with most only tested in vitro (Sinigaglia et al. 2020). Several investigated therapeutic approaches in humans include immune γ-globulin, WNV-specific neutralizing monoclonal antibodies, corticosteroids, ribavirin, interferon α-2b, and antisense oligomers (Beasley 2011; Chowers et al. 2001; Diamond 2009; Gnann Jr et al. 2019). No study has documented efficacy, largely because of difficulty in recruiting enough patients. Case reports suggesting efficacy should be interpreted with extreme caution because of WNV's highly variable clinical course. No clinical studies have been conducted in horses.

46.11 Future Directions

The pattern of sporadic cases and outbreaks of WNV that has emerged in Europe and North America shows no signs of abating. While broad areas of high risk can be identified, the sporadic, local and regional outbreaks that occur within these areas remain elusively unpredictable. In populated areas within high-risk zones,

establishing effective surveillance and response capacity, and assessing the effectiveness of these activities are priorities. Further evaluation of target populations and cost-efficacy of a human WNV vaccine will help determine the need for continued human vaccine development. Practical regulatory pathways and paradigms for testing and approval of WNV vaccines and therapeutics adapted to the sporadic outbreak nature of WNV are required.

46.12 Conclusion

Within the last three decades, the West Nile virus has become a formidable public health problem in North America and Europe. Many mysteries remain. For example, although the virus has been detected in East Asia and Latin America and the Caribbean, significant clinically apparent human infection remains uncommon in those locations. Prediction and control of outbreaks remain problematic; thus, outbreaks will continue largely unabated for the foreseeable future.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_39

Abstract

Crimean-Congo hemorrhagic fever virus (CCHFV) is a tick-borne zoonosis distributed in Africa, Asia, Eastern Europe, and the Balkans. Humans become infected by tick-bite or from contact with infected blood or other tissues of livestock or human patients. Human infection is usually characterized by febrile illness, which can progress to a hemorrhagic state with a fatal outcome. The virus has the propensity to cause nosocomial infections, however implementation of molecular assays has facilitated rapid and safe diagnosis, especially in regions where high containment access is limited. Early diagnosis contributes toward protection of healthcare workers. The absence of any specific anti-viral treatment or approved efficacious vaccines contributes toward the public health concern regarding emergence, re-emergence, and spread of CCHFV. While the immune correlates of protection remain unclear, available data indicate that both humoral and cellular responses are required. Vaccine development has, however, in recent years been facilitated by the availability of novel animal models.

The distribution of CCHFV correlates with that of the primary vector of the virus, ticks belonging to the genus *Hyalomma*. The importance of the tick-vertebrate-tick cycle in maintaining CCHFV transmission is well established and sero-surveillance studies have contributed toward understanding the role of wild and domestic animals and birds as reservoirs and amplifying agents. The distribution of these ticks has, in recent years, expanded to regions where conditions are favorable for the species to establish endemnicity. Hence, there is growing concern that this virus has the potential to emerge and spread to new geographic regions.

Keywords

CCHFV · Arbovirus · Emerging and re-emerging pathogen · Orthonairovirus · Tick-borne virus · Emerging pathogen · Public health concern · Global concern · Biosafety level 4 pathogen

47.1 Introduction

Crimean-Congo hemorrhagic fever (CCHF) is a tick-borne viral zoonosis distributed in Africa, Asia, Eastern Europe, and the Balkans. The broad geographic range correlates with that of the principal vector of the virus, ticks belonging to the genus *Hyalomma* (Hoogstraal 1979). The virus is a member of the *Orthonairovirus* genus of the family *Nairoviridae* (Adams et al. 2017; Hoogstraal 1979). A disease with symptoms suggestive of CCHFV infection was described as early as the twelfth century in regions of Eastern Europe and Asia. In 1944, a disease was described among peasants that became ill following exposure to tick-bites while harvesting crops on the Crimean Peninsula and was given the name Crimean hemorrhagic fever (CHF). The disease was subsequently shown to be caused by a filterable agent

present in suspensions prepared from certain tick species and in human blood samples collected from patients during the early stages of disease. It was only in 1967 that the etiologic agent was isolated in a laboratory using newborn mice. The availability of a laboratory host made it possible to characterize the virus, and it was shown in 1969 that isolates of CHF were antigenically identical to an African virus, named Congo virus, isolated from a febrile child in Stanleyville in the Belgian Congo (now referred to as Kisangani in the Democratic Republic of the Congo). Studies on physicochemical characteristics, morphology, and morphogenesis showed that the viruses were indistinguishable (Casals 1969; Chumakov et al. 1970; Hoogstraal 1979; Korolev et al. 1976; Simpson et al. 1967). The names were subsequently combined and the virus referred to as Crimean-Congo hemorrhagic fever virus (CCHFV).

Humans become infected by tick-bite or from contact with infected blood or other tissues of livestock or human patients. Human infection is usually characterized by febrile illness with headache, myalgia, and petechial rash, which can progress to a hemorrhagic state with a fatal outcome. In livestock, including ostriches, and in potential reservoir hosts, usually small mammals such as hares and ground frequenting birds, infection is either asymptomatic or causes mild fever which is frequently associated with a short period of viraemia playing a role in transmission as well as amplification of the virus in nature.

The distribution of CCHFV correlates with that of the primary vector of the virus, ticks belonging to the genus *Hyalomma*. The distribution of these ticks has, in recent years, expanded to regions where conditions are favorable for the species to establish endemnicity. Hence, there is growing concern that this virus has the potential to emerge and spread to new geographic regions. The absence of any specific anti-viral treatment or approved efficacious vaccines contributes toward the public health concern regarding emergence, re-emergence, and spread of CCHFV.

47.2 Crimean-Congo Hemorrhagic Fever Virus, an Emerging and Re-Emerging Pathogen

47.2.1 The Virus

CCHFV is classified as a member of the genus *Orthonairovirus*, within the family *Nairoviridae* (Adams et al. 2017; Calisher 1991; Casals 1969; Garrison et al. 2020; Karabatsos 1985). Nairoviruses are classified into three genera: *Orthonairovirus*, *Shaspivirus*, and *Striwavirus* (Garrison et al. 2020). The *Orthonairovirus* genus currently includes 54 viruses, and 14 species. Within the genus, CCHFV is known to be a significant human pathogen associated with fatalities. The only other members of the genus associated with disease in humans are Dugbe virus, Nairobi sheep disease virus, and, possibly, Erve virus, which have all been reported as causing mild, non-lethal disease in humans (Garrison et al. 2020). Although the classification of the Orthonairoviruses was originally based on antigenic

relationships, the groupings have subsequently been substantiated using molecular analyses to determine genetic relationships between the viruses (Calisher and Karabatsos 1989; Casals and Tignor 1980; Garrison et al. 2020).

Members of the genus *Orthonairovirus* are spherical structures, 90–120 nm in diameter (Donets et al. 1977). As for all the orthonairoviruses, the genome of CCHFV is comprised of three single-stranded RNA segments in a negative-sense orientation. The segments, designated small (S), medium (M), and large (L), encode for the viral nucleoprotein (NP), glycoprotein precursor (GPC), and RNA dependent RNA polymerase (RdRp) proteins, respectively (Schmaljohn and Patterson 1990). Each of the three RNA segments is encapsulated in the viral encoded nucleoprotein to form ribonucleoprotein particles (RNP) within the virion (Clerx et al. 1981). Each segment comprises a non-translated region (NTR) at the 3′ and 5′ termini flanking a single transcriptional unit. The NTRs have genus specific sequences at the termini, with cis-acting signals for RNA synthesis and segment packaging, and internal regions that are neither genus specific nor conserved between segments within a species, which are likely associated with genome replication (Barr et al. 2003). The 3′ and 5′ NTRs have significant nucleotide complementarity, and base pairing of these regions leads to formation of panhandles resulting in circular conformation of each segment. The base-pairing structure likely provides a functional promotor region for the viral polymerase, RdRp (Flick et al. 2002).

The L segment of CCHFV is approximately 12,000 bases in length and has a single ORF encoding for a large, approximately 450 kDa, protein (Honig et al. 2004; Kinsella et al. 2004). The L protein of CCHFV, and other orthonairoviruses, is significantly larger than the RdRps of other orthonairoviruses and comparison of sequence data led to the identification of an ovarian tumor (OTU) like protease motif in the amino terminal region of the L protein (L-OTU) of CCHFV followed by a zinc finger motif and helicase domain (Honig et al. 2004). The OTU domains are a superfamily of proteases. Viral OTU domains specifically have ubiquitin (UB) deconjugating activity. Conjugation of UB and ubiquitin like (UBL) molecules to specifically targeted proteins plays a role in the regulation of innate immune responses (Frias-Staheli et al. 2007). Deconjugation of these molecules has an inhibitory effect on antiviral pathways dependent on UB and UBL activation. The size of the polyprotein and the identification of amino terminal domains led to the proposal that the L protein is potentially a polyprotein that is cleaved auto-proteolytically. Although in the absence of L-OTU activity the RdRp has been shown to function, and viral replication is unaffected; to date there is no evidence of proteolytic processing of the L protein and the function of the L-OTU has yet to be fully clarified (Bergeron et al. 2010). The protease could likely have a role in evasion of the host immune response by suppression of the innate immunity activated by UB and UBL molecules (Bergeron et al. 2010; Frias-Staheli et al. 2007).

The synthesis of orthonairovirus glycoproteins, encoded on M segment RNA, appears to involve a precursor polypeptide, a coding strategy which is quite distinct from that used by other genera of orthonairoviruses. The M segment of CCHFV is approximately 5400 bases and has one ORF, which encodes a precursor polypeptide with a highly variable amino-terminal domain and a fairly conserved carboxyl-terminal region. The two mature glycoproteins, Gn (37 kDa) and Gc (75 kDa), are

derived by signalase cleavage of two precursors, designated preGn (140 kDa) and preGc (85 kDa) (Sanchez et al. 2002). Post-translational cleavage of the precursors by SKI-1 and SKI-1 like proteases generates mature Gn and Gc and a mucin-like and GP38 domain (Sanchez et al. 2006). Formation of infectious virus has been shown to be dependent on the presence of cellular serine endoprotease (Bergeron et al. 2007). Further processing of the mucin like GP38 domain by furin/proprotein convertases generates three secreted glycoproteins GP160, GP85, and GP38 of unknown function. More recently, a non-structural (NSm) protein has been identified although its function is currently unknown (Altamura et al. 2007).

By analogy with other genera of the *Nairoviridae*, it can be assumed that glycoproteins are responsible for recognition of receptor sites on susceptible cells and consequently cell tropism and pathogenicity of the virus in humans, for the induction of protective immune response, and probably play a role in tick host selection. Monoclonal antibodies directed against Gc have been shown to prevent CCHFV infection using in vitro neutralization assays, although not all protected mice against lethal infection in passive immunization experiments (Bertolotti-Ciarlet et al. 2005). In contrast, non-neutralizing monoclonal antibodies directed against Gn protected mice against lethal challenge suggesting a role for antibody dependent cell-mediated cytotoxicity in viral clearance (Bertolotti-Ciarlet et al. 2005). The exact immune correlates of protection have yet to be determined.

The CCHFV S segment is approximately 1600 bases in length with a single open reading frame which encodes a 482 amino acid NP (approximately 54 kDa), the major structural protein of the virus (Marriott and Nuttall 1992). Viral RNA is encapsidated by NP to form the ribonucleoprotein (RNP) complex. The exact mechanism of this interaction is unknown; complex formation, however, is essential for RNA synthesis and segment packaging.

CCHFV is classified as a class four pathogen because it has the propensity for human-to-human transmission, can be responsible for laboratory infections, and causes severe human disease with possible fatal outcome. This dictates that culture of the virus is permitted only in biosafety level four, maximum-security, laboratories.

47.2.2 CCHFV in Nature

The importance of the tick-vertebrate-tick cycle in maintaining CCHFV transmission is well established. Although the virus has been isolated from at least 31 species of ticks of 7 genera, including 29 ixodids and 2 argasids, in most instances the isolations likely resulted from recent ingestion of a blood meal from a viraemic host and are therefore no definite proof that these ticks can act as competent vectors in all these cases (Hoogstraal 1979; Watts et al. 1989). However, the distribution of human cases, serological evidence, and virus isolations from ticks correlate exactly with that of the ticks belonging to the genus *Hyalomma*, providing strong evidence that these ticks are the principal vectors associated with CCHFV (Hoogstraal 1979; Watts et al. 1989). Transtadial transmission has been shown for members of three genera of ixodid ticks, *Hyalomma*, *Dermacentor*, and *Rhipicephalus* (Hoogstraal 1979; Watts

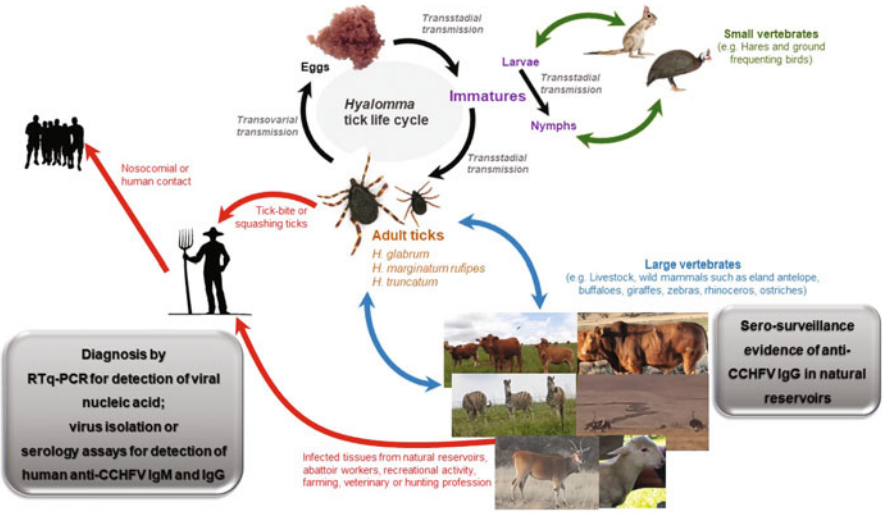

Fig. 1 The natural cycle of Crimean-Congo hemorrhagic fever orthonairovirus in a two host tick

et al. 1989). Similarly, transovarial transmission has been shown to occur within some species from these genera (Gonzalez et al. 1992; Gordon et al. 1993; Logan et al. 1989; Wilson et al. 1991).

Hyalomma ticks are referred to as two-host-ticks with regards to their life cycle in nature. Each stage in the tick life cycle attaches to a vertebrate host and takes a blood meal before molting to the next instar. The immature ticks, larvae, and nymphs, attach to small vertebrate hosts and feed before molting to the next instar. Infection acquired by the larvae feeding on a viremic host can be transmitted after the molt to the next instar. Similarly, virus acquired by the immature stages can be transmitted to adult ticks. Transovarial transmission of CCHFV to larvae, and the ability of larvae to transmit infection to vertebrates, was found to occur but at low levels considered below a threshold that would be adequate to perpetuate the virus in the absence of amplification in mammalian hosts (Hoogstraal 1979; Watts et al. 1989). An illustration of the natural cycle of CCHFV in ticks is shown in Fig. 1.

47.2.3 Zoonotic Hosts and Their Role in Transmission

Small mammals are considered important amplifying hosts of CCHFV. Viremia has been demonstrated in several small vertebrates such as little susliks, hedgehogs, and scrub hares (Shepherd et al. 1989a; Watts et al. 1989) and in some instances it has been shown that these hosts are capable of infecting ticks (Hoogstraal 1979; Shepherd et al. 1989a, 1991; Watts et al. 1989). Domestic livestock show mild or no clinical signs of illness but develop a short period of viremia, lasting up to a week, during which the virus can be transmitted to humans and to naïve ticks. Humans acquire infection through broken skin from infected blood or tissues while

performing procedures on animals such as castration or during slaughtering. Hence, there is an occupational risk associated with employment in the livestock industry among farmers, farm workers, abattoir workers and veterinarians. Within abattoirs, infection tends to occur among workers involved in handling animals during the initial bleeding stages of the slaughter process or the workers handling animal hides that are likely tick infested. Virus infectivity is likely reduced as the pH of the tissues decreases after time reducing the risk to workers at later stages in the slaughter process and to meat consumers (Swanepoel et al. 1998).

Immature *Hyalomma* ticks feed on small mammals and ground-frequenting birds, and this plays a significant role in maintenance of the virus in nature (Hoogstraal 1979; Watts et al. 1989). The role of large vertebrates in the cycle of CCHFV in nature is limited by the low frequency of transovarial transmission from adult ticks. Acquisition of infection by immature ticks on small vertebrates likely constitutes the most important amplifying mechanism, which ensures perpetuation of the virus (Watts et al. 1989).

Birds tend to be refractory to CCHF infection, with the exception of ostriches, which, in the absence of clinical disease, develop a high-level viremia demonstrable for 4 days and a strong antibody response following experimental infection (Hoogstraal 1979; Shepherd et al. 1987; Swanepoel et al. 1998). However, an additional mechanism of transmission referred to as "non-viraemic" transmission has been demonstrated in birds in which infected ticks are able to transfer infection to uninfected ticks during feeding on a non-viremic host. Non-viremic transmission of infection between ticks is believed to be facilitated by factors present in tick saliva (Jones et al. 1987) and has been demonstrated for CCHFV using infected adult and non-infected immature *H. truncatum*, and *H. impeltatum* ticks fed together on non-viremic mammals.

Serological surveillance of domestic livestock, birds, and wild animals have detected anti-CCHFV antibody in a wide range of species (Spengler et al. 2016). With the exception of humans, CCHFV is not known to be pathogenic in other species and infections are asymptomatic. The role of many of these species as reservoirs and/or amplifying hosts is not always clear, as some may be incidental hosts. Infected domestic livestock are, however, an important source of transmission and antibody detection in these animals has provided one of the most important markers for determining the presence and prevalence of CCHFV within regions.

47.2.4 Epidemiology and Genetic Diversity

CCHFV has the most extensive worldwide distribution of any of the arboviruses. Prior to 2002, cases of naturally acquired human infection had been documented in the former Soviet Union, China, Bulgaria, Yugoslavia, Albania, Kosovo (formerly Yugoslavia), Afghanistan, Pakistan, Iran, Iraq, United Arab Emirates, Saudi Arabia, Oman, Tanzania, Central African Republic, Democratic Republic of the Congo (formerly Zaire), Uganda, Kenya, Mauritania, Burkina Faso, South Africa, and Namibia (Al Tikriti et al. 1981; Burney et al. 1980; Drosten et al. 2002a, b; Dunster et al. 2002; El Azazy and Scrimgeour 1997; Gear et al. 1982; Hassanein et al. 1997; Hoogstraal 1979; Khan et al. 1997; Papa et al. 2002b; Saluzzo et al. 1984, 1985;

Schwarz et al. 1995; Suleiman et al. 1980; Tantawi et al. 1980; Watts et al. 1989; Yen et al. 1985). More recently, reports of human infections have been documented in India, Sudan, Senegal, Greece, Nigeria, and Georgia (Aradaib et al. 2010; Bukbuk et al. 2016; Mishra et al. 2011; Nabeth et al. 2004; Papa et al. 2010; Zakhashvilli et al. 2010).

Evidence for the presence of CCHFV either from isolation of the virus or detection of viral nucleic acid from ticks or non-human mammals has been documented in Egypt, Madagascar, Senegal, Nigeria, Central African Republic, Ethiopia, and, more recently, Morocco (Bendary et al. 2022; Palomar et al. 2013; Watts et al. 1989). Serological evidence alone either in humans or livestock has been reported from Cameroon, Mozambique, Egypt, Zimbabwe, Benin, Kuwait, Portugal, and France (Muianga et al. 2017; Watts et al. 1989).

In most countries, cases occur sporadically; however, cases in Turkey occur far more frequently for reasons that are not known. The virus was first identified in Turkey in 2002 and the country now has the highest number of laboratory confirmed cases globally with over 10,000 cases reported and a fatality rate of approximately 5% (Leblebicioglu et al. 2016; Maltezou et al. 2010).

Whereas recent identification of the virus in African countries is more likely due to increased awareness rather than emergence and spread, in Europe the virus appears to have spread to new endemic regions. Serological evidence of CCHFV was recently detected in Romania (Ceianu et al. 2012) and in 2010 virus was detected in adult *Hyalomma lusitanicum* ticks collected from red deer (*Cervus elaphus*) in Spain (Estrada-Peña et al. 2012). Phylogenetic analysis showed the virus was genetically similar to strains circulating in Africa. CCHFV detected in ticks collected from migratory birds in Morocco showed 100% identity with isolates from Sudan and Mauritania and 98.9% identity with the isolate from Spain (Palomar et al. 2013). The first autochthonous case of CCHF in south western Europe was reported from Spain in 2016 with additional cases reported in 2018 and 2020 (European Centre for Disease Prevention and Control 2022; Negredo et al. 2017; Portillo et al. 2021). Phylogenetic analysis placed the human isolate in genotype III (Africa III) confirming the genetic similarity with previous isolates from ticks collected in Spain and Morocco (de Arellano et al. 2017).

The emergence of CCHFV from 2002 in several countries in the Balkans and re-emergence in southwestern regions of the Russian Federation in 1999 after a 27 year absence had previously raised concerns that this virus could expand its current geographic distribution and establish new endemic foci (Maltezou et al. 2010). Serological evidence of the virus circulating in livestock in Bosnia and Herzogovina and human cases identified in Spain have confirmed the distribution of this virus extends from southwestern Europe to the western most region of the Balkans (Satrovic et al. 2022).

The reasons for reemergence are likely multi-factorial and include global warming with changes in weather patterns that influence tick populations, increased animal movement as a result of livestock trade, as well as human activities such as changes in farming practices and land development (Maltezou et al. 2010; Maltezou and Papa 2010; Randolph and Rigers 2007).

Molecular methods have facilitated the identification and differentiation of genotypes of CCHFV. Partial and complete genome sequence data have been used to determine the genetic relationship between strains of CCHFV within specific geographic locations and between geographically distinct regions (Burt and Swanepoel 2005; Chinikar et al. 2004; Deyde et al. 2006; Drosten et al. 2002a, b; Hewson et al. 2004a, 2004b; Papa et al. 2002a, b, c, 2004, 2005; Seregin et al. 2004; Tonbak et al. 2006; Yashina et al. 2003). The studies concur that a high degree of nucleotide diversity exists although amino acid diversity is less, particularly within the NP, which could account for the serological cross-reactivity between geographically distinct isolates of the virus. Analysis of global diversity has shown that CCHFV isolates group within at least six genotypes, designated genotypes I, II, and III endemic within the African continent, genotype IV (Asia), V (eastern Europe or Europe 1), VI (Europe 2 or AP-92 like). More recently, genotype VI viruses, which include the AP-92 like isolates from Greece, have been reclassified into a novel orthonairovirus species *Congoid orthonairovirus*, distinct from *CCHF orthonairovirus* species. The AP-92 like viruses, now referred to as Aigai virus (AIGV), originally considered apathogenic for humans, have been associated with acute febrile disease (Papa et al. 2022).

Previous analysis of tree topologies for each segment has shown incongruencies in groupings, particularly for the M segment, providing evidence for the natural occurrence of segment reassortment (Burt et al. 2009; Deyde et al. 2006; Hewson et al. 2004b). There appears to be a higher frequency of reassortment events for the M segment. Alternatively, M segment switching may result in a more viable virus compared with other segment reassortment. RNA viruses have the ability to reassort when dual infection occurs. It has been proposed that these events are more likely to occur within vectors rather than vertebrate hosts as ticks remain infected for longer periods and are exposed to multiple hosts potentially infected by different strains of CCHFV (Deyde et al. 2006; Hewson et al. 2004b; Morikawa et al. 2007). Reassortment events provide a mechanism for genetic diversity and, although relatively rare, genetic recombinantion events have also been shown to occur for CCHFV contributing to genetic variability (Deyde et al. 2006).

The same genotypes can be found in geographically distinct locations and different genotypes can be located in similar regions. CCHFV appears to circulate within and between continents with phylogeny studies supporting the proposed mechanisms for dispersal of the virus. Genetic diversity within regions has likely resulted from movement and trade in livestock and bird migration with resultant introduction of multiple lineages from carriage of infected ticks. In addition, reassortment and recombination provide additional mechanisms for the generation of genetic diversity.

47.3 Disease in Humans

The incubation period of CCHFV in humans following infection from a tick bite is usually 1 to 3 days (maximum 9) and 3 to 6 days (maximum 13) from exposure to infected blood or tissues of animals or humans including secondary infections in a

nosocomial setting. The onset of illness is often sudden, with non-specific symptoms including headache, dizziness, sore throat, sore eyes, and photophobia. Myalgia and malaise are also common with backache and leg pains. High fever and rigors often become apparent at this stage and the fever may be intermittent. Gastrointestinal symptoms may include nausea, vomiting, diarrhea, and abdominal pain. During the early stages of illness, lassitude, depression, and somnolence may be noted as well as neuropsychiatric changes such as confusion and aggression. Other signs include hyperemia of the face, neck, and chest; injected conjunctivae; and chemosis. Hepatomegaly with right hypochondrial pain, tachycardia, and hypovolemia are often present. On days 3 to 6 of illness, a petechial rash often appears especially on the trunk and limbs. This may progress to large ecchymoses and bruising (Hoogstraal 1979; Kilinc et al. 2016; Swanepoel et al. 1987). Other skin presentations include a macular or maculopapular rash, and facial rash (Akyol et al. 2010; Duygu et al. 2018; Ergönül et al. 2004). When present, hemorrhagic manifestions appear at day 4 to 5 including hematemesis, melena, hematuria, epistaxis, vaginal and gingival bleeding. Subconjunctival and retinal hemorrhages have also been described (Engin et al. 2009). In other cases, the bleeding tendency may be limited to leakage or oozing from injection or venipuncture sites. Jaundice may be present during the second week of illness (Hoogstraal 1979; Swanepoel et al. 1987). Isolated cases of epididymo-orchitis, parotitis, peritoneal and pleural effusions, acalculous cholecystitis, intraabdominal abscesses, compartment syndrome, and ascending paralysis have been described during the acute stage of disease (Aijazi et al. 2020; Aksoy et al. 2010; Guner et al. 2011; Kaya et al. 2012; Kerget et al. 2021; Prasad et al. 2020; Sahin et al. 2016; Şensoy et al. 2011; Ture et al. 2016). Although uncommon, hemophagocytic lymphohistiocytosis has also been described in both adult and pediatric patients (Gayretli Aydin et al. 2021; Yakut et al. 2021).

Fatalities are usually due to multiorgan failure or hemorrhagic complications such as intracranial hemorrhage, occurring mostly on days 5 to 14 of illness. The mortality rate is reported to be 5–50% with higher mortality rates following nosocomial infections than for infection via tick bites (Gozalan et al. 2007; Hoogstraal 1979). Distinct geographical variations in mortality rates are noted, with rates in Turkey described at 1–5% compared to approximately 30% in South Africa (Ergönül et al. 2006a; National Institute for Communicable Diseases 2020; Swanepoel et al. 1987). Differences observed in mortality rates may be influenced by the significantly higher numbers of cases occurring in eastern Europe compared to South Africa, as well as likely circulation of strains of low virulence identified in Greece and Turkey (Elevli et al. 2010; Midilli et al. 2009; Ozkaya et al. 2010). Recovery usually begins by day 9 or 10 of illness, although conjunctivitis, weakness, confusion, and amnesia may persist beyond a month. Other residual symptoms and signs may include polyneuritis, headache, dizziness, nausea, anorexia, alopecia, vision and hearing loss, and poor memory (Hoogstraal 1979; Swanepoel et al. 1987). Post-traumatic stress disorder and impaired health-related quality of life have been described in the long-term follow up of CCHF patients, with intensive care admission, bleeding, and administration of blood products identified as risk factors (Gul et al. 2012). Similar findings have been described in survivors of other acute, life-threatening

conditions and it seems likely that this is related to the severity of the illness rather than the infectious organism.

The clinical picture of CCHFV infection in children is similar to that in adults, although tonsillopharyngitis and gastrointestinal complaints are more common in this age group. While initial reports which included relatively small number of cases identified in children suggested a tendency toward milder disease, reported mortality rates have varied widely (Aslani et al. 2017; Dilber et al. 2009; Tezer et al. 2010; Tuygun et al. 2012). Intrauterine or perinatal infection of infants has been described following maternal infection with CCHFV during pregnancy and resulting in abortion or hemorrhagic manifestation at birth, with high rates of maternal and fetal/neonatal deaths reported (Ergönül et al. 2010; Pshenichnaya et al. 2017). Transmission by breastfeeding has not been detected in exposed infants (Erbay et al. 2008).

Abnormal clinical pathology values in patients with CCHF include elevated aspartate aminotransaminase (AST), alanine aminotransaminase (ALT), alkaline phosphatise (ALP), γ-glutamyltransferase (GGT), lactic dehydrogenase (LDH), creatine kinase (CK), bilirubin, and creatinine levels, respectively. These elevations are marked in patients with fatal infections. Leukocyte levels may be elevated or decreased, with leukocytosis more common in fatal cases. Thrombocytopenia is found in all patients with CCHF; low thrombocyte counts at an early stage of illness are associated with an increased mortality. In addition, markedly abnormal prothrombin ratio (PR), activated partial thromboplastin time (APPT), thrombin time (TT), fibrinogen, and fibrin degradation products (FDP) are found early in patients with a fatal outcome, with milder abnormalities in nonfatal cases. The hemoglobin levels often decline even in the absence of overt bleeding (Ergönül et al. 2006a; Swanepoel et al. 1989).

47.4 Pathogenesis

Many similarities exist between the pathogenesis of CCHF and other viral hemorrhagic fevers. Following inoculation, the virus replicates in local cells before spreading to regional lymph nodes. Local cells which may act as early targets for viral infection include macrophages, dendritic cells, and Langerhans cells, which have been shown to be susceptible and permissive to CCHFV infection (Connolly-Andersen et al. 2009; Peyrefitte et al. 2010; Rodriguez et al. 2018; Welch et al. 2019). The virus then disseminates hematogenously to various tissues and organs both in lymph and blood monocytes. Early in infection, impairment of the innate immune response by CCHFV may delay activation of the adaptive immune response, which prevents viral clearance and therefore facilitates viral replication, particularly in the liver and spleen, and dissemination (Bente et al. 2010; Peyrefitte et al. 2010; Saksida et al. 2010). High levels of viral replication in organs such as the liver and adrenal glands contribute to the clinical picture by decreasing synthesis of coagulation and plasma proteins and dysregulation of blood pressure homeostasis (Geisbert and Jahrling 2004). This is supported by histopathological findings of coagulative necrosis in the liver, kidneys, and adrenal glands (Burt et al. 1997). The

liver injury which occurs during CCHFV infection occurs due to the direct effects of viral replication, but also due to the activation of extrinsic death receptor signaling pathways (Lindquist et al. 2018). The effect of CCHFV on endothelial cells resulting in capillary leakage appears to be exerted chiefly by immunologically mediated mechanisms including immune complex deposition and complement activation, although direct viral replication in endothelial cells has been demonstrated (Connolly-Andersen et al. 2011; Joubert et al. 1985). Release of inflammatory mediators such as tumor necrosis factor alpha (TNF-α) also increases endothelial permeability. Increased levels of TNF-α are significantly associated with severe CCHF disease (Ergönül et al. 2006b; Papa et al. 2006). TNF-α is known to be associated with macrophage activation leading to hemophagocytosis and also stimulates vasodilating substances and antifibrinolytic activity. Interleukin-6 (IL-6), which is released by Kupffer cells due to liver injury, is increased in all patients with CCHF including both mild and severe disease presentations (Ergönül et al. 2006b; Papa et al. 2006). Both TNF-α and IL-6 are Th1 cytokines which stimulate activation of monocytes and contribute to hemophagocytosis. Hemophagocytosis has been described in both adults and children with CCHFV infection and may contribute to the cytopenias observed (Dilber et al. 2009; Fisgin et al. 2008; Karti et al. 2004). High levels of interleukin-10 (IL-10) and interferon gamma (IFN-γ) are also associated with a fatal outcome (Ergönül et al. 2006b). It seems likely that high levels of IL-10 released early in infection result in a degree of immunosuppression, which allows high levels of viral replication. This in turn stimulates release of IFN-γ and TNF-α (Saksida et al. 2010). These findings are also supported by studies in mouse models (Bente et al. 2010). RIG-1 has been identified as a pattern recognition receptor for CCHFV, which results in activation of type 1 interferon and other proinflammatory cytokines that play a role in the antiviral response (Spengler et al. 2015). The pathogenesis of CCHF also includes disseminated intravascular coagulopathy (DIC) early in infection (Swanepoel et al. 1989).

47.5 Laboratory Diagnosis

The recent emergence and re-emergence of CCHFV in Eastern Europe, southwestern Europe, and the Balkans and the threat of spread to new geographic locations where competent vectors are emerging, emphasizes the importance of increasing diagnostic capacity and developing standardized, rapid, and sensitive assays. Although human cases of infection with CCHFV can be identified based on clinical and laboratory criteria, laboratory confirmation is essential for distinguishing CCHF from conditions with similar clinical features (Ergönül 2006; Swanepoel et al. 1987, 1989). Classification of the virus as a biosafety level four pathogen determines that the virus can only be cultured within the confines of a biosafety level four laboratory and that laboratories with less sophisticated biosafety levels must inactivate clinical samples prior to testing.

Virus can be isolated in a variety of susceptible mammalian cell cultures, although Vero cells are most frequently used. The virus seldomly induces cytopathic

effects and infection must be confirmed using IF tests. Alternatively, the virus can be isolated by intracerebral inoculation of day-old mice (Clerx et al. 1981; Hoogstraaal 1979; Watts et al. 1989). Isolation of the virus in cell cultures can take 1–6 days whereas mice need 5–10 days to succumb to infection (Shepherd et al. 1986). Although isolation in cells is more rapid, mouse inoculation is a more sensitive technique.

During the acute stage of illness, viral nucleic acid can be readily amplified and detected using reverse transcription polymerase chain (RT-PCR) assays. Viral RNA is extracted from clinical samples and as negative sense RNA is not infectious, the amplification can be performed without the requirement of a biosafety level four laboratory. Diagnostic RT-PCR is based on amplification of a conserved region of the genome.

The first diagnostic RT-PCR for CCHFV was based on two nested primer pairs designed by an alignment of the S segment from seven geographically distinct isolates (Burt et al. 1998; Rodriguez et al. 1997; Schwarz et al. 1995). Subsequently, there has been significant development and implementation of diagnostic real time RT-PCR assays. Amplicons can be detected using an intercalating dye and the use of a melt curve analysis to detect specific amplified products or sequence specific probes in which probes are hybridized to complementary regions of the genome (Burt et al. 1998; Drosten et al. 2002a, b; Duh et al. 2006, 2007; Garrison et al. 2007; Kondiah et al. 2010; Papa et al. 2007; Rodriguez et al. 1997; Schwarz et al. 1995; Wölfel et al. 2007; Wölfel et al. 2009; Yapar et al. 2005). Real time molecular assays can be designed to determine viral load. Quantification of viral load using real time RT-PCR has been used as a prognostic indicator with reports that a viral load greater than $1x10^8$ RNA copies/ml plasma can be considered to predict a fatal outcome (Cevik et al. 2007; Duh et al. 2006; Garrison et al. 2007; Kondiah et al. 2010; Wölfel et al. 2007). The considerable genetic diversity of the various genotypes must be taken into consideration when developing molecular assays. Hence, most molecular assays have targeted conserved regions of the gene encoding the nucleoprotein. To facilitate diagnosis and eliminate the need for sophisticated laboratory equipment, nucleic acid tests (NAAT) have been described that do not require thermal cyclers, such as reverse transcription loop–mediated isothermal amplification (RT-LAMP) and recombinase polymerase amplification assay (Bonney et al. 2017; Kumar et al. 2022; Osman et al. 2013). These assays targeted conserved regions of the S gene and were shown to have good correlation with conventional assays with regard to sensitivity. Rapid isothermal assays have potential application in field settings.

Enzyme linked immunosorbent assays (ELISA) have been described for detection of viral antigen. Although having the advantage that sophisticated laboratory equipment is not required, they lack the sensitivity of molecular amplification or viral isolation and are not frequently used for routine diagnosis (Saijo et al. 2005a; Shepherd et al. 1988).

Serological assays have an important diagnostic role during the convalescent stage of infection. Infection is confirmed based on demonstration of seroconversion, a fourfold or greater increase in IgG antibody activity in paired serum samples, or IgM activity in a single specimen. In contrast, indirect immunofluorescence

(IF) assays and ELISA are frequently employed as diagnostic tools. These assays can distinguish between IgG and IgM responses and are rapid and sensitive techniques for detecting an early immune response (Burt et al. 1994; Shepherd et al. 1989b). Although traditionally most reagents were prepared in house requiring culture of the virus in maximum containment laboratories with subsequent inactivation of the reagents, there are now commercially available ELISA and IF assays. In addition, recombinant antigens have been developed for use as diagnostic and surveillance tools (Samudzi et al. 2012).

In fatal cases, antigen and viral nucleic acid can be detected in post mortem tissues. Histopathologic features are not pathognomonic and definitive diagnosis requires virological assays or antigen detection in formalin fixed tissue samples using immunohistochemistry (Burt et al. 1997).

To date no commercial rapid lateral flow assays (LFA) are available for point of care testing. Development of LFA for detection of CCHFV antigen, and for detection of IgG and IgM antibody, would have important public health implications particularly in low resource countries.

47.6 Kinetics of Viremia and Antibody Responses

CCHFV is most frequently isolated from sera collected from patients on days 1 to 6 after onset of illness when virus titers are highest, although virus has also been isolated from samples collected from days 1 to 12 (Shepherd et al. 1986). Viral nucleic acid has been detected in samples collected up to 18 days after onset of illness; the diagnostic sensitivity, however, decreases with the presence of an antibody response. The development of molecular assays has significantly improved diagnostic capability during the acute stage of illness when patients lack immune markers and virus isolation is dependent on severity of illness and levels of viremia. In non-fatal infections, the ability to isolate virus decreases from days 7 to 12. Although IgG and IgM antibodies have been detected as early as day 3 of illness, they are more frequently detected from day 5 onwards (Burt et al. 1994; Saijo et al. 2005b; Shepherd et al. 1989b; Tang et al. 2003). Patients with a fatal outcome frequently do not develop a detectable antibody response. IgG antibodies remain detectable at least 10 to 12 years after illness and possibly for longer, whereas IgM antibodies decline to undetectable levels in most patients 4–6 months post-infection (Burt et al. 1994; Shepherd et al. 1989b).

To date it is unclear what facilitates clearance of the virus. Appearance of a humoral antibody response does not always correlate with clearance of CCHFV. Conserved immunogenic epitopic regions in the G_C, G_N, GP38, and mucin like domain have been described; however, although immunogenic, these epitopes are unlikely to be involved in inducing neutralizing responses (Fritzen et al. 2018; Goedhals et al. 2015). Although survivors develop neutralizing antibody responses, the levels of neutralizing antibody remain low (Shepherd et al. 1989b). The role and mechanism of non-neutralizing antibodies is still to be determined. In an investigation to try and elucidate the effect of antibodies on viral load, it was deduced that the detection of IgM had no influence on survival or viral load. While IgG levels

appeared to be inversely related to viral load, the virus titers decreased in non-fatal infections independent of detectable antibodies (Duh et al. 2007; Wölfel et al. 2007). The results indicate a role for innate or cellular immune responses in viral clearance.

In summary, during the acute phase of illness confirmation of infection is achieved by isolation of the virus, detection of viral nucleic acid using molecular techniques, or detection of viral antigen in ELISA. During convalescent stages antibody responses are detected using ELISA or indirect IF assays. Accurate interpretation of the results is facilitated by an accurate history of date of onset of illness and consideration of the kinetics of viremia and antibody responses.

47.7 Differential Diagnosis

A number of conditions must be considered in the differential diagnosis of CCHFV infection. The geographic location and travel history of patients presenting with a compatible clinical picture can assist in excluding unlikely infectious conditions. Conditions which should be considered include other tick-borne infections such as rickettsiosis (especially by *Rickettsia conori* and *Rickettsia africae*), Q fever (*Coxiella burnetti*), ehrlichiosis, babesiosis, borreliosis, and severe fever with thrombocytopenia syndrome virus. Other viral hemorrhagic fevers must be considered dependent on the geographic location, e.g., Ebola virus, Marburg virus, Lassa virus, and Lujo virus in Africa, Rift Valley fever virus in Africa and the Middle East, yellow fever virus in Africa, South and Central America, and dengue virus in tropical and subtropical regions. In addition, other infectious conditions should be ruled out such as bacterial sepsis (including meningococcaemia), malaria, leptospirosis, salmonellosis, brucellosis, viral hepatitis, and disseminated herpes simplex virus infection (Burt 2011; Ergönül 2006). Non-infectious conditions may include hematological diseases and malignancies, drugs, auto-immune diseases, and HELLP syndrome (hemolytic anaemia, elevated liver enzymes, low platelet count) in pregnancy (Ergönül et al. 2010; van Eeden et al. 1985).

47.8 Treatment

Strict barrier nursing should be implemented when managing CCHF patients to prevent nosocomial transmission. Supportive therapy should include maintenance of fluid and electrolyte balance and administration of platelets, fresh frozen plasma, and red cell preparations as needed (Ergönül 2008).

Limited information is available regarding the use of specific CCHFV immunoglobulin or monoclonal antibody preparations. Randomized controlled trials demonstrating efficacy in a clinical setting for both treatment and post-exposure prophylaxis are lacking (Keshtkar-Jahromi et al. 2011).

Similarly, the use of oral or intravenous ribavirin for the treatment of CCHF remains controversial. Although the majority of systematic reviews and meta-analyses of the available randomized trial and observational studies showed insufficient evidence for a clear benefit to using ribavirin in the treatment of CCHFV infection, this

antiviral agent is included in the World Health Organization Model List for Essential Medicines for treatment of viral hemorrhagic fevers (Ascioglu et al. 2011; Johnson et al. 2018; Soares-Weiser et al. 2010; World Health Organization 2021). In studies where a reduced risk of death was noted with ribavirin use, the timing of administration was an important consideration, with early initiation within the first 2–4 days of disease onset being required (Arab-Bafrani et al. 2019; Ergönül et al. 2018). Adverse drug effects are uncommon, but may include mild hemolytic anemia and thrombocytosis (Ergönül et al. 2004; Fisher-Hoch et al. 1995; Ozkurt et al. 2006).

Favipiravir (T-705) is a nucleoside analogue, which is approved in Japan for the treatment of influenza virus infections and has been shown to have activity against a number of RNA viruses, including Lassa virus (Shiraki and Daikoku 2020). Favipiravir has shown benefit in both mouse and non-human primate models for CCHF; however, clinical data are lacking (Dülger et al. 2020; Hawman et al. 2018, 2020; Oestereich et al. 2014). A novel nucleoside analogue, H44, was able to protect mice against lethal challenge and may warrant further studies (Wang et al. 2022).

Therapeutic plasma exchange (TPE) is another therapeutic modality that has been investigated in critically ill patients with CCHF. While a lower mortality rate was noted following TPE, patients receiving standard supportive therapy had a shorter duration of hospitalization and shorter time to recovery of platelet counts (Beştepe Dursun et al. 2021). A role for TPE in the management of CCHF thus remains unclear at present.

47.9 Developments in Vaccine Developments

Currently, there is one vaccine for human use that is only available in Bulgaria. The vaccine is an inactivated suckling mouse brain derived preparation (Papa et al. 2011). The vaccine elicits both T-cell responses and high levels of antibodies, but multiple doses are needed to induce antibodies with neutralizing activity (Mousavi-Jazi et al. 2012). Widespread use of the vaccine has been limited by the lack of clinical trials and efficacy data and due to concerns regarding myelin basic protein induced auto-immune and allergic responses (Dowall et al. 2017).

While the immune correlates of protection remain unclear, available data indicate that both humoral and cellular responses are required. Vaccine development has been facilitated by the availability of animal models including interferon α/β receptor knockout mice (IFNAR−/−), STAT-1 knockout mice, transiently immune-suppressed (IS) mice, and cynomolgous macaques. Vaccines targeting the viral nucleoprotein and/or glycoproteins currently under investigation, using various approaches including inactivated vaccines, subunit vaccines, virus-like replicon particles, viral vectored vaccines, DNA vaccines, mRNA, and plant-based vaccines (Aligholipour Farzani et al. 2019a, 2019b; Appelberg et al. 2022; Berber et al. 2021; Buttigieg et al. 2014; Canakoglu et al. 2015; Dowall et al. 2016; Garrison et al. 2017; Ghiasi et al. 2011; Hawman et al. 2021; Hinkula et al. 2017; Kortekaas et al. 2015; Pavel et al. 2020; Rodriguez et al. 2019; Scholte et al. 2019;

Spengler et al. 2019, 2021; Spik et al. 2006; Suschak et al. 2021; Tipih et al. 2021; Zivcec et al. 2018). A number of these vaccines have been shown to be both immunogenic and protective in animal models, thus warranting further investigation.

47.10 Prevention and Control

Widespread control of ticks using acaricides is an impractical approach to infection control. Prevention of infection and awareness of the disease is a more practical method of reducing the risk of infection and the number of cases. Exposure to tick bites should be minimized through the use of tick repellents such as pyrethroids and protective clothing by individuals who are at risk of CCHF through occupational or recreational activities. The correct removal of ticks should also be implemented. Anti-tick vaccines for use in animal amplifying hosts are a novel approach to the prevention of CCHF, which are still in the early stages of development (Manjunathachar et al. 2019; Shrivastava et al. 2020).

Although the use of ribavirin as post-exposure prophylaxis is controversial, it has been recommended for administration to high-risk contacts. High-risk cases include those with direct contact with infectious fluids, contamination of mucosae with infectious fluids, and needle stick injuries (de la Calle-Prieto et al. 2018; Ergönül et al. 2018). Ribavirin is usually well tolerated in this context, but side effects described include anemia, myalgia, allergic skin reactions, gastrointestinal symptoms (nausea, vomiting diarrhea), hemolysis, and mildly elevated liver functions (Guven et al. 2017).

47.11 Conclusions

CCHFV remains a pathogen of significant public health concern with the propensity to cause nosocomial infections and outbreaks among occupationally exposed workers, and people at risk of exposure to tick-bite due to recreational activities or residing in rural areas. Molecular assays based on amplification of conserved genome regions have facilitated a more rapid diagnosis, allowing laboratory confirmation to occur in the absence of high containment laboratories. However, in the absence of sophisticated equipment and skilled technicians, the development of rapid lateral flow assays and point of care assays are essential, especially for lower resource countries and to facilitate early detection to protect health care workers. The spread and emergence of this virus has been confirmed in recent years and this threat will continue with climate change and expansion of vector populations into new endemic regions. Vaccine development has traditionally been hampered by lack of a suitable animal model for challenge studies; however, several animal models have been described for CCHFV in recent and this has advanced development of vaccines. Further understanding of the immune correlates of protection will contribute toward development of an efficacious vaccine for a virus with potential to cause significant human disease. In the absence of vaccines or treatment, raising awareness of CCHFV as a tick-borne zoonosis is crucial.

A Review of Hendra Virus and Nipah Virus Infections in Man and Other Animals

48

Kim Halpin and Paul A. Rota

Contents

Abstract

Hendra virus (HeV) and Nipah virus (NiV) emerged in the 1990s. They have been the cause of outbreaks of respiratory and neurological disease infecting horses and pigs. Transmission from infected domestic animal species has resulted in human infections with high case fatalities. Direct transmission from the reservoir host to humans has occurred with NiV in yearly disease outbreaks in Bangladesh and India. HeV causes sporadic disease outbreaks in horses in northeast to mideastern Australia with occasional spillover from infected horses to humans. Due to their zoonotic nature, they have been ideal candidates for collaborative projects and coordinated disease outbreak investigations in the One Health space, bringing public health and animal health professionals together. This has led to practical disease outbreak investigations, disease prevention solutions including a

horse vaccine for HeV, and NiV spillover prevention interventions in the field. As more surveillance is undertaken, their known distributions have expanded, as has the geographical range of the reservoir host species. Most bat species for which there is evidence of HeV and NiV infection belong to the group known as the Old World fruit- and nectar-feeding bats (Family *Pteropodidae,* Suborder *Yinpterochiroptera, and* Order *Chiroptera*). This chapter of HeV and NiV discusses the epidemiology, pathology, transmission, and disease symptoms in these closely related viruses which belong to the Genus *Henipavirus,* Family *Paramyxoviridae.*

Keywords

Reservoir host · Nipah virus · Hendra virus

48.1 Epidemiology of Hendra Virus in Animals

On August 1, 1994, a heavily pregnant 10-year-old thoroughbred brood mare died suddenly in a paddock in northern coastal Australia. Ironically the first of August is deemed the birthday of all thoroughbred horses in the southern hemisphere. (All thoroughbreds have the same birthday so that their ages can be standardized for comparison. In the southern hemisphere, the date is the first of August.) This date in 1994 would go down in history as the day Hendra virus (HeV) emerged. In 2021, a second variant was identified in a horse sample collected in 2015 (Annand et al. 2022). The original variant is now called HeV-g1 (genotype 1), and the new variant is HeV-g2 (genotype 2) (Wang et al. 2021).

Hendra virus was first discovered in horses, and horses remain the most infected domestic species. The reservoir host of this virus are bats of the genus *Pteropus*, family *Pteropodidae* (called *Pteropus* bats). Finding the reservoir host for this virus resulted in the first reported isolation of a zoonotic paramyxovirus from *Pteropus* bats (Halpin et al. 2000). To date, only horses have become directly infected from *Pteropus* bats. Horses act as HeV-amplifying hosts.

As of November 2022, there have been 99 horses infected, usually in events which only involved one horse, with winter having the most outbreaks, followed by spring (Fig. 1). Only two outbreaks have involved more than three horses, and the spread of the virus between the stabled horses in these outbreaks was a result of close contact and assisted mechanical transmission of the virus. Aerosol transmission is unlikely as sneezing and coughing were not features of the syndrome, and the spatial distribution of cases in the stables was not consistent with this form of spread (Baldock et al. 1996; Field et al. 2010).

Experimentally, we know that some horses can survive infection. In the outbreaks where there have been numerous horses infected, this has also been the case. In the 1994 outbreak in Hendra, 7 out of 20 horses apparently survived a lethal infection and seroconverted before being euthanized (Murray et al. 1995). In the 2008 Redlands outbreak, one horse survived for 42 days after clinical signs abated before being euthanized (Field et al. 2010).

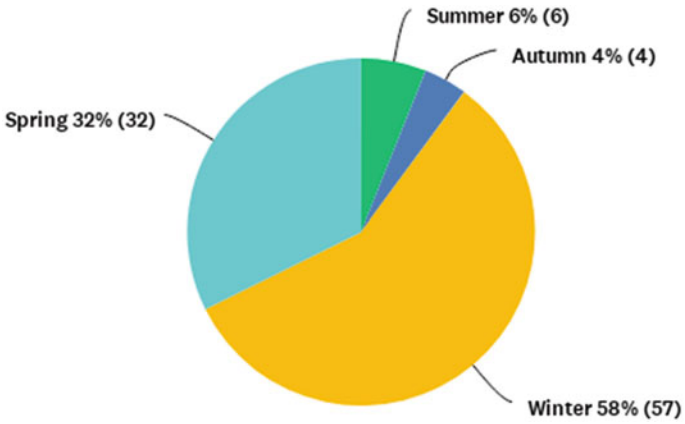

Fig. 1 Total number of HeV infected horses by season (1994–2022)

Experimentally, cats can be infected and succumb to the virus (Westbury et al. 1995; Williamson et al. 1998), but no cat has been found to be naturally infected in the field, to date. In one of the 2011 outbreaks, a dog on a property under investigation was found to have antibodies to the virus. It most likely had close contact with HeV-laden material from an infected horse but was clinically well and remained so until it was euthanized in accordance with national policy at the time (Promed 2011). In 2013, HeV RNA was detected in the EDTA-treated blood and serum, but not from the oral swab samples, from a dog which resided on the same property as an HeV-infected horse (Kirkland et al. 2015). Experimental infections in dogs have been conducted at the Australian Centre for Disease Preparedness (ACDP), to better understand the role that dogs might play in the epidemiology of the disease. In these studies, dogs could be reliably infected with HeV. Consistent with the field observation, few if any clinical signs were noted during the acute stage of infection. Viral shedding from the oral cavity occurred for a relatively short period of time, and oral secretions collected from dogs during this period were capable of transmitting infection to naïve ferrets (Middleton et al. 2017). Neutralizing antibody titers generated in these dogs were similar to that observed in the recorded canine field case of HeV infection (Promed 2011). In dogs, the key site of virus replication within the oral cavity was the tonsil, with authors concluding that it is feasible for Hendra virus to be transmitted to people from acutely infected dogs.

Infection in horses most likely occurs after close contact with *Pteropus* bat urine and birthing material which contain sufficiently high enough titers of virus to infect a horse (Halpin et al. 2000; Edson et al. 2015). Luckily for horses, these bat samples rarely contain high titers of virus. The risk of transmission to horses was found to be increased during *Pteropus* bat-reproductive periods (especially late pregnancy) and at times when the colonies were undergoing nutritional stress, such as during lactation and during food shortages (Plowright et al. 2008; Breed et al. 2011). More recent studies build on these observations and suggest that in addition to

seasonal effects, bat density and local climatic conditions interact to drive Hendra virus infection dynamics in *Pteropus* bat populations (Páez et al. 2017).

Evidence of Hendra virus infection has been found in all four mainland *Pteropus* species of bats in Australia, namely, the black flying fox (*Pteropus alecto*), the gray-headed flying fox (*P. poliocephalus*), the spectacled flying fox (*P. conspicillatus*), and the little red flying fox (*P. scapulatus*). However, spillover events to date have been restricted to regions where *P. alecto* and/or *P. conspicillatus* are found (Edson et al. 2015), noting that the geographical distribution of *P. alecto* is extending further south.

It appears that the reservoir host coexists with this virus in complete harmony. The virus spreads quite easily among *Pteropus* bats, with the HeV seroprevalence in bat colonies fluctuating over time and geographical spread. In one bat colony, seroprevalence steadily increased from 45 to 69% over a 2-year period supporting a model of endemic infection in the population (Breed et al. 2011). Absence of disease attributable to HeV infection is supported by experimental observations (Halpin et al. 2011). This is consistent with the observation that many viruses do not cause disease in their reservoir host. The long-term coexistence of viruses and their reservoir hosts has given coevolution a good chance to reach a relative equilibrium (Domingo 2010). The theory of viral coevolution with chiropteran hosts has been previously suggested, and all field observations and experimental evidence to date support this (Halpin et al. 2007).

48.2 Epidemiology of Nipah Virus in Animals

Since HeV was detected in *Pteropus* bats, they were among the first species investigated as possible reservoirs for Nipah virus (NiV) after its emergence in 1999. Neutralizing antibodies to NiV have been detected in a wide range of *Pteropus* bats, including *Pteropus hypomenalus*, and *Pteropus vampyrus* (Yob et al. 2001). In 2000, NiV was isolated from a urine sample collected underneath the roost of *Pteropus lylei* bats in Cambodia (Reynes et al. 2005). Nipah virus was eventually isolated from *Pteropus vampyrus* in Malaysia (Sohayati et al. 2011). Serologic evidence of Nipah infection was also obtained from *Rousettus leschen* and *Cynoptera sphinx* in Vietnam (Hasebe et al. 2012). Several species of Chinese bats also contained antibodies to Nipah or Nipah-like viruses (Li et al. 2008). A very thorough study of the presence of henipaviruses in Australasia indicated that NiV was present in East Timor and that non-NiV and non-HeV henipaviruses were present in Sumba, Sulawesi, and possibly Papua New Guinea (Breed et al. 2013). The authors suggested that NiV can be detected in areas where *Pteropus vampyrus* is present. In India and Bangladesh, the primary reservoir of NiV is *Pteropus medius* (Epstein et al. 2020; Yadav et al. 2019).

In Madagascar, seropositive *Pteropus rufus* and *Eidolon dupreahum* bats have been found, and 39% of *Eidolon helvum* from Ghana had NiV reactive antibodies (Hayman et al. 2008; Iehle et al. 2007). Henipavirus-like sequences were obtained from *Eidolon helvum* in Ghana (Drexler et al. 2009). The detection of antibodies to and sequences of henipaviruses in African bats suggest that the range of potential

NiV infections may be wider than previously thought, though no human cases of NiV have been reported from any region other than South Asia and Southeast Asia.

Experimentally infected *Pteropus* bats develop subclinical NiV infection with only sporadic viral excretion in urine. Some bats seroconvert, and some show evidence of infection by detection of viral antigen in tissues (Middleton et al. 2007; Halpin et al. 2011).

Regarding domestic species affected by NiV, pigs featured in the first outbreak in Malaysia (Chua et al. 2000). Pigs presumably became infected from *Pteropus* bats, and the disease spread throughout piggeries with pigs serving as an amplifying host. Most of the human infections occurred in people with direct contact to sick pigs. Serologic studies demonstrated evidence of infection among other domestic species of animals in Malaysia, including horses, dogs, and cats (Chua et al. 2000; Hooper and Williamson 2000).

In most of the outbreaks in India and Bangladesh, no intermediate domestic species has been implicated in epidemiology of the virus infection. However, in the outbreak in the Philippines, horses were infected. Epidemiologic data suggest that the most common route of virus transmission to humans was direct exposure to infected horses, contact with contaminated body fluids during slaughtering of sick horses, and/or consumption of undercooked meat from infected horses. Serological evidence of infection was also detected in four dogs; however, they were asymptomatic (Ching et al. 2015).

48.3 Epidemiology of Hendra Virus in Humans

To date, there has been no human-to-human spread of HeV; all infected people have had close contact with an infected horse. The first person to become infected and die from HeV was assisting his wife, a veterinarian, to perform an autopsy on a horse that had died suddenly in a paddock (Rogers et al. 1996). This patient recovered from a short illness but went on to die 13 months later after a relapse with encephalitis (O'Sullivan et al. 1997). In the second outbreak of Hendra virus, a horse trainer and a strapper, who had very close contact to HeV-infected horses in their racing stables, became infected (Selvey et al. 1995). The next person to become infected was a veterinarian who had performed an autopsy on a horse who had died from colic-like symptoms. At the time, colic-like symptoms had never been associated with HeV infection in horses. The veterinarian came down with a flu-like illness but recovered and for many years had neutralizing antibodies to the virus (Taylor et al. 2012). The next two people to become infected were a veterinarian who performed a nasal lavage on a horse with respiratory symptoms and the veterinary nurse who assisted with the procedure (Playford et al. 2010). The veterinarian died. The last person to become infected with Hendra virus was a veterinarian who cared for a horse which was also diagnosed with HeV infection (Field et al. 2010).

The human case fatality rate stands at 57%, with four deaths and three survivors. Interestingly to date, only male patients have died; however, with such a small sample size this should not be overinterpreted. The risk remains for people who have very close contact with bodily fluids from HeV-infected horses through performing invasive procedures, and/or by not wearing fully protective PPE.

48.4 Epidemiology of Nipah Virus in Humans

The first detected outbreak of NiV infection occurred in Malaysia with 276 human cases reported and 106 deaths (Chua et al. 2000). Nipah virus was transmitted to pigs and spread rapidly among swine herds causing primarily respiratory symptoms in pigs. Pig-to-human transmission resulted in acute febrile encephalitis mostly among adult males who worked in the pig industry. The outbreak spread to Singapore via the transport of infected live pigs from Malaysia (Chua et al. 2000; Paton et al. 1999). Culling of more than one million pigs in Malaysia was undertaken to control the outbreak (Chua et al. 2000).

Since the outbreak in Malaysia, outbreaks have been reported almost annually in Bangladesh and India from 2001 (Fig. 2) (Chadha et al. 2006; Luby and Gurley 2012; Luby et al. 2009a; Sudeep et al. 2021). The epidemiologic characteristics of the outbreaks in Bangladesh differed from the Malaysia outbreaks in several respects. Most notably, the case fatality rate in Bangladesh (2001–2010) ranged from 38% to as high as 100%, with an average mortality rate of 73%, while the mortality rate for Malaysia was approximately 38% (Luby and Gurley 2012). Infected individuals in Bangladesh were more likely to have respiratory symptoms, and there was evidence of human-to-human spread. Drinking fresh date palm sap contaminated by fruit bat saliva, urine, or excreta has been identified as the likely route of transmission from the wildlife reservoir to humans (Luby et al. 2006).

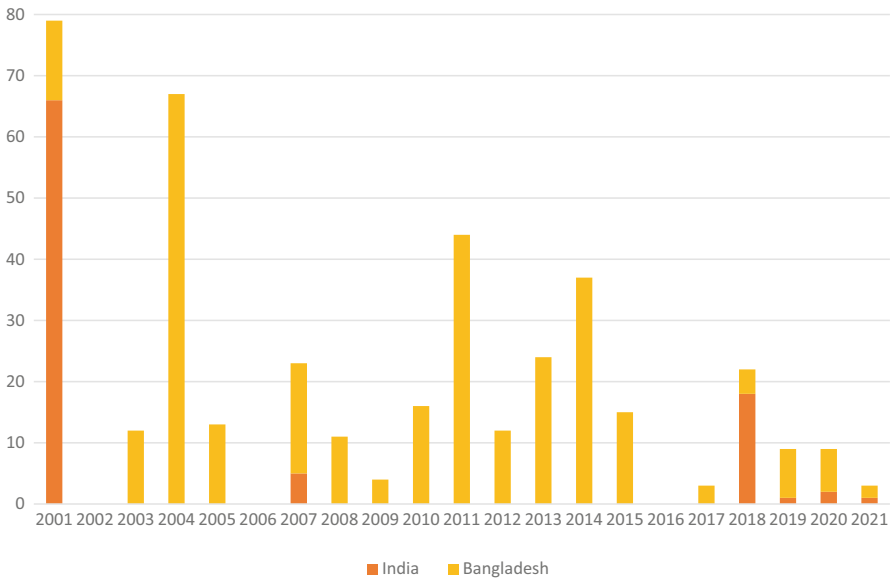

Fig. 2 Total number of deaths in NiV-infected people by year in Bangladesh and India. (Data taken from http://www.iedcr.org and http://www.searo.who.int/entity/emerging_diseases/links/nipah_virus_outbreaks_sear/en/index.html and Yadav et al. 2022)

Luby et al. (2009b) showed in their study that Nipah case-patients who had difficulty breathing were more likely than those without respiratory difficulty to transmit Nipah. Although a small minority of infected patients transmit Nipah virus, more than half of identified cases result from person-to-person transmission. In these cases, virus was spread during close contact while caring for sick individuals or preparing bodies for burial (Blum et al. 2009; Chadha et al. 2006; Luby et al. 2009b).

All confirmed Nipah outbreaks in Bangladesh have occurred in the same central and northwestern regions (Luby et al. 2009b). The first two Indian outbreaks have been in regions within 50 km of the border with Bangladesh and immediately contiguous with the affected areas in Bangladesh (Chadha et al. 2006). However, in 2018 there was a large outbreak on the western coast of India, in the Kozhikode district, Kerala state, approximately 2000 kms away from Bangladesh, where 21 people died and 2 people survived (Arunkumar et al. 2019). The source of infection for the index case is unknown but suspected to be a bat. Risk factors for infection of the other cases included proximity (i.e., touching, feeding, or nursing an NiV-infected person), enabling exposure to droplet infection (Arunkumar et al. 2019). The public health response included isolation of cases, contact tracing, and enforcement of hospital infection control practices. In the same district, a single case who survived was identified in 2019, and another case in 2021 who died (Yadav et al. 2022).

In 2014, Philippines had an outbreak of disease in horses and humans in two villages, Tinalon and Midtungok, in the municipality of Senator Ninoy Aquino, province of Sultan Kudarat, island of Mindanao. Limited sequence information from samples indicates that the virus was Nipah virus. Epidemiological data suggest that the most common route of virus transmission to humans was direct exposure to infected horses, contact with contaminated body fluids during slaughtering of sick horses, and/or consumption of undercooked meat from infected horses (Ching et al. 2015). However, for at least 5/17 cases, clinical and epidemiologic evidence suggest direct human-to-human virus transmission. No protective equipment was used by those who cared for case-patients in the home, and health care workers used gloves and a face mask but not eye protection (Ching et al. 2015).

48.5 Evidence of Animal to Human Transmission of Hendra Virus

While *Pteropus* bats are the reservoir host of the virus, humans have only become infected after close contact to infected horses. In Australia, there are many bat carers who have close contact to sick and injured *Pteropus* bats. They get bitten and scratched and come into contact with urine and fecal material, as well as placenta and birthing fluids. However, no bat carer has ever been diagnosed with HeV infection. An extensive serological survey of bat carers in Queensland was performed in the mid-1990s, and there was no serological evidence of exposure to the virus (Selvey et al. 1996). However, bat carers are at risk of becoming infected with Australian bat lyssavirus and should be vaccinated with the rabies vaccine.

In one HeV experiment, a small amount of viral RNA was detected in the nasal secretions of HeV-infected horses 2 days after exposure to the virus and at least 2 days before the onset of clinical signs, suggesting that transmission of the virus from the infected horse may be possible before it is obviously unwell (Marsh et al. 2011). However, at this early stage of infection, the amount of viral genome detected was very low and it is unlikely that this would be enough to infect another host. The findings also supported the observation in experimentally infected *Pteropus* bats that a local mucosal infection, from days 2 to approximately 6 post exposure, precedes a systemic infection (Halpin et al. 2011). Only after the systemic infection has been established does it become possible to isolate infectious virus from urine and blood.

Sequence analysis of different isolates from both horses and *Pteropus* bats reveals extreme conservation at the genome and protein levels (Marsh et al. 2010; Smith et al. 2011). In one study comparing five horse isolates from five locations (all HeV-g1) which spanned almost 2000 km, across three time points, to the original 1994 isolate, less than 1% variation at both the nucleotide and amino acid levels was shown across the 18.2-kb genome (Marsh et al. 2010). This genetic stability supports the theory of coevolution where HeV is well adapted to its host resulting in minimal pressure to change over time (Halpin et al. 2007; Smith et al. 2011).

48.6 Evidence of Animal-to-Human Transmission of Nipah Virus

In contrast to Malaysia where pigs clearly served as the amplifying host that facilitated spread of the virus from *Pteropus* bats to humans, no intermediate animal host was identified in the Bangladesh and Indian outbreaks. In the Philippines outbreak, the intermediate hosts were horses.

Several routes of transmission of NiV from *Pteropus* bats to humans have been identified by studying the nearly annual outbreaks in Bangladesh and the single outbreak in India. Consumption of contaminated date palm sap or contaminated fruit has been linked to several cases and outbreaks in Bangladesh (Rahman et al. 2012). Case-patients reported no history of physical contact with *Pteropus* bats, though community members often reported seeing bats. Infrared camera photographs have shown that *Pteropus* bats frequently visited date palm trees in those communities where sap was collected for human consumption. This provided an opportunity for intervention to prevent NiV spillover to humans. It has been shown that skirts (made from bamboo, dhoincha, jute stick, and/or polythene) covering the sap-producing areas of a tree effectively prevented bat-sap contact (Khan et al. 2012).

Genetic analysis of NiV isolates and sequences obtained from clinical samples indicated that the outbreaks in Bangladesh were the result of multiple, independent introductions of virus into the human population (Harcourt et al. 2005; Luby et al. 2009b).

The Indian flying fox (*Pteropus medius*) is the major reservoir of Nipah virus in Bangladesh and India (Yadav et al. 2019; Epstein et al. 2020). Longitudinal surveys indicate that exposure to Nipah virus is high (≈40%) in some *P. medius* populations

in Bangladesh based on serologic tests, but the prevalence of detectable Nipah virus RNA is low (<5%) at any given time (Yadav et al. 2019).

Sequences obtained from Malaysia and Cambodia are designated as genotype M, while sequences obtained from Bangladesh and India are designated genotype B. Genotypes can be assigned based on the sequence of a 729-nucleotide window in the N-terminal region of the N gene ORF. Levels of nucleotide variation among full-length ORFs between genotypes M and B ranged from 6 to 9%, and between the complete genomes nucleotide variation is approximately 8% (Lo et al. 2012). Differences in transmission patterns and mortality rates suggest that NiV-Bangladesh may be more pathogenic than NiV-Malaysia. Data has shown that NiV-B is more pathogenic in African green monkeys (Mire et al. 2016), and in ferrets NiV-B sheds more (Clayton et al. 2012).

48.7 Pathogenesis and Containment

NiV and HeV enter cells by binding to the receptor Ephrin-B2, which is expressed on neurons, smooth muscle, and endothelial cells surrounding small arteries (Bonaparte et al. 2005; Negrete et al. 2005). Ephrin-B3 serves as an alternative receptor for NiV, but not HeV (Negrete et al. 2006). After receptor binding by the attachment protein, G, the fusion protein (F) which is cleaved to create two linked polypeptides, F_1 and F_2, fuses to the host cell membrane, initiating endocytosis (Wang et al. 2001). Following fusion between the viral envelope and the host cell membrane, the viral ribonucleocapsid is released into the cytoplasm (Lamb and Parks 2007). The polymerase complex composed of the polymerase (L) and phosphoprotein (P) initiates transcription of viral mRNAs. As translation of viral mRNA occurs, viral proteins accumulate in the cell, and the polymerase switches from transcription to genome replication.

Newly made genomes are encapsidated by the nucleoprotein (N), and polymerase complexes become associated with packaged nucleocapsids. The glycoproteins are synthesized in the endoplasmic reticulum (ER), mature through the Golgi network, and are transported to the cell membrane. The processing of the fusion (F) glycoprotein occurs in the endosome (Diederich et al. 2005). The cytoplasmic tails of the F and G glycoproteins play a role in the interaction with the matrix (M) protein, which initiates virus maturation and budding (Ciancanelli and Basler 2006; Lamb and Parks 2007; Ong et al. 2009; Patch et al. 2007, 2008).

This tropism for endothelial cells results in a pathology characterized by vasculitis, thrombosis, ischemia, necrosis, and CNS parenchymal infection (Wong et al. 2002, 2009; Weingartl et al. 2009).

A postmortem study of human NiV infection determined that a systemic multiorgan vasculitis associated with infection of endothelial cells was the main pathologic feature, with infection being most pronounced in the central nervous system (CNS) (Wong et al. 2002). In the CNS vascular endothelium, immunohistochemical analysis showed intense staining of endothelial, parenchymal, and multinucleate giant cells which are characteristic of paramyxovirus infection. Evidence of

endothelial infection and vasculitis was also observed in other organs, including lung, heart, spleen, and kidney. NiV has been isolated from cerebrospinal fluid, tracheal secretions, throat swabs, nasal swabs, and urine specimens of patients (Chua et al. 2001; Goh et al. 2000; Wong et al. 2002), and detection of viral RNA by RT-PCR in urine and throat swabs samples is routinely used to confirm NiV infection (Arunkumar et al. 2019).

Both viruses are designated biosafety level (BSL) 4 agents which makes it difficult for researchers to work with these viruses. Furthermore, diagnostic tests requiring the use of live virus are restricted to laboratories that have BSL4 containment. Molecular detection of viral genome is currently the central arm of henipavirus infection diagnosis and can be done in laboratories with lower levels of containment (BSL2 and BSL3). Expanding the surveillance and laboratory capacity for rapid diagnosis of outbreaks is crucial to early detection and containment in areas at risk for NiV and HeV. Point-of-care tests are under development.

48.8 Disease Symptoms in Humans and Animals

Early cases of Hendra virus infection in horses had clinical signs of an acute respiratory disease (Murray et al. 1995). However, as more cases appeared, the spectrum of clinical signs widened to include colic-like symptoms, sudden death, and neurological manifestations. The incubation period is between 4 and 16 days (Baldock et al. 1996), after which time clinical signs such as fever, tachycardia, inappetence, depression, dyspnea, and restlessness may be observed (Marsh et al. 2011). Associated with the labored breathing, a nasal discharge which may be frothy or blood-tinged might develop. Neurological signs such as depression and ataxia are common (Rogers et al. 1996; Ball et al. 2014).

The first fatal human case of Hendra virus infection died of an acute respiratory illness (Selvey et al. 1995). The second fatal human case suffered from relapsing encephalitis (O'Sullivan et al. 1997) with the third and fourth cases succumbing to encephalitis (Field et al. 2010; Playford et al. 2010). Two of the surviving human cases suffered from a self-limited influenza-like illness at the time of HeV infection (Hanna et al. 2006). The third survivor showed development of an influenza-like illness that progressed to acute encephalitis and suffered a long and debilitating neurological illness (Playford et al. 2010).

The incubation period for NiV ranges from 6 to 14 days; after symptom onset patients deteriorated rapidly usually requiring hospitalization (Eaton et al. 2007; Hossain et al. 2008; Arunkumar et al. 2019). In humans, NiV causes acute febrile encephalitis including fever, headache, drowsiness, dizziness, myalgia, and vomiting with reduced consciousness and evidence of brainstem involvement being a poor prognostic factor. Some patients with NiV initially present with pulmonary symptoms such as cough, atypical pneumonia, and acute respiratory distress. The percentage of NiV patients presenting with respiratory disease was higher in Bangladesh (69%) than in Malaysia (25%) (Luby et al. 2009b; Tee et al. 2009). Some NiV cases experienced relapse of disease or late onset encephalitis after

initial infection, which occurred on average approximately 8 months after initial infection (range: 9 days to 22 months), and both syndromes have similar clinical manifestations (Goh et al. 2000; Tan et al. 2002; Tyler 2009). Upon postmortem examination, viral antigen was found in the brains of patients with relapse and late onset encephalitis indicating viral replication took place in these tissues. Unlike acute NiV encephalitis cases, relapse and late onset encephalitis cases did not show vasculitis in the CNS (Tan and Chua 2008; Tan et al. 2002; Tyler 2009). Several NiV-infected individuals also experienced residual neurological symptoms that ranged from mild cognitive or cerebellar disabilities to more severe cognitive impairment, with some remaining in a vegetative state (Goh et al. 2000).

In the NiV outbreak in Malaysia, a newly identified porcine respiratory and neurologic syndrome developed in some pigs infected with NiV. This syndrome was characterized by fever, barking cough, behavioral changes, uncoordinated gait, spasms, and myoclonus (Mohd Nor et al. 2000). In the 2014 outbreak in the Philippines, seven horses showed neurologic signs (head tilting, circling, and ataxia) with rapid progression of clinical signs (Ching et al. 2015).

48.9 Future Considerations

NiV and Henipavirus diseases are currently listed as one of the WHO priority diseases that pose the greatest public health risk due to their epidemic potential and the insufficient countermeasures to mitigate them (WHO 2020). There are currently no vaccines or therapeutics approved for human henipavirus infections. Numerous studies have identified potentially valuable vaccines and antiviral compounds (Gómez Román et al. 2020). A review in 2018 found there were at least 13 NiV vaccine candidates confirmed to be under development in preclinical stages (Gouglas et al. 2018). A promising therapeutic monoclonal antibody which neutralizes both HeV and NiV has undergone Phase 1 trials (Playford et al. 2020).

HeV poses a serious threat to the veterinary profession with five of the seven (71%) people infected with Hendra virus associated with this profession. Any horse which is infected with Hendra virus poses a serious threat to all who come in close contact with the animal, and this includes people, dogs, cats, ferrets, and possibly other animals. This situation prompted the development of a vaccine for horses which was released at the end of 2012 (HeV Equivac® Hendra virus vaccine). The vaccine is highly effective. In a study of 332 vaccinated horses, provided horses received at least three vaccinations (consisting of two doses 3–6 weeks apart, and a third dose 6 months later), horses had high neutralizing antibody titers and none tested negative (Halpin et al. 2021). Regarding vaccine uptake, an estimate suggested that assuming most vaccine sales are in the HeV endemic states, vaccination coverage between years 2016 and 2019 ranged from 10.1% to 13%, which is very low when compared to uptake of the equine tetanus vaccine (Halpin et al. 2021). A successful equine vaccination program has the potential to reverse the current trend of veterinarians exiting equine practice in HeV-endemic regions due to perceived personal risk and workplace liability (Mendez et al. 2012).

Two recent detections of HeV in horses have been managed with a One Health approach (Williamson et al. 2020; Taylor et al. 2022). This involved a coordinated response from animal health and human health agencies, and ecological investigations (Taylor et al. 2022). These responses serve as a blueprint for how outbreaks of zoonotic diseases, such as Hendra virus and Nipah virus, should be managed in the future.

Borna Disease (Borna Disease Virus-1, BoDV-1)

49

Beware of the Bicoloured White-Toothed Shrew

Merle M. Böhmer and Markus Bauswein

Contents

Abstract

In this chapter, we describe the virologic and diagnostic aspects of Borna disease virus 1 (BoDV-1), the clinical presentation, epidemiology, transmission, and potential infection control in animals and humans. Known as an equine disease for more than 250 years, it was proven only in 2018 that BoDV-1 can cause severe encephalitis in humans and thus has zoonotic potential. BoDV-1 is an enveloped virus with negative-stranded, nonsegmented RNA belonging to the genus

Orthobornavirus in the family of *Bornaviridae*. The only known reservoir host for BoDV-1 is the bicolored white-toothed shrew (*Crocidura leucodon*). This species can excrete the virus, e.g., via saliva, urine, and feces without showing symptoms itself. Particularly, not only horses, sheep, and alpacas, but also a number of other mammals, including humans, are susceptible to infections with BoDV-1. They act as so-called "dead-end hosts" and do not excrete the virus. In dead-end hosts, the virus can lead to brain infections and to severe, often lethal encephalitis (Borna disease). Known endemic areas for BoDV-1 are located in parts of southern and eastern Germany, Switzerland, Austria, and Liechtenstein. BoDV-1 can be transmitted to humans via transplanted organs, but the natural transmission route in humans and also other dead-end hosts has not yet been fully clarified. Further research is needed on, among other things, the clinical spectrum of human BoDV-1 infections and the reservoir. In order to prevent BoDV-1 infections in humans, a better understanding of transmission routes is also crucial.

49.1 Introduction

Borna disease was confirmed as a zoonosis only a few years ago, though the zoonotic potential of this viral disease has been discussed in scientific circles for many decades. Following transmission via organ transplantation, it was demonstrated for the first time in 2018 that Borna disease virus 1 (BoDV-1) can cause severe encephalitis in humans (Schlottau et al. 2018). The neurological symptoms and behavioral disorders typical of Borna disease, however, have been reported in horses and sheep from certain areas in Germany for more than 250 years (Durrwald and Ludwig 1997; Working Group Blood of the German Ministry of Health 2019). For many decades, the characteristic clinical picture resulting from a severe encephalitis was referred to as "heated head disease of horses." Between 1894 and 1896, an outbreak of the disease had been observed among cavalry horses in the Saxon town of Borna in eastern Germany. A few hundred horses succumbed to the disease at that time, and from then on it was called Borna disease (Durrwald and Ludwig 1997; Dürrwald et al. 2014; Working Group Blood of the German Ministry of Health 2019). The name was later also adopted in scientific nomenclature. About a decade later, in 1909, the German researchers Ernst Joest and Kurt Degen described intranuclear inclusion bodies in the ganglia of the hippocampal Ammon's horn in material from horses that had died from Borna disease (Joest and Degen 1909, 1911). Up to the present day, the detection of so-called Joest-Degen inclusion bodies is

regarded as confirmation of Borna disease in the differential diagnosis of neurological diseases in horses. These inclusion bodies were later also detected in sheep suffering from Borna disease and recently in human cases (Liesche et al. 2019). In the 1920s, Zwick and colleagues proved the viral etiology of the pathogen. Subsequently, Zwick's research team experimentally infected species such as rabbits, guinea pigs, rats, and rhesus monkeys by intracerebral inoculation, thereby giving a first indication of the virus' potential to infect a variety of warm-blooded animal species (Zwick 1927; Zwick and Seifried 1925).

In this chapter, we give an overview of the newly identified zoonosis Borna disease, methods to detect BoDV-1, pathophysiological aspects, the reservoir host (the bicolored white-toothed shrew), and possible transmission routes as well as the clinical symptoms and epidemiological situation of Borna disease in animals and humans. Additionally, we give an overview about questions that have arisen following the confirmation of Borna disease as a zoonosis. The chapter also contains a digression on another bornavirus with zoonotic potential, the varrigated squirrel bornavirus (VSBV-1).

49.2 Pathogen: Genome Organization and Viral Structure

Bornaviruses are enveloped, nonsegmented single stranded negative sense RNA viruses with the unique property among the order of *Mononegavirales* to replicate and transcribe within the host cell nucleus (Briese et al. 1994; Jordan and Lipkin 2001; Tizard et al. 2016). The virus species BoDV-1 and VSBV-1, belonging to the genus *Orthobornavirus*, are the only bornaviruses for which pathogenicity for humans has yet been demonstrated. The genome of bornaviruses has a length of 8.9 kb containing six open reading frames (ORF) that encode six viral proteins in the following order 3′-N-X-P-M-GP-L-5′ (Pyper et al. 1993).

Virus entry is mediated by the glycosylated membrane protein GP (nonglycosylated form: 56kD; glycosylated form: 84–94kD) which, after synthesis in the infected cell, is cleaved in the Golgi vesicle by the host protease furin into two subunits: an N-terminal gp56 external type I membrane protein GP1 and a C-terminal gp43 membrane-bound protein GP2 (Richt et al. 1998). Binding of GP1 to a so far unknown receptor initiates virus entry by clathrin-mediated endocytosis (Clemente and de la Torre 2009; Makino et al. 2009). Antibodies against GP are neutralizing (Furrer et al. 2001; Modrow et al. 2010). After pH-dependent membrane fusion with the early endosomal compartment, ribonucleoprotein complexes (RNP) containing the nucleocapsid protein N (40 kDa), the phosphoprotein P (23 kDa), the RNA-dependent RNA polymerase L (large protein, 190 kDa), and the RNA are released into the cytoplasm and translocate into the nucleus where viral replication and transcription take place (Clemente and de la Torre 2009; Jordan and Lipkin 2001). The matrix protein M (18 kDa) is associated with the inner membrane (Kraus et al. 2002). The accessory protein X (10 kDa) has various functions: As a counterpart of the P protein, it regulates the activity of the RNA-dependent RNA

polymerase (Poenisch et al. 2004). Further, a neuroprotective, antiapoptotic effect has been demonstrated so that the X protein likely contributes to viral persistence (Poenisch et al. 2009; Szelechowski et al. 2014). Only a small number of infectious particles are released from bornavirus-infected cells (Tizard et al. 2016). RNPs are tethered to chromosomes and are passed from cell to cell upon cell division to maintain a persistent infection (Garcia et al. 2021).

49.3 Diagnostics

The potential of BoDV-1 to cause severe human encephalitis is now accepted in the scientific community, while studies and diagnostic approaches that aimed to show a correlation between direct as well as indirect detections of BoDV-1 and human psychiatric disorders remain controversial (compare "Bornavirus infections and mental disorders – a controversial issue") (Schwemmle 2001). The assessment of diagnostic tests for BoDV-1 in humans should take this controversial aspect of bornavirus research (history) into consideration. Therefore, a diagnostic algorithm for a case definition of human BoDV-1 infections has been proposed (Eisermann et al. 2021). The fundamental pillar of this case definition is the clinical presentation of an encephalopathy or encephalitis. For a confirmed case, additionally the detection of BoDV-1-specific RNA from a neural tissue sample/cerebrospinal fluid (CSF) or the detection of a BoDV-1 protein in a tissue section by immunohistochemistry (IHC) is required. Patients presenting with an encephalopathy or encephalitis and showing a positive serological test result are defined as probable case. For the retrospective postmortem confirmation of BoDV-1 cases, direct and indirect methods have been used.

As mentioned before, in the early twentieth century Joest and Degen described nuclear inclusion bodies in ganglion cells of diseased animals and herewith provided a first specific histological indication for the disease (Joest and Degen 1909). After the identification of a virus as causative pathogen and after deciphering its sequence and genome organization in 1994 (Briese et al. 1994; Cubitt et al. 1994), diagnosing Borna disease in animal dead-end hosts nowadays relies on histological and molecular biological approaches like reverse transcription-quantitative polymerase chain reaction (qRT-PCR) from neural tissue, supplemented by detection of BoDV-1 RNA (RNA in situ hybridization) and BoDV-1 proteins (IHC) in tissue sections (Schulze et al. 2020). For humans, qRT-PCR has been shown to be positive in samples from central and in some cases also from peripheral nerve tissue (Neumann et al. 2022; Niller et al. 2020). According to a published protocol, primers and probes for qRT-PCR were designed to target two genomic regions of BoDV-1, one in the x/p region, one in the m/g region (Schlottau et al. 2018). Depending on the test evaluation algorithm, a dual target PCR assay may increase specificity or sensitivity of the test system. The short amplicon of 75 bp within the m/g gene might be particularly suitable to detect degraded RNA in tissue samples of biobanks (Niller et al. 2020). In 2010, it has been shown that elements homologous to the nucleoprotein (N) gene of bornavirus have been integrated in the genomes of several mammalian species, including humans, as so-called endogenous Borna-like N (EBLN) elements (Horie et al. 2010). Therefore, qRT-PCR primers and probes for detection of BoDV-1 should be designed for genetic regions

that are not integrated in the human genome in order to avoid false positive test results. As a second molecular biological approach, next generation sequencing (NGS) further underlines the accuracy for the detection of BoDV-1 as human pathogen. In the first published cases of a BoDV-1 encephalitis, almost the complete 8.9 kb BoDV-1 genome could be derived from tissue samples of infected patients (Korn et al. 2018; Schlottau et al. 2018). Based on NGS-obtained sequences, BoDV-1 strains can be grouped into several regional clusters. Sequences derived from shrews, infected patients, and animals in regional proximity show closest similarities, rendering the possibility of a contamination by a laboratory strain unlikely (Niller et al. 2020). In addition, BoDV-1-specific RNA and proteins were detected in tissue sections of patients (Liesche et al. 2019). Direct detection methods are accompanied by serological tests. Indirect immunofluorescence assay (iIFT) is the most abundantly used in-house serological laboratory test. Persistently BoDV-1-infected cell lines (for example, Vero cells) are heat-fixed for staining with samples and a secondary, fluorophore-conjugated antibody. Positive samples show a nuclear fluorescence pattern. As a control for unspecific staining, uninfected cells should be included (Neumann et al. 2022). Disadvantages of the test are the time-consuming evaluation and the partly subjective and examiner-dependent accuracy of test results. Additional serological tests utilizing recombinantly expressed BoDV-1 proteins (mainly nucleocapsid and phosphoprotein) in form of line assays, immunoblots, Western blots, or ELISA are recommended (Eisermann et al. 2021). Recently, an ELISA using recombinant viral N, X, and P proteins has been described (Neumann et al. 2022). These tests are not commercially available but are performed as in-house tests. Thorough validations of these in-house tests are recommended to enable an evaluation with regard to sensitivity and specificity. Whether immune reactions against expressed EBLN might lead to false positive results in these tests remains unclear (Working Group Blood of the German Ministry of Health 2019).

In contrast to a postmortem diagnosis, a timely *intravitam* diagnosis of a BoDV-1 infection is challenging for several reasons: First, patients may initially present with an encephalopathy-like or Guillan-Barré-Syndrome (GBS)-like clinical picture (Coras et al. 2019). Initial CSF may only show elevated protein, but normal cell count. As a consequence, initiating BoDV-1 diagnostic might be delayed. Second, BoDV-1 is a cell-associated virus. RNA-loads are high in neural tissue but are low or in the range of the lower limit of qRT-PCR in CSF, if detectable at all (Niller et al. 2020). A negative qRT-PCR from CSF may not completely rule out BoDV-1 infection. As brain biopsies are invasive and not the first diagnostic approach, a direct detection *intra vitam* is challenging. Third, seroconversion mainly occurs only during the later course of the disease and, depending on the serological test system used, unspecific reactions might make a serological diagnosis difficult.

49.4 Pathophysiology of Symptomatic BoDV-1 Infection

Bornaviruses do not cause a cytopathic effect in cell culture. In affected individuals, neurons, oligodendrocytes, and astrocytes are infected in a nonlytic fashion. The pathophysiology of symptomatic bornavirus infections is attributed to three main

hallmarks: T-cell-mediated immunopathology, microglial activation, and metabolic disturbances of neurons (Tizard et al. 2016).

On the one hand, evidence for the T-cell-driven immunopathogenesis of bornavirus infections comes from animal experiments: Despite persistently high viral loads in brain and CNS, rats experimentally infected with BoDV-1 do not develop neurological symptoms when the immunosuppressive drug cyclophosphamide is administered shortly after virus inoculation – in contrast to animals without this immunosuppressive treatment (Narayan et al. 1983a). In a further study with rats, the immunosuppressive drug cyclosporine prevented neurological disease in infected rats only when administered before virus inoculation (Stitz et al. 1989). In infected rabbits, treatment with cyclophosphamide and/or glucocorticoids altered clinical signs and prolonged survival (Gierend and Ludwig 1981). Further, intracerebral infection of newborn β2-microglobulin-deficient C57BL/6 and MRL mice both lacking CD8 T cells did not cause neurological symptoms (Hallensleben et al. 1998). As further evidence for the immune-driven pathogenesis, adoptive transfer of spleen or lymph cells into immunosuppressed animals induced the manifestation of clinical symptoms (Narayan et al. 1983b; Richt et al. 1989).

On the other hand, there is evidence of immunopathogenesis in human patients as well: Brain tissue sections show parenchymal and perivascular infiltrates of CD4 and CD8 lymphocytes (Liesche et al. 2019). Patients with immunosuppression due to another medical condition (e.g., after organ transplantation) tended to survive longer than patients without immunosuppression (Niller et al. 2020). One of the two so far described survivors of a symptomatic BoDV-1 infection in the literature received cyclosporin as immunosuppressive medication because of a liver transplantation (Schlottau et al. 2018). T-cell pathology is assumed to be mediated by cytotoxic CD8 T cells that require help from CD4 T cell subsets. Neuronal damage is obviously mediated by CD8 T cells that are directed against viral proteins like BoDV-1 N protein and produce both IFNγ and TNFα (Amor et al. 2014; Baruch and Schwartz 2013; Tizard et al. 2016).

In experiments with rats, the peptide ASYAQMTTY within the viral N protein has been identified as a main epitope of MHC-I-(RT1.A)-restricted cytotoxic T cell response (Planz et al. 2001). Of special note is that transgenic mice expressing the nucleoprotein in neurons are resistant to experimental infection and clinical symptoms, which is presumably attributable to untimely expression of a viral nucleocapsid component, on the one hand, and immunological tolerance, on the other hand (Rauer et al. 2004). After the discovery of endogenous bornavirus-like elements that are integrated in a broad spectrum of vertebrate genomes, but are absent in the genomes of the most frequent accidental dead-end hosts such as horse, sheep, and most bird species, one could speculate on a potentially protective function of the endogenous bornavirus-like element N (EBLN), which is transcribed and translated into a protein in different tissues (Belyi et al. 2010; Fujino et al. 2014; Horie et al. 2010; Nobach et al. 2020). While CD8 T cells are found most abundantly in the brain parenchyma, perivascular infiltrates predominantly consist of CD4 T cells (Sobbe et al. 1997).

The infiltration of T cells in the brain is preceded by high levels of chemokines, especially IP-10. In a mouse model, astrocytes have been identified as a source of IP-10 (Sauder et al. 2000). Astrocytes induce the synthesis of IP-10 following stimulation with IFNα/β and other cytokines such as IL-1β and TNFα. IP-10 serves as a chemokine to attract especially T cells to the brain. Besides T-cell recruitment, microglial activation is an independent factor for neurocytotoxicity (Tang et al. 2021; Tizard et al. 2016). In addition, metabolic disturbances contribute to symptoms of BoDV-1 infections, for example, by inhibition of glutamate reuptake by astrocytes resulting in excessive extracellular glutamate concentrations that lead to neuronal damage (Ovanesov et al. 2007). Further, it has also been shown that neurogenesis is impaired by viral proteins (Scordel et al. 2015).

49.5 Clinical Presentation in Animals

Under natural conditions, BoDV-1 mainly infects horses, sheep, alpacas, and rarely other mammals living in endemic regions (Malbon et al. 2021; Metzler et al. 1976; Richt et al. 2000; Schmidt 1912, 1952; Schulze et al. 2020; Waelchli et al. 1985). Those animals are considered so-called *dead-end hosts*, meaning a host organism, which has suboptimal conditions for a pathogen leading to no further onward transmission of the disease. As a rule, Borna disease in horses is characterized by acute, frequently severe, and lethal encephalitis. The incubation period ranges from a few weeks to several months (Richt et al. 2000). The equine disease has usually a biphasic course: It starts with nonspecific symptoms such as hyperthermia, colic, anorexia, and constipation, followed by ataxia, depression, nervousness, and lethargy (Richt et al. 1997, 2000). In addition, behavioral changes occur, such as spreading and crossing the legs, pressing the head against the wall or other objects, as well as empty chewing and "pipe smoking" (horses remain still with feed hanging out of their mouths being unable to chew and swallow it). Due to these characteristic symptoms, Borna disease is also called "sad horse disease." As the disease progresses, paralysis can occur, animals frequently fall into a coma and decease. Retinitis also frequently occurs as a disease manifestation, often resulting in blindness. In 80–100% of cases, horses succumb due to Borna disease (Richt et al. 1997; Schmidt 1912, 1952). In sheep and alpacas, the course of the disease is similar to Borna disease in horses (Jacobsen et al. 2010; Malbon et al. 2021; Metzler et al. 1976; Schulze et al. 2020; Waelchli et al. 1985). In rare cases, similar disease courses have also been in described for zoo animals that had become infected naturally with BoDV-1 in endemic regions (Schüppel et al. 1994). In addition, a large number of other mammal species (e.g., rats, bank voles, and hamsters (Anzil et al. 1973; Gosztonyi et al. 2020; Kinnunen et al. 2011)) have been experimentally infected with BoDV-1.

There is controversy among experts as to whether the so-called *feline staggering disease* in cats can be attributed to a naturally acquired BoDV-1 infection (Lundgren et al. 1997; Nowotny 1999; Nowotny and Weissenböck 1995; Wensman et al. 2014; Working Group Blood of the German Ministry of Health 2019). Final proof that the

clinical picture of staggering disease does not only occur following experimental infection in the laboratory setting is still pending (Working Group Blood of the German Ministry of Health 2019).

49.6 Clinical Presentation in Humans

The clinical picture of Borna disease in humans has so far been described only for a two-digit number of cases (Coras et al. 2019; Eisermann et al. 2021; Finck et al. 2020; Frank et al. 2022; Korn et al. 2018; Liesche et al. 2019; Meier et al. 2022; Niller et al. 2020; Pörtner et al. 2019, 2020; Schlottau et al. 2018; Tappe et al. 2021). It is assumed that the incubation period of BoDV-1 in humans ranges from a few weeks to months, similarly to other dead-end hosts (Pörtner et al. 2019). In the initial transplantation cluster, infected organ recipients started to develop symptoms around 3 months after the transplantation; however, symptom onset might have been delayed by immunosuppressive therapy (Niller et al. 2020; Schlottau et al. 2018). According to current knowledge, humans infected with BoDV-1 show a short phase with nonspecific flu-like symptoms like fatigue, headache, elevated temperatures, and reduced general performance (Niller et al. 2020; Pörtner et al. 2019, 2020). This phase is followed by the occurrence of various neurological symptoms such as gait ataxia, dysphagia, confusion, memory deficits, seizures, hemiparesis, and progressive loss of consciousness (Finck et al. 2020; Niller et al. 2020). As mentioned before, in a few cases, patients showed symptoms mimicking a GBS (Coras et al. 2019; Liesche et al. 2019). In the further course, the disease progresses rapidly after a few days to weeks with increasing inflammatory parameters and dysphagia, progressive paresis, respiratory insufficiency, somnolence, and finally deep irreversible coma and death (Eisermann et al. 2021; Finck et al. 2020; Frank et al. 2022; Korn et al. 2018; Liesche et al. 2019; Meier et al. 2022; Niller et al. 2020). Refractory fever was also described for several cases (e.g., Finck et al. 2020; Niller et al. 2020; Pörtner et al. 2019).

Neuropathologically, a nonpurulent, lymphocytic sclerosing panencephalomyelitis is typical for BoDV-1 patients (Liesche et al. 2019). BoDV-1 encephalitis is characterized by marked inflammation with diffuse parenchymal lymphohistiocytic infiltration and perivascular cuffing and strong microglial activation (Frank et al. 2022; Liesche et al. 2019). However, on individual level, the inflammatory distribution patterns vary (Liesche et al. 2019). A substantial softening of brain tissue is present only in some patients. The same goes for edema (Liesche et al. 2019). Moreover, in most cases BoDV-1 patients show a characteristic pattern in MRI in both the early and the late disease stage. Since imaging in BoDV-1 patients can mimic Creutzfeldt-Jakob disease, it should be considered in differential diagnosis (Finck et al. 2020).

With the exception of one BoDV-1-infected transplant recipient (Schlottau et al. 2018) and another patient (Frank et al. 2022), all patients with a confirmed BoDV-1 infection died after a fulminant course of disease. In the majority of cases, the diagnosis could only made *postmortem*. However, with increasing frequency, the

diagnosis is made before the patient's death, which allows room for therapeutic attempts, e.g., with antiviral drugs that have proven effective against BoDV-1 in cell culture and animal experiments (Cubitt and de la Torre 1997; Jordan et al. 1999; Mizutani et al. 1998; Tokunaga et al. 2017). Whether there are other – possibly less severe or even asymptomatic – manifestations of BoDV-1 infections in humans is subject of current research.

49.7 Reservoir

The only proven natural reservoir host for BoDV-1 is the bicolored white-toothed shrew (*Crocidura leucodon*) (Bourg et al. 2013; Dürrwald et al. 2014). It was first discovered in Switzerland that this particular shrew species acts as a reservoir for BoDV-1 (Hilbe et al. 2006; Puorger et al. 2010). Further evidence for this was subsequently obtained by numerous detections of BoDV-1 in bicolored white-toothed shrews in endemic areas in Bavaria and other German federal states (e.g., Bourg et al. 2013). In *Crocidura leucodon*, the virus replicates in a large number of tissues (e.g., nervous system, epithelial and mesenchymal tissues) without causing pathological alterations. The virus is then excreted via many different routes, e.g., urine, feces, saliva, skin, and lacrimal fluid. It is assumed that there is a self-sustaining infection cycle in bicolored white-toothed shrews, and research points to the possibility of vertical and sexual transmission within the shrew population (Dürrwald et al. 2014; Nobach et al. 2015; Puorger et al. 2010). However, it needs to be further investigated whether other closely related species of the genus *Crocidura* can serve as virus reservoirs as well. Moreover, studies on the regional distribution of *Crocidura leucodon* and the proportion of BoDV-1-infected individuals in the shrew population would also be useful to better assess the potential (region-dependent) risk of human BoDV-1 infections.

49.8 Host Range

A wide range of mammal species can be infected with BoDV-1. Under natural conditions, horses and sheep are the species most frequently affected by Borna disease (Durrwald and Ludwig 1997). However, recently also alpacas have been increasingly affected as they seem to be highly susceptible to the virus (Jacobsen et al. 2010; Malbon et al. 2021; Schulze et al. 2020). Single cases of Borna disease have also been described in zoo animals (pygmy hippopotamus and sloth (Schüppel et al. 1994)), as well as rabbits (Metzler et al. 1978), donkeys (Bilzer et al. 1995; Zimmermann et al. 1994), goats (Caplazi et al. 1999), and cattle (Caplazi et al. 1994). Additionally, domestic animals such as cats (Wensman et al. 2014) or dogs (Weissenböck et al. 1998) can contract Borna disease. Humans can be infected with BoDV-1 as well (Coras et al. 2019; Korn et al. 2018; Niller et al. 2020; Schlottau et al. 2018). However, it is assumed that infections in larger mammals and humans functioning as dead-end hosts are due to rare, accidental spillover events.

49.9 Burden of Disease in Animals

Estimating the disease burden of BoDV-1 in domestic and farm animals is rather intricate. The obligation to report BoDV-1 infections in animals was only reintroduced in Germany in April 2020, after being suspended between 2011 and 2020 (Federal Ministry of Food and Agriculture: [Notifiable animal diseases] 2021). However, based on available reporting data, it can be assumed that Borna disease in animals – similar to infection in humans – is a rare incident that mostly occurs in sporadic cases. Large outbreaks associated with high mortality (and corresponding financial losses for animal owners), such as the name-giving outbreak among cavalry horses in Borna in the nineteenth century (Durrwald and Ludwig 1997) or recently in an alpaca herd in eastern Germany (Schulze et al. 2020), may be an exception.

49.10 Burden of Disease in Humans

Currently, it is almost impossible to assess the disease burden of human BoDV-1 infections. As of February 2022, the number of identified human cases, which occurred between 1996 and 2022 in Germany (of which a vast majority is in the federal state of Bavaria), is in the mid two-digit range. Mandatory notification of BoDV-1 infection in humans was introduced in Germany not before March 2020. No human cases have been reported from other countries (such as Switzerland, Austria, and Liechtenstein) where BoDV-1 is present in animals.

With the exception of two patients (Frank et al. 2022; Schlottau et al. 2018), all cases have died as a result of severe encephalitis and had to be hospitalized and given intensive medical care beforehand due to the disease. According to current knowledge, encephalitis caused by BoDV-1 is a very rare disease. Whether and to what extent there are underdiagnoses of this disease cannot be estimated at present.

49.11 Transmission

As already mentioned above, three cases of severe encephalitis occurred in organ recipients in 2016 after transplantation of solid organs (liver, kidneys) from the same donor (Schlottau et al. 2018). The organ donor – from whom no signs of a neurological or infectious disease previous to death are known – lived in a region in Bavaria in the south of Germany that is considered an endemic area for BoDV-1. Due to the BoDV-1 infection, two of the transplanted persons (kidney recipients) died; the third person (liver recipient) survived with severe health damage (Schlottau et al. 2018). The possibility of BoDV-1 transmission from person to person via organ transplantation is thus proven, even though this is likely an extremely rare transmission route.

The precise circumstances leading to transmission of BoDV-1 from the reservoir host, the bicolored white-toothed shrew, or possibly a so far unknown intermediate host to humans in a natural setting has not yet been conclusively clarified (Pörtner

et al. 2019, 2020). Several possible transmission routes are conceivable in this regard (compare "Unresolved issues").

The exact route of infection for natural BoDV-1 infection in animal dead-end hosts, such as horses, sheep, alpacas, and other susceptible mammals is also not fully understood yet. However, it is assumed that the infection might occur intranasally (Kupke et al. 2019; Morales et al. 1988). It is conceivable that the animals mentioned above come into contact with the infectious excretions of shrews with their nose and mouth while eating grass and hay. Moreover, it is assumed that BoDV-1 could then enter the brain via the nerve endings of the olfactory epithelium and the olfactory nerve (Gosztonyi 2008; Kupke et al. 2019; Morales et al. 1988). In experimental animal tests, rats could moreover be infected with BoDV-1 intracerebrally, intraocularly, and intraperitoneally (Gosztonyi and Ludwig 1995).

49.12 Bornavirus Infections and Mental Disorders: A Controversial Issue

Since the 1980s, there has been a scientific dispute about whether BoDV-1 is transmissible to humans and if so, what range of symptoms an infection with the virus may cause. Before the first evidence of BoDV-1 as a zoonotic pathogen causing severe encephalitis was provided in 2018 (Coras et al. 2019; Korn et al. 2018; Schlottau et al. 2018), the research focus on human BoDV-1 infections was on psychiatric diseases (Dürrwald et al. 2007; Hornig et al. 2012; Lipkin et al. 2011). Psychiatric or neurological diseases such as depressive disorders, bipolar disorders, schizophrenia, anxiety disorders, primary psychosis, and chronic fatigue syndrome were considered to be associated with human BoDV-1 infection. This was supposedly proven in studies in which the seroprevalence of persons with these diseases was investigated in comparison with healthy persons (e.g., Bode et al. 2001; Mazaheri-Tehrani et al. 2014; Zaliunaite et al. 2016).

A fundamental problem of this early research on human bornavirus infections was that the diagnostic detection methods used in the respective studies were nonstandardized procedures that have – up to the present day – never been independently validated. Later, research revealed a close genetic similarity of those virus strains reported before 2018 with laboratory BoDV-1 strains (Dürrwald et al. 2007; Schwemmle 2001). These findings suggest that sample contamination in the laboratory cannot be excluded (Dürrwald et al. 2007; Rubbenstroth et al. 2019). Moreover, the results of those early seroprevalence studies were non-reproducible. Another argument that speaks against the thesis of a large-scale occurrence of BoDV-1 in humans and for (rather rare) spillover events is the regional clustering (Rubbenstroth et al. 2020). In BoDV-1 infections confirmed since 2018, the detected virus strains almost always clustered with the types occurring locally (i.e., in the region of residence of the affected person) in the population of bicolored white-toothed shrews or also with virus isolates from other dead-end hosts (succumbed horses, sheep, alpacas, etc.) (Dürrwald et al. 2006; Rubbenstroth et al. 2019). In conclusion, robust and reproducible evidence of widespread human BoDV-1 infection – also outside known endemic areas in

parts of Germany, Switzerland, Austria, and Liechtenstein – and its association with psychiatric or neurological disorders are lacking up to the present day (Rubbenstroth et al. 2020).

49.13 Conclusion

As previously mentioned, it was proven only recently that BoDV-1 has the capability to cause severe encephalitis in humans (Schlottau et al. 2018). Subsequently, a few dozen human cases of BoDV-1 infections – which have mainly occurred in the German federal state of Bavaria – have been identified and reported to the public health authorities in Germany (Eisermann et al. 2021; Frank et al. 2022; Korn et al. 2018; Liesche et al. 2019; Meier et al. 2022; Niller et al. 2020; Schlottau et al. 2018; Tappe et al. 2021). Many of those cases have been detected by the retrospective screening of preserved brain material of persons deceased from encephalitis of unknown cause (Finck et al. 2020; Liesche et al. 2019; Niller et al. 2020). The earliest known case dates back to 1996 (Coras et al. 2019). Nevertheless, quite a few issues related to human BoDV-1 infections remain unresolved until the present day. For example, the question of how BoDV-1 is transmitted to humans has not been determined yet. Is transmission possible via virus-containing dusts or aerosols, similar to the possible transmission mode of hantavirus infections? Contaminated dusts or aerosols could, for instance, be generated when shrews excrete urine or feces in sheds, garages, haylofts, or similar premises. If these are then inhaled by humans, an infection may occur (Nobach et al. 2015). Or is there possibly an intermediate host? It might be conceivable, for example, that a domestic cat catches an infected shrew leading to BoDV-1 containing blood and/or tissue residues on its mouth or paws. If there is a direct contact with a human afterward, e.g., during cuddling or petting the cat, transmission of BoDV-1 could occur via smear infection. Another possibility could be the oral transmission of the virus via food contaminated, for example, with shrew urine or feces. Further, the uptake of the virus from the environment via skin lesions seems conceivable (Pörtner et al. 2019). In any case, first results from ongoing epidemiological studies suggest that transmission from shrews to humans via a direct contact is rather unlikely (Pörtner et al. 2020). Exploring and identifying routes of transmission is, however, crucial to prevent BoDV-1 infections in humans.

Furthermore, it has not yet been possible to clarify with certainty whether there are other, possibly milder manifestations of BoDV-1 infections in humans than the known encephalitis. Therefore, it might be worthwhile to conduct seroprevalence studies in endemic regions where several cases of BoDV-1 have been reported in humans and/or in animal dead-end hosts.

The question of whether other species besides *Crocidura leucodon* can be reservoir hosts for BoDV-1 has also not yet been conclusively clarified. A recent study, for example, found no evidence that European bats serve as reservoirs for BoDV-1 (Nobach and Herden 2020). For many other species, however, this still needs to be ruled out. Therefore, this issue should be the focus of further investigation, particularly with regard to species closely related to *Crocidura leucodon*.

Finally, it should be mentioned that hitherto the regional spread of BoDV-1 in Germany, Europe, and also worldwide has not been sufficiently investigated. Every year, encephalitis of unknown cause occurs in almost every region of the world. In the interest of early detection of encephalitis caused by BoDV-1 (or other, not yet identified, bornaviruses pathogenic to humans) and the identification of endemic areas, it seems reasonable to sensitize treating physicians (especially neurologists) to the possibility of a bornavirus infection. This applies to both human and veterinary medicine.

Also Beware of Varrigated and Provost's Squirrels: Human Infections with VSBV-1

In 2015, it became known that between 2011 and 2013, three breeders of varrigated squirrels (*Sciurus variegatoides*) in eastern Germany died of a newly discovered zoonotic pathogen, the varrigated squirrel bornavirus 1 (VSBV-1) (Hoffmann et al. 2015). Extensive molecular biology and immunohistological investigations indicate that the breeders had contracted VSBV-1 from infected squirrels (Hoffmann et al. 2015). Three years later, in 2018, it was retrospectively proven that an animal caretaker, who used to work in a zoological garden in northern Germany, died of VSBV-1 in 2013 as well. This person had contracted the disease from Provost's squirrels (Tappe et al. 2018). In the meantime, VSBV-1 has also been detected in several other squirrel species (Schlottau et al. 2017a, b). Like BoDV-1, VSBV-1 belongs to the genus *Orthobornavirus* in the family *Bornaviridae* (Hoffmann et al. 2015). At present, it is not clear whether VSBV-1 is present in animals other than squirrels. Transmission routes of VSBV-1 between squirrels as well as from squirrels to humans are also currently unknown. The squirrel breeders as well as the zoo animal caretaker had very close contact with the infected squirrels; therefore, a direct transmission (e.g., by scratching or biting) is likely (Hoffmann et al. 2015; Tappe et al. 2018). The infected squirrels themselves did not show any symptoms of the disease (Hoffmann et al. 2015; Schlottau et al. 2017a, b). Similar to BoDV-1, the infected individuals developed a severe encephalitis, from which they died after a period of 2–4 months after occurrence of first symptoms (Hoffmann et al. 2015; Tappe et al. 2018, 2019).

(Wang et al. 2020). The virus was identified among patients who had pneumonia and were linked to a wet-seafood market. This virus was initially known as novel coronavirus 2019 (nCoV-19) and then later was designated as severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) (Gorbalenya et al. 2020). This chapter summarizes the current understanding of the disease, the emergence of variants, and outcome.

Keywords

SARS-CoV-2 · COVID-19 · Coronaviruses

50.1 Introduction

The severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) was initially described in late 2019 in Wuhan City, China, and was reported to the World Health Organization (WHO) in December 2019 (Wang et al. 2020). The virus was identified among patients who had pneumonia and were linked to a wet-seafood market. This virus was initially known as novel coronavirus 2019 (nCoV-19) and later was designated as severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) (Gorbalenya et al. 2020). This chapter summarizes the current understanding of the disease, the emergence of variants, and outcome.

50.1.1 The Virus

SARS-CoV-2 is a member of the β-type of coronaviruses. The coronaviruses are large, enveloped, positive strand RNA viruses and have four genera (alpha, beta, delta, and gamma). Human coronaviruses belong to the alpha or the beta genera (Chan et al. 2015). The initial four known coronaviruses were HCoV-229E, NL63, HCoV-OC43, and HKU1, and these caused human common cold and gastrointestinal symptoms. Two of these viruses, HCoV-229E and HCoV-OC43, were known since the 1960s. The HCoV-229E is an alphacoronavirus, and its animal host is thought to be bats and alpacas as the intermediate host (Crossley et al. 2012). The HCoV-OC43 is a betacoronavirus, with rodents as the host and cattle as the intermediate host (Corman et al. 2015). The HCoV-NL63 is an alphacoronavirus and HCoV-HKU1 is a betacoronavirus, and these emerged from bats and rodents, respectively (Tao et al. 2017; Van Der Hoek et al. 2004; Woo et al. 2005). In 2002, Severe Acute Respiratory Syndrome Coronavirus (SARS-CoV) emerged and caused a limited outbreaks in many countries. The Middle East respiratory syndrome coronavirus (MERS-CoV) was initially identified in Saudi Arabia in 2012 and had caused limited outbreaks internationally. In 2019, the SARS-CoV-2 was identified initially in Wuhan, China (Lu et al. 2020; Zhu et al. 2020).

SARS-CoV-2 belongs to the coronaviruses, and the 5′-end of the genome includes the replicase gene and has two overlapping open reading frames (ORF).

Table 1 Function of coronavirus structural proteins

Structural protein	Function	Host cell receptors
Spike (S)	Facilitates viral attachment to host cell receptors Fusion between the envelope and plasma membrane Inducer of neutralizing antibodies	HLA-A2-restricted CD8 + T cells (SARS-CoV and MERS-CoV) Neutralization antibodies (SARS-CoV)
Envelope (E)	Viral envelope assembly	
Membrane (M)	Type III glycoprotein Has three parts: amino-terminal ectodomain, a triple-spanning transmembrane domain, and carboxyl-terminal inner domain	
Nucleocapsid (N) proteins	Highly basic phosphoprotein Needed in the virion Modulates viral RNA synthesis	CD4 + T cells (SARS-CoV)

Table 2 Comparison between the different coronaviruses

	Year of emergence	Infected cells	Receptors
SARS-CoV	2002	Epithelial respiratory cells, T cells	Angiotensin-converting enzyme 2 (ACE2)
MERS-CoV	2012	Alveolar epithelial cells and immune cells	DPP-4
SARS-CoV-2	2019	Epithelial respiratory cells, T cells	Angiotensin-converting enzyme 2 (ACE2)

These ORF are as follows: ORF 1a and 1b (Decaro and Lorusso 2020) and four ORFs encoding the common coronavirus structural proteins. These structural proteins are spike (S), envelope (E), membrane (M), and nucleocapsid (N) proteins (Decaro and Lorusso 2020) with different functions (Table 1). The receptor for the SARS-CoV-2 is the angiotensin 1-converting enzyme 2 (ACE2) (Lan et al. 2020; Shang et al. 2020) (Table 2).

50.2 Zoonotic Origin

The origin of the SARS-CoV-2 had been debated with two possibilities of being a zoonotic disease or a laboratory escape (Holmes et al. 2021). Phylogenetic analysis suggests one or more events of contacts with infected animals and/or traders with multiple spillover events (Holmes et al. 2021; Rambaut et al. 2020). One study found that SARS-CoV-2 is 96.2% identical to a bat CoV, RaTG13, and share 79.5% identity (Wrobel et al. 2020).

Zoonotic origin of previous coronaviruses had been studied and specifically for the previously emerged MERS-CoV and had been reviewed previously (Al-Tawfiq

et al. 2014). The first indication of the animal origin was related to the isolation of a bat coronavirus that resembles MERS-CoV from wild bats in the Kingdom of Saudi Arabia (Memish et al. 2013). This evidence was based on one piece of 190-nucleotide fragment of the RNA-dependent RNA polymerase (*RdRp*) from an Egyptian tomb bat (*Taphozous perforatus*) (Memish et al. 2013). The amplified sequenced was identical to that of the MERS-CoV sequence from the first index human case (Memish et al. 2013). Subsequent studies found high prevalence of MERS-CoV antibodies in dromedary camels from different regions of the globe, including the Arabian Peninsula, North Africa, and Eastern Africa (Reusken et al. 2013a, b, 2014; Hemida et al. 2013; Alexandersen et al. 2014; Nowotny and Kolodziejek 2014; Corman et al. 2014). Anti-MERS-CoV antibodies were found in camel sera collected in the 1990s (Corman et al. 2014; Hemida et al. 2014a; Alagaili et al. 2014). In addition to the detection of anti-MERS-COV antibodies, rt-PCR detected MERS-CoV from samples obtained from dromedary camels (Alagaili et al. 2014; Hemida et al. 2017; Wernery et al. 2015; Khalafalla et al. 2015; Farag et al. 2015; Stalin Raj et al. 2014; Yusof et al. 2015). Viral cultures also showed viable MERS-CoV from samples obtained from dromedary camels (Wernery et al. 2015; Stalin Raj et al. 2014; Hemida et al. 2014b; Briese et al. 2014; Haagmans et al. 2014). Sequence of the MERS-CoV spike, ORF3-4a, and nucleocapsid regions were identical from asymptomatic human contacts and their camels (Al Hammadi et al. 2015).

50.3 Clinical Features

All coronaviruses share the ability to cause mild or asymptomatic disease to severe and fatal illness. For COVID-19, a cohort of initial 41 reported cases showed a case-fatality rate of 14·6% (Huang et al. 2020a) and 11% of another 99 cases died due to multi-organ failure (Chen et al. 2020). In a meta-analysis, patients had a mean age of 51 years with 1:2:1 of male to female (Baradaran et al. 2020). The most common clinical symptoms were studied in a meta-analysis and included 281,461 patients and found that the mean age was 46.7 years and 51.8% were male (Li et al. 2021). The rate of severe disease was 22.9% and an overall case-fatality rate of 5.6%. The associated factors with higher mortality were older age, male gender, diabetes, and hypertension (Li et al. 2021). Another meta-analysis found that the most common symptoms were as follows: fever 81.2%, cough 58.5%, fatigue 38.5%, dyspnea 26.1%, and production of sputum 25.8% (Alimohamadi et al. 2020). Patients with SARS-CoV-2 infection may also have coinfection or superimposed infection. One meta-analysis included 31,953 patients with an overall pooled rate of a laboratory-confirmed bacterial infection of 15.9% (95% CI 13.6–18.2), 3.7% (95% CI 2.6–4.8) had fungal infections, and 6.6% (95% CI 5.5–7.6) had other respiratory viruses (Alhumaid et al. 2021). There had been multiple studies showing disparity in clinical outcome and presentation of patients with COVID-19 among different racial and geographic locations (Tirupathi et al. 2020). The presence of comorbidities was significantly higher in the Americas than in Asia. Most Asian patients had fever

(95% CI 0.70–0.81), most Oceanian patients had cough (95%CI 0.68–0.70), and dyspnea was common in the Americas (95%CI 0.33–0.64), and Europe (95%CI 0.29–0.64) (Tian et al. 2022). The loss of smell and taste were more common among European patients (95%CI 0.60–0.97) (Tian et al. 2022).

The case fatality rate was estimated to be 0.4% for symptomatic cases, 0.05% for those 0–49 years of age, and 1.3% for those ≥65 years (Giannouchos et al. 2020). The presence of other comorbidities, such as hypertension, obesity, and diabetes, were common among COVID-19 patients and were independent correlates of hospitalization and adverse outcomes (Guan et al. 2020a; Docherty et al. 2020). Adverse events were associated with COPD (HR 2.681), diabetes mellitus (1.59), hypertension (1.58), and malignancy (3.50). The risk of death was lower in those with one comorbidity (HR 1.79) compared to those two or more comorbidities (HR 2.59) (Guan et al. 2020b). The occurrence of comorbidities was as follows: hypertension (21%), diabetes mellitus (11%), cerebrovascular disease (2.4%), cardiovascular disease (5.8%), chronic kidney disease (3.6%), chronic liver disease (2.9%), chronic pulmonary disease (2%), malignancy (2.7%), and smoking (8.7%) (Baradaran et al. 2020). In another meta-analysis of 2401 COVID-19 patients, 66.6% of the deceased were male, with a median age of 69.9 years (Qiu et al. 2020). The deceased patients were more likely to have thrombocytopenia, higher C-reactive protein (CRP), and lactate dehydrogenase (LDH) at admission and more likely to develop acute respiratory distress syndrome (ARDS) (OR = 100) and shock (OR = 96.6) (Qiu et al. 2020). In children, multiple risk factors are also associated with severe disease and include the following: obesity (RR, 1.43), diabetes (RR, 2.26), chronic lung disease (RR, 2.62), heart disease (RR, 1.82), neurologic disease (RR, 1.18), and immunocompromised status (RR, 1.44) (Choi et al. 2022).

50.4 Diagnosis

The diagnosis of SARS-CoV-2 relies mainly on real-time PCR of respiratory tract samples. There are multiple RT-PCR based assays for the diagnosis of SARS-CoV-2. These tests detects one or more of the subunits of SARS-CoV-2 such as: the E-gene PCR (specific for bat(−related) betacoronaviruses, and thus detects both SARS-CoV-1 and SARS-CoV-2), S-gene, ORF1ab, N, or RdRp, in combination (van Kasteren et al. 2020). In a comparison of 7 RT-PCR tests for the detection of SARS-CoV-2, all tests detected all samples with the highest concentrations of SARS-CoV-2 RNA (Ct ≤ 34.5 in an in-house E-gene PCR assay). It was stated that of all 416 samples in one report, Ct value >34.5 was present in 3.6% of samples (van Kasteren et al. 2020). Since patients with mild or no symptoms or those during later stages of the infection may have a lower viral load (Zou et al. 2020), and thus the choice of the diagnostic PCR tests was limited to those from R-Biopharm AG, BGI, KH Medical, and Seegene (van Kasteren et al. 2020). The diagnostic accuracy of routinely used PCR tests are still able to detect different variants such as Delta and Omicron (World Health Organization 2021a). Omicron variant has a large number of

mutations in the S including Δ69–70 (Quarleri et al. 2021), and this deletion leads to a dropout in the TaqPath PCR test (Ferré et al. 2021).

Serologic testing of SARS-CoV-2 relies on the detection of anti-spike (S) protein, and it is not known which part of the S-protein offers the best site for antibody development (Petherick 2020). The presence of anti-SARS-CoV-2 IgM antibodies was detected in 50%–81%, and IgG antibodies were present in 81%–100% of tested patients (Zhang et al. 2020). The S1 IgG and IgA ELISAs showed lower specificity and variable sensitivity (Okba et al. 2020). In a meta-analysis, an overall sensitivity of IgG and IgM was 84.3% for enzyme-linked immunosorbent assays (ELISA), 66.0% for lateral flow immunoassays (LFIAs), and 66% for chemiluminescent immunoassays (CLIAs) (Lisboa Bastos et al. 2020). In another meta-analysis, the overall pooled sensitivity was 0.5856 for IgG, 0.4637 for IgM, and 0.6886 for IgG-IgM based on LFIA tests as compared to rRT-PCR method (Vengesai et al. 2021). It was also found that the sensitivity of commercial kits was 65% compared to 88.2% for noncommercial tests utilizing LFIAs (Lisboa Bastos et al. 2020).

The utilization of N protein as serology was evaluated in 914 sera, and the study showed that the test had a sensitivity and specificity of 76.27 and 98.78%, respectively (Deng et al. 2021). Another study showed that the positivity rate of S1 and N antigens was 64.06% of 64 COVID-19 patients (Ogata et al. 2020), and an additional study found a sensitivity and specificity of 98.4% and 79.3%, respectively, within the first 2 weeks from symptoms onset (Ahava et al. 2022). Thus, it was suggested that this type of serology for N protein could be used in the diagnosis of an acute COVID-19 disease (Le Hingrat et al. 2021; Lebedin et al. 2020).

50.5 Emergence of Variants

The emergence of multiple SARS-CoV-2 variants is of great concern globally (Temsah et al. 2021). The variants are classified as variants of interest (VOI) and variants of concern (VOC) (Centers for Disease Control and Prevention (CDC) 2021). VOC refers to variants that have increased transmissibility or virulence, and VOI refers to those with the potential to cause the disease. According to the United Sates CDC, VOC is defined as “any variant with increased transmissibility, more severe disease (as defined by increased hospitalizations or deaths), significant reduction in neutralization by antibodies generated during previous infection or vaccination, reduced effectiveness of treatments or vaccines, or diagnostic detection failures” (Centers for Disease Control and Prevention (CDC) 2021). On the other hand, the definition of VOI is “any variant with specific genetic associated with changes to receptor binding, reduced neutralization by antibodies generated against previous infection or vaccination, reduced efficacy of treatments, potential diagnostic impact, or predicted increase in transmissibility or disease severity” (Centers for Disease Control and Prevention (CDC) 2021). These mutations that could appear due to mutation on the RBD and the NTD (Greaney et al. 2021). The Delta variant

was first identified in India late 2020 and then had spread worldwide and caused a new wave (Centers for Disease Control and Prevention (CDC) 2021; ECDC 2021). Delta variant, B.1.617.2, has a high rate of transmission (Yadav et al. 2021). On November 24, 2021, the WHO was notified of the emergence of the Omicron variant (World Health Organization (WHO) 2021b, c). The Omicron variant has about 50 mutations including 30 mutations in the S-protein (World Health Organization 2021; Thakur and Kanta Ratho 2021). The estimated re-infection hazard during the Omicron variant in South Africa was 2.39 (95 CI: 1.88–3.11) vs. the first wave of the epidemic (Pulliam et al. 2021). There was reduction in the neutralization of convalescent serum against the Beta and Delta variants in comparison to the initial variant (Liu et al. 2021; Wibmer et al. 2021; Planas et al. 2021).

50.6 Vaccines

Efforts to fight the SARS-CoV-2 have focused on the spike protein, which is crucial for the virus to enter the cells (Du et al. 2009). The spike protein is divided into an N-terminal S1 domain, which allows the virus to attach to the host cells through the angiotensin-converting enzyme (ACE) 2 receptor and a C-terminal S2 domain, which allows the virus to adhere to the cell membrane (Hoffmann et al. 2020; Huang et al. 2020b). The S1 domain has two specific domains known as the N-terminal domain (NTD) and a receptor-binding domain (RBD) (Lan et al. 2020). Most of the vaccines that have been developed and some monoclonal antibodies that have been used in combatting this virus have specifically focused on the S domain (Krammer 2020; Baden et al. 2021). Vaccines efficacy depends on stimulating an appropriate antibody and T cell response to S protein (Krammer 2020). The emergence of the Omicron variant had increased the debate about the need for COVID-19 vaccine booster dose, as the current dosing regimen might not provide an adequate antibody response to protect against this variant (Graham 2021).

The neutralizing antibodies against the Omicron variant were reduced at 11.4, 37.0, and 24.5 times for those who had two or three doses of the BNT162b2 vaccine (Wilhelm et al. 2021). Additionally, the neutralizing effects from heterologously vaccinated ChAdOx1 and BNT162b2 were not detected (Wilhelm et al. 2021). Receiving a booster dose of BNT162b2- vaccine was associated with a significant increase in the levels of neutralizing antibodies against Omicron variant (Wilhelm et al. 2021).

The results from the inactivated whole-virion SARS-CoV-2 (CoronaVac) vaccine did not show any detectable neutralizing antibodies against the Omicron variant and BNT162b2 vaccine showed 35.7–39.9-fold reduction in antibodies activity (Lu et al. 2021). Another study showed 29·eightfold reduction in neutralizing antibodies in patients who had homologous BNT162b2 vaccine (Dejnirattisai et al. 2021). Another study showed a 22-fold reduction in neutralizing antibodies in infected-vaccinated and vaccinated patients (Cele et al. 2021). Thus, there seems to be a need for booster doses (Burki 2021) and possibly the need to develop a universal coronavirus vaccines (He et al. 2021; Cohen 2021; Morens et al. 2021).

50.7 Therapy

The use of convalescent plasma was investigated early in the course of COVID-19. A meta-analysis included 1138 control and 1231 randomized to convalescent plasma therapy (Troxel et al. 2022). The mortality odd ratio was 0.88 at day 14 and 0.85 at day 28 (Troxel et al. 2022). Another meta-analysis showed that convalescent plasma was associated an overall discharge rate of 75.7% and a lower risk of staying in hospital with a relative risk of 0.946 (Agarwal et al. 2021).

The use of steroid for COVID-19 patients followed the publication of the RECOVERY trial and was the landmark for such improvement in the survival of patients requiring supplemental oxygen. The study used daily dexamethasone at a dose of 6 mg intravenous or oral (RECOVERY Collaborative Group 2020). The rate of death was 29.3% vs. 41.4% among those on mechanical ventilation and 23.3% vs. 26.2% among those receiving oxygen, in the dexamethasone group vs. the control group, respectively (RECOVERY Collaborative Group 2020). A meta-analysis found that all-cause mortality was lower with methylprednisolone (odds ratio [OR]: 0.16, 95% CI: 0.03–0.75] (Cheng et al. 2021).

50.8 Post-COVID-19 Syndrome

The development of persistent symptoms after COVID-19 recovery was noted in 13.3–96% of patients (Chopra et al. 2021; Davis et al. 2021; Sudre et al. 2021; Norton et al. 2021; Michielsen et al. 2003). The occurrence of such symptoms after 14 weeks was 50.9% (Moreno-Pérez et al. 2021). The exact reasons for the occurrence of post-COVID-19 symptoms is not known, and it is thought that the virus may trigger a substantial immunologic responses (Buonsenso et al. 2021; Kayaaslan et al. 2021; Menges et al. 2021).

It is also thought that disease severity, age, and comorbidity were associated with persistent symptoms (Kamal et al. 2021; Tenforde et al. 2020). The most common post-COVID-19 symptom was fatigue (Chopra et al. 2021; Davis et al. 2021; Sudre et al. 2021; Norton et al. 2021). In addition, 9.5% and 13.2 may have depression or anxiety, respectively. In a meta-analysis, the prevalence of depression, anxiety, and insomnia were 15.97%, 15.15%, and 23.87%, respectively (Cénat et al. 2021).

50.9 Conclusion

The current estimates may be variable depending on the definition used and the time frame. According to the US CDC, post-COVID conditions include: long COVID; post-acute COVID-19; long-term effects of COVID; post-acute COVID syndrome; chronic COVID; long-haul COVID; late sequelae; and post-acute sequelae of SARS-CoV-2 infection (PASC) (CDC: https://www.cdc.gov/coronavirus/2019-ncov/hcp/clinical-care/post-covid-conditions.html). According to the US CDC, "post-COVID conditions are present if recovery does not occur after the 4-week acute phase even though many patients continue to recover between 4 and 12

weeks." In conclusion, the current SARS-CoV-2 pandemic had caused significant morbidity, mortality, and healthcare disparity. Scientific studies had confirmed the efficacy and safety of vaccines and the advantage of steroid especially for patients requiring supplemental oxygen therapy. The continued emergence of SARS-CoV-2 variants is a continued challenge for ending this pandemic.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_42

Abstract

First reports on biological warfare date as early as the fourteenth century BC, while bioterrorism is a phenomenon of modern times. Bioterrorism means the deliberate release of viruses, bacteria, or other agents used to cause illness or death in people, animals, or plants. Infectious agents or their toxins, often known for long as the cause of classical infectious diseases may be used for bioterroristic purposes, but not all of them are equally suited as biological weapons.

Anthrax, caused by *Bacillus (B.) anthracis*, a gram-positive spore-forming rod, is a very long known animal disease with zoonotic potential. The ability to form endospores makes *B. anthracis* especially suitable for bioterroristic use as these endospores are highly resistant to environmental influences, disinfectants, heat, or radiation and can easily be aerosolized. *B. anthracis* possesses two main virulence factors, the anthrax toxin and the ability of capsule formation. Both virulence factors are plasmid-encoded. Human anthrax manifests itself as cutanaeous anthrax, alimentary anthrax, inhalational anthrax, and sometimes as injectional anthrax, especially in intravenous drug addicts.

Tularemia is a zoonosis with a broad host range. Wildlife animals are the main reservoir for humans. It is especially a disease of hares, rabbits, and other rodents. As humans are highly susceptible for tularemia, its agent, *Francisella (F.) tularensis*, which can be transmitted by arthropod vectors, by contact, by contaminated water or food, or even by aerosol, is supposed to have a bioterroristic potential, although no attempts of bioterroristic misuse have been known so far. While the most virulent subspecies *F. tularensis ssp. tularensis* is confined to North America, a less virulent subspecies, *F. tularensis ssp. holartica*, is widely distributed over the Northern hemisphere, predominantly over North America, Scandinavia, Russia, and Japan. Human tularemia is a febrile, inflammatory disease, which starts with unspecific symptoms like headache, growing pains, fever, chills, and weakness. The further course of disease depends on the agent's virulence and its route of entry.

Keywords

Bioterrorism · Anthrax · Tularemia · Bacillus anthracis · Francisella tularensis

First reports on biological warfare date as early as the fourteenth century BC, when the Hittites sent diseased rams, possibly infected with tularemia to their enemies (Barras and Greub 2014). Successful attempts of biological warfare with bubonic plague or small pox are known from medieval times up to the nineteenth century (Barras and Greub 2014; Oliveira et al. 2020). During World War I and II some countries had scientific programs for developing biological weapons, but an applicable weapon has never been delivered (Oliveira et al. 2020). During World War I, the German Reich tried to infect animals in neutral countries with anthrax or glanders, especially to hinder the delivery of horses for military use (Mogridge et al. 2010).

The Geneva Protocol for the Prohibition of the Use in War of Asphyxiating Poisonous or Other Gases and of Bacteriological Methods of Warfare was ratified in

1925 as a consequence of World War I. In 1972 the Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction (Biological Weapons Convention, BWC) was signed by more than 100 nations (Barras and Greub 2014; Oliveira et al. 2020).

Bioterrorism means the deliberate release of viruses, bacteria, or other agents used to cause illness or death in people, animals, or plants. Bioterrorism intends to initiate mass casualties, terror, panic, social disruption, and economic loss due to ideological, religious, or political beliefs (Jansen et al. 2014; Barras and Greub 2014; Oliveira et al. 2020; Janik et al. 2019). In the near past Anthrax spores were used in a bioterroristic raid in the USA ("Amerithrax") during autumn 2001 shortly after the attack of 9–11, when letters containing highly concentrated anthrax spores were sent by mail. Twenty-two cases were reported, 11 of them suffered from inhalational anthrax with 5 fatalities and the remaining 11 cases were cutaneous anthrax (Oliveira et al. 2020).

Infectious agents or their toxins, often known for long as the cause of classical infectious diseases may have a dual use option in using them for bioterroristic purposes. Therefore it can be quite difficult to discern a naturally occurring outbreak from the deliberate release of pathogens or their toxins, especially as for the last three decades outbreak events rose constantly in number and complexity (Barras and Greub 2014; Koch et al. 2020).

Not all naturally occurring pathogens or their toxins are equally suited as biological weapons. The CDC displays three categories of organisms or toxins according to their easiness of spread, the severity of the illness, and the public and social aspects following their release. Category A comprises biological agents and toxins, which can be easily disseminated or transmitted from person to person; result in high mortality rates and have the potential for major public health impact; might cause public panic and social disruption and require special action for public health preparedness such as *Bacillus anthracis* (anthrax), *Clostridium botulinum* toxin (botulism), *Yersinia pestis* (plague), *Variola major* virus (smallpox), *Francisella tularensis* (tularemia) or filoviruses, arenaviruses, and other hemorrhagic fever viruses (viral hemorrhagic fevers) (N N 2007; CDC 2021).

In the following, anthrax and tularemia will be presented as examples for zoonotic bacterial agents with an indwelling bioterroristic potential.

51.1 Anthrax

Anthrax is a very old disease, which is supposed to be mentioned in the Holy Bible as the fifth plague of Egypt. It has been reported since about 1500 B.C., depicted by the oldest Hebrew, Greek, and Roman authors (Böhm 1995; Koch 1885). The etiology of anthrax was proven by Robert Koch in 1876 (Selbitz 2011). Anthrax is primarily an animal disease, but with a broad host range including man. Especially in former times lots of people fell ill and often died from gastrointestinal anthrax (Koch 1885). In those days eating anthrax infected animals was a major source of human infection besides inhalational and cutaneous anthrax.

51.1.1 Etiology

Anthrax is caused by *Bacillus anthracis*, a large, facultatively anaerobic, Gram-positive rod, which is nonmotile and nonhemolytic on blood agar, although a few strains may show a weak hemolysis under the colony. The bacilli appear as single rods or in chains, especially in host tissue. *Bacillus anthracis* grows with flat, dry, rough, grayish colonies with curved and curled peripheral projections, which give them a "medusa head"-like appearance. As a non-fastidious organism, *Bacillus anthracis* grows well on a broad range of nonselective nutrient media (Picture 1).

Bacillus anthracis belongs to the *Bacillus cereus* group together with *Bacillus cereus*, *Bacillus thuringiensis*, *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus weihenstephanensis*, *Bacillus cytotoxicus*, *Bacillus toyonensis*, and other species (Ehling-Schulz et al. 2019; Méndez Acevedo et al. 2020). All members share a closely related phylogeny, a highly conserved genome, and a very similar 16S RNA sequence (24). Recent genomic analyses reveal a much greater variety among the *Bacillus cereus* group, suggesting the existence of at least 57 genomospecies (Ehling-Schulz et al. 2019; Torres Manno et al. 2020). Thus, it is difficult to discern those species by mere biochemical means, so that besides phenotypical criteria like biochemical reactions, motility, penicillin susceptibility, gelatin liquefaction, or capsule formation under 10% CO_2, the detection of virulence plasmids is useful for species identification (Böhm 1995; Selbitz 2011; Quinn et al. 2011; Markey et al. 2013; Ehling-Schulz et al. 2019). Meanwhile, however, *Bacillus cereus* strains were detected, harboring anthrax-like virulence plasmids and causing an Anthrax-like disease in primates in Cameroon and Côte d'Ivoire as well as cutaneous lesions and respiratory disease resembling anthrax in metal workers (Ehling-Schulz et al. 2019; Leendertz et al. 2006; Klee et al. 2006).

Bacillus anthracis possesses the ability to form endospores. These endospores have a remarkable tenacity towards environmental factors such as heat, cold, dryness, radiation, and a great range of disinfectants. To reduce anthrax spores by 90% within a minute, temperatures up to 110 °C are necessary (Böhm 1995). The

Picture 1 *Bacillus anthracis* on sheep-blood agar (Incubation 37 °C, 18 h)

endospore formation is enhanced by oxygen and starts when *Bacillus anthracis* is set free from an infected host by bleeding or opening of the carcass. The first endospores can be detected after 4–10 h and the sporulation process is finished after 24–48 h (Mogridge et al. 2010). Those endospores remain viable in soil for decades. Under laboratory conditions a viability of up to 70 years is proven (Böhm 1995). After inhalation or ingestion the spores are phagocytosed by phagocytes and dendritic cells and transported to the lymph nodes. Some spores germinate quickly, but others can remain ungerminated for multiple days (Ehling-Schulz et al. 2019).

51.1.2 Global Distribution

Anthrax was once known all over the world, but national reduction programs in the first half of the twentieth century like the ban to bury animal carcasses and slaughter waste as well as vaccination programs have confined anthrax to some endemic regions in the Mediterranean region, Central and South America, Africa, Asia, and the Far and Middle East, known as the "anthrax belt" from Turkey to Pakistan. In North America, northern Alberta and the Northwest territories are endemic regions, while sporadic outbreaks are reported from northwest Mississippi, southeast Arkansas, and western Texas. However, sporadic cases may occur in nearly all countries (OIE 2021; WHO 2008; Ehling-Schulz et al. 2019; Pilo and Frey 2018).

51.1.3 Virulence Factors

Bacillus anthracis expresses different minor virulence factors such as phospholipases, proteases, iron uptaking proteins, siderophores, Immune Inhibitor A (InhA), and Anthrolysin O, which are encoded chromosomally or on plasmids (Mogridge et al. 2010; Ehling-Schulz et al. 2019; Schacherl and Baumann 2016). Moreover, virulent strains of *Bacillus anthracis* possess two major plasmids, pX01 and pX02. The 182 kb plasmid pX01 contains 217 genes including the three components of anthrax toxin, PA (protective antigen), EF (edema factor), and LF (lethal factor). Plasmid pX02 consists of 95 kb with 113 genes including the operon capBCDAE containing the capsule forming genes (Mogridge et al. 2010; Pilo and Frey 2018). *Bacillus anthracis* strains, which bear only one of these two virulence plasmids are non-virulent or significantly attenuated (Markey et al. 2013). Those attenuated strains may be used as live vaccines (Böhm 1995).

51.1.4 Anthrolysin O

Anthrolysin O is a cholesterol-dependent cytolysin resembling pore-forming toxins of other Gram-positive pathogens. It shows lytic effects against phagocytes by membrane destabilization and weakens the barrier function of epithelial cells (Ehling-Schulz et al. 2019).

51.1.5 Immune Inhibitor A (InhA)

InhA is a protease with low specificity thus having different effects. It damages the blood–brain barrier and contributes to hemorrhagic anthrax meningitis by cleaving zonula occludens-1 protein. InhA generally supports the spreading of *Bacillus anthracis* by degrading host tissue. InhA cleaves the vonWillebrand factor and its regulator ADAMTS13 promoting coagulopathy. InhA contributes to the activation of acute-phase response proteins in the liver supporting inflammation and by cleaving BsIA, an adhesion factor of *Bacillus anthracis* itself; it modulates adhesion and dissemination of *Bacillus anthracis* (Ehling-Schulz et al. 2019; Schacherl and Baumann 2016).

51.1.6 Capsule

The capsule consists of anionic polypeptides, i.e., linear chains of poly-γ-D-glutamic acid linked to the peptidoglycan of the bacterial cell wall. These long chains exceed a molecular weight of 400 kDa. They are protease-resistant and confer protection against the complement system and phagocytosis being poorly recognized by phagocytes due to their anionic charge. By masking immunogenic surface structures they prevent the humoral immune response. The capsule is of low immunogenicity itself. Shedding capsule poly-γ-D-glutamic acid into the bloodstream during infection leads to the production of inflammatory cytokines and contributes to the systemic inflammation at the terminal state of the infection. The capsule is expressed especially within the host. These conditions can be mimicked during culture, growing the bacteria on bicarbonate agar under enhanced CO_2 partial pressure (5–10%). This yields very moist and even slimy colonies – a phenomenon unique to *Bacillus anthracis* compared to other members of the *Bacillus cereus* group. *Bacillus anthracis* tends to lose the capsule coding plasmid pX02 easily, especially when growing in rich soil (Böhm 1995; Quinn et al. 2011; Markey et al. 2013; Mogridge et al. 2010; Ehling-Schulz et al. 2019; Pilo and Frey 2018).

51.1.7 Anthrax Toxin

The production of anthrax toxin is also enhanced by a higher CO_2 pressure (5–10%) and temperatures of about 37 °C. The highest toxin production occurs during the late logarithmic growth phase. Anthrax toxin consists of two binary components, lethal toxin and edema toxin. Both toxins are formed with lethal factor (LF, 90 kDa) or edema factor (EF, 89 kDa) as the enzymatic component and protective antigen (PA, 83 kDa), which is the receptor-binding subunit (Mogridge et al. 2010). PA recognizes two cell receptors, the capillary morphogenesis genes 2 product (CMG2 or ANTXR2) and the tumor endothelial marker 8 (TEM8 or ANTXR1) and is cleaved after binding by a furin-like protease. The resulting 63 kDa protein forms heptamers or octamers in the host cell membrane, which LF or EF binds to. These complexes are internalized by endocytosis and LF or EF is set free in the cytosol by

conformational changes of PA due to the acidic environment in the endosome (Pilo and Frey 2018).

Edema toxin is a calcium- and calmodulin-dependent adenylate cyclase. Its catalytic rate exceeds this of mammalian adenylate cyclases 100fold. Disturbing cellular signaling pathways edema toxin has numerous effects like impairing the phagocytic abilities of phagocytes and altering their cytokine production, causing necrosis in some tissues or decreasing the circulation of the lymphocyte population. High concentrations of cAMP promote water efflux from affected cells into the surrounding tissue effectively causing massive edema (Mogridge et al. 2010; Pilo and Frey 2018).

Lethal toxin is a zinc-dependent metalloprotease, which interferes in cellular signaling pathways impairing numerous cellular functions of immune cells. The inactivation of some MAPKK kinases (mitogen-activated protein kinase kinases) leads to excessive release of cytokines, apoptosis, hypoxia, and necrosis. Lethal toxin induces cell death in macrophages, dendritic cells, and neutrophils as well as in lung epithelial cells and endothelial cells (Mogridge et al. 2010; Ehling-Schulz et al. 2019; Pilo and Frey 2018).

51.1.8 Host Range

Anthrax is a disease with a broad host range. It is primarily an animal disease with ruminants, especially cattle, sheep, and goats being highly susceptible. Reports of anthrax in buffaloes, horses, camels, elephants, rein deer, and other domesticated or wild living herbivores are not seldom either.

Carnivores and humans are moderately susceptible, while pigs are of low susceptibility. Most birds are nearly unsusceptible, but rare reports on the disease in ostriches, ducks, or birds of prey exist (Böhm 1995; Selbitz 2011).

51.1.9 Epidemiology

Soil is the natural reservoir of endospores being formed during the decomposition of carcasses of animals that have died of anthrax. The endospores remain soil-bound and infectious for decades due to their high tenacity toward environmental factors. Endospores from animal carcasses having been buried can reach the surface during heavy rain and flooding of pastures after years and even decades and become a source of infection again. Herbivores catch the infection by inhalation of aerosolized endospores or their ingestion during grazing. Carnivores are infected by devouring infected animals or their carcasses. Anthrax is not a contagious disease. It can barely be transmitted from an infected animal to another except by direct contact with body fluids, especially blood, which is shed by animals near agony. Biting insects or flies are discussed as vectors and are made responsible for explosive outbreaks. Transfer to different regions is supported by human activities like trade with animal products as hides, wool, bone meal, or meat meal (Selbitz 2011; Mogridge et al. 2010; WHO 2008).

51.1.10 Infectious Dose

LD_{50} ranges from <10 spores in susceptible herbivores to 10^7 spores in less susceptible animals, when administered parenterally. The normal way of infection is inhalation or ingestion of endospores, hereby the infectious dose even in susceptible animals is in the order of tens of thousands endospores (WHO 2008).

51.1.11 Disease in Animals

The incubation period is 3 to 5 days with a range between 1 and 14 days.

Ruminants predominantly fall ill with septicemic anthrax, often suffering from sudden death within minutes or hours. The acute illness is highly febrile (fever above 40 °C) and shows signs of severe disease like apathy, dyspnea, tremor, colics, cramps, and cyanosis. Near agony there is shedding of dark, non-coagulable blood from mouth, nose, anus, and with the urine. This blood contains lots of sporulating bacilli and is highly infectious. Death occurs within about 12 h. In some cases prolonged forms occur with edema, colic, dyspnea, and indigestion (Böhm 1995; WHO 2008).

Horses normally show an acute disease with high fever (40–41 ° C), dyspnea, cyanosis, and colics. Hemorrhages, bloody diarrhea, and local, necrotizing swellings are described. Near agony bleeding from different orifices may be seen. Death occurs within 1–3 days (Böhm 1995; WHO 2008).

Septicemic anthrax with an incubation period of 2–4 days is seldom in the pig. Normally, aching, pharyngeal swellings with fever, pharyngitis, dyspnea, and edema develop. Black, necrotizing nodules may be seen in the mucosa and the skin (pharyngeal form). Icterus, vomiting, and diarrhea are signs of intestinal anthrax. Lethality is much lower in the pig compared to ruminants and horses. Chronic, localized anthrax with no clinical signs is possible and the infection is only detected at the slaughterhouse (Böhm 1995; WHO 2008).

Carnivores may fall ill with septicemic anthrax with an incubation period of 2–6 days and fever up to 40 °C. They die within hours or a few days with symptoms similar to those of ruminants. Dogs are considered much more resistant than cats. Subacute cases show diarrhea, edema predominantly in the laryngeal area or the mouth with central necrosis. Death occurs within 3–5 days. Minks are very susceptible to anthrax showing septicemic anthrax with a mortality up to 100%, depending on the level of feed contamination (Böhm 1995).

51.1.12 Human Anthrax

Humans are much less susceptible than herbivores. The infectious dose (ID_{50}) is estimated to be thousands or tens of thousands endospores (WHO 2008). Infection occurs by contact to infected animals or contaminated animal products (WHO 2008; Bauerfeind et al. 2013). Thus, human anthrax is more or less an occupational disease of farmers, veterinarians, butchers, slaughterhouse workers, or workers in the fur, leather, or wool industry, and also of transport or dock workers (Bauerfeind et al. 2013).

Endospores penetrate through small wounds or by inhalation. Ingestion by eating infected meat is of little importance nowadays, but was in former times a major route of transmission. Human anthrax manifests itself as cutanaeous anthrax, alimentary anthrax, or inhalational anthrax (Koch 1885; WHO 2008; Bauerfeind et al. 2013).

More than 95% of cases are cutaneous anthrax. The incubation period is 2–5 days with a range from ½ to 17 days. The endospores penetrate through little skin lesions or wounds and germinate. The disease starts with local reddening, followed by the formation of a papule, which becomes a vesicle within 12–24 h, containing serous or putrid liquid. After a week there is a marked edema with swollen edges while the center necrotizes and a characteristic blue-black eschar is formed. The local process is painless, but pain and fever occur when the regional lymph nodes are affected (WHO 2008; Bauerfeind et al. 2013).

Alimentary anthrax has an incubation period from 1 to 7 days. Symptoms are loss of appetite, vomiting, and nausea, later abdominal cramps, hematemesis, and bloody diarrhea with gut necrosis, ulceration, and ascites. The mesenterial lymph nodes are heavily involved. The clinical picture is that of an acute abdomen (WHO 2008; Bauerfeind et al. 2013).

Ingestion of endospores may cause oropharyngeal anthrax with sore throat, dysphagia, regionary lymphadenopathy, and a marked edema of the throat together with a pseudomembranous inflammation of the tongue and the tonsils (WHO 2008; Bauerfeind et al. 2013).

Inhalational anthrax is the most severe form of human anthrax. The ID_{50} is estimated as 8.000–50.000 endospores. The incubation period is 4–6 days. There is a preset of unspecific, influenza-like symptoms like malaise, cough, sore throat, and fever, followed by worsening dyspnea, headache, sweating, high fever, tachypnea, tachycardia, pleural effusion, cyanosis, disorientation, and, finally, coma and shock. There is massive involvement of the pleural lymphatic system leading to lung congestion and interstitial edema aggravated by toxin-mediated endothelial damage of lung capillaries (WHO 2008; Bauerfeind et al. 2013).

Since 2009, a special form of human anthrax – injectional anthrax – was seen in intravenous drug addicts. It is supposed that the injection of heroin contaminated with anthrax endospores sets a severe soft tissue infection of muscle, fasciae, and connective tissues around the injection site. The patients develop a severe local inflammation with swelling, reddening, edema, abscessation, necrotizing fasciitis, and compartment syndrome with nausea and dyspnea. The local infection may generalize to septicemic anthrax with a very poor prognosis (Bauerfeind et al. 2013; Holzmann et al. 2012; Ramsay et al. 2010). The first cases were detected in Scotland. From December 2009 to December 2010 there were 119 cases of injectional anthrax in intravenous drug users in Scotland of whom 14 people died. Another five cases with four fatalities were reported from England and two cases from Germany (N N 2011). Since June 2012 there were 14 further cases: four in Germany, two in Denmark, one in France, and seven in the UK (one in Scotland, five in England, and one in Wales). Six of these cases were fatal (ECDC 2014).

All known manifestations may lead to septicemic dissemination and anthrax meningitis with fever, somnolence, myalgia, nausea, vomiting, cramps, delirium, and toxic shock (WHO 2008; Bauerfeind et al. 2013).

51.1.13 Diagnosis

The diagnosis of anthrax comprises clinical symptoms and clinical tests together with laboratory tests. Besides the microscopic detection of Gram-positive, spore- and capsule-forming rods in chains directly from infected tissue or blood, the most important test is the isolation of the agent by culture. Culture from infected tissue should always be combined with a PCR for both virulence plasmids as an antibiotic pretreatment may effectively kill the bacteria so that culture alone may yield false negative results. Isolates may be identified and further characterized by biochemical differentiation in combination with other morphological parameters, MALDI-TOF, immunofluorescence, or other antibody techniques and molecular methods to detect anthrax-specific chromosomal sequences and plasmid-located toxin and capsule genes or reveal the clonal descent of the isolated strain. A special bacteriophage (γ-phage) may be used to identify anthrax strains (WHO 2008; Bauerfeind et al. 2013; Pilo and Frey 2018). Meanwhile, *Bacillus cereus* strains are known to harbor anthrax-like virulence plasmids and cause an anthrax-like illness (Ehling-Schulz et al. 2019; Leendertz et al. 2006; Klee et al. 2006).

51.1.14 Therapy

Bacillus anthracis is a bacterium with a wide susceptibility against antibiotics. β-lactam-antibiotics, streptomycin, tetracyclins, erythromycin, clindamycin, or ciprofloxacin are recommended for treatment (Selbitz 2011; WHO 2008; Bauerfeind et al. 2013).

51.2 Tularemia

Tularemia is a zoonosis with a broad host range. The disease was first described by McCoy in rodents in 1911 and in 1914 in humans (Pilo 2018). Wildlife animals are the main reservoir for humans. It is especially a disease of Lagomorpha (especially hares and rabbits) and rodents. As humans are highly susceptible for tularemia, its agent, *Francisella tularensis*, which can be transmitted by aerosol, is supposed to have a bioterroristic potential, although no attempts of bioterroristic misuse have been known so far.

51.2.1 Etiology

Francisella tularensis are small, coccoid, pleomorphic, Gram-negative rods. They are strictly aerobic, oxidase-negative, weakly catalase positive and non-motile. Their cell wall is rich in lipids and gives them a high tenacity in the environment allowing *Francisella tularensis* to survive in soil, mud, or water for weeks and even months (Markey et al. 2013; Bauerfeind 2011).

Picture 2 *Francisella tularensis* ssp. holarctica, isolated from a European hare

As fastidious organisms they need rich, cysteine supplemented media, e.g., cysteine-heart agar with chocolatized blood, chocolate agar with Iso-VitaleX, Thayer-Martin agar, or Martin-Lewis agar. Antibiotics should be added to suppress the contaminant flora (Picture 2). The incubation under 5% CO_2 supports the growth of *Francisella spp.* The incubation period should be at least 48 h and be extended to 10 days (Markey et al. 2013; Müller et al. 2013; Bauerfeind 2011).

Francisella (F.) is the only genus of the family *Francisellaceae*. It comprises the species *F. tularensis, F. hispaniensis, F. noatunensis, F. philomiragia*, and *F. halioticida*. The last three species are linked to water and sometimes isolated from fish. *F. tularensis* consists of four subspecies, i.e., *F. tularensis ssp. tularensis* (type A), *F. tularensis ssp. holarctica* (type B), *F. tularensis ssp. Mediasiatica*, and *F. tularensis ssp. novicida,* which share large genetic homogeneity of more than 98%. The four subspecies differ especially in geographical distribution and pathogenicity, and also in biochemical activities and host specificity (Markey et al. 2013; Larson et al. 2020; Pilo 2018). *F. tularensis ssp. tularensis* is separated in the subtypes A.I and A.II with subtype A.I being the most virulent. For *F. tularensis ssp. holarctica* 3 biovars are proposed: biovar I (erythromycin sensitive), biovar II (erythromycin resistant), and biovar japonica, which can ferment glycerol (Markey et al. 2013; Müller et al. 2013; Larson et al. 2020; Pilo 2018). *F. tularensis ssp. tularensis* is the most virulent subspecies and therefore classified into risk group 3, while the other subspecies belong to risk group 2.

51.2.2 Virulence Factors

The virulence factors of *F. tularensis* are poorly understood yet. *F. tularensis* form a capsule of polysaccharides identical to the O antigen. The capsule is responsible for serum resistance and important for the virulence of *F. tularensis*. In the host they live inside macrophages. They can manipulate the host's immune response by phase variation of their lipopolysaccharide (LPS), concerning the O antigen and the lipid A

moiety. The LPS of *F. tularensis* differs from that of other Gram-negative bacteria. Francisella-LPS is tetraacylated instead of hexaacylated, has longer fatty acids with 16–20 carbons, and a reduced or no lipid A phosphorylation. Francisella-LPS does not induce interleukin 1-release from mononuclear cells and poorly induces tumor necrosis factor. As other intracellular pathogens they modulate the phagosome biogenesis, hinder them from fusion with lysosomes, and escape to the cytoplasm (Rowe and Huntley 2015; Markey et al. 2013). *F. tularensis* as an intracellular pathogen is called a "stealth" pathogen, which manipulates the immune system, host cell entry, and intacellular pathways to limit inflammation and promotes its intracellular survival (Rowe and Huntley 2015).

51.2.3 Epidemiology and Geographical Distribution

F. tularensis is widely distributed over the Northern hemisphere, predominantly in North America, Scandinavia, Russia, and Japan (Markey et al. 2013). *F. tularensis ssp. tularensis* mainly occurs in North America with some findings of probably imported cases in Austria and Slovakia. Type A.I strains are found throughout the United States, while type A.II strains seem to be confined to the western regions of the USA. *F. tularensis spp. holarctica* – the less virulent variant – is distributed over North America, Europe, Siberia, Israel, Iran, and Asia. *F. tularensis ssp. mediasiatica* is confined to Central Asia, while *F. tularensis ssp. novicida* can be found in North America, Spain, and Australia (Markey et al. 2013; Bauerfeind et al. 2013; Larson et al. 2020).

F. tularensis has been isolated from about 250 wildlife animal species, which serve as natural reservoir for humans. The most important host animals are hares, rabbits, squirrels, voles, mice, rats, beavers, and other rodents, but also deer, foxes, bears and other carnivores, and birds as well as reptiles and amphibians or fish may be infected (Markey et al. 2013; Bauerfeind et al. 2013). Biting arthropods play a vital role in the transmission of *F. tularensis*. These include flies, mites, mosquitoes, lice, fleas, and especially ticks, of which some species may transmit the agent transovarially and are thus a natural reservoir themselves (Markey et al. 2013; Bauerfeind et al. 2013; Bauerfeind 2011). Aquatic protozoae are discussed as reservoirs, too (Bauerfeind et al. 2013; Bauerfeind 2011; Larson et al. 2020).

Tularemia is transmitted to man by direct contact with infected animals, their excretions, and organs or by bites. Further sources of infection are contaminated water or food and biting arthropods. Aerosol transmission may occur by processing agricultural products. The agent invades the host through small lesions of the skin or through the conjunctivae or the mucosae of the upper gut or respiratory tract (Markey et al. 2013; Bauerfeind et al. 2013; Bauerfeind 2011; Larson et al. 2020).

Human tularemia is an occupational disease, especially for hunters, butchers, cooks, or agricultural and forest workers. Carnivores, especially cats, may transmit the disease to humans, while dogs are relatively resistant (Markey et al. 2013; Bauerfeind et al. 2013; Bauerfeind 2011). Most human infections occur while treating and preparing hunted hares. A direct human-to-human transmission has not been described yet (Bauerfeind 2011).

51.2.4 Infectious Dose

The infectious dose for inoculation into wounds is with 10 bacteria very low, followed by an infectious dose of 10–50 bacteria for inhalation and about 10^8 bacteria for ingestion (Bauerfeind et al. 2013).

51.2.5 Disease in Animals

Animals develop an acute or chronic general disease with a wide range of symptoms from mild, regionary lymphadenopathy to acute septicemia. Further signs are depression, anorexia, fever, vomiting, diarrhea, lymphadenomegaly, ulcers, and hemorrhage (Markey et al. 2013; Bauerfeind 2011). Outbreaks with high morbidity and mortality are seen in hares. The main organs infected are lymph nodes, lung, pleura, spleen, liver, and kidneys, where miliary, whitish to yellowish necroses are formed, which resemble pseudotuberculosis lesions. In sheep, late abortions or the birth of weak lambs are described (Bauerfeind 2011).

51.2.6 Human Tularemia

The incubation period is 3–10 days with a range of 1–21 days. The disease lasts for 2–3 weeks without treatment and is followed by a long phase of reconvalescence. The case fatality rate is 4–6%, with sepsis up to 30% despite treatment. Infections with *F. tularensis ssp. holarctica* take a lighter course than those with *F. tularensis ssp. tularensis*. The disease normally leaves life-long immunity (Bauerfeind 2011).

The disease starts with unspecific symptoms like headache, growing pains, fever, chills, and weakness. The further course of disease depends on the agent's virulence and its route of entry.

The **ulceroglandular form** starts with a red papule at the site of entry, which undergoes necrosis and finally forms an ulcus. The regionary lymph nodes (often axillary or inguinal lymph nodes) are swelling and develop purulent inflammation and abscessation. If the local skin necrosis is missing, the disease is known as **glandular form**.

Invasion through the conjunctivae results in a heavy conjunctivitis with lymphadenopathy (**oculoglandular form**).

The **oropharyngeal form** manifests with stomatitis, pharyngitis, tonsillitis, and otitis with involvement of the cervical lymph nodes.

Pneumonia and pleuritis with retrosternal pain is characteristic for the **pneumonic form**, while nausea, vomiting, diarrhea, intestinal pain, and gastrointestinal hemorrhage are symptoms of the **gastrointestinal form**.

The **typhoidal or septic form** shows high, continuous or intermittent fever, chills, headache, meningitis, myalgia, apathy, diarrhea, intestinal pain, hepatosplenomegaly, renal failure, and shock with multiple organ failure (Markey et al. 2013; Bauerfeind 2011).

51.2.7 Diagnosis

Tularemia should be suspected when the above mentioned clinical symptoms meet an anamnesis of contact to wildlife animals. The diagnosis is proven by bacteriological examination or serological tests. Clinical specimens like swabs from ulcers, wounds or conjunctivae, pus, bioptates, or sputum are cultured. Importantly, *Francisella tularensis* does not grow on normal media, but needs special, cysteine supplemented media. The culture is not always successful; therefore PCR from clinical specimen should be undertaken in parallel, if tularemia is suspected. Isolates are differentiated by immunofluorescence or by PCR. Molecular methods including 16S rRNA sequencing are used to determine species and subspecies (Markey et al. 2013; Bauerfeind et al. 2013; Bauerfeind 2011).

51.2.8 Therapy

Francisella tularensis may be resistant to β-lactam antibiotics, azithromycin, and macrolides. They are susceptible to aminoglycosides, fluorquinolones, tetracyclines, and chloramphenicol. In therapy for humans, gentamicin, streptomycin, ciprofloxacin, or doxycycline is recommended (Markey et al. 2013; Bauerfeind et al. 2013; Bauerfeind 2011).

Dangerous Viral Pathogens of Animal Origin: Risk and Biosecurity

52

Zoonotic Select Agents

Jean-Paul Gonzalez and Gavin Macgregor-Skinner

Contents

Abstract

Most of emerging infectious diseases affecting humans are of animal origin and transmitted under natural circumstances from either, wild or domestic vertebrate animals giving the way of zoonotic infection or epidemics. Zoonotic diseases carry a common ancient history between human and animals as a result of pathogen exchanges involving transgression of the species barrier. Nowadays, several agents have been targeted for their potential to be a major risk for human and animal populations and, have been characterized by their potential to be highly pathogenic and/or transmissible, and lacking of any means of protection. Those agents have been listed as "Select Agents" having the potential to pose a severe threat to both human and animal health, as well as to animal and plant products. Several of the most dangerous agents responsible of viral hemorrhagic

52.1 Introduction

More than 75% of recently emerging infectious diseases affecting humans are of animal origin; about two third of all human pathogens have an animal source as a natural reservoir (Taylor et al. 2001). The nosologic term of "Zoonosis" has been crafted to gather all transmissible diseases harboring a potential to infect both human and animal (Palmer et al. 2001). Zoonosis (i.e. zoonotic diseases) are transmissible diseases between animals and man with an infectious (microbes and prions) or parasitic origin. In another term, a zoonotic disease represents any animal disease communicable to human and/or vice versa. Ultimately, zoonosis can be transmitted from animals to humans, directly or indirectly, sometimes by a vector or an intermediate host, or also from humans to other animals. This is considered as reverse zoonosis and called anthroponotic disease, or zooanthroponosis. Zoonoses can be of viral (Yellow Fever, HIV, hantavirus), bacterial (tularemia, leptospirosis, lyme disease), rickettsial (Q-fever), fungal (aspergillosis, histoplasmosis), parasitic (giardiasis, cryptosporidiasis), or prions (Creutzfeldt–Jakob disease) origins. Also the mechanisms of transmission are the main factors driving the risk of human infection. Infectious agents are transmissible under natural circumstances from wild or domestic vertebrate animals to humans. They can also be transmitted from animal products causing foodborne diseases, e.g., *Escherichia coli* O157:H7, Campylobacter, Calicivirus, or Salmonella.

The origin of zoonotic diseases occurred probably when humans came in close contact (scavenging or hunting) with wild animals. Indeed, several zoonoses have been known since early prehistoric times. The first hominids were in direct contact with animal groups which previously appeared on Earth some 540 million years ago (ya.). The history of mankind, starting with Australopithecus, begins about 5 million ya. and coincides with the first contact and potential of microbe exchanges between fauna and this human precursor. Also, one of the most ancient hominids, Australopithecus, was not hunter, but a pretty game (!) hunted by large and powerful carnivorous. Also sick and infected individuals were eaten by such large predators, and human epidemics turned short (Debré and Gonzalez 2013). Earlier *Homo* species from the Pleistocene era (2.6 million–11,700 ya.) utilized larger animals for subsistence (Rabinovich et al. 2008) including mammoths, long horned bisons, saber-toothed cats, giant ground sloths, among others mammals of North America,

Asia, and Europe. It is quite acceptable that these creatures were able to exchange their parasites, e.g., intestinal and blood parasites or fur ectoparasites, with humans.

Hunting remained a crucial component of hunter-gatherer societies before the domestication of livestock and the dawn of agriculture 11,000 ya. First attempts to domesticate dogs, goats, and sheep, occurred as early as 15,000–9000 ya., giving rise to domestic zoonotic parasitic disease. Ultimately, about 1000 ya., 22 species were domesticated including dog, goat, sheep, cattle, camel, pigs, and chicken. Later, during the Neolithic period, when agricultural practices appeared, domestication was well under way supporting the appearance of e.g., flea-or louse-transmitted bacterial zoonoses or pyogenic infections after contact to wild and domestic animals Domestic animals. In fact, in prehistoric times, when human populations were organized in small tribes with a limited number of 100–200 individuals, the human population was actually an accidental victim of infectious diseases, developing rapidly an herd immunity and leaving the pathogens to infect and survive in the more abundant animal populations (e.g., anthrax, rabies, tularemia, cysticercosis) (Debré and Gonzalez 2013).

Indeed, zoonotic diseases carry a common history between human and animals as a result of pathogen exchanges involving a transgression of the species barrier. Altogether, such events occur in a variety of situations involving different hosts, vectors, the pathogens natural cycle's, and the ability of a pathogen to target specific host cells or organs sharing some structural identity between taxonomically distant species (i.e.: human to non-human mammal species).

52.1.1 Zoonotic Risk

Essentially, a zoonotic risk exists and increases with the frequency of contact between infected animals and uninfected permissive human hosts, as well as with the capacity of a pathogen to infect both.

Transgressing the Species Barrier The pathogen species-jumping ability is relevant from wild as well as domestic animal species that can transmit their own microbes to human. The species barrier can easily be violated when species are sympatric and/or taxonomically closely related (e.g.: Arenavirus and different rodent species). Although some pathogens have a high infectious specificity and are usually restricted to infect one host species, some of them can pass the species barrier after a mutation or genetic re-assortment (e.g.: the SARS coronavirus from chiropteran to Palm civet, avian influenza from bird to pig) Influenza:avian and/or after an alteration of the permissive host (e.g., due to immunodeficiency). Ultimately, zoonotic diseases result from parasites, *sensu lato*, that can live apparently harmlessly in a natural host while producing disease upon entry into a different host. Some prominent examples are e.g., HIV having a non-human primate origin and influenza viruses generated from pig and bird viruses after genetic re-assortment, both subsequently evolving to be adapted to a human-to-human virus transmission.

Disease Emergence in Humans A variety of classical human viral diseases are suspected to be the consequence of such a virus jump from animal to human. The origin of such species-jumping leading to disease emergence in the human population takes place in different situations generally associated with human behavior. As mentioned above, the first pathogen exchanges between humans and animals probably occurred sequentially from hunting wild animals to animal domestication.

For example, it is hypothesized that the following diseases originated from either domestic and wild animals: smallpox from rodents more than 10,000 ya., common cold rhinovirus from cattle more than 4000 ya., influenza from pigs more than 8000 ya., measles from cattle plague 300 ya., HIV from non-human primates (NHP) less than 100 ya (Hughes et al. 2010).

Human Population at Risk While many of the zoonotic microbial agents (e.g., the bacteria causing tuberculosis or diphtheria) are resident in domestic mammals and birds, farmers, breeders and all those involved in food animal production are at risk, since the growing contact between humans and wildlife clearly increases the zoonotic risk (e.g., the example of Ebola fever) (Daszak et al. 2000). Wildlife. This can be caused either by encroachment of human activity into wilderness areas or by movement of wild animals into areas of human activity (Artsob 2004).

There are undoubtedly many zoonotic agents waiting in Nature that have the potential to be introduced into humans. Among animal reservoirs with a high and manifest risk for zoonotic transmission are the NHP because of their genetic closeness to humans (Gonzalez et al. 2013) and pigs because of the similarity of their digestive, respiratory and immune systems with the human ones (Martien et al. 2012).

Besides the "natural" risk of an emergence of a certain zoonosis that is directly linked to pathogen evolution (i.e.: change in pathogenicity) and ecology (e.g., extreme weather events, natural catastrophies, climate change) Climate change, more cryptic threats exist and are a cause of concern: the possibility of zoonotic emergence from xenotransplantation from an infected animal biological product (Allan 1996) and the deliberate release of infectious agents into human or animal populations by people (Atlas 2001).

Altogether, most of the factors involved in zoonotic emergence are of human origin, e.g., occupational (poaching, hunting, butchering), due to individual behavior (pets, eating bush meat), by man-made environmental changes (landscape fragmentation, protected area parks and recreational activities), or through social behavior (migration).

52.1.2 Biosecurity

Biosecurity is a set of preventive measures designed to reduce the risk of infection by multiple actions (quarantined pests, contain invasive alien species, master viable

genetically modified organisms [GMO], identify pathogen genetic shift, etc.) modulated by the foundations of risk in line with the assessment of biological risk. To this end, scientific research became the principal actor in a complex process aimed at understanding and mastering the emergence of pathologies (Gonzalez and Fair 2013).

Risk Assessment The biological risk can be either of natural (i.e.: the random encounter of the pathogen, the natural host and human), accidental (i.e.: unexpected "spill over" of the pathogen that infect another host including human), or deliberate origin (i.e.: an individual – criminal – or a group – terrorist – undertaking taking action to infect human or animals). Preventive measure needs a risk assessment with respect to the identified pathogen and its potential to target human and animal (or vector) populations. Several pathogens have been identified as particularly dangerous in that matter regarding their intrinsic characteristics. Ultimately, human and animal populations can consequently be identified concerning their vulnerability to the agent (i.e.: pathogenicity and occurrence in the same environment) (Table 1).

Select Agents Several classes of diseases and agents have been identified as presenting a particular high level of danger including hemorrhagic fever of viral or bacterial origin, infectious neurological syndromes, severe respiratory syndromes among others. Also, regarding the pathogenicity of infectious agents (virulence) and infectiousness (potential to spread) with respect to the risk for either the general human population or laboratory workers, they have been classified as P3–4 level of containment agents (Richmond and McKinney 1999).

For practical reasons, several agents have been targeted for their potential to be a risk for human and animal populations and characterized according their potential to be highly pathogenic or to be highly transmissible – in particular by aerosols – and the lack of any means of protection, e.g., by a vaccine. Those agents have been listed by HHS and USDA as "Select Agents" having the potential to pose a severe threat to both human and animal health, (potentially plant health), or to animal and plant products. Among these 45 Select Agents (33 viruses and 12 bacteria) 31 (69%) are zoonotic, while the remaining are known to infect only animals (Table 2) (http://www.selectagents.gov/Select%20Agents%20and%20Toxins%20Exclusions.html).

Risk Mitigation and International Perspective Major factors have to be taken in account in order to reduce the risk of transmission between animals and humans. Besides reducing the direct contact among the two populations, tools and strategies to fight zoonoses has to be specifically developed. Select Agents have to be surveyed for their emergence, circulation and evolution. Highly pathogenic agents, as well as Select Agents, have to be diagnosed and handled by well-trained workers in certified appropriate laboratory structures (P3 and P4 laboratories, etc.) and their circulation controlled (i.e.: shipping, transferring from one laboratory to another, etc.).

Table 1 Common human and animal highly pathogenic viruses

Virus family	Virus name	Geographical origin	Hosts: Main/ secondary	Vector	Transmission and public health issues	Risk assessment	Human pathogenic	Reference
Arenavirus	Barmah forest	Australia	Possums, kangaroos and wallabies	Mosquito	HT: by bites from infected mosquitos	Z	Mild illness, ILS (pain) recovery	Marshall et al. (1982)
	Venezuelan equine encephalits	America	Horse/zebra, donkey		HT: Zoonosis fever epizootics	SA/P3/	ILS/ENC	Gardner et al. (2008)
	Chapare[a]	America	Rodent, potentially but no evidence yet/-?		HT: ?	SA/P4	H, HF: ILS + vomiting + hemorrhagic signs	Delgado et al. (2008)

52.2 Highly Pathogenic Viral Zoonoses

52.2.1 Viral Hemorrhagic Fevers (VHF)

Viral Hemorrhagic Fevers (VHF) appear as a whole clinical entity characterized by (high) fever and bleeding that can progress to shock and death. The first severe VHF identified was the Ebola Hemorrhagic Fever (1976), although the Marburg virus

Marburg virus was isolated and characterized earlier in 1967; Marburg virus, however, appears in the medical literature as part of the nosocomial framework of VHF only in 1977 when published aside with the Ebola virus (Bowen et al. 1977). Later, several already known VHF joined the concept including: the Hemorrhagic Fevers with Renal failure (known since 1951), the Hantavirus in 1978 (Lee et al. 1978); the Lassa fever and Bolivian and Argentine HF, Yellow Fever, Rift Valley Fever, Crimean Congo Hemorrhagic fever (CCHF), and others. The group of VHF was identified as a nosologic entity associated with viruses belonging essentially to five distinct families of RNA viruses: the four Arenaviridae, Filoviridae, Bunyaviridae, and Flaviviridae. Only recently in September 2012 scientists reported the isolation of a member of the Rhabdoviridae family responsible for VHF in the Bas-Congo district of the Democratic Republic of Congo (Grard et al. 2012). Several VHFs share many important features: (1) many of them may be transmitted by arthropod-borne agents (usually mosquito vector), (2) person-to–person transmission is possible through direct contact with infected patients, their blood or other body fluids; (3) natural animal reservoirs are mainly rats and mice Mice, but also domestic livestock Livestock:domestic, monkeys or other NHP may serve as intermediate hosts. Moreover, with the increasing international travel, these mainly tropical viruses may now be imported into non-endemic countries thus posing a major global risk for human public health. Furthermore, several of these agents have been associated with nosocomial outbreaks Outbreaks:nosocomial involving health care and laboratory workers.

Due to special biosecurity concerns, we will mainly focus in the following on Filoviruses, RVFV, other flavivirus responsible of hemorrhagic fevers, Kyasanur Forest disease and Omsk HF. Alkhurma HF virus is cited in cursory detail because its limited geographic distribution.

52.2.1.1 Filoviruses (Ebola and Marburg)

Filoviruses

Ebola and Marburg viruses Marburg virus are the only members of the genus Filovirus in the *Filoviridae* family and can cause severe hemorrhagic fever in humans and NHP.

The genus *Marburgvirus* consists of a single species, *Marburg marburgvirus*, with 2 member viruses, Marburg virus (MARV) and Ravn virus (RAVV).

The genus *Ebolavirus* contains five species: *Bundibugyo ebolavirus*, *Zaire ebolavirus*, *Reston ebolavirus*, *Sudan ebolavirus*, and *Taï Forest ebolavirus*, whose members are Bundibugyo virus (BDBV), Ebola virus (EBOV) Ebola virus (EBOV), Reston virus (RESTV), Sudan virus (SUDV), and Taï Forest virus (TAFV), respectively (Kuhn et al. 2010). Ebola-Reston is the only known Filovirus that does not cause severe disease in humans; however, it can still be fatal in monkeys and it has been recently recovered from infected pigs in South-East Asia. A third, tentative genus ("*Cuevavirus"*) has been suggested for a novel filovirus, Lloviu virus (LLOV; species "*Lloviu cuevavirus*"), which has not yet been isolated in culture. With the exception of RESTV and possibly LLOV, all of these viruses cause severe and often fatal viral hemorrhagic fever (VHF) upon infection in humans (Negredo et al. 2011).

The Pathogen

Ebola and Marburg viruses are elongated filamentous molecules, highly variable in length, and are typically between 800–1000 nm long, and can be up to 1400 nm long due to concatamerization, with a uniform diameter of 80 nm. The viral fragment is pleomorphic, and may appear in the shape of a "6", a "U", or a circle, and it is contained within a lipid membrane. Each virion contains one molecule of single-stranded, negative-sense viral genomic RNA, complexed with the proteins *NP*, *VP35*, *VP30*, and *L* (Kiley et al. 1982; Sanchez et al. 1992; Geisbert and Jahrling 1995; Mwanatambwe et al. 2001; Pringle 2005).

Pathogenesis

Two independent studies reported that Ebola virus cell entry and replication requires the cholesterol transporter protein Niemann-Pick C1 (NPC1). The studies described that when cells from Niemann Pick Type C1 patients were exposed to Ebola virus in the laboratory, the cells survived and appeared immune to the virus, further indicating that Ebola relies on NPC1 to enter cells. The same studies described similar results with Ebola's cousin in the filovirus group, Marburg virus, showing that it too needs NPC1 to enter cells (Carette et al. 2011; Côté et al. 2011). Furthermore, NPC1 was shown to be critical to filovirus entry because it mediates infection by binding directly to the viral envelope glycoprotein (Côté et al. 2011). Miller et al. (2012) confirmed the findings that NPC1 is a critical filovirus receptor that mediates infection by binding directly to the viral envelope glycoprotein and that the second lysosomal domain of NPC1 mediates this binding. Carette et al. (2011) showed mice that were heterozygous for NPC1 were protected from lethal challenge with mouse adapted Ebola virus Ebola virus (EBOV). Together, these studies suggest NPC1 may be a potential therapeutic target for an Ebola anti-viral drug.

Clinical Signs

Ebola and Marburg virions enter the host cells through endocytosis and replication occurs in the cytoplasm. Upon infection, the virus targets the host blood coagulative and immune defense system and leads to severe immunosuppression (Harcourt et al. 1999).

Ebola virus disease is clinically indistinguishable from Marburg virus disease Marburg virus, and both are similar to many other diseases prevalent in Equatorial Africa (Grolla et al. 2005).

Early signs of infection are non-specific and flu-like, and may include sudden onset of fever, asthenia, diarrhea, headache, myalgia, arthralgia, vomiting, and abdominal pains (Bwaka et al. 1999). Less common early symptoms such as conjunctival injection, sore throat, rashes, and bleeding may also appear. Shock, cerebral oedema, coagulation disorders, and secondary bacterial infection may co-occur with onset of infection (Feldmann 2010). Hemorrhagic symptoms begin 4–5 days after onset, which includes hemorrhagic conjunctivitis, pharyngitis, bleeding gums, oral/lip ulceration, hematemesis, melena, hematuria, epistaxis, and vaginal bleeding. Hepatocellular damage, marrow depression (such as thrombocytopenia and leucopenia), serum transaminase elevation, and proteinuria may also occur.

Persons that are terminally ill typically present with obtundation, anuria, shock, tachypnea, normothermia, arthralgia, and ocular diseases. Hemorrhagic diathesis is often accompanied by hepatic damage and renal failure, central nervous system involvement, and terminal shock with multi-organ failure. Contact with the virus may also result in symptoms such as severe acute viral illness, malaise, and maculopapular rash. Pregnant women will usually abort their foetuses and experience copious bleeding. Fatality rates range between 50% and 100%, with most dying of dehydration caused by gastric problems (Casillas et al. 2003).

Diagnosis can be confirmed by virus isolation, ELISA to detect viral antigens or patient antibodies in serum or organ homogenates, RT-PCR, immunohistochemistry, and electron microscopy of tissue sections and/or biopsies (Grolla et al. 2005).

Ebola and Marburg virus are morphologically indistinguishable; laboratory studies are extremely hazardous and should be performed in a Biosafety Level 4-equivalent containment Level 4 facility. Laboratory researchers have to be properly trained in BSL-4 practices and wear proper personal protective equipment.

Ebola Virus Epidemiology

Occurrence of Ebola and Marburg virus disease has been primarily limited to countries in sub-Saharan Africa. The name, Ebola, comes from the Ebola River in the Democratic Republic of the Congo, where it was first found in 1976. Marburg virus was first discovered in 1967 and is named after the German city of Marburg.

Ebola virus disease (EVD) Ebola virus (EBOV):epidemiology was first described after almost simultaneous viral hemorrhagic fever outbreaks occurred in Zaire and Sudan in 1976 (WHO 1978a). EVD is believed to occur after an ebolavirus is transmitted to a human index case via contact with an infected animal host. Human-to-human transmission occurs via direct contact with blood or bodily fluids from an infected person (including embalming of a deceased victim) or by contact with contaminated medical equipment such as needles. In the past, explosive nosocomial transmission has occurred in underequipped African hospitals due to the reuse of needles and lack of implementation of universal precautions. Aerosol transmission has not been observed during natural EVD outbreaks, although there are reports suggesting or suspecting aerosol transmission between NHP or in humans based on epidemiological observations (Dalgard et al. 1992; Jaax et al. 1995; Johnson et al. 1995; Roels et al. 1999). The potential for widespread EVD epidemics is considered low due to the high case-fatality rate, the rapidity of demise of patients, and the remote rural areas where infections occur Ebola virus (EBOV): epidemiology.

Marburg Virus Epidemiology

In 1967, simultaneous outbreaks occurred in laboratory workers handling African green monkeys imported from Uganda in Marburg, Frankfurt (Germany), and Belgrade (Yugoslavia, now Serbia) Marburg virus:epidemiology. There were 25 reported primary laboratory-acquired cases with seven deaths. The 25 cases arose from contact and accidents with blood and tissues from infected African green monkeys and six secondary cases (medical personnel, one spouse) developed

from the primary cases (Siegert 1972). Between 1975 and 1987, isolated cases were reported in South Africa (originating from Zimbabwe), Kenya, Zimbabwe, Kenya, and the Democratic Republic of Congo (Gear 1977; Smith et al. 1982). A large long running outbreak occurred between 1998 and 2000 in the Democratic Republic of Congo, resulting in 154 cases and 128 deaths, and two different Marburg viruses, MARV and RAVV, co-circulated and caused disease (Bausch et al. 2006). The largest outbreak to date occurred in 2004 and 2005 centered in Uige, Angola where 374 cases were reported with 329 deaths (Roddy et al. 2010). Since 2007, a number of cases have been reported in Uganda, some of which have been diagnosed into other countries (i.e. USA, The Netherlands) in individuals returning from Uganda (CDC 2003; Timen et al. 2009). Marburg virus has been isolated from blood; serum; secretions, including respiratory and throat secretions; semen; urine; and various tissues and organs from human or animal hosts, or their homogenates (Fisher-Hoch 2005). Marburg virus:epidemiology.

Crossing the Species Barrier and Transmission: Ebola Virus

Between 1976 and 1998, from 30,000 mammals, birds, reptiles, amphibians, and arthropods sampled from outbreak regions, no *Ebolavirus* was detected apart from some genetic traces found in six rodents (*Mus setulosus* and *Praomys* sp.) collected from the Central African Republic (Pourrut et al. 2005). Traces of EBOV were detected in the carcasses of gorillas and chimpanzees during outbreaks in 2001 and 2003, which later became the source of human infections. However, the high lethality from infection in these species makes them unlikely as natural reservoir (Pourrut et al. 2005). Plants, arthropods, and birds have also been considered as possible reservoirs; however, bats are considered the most likely candidate. Bats were known to reside in the cotton factory in which the index cases for the 1976 and 1979 outbreaks were employed, and they have also been implicated in Marburg virus infections in 1975 and 1980 (Pourrut et al. 2005). Of 24 plant species and 19 vertebrate species experimentally inoculated with EBOV, only bats became infected (Swanepoel 1996). The absence of clinical signs in these bats is characteristic of a reservoir species. In a 2002–2003 survey of 1030 animals that included 679 bats from Gabon and the Republic of the Congo, 13 fruit bats were found to contain EBOV RNA fragments (Leroy et al. 2005). As of 2005, three types of fruit bats (*Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*) have been identified as being in contact with EBOV. They are suspected to represent the EBOV reservoir hosts (Pourrut et al. 2007).

The existence of integrated genes of filoviruses in some genomes of small rodents, insectivorous bats, shrews, tenrecs (insectivora from Madagascar), and marsupials indicates a history of infection with filoviruses in these groups as well. However, it has to be stressed that infectious Ebola virus Ebola virus (EBOV) have not yet been isolated from any nonhuman animal (Taylor et al. 2010).

Transmission between natural reservoirs and humans are rare, and outbreaks are usually traceable to a single index case where an individual has handled the carcass of a gorilla, chimpanzee, or duiker (a small antelope species) (Peterson et al. 2004). The virus then spreads person-to-person, especially within families, hospitals, and

during some mortuary rituals where contact among individuals becomes more likely (Hewlett and Amolat 2003).

The virus can be transmitted through body fluids. Transmission through oral or conjunctiva exposure is likely and has been confirmed in NHP (Jaax et al. 1995). Filoviruses are not naturally transmitted by aerosol. They are, however, highly infectious as breathable 0.8–1.2 μm droplets in laboratory conditions; because of this potential route of infection, these viruses have been classified as Category "A" biological weapons (Johnson et al. 1995; Leffel and Reed 2004) (National Institutes of Health, National Institute of Allergy and Infectious Diseases. Category A, B & C Priority Pathogens. 2013. http://www.niaid.nih.gov/topics/biodefenserelated/biodefense/pages/cata.aspx. Accessed May 27, 2013).

Crossing the Species Barrier and Transmission: Marburg Virus

The natural reservoirs of Marburg viruses remain to be identified unequivocally. However, the isolation of both MARV and RAVV from bats and the association of several MVD outbreaks with bat-infested mines or caves strongly suggest that bats are involved in Marburg virus transmission to humans. Avoidance of contact with bats and abstaining from visits to caves is highly recommended, but may not be possible for those working in mines or people dependent on bats as a food source. Monkeys are susceptible but are incidental hosts and individuals handling infected monkeys or their fluids and cell cultures of Marburg virus have become ill (Towner et al. 2009; Timen et al. 2009; Swanepoel et al. 2007).

In 2009, the isolation of infectious MARV was reported from healthy Egyptian rousettes (*Rousettus aegyptiacus* or Egyptian fruit bat) (Towner et al. 2009). This isolation, together with the isolation of infectious RAVV, strongly suggests that Old World fruit bats are involved in the natural maintenance of marburgviruses. Further studies are necessary to establish whether Egyptian rousettes are the actual hosts of MARV and RAVV or whether they get infected via contact with another animal and therefore serve only as intermediate hosts.

The first experimental infection study of *Rousettus aegyptiacus* with MARV provided further insight into the possible involvement of these bats Bats in MARV ecology. Experimentally infected bats developed relatively low viremia lasting at least 5 days, but remained healthy and did not develop any notable gross pathology. The virus also replicated to high titers in major organs (liver and spleen), and organs that might possibly be involved in virus transmission (lung, intestine, reproductive organ, salivary gland, kidney, bladder and mammary gland). The relatively long period of viremia noted in this experiment could possibly also facilitate mechanical transmission by blood sucking arthropods or infection of susceptible vertebrate hosts by direct contact with infected blood (Paweska et al. 2012).

Biosecurity of Filoviruses

Filoviruses Biosecurity:of filoviruses (Ebola viruses and Marburg viruses) are listed as World Health Organization Risk Group 4 Pathogens, National Institute of Allergy and Infectious Diseases (NIAID) Category A Priority Pathogens, Select Agents, and Centers for Disease Control and Prevention (CDC) Category "A" Bioterrorism

Agents due to the absence of prophylaxis or treatment regimens, their high lethality (up to 90% in larger outbreaks), their high infectivity ($LD_{50} = 1$ virion in rodent models), and their stability in artificial aerosols. Research on infectious filoviruses requires Biosafety Level 4 (BSL-4) laboratories.

Filoviruses can survive up to 4–5 days on contaminated surfaces, and can survive in liquid or dried material for a number of days (Belanov et al. 1996; Bray 2003). They are susceptible to sodium hypochlorite, beta-propiolactone, 3% acetic acid (pH 2.5), phenolic disinfectants, formaldehyde and paraformaldehyde, 1% glutaraldehyde, formalin, lipid solvents, and detergents such as SDS. They are physically inactivated by heating for 30–60 min at 60 °C, boiling for 5 min, gamma irradiation (1.2×10–1.27×10 rad), and UV radiation (Elliott et al. 1982; Kurata et al. 1983; Mitchell and McCormick 1984; Mahanty et al. 1999) Biosecurity: of filoviruses.

Ebola Vaccine
Most of the Ebola virus VP proteins are capable of eliciting protective immune responses and therefore are important to consider as potential components of a vaccine to protect humans from Ebola hemorrhagic fever. An "Ebola ΔVP30" strain replication incompetent virus as been generated with a lack of the gene encoding for the VP30 protein, therefore it cannot replicate and do not form infectious progeny in wild-type cells. The genome is stable, without a single event of virus replication; experimental infection of animals did not cause disease in infected animals (Halfmann et al. 2008, 2009).

52.2.1.2 Arenavirus

Arenaviruses are negative stranded RNA viruses of the *Arenaviridae* family. They naturally and chronically infect asymptomatic rodent host-reservoirs. Each rodent species is persistently infected by a specific virus and represents a model of virus-host coevolution (Gonzalez et al. 2007). One exception is made with the Tacaribe virus that has been isolated from naturally infected chiropteran (Downs et al. 1963).

Clinical Signs Several arenaviruses can accidentally infect humans and are responsible for mild to severe zoonotic diseases. Although the arenavirus prototype species, Lymphocytic Choriomeningitis Virus of mice (LCMV) is responsible for a neurological syndrome in humans, at least seven out of the 24 arenavirus species are known to be highly pathogenic for humans and responsible of Viral Hemorrhagic Fever (VHF). Six of them are classified as Select Agents (http://www.selectagents.gov/resources/List_of_Select_Agents_and_Toxins_2012–12-4-English.pdf) including the South American Arenaviruses (Guanarito from Venezuela, Junín from Argentina, Machupo and Chapare from Bolivia and Sabía from Brazil) and the African one, Lassa Fever Virus (from Guinea, Nigeria and Sierra Leone). Also the Lujo virus, not yet a Select Agent, has been recently described in AustralAfrica and represents an emerging potential threat for the region (Paweska et al. 2009).

Although bleeding tendencies are often recorded but not always life threatening, a high mortality of 30% of infected patients can occur during epidemics. Four others

arenaviruses including Flexal (Brazil), Pichínde (Columbia), Tacaribe (Trinidad and Tobago) and White Water Arroyo (California) viruses have been found to potentially infect humans and potentially represent also highly dangerous agents (for a review, Gonzalez et al. 2007).

Epidemiology Asymptomatic infections of rodents are generally suspected to be associated with an insufficient or inappropriate host immune response (Hayes and Salvato 2012) resulting in chronic viremia and/or viruria which leads to shedding of the virus into the environment via urine or faeces.

Exceptionally, chronic infection may have a deleterious effect on their reservoir's fitness, which reduces rodent host fertility (Webb et al. 1975). NHP can be experimentally infected, but there is no evidence that these viruses are pathogenic for domestic animals (e.g.: livestock, cats, dogs), while exotic pets (hamster, mice, etc.) represent a potential source of infection.

Besides the specific association between "arenavirus species – rodent species", the geographic range of an arenavirus ecologic niche appears to be more restricted than the one of its rodent reservoir-host with a more circumscribed enzootic domain, which is often limited by natural barriers (e.g., rivers, elevations, climate, food access). This appears as one of the major characteristics of the epidemiological and dispersion patterns of arenaviruses and therefore VHFs associated with them (Salazar-Bravo et al. 2002).

Argentine HF (Junín virus) was identified in the early 1940s in Argentina and described in the 1950s in the rural area of Buenos Aires province, while the virus was characterized only in 1958. Today the virus distribution expend to 150,000 km^2 of the Pampa. The Vesper mouse (*Calomys* spp.) is the natural host and direct rodent-to-human transmission occurs via ingestion of contaminated food or water, inhalation of rodent urine infested particles or via direct contact of broken skin with rodent excrements. Currently, Argentine HF remains a major and severe enzootic disease of public importance in Argentina with an endemic risk of crossing the natural barrier of the Rio Paraná and spill over Spill over to the closest neighboring countries of Uruguay (Polop et al. 2008).

Bolivian HF (BHF) (Machupo virus) was identified after several outbreaks of BHF in 1963 in the Beni province of Bolivia. Although BHF incidence increases late during the rainy season, small outbreaks are a dominant feature of the epidemiological pattern with several years of dormancy thereafter. The natural host *Calomys callosus* invades houses during floods of the rainy season resulting in close contact and human infection (Kilgore et al. 1997).

Chapare virus was isolated once from a fatal human case of hemorrhagic fever during a unique reported outbreak of HF that occurred in 2003 in the Chapare River region close to Cochabamba in Bolivia, the original setting of Machupo virus responsible of the BHF (Delgado et al. 2008). There is no information concerning an eventual natural rodent host.

Venezuela HF emerged in 1989, with several cases that occurred in the central plains of Venezuela. A new Guanarito virus was isolated and named after the region

where the first outbreak occurred (Salas et al. 1991). The main affected populations are settlers moving into cleared forest areas to practice small agriculture. *Zygodontomys brevicauda* appears to be the principal host (i.e.: reservoir) of the virus.

Lassa fever (LF) was described in 1956 in the eponym village of Lassa. LF occurs in rural West Africa, and appears to be hyper-endemic in Sierra Leone with an antibody prevalence of 8–52%, Guinea (4–55%) and Nigeria (21%). Natural transmission of Lassa virus (LASV) occurs from its domestic, ubiquitous, prolific and common multimammate rodent virus reservoir, *Mastomys natalensis*. As for other Arenaviruses it is transmitted to humans directly through rodent urine and faeces or indirectly by contaminated food. Person-to-person transmission has been described posing a risk for healthcare workers. The virus can also be contracted by an airborne route or by direct contact with infected human blood, urine, or semen, up to 3 months after clinical recovery. LF is a prominent threat outside the endemic area with several imported cases in Germany (Gunther et al. 2000), Japan (Hirabayashi et al. 1988), the United States (Holmes et al. 1990), the United Kingdom (Kitching et al. 2009) among others. About 80% of patients experience a mild or asymptomatic infection. LF has a relatively low mortality rate up to 5%. Among the endemic countries, it is estimated that LF is responsible for about 5000 deaths a year. Pregnant women have the greatest risk of fatality. After an incubation period of 1–3 weeks an acute illness develops while the virus infects every tissue from the mucosa (e.g., intestine, lungs and urinary system) and subsequently progresses to the vascular system. Initial non-specific symptoms include fever, facial swelling, muscle fatigue, conjunctivitis and mucosal bleeding. Later on there might develop gastrointestinal tract bleeding, bloody vomiting, dysphagia, melena, accompanied with cough, dyspnea worsening to cardiovascular system dysfunctions (pericarditis, tachycardia) and hepatitis; finally hearing deficit, meningo-encephalitis and seizures occur. Death is due to multiorgan failure. With respect to this multiple organ infection and accompanying HF signs differential diagnoses include other VHFs such as Ebola or Marburg, malaria or influenza (Yun and Walker 2012; for a review (http://www.cdc.gov/ncidod/dvrd/spb/mnpages/dispages/lassaf.htm; http://www.cdc.gov/ncidod/dvrd/spb/mnpages/dispages/lassaf.htm; http://www.pasteur.fr/ip/easysite/pasteur/fr/presse/fiches-sur-les-maladies-infectieuses/fievre-de-lassa).

After LASV, Lujo virus is the second known to date human pathogenic arenavirus of Africa. Among the five identified cases in 2008, four died; the fifth case was treated with ribavirin early after onset of clinical disease and survived. It has been only reported from a few patients from Zambia and from a subsequent nosocomial outbreak in South Africa (Briese et al. 2009). A natural reservoir has not yet been identified.

Sabía virus was first isolated from a fatal case of Brazilian HF (BrHF) in the village of Sabía, outside of Sao Paulo, Brazil in 1990 (Lisieux et al. 1994). Two other non-fatal accidental infections were later recorded (Gandsman et al. 1997). Chapare virus infected patients were also clinically considered as BrHF cases. Both viruses

do not have an identified reservoir, however, like the other arenaviruses, they naturally appear to have only a limited geographical distribution.

Crossing the Species Barrier Transmission Virus transmission within rodent populations occurs through vertical (mother to progeny), or horizontal routes (directly through bites or indirectly by contacts with urine or feces). Arenavirus transmission from natural rodent hosts to humans occurs through contacts with infected rodent biological fluids (i.e., blood, saliva or urine), when people (through rodent bites, trapping or eating rodents) are directly exposed to the infected rodent, or indirectly, when exposed to food contaminated with rodent urine and/or by inhalation of infested rodent excreta. Also, human-to-human transmission may occur and arenaviruses can be transmitted trough aerosolized particles and sperm fluid. Moreover, transmission to humans may occur by accidental inoculation with infected body fluids and through tissue transplantation (Emonet et al. 2006; Paweska et al. 2009).

Biosecurity, Therapy and Prevention

Prevention of arenavirus infection consists of interrupting virus transmission from rodents to humans, and from humans to humans. Rodent control seems to be efficient only in certain conditions (i.e.: urban settings). Hospital based nursing barrier appears highly efficient, including personal protective measures (gloves, masks and gowns), good hygiene and appropriate sterilization of equipment. The highest-risk of infection occurs during unprotected contact with body fluids from an infected person. Linens should be handled per CDC guidelines (http://www.cdc.gov/mmwr/preview/mmwrhtml/00037085.htm). Environmental surfaces and contaminated equipment are properly disinfected by 1:10–1:100 dilution of sodium hypochlorite or other EPA-registered disinfectants. The viruses can also be inactivated by ultra-violet, gamma irradiation, temperatures of 56 °C for 20 min and, by a pH less than 5.5 or greater than 8.5.

One anti-virus drug against arenavirus infection has been identified: Ribavirin® is an anti-viral drug that interferes with RNA viral replication. It has been proved to be an efficient treatment against LASV if administered early and might in some cases also be effective against other arenaviruses including BHF, Sabía virus or Lujo virus. Also it has been shown to be effective in advanced stages of LASV infection by reducing the virus load (McCormick et al. 1986; Barry et al. 1995; Enria and Maiztegui 1994; Kilgore et al. 1997; Briese et al. 2009).

Several antiviral molecules are under development with the most promising one directed to interfere with arenavirus cell entry (Larson et al. 2008; York and Nunberg 2006; Charrel et al. 2011). Although hyperimmune serum has been effectively used in several instances, clinical experiences are limited and only circumstantial reports are available. Hyperimmune serum treatment has been used successfully for AHF patients and a plasma bank was established in Argentina (Maiztegui et al. 1979). Also, neutralizing antibodies contained in Human immune plasma appear to be

effective in patients with BHF by reducing viremia. However, LASV infection only leads to a limited neutralizing antibody reaction and hyperimmune serum treatment is not applicable.

Among all arenaviruses, only one vaccine, i.e. the live attenuated Junín virus vaccine Candid #1, has been conclusively developed and produced: its immunogenicity and efficacy in humans was proven to be greater than 84% without causing any serious adverse effects (Maiztegui et al. 1998). Other vaccines tested in animal models include: an attenuated recombinant LASV vaccine using vesicular stomatitis virus as vector that causes a protective immune response in NHP against a lethal LASV challenge (Geisbert et al. 2005); an attenuated Lassa/Mopeia construct ML-29 virus demonstrated protection against LASV challenge in guinea pigs and Rhesus macaques (Lukashevich and Patterson 2008); a yellow fever 17D vaccine expressing LASV glycoprotein precursor protected also guinea pigs against LASV challenge (Bredenbeek et al. 2006; Charrel and de Lamballerie 2010 for review).

52.2.1.3 Rift Valley Fever

Rift Valley Fever (RVF) is a viral zoonosis that primarily affects domestic livestock and also humans in Africa. RVF present a clinical spectrum from mild fever to fatal hemorrhagic syndrome Rift Valley Fever (RVF). RVF virus is spread by infected *Aedes* spp. Aedes spp. or *Culex* spp. Culex spp. mosquitoes. RVF virus is a member of the Phlebovirus genus of the Bunyaviridae family.

Clinical Signs Only a small percentage of patients develops a severe form of the disease including: ocular disease with retinal lesions (0.5–2% of patients); meningoencephalitis (<1%) with headache, loss of memory, confusion, convulsions, and coma; hemorrhagic fever (<1%) starting with severe liver impairment, jaundice, followed by hemorrhage, vomiting blood, melena, purpuric rash, nose and gums bleedings, or menorrhagia. Hemorrhagic forms have a case-fatality as high as 50%. The virus may be detected in blood for up to 10 days.

RVFV is also able to infect many animal species causing particularly severe disease in domesticated animals including cattle, sheep Sheep, camels and goats Goats. Sheep are very sensitive to infection: 90% of infected lambs die, and abortion occurs in up to 100% of infected pregnant ewes.

Epidemiology Human infections can result from direct contact with infected animal biological products, by handling of animal tissue during slaughtering or butchering, conducting veterinary procedures, or from the disposal of carcasses or fetuses. Consequently, herders, slaughterhouse workers, farmers and veterinarians are at high risk of infection. The virus can infect humans through inoculation (i.e.: wound), inhalation of aerosols, by ingesting unpasteurized or uncooked milk or from mosquito bites Bites:mosquito. To date, no human-to-human transmission of RVF has been documented. Outbreaks of RVF occur essentially in rural

environment (see WHO (http://www.who.int/mediacentre/factsheets/fs207/en/) for review).

RVF may occur as large outbreaks when heavy rains favor intense breeding of mosquito vectors. Deaths of newborn animals and abortion in pregnant sheep, goats, and cattle may happen and humans can become infected by contact with infected animal tissues or by mosquito bites. The active circulation of RVFV in Africa and the Arabian Peninsula constitutes a threat for human and animal health all over the African continent and beyond (Grobbelaar et al. 2011).

Biosecurity and Prevention Rift Valley fever belongs to the Select Agent list. It is a potential biological weapon particularly because of its high pathogenicity and its potential to be airborne transmitted (Borio et al. 2002).

Basic nursing barrier and standard infection control precautions are recommended to avoid RVFV transmission to health care workers.

A live-attenuated MP-12 RVFV strain has been developed as a vaccine; the vaccine has been shown to protect bovine and ovine dams against RVFV challenge and is safe and efficacious for use in neonatal calves and lambs (Morrill et al. 1997). Another live attenuated RVFV vaccine lacking the NSs and NSm genes cannot be transmitted by mosquitoes (Bird et al. 2011; Crabtree et al. 2012).

52.2.1.4 Kyasanur Forest Disease

The Kyasanur Forest Disease (KFD) is a tick-borne VHF endemic to and geographically limited to Karnataka State of Central-West India (Work and Trapido 1957). The KFD virus belongs to the Flaviviridae family.

In the early 1990s a new and close related highly pathogenic virus (more than 30% mortality rate), the Alkhurma virus, was isolated in Saudi Arabia and represents another threat for the local population (Charrel et al. 2001).

Clinical Signs

After an incubation period of 3–8 days, KFD starts with a sudden onset of fever, headache, severe muscle pain, cough and dehydration: later on a gastrointestinal syndrome and bleeding occurs. 10% of the patients develop low blood pressure and pancytopenia. Some patients show a biphasic form and experience after 2 weeks a second phase of fever and neurological syndrome leading to a case fatality rate (CFR) of 3–5%. Approximately 400–500 cases of KFD occur in India per year.

Epidemiology (http://www.phac-aspc.gc.ca/lab-bio/res/psds-ftss/kyasanur-eng.php#note10)

Although the main hosts of KFDV are rodents, shrews, bats, and monkeys may also carry the virus. Cattle, goats and sheep may become infected without playing a role in the transmission of the disease. KFDV is transmitted from the bite of an infected tick, principally *Haemaphysalis spinigera* (Work et al. 1959).

Crossing the Species Barrier
Humans can get infected from tick bites or by contact with an infected animal (often sick monkeys: *Presbytis entellus* or *Macaca radiata*). KFDV is common in young adults exposed during the dry season in the forest.

Biosecurity and Prevention
A formalin-inactivated tissue-culture vaccine has been used for vaccination campaigns since the early 1990s in the endemic area of India with an efficacy of 79.3–93.5% after respectively one or two doses (Dandawate et al. 1994).

52.2.1.5 Omsk Hemorrhagic Fever

The tick-borne arbovirus Omsk Hemorrhagic Fever Virus (OHFV) is a member of the Flaviviridae family and classified as a biosafety level 4 virus. Several tick species can transmit the virus including *Dermacentor reticulatus*, *D. marginatus* and *Ixodes persulcatus*.

Clinical Signs As for KHFD, after a one week-incubation period, a first clinical phase of infection, begins with several symptoms including fever, chills, headache, muscular pain, rash, and cervical adenopathy. After 2 weeks a neurological syndrome appears sometimes accompanied by a hemorrhagic syndrome with severe platelet loss and leucopenia. A third of patients develops pneumonia, nephritis, meningitis, or a combination of these complications. The CFR ranges from 1% to 10%, surviving patients acquire life-long immunity.

Epidemiology
The geographic distribution of the OHFV appears restricted to western Siberia (Kharitonova and Leonov 1985) in Omsk, Novosibirsk, Kurgan, and Tyumen oblasts. The main hosts of OHFV are rodents and in particular the non–native muskrat (*Ondatra zibethica*) as a natural OHFV reservoir. Muskrat was imported to Siberia from Canada in the 1920s and the virus finds a particular receptive host to replicate and spread efficiently.

The sylvatic cycle of OHFV involves rodents and in particular the non–native muskrat as a natural OHFV reservoir, but also water voles (*Arvicola terrestris*), while most animals within endemic areas can be infected and bitten by the tick vectors. OHFV survives in water and is transferred to humans via contaminated water or an infected tick.

Crossing the Species Barrier Humans become infected through tick bites or contact with blood, feces or urine of infected muskrats (and other hosts). Gamasid mites are also thought to play a minor role in transmission within the sylvatic cycle. OHFV can also spread through milk from infected goats or sheep.

Prevention
Preventing OHF consists of avoiding tick exposure; consequently persons engaged in farming, forestry, and hunting (i.e.: Siberian muskrat) are at highest risk of infection.

52.2.2 Viral Encephalitis

52.2.2.1 Eastern Equine Encephalitis

The Pathogen Eastern equine encephalitis virus (EEEV) Eastern equine encephalitis virus (EEEV) is a member of the genus Alphavirus, family Togaviridae. Other medically important alphaviruses found in the Americas include Western equine encephalitis virus (WEEV) and Venezuelan equine encephalitis virus (VEEV). EEEV has a single-stranded, positive-sense RNA genome. The virus particles are spherical and have a diameter of 60–65 nm (Snyder et al. 2009). Of the four lineages of EEEV, Group I is endemic in North America and the Caribbean and causes most human disease cases; the other three groups (IIA, IIB, and III) cause primarily equine illness in Central and South America (Zacks and Paessler 2010).

Clinical Signs The incubation period for Eastern equine encephalitis virus (EEEV) Eastern equine encephalitis virus (EEEV) disease ranges from 4 to 10 days. EEEV infection can result in one of two types of illness, systemic or encephalitic (involving swelling of the brain, referred to as EEE). The type of illness will depend on the age of the person and other host factors. It is possible that some people who become infected with EEEV may be asymptomatic.

Systemic infection has an abrupt onset and is characterized by chills, fever, malaise, arthralgia and myalgia. The illness lasts 1–2 weeks, and recovery is complete when there is no central nervous system involvement. In infants, the encephalitic form is characterized by abrupt onset; in older children and adults, encephalitis is manifested after a few days of systemic illness. Signs and symptoms in encephalitic patients are fever, headache, irritability, restlessness, drowsiness, anorexia, vomiting, diarrhea, cyanosis, convulsions, and coma.

EEE is the most severe of the arboviral encephalitis entities and has a mortality of 50–75% (Petersen and Gubler 2003). Death usually occurs 2–10 days after onset of symptoms, but can occur much later. Of those who recover, 15–50% are left with disabling and progressive mental and physical sequelae, which can range from minimal brain dysfunction to severe intellectual impairment, personality disorders, seizures, paralysis, and cranial nerve dysfunction. Many patients with severe sequelae die within a few years (Zacks and Paessler 2010).

No human vaccine against EEEV infection or specific antiviral treatment for clinical EEEV infections is available. Patients with suspected EEE should be evaluated by a healthcare provider, appropriate serologic and other diagnostic tests ordered, and supportive treatment provided.

Epidemiology EEEV is transmitted to humans through the bite of an infected mosquito. Human EEEV cases occur relatively infrequently, largely because the primary transmission cycle takes place in and around swampy areas where human populations tend to be limited. Overall, only about 4–5% of human EEEV infections result in EEE. EEEV infection is thought to confer life-long immunity against

re-infection. It does not confer significant cross-immunity against other alphaviruses (e.g., Western Equine Encephalitis Virus), and it confers no cross-immunity against flaviviruses (e.g., West Nile Virus) or bunyaviruses (e.g., La Crosse Virus).

In the United States, about six human cases of EEE are reported annually. Most cases of EEE have been reported from Florida, Georgia, Massachusetts, and New Jersey. EEEV transmission is most common in and around freshwater hardwood swamps in the Atlantic and Gulf Coast states and the Great Lakes region. Between 1964 and 2010, there were 270 confirmed cases of EEE in the US. Several states in the northeastern USA have seen increased virus activity since 2004. Between 2004 and 2006, there were 17 equine cases and at least 13 human cases of EEE reported in Massachusetts. In 2006, approximately 500,000 acres (2000 km^2) in southeastern Massachusetts were treated with mosquito adulticides to reduce the risk of humans contracting EEE. Subsequently, between 2007 and 2010, there were two confirmed human cases and six equine cases reported to CDC and USDA respectively.

In October 2007, a citizen of Livingston, West Lothian, Scotland became the first European victim of this disease. The man had visited New Hampshire during the summer of 2007 on a fishing vacation, and was diagnosed as having EEEV on 13 September 2007. He fell ill with the disease on 31 August 2007, just one day after flying home [5].

In 2012, 209 equine cases of EEE were reported from 19 US States, and 15 human cases of EEE reported from six US States. In 2012, two residents of Vermont were confirmed to have EEE, and this was the first time the illness had been reported in this state.

Crossing the Species Barrier Eastern equine encephalitis virus (EEEV) Eastern equine encephalitis virus (EEEV) is maintained in a cycle between *Culiseta melanura* mosquitoes and avian hosts in freshwater hardwood swamps. *Cs. melanura* is not considered to be an important vector of EEEV to humans, because it feeds almost exclusively on birds. Transmission to humans requires mosquito species capable of creating a "bridge" between infected birds and uninfected mammals such as some *Aedes*, *Coquillettidia*, and *Culex* species.

Wild birds are the main reservoir for transmission of EEEV. Humans, horses, and other animals (domestic fowl, feral pigs, cattle and rodents) are not significant reservoir hosts (Zacks and Paessler 2010). Amphibians and reptiles are a possible reservoir for the virus to overwinter. Mosquitoes and infected eggs are also a reservoir for the viruses (Pfeffer and Dobler 2010).

Person-to-person transmission has not been reported for EEEV viruses. Direct bird-to-human infection can occur, although humans and horses are not amplifying hosts as virus titers in their bodies are insufficient to infect mosquitoes. Eggs of mosquitoes can be infected by the female (Pfeffer and Dobler 2010).

Horses are susceptible to EEEV infection and some cases are fatal. EEEV infections in horses, however, are not a significant risk factor for human infection, because horses (like humans) are considered to be "dead-end" hosts for the virus

(i.e., the concentration of virus in their bloodstreams is usually insufficient to infect mosquitoes) (Zacks and Paessler 2010).

Biosecurity and Prevention All residents of and visitors to areas where virus activity has been identified are at risk of infection with EEEV, particularly persons who engage in outdoor work and recreational activities in these areas. Persons over age 50 and younger than age 15 are at greatest risk for severe disease (encephalitis) following infection. EEEV infection is thought to confer life-long immunity against re-infection.

EEEV is difficult to isolate from clinical samples; almost all isolates (and positive PCR results) have come from brain tissue or CSF. Laboratory acquired infections have been reported, and accidental parenteral inoculation, contact of the virus with broken skin or mucous membranes, and bites Bites from infected laboratory arthropods or rodents are the primary hazards associated while working with these viruses.

EEEV do not persist in the environment, and are susceptible to many common disinfectants including 1% sodium hypochlorite, 70% ethanol, 2% glutaraldehyde and formaldehyde. EEEV can be inactivated by exposure to 50% ethanol at concentration for 60 min, also by moist or dry heat, or by drying, or by UV rays (Aguilar et al. 2005).

EEEV was one of more than a dozen agents that the United States researched as potential biological weapons before the nation suspended its biological weapons program. Samples taken from people and animals with suspected EEEV infection should be handled by trained staff working in Biosafety Level 3 (BSL-3/ABSL-3) **containment** laboratories (CDC 2007).

52.2.2.2 Venezuelan Equine Encephalitis

The Pathogen Venezuelan equine encephalitis virus (VEEV) is a spherical arbovirus that belongs to the Togaviridae family and is an alphavirus (Atasheva et al. 2010). It is 70 nm in diameter and has an enveloped single stranded RNA genome (Gardner et al. 2008).

The Venezuelan equine encephalomyelitis complex contains at least six viral subtypes, I–VI. Subtype I, the Venezuelan equine encephalomyelitis virus (VEEV), is divided into five antigenic variants or serovars, AB to F. Some of the other five subtypes also have official species names; subtype II is known as Everglades virus, subtype III as Mucambo virus, and subtype IV as Pixuna virus.

VEE complex viruses are divided into epizootic (or epidemic) and enzootic (or endemic) groups. The epizootic viruses, which are amplified in equines and are responsible for most epidemics, are found in VEEV subtypes I-AB and I-C. The remaining viruses, including VEEV I-D, VEEV I-E and variants in subtypes II-VI are enzootic (sylvatic) subtypes. These viruses are generally found in limited geographic areas, where they usually occur in natural cycles between rodents and mosquitoes. The enzootic subtypes are typically non-pathogenic for

horses and are not amplified in this host; however, in 1993 an enzootic I-E variant was responsible for an outbreak of VEE among horses in Mexico (Weaver et al. 2004).

Clinical Signs In humans, VEEV usually causes mild to severe influenza-like symptoms; 4–14% of cases, however, develop neurological complications (Gardner et al. 2008). Children and young adults are more likely to develop encephalitis; however, fatalities in humans are rare reaching about 1% of all reported cases (de la Monte et al. 1985). Usually, flu-like symptoms such as headache, myalgia, fatigue, vomiting, nausea, diarrhoea, pharyngitis and fever appear abruptly, 2–5 days after exposure to the virus. The VEE virus can also cause retro-orbital and occipital headaches as well as leucopenia and tachycardia. Symptoms of encephalitis, only appearing in a minority of cases, occur 4–10 days after exposure and include somnolence, convulsions, confusion, photophobia, and coma. Fatal human cases are usually caused by encephalitis as well as brain, lung and gastrointestinal bleeding (Weaver et al. 2004). Long-term neurological damage can be caused by this virus and it can infect the foetus in pregnant women causing birth defects and stillbirths (de la Monte et al. 1985). Generally, the symptoms last between 3 and 8 days and can be biphasic, recurring 4–8 days after the initial symptoms (Sidwell et al. 1967).

Enzootic VEEV usually infects horses sub-clinically or cause mild symptoms. Epizootic subtypes may cause a generalized acute febrile disease with or without neurologic signs. Asymptomatic infections also occur.

Fatal VEE has been reported in various mammals including rabbits, goats, dogs and sheep during epizootics. Some VEE viruses also kill laboratory rodents including hamsters, guinea pigs and mice Mice; however, natural reservoir hosts for enzootic strains usually remain asymptomatic. Experimentally infected, NHP develop a nonspecific febrile illness similar to human disease.

Epidemiology Epizootic VEE viruses (VEEV I-AB and I-C) are found in South and Central America. Most VEE epidemics occur in northern and western South America, but some may spread into adjacent countries, including the US. Enzootic VEE viruses have been found in Mexico, parts of the US, and South and Central America.

The virus was first observed in horses in 1935 after outbreaks in Columbia, Venezuela and Trinidad, and was isolated in 1938. In the 1960s, over 200,000 human cases and 100,000 equine deaths were reported in Colombia and smaller epidemics occurred in Venezuela and Mexico. Between 75,000 and 100,000 infections were reported in Venezuela and Colombia in 1995. The outbreaks usually occur after a season of heavy rains, due to increases in the mosquito population (Weaver et al. 2004).

VEE can be widespread in human populations during epidemics; more than 10% of the population in an area may be affected. Between epidemics, sporadic cases of VEE are caused by enzootic viruses. Humans are highly susceptible to VEE;

approximately 90–100% of exposed individuals become infected, and nearly 100% develop clinical signs. However, most infections are mild. Less than 1% of adults develop encephalitis, with approximately 10% of these cases ending in death; the overall CFR in adults is less than 1%. Very young or elderly patients are more likely to develop severe infections. Encephalitis, with a CFR of 35%, occurs in approximately 4% of children less than 15 years of age. More severe disease, with a higher incidence of neurologic signs, might occur in both children and adults after a biological attack with aerosolized virus.

Instances of person-to-person transmission have not been reported for the VEE virus, although an infected individual can transmit the virus to mosquitoes. Generally, humans and equines become infected by mosquitoes of the *Psorophora* and *Ochlerotatus* genus. Equines can spread the virus to each other through aerosols and to mosquitoes via bites (Pfeffer and Dobler 2010).

Crossing the Species Barrier There are two types of cycles involved in the VEE virus. The enzootic cycle is maintained by rodents and mosquitoes. The epizootic cycle implicates horses, mosquitoes and humans, although there is the potential for the virus to affect many other animal species (Pfeffer and Dobler 2010). Horses are the amplifying host in the cycle and are necessary for a larger outbreak of VEE (de la Monte et al. 1985).

VEEV is typically spread by mosquitoes, although certain types of ticks and mites can spread the virus as well (Weaver et al. 2004). The *Culex (Melanoconion)* mosquito is normally responsible for the dispersal of the enzootic strain of the VEE virus (Zacks and Paessler 2010). *Ochlerotatus taeniorhynchus, Psorophora confinnis, Psorophora columbiae, Ochleratus sollicitans, Mansonia titillans* and *Anophilis aquasalis* are some of the species of mosquitoes known to carry the epizootic varieties of the VEEV (Weaver et al. 2004).

VEE epidemics typically begin in horses, with human cases developing weeks later: Unlike EEE outbreaks, which usually end with the onset of colder temperatures, VEE epidemics can last for several years. Epizootic subtypes of VEEV can cause significant morbidity and mortality in equids; the infection rate can be as high as 90%, and the morbidity rate varies from 10–40% in some areas to 50–100% in others. The CFR in horses is 38–90%. Fatal infections have also been reported in goats, rabbits, dogs and sheep during epizootics, as well as in laboratory rodents infected with some isolates.

Most enzootic VEEV subtypes do not result in serious disease or deaths in horses, but limited outbreaks of encephalitis have been reported with some variants.

Rodents are usually the natural hosts for enzootic VEEV, but birds are involved in a few cycles. The maintenance host for epizootic VEEV between outbreaks is unknown; during epidemics, these viruses are amplified mainly in equids.

Epidemic VEEV can cause serious disease in horses, mules, burros, donkeys and zebras. During epizootics, fatal cases have also been reported in domesticated rabbits, dogs, goats and sheep. Cattle, pigs, bats Bats and opossums can also be infected. Experimental infections have been reported in NHP, guinea pigs, mice

Mice and hamsters; some isolates are fatal for laboratory rodents, although they are usually asymptomatic in their normal rodent hosts.

Biosecurity and Prevention VEEV can be found in the body fluids of horses, and transmission by direct contact or aerosols is theoretically possible in this species. However, natural transmission of VEEV between horses or from horses to humans has not been seen. Infected laboratory rodents can also shed this virus, and people have been infected after exposure to aerosolized debris from cages.

Vaccinations of equines with the TC-83 vaccine and protection against mosquitoes (protective clothing, insecticides) are some of the proposed ways to reduce VEE outbreaks. While the TC-83 vaccine is recommended for laboratory workers, there is no licensed vaccine available for the general population (Weaver et al. 2004).

Arboviruses may be present in blood, cerebrospinal fluid, urine and exudates. The virus may be found in nasal, eye and mouth secretions of infected animals as well as in contaminated animal bedding. The greatest risks when working with VEEV are exposure to infected aerosols, accidental subcutaneous inoculation, and contact with broken skin or contaminated animal bedding. VEEV is stable in dried blood and exudates as well as in freeze dried materials (aerosols) (Chosewood and Wilson 2009). One viral infectious particle injected subcutaneously is enough to infect an individual with VEEV (Collins and Kennedy 1983).

Like other enveloped viruses, VEEV virus is susceptible to disinfectants such as 1% sodium hypochlorite, 4% formaldehyde, 2% gluteraldehyde, 70% ethanol, 3–6% hydrogen peroxide, 2% and peracetic acid (Collins and Kennedy 1983). Microbial inactivation is possible using moist or dry heat (Block 2001). Togaviruses can be inactivated by 15 min of heat at 65 °C (Lelie et al. 1987).

During the Cold War, both the United States biological weapons program and the Soviet biological weapons program researched and weaponized VEEV. In April 2009, the U.S. Army Medical Research Institute of Infectious Diseases at Fort Detrick reported that samples of VEEV were discovered missing during an inventory of a group of samples left by a departed researcher. The report stated the samples were likely among those destroyed when a freezer malfunctioned.

52.2.2.3 Tick-Borne Encephalitis

The Pathogen Tick-borne encephalitis virus (TBEV) is a single-stranded RNA virus that belongs to the genus *Flavivirus*, and was initially isolated in 1937. TBEV has three subtypes: European, Siberian, and Far Eastern, and is the most important arthropod-borne virus in Europe (Ramelow et al. 1993; Barrett et al. 2008).

The family Flaviviridae includes other tick-borne viruses affecting humans and these viruses are closely related to TBEV and Russian Spring Summer encephalitis, such as Omsk hemorrhagic fever virus in Siberia, Al Khumra virus in Saudi Arabia, and Kyasanur Forest disease virus in India. Louping ill virus (United

Kingdom) is a member of this family; it causes disease primarily in sheep and has been reported as a cause of a TBE-like illness in laboratory workers and persons at risk for contact with sick sheep (e.g.: veterinarians, butchers) (see above paragraphs 5.2.1.4 and 5.2.1.5).

Clinical Signs Tick-borne encephalitis (TBE) is a human viral infectious disease involving the central nervous system. The disease most often manifests as meningitis, encephalitis or meningoencephalitis. Although TBE is most commonly recognized as a neurologic disease, mild febrile illnesses can also occur. Long-lasting or permanent neuropsychiatric sequelae are observed in 10–20% of infected patients. Approximately two thirds of infections are asymptomatic. The median incubation period for TBE is 8 days (range, 4–28 days). The incubation period for milkborne exposure is usually shorter (3–4 days). Hemmer et al. (2005) recommended that tickborne encephalitis should be included in the differential diagnosis of meningoencephalitis in northeastern Germany, even if the patient has not been in tickborne encephalitis–endemic areas.

Among patients with central nervous system involvement, approximately 10% require intensive care and 5% need mechanical ventilation. Clinical course and long-term outcome vary by subtype of TBEV. The European subtype is associated with milder disease, a case-fatality ratio of <2%, and neurologic sequelae in up to 30% of patients. The Far Eastern subtype is often associated with a more severe disease course, including a case-fatality ratio of 20–40% and higher rates of severe neurologic sequelae. The Siberian subtype is more frequently associated with chronic or progressive disease and has a case-fatality ratio of 2–3%.

Epidemiology Tick-borne encephalitis (TBE) has become a considerable public health risk in several European countries, and on average, between 1990 and 2009, nearly 8500 cases of TBE were reported annually in Europe including Russia, although with considerable variability in incidence from year to year (Suss 2011). Many factors contribute to this increase: expanding tick populations due to climatic factors (Randolph 2009; Randolph 2010), social and behavioral changes (Kriz et al. 2004), as well as changes in land use and leisure activities (Sumilo et al. 2007). Reporting of TBE cases has improved as it is a notifiable disease in 16 European countries, including 13 European Union (EU) Member States (Austria, Czech Republic, Estonia, Finland, Germany, Greece, Hungary, Latvia, Lithuania, Poland, Slovak Republic, Slovenia, Sweden) and three non-EU Member States (Norway, Russia and Switzerland) (Donoso et al. 2008).

TBE is endemic in temperate regions of Europe and Asia (from eastern France to northern Japan and from northern Russia to Albania) and up to about 4921 ft (1500 m) in altitude. Russia has the highest number of reported TBE cases, and western Siberia has the highest incidence of TBE in the world. Other countries where the incidence is high include the Czech Republic, Estonia, Germany, Hungary, Latvia, Lithuania, Poland, Slovenia, Sweden, and Switzerland. High vaccination rates in Austria have reduced the incidence of TBE; however, unvaccinated travelers

to this country are still at risk. European countries with no reported cases are Belgium, Iceland, Ireland, Luxembourg, the Netherlands, Portugal, Spain, and the United Kingdom (Suss 2008). Asian countries known to be endemic for TBE include China, Japan, Mongolia, and South Korea (Lu et al. 2008; Walder et al. 2006).

Crossing the Species Barrier TBEV is transmitted to humans through the bite of an infected tick of the Ixodes species, primarily *I. ricinus* (European subtype) or *I. persulcatus* (Siberian and Far Eastern subtypes). The virus is maintained in discrete areas of deciduous forests. Ticks act as both vector and virus reservoir, and small rodents are the primary amplifying host. Tickborne encephalitis (TBE) can also be acquired by ingesting unpasteurized dairy products (such as milk and cheese) from infected goats, sheep or cows, and reports of this route of infections come from Slovakia, Poland, the Baltic States, and other Eastern European countries (Kerbo et al. 2005; Vaisviliene et al. 2002; Balogh et al. 2010). TBEV transmission has infrequently been reported through laboratory exposure and by slaughtering viremic animals. Direct person-to-person spread of TBEV occurs only rarely, through blood transfusion or breastfeeding (Dumpis et al. 1999).

TBE is also emerging in Europe's canine population, and the numbers of clinical cases in dogs are expected to increase (Leschnik et al. 2002; Beugnet and Marie 2009). Humans are accidental dead-end hosts for ticks and for TBEV as, humans do not transmit the disease despite showing noticeable viremia (Heinz 2008) (http://www.eurosurveillance.org/ViewArticle.aspx?ArticleId=18848).

Biosecurity and Prevention Reducing exposure to ticks is the best method to prevent TBE in humans. It is also recommended to avoid consuming unpasteurized dairy products (Rendi-Wagner 2004). Repellents or insecticides provide unreliable protection against tick bites, and there is no specific antiviral treatment for TBE; therapy consists of supportive care and management of complications (Ginsberg and Stafford 2005).

Being a zoonosis, TBE cannot be easily eliminated from endemic areas. However, the introduction of large-scale vaccination campaigns has proven to be highly effective in reducing the burden of disease. In Austria, where the vaccination coverage in the general population has reached approximately 90%, the number of clinical cases could be reduced to about 10%, as compared to the prevaccination era (Heinz et al. 2007). In most highly TBE-endemic countries, large-scale vaccination campaigns are not implemented (Heinz 2008). The risk of acquiring TBE in a highly endemic area in Austria was calculated at approximately 1/10,000 per person-month (Rendi-Wagner 2004). WHO (2012) recommends tick bite prevention in endemic areas during the summer months; only at-risk travellers should be offered vaccination. Travellers are considered to be at risk when hiking or camping in rural and forested areas up to altitudes of 1400 m (WHO 2012).

52.2.3 Other Severe Clinical Syndromes

52.2.3.1 Monkeypox

The Pathogen *Monkeypox* is a viral disease caused by the Monkeypox virus Monkeypox virus (MPXV), an orthopoxvirus. Human cases have been reported from nine countries in central and western Africa where the disease is endemic – Democratic Republic of Congo, People's Republic of Congo, Central African Republic, Gabon, Cameroon, Nigeria, Cote d'Ivoire, Liberia, and Sierra Leone.

The virus was first identified in the State Serum Institute in Copenhagen, Denmark, in 1958 during an investigation into a pox-like disease among monkeys. Monkeypox virus is pathogenic for both animals and humans: Human monkeypox infection was first identified in 1970 in a 9 month old child in the town of Basankusu, Equateur Province, Democratic Republic of Congo and initially NHP were suspected as the source of outbreaks (Ladnyj et al. 1972; Marrennikova et al. 1972).

Over the next year, six further human cases of monkeypox infection were reported in Liberia, Sierra Leone and Nigeria (Foster et al. 1972). From 1970 to 1979, 47 human cases of monkeypox were identified, 38 of which were from Zaire, and the majority were in close proximity to the tropical rainforest (Nalca et al. 2005). A total of 79 cases were subsequently reported over the next 12 years. In 1996–1997 a major outbreak involving 88 cases occurred; between 2001 and 2002 51 human cases were reported in the Democratic Republic of Congo (Hutin et al. 2001; Heymann et al. 2008).

During May and June 2003, the first cases of human monkey pox disease outside of the African continent were reported in an outbreak in Midwestern United States (Illinois, Indiana, Kansas, Missouri, Ohio and Wisconsin) due to direct contact with ill prairie dogs that were kept or sold as pets and which had been recently exposed to imported Monkeypox virus-infected West African rodents from Ghana (Reed et al. 2004).

There were ten confirmed cases and nine probable cases of monkeypox between September and December of 2005 reported in Unity, Sudan (now South Sudan). The particularly intriguing aspect of this outbreak is the evidence of possible human-to-human transmission. In this case, a traditional healer was linked to three of the four transmission chains in the outbreak. The healer had a confirmed case of monkeypox, and a number of the monkeypox patients were either children whom the healer had recently treated for illnesses or young adults who had gone to him for a tooth extraction procedure (removal of the incisors to signify passage into adulthood is a cultural tradition in this part of Sudan) (Nakazawa et al. 2013).

Clinical Signs Monkeypox disease is characterized by the onset of non-specific symptoms which can include fever, headache, backache, and fatigue during a prodromal period of 2–3 days (Reynolds et al. 2006). This is followed by a 2–4 week period in which a rash develops and progresses from macules, to papules,

to vesicles, and then to pustules, followed by umbilication, scabbing and desquamation (CDC 2003). The rash is usually confined to the trunk, but can spread to the palms and soles of the feet, occurring in a centrifugal distribution (Parker et al. 2007). Lesions can also develop on mucous membranes, in the mouth, on the tongue, and on the genitalia (Nalca et al. 2005). The pathogenicity of monkeypox is similar to that of smallpox except for the pronounced lymphadenopathy associated with monkeypox and generally milder symptoms (Heymann 2008). Lymphadenopathy is thus considered to be a key distinguishing feature of monkeypox (Weber and Rutala 2001). The CFR is approximately 1–10% in Africa, with higher death rates among young children (Parker et al. 2007). In children unvaccinated against smallpox, the case-fatality rate ranges from 1% to 14% (Heymann 2008). In addition, children may be more susceptible to monkeypox due to the termination of regular smallpox vaccinations following the worldwide eradication of the disease in 1980.

The incubation period varies from 6 to 16 days. The number of lesions varies from a few to several thousands, affecting oral mucous membranes (in 70% of cases), genitalia (30%), and conjunctivae (20%), as well as the cornea.

There are no drugs or vaccines available for monkeypox, although vaccination against smallpox has been proven to be 85% effective in preventing monkeypox in the past (Parker et al. 2007). Prophylactic vaccination with the smallpox vaccine may be useful within 4 days and up to 14 days after initial contact with a confirmed monkeypox case (CDC 2007).

Epidemiology Monkeypox affect all age groups; however, children under age of 16 have constituted the greatest proportion of cases (Heymann 2008).

Infections of index cases result from direct contact with blood, bodily fluids, or rashes of infected animals. In Africa, human infections have been documented through handling of infected monkeys, Gambian rats or squirrels.

Secondary transmission is human-to-human, resulting from close contact with infected respiratory tract excretions, with skin lesions of an infected person or with recently contaminated objects. Transmission via droplet respiratory particles has also been documented. Transmission can also occur by inoculation or via the placenta (congenital monkeypox). There is no evidence to date that person-to-person transmission alone can sustain monkeypox in the human population.

The differential diagnoses include usually smallpox, chickenpox, measles, bacterial skin infections, scabies, medicamentous allergies and syphilis.

Monkeypox can be definitively confirmed by a number of different tests (ELISA, antigen detection tests, PCR, virus isolation).

Crossing of the Species Barrier In Africa, monkeypox infection has been found in many animal species: rope squirrels, tree squirrels, Gambian rats, striped mice, dormice and NHP. Doubts persist on the natural history of the virus and further studies are needed to identify the exact reservoir of the monkeypox virus Monkeypox virus (MPXV) and how it is maintained in nature.

In the USA, the virus is thought to have been transmitted from African animals to a number of susceptible non-African species (like prairie dogs) with which they were co-housed.

Multiple events of human-to-human transmission have been reported, but sustained Monkeypox virus infection cycles among humans have not been documented (Damon et al. 2006; Formenty et al. 2010).

Likos et al. (2005) investigated phylogenetic relationships between Monkeypox virus isolates by examining five whole-genome sequences and confirmed the existence of two distinct groups: the first group contained isolates from the Congo Basin (Congo Basin clade), and the second group included isolates from countries in western Africa. Differences in epidemiologic and clinical features between Monkeypox virus isolates (e.g., higher morbidity and CFR caused by the Congo Basin clade) support the differentiation between these two clades.

Biosecurity and Prevention During monkeypox outbreaks, close contact with other patients is the most significant risk factor for monkeypox virus infection. In the absence of specific treatment and a vaccine, the only way to reduce infection in people is by raising awareness of the risk factors and educating people about the measures they can take to reduce exposure to the virus.

Public health educational messages should focus on the following risks.

- Reducing the risk of human-to-human transmission. Close physical contact with monkeypox infected people should be avoided. Gloves and protective equipment should be worn when taking care of sick people. Regular hand washing should be carried out after caring for or visiting patients.
- Reducing the risk of animal-to-human transmission. Efforts to prevent transmission in endemic regions should focus on thoroughly cooking all animal products (blood, meat) before eating. Gloves and other appropriate protective clothing should be worn while handling sick animals or their infected tissues, and during slaughtering procedures.

Restricting or banning the movement of small African mammals and monkeys may be effective in slowing the expansion of the virus outside Africa.

Captive animals should not be inoculated with smallpox. Instead, infected animals should be isolated from other animals and placed into immediate quarantine. Any animals that might have come into contact with an infected animal should be quarantined and observed for monkeypox symptoms for 30 days.

Health-care workers caring for patients with suspected or confirmed monkeypox virus infection, or handling specimens from them, should implement standard infection control precautions. Healthcare workers and those treating or exposed to patients with monkeypox or their samples should consider being immunized against smallpox. However, the smallpox vaccination should not be administered to people with comprised immune systems.

Samples taken from people and animals with suspected monkeypox virus infection should be handled by trained staff working in Biosafety Level 3 (BSL-3/ABSL-3) **containment** laboratories (CDC 2007). Orthopoxviruses are susceptible to 0.5% sodium hypochlorite, chloroxylenol-based household disinfectants, glutaraldehyde, formaldehyde, and paraformaldehyde; and are inactivated by heat (autoclaving and

incineration) (Butcher and Ulaeto 2005). Orthopoxviruses are stable at ambient temperatures when dried (CDC 2007) Orthopoxvirus(es).

52.2.3.2 Severe Acute Respiratory Syndrome

The Severe Acute Respiratory Syndrome (SARS) Coronavirus (SARS-CoV) is responsible for an acute and often fatal respiratory syndrome that was identified for the first time in the Guangdong province of South China in 2003 (Peiris et al. 2003). SARS-CoV consequently expended encompassing 37 countries and created the first emerging pandemic of the twenty-first century.

Clinical Signs SARS-CoV may cause an often-severe illness marked initially by systemic symptoms of muscle pain, headache, and fever, followed in 2–10 days by a respiratory symptoms (cough, dyspnea, and pneumonia) and a marked lymphocytopenia. Increased respiratory distress led to a CFR of 9.6% (Smith 2006).

Epidemiology SARS emerged as a unique pandemic starting as an epidemic in Guangdong Province, China in November 2002. It further expanded from person to person worldwide as a pandemic in less than 9 months and ultimately infected more than 8000 persons killing more than 700. The pandemic ended in May 2004.

The virus is supposed to have originated from its natural host, a horseshoe bat (*Rhinolophus sinicus*). Subsequently, it is thought to have been transmitted to and mutated within a secondary host, the palm civet (*Panguma larvata*) serving also as an amplification host, before it was passed into humans as a new human-pathogenic virus, the SARS-CoV (Zhong et al. 2003). SARS-CoV was found to infect also raccoon dogs (*Nyctereuteus* sp.), ferret badgers (*Melogale* spp.) and domestic cats. SARS-CoV emerged several times from the same intermediate host, the palm civet, to transgress the species barrier and infect humans. Nevertheless, SARS-CoV seems to have also emerged several times in the past in the province of Guangdong, but remained unnoticed as potential epidemic risk. The conclusion was that bats acted as a reservoir of SARS-CoV with the potential to infect other mammals including humans (Li et al. 2005).

Likewise but surprisingly, 10 years after the SARS-pandemic, a novel human coronavirus (HCoV-EMC) emerged in the Middle East in 2012 (Bermingham et al. 2012). The HCoV-EMC was identified following respiratory infections with a clinical presentation of severe acute respiratory syndrome of a Qatari man in a British hospital and, a woman who died in Saudi Arabia. The virus consequently caused 12 other confirmed cases and five deaths worldwide (Saudi Arabia, Jordan, and Britain). HCoV-EMC, that appears distant genetically from the former SARS-CoV, seems to have a zoonotic origin naturally infecting chiropteran species (Kelland 2013; Kindler et al. 2013).

Crossing of the Species Barrier SARS-CoV appears to have transgressed efficiently and successively two species barrier from bat to carnivores to humans and,

ultimately, be highly pathogenic for the later with the potential to infect human pulmonary and intestinal epithelium (Sims et al. 2008).

Interestingly, HCoV-EMC appears genetically in the same phylogenetic clade as other bat coronaviruses (Chan and Poon 2013) Coronaviruses.

In the past decade chiropterans have been confirmed as hosts or reservoirs of several emerging diseases including SARS, nipah, hendra, Ebola, Marburg and rabies viruses posing a zoonotic risk (Gonzalez et al. 2008).

Prevention Because SARS-CoV may be be transmitted by aerosol (i.e., aerosolized droplets from coughing), and due to its physical stability in the environment, the low or absent protective immunity in the human population, and the lack of effective antivirals or vaccines, infection control against SARS relied primarily on the prevention of person-to-person transmission (see for review Cheng et al. 2007).

52.3 Conclusion and Perspectives

Humans and animals did host, share and exchange their pathogens since prehistoric times.

A literature review by Olival, Bogich, Karesh et al. (pers. comm. 2013) on virus isolation from different animal hosts shows that NHP, primates and small domestic ungulates are the mammals that share the most virus species with humans; when corrected for the number of species and by the respective sampling/research methods, monkeys, rodents and bats Bats are the most important reservoirs for zoonotic agents. Moreover, if we focus on known viruses and correct for the number of species and sampling per taxonomic order, chiropterans appear to potentially harbor three and six time more different virus species than rodents and NHP, respectively. Also Rodent and Chiropteran are one of the most species richness among the vertebrate orders, they harbor a variety of viruses that can be potentially infectious for human. Moreover, apes share a so close relationship by nature with human, i.e. $>$ 90% of genomic identity, that they theoretically can easily exchange pathogens and pass such "thin" inter species barrier form NHP to Human Primates.

There is no more *terra incognita* on Earth. Humans, by migratory habits, professional or recreation occupations explored already the entire natural environments on the planet, stepping into the immense variety of its ecosystems. While the vast ocean is still open for discovery, zoonotic risk is not out of the scope. As an example, humans are more likely to interact with pinnipeds, than with any other marine mammals and a newly described influenza from seals may potentially infect humans (White 2013). Influenza B virus as well as measles can be shared by human and seals Seals. Also it is well documented that transmission occurs from human to animals like *Coxiella burneti* found infecting seals in Alaska. Moreover, *Streptococcus agalactiae*, a member of human gastrointestinal normal flora, is known to infect sea mammals as well as other marine fauna including fishes (!) among others (Delannoy et al. 2013; Duncan et al. 2012).

Understanding the fundamentals of virus emergence from an animal reservoir and its transmission to humans – but also from one animal species to another – as well as mastering the territories at risk with regard to their environments – including biological and physical environmental components (i.e. increase of the human population, climate change and exceptional weather or natural events) – are essential for controlling and preventing zoonoses and potentially emerging zoonoses.

Viruses will continue to pass the species barrier without geographical borders and acquire new abilities to survive within new hosts without losing their intrinsic pathogenic potential.

More than 60% of 335 emerging infectious diseases identified since 1940 have a zoonotic origin. Among them more than two third are from wildlife animal (Jones et al. 2008). Furthermore, specific territories or domains of emergence, within a given environment, where people, livestock and wildlife encounter each other, have been identified and characterized. An analysis of all documented events has led to develop a spatial and temporal approach for a better understanding of dynamic risk factors (so-called drivers) associated with disease emergence (Souris et al. 2010). By understanding these variable drivers of different scales (e.g. from molecular to spatial, including environmental factors) using computing assisted analysis and mathematical models we might finally be able to predict and hopefully prevent emerging zoonotic infections (Morse et al. 2012). Obviously, theoretical models will have always to be sustained by accurate survey networks coupled with multidisciplinary research. Several of these drivers have to be carefully monitored, e.g. human expansion and its propensity to invade animal territories (i.e. protected area), the emergence of new pathogens from the natural fauna, ecological and environmental conditions, human and animal behaviors, socioeconomic changes, etc.

Biodiversity plays a role in both directions, favoring the risk of exposure to new potentially pathogenic agents and protecting the host against unknown microbes. On one hand, biodiversity exists for the microorganisms as well as for all the other animals, such increasing the variety of potential human pathogens that have not yet "jumped" from animals to humans. On the other hand, the biodiversity of the human major histocompatibility complex, MCH, helps to prevent infection by new pathogens. Eventually, new pathogens may adapt to a new human host (humanization) and ultimately resist to disappearance (i.e. drug resistance) (Maillard and Gonzalez 2006).

Climate change Climate change and societal behavior favor the encounters of hosts, vectors and pathogens that never "met" before: Human and animal populations are highly reacting to climate change (e.g.: mosquitoes) and move or expand towards new territories. Human density, i.e. risk of encounter/transmission from animals to humans, and changes in behavior (pets, hunting) are the driver of emerging zoonoses.

Survey and networking, connected to research, molecular biology and/or virus discovery are the strategic key to predict and prevent the emergence of new zoonoses as well as the next pandemic zoonosis (Gonzalez et al. 2011). Moreover technological advances in molecular diagnostics, mathematical modeling, communication, and informatics enable a targeted global surveillance of emerging and previously unknown infections in both human beings and other species (Morse et al. 2012).

https://doi.org/10.1007/978-3-031-27164-9_43

Abstract

Mycobacterium avium ssp. *paratuberculosis* (MAP) is an acid-fast bacterium, which causes paratuberculosis, an infectious enteric disease of ruminants, also called Johne's disease (JD). Since the publication by Thomas Kennedy Dalziel in the year 1913, MAP has been discussed as probable causative agent of Morbus Crohn (syn. Crohn's disease (CD)), an inflammatory disease of the human intestinal tract. Here, we describe the history, etiology, diagnosis, clinical, and epidemiological aspects of paratuberculosis and CD to elucidate the role of MAP in the pathogenesis of CD. The theory still remains open for controversial discussion and future studies are needed to find a final conclusion. At the moment, however, there is not enough evidence to convincingly demonstrate that MAP is the etiological agent for CD.

Keywords

Mycobacterium avium subsp. *paratuberculosis* · Crohn's disease · Johne's disease · Zoonotic potential

53.1 Introduction

Morbus Crohn (syn. Crohn's disease (CD)) is an inflammatory disease that has the potential to involve any part of the human intestinal tract anywhere from the mouth to the anus. The disease is generally located at the terminal ileum and the proximal colon. A linkage between CD and *Mycobacterium avium* ssp. *paratuberculosis* (MAP) is discussed since the publication by Thomas Kennedy Dalziel in the year 1913 (Dalziel 1989).

53.2 Johne's Disease/Paratuberculosis

Paratuberculosis, also called Johne's disease (JD) is an infectious disease of ruminants caused by MAP. Paratuberculosis can be found worldwide. Only Sweden and some states in Australia are proven to be free of this disease (Spickler 2007). Norway as well has no known cases since 2015 (Whittington et al. 2019).

Primary susceptible species are cattle, sheep, goats, deer including wild ruminant species, and other ruminants like camels (Kennedy and Benedictus 2001; Tiwari et al. 2006). The host range of JD is wide. Infections of nonruminants, like wild rabbits, foxes, stoats (a weasel species), mandrills, or macaques, and even bird species, like dows, gulls, and sparrows, are described (Beard et al. 2001; McClure

et al. 1987; Zwick et al. 2002; Waddell et al. 2016). Calves inoculated with MAP from a free-living rabbit developed typical histological lesions consistent with JD, demonstrating that wild animals other than ruminants may also contribute to the spread of the disease. But the main source of infection for calves is the exposure to feces of infected mature cattle (Beard et al. 2001).

53.3 History

Since the middle of the nineteenth century, both the clinical signs and pathological anatomy of paratuberculosis are known as chronic enteritis with marked transformation of the intestinal mucosa. Johne and Frothingham demonstrated acid-fast bacilli in altered tissues and described for the first time this disease as a singular case of tuberculosis in cattle (Johne and Frothingham 1895).

Due to the different biological properties of the infectious agent and due to the different pathological patterns, Bang proposed in the year 1906 to separate the illness from tuberculosis. Since then, bovine paratuberculosis is classified as a separate disease (Bang 1906).

In 1910/1912, Twort published the isolation and cultivation of the infectious agent for the first time. Finally, in 1933 the experimental infection of cattle with MAP succeeded. By that, the Henle-Koch postulates were fulfilled. Since then, it is proven that MAP is the monocausal agent of bovine paratuberculosis (Twort and Ingram 1912).

53.4 Etiology

53.4.1 Infectious Agent

MAP belongs to the *Mycobacteriaceae*, a family of gram-positive bacteria, which comprises more than 100 species. They proliferate intracellularly and are characterized by their acid-stability and lipid-enriched cell wall. The subspecies MAP is clearly distinct from other pathogens of the family like *Mycobacterium tuberculosis*, the infectious agent of tuberculosis, or *Mycobacterium leprae,* the infectious agent of leprosy. MAP is a mycobacterial subspecies with a slow replication rate and a generation time of over 20 hours. Its cultural growth in vitro is dependent on the addition of mycobactin, an iron chelator, that most other mycobacteria produce on their own and are therefore able to replicate outside of their host (Rowe and Grant 2006; Barclay and Ratledge 1983). MAP is a subspecies member of the *M. avium* complex (MAC), a complex of several phenotypically and serologically extremely similar mycobacteria, comprising of MAP, *Mycobacterium avium* ssp. *avium*, *Mycobacterium avium* ssp. *silvaticum*, *Mycobacterium avium* ssp. *hominissuis*, and *Mycobacterium intracellulare* (Busatto 2019). While members of the MAC typically cause disease in immunocompromised hosts, MAP has been elucidated as causative agent of JD even in immunocompetent ruminants (Behr and Kapur 2008).

53.4.2 Pathogenesis of Johne's Disease

MAP can be transmitted directly, most commonly fecal-orally or orally by colostrum, but infections by the intrauterine route or semen are also reported (Uzoigwe et al. 2007).

The vast majority of animals (ca. 85%) is infected within the first days of their life, 5% during the first year and 10% in utero. Commonly, the infection starts in the first 30 days of life; later on, an increasing age-resistance is acquired. Calves are mainly infected orally by fecally contaminated dugs or by colostrum, while older animals tend to get infected by contaminated food, water or pastures (McAloon et al. 2019; Richardson et al. 2019). Even the possibility of airborne transmission via bioaerosols and dust is being discussed (Eisenberg et al. 2011).

After oral ingestion, MAP is taken up by M cells of the Peyer's patches, mainly in the ileum, or enterocytes and transported into the submucosa (Bermudez Luiz et al. 2010; Momotani et al. 1988). Additionally, MAP weakens the tight junctions and therefore the integrity of the intestinal barrier, leading to paracellular introduction of more MAP into the submucosa (Bannantine John et al. 2013). There the organism is phagocytized by resident macrophages and persists in their phagosomes, thereby emitting interleukin-1β (IL-1 β), which leads to more macrophages being lured to the entry point and more MAP being phagocytized (Lamont et al. 2012a). By inhibiting the formation of an phagolysosome, MAP are able to persist and even proliferate in these macrophages (Lindsay Sweet et al. 2010). Furthermore, MAP decreases pro-inflammatory immune response by suppressing expression of interferon gamma (IFNγ), and tumor necrosis factor (TNF) (Khare et al. 2012).

Histologically, MAP infection can be divided into two major forms, the tuberculoid or paucibacillary form and the lepromatous or pluribacillary form (Clarke 1997).

The tuberculoid form is dominated by a cellular (Th1) immune response and therefore IFNγ-mediated activation of macrophages (Chiodini et al. 1984). The intensity of the IFNγ response is crucial for determining the further course of disease. In an infection experiment, Begg et al. (2018) demonstrated a direct correlation between IFNγ response and severity of histopathological lesions, with even single cases of apparent elimination of MAP and remission of lesions in animals with high IFNγ levels (Begg et al. 2018). Due to the histopathological features of CD, which closely resemble those found in animals with the paucibacillary form of JD, it has been suggested that the two diseases may share the same etiology (Collins et al. 2000; Grant 2003; Greenstein 2003; Moss et al. 1992).

As the infection progresses, a shift from cell-mediated Th1 immunity to a humoral Th2 response can be observed (Stabel 2000; Koets et al. 2015).

The resulting lepromatous form is characterized by the production of large amounts of antibodies, while cell-mediated immunity seems to decrease (Stabel et al. 2011). This humoral response, however, is not protective against the progression of disease and leads to a quick spread of the infectious agent and manifestation of the clinical disease (Manning and Collins 2001). The clinical disease is characterized by a profuse and intractable diarrhea that ends up in severe weight loss and death.

The incubation time is reported to range from 2 to 10 years (Chiodini et al. 1984).

The disease develops chronically and intermittently. Over a very long period, infected animals show no signs of illness. Therefore, JD usually stays undetected for

a long time. However, the spreading of bacteria starts before the onset of clinical symptoms.

Hence, mainly animals in a late subclinical stage play an important role in the propagation of paratuberculosis. Whitlock and Buergelt described that one animal with clinical symptoms represents only the tip of an iceberg. Every cow with symptoms may indicate 15–25 more affected animals in the herd (Whitlock and Buergelt 1996).

Furthermore, the intermittent spread is another cornerstone of the maintenance of MAP in the herd. While one clinically affected cow releases up to ten million infectious particles per gram feces (Whitlock et al. 2005), the excretion dose of a subclinically diseased cow ranges between 10 and 100 infectious agents per gram.

The infection dose is reported to be 10,000 agents for the infection of one calf (Gerlach 2002).

53.4.3 Time Line of Paratuberculosis in Cattle

The course of disease can be divided into four phases of different immunology, clinical signs, and pathomorphology (Whitlock and Buergelt 1996):

1. The silent early stage of infection
2. The subclinical stage
3. The clinical stage
4. The advanced clinical stage

53.4.3.1 The Silent Early Stage of Infection

In this stage, there is no detectable spread of the agent by feces. The only viable way to diagnose an infection in this stage is by histological investigation of tissue samples, as any detection of MAP-DNA or cultivation of viable MAP could also be the product of "passive shedding" after MAP had been introduced orally and are shed in the feces without infecting the animal (Begg et al. 2018).

The animal shows no signs of disease. When examining the tissue, acid-fast bacilli can be seen histologically in intestinal lymph nodes or intestinal sections and MAP can be cultivated (Whitlock and Buergelt 1996).

53.4.3.2 The Subclinical Stage

The intracellular proliferation of the pathogen in macrophages ultimately results in cell death and release of the agent into surrounding tissues and the gut lumen. As soon as the MAP cells are liberated, the humoral immune response is initiated. Acid-fast bacilli can (intermittently) be detected in the feces (Coussens 2001; Sweeney et al. 1992).

The animal still shows no signs of disease. Stages 1 and 2 correspond to the incubation time of the disease and can range between 2 and 10 years (Chiodini et al. 1984).

Pathomorphologically, a moderate hypertrophy of the mucosa and an enlargement of the mesenterial lymph nodes are accompanied by infiltration of epithelioid and Langhans giant cells and foamy macrophages containing phagocytized acid-fast

bacilli. In some cases, diagnosis via a measurable immune response – either humoral or cell mediated – can be possible (Whitlock and Buergelt 1996). Intermittent fecal shedding of MAP in this stage is possible, but due to its sporadic nature and the low prevalence of anti-MAP antibodies in the herd, many infected (and shedding) animals will likely remain undetected and therefore pose the biggest risk factor in transmission of the disease (Begg et al. 2018; McKenna et al. 2006). Additionally, those subclinical animals are responsible for a great part of the considerable economic losses due to Johne's disease in form of long-term decreased milk production and slow growth rates of subclinical infected animals on top of the more obvious losses due to culling of sick animals (Tiwari et al. 2006; Bates et al. 2018; Raizman et al. 2009).

53.4.3.3 The Clinical Stage/Advanced Clinical Stage

Initial clinical signs follow the subclinical stage. The first apparent sign is gradual weight loss. Congruent with the weight loss, the manure consistency becomes more fluid. The clinical symptoms can be seen for months with intermittent times of amelioration. Later, clinically affected animals become increasingly lethargic, weak, and emaciated. "Water-hose" or "pipe-stream" diarrhea, hypoproteinemia, and intermandibular edema (bottle jaw) characterize the advanced stage of the disease (Tiwari et al. 2006).

Morphological changes in JD include chronic inflammation involving all layers of the intestinal wall (transmural involvement), thickening of involved segments, with narrowing of the lumen, linear ulceration of the mucosa, and a submucosal edema with elevation of the surviving mucosa, producing a characteristic cobblestone appearance.

A clinical or advanced clinical stage inevitably leads to the death of the diseased animal (Eslami et al. 2019).

53.5 Therapy and Vaccination

Animals in early stages of the disease sometimes show remission and/or elimination of the infectious agent and the respective histopathological lesions (Begg et al. 2018). It is not possible to cure MAP infected, animals in a clinical state of disease. Antibiotics, although showing growth inhibition in vitro, do not lead to permanent treatment success in animals. A short-term alleviation of clinical symptoms by use of various antibiotics or antihistamines has been described in the literature but eventually all clinical cases and with the death of the diseased animal (Eslami et al. 2019). The MAP excretion, however, could not be prevented. Therefore, treating clinically ill animals not only leads to unnecessary suffering but also poses a severe threat to the rest of the herd, if strict isolation cannot be guaranteed.

In Germany, no vaccine is currently approved. However, in principle vaccinations are possible. The first vaccine was developed in 1926. Many authors describe the use of vaccines in terms of advantages and disadvantages.

The excretion of the pathogen and thus the spread of infection can be reduced by vaccination. Available vaccines, based on whole, killed, or live-attenuated bacteria, however, will not protect against infection and disease, and the use of serological methods for animal disease control in vaccinated herds is no longer suitable. Furthermore, interference with the tuberculin skin test used for the control of bovine tuberculosis is described (Bastida and Juste 2011; Juste 2012; Patton 2011; Rosseels and Huygen 2008). As this interference can lead to false-positive results in the tuberculosis skin tests, vaccination against paratuberculosis is prohibited in many countries (OIE 2021).

53.6 MAP in Milk and Dairy Products

53.6.1 Tenacity and Ability to Survive

Mycobacteria are characterized by having a thick, waxy cell wall that grants them remarkable resistance to environmental influences, disinfectants, and even antimicrobial chemotherapy (Chiaradia et al. 2017). This multilayered cell wall contains large amounts of long chained fatty acids (mycolic acids), responsible for its hydrophobic nature as well as glycopeptidolipids, which function as pathogenic factors for members of the *Mycobacterium avium* complex (Busatto 2019; Chiaradia et al. 2017). This unique tenacity leads to an eminent survivability of MAP in the environment. MAP have been described to survive long time periods in manure, on contaminated pastures, and, after being flushed away by rain, in rivers or other bodies of water (Richardson et al. 2019; Pickup et al. 2005; Pickup et al. 2006; Whittington et al. 2005). This survivability in water and resistance to established measures of drinking water decontamination leads to the possibility of MAP reaching the domestic water supply (Rhodes et al. 2014; Sousa et al. 2021).

53.6.2 MAP in Milk

One of the most discussed routes of human exposure to viable MAP is via dairy products from raw or even pasteurized milk (Todd Kuenstner et al. 2017). In principle, there are two possibilities for MAP to get into raw milk: either by direct shedding over the mammary gland of infected animals or indirectly through fecal contamination (Gerrard et al. 2018; Michael and Mullan 2019). In terms of numbers, however, the quantitative relation of fecal contamination to direct shedding is estimated to be 90–10% (Rani et al. 2019).

As growth of MAP is dependent on the presence of mycobactin as a siderophore for iron uptake, it is unlikely that MAP will multiply in milk. This, however, does not rule out milk as a possible means of transmission. In fact, MAP have been shown to change the lipid profile of their cell walls and express more proteins connected to cell invasion after being incubated in milk (Alonso-Hearn et al. 2009). Moreover,

significant changes in the MAP proteome after incubation in milk were described, including upregulation of proteins associated with stress response and immune evasion (Kleinwort et al. 2021). This can be interpreted as MAP sensing milk as a hostile environment and inducing respective counteractions (Kleinwort et al. 2021). Whether these counteractions, however, lead to an increased survivability of MAP in milk needs to be further elucidated.

Pasteurization of milk is generally considered a reliable method to protect consumers from bacterial pathogens in milk (Juffs and Deeth 2007). In the dairy industry, different heating methods are used. According to the international dairy foods association, the most important one is the high-temperature, short-time (HTST) pasteurized milk process (72–75 °C, 15–30 s), as dairy products are mainly produced on the bases of HTST milk (International Dairy Foods Association n.d.).

Despite this measure, there have been several reports of MAP in pasteurized milk products, leading to the discussion if MAP could be able to survive pasteurization (Gerrard et al. 2018; Chiodini and Hermon-Taylor 1993; Grant et al. 1999; Paolicchi et al. 2012).

To investigate the thermal resistance of MAP in milk, numerous experimental investigations were performed. After the UHT process, no surviving MAP were found in milk (Büttner et al. 2006).

In HTST-treated milk, experimentally infected with 10^2–10^3 colony-forming units (CFU)/ml of milk, viable MAP could be detected. However, there was a reduction of microbial count to five orders of magnitude. This corresponds to a reduction of 99.999%. After experimental contamination of milk with lower bacterial counts (10 CFU/ml), no viable pathogen could be detected (Büttner et al. 2006).

For interpretation of these data, it is important to consider which methodology of thermal inactivation was applied. In terms: was the experiment conducted with commercial-type pasteurizers with continuous turbulent flow for heat distribution comparable to the ones used in the dairy industry? This has been neglected in many studies and could be the cause of conflicting results (Grant et al. 1996; Meylan et al. 1996; Robertson et al. 2012). Some studies, which were conducted under industrial standards, describe an inactivation of MAP (Lynch et al. 2007; Rademaker Jan et al. 2007). Other studies, however, describe a survival of MAP under these circumstances (Grant Irene et al. 2002).

Several mechanisms for this survivability have been discussed, including clumping of MAP cells, inhomogeneous distribution, or intracellular localization in milk as well as the formation of heat resistant, spore-like forms (Gerrard et al. 2018; Lamont et al. 2012b; Grant Irene et al. 2005). Additionally, other factors like post-pasteurization contamination of the milk or malfunction of technical facilities could be reasons for the presence of viable MAP in retail milk and dairy products (Robertson et al. 2017). Independently of MAP being able to survive pasteurization or not, the repeated detection of viable MAP in pasteurized milk, even if in small numbers, leads to the possibility of human consumption of viable MAP (Michael and Mullan 2019).

53.6.3 MAP in Other Milk Products

Only limited data are available on the occurrence of MAP in raw milk cheeses: experimental production of cheese from artificially contaminated raw milk showed that MAP are also greatly reduced during the ripening process (Donaghy et al. 2004; Spahr and Schafroth 2001; Sung and Collins 2000). Besides from cheese, viable MAP have also been cultivated from calf's milk replacers and powdered infant formula (Botsaris et al. 2016; Ikonomopoulos et al. 2005; Khol et al. 2017).

53.6.4 MAP in Retail Milk

To address the occurrence of MAP in HTST-treated milk from the market field, studies in the USA (Ellingson et al. 2005), Great Britain (GB) (Grant 2003), and Ireland (O'Reilly Ciara et al. 2004) were conducted. MAP in low numbers and frequency have been detected in the USA and UK: In the UK, 67 out of 567 tested packages (11.6%) contained MAP-DNA, whereas viable MAP could only be cultivated from ten samples (1.7%). In the USA, 2.8% out of 702 examined packs were positive in MAP culture. In an Irish study, which was published in 2004, no viable MAP were cultured in any of the 357 examined milk cartons. However, MAP-DNA was detected in 35 (9.8%) of respective samples. In the Irish study, 56% of the investigated manufacturing firms treated the milk at least at 75 °C for 25 s.

53.7 Detection Methods for MAP in Food and Environment

For microbiological diagnosis of MAP, direct and indirect methods are distinguished. While the first detect the agent or parts of the agent itself, the latter are based on specific immune responses that occur after contact with the pathogen (exposure, infection, immunization).

53.7.1 Indirect Detection of MAP in Serum or Milk

Probably the most efficient way to ensure MAP-free foods is by removing MAP-shedding animals from the production chain. For the diagnosis of MAP in animals, the detection of MAP-specific antibodies by ELISA or similar methods is a popular method due to its fast turnaround time, low price, and ease of use (Slana et al. 2008). This method can be employed with either serum or milk samples. A detection of MAP-specific antibodies in cattle is an indicator for more or less recent contact to the infectious agent. It is, however, not possible to conclude active shedding of MAP from serological positivity. The most eminent problem with this detection method is that the humoral immune response against MAP is intermittent; therefore, bacterial shedding and presence of detectable antibodies do not necessarily correlate (Begg et al. 2018).

The test performance of antibody detection tests varies, depending on the used antigens. Most tests use MAP whole-cell extract, lipoarabinomannan, or MAP surface proteins (Karuppusamy et al. 2019).

In Germany, several different commercial ELISA assays are licensed for the detection of paratuberculosis-specific antibodies. The sensitivity of these methods, however, is also very limited, with none of the tests reaching a sensitivity above 60% (Friedrich Löffler Institute Germany 2021).

As mentioned above, the early stages of bovine paratuberculosis are characterized predominantly by a cell-mediated immune response. Therefore, antibody detection will most likely render those animals as false negative, which is why detection methods for cell-mediated immunity are more advised.

There are two tests for detection of a cell-mediated immunity: the gamma interferon release assay for blood samples and the skin test for delayed-type hypersensitivity. Cell-mediated immunity is typically the predominant form of immune response in early stages of infection and decreases over the course of ongoing disease development. In clinical cases, it may not be detectable at all (OIE 2021). In addition to being challenging in their interpretation due to lacking established cutoff values, these tests do struggle with specificity. MAP and other members of the *Mycobacterium avium* complex share an extraordinary similarity and are often times not distinguishable by phenotype or serological measures (Busatto 2019). Therefore, many animals may be sensitized to environmental mycobacteria or members of the *Mycobacterium avium* complex and therefore yield ambiguous results due to cross-reactivity.

According to the OIE manual both, the gamma interferon release assay and the skin test, have limited value in the field at present, and further research is needed with respect to the interpretation criteria (OIE 2021).

Because of the limited sensitivity, antibody tests are useful to determine the health status in a herd but are not an adequate tool for determining the disease in individual animals, unless typical clinical signs are observable.

53.7.2 Direct Detection of MAP

The gold standard for the diagnosis of paratuberculosis is the cultural detection of the pathogen (OIE 2021). It is considered as 100% specific, but regarding its sensitivity, it has to deal with several difficulties:

MAP is an extremely slow-growing organism and very difficult to cultivate. Not only is it dependent on the addition of an iron chelator, like mycobactin, but also on chemical decontamination of the examined material (i.e., with hexadecylpyridinium chloride), in order to prevent overgrowth of MAP cultures with nonspecific bacterial flora (OIE 2021; FLI 2020). This decontamination step markedly decreases the sensitivity of culture methods (Gao et al. 2005).

For the detection of MAP in food, however, the long incubation period is the most pivotal factor, as detection can require an incubation period of up to 18 weeks in primary culture (Whan et al. 2005; Cocito et al. 1994). At this time, examined food has either already been consumed or been taken out of stock, regardless of the culture

results. A positive result, however, is proof for the presence of living reproductive MAP in the animal or the food product.

In case of massive shedding, MAP can be detected directly in the feces by light microscopy after Ziehl-Neelsen staining, if large numbers of MAP cells with intact cell walls are present in the sample. MAP isolated from humans, however, can show a cell-wall-deficient phenotype that would not be detectable by Ziehl-Neelsen staining (Sechi et al. 2005).

Another, more sensitive, method for the direct detection of MAP is PCR (Michael and Mullan 2019). This method detects MAP by amplification of MAP-specific DNA sequences. At this time, there are six licensed real-time PCR assays for the detection of MAP in Germany (https://www.fli.de/de/institute/institut-fuer-molekulare-pathogenese-imp/referenzlabore/nrl-fuer-paratuberkulose/ (last accessed November 2021)). Probably the most popular of those target sequences is the insertion sequence 900 (IS*900*). It is highly abundant in the MAP genome and is therefore the most sensitive target for MAP-specific PCRs (Möbius et al. 2008). It has, however, been shown that IS*900* can also occur in other mycobacteria, limiting its usefulness in regard to specificity (Englund et al. 2002). Alternative target sequences to IS*900* are f57, ISMav2, and ISMap02. F57 is a single copy target, which offers far more specificity but, due to its single copy nature, a lower sensitivity than IS*900* (Möbius et al. 2008; Poupart et al. 1993). Its high sensitivity makes PCR a useful tool in the detection of infected, MAP-shedding animals. However, its sensitivity largely depends on the quality of the extracted DNA and therefore on the extraction method (Park et al. 2014). Moreover, for the detection of MAP in food, the PCR method has to cope with some additional limitations: In milk, for example, PCR is often times inhibited by high concentrations of calcium ions or fat, leading to diminished sensitivities. Additionally, PCR is not able to differentiate between viable, infectious MAP cells, and DNA originating from dead MAP cells that have been killed, i.e., during pasteurization (Slana et al. 2008).

This limitation can be circumvented by detection methods using bacteriophages. Phage-based methods for the detection of MAP all rely on the D29 bacteriophage (Grant 2021). This phage infects viable bacterial cells of several mycobacteria, is multiplied there, and causes the cell to burst, which again leads to the release of progeny phage generations. The final detection step then mostly consists on the detection of the released host DNA in combination with detection of the progeny phages via plaque assay or ELISA. A big advantage of this method is the selectivity for viable mycobacteria, ensuring that all of the detected MAP-DNA heirs from viable, infectious MAP cells. For a feasible application in complex matrices like milk or feces, however, sample preparation methods like immunomagnetic or peptide-mediated magnetic separation (PMS) are needed (Grant 2021).

Those magnetic separation methods separate MAP from accompanying nontarget bacteria and inhibitory substances and concentrate the target bacteria into a smaller volume (Husakova et al. 2017). Various types of MAP-binding molecules have been utilized in those methods, including mono- and polyclonal antibodies, MAP-binding peptides, derived from phage display, or plant lectins (Husakova et al. 2017; O'Brien et al. 2016; Stratmann et al. 2002; Hobmaier et al. 2019).

In 2019, Butot et al. published a direct comparison of the three direct detection methods in raw milk, heat-treated milk, and powdered milk In this comparison, the achieved sensitivities for each method were 94% (IS900 qPCR), 76% (f57 qPCR), 83% (culture), and 40% (PMS-phage) (Butot et al. 2019). It has to be mentioned, however, that the examined samples in this study were artificially spiked with MAP, which were previously de-clumped by filtration. Therefore, the sensitivity results are probably not transferable to the performance in naturally contaminated samples (which is likely to be markedly lower). For a systematic comparison of different methods under laboratory conditions, however, this procedure is necessary and reasonable.

In summary, at present there are various diagnostic methods suitable for the detection of animals with JD in a progressive stage. Nevertheless, in spite of intense research, they still have considerable sensitivity problems. A reliable diagnosis of the early stages of the disease is still missing. The fact that MAP is shed intermittently in feces and milk leads to postmortem screening attempts, like testing of lymph nodes in the slaughterhouse, as mesenteric lymph nodes are generally accepted to be the main locus of MAP colonization (Munster et al. 2011).

In conclusion, the time-consuming culture is still presumed to be the most significant tool to identify MAP (OIE 2021).

53.8 Crohn's Disease

CD is a chronic, relapsing inflammatory bowel disease (IBD) affecting the human gastrointestinal tract with preference for the terminal ileum and colon but possible involvement of all its other parts (Baumgart and Sandborn 2012). All age groups and both genders can be affected, with the main peak for disease onset being between the ages of 17 and 40 years (Thia et al. 2010). Patients are often febrile and suffer from painful abdominal cramps and chronic diarrhea; their stool is bloody or mucous. The Montreal classification was established to categorize the different phenotypic behavior of CD, with the majority of patients being affected by the non-stricturing non-penetrating phenotype and the remainder by the more aggressive stricturing or penetrating phenotypes, which are characterized by gut stenoses or fistulas, respectively (Satsangi et al. 2006). The etiology of the disease is unknown, but genome-wide association studies have identified an enormous amount of susceptibility loci (Franke et al. 2010; Jostins et al. 2012). Besides a genetic susceptibility to the disease, environmental factors also play a very important role in its development. A whole lot of such lifestyle factors have been found to be associated with CD, e.g., a reduction in women breastfeeding, air pollution, tobacco use, increased hygiene conditions, or the consumption of Western diet. Interestingly, CD is frequently triggered or exacerbated after an infectious gastroenteritis (Garcia Rodriguez et al. 2006). In an animal model, a virus infection was able to induce a CD-like phenotype in genetically susceptible individuals (Cadwell et al. 2010). It has been tempting to speculate from the first discovery of CD up to now that a pathogen might be the etiological agent for the development of CD.

53.8.1 Theories and Attempted Methods to Elucidate the Role of MAP in CD

As early as 1913, Thomas Kennedy Dalziel suggested that the histological characters of CD and JD are so similar as to justify the proposition that they might be the same, even though, as he also stated, the absence of the acid-fast bacillus would suggest a clear distinction (Dalziel 1989). Since then, there have been many attempts to verify the hypothesis of MAP being an etiological agent for CD, using different approaches like immunohistochemistry, attempts to cultivate the bacterium, experiments to transmit CD to animals, serological tests, molecular methods, and treatment programs of CD with antimycobacterial antibiotics.

53.8.2 Microbiological Approach

It is amazing that up to now, no final conclusion about the role of MAP in CD could be drawn. The reason for this most probably lies in the elusive behavior of MAP in the human body. Histological immunostaining of resected granuloma tissue of CD patients against MAP antigen could up to now in most cases only confirm the primary statement of Dalziel that the acid-fast bacillus is absent, even though it has been performed repeatedly by several work groups (Van Kruiningen 2011). In contrast, Jeyanathan et al. (2007) reported mycobacteria in 59% (10/17) of paraffin-embedded surgical resections of CD patients by acid-fast staining combined with in-situ hybridization for ribosomal RNA. In control patients, mycobacteria were only detected in 14% (5/35) of the samples (Jeyanathan et al. 2007). It is important to mention, however, that the methods in respective study are not able to differentiate between members of the *Mycobacterium avium* complex. Therefore, the identity of MAP cannot be completely assured (Jeyanathan et al. 2007). MAP has been described in humans to also exist in a cell-wall-deficient spheroplastic form, making acid-fast staining an insufficient measure to completely exclude the presence of MAP (Sechi et al. 2005). In the aforementioned study, results of acid-fast staining and in situ hybridization were not always concordant. A considerable amount of samples (9/52) showed positive results for in situ hybridization but were negative for acid-fast staining (Jeyanathan et al. 2007).

Cultural growth of MAP requires extremely long culture times, special selective cultural media, and experienced lab personnel (Turenne et al. 2007). Cultivation of MAP spheroplasts additionally requires specific culture media and conditions and poses a major obstacle for many researchers (Agrawal et al. 2021). This extremely difficult cultivation complicates comparison of results between different laboratories and makes determination of the real proportion of MAP-positive specimens challenging. Additionally, because of the difficult handling procedures, laboratory cross-contamination in mycobacterial laboratories is not rare, which should always be regarded when interpreting mycobacterial culture results (Van Kruiningen 2011). This might, in some cases, explain the discrepancies between different studies, where, in a few smaller studies, MAP could be detected in very small patient

collectives, while it was undetectable in major study groups. MAP was detected in breast milk samples of two patients with CD, but not in 5 controls (Naser et al. 2000a); in another study, it could be cultivated from four out of ten biopsies of children with early onset of CD but not in two ulcerative colitis or four non-IBD patients (Kirkwood et al. 2009). The group of Naser also reported the detection of MAP from blood samples of CD patients; however, there was also growth of MAP in samples from ulcerative colitis and healthy patients (Naser et al. 2004). Conversely, in a major culturing attempt on IBD samples from 191 patients, including 79 CD patients, from the USA and Denmark, not one of 3985 cultures had been positive (Collins et al. 2000).

53.8.3 Serological Approach

Alternative to culture, many studies compare antibody titers against MAP in serum of CD patients and controls. In this context, different capture antigens in the assays with expectably different specificity for MAP antibodies were used (Van Kruiningen 2011). The results gained by these antibody measurements were often inconclusive. In some cases, there were significantly higher antibody responses for CD than for control patients (Collins et al. 2000; Naser et al. 2000b); in other studies, no significant differences could be found (Bernstein et al. 2004; Cho et al. 1986; Kobayashi et al. 1988). This sometimes even occurred when using the identical test in different countries (Collins et al. 2000). As atypical mycobacteria comprise a huge group of different species, with many of them existing ubiquitously in the environment, e.g., in tap water or in the soil, and with probably also a considerable amount of still undiscovered species, it is tempting to speculate that cross-reactivity of MAP-"specific" antibodies toward antigens of different atypical mycobacteria is highly probable (Osterstock et al. 2007). Therefore, it is very difficult to interpret the meaning of positive serological test results regarding their specificity for previous or present MAP colonization, infection, or immunity.

53.8.4 Molecular Biological Approach

Comparably, an enormous amount of studies has been published with a focus on MAP-DNA detection in intestinal tissue, granulomas, or peripheral blood mononuclear cells (PBMC). In most studies, the main target gene was the IS element IS*900*, which has been postulated to be specific for MAP. Most of these studies were based on classical PCR or nested PCR on biopsies, buffy coat of blood, or PBMC (Kirkwood et al. 2009; Naser et al. 2004; Autschbach et al. 2005; Bernstein et al. 2003; Bull et al. 2003; Juste et al. 2009; Suenaga et al. 1995); one study used laser-microdissected tissue (Ryan et al. 2002), and another performed in situ labeling on paraffin-embedded tissues (Hulten et al. 2001). Also – similar to the serological analyses – there were many conflicting results between these studies, with some studies showing a significantly higher presence of IS*900* DNA in CD samples and

others showing no difference to controls. However, a meta-analysis of NAT-based techniques detected an association between MAP and CD (Abubakar et al. 2008). Given that the IS*900* element would be exclusively present in MAP and therefore indeed highly specific, then one possible explanation might be a variable sensitivity of the applied NAT in the study-specific analyzed tissues. Alternatively, as NAT are extremely sensitive methods, sample contamination could be a major issue in some of these studies. Even the water used during endoscopy for taking the biopsies could be contaminated with mycobacteria (Van Kruiningen 2011). Moreover, it becomes increasingly clear that IS*900* is indeed also present in other mycobacteria species; it could be detected by NAT in mycobacterial isolates related to *M. cookii*, *M. scrofulaceum*, and the *M. avium-intracellulare* complex (Englund et al. 2002; Van Kruiningen 2011; Cousins et al. 1999; Motiwala et al. 2004), which questions the specificity of the IS*900* PCR method and heightens the contamination risk. This may shift the focus of IS*900* PCR away from being a screening tool, to a measure for exclusion of infection.

53.8.5 Current Data Situation

A recent meta-analysis investigated data about correlation of MAP with CD, performed by culture, as well as by PCR (Patterson et al. 2021a). It is based on a collection of studies described in a review article by Naser et al. (Naser et al. 2014). Regarding cultural methods, 1795 patients were examined (820 with CD and 975 controls). MAP culture was positive for 31.41% of CD patients and 4.95% of controls, suggesting a strong correlation between MAP and CD. For PCR analysis (IS900), 3528 patients were involved (2012 CD patients and 1516 controls). MAP-DNA was detected in 28.83% of CD patients as opposed to 12.99% in controls (Patterson et al. 2021a).

The authors conclude that, despite the difficulties of detecting MAP, "...there is no denying, that Crohn's disease and *Mycobacterium avium* subspecies *paratuberculosis* are, at the very least, related to each other" (Patterson et al. 2021a).

However, when investigating the association of MAP detection with CD, it is important to keep in mind that, even if MAP is detected in a majority of CD cases, this could be either due to a causative relationship or due to CD patients being more prone to become colonized with MAP (Liverani et al. 2014).

53.8.6 Infection Experiments

According to Koch's third postulate, if an organism is causative for a disease, it must be able to cause this disease, if introduced into a susceptible host (Koch 1882; Loeffler 1884). This, however, is not applicable in some diseases. In leprosy, for example, the isolation of the bacterial agent with subsequent cultivation is not practicable. In tuberculosis, the number of infected people worldwide is estimated

to be about 2 billion. However, only 5–10% of infected people will develop a clinical disease in their lifetime (WHO 2020).

The isolation of MAP from CD patients and subsequent inoculation into a susceptible host have been attempted several times. Up to now, all inoculation experiments of animals with triturated intestinal material from CD patients were unsuccessful in induction of a JD-like infection, even though also susceptible animals, like goats or rabbits, were infected (Van Kruiningen 2011).

It is important in this case to consider that MAP, in animals, is present in its cell walled form, whereas in humans, it might be present in a cell-wall-deficient form. For infection experiments, it is therefore crucial to cultivate MAP up until the formation of a cell wall (Agrawal et al. 2021). The lack of such a readily available human isolate of a cell-wall-deficient form from infected Crohn's tissue, which can be introduced into an animal, together with the lack of a reliable method to re-isolate the cell-wall-deficient MAP from this animal, is a substantial barrier for a conclusive resolution of the question, if Koch's postulates can be seen as fulfilled (Agrawal et al. 2021).

53.8.7 Therapeutical Approach

As MAP obviously is the sole causative pathogen in cattle with JD, but very elusive and highly debated in humans, other researchers tried to demonstrate the implication of MAP or mycobacteria in CD indirectly by studying the effect of antimycobacterial antibiotic therapy on CD patients.

A recent meta-analysis of studies on this topic identified 36 clinical trial studies with a total of 3346 patients. Twelve of those 36 studies reported remission, whereas 24 "only" reported a clinical response (Patterson et al. 2021b). The authors come to the conclusion that ". . .the odds of a Crohn's Disease patient getting better is higher among those who take antibiotics. . ." (Patterson et al. 2021b).

This result, however, should not be seen as the ultimate proof for the role of MAP in CD. The application of antibiotics can influence many factors other than MAP, e.g., by their antiphlogistic effects on the immune system or maybe by elimination of other unknown causative bacteria or even sometimes by their curative effect on an existing but unrecognized gut tuberculosis. Even more problematic for this approach is the actual possibility that MAP disease might not even be curable by antibiotics, as it is the case with its hypothetical animal counterpart JD.

Another notable phenomenon in antibiotic trials is that not all antimycobacterial drugs seem to have the same extent of positive effects. So why do some therapeutics, despite being efficacious against mycobacteria, have lower effects in CD patients? A possible explanation for this may be the target of those drugs. In CD patients, a good proportion of MAP is present as cell-wall-deficient spheroplasts. Therapeutics targeting the cell wall or mycolic acid synthesis are not expected to have as much of a therapeutic effect in those cases as opposed to drugs targeting ribosomal function (Monif 2018).

In contrast to the apparent improvement of symptoms under antimycobacterial treatment stands the circumstance that no deterioration can be seen under

immnosuppressive treatment, as seen in other mycobacterial diseases like *Mycobacterium tuberculosis* (MTB) infection (Solovic et al. 2010). One difference, however, between MTB and MAP is the invasive character of MTB, whereas MAP (in CD) relies more on inducing a pro-inflammatory immune response (Agrawal et al. 2021). Furthermore, some immunomodulatory drugs, which are also used in therapy of CD, have been reported for successful antimycobacterial treatment (Chowdhry et al. 2016).

53.8.8 Epidemiological Approach

If MAP infection really were an etiological agent for CD, one would imagine that CD more often afflicts cattle farmers who are exposed to animals with JD than farmers with healthy animals. However, studies from the USA and UK could not show a higher prevalence of CD in farmers handling JD animals (Jones et al. 2006; Qual et al. 2010). A few restrictions, however, have to be added to this conclusion: First and foremost, the assumption that CD prevalence would be higher in populations with higher exposure to MAP is only applicable, if MAP is the only etiologic agent of CD. If the pathogenesis of CD, however, is a multifactorial event (e.g., a genetic disposition or other risk factors that alter the susceptibility to MAP infection), relying solely on the frequency of contact to the bacterial agent will yield lower correlation than in the case of a monocausal disease. Additionally, in the case of MAP, it is difficult to determine a suitable, nonexposed control group, as MAP is widespread in the environment and food supply and exposure to MAP can therefore not easily be ruled out (Agrawal et al. 2021).

Another point to consider is that MAP infections in susceptible species seem to be very age dependent, occurring mainly at a very young age with symptoms developing several years later in an adolescent or adult age (Windsor and Whittington 2010). Therefore, studies that correlate MAP exposure and CD prevalence should take that into account.

One epidemiological detail, which is often presented by supporters of the causation theory, is that the prevalence of CD is increasing. This is untypical for classic autoimmune diseases like rheumatoid arthritis or multiple sclerosis and suggests the involvement of an environmental factor in the pathogenesis (Molodecky et al. 2012).

53.8.9 Breastfeeding and the Hruska Postulate

The Hruska postulate describes a theory that has become more and more popular in the scientific community when discussing MAP involvement in the genesis of CD. It is based on the observation that breastfeeding seems to significantly reduce the risk of developing CD (Barclay et al. 2009; Thompson et al. 2000).

The Hruska postulate states that pathogenesis of CD is the consequence of two distinct interactions between MAP and the immune system (Monif 2018; Monif 2015):

1. Infectious challenge with MAP in absence of acquired immunity
2. Loss of immune tolerance to MAP antigens and formation of an immunological memory

The theory suggests that MAP exposure of newborn children who lack a competent acquired immune system leads to a continuous replication of MAP. This replication then has to be brought under control by innate immunity, which is followed by loss of immunological tolerance toward MAPs antigenic array, as the pro-inflammatory response is being fixated in the immunologic memory.

This conclusion is supported by similar phenomena, which can be observed with organisms like *Rubella* sp., *Herpes simplex* or *Mycobacterium tuberculosis.* Those organisms are mainly contained by cellular immunity, but if acquired immunity is absent, the reactions are markedly exaggerated in comparison to when acquired immunity is present (Monif 2018).

So how does breastfeeding and economic status play into this? As mentioned above, a pivotal element for the development of CD is exposure to MAP before acquired immunity can develop properly. Since viable MAP have repeatedly been reported to be present in retail milk, municipal water supplies, and even powdered infant formula, theory supporters suspect those products to be the main vessel for MAP exposure in neonates (Hruska and Pavlik 2014). Therefore, breastfeeding is an effective measure to postpone this exposure until competence of the acquired immune system is present. The very low incidence of CD in economically stressed population supports this theory, as breastfeeding is far more common there than in wealthier communities (Monif 2021).

53.9 Conclusions

In conclusion, the scientific community is still divided into supporters and critics for a possible role of MAP in CD. While the supporters bring forward the detection of MAP in blood, intestine, and even milk samples of human CD patients, the opponents still miss the final convincing evidence that the presence of MAP in the human body can really initiate CD. One of the main arguments of critics still stands fast, namely, that in all of recorded medical and veterinary medical history, there are no published accounts of the transmission of JD to humans (Van Kruiningen 2011). Data from a meta-analysis of CD genome-wide association scans detected considerable overlap between susceptibility loci for IBD and mycobacterial infection (Jostins et al. 2012), which could indeed mean that mycobacteria are involved in the development of IBD or that the associated changes in these susceptibility loci necessary for mycobacterial control somehow auto-induce autoimmune processes with subsequent pathogen-free granuloma formation. Therefore, the theory remains open for controversial discussion, and future studies will hopefully lead to a final conclusion. At the moment, however, there is not enough evidence to convincingly demonstrate that MAP is a possible etiological agent for CD.

Clostridia: Botulinum-Neurotoxin (BoNT)-Producing Clostridia, *Clostridium perfringens*, and *Clostridioides difficile*

54

Ute Messelhäusser

Contents

Abstract

Clostridium spp., anaerobic spore-forming bacteria, are not commonly counted among the classical zoonotic agents. They are regularly found in the environment, e.g., in soil, dust, or sludge, and also in the intestine of healthy humans and animals without causing any symptoms. Botulism is a typical intoxication, normally caused by the ingestion of contaminated food or animal feeding stuff or in rare cases by the bacterial contamination of deep wounds. Based on the classical foodborne transmission route, the European Union classified botulism as a zoonotic intoxication. During the last few years, some scientists thought to have

A notorious and underestimated class of (potentially) zoonotic agents?

indications for a zoonotic transmission of an infective form of botulism, so-called chronic botulism. However, there is no resilient evidence for this theory. The transmission routes for *Clostridium (C.) perfringens* resemble those of Botulinum-neurotoxin (BoNT)-producing clostridia. Normally the ingestion of food highly contaminated with spores of *C. perfringens* causes a self-limiting watery diarrhea, whereas the contamination of deep wounds can lead to a clostridial myositis/myonecrosis. Even if *C. perfringens* normally do not rank among the classical zoonotic agents, at least the toxicoinfection via food fulfills the criteria of a zoonosis. An infection with *Clostridioides difficile* can result in heavy diarrhea in humans and is supposed to infect also animals, but the importance of a transmission via food or the classical way of zoonotic infection, the direct transmission between human and animal, is still unclear. However, scientific data suggest that the zoonotic potential of the organism might be higher than thought until now. Therefore, the contact with food or animals, carrying *Clostridioides difficile*, could be one source of human colonization known also from other antibiotic-resistant bacteria.

BoNT · *Clostridium perfringens* · *Clostridiodes difficile*

54.1 Botulinum-Neurotoxin (BoNT)-Producing Clostridia

54.1.1 Botulinum-Neurotoxin (BoNT)-Producing Clostridia: The Organisms and the Toxins

Botulinum-neurotoxin (BoNT)-producing clostridia are a strictly anaerobic, spore-forming, rod-shaped, gram-positive bacteria mainly occurring in the soil of both terrestrial and aquatic environments. Spores of the organisms can also be found in the intestine of healthy humans and animals. The term "BoNT-producing clostridia" comprises four genetically and physiologically different groups of bacteria, which are connected through their ability to produce Botulinum-neurotoxin (BoNT). Therefore, for some years the scientific world does not speak of "*Clostridium botulinum*" any longer, but of "Botulinum-neurotoxin-producing clostridia." BoNT exists in seven different confirmed antigenic types (BoNT/A to BoNT/G), of which BoNT/E and BoNT/F are known to be toxic for humans, BoNT/C and BoNT/D mainly for different animals, and BoNT/A and BoNT/B for both animals and humans. The toxicity of BoNT/G is largely unknown so far. In 2013 a possible eighth antigenic type (BoNT/H) was described, but the terminology for this type is not yet consistent in scientific literature. In different reports the novel BoNT is referred to as "BoNT/H," "BoNT/FA," or BoNT/HA" (Peck et al. 2017). In addition at least the seven confirmed antigenic types are subdivided into a different amount of subtypes, e.g., BoNT/A in the subtypes BoNT/A1 to A8 and BoNT/B in the subtypes BoNT/B1 to B8 (Peck et al. 2017). This huge amount of genetic and

subsequently immunological variations of the BoNT complicates the development and use of in vitro diagnostics like ELISA-based methods. Therefore, the mouse bioassay is still the "gold standard" detecting BoNT in human samples especially serum.

BoNT/A, B, E, and F are simply constructed polypeptides, consisting of a 100 KDa "heavy" chain and a 50 kDa "light "chain linked through a disulfide bond. The light chain is a zinc-containing endopeptidase, which blocks the release of acetylcholine. This is the reason of the atonic paralysis, the classical symptom of BoNT intoxication. BoNT is one of the most lethal biological toxins; the lethal dose for a healthy adult person is as low as 0.1–1 μg.

The formation of neurotoxin occurs under strict anaerobic conditions after germination of the spores in the last growth phase and the toxin is released after lysis of the bacterium. Growth and toxin production can take place in nearly every food matrix or tissue except those with a low pH < 4.6 or low $a_w < 0.94$ (EFSA 2005). The temperature for optimal growth and toxin formation differs between the groups of BoNT-producing clostridia, and proteolytic strains are normally not able to grow and produce toxin below 10 °C. In contrast non-proteolytic strains, also called "psychotrophic" strains, can grow at temperatures as low as 3 °C (Graham et al. 1997). BoNT belongs to the group of heat-labile toxins; normal cooking temperatures can destroy (pre)formed toxin, but not the spores. Spores are safely eliminated using a temperature-time combination of 3 min at 121 °C for proteolytic strains or of 10 min at 90 °C for non-proteolytic strains (ACMSF 1992).

54.1.2 The Four "Classical" Forms of Botulism

54.1.2.1 Foodborne Botulism

Foodborne botulism is the most common form of botulism in animals and humans. Illness is caused by ingestion of food or animal feeding stuff like silage containing (pre)formed toxin. In both animals and humans the classical symptoms of botulism are atonic paralysis of extremities and at an advanced state respiratory paralysis. In humans intoxication manifests itself after 12–48 h first with the classical symptoms of a foodborne illness like nausea, vomiting, and acute abdominal pain followed by double vision, dysphagia, and atonic paralysis of extremities. Without early treatment (antitoxin therapy and artificial respiration, sometimes over months), botulism mostly leads to death. In cattle and horses the first symptoms are an atonic paralysis of the mastication muscles with prolapse of the tongue also followed by atonic paralysis of the extremities. Death occurs as a result of respiratory paralysis. Poultry and waterfowl show after an incubation time of a few hours to 3 days paralysis of the wings and weakness and death within 10 days; waterfowl drown with clear sensorium. Foodborne botulism can also be acquired by minks and ferrets. Dogs, cats, and pigs are much less susceptible to the toxin; foodborne botulism is rarely described in these animals.

Sources of human foodborne botulism are insufficiently heated, mostly homemade and canned foods, such as meat, sausages, and vegetables, or cured meat

products with low salt concentrations. In animals foodborne botulism mainly occurs in cases of deficient ensiling or of contamination of hay or silage with cadavers. Via cadavers the spores and the toxin can also reach the environment. Waterfowl is mostly poisoned in the summer months by ingestion of toxin-containing slurry.

54.1.2.2 Wound Botulism

In rare cases spores of BoNT-producing clostridia can contaminate deep wounds, e.g., through drug abuse or iatrogenic contamination. The spores can germinate under anaerobic conditions, grow, and produce the toxin directly in the tissue. Four to 14 days after the entry of the spores the affected person shows the classical symptoms of botulism as described above.

54.1.2.3 Infant Botulism (Infant Intestinal Toxemia Botulism)

Infant botulism is a toxicoinfection in children under 6 months and in rare cases also of older children up to 12 months of age. Spores of BoNT-producing clostridia are ingested with contaminated food, e.g., honey or infant formula, or from the environment. Due to a less developed and diversified intestinal microflora, the spores can colonize and germinate in the large intestine of the infant. The produced toxin leads to the classical botulism symptoms, which are preceded at first by constipation, weakness, and poor feeding. Later a typical atonic paralysis occurs. Fortunately, today the toxicoinfection leads only in very rare cases to the death of the patient. Normally, treated patients recover fully from infant botulism (Arnon 1995).

54.1.2.4 Infective Botulism (Adult and Toddler Intestinal Toxemia Botulism)

Approximately a dozen cases of intestinal toxemia botulism have been described in toddlers and adults so far. In most cases there are predisposing factors, which negatively affect the intestinal microflora and allow spores of BoNT-producing clostridia to colonize an adult intestine. Possible factors can be a longstanding treatment with broad-spectrum antibiotics and illnesses, which affect the intestinal anatomy and physiology, e.g., inflammatory bowel diseases, vagotomy, or considerable decreased intestinal motility (Arnon 1995). The patients develop the classical symptoms of botulism described above. Importantly, intestinal toxemia botulism without the typical atonic paralysis has not been described in the scientific literature so far.

In the veterinary literature a similar disease is reported, the equine grass sickness. The disease results in a partial or complete paralysis of the gastrointestinal tract and normally ends with the death of the horse (Hunter et al. 1999). However, a link between equine grass sickness and BoNT has not been scientifically verified until now. In recent times the scientific community assumed that equine grass sickness could be more likely a pasture mycotoxicosis than an infective botulism (McGorum et al. 2021).

54.1.2.5 "Chronic or Visceral Botulism"

Since the mid-1990s some veterinary research groups postulate – besides the classical forms of botulism – the existence of a chronic disease entity in cattle called "chronic" or "visceral botulism" (Böhnel et al. 2001). This disease is said to originate from the ingestion of spores of BoNT-producing clostridia from the feed or the environment. The path of infection and intoxication is compared by these research groups to the adult intestinal toxemia botulism; however, the chronic form of botulism would not lead to an acute and life-threatening intoxication, but to a chronic intake of minimal dose rates of BoNT. This chronic contamination is hypothesized to cause unspecific symptoms in the individual cow, e.g., apathy, indigestion, edemas, chronic lameness, and sudden unexpected death (Böhnel et al. 2001). On farms affected by this so-called "chronic botulism," the groups claim that the milk yield and the fertility rate decrease significantly (Krüger et al. 2014). Medical symptoms simultaneously and coincidentally found among a few farmers on affected farms such as weakness of the extremities and dysfunction of vegetative nerve system, e.g., pupillary motoric, were claimed by one medical research group to be linked to a chronic intake of BoNT (Dressler and Saberi 2009; Rodloff and Krüger 2012). The story of a new, emerging zoonotic disease, the "chronic" or "visceral botulism," which affects farmers, veterinarians, and cattle and can be transmitted, alternating between humans and animals, was born. Until today, more than 20 years later, scientifically sound evidence for the existence of a chronic form of botulism and also for the transmission of spores or vegetative cells of BoNT-producing clostridia between humans and animals in terms of a zoonosis is still missing. The discussion found an (preliminary) end with the results of two extensive scientific studies on dairy farms in two different regions in Germany neither detecting BoNT in fecal samples nor showing differences of shedding of spores of BoNT-producing clostridia between case and control animals (Seyboldt et al. 2015; Fohler et al. 2016; Dietsche et al. 2017).

54.1.2.6 Occurrence of Botulism Cases

In summary, botulism can be classified as a classical foodborne zoonosis transmitted via food from healthy animals, shedding spores of BoNT-producing clostridia (Rasetti-Escargueil et al. 2019). In contrast to other zoonotic illnesses, the transmission of the spores occurs only very rarely and in cases of subsequent toxin production in the contaminated food to a disease in humans. In Europe the confirmed case rate of human botulism constantly ranges between 0.02 and 0.03 cases per 100,000 population. The most frequent reported form of botulism in Europe is foodborne botulism; infant botulism and wound botulism are only seen in single cases (ECDC 2013). This main foodborne transmission route in Europe is one of the reasons why the European Union classified botulism as a bacterial zoonotic intoxication which has to be monitored in the different member states depending on the epidemiological situation according to Annex I B no. 1 of Directive 2003/99/EC (EU 2003).

In the USA the CDC reported for the year 2018 231 confirmed human botulism cases, of which 104 (70%) cases were due to infant botulism (CDC 2021).

54.2 *Clostridium perfringens*

54.2.1 *Clostridium perfringens*: Much More than a Bacterial Contamination of Food

Clostridium (C.) perfringens was first described by Welch and Nutall in 1892 and assigned to the genus *Bacillus*. After a change in nomenclature the bacterium was named after its discoverer "*Clostridium welchii*," until it get its present name "*Clostridium perfringens*." The name "*perfringens*" (Latin for "disrupt") is derived from one of the clinical pictures caused by *C. perfringens* so-called "gas gangrene." Concerning the morphology *C. perfringens* is similar to other clostridia, but in contrast to BoNT-producing clostridia, the organism is less susceptible against oxygen and can therefore survive and grow under not strictly anaerobic conditions.

According to the ability of producing four "major toxins" and a number of "minor toxins," the species *C. perfringens* is subdivided into different toxinotypes. In 2018 the old scheme of five toxinotypes A to E was revised and extended to seven toxinotypes A to G with six major toxins (Rood et al. 2018). The scheme comprises toxinotypes causing illness exclusively in different animals (B, E, and G), exclusively in humans (F), and in both humans and animals (A, C, D) (EFSA 2005). Relevant for humans is the new toxinotype F carrying the *cpa* gene (encoding the alpha toxin) and the *cpe* gene (encoding the enterotoxin) but also the toxinotypes A, C, and D. Strains of toxinotype F are responsible for foodborne toxicoinfections and antibiotic-associated diarrhea, while the toxinotypes C and D are associated mainly with necrotic enteritis. Toxinotype A carrying the *cpa* gene (encoding the alpha toxin) is responsible for the classical illness first associated with *C. perfringens* so-called "gas gangrene" (myonecrosis).

In veterinary diagnostics, it is distinguished between two different disease complexes caused by *C. perfringens*:

- Necrotizing enteritis in young animals (e.g., lamb dysentery [type B] or necrotizing enteritis in suckling piglets [type C])
- Enterotoxemia, e.g., also in older animals, after a sudden change in feed, overfeeding, and too little raw fiber ("protein disease")

In veterinary medicine, the term "enterotoxemia" refers to peracute diseases in which toxin formation takes place in the intestine, is absorbed, and enters the bloodstream. Furthermore, *C. perfringens*, along with other animal pathogens *Clostridium* spp., plays an important role in gas edema diseases and can cause necrotizing mastitis in ruminants. The symptoms and the development of the different diseases in animals are very similar in comparison to human diseases caused by *C. perfringens* described below (EFSA 2005).

54.2.1.1 Foodborne Toxicoinfections

The *C. perfringens* enterotoxin (CpE) is produced during sporulation mainly in the ileum but also in other parts of the intestine. The enterotoxin binds on the epithelial cells in the intestine, destroys the intestinal villi, and results in a desquamation of the

cell membranes. As a consequence, the adsorption of electrolytes and water from the intestine is blocked and this results in the predominant AAD symptom of a *C. perfringens* toxicoinfection, a watery diarrhea. Besides *C. perfringens* type F also strains of *C. perfringens* type C and D can carry the *cpe* gene that is responsible for the production of CpE.

C. perfringens can grow under completely anaerobic conditions, e.g., in oxygen-free canned food but also with a rest amount of oxygen at the bottom of big pots of stew and soups (preferable with meat), and cause the so-called "toxicoinfections." In contrast to an intoxication, the bacterial pathogens produce in this case the toxin not directly in the food but after sporulation in the human intestine. *C. perfringens* toxicoinfections occur mainly in (mass) catering facilities, in canteens, or on buffets, where food is kept warm over a longer period under inadequate temperature conditions. Mostly self-limiting symptoms of a foodborne *C. perfringens* toxicoinfection, especially watery diarrhea, arise after 8–24 h and last not more than 24–48 h.

54.2.1.2 Sporadic and Antibiotic-Associated Diarrhea

Besides foodborne toxicoinfection, *C. perfringens* type F can also cause sporadic and antibiotic-associated diarrhea (AAD) similar to *Clostridioides difficile*. A worldwide systematic review showed that in AAD cases the prevalence of *C. perfringens* was 14.9% behind *Clostridioides difficile* (19.6%) and *Klebsiella oxytoca* (27.0%) (Motamedi et al. 2021). A necessary precondition for developing an antibiotic-associated diarrhea caused by *C. perfringens* type F is an intensive treatment with broad-spectrum antibiotics. This can lead to the destruction of the normal intestinal flora and an uncontrolled growth and toxin productions of *C. perfringens* type F in the intestine.

54.2.1.3 Enteritis Necroticans

Between 1946 and 1948 a new epidemic disease was observed in different cities in the northern part of Germany. Because of progress and symptoms, the disease was called "enteritis necroticans." Researchers described the disease in the way that healthy adults developed, few hours after consumption of canned meat, game or fish abdominal pain and diarrhea. In some cases symptoms were slight and self-limiting, but in other cases the patients developed bloody diarrhea with serious abdominal pain and died of dehydration and cardiovascular failure or of intestinal obstruction (Hobbs et al. 1953; Kreft et al. 2000). In fecal samples of patients and at autopsies, huge amounts of *C. perfringens* type C with the ability to produce beta toxin were detected. Additionally the spores of the isolates were characterized by a very high heat resistance. Therefore, the spores survived the heat treatment of the preservation process. Meanwhile enteritis necroticans is very rare in Europe, but in crisis areas, it can occur again at any time because one of the predisposing factors responsible for the occurrence of this disease is malnutrition. Malnutrition can lead i.a. to an inadequate production of trypsin, which enables the effect of the beta toxin formed in the intestine.

54.2.1.4 Gas Gangrene

The classical illness first associated with *C. perfringens* was not diarrhea but myonecrosis so-called "gas gangrene." The cause of gas gangrene is

C. perfringens spores from the environment getting into deep wounds, where the spores germinate and multiply in this anaerobic environment. According to the current state of science, the symptoms underlying such an infection process can essentially be assigned to two pathogenicity factors formed by *C. perfringens* type A, alpha and theta toxin. The alpha toxin (phospholipase C), a lecithinase, splits the lecithin present in the membrane into phosphorylcholine and diacylglycerol. Theta toxin (perfringolysin O) is a cytolysin that leads to complete hemolysis of red blood cells (Harris et al. 1991). Like most anaerobes, *C. perfringens* is one of the gas-forming microorganisms. When the wound is palpated, gas formation can sometimes be perceived as a characteristic "crackling." Without treatment the patient may develop septic shock and dies within hours due to multiorgan failure (Di Fazio et al. 2022).

54.2.2 *Clostridium perfringens*: Only an Environmental Contamination or a Zoonotic Agent?

C. perfringens exists, like other clostridia, in a form of spores ubiquitous in the environment and can be found in higher amounts in soil and dust. Therefore, it can be assumed that *C. perfringens* spores are part of the normal flora in soil. Furthermore *C. perfringens* is found regularly in feces of healthy humans and animals in higher concentrations (around 10^4–10^6 cfu/g feces). Considering *C. perfringens* as a normal part of the intestinal flora, human fecal samples are not routinely tested for *C. perfringens* in case of diarrhea or other intestinal illnesses. So *C. perfringens* is not counted to the obligate pathogenic organisms, but depending on the subtype or strain-specific ability to produce different major or minor toxins, it has the potential to cause the entire spectrum from mild self-limiting to severe life-threatening diseases. As a normal inhabitant of the human or animal intestine *C. perfringens* can be transmitted directly or indirectly (via food) between humans and animals causing under special circumstances also illnesses. Therefore, *C. perfringens* meet, like the other (potentially) pathogenic clostridia, all criteria of a (bacterial) zoonotic agent as defined by the European Union in Directive 2003/99/EC (EU 2003).

54.3 *Clostridioides difficile*

54.3.1 *Clostridioides difficile*: The Causative Agent of Nosocomial Pseudomembranous Colitis in Humans

Clostridioides (C.) difficile is also a gram-positive, rod-sharped, strictly anaerobic bacterium, which was first described as "*Clostridium difficile*" by Hall and O'Toole in 1935 as part of the microbial intestinal flora of infants (Hall and O'Toole 1935). The species was assigned to the new genus "*Clostridioides*," which means "similar to clostridia," and renamed in August 2016 based on 16S rRNA gene sequence

analysis (Lawson et al. 2016). *C. difficile* is counted to the group of facultative pathogenic bacteria, because it can be detected also in the intestine of healthy persons without any characteristic symptoms. Predominantly the organism causes nosocomial disease linked to antibiotic treatment; however, there are also community-acquired *C. difficile* infections without any correlation to hospitalization. The pathogenicity of *C. difficile* is based on the ability to produce different toxins, an enterotoxin A, a cytotoxin B, and in some strains (ribotype 027) also a binary toxin, which is linked to more severe symptoms (Schroeder 2005).

Usually a *C. difficile* infection (CDI) develops after an intensive therapy with broad-spectrum antibiotics, which destroy the normal microbial intestinal flora. In such a situation *C. difficile* spores can colonize the intestine, germinate, and overgrow the remaining normal microbial flora. The severity of the symptoms depends on the immune status of the patient and can vary from mild diarrhea to a pseudomembranous colitis with a case fatality rate of 6–30%. For a long period it was assumed that most patients who develop severe symptoms like a pseudomembranous colitis are infected in the hospital and that only a small part carries the causative organism already before hospitalization (Schroeder 2005). However, recent studies showed that by using, e.g., whole-genome sequencing, according to genetic correlation only a substantially low number of isolates suggested a hospital-acquired transmission. In a high number of cases alternative environmental reservoirs besides the hospital have to be taken into account (Eyre et al. 2013; Lim et al. 2021). Therefore, it can be assumed that *C. difficile* is a zoonotic agent, which also can be transmitted via animals, food, or the environment to humans. However, these new findings are not in contradiction with the fact that hygienic deficiencies in hospitals and healthcare facilities can also cause transmission of *C. difficile* between patients and lead to outbreaks with a major number of deaths, especially if hypervirulent strains of increasing importance such as ribotype 027 are involved.

54.3.2 *C. difficile* in Animals, Food, and the Environment

Like different potentially pathogenic clostridia, e.g., BoNT-producing clostridia and *C. perfringens*, *C. difficile* is ubiquitous in the environment and can be found more or less frequently in soil, dust, and water but also in compost and biogas plants (Fröschle et al. 2015; Le Maréchal et al. 2020; Rodriguez Diaz et al. 2018). The exposure of *C. difficile* in the environment arises most probably from animal (and human) feces, because the mammalian gastrointestinal tract is known as the primary reservoir of *C. difficile*. Similar to *C. perfringens* the *C. difficile* strains can colonize the mammalian gastrointestinal tract without causing any symptoms (Knight and Riley 2019).

The prevalence of *C. difficile* in farm animals differs depending on the age of the animals investigated, but also on the geographic region/country and relating thereto the different veterinary and agricultural practices (Knight and Riley 2019). In general the prevalence of *C. difficile* decreases with the age of the animals. In calves, for example, detection rates up to 56.4% are reported, whereas the detection rates in

cows vary between 0.6% and 12.9% (Knight and Riley 2019). In piglets and pigs the prevalence seems to be in general higher, rising up to 100% (Lim et al. 2019). The relevance of *C. difficile* as a pathogenic agent in animals in general is not completely clarified until now. It is known that *C. difficile* can be isolated from feces of foals, piglets, dogs, or cats with clinical signs of diarrhea (Schneeberg et al. 2013; Songer 2010), but also from healthy animals (Rodriguez-Palacios et al. 2013). It seems that *C. difficile* cause clinical signs of disease mostly in young animals; in older ones a colonization without any clinical signs (like a commensal) is reported. This is also known from other zoonotic agents and from potentially pathogenic clostridia like *C. perfringens*.

Via farm animals *C. difficile* is also entering the food chain and can be detected in different processed and non-processed food of animal origin (de Boer et al. 2011). But also in food of non-animal origin *C. difficile* is found regularly with remarkable differences in the detection rates in Europe and North America (3–8%) on one side and Australia (20–56%) on the other side (Knight and Riley 2019).

54.3.3 *C. difficile*: A Prime Example for the One Health Approach

Summarizing the current state of scientific knowledge, the zoonotic potential of *C. difficile* is unquestionable and there is no point of discussion any longer. Normally an indirect zoonotic transmission between animals and humans via food or the environment can be assumed, but also a direct zoonotic transmission between pigs and pig farmer is reported (Knetsch et al. 2014, 2018). Against the background of an increasing number of community-acquired *C. difficile* infections in healthy people without the classical risk factors for CDI (e.g., old age, prolonged hospital stay, a recent surgical procedure) and the ubiquitous occurrence of *C. difficile*, a One Health approach for long-term management of this zoonosis should be taken into account (Lim et al., 2019). Based on the ubiquitous nature of this spore-performing organism, it seems to be impossible to prevent humans getting in contact with *C. difficile*. However, for normal immunocompetent persons this contact can lead to an asymptomatic colonization, but usually not to a symptomatic infection. Therefore, it is important to investigate more in depth the predisposing factors for community-acquired CDI, especially the question what has to be happened to change the status of *C. difficile* in the mammalian gastrointestinal tract from "commensal" (colonization) to "pathogen" (infection)? (Lim et al., 2019). Active sentinel surveillance in the State of New York over a period of 6 months showed, for example, that 76% of patients with a community-acquired CDI had used antimicrobial drugs within 12 weeks before infection. Strong evidence that certain kinds of food or animal exposure were involved was not found (Dumyati et al. 2012). But the use of antimicrobial substances cannot be the only major risk factor for a community-acquired CDI. Therefore, in future it is necessary to identify further predisposing factors to develop prevention strategies especially for severe and life-threatening progressions of disease not only in intensive care or healthcare units with critically ill persons but also in the community.

Making Sense and Acting on the Socio-economic Impact of Zoonoses in Our Food Systems

Sara Babo Martins, Peregrine Rothman-Ostrow, Grace Patterson, Barbara Häsler, and Jonathan Rushton

Contents

Abstract

Livestock food systems are changing rapidly with increasingly complex, dynamic, and globally connected production, harvesting, distribution, and consumption patterns. These changes carry new challenges from zoonotic diseases,

which require an understanding of the socio-economic impact to develop, prioritize, and advocate for proportionate mitigation actions.

A full assessment of the socio-economic impacts of zoonotic diseases from a societal perspective can be challenging. Recognizing pathways for burden and loss and selecting appropriate tools, frameworks and data, form the foundation for that assessment. The value-add of this investment in understanding zoonotic impacts is the ability to recognize where the balance lies between costs of mitigation actions and avoidance of losses due to ill-health and poor animal welfare. This balance may equate to a wider economic efficiency view, which includes investments in research, education, and coordination that allows people and livestock keepers improved access to zoonotic disease mitigation options.

This chapter presents the case for better use of socio-economic impact assessments to improve our understanding of the burden and subsequent control of zoonoses.

Zoonoses · Economic assessment · Burden of disease · Food systems · Impact

55.1 Introduction

The initial successes in the control of infectious diseases in animals were the control and eradication of rinderpest and contagious bovine pleuropneumonia in Europe in the late 1800s (Fisher 1998). The distribution of livestock diseases began to change more rapidly in the 1960s and 1970s as European and North American countries and Japan began to make serious inroads into the control of a range of both transboundary and endemic animal diseases. This was achieved through significant investments in human skills, building on previous investments in veterinary organizations, education, and infrastructure from the mid-nineteenth century onwards. With the establishment of the World Organisation for Animal Health (WOAH, formerly OIE) in 1924, an important foundation was created for standard setting in animal health. Moreover, WOAH helped to build capacity for national veterinary services with their Performance of Veterinary Services (PVS) Pathway.

In human health, attempts to manage diseases affecting societies appear to have been in place in Europe as early as the 1500s and addressed the problems caused by the plague (Harrison 2004). The period of enlightenment expanded the knowledge of causal agents of disease (Hays 2009), and there were breakthroughs in the control of diseases such as smallpox with the use of vaccines, ultimately leading to the official eradication of the disease in 1979 (Harrison 2004). In terms of overall service delivery, much work has gone into the management of human health, with most countries recognizing the need for coordinated health services. This culminated in the recognition of the need for the International Health Regulations in 2005. These initiatives have been prompted largely by disease shocks and the core contagious diseases that spread between humans.

While both animal and human health sectors have strengthened their capacity to tackle major diseases, the use of collaborative approaches across sectors in the prevention and control of zoonoses using a One Health perspective has also been expanding. At the heart of long-standing policies and research approaches for endemic zoonotic and foodborne diseases, the recognition of One Health has been accelerated by its central place in global health efforts to tackle antimicrobial resistance (AMR) and by recent crises linked to emerging pathogens, most notably avian influenza virus, Middle East respiratory syndrome–related coronavirus (MERS), and the COVID-19 pandemic. Also driving the recognition of One Health is a better understanding of the burden of zoonoses and other health issues arising at the interface of the health of animals, humans, and the ecosystems they share. A systems thinking approach, such as that expounded by the One Health concept, allows for the recognition and capture of disease impacts across sectors and fosters an umbrella under which multiple species' health and welfare can be monitored in the context of disease, control programs, and overall influence on food systems.

The heightened awareness of problems with salmonella in the 1980s, followed by the emergence of bovine spongiform encephalopathy (BSE), drew attention towards the insidious nature of zoonoses in the food system. A rise in challenges surrounding the management of highly pathogenic avian influenza (HPAI) in poultry systems, the re-emergence of the pandemic form of H1N1 from pigs, and a range of coronaviruses associated with wild and domesticated animals further brought zoonoses into stark focus. Concurrent to these major zoonotic disease threats, changing patterns in foodborne diseases have driven a change in food security and investment, with campylobacter being a pathogen of greatest significance. These disease shifts reflect the increasing complexity of our food systems and have led to investments in rigorous and organized programs that employ epidemiology and economics research to assist in decision-making. Similar to the disease and response processes of the major diseases in animals and humans, major foodborne diseases have created a need to invest and further investigate the impact of zoonoses in global food systems.

The economic impact of zoonoses in food systems is dependent on epidemiological parameters such as incidence, mortality, and morbidity effects in animals, the effects on human health and welfare, and the efforts to respond to the disease across relevant species groupings. Further impacts include food security, nutritional availability, and environmental management (Häsler et al. 2017; Rushton et al. 2018), while knock-on impacts due to food scares, trade restrictions, labor shortages, and value chain bottlenecks can drive significant negative effects on food security both in the short and long term (Chapot et al. 2021). We review how zoonoses impact food system sectors in the context of an increasingly complex value chain, address the economic concepts behind the balance between losses due to direct costs of disease and expenditures in reaction to disease presence, and identify possible economic tools and frameworks to assess the burden of zoonoses and the value of interventions to tackle them.

55.2 Context

The increasing complexity of livestock production systems and their associated value chains is underpinned by changes in political and institutional environments. From the late 1940s to the 1970s, state action was accepted as pivotal in economic and agricultural development. However, during the 1980s, there was a change in thinking that positioned the market as the primary way to organize economic activity, supported by a minimal role for the state. Different elements of these changes in public policy have had varying impacts on zoonoses management and public health in general. The 1970s saw the emergence of a perceived problem of government and its role in society as a major organizer and contributor to society. The 1980s saw the rise in deregulation of economic activity and the privatization of state-owned companies and services. This change also applied to veterinary services in many countries and was particularly contentious in Africa (Leonard 2000, 2004). Pressure on public budgets and an increasing role for the private sector saw the privatization of many former governmental veterinary services and activities. The public health systems suffered less, but zoonoses control often fell between weakened veterinary systems and relatively powerful human health institutions and agencies with a focus on diseases and health problems that largely affect people.

In addition to the changes in the public funding of health infrastructure, global food systems have evolved in response to growth and change in demand and dietary preferences, creating more difficulties in the management of pathogens.

55.2.1 Changing Context of the Food Systems That Feed Us

Over a period of around 200 years, the world has moved from relatively simple livestock value chains to increasingly complex ones. The pace of this change has accelerated in the livestock sector with the increasing use of intensive systems where animals are housed and fed defined diets and no longer allowed to scavenge or graze. In the case of poultry, this has been particularly dramatic. Scavenge-based systems for poultry production were common and used mainly local resources, with the household consumption of products and infrequent sale to local markets (see Fig. 1). The presence of these systems in a local environment allowed people to observe the

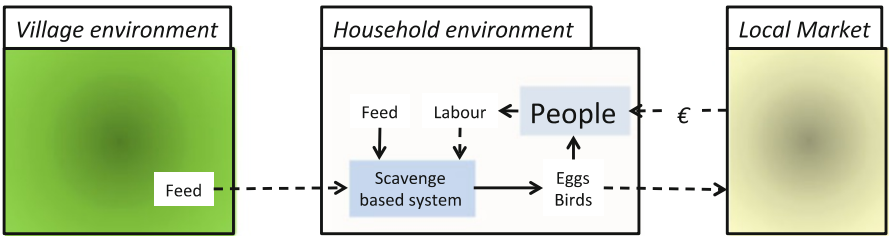

Fig. 1 Scavenge-based poultry system

health of the animals, and it is also probable that they witnessed the slaughter of the animals. The information on production and processing allowed people to make individual judgments of how best to prepare and eat their food while also limiting the distance of the value chain.

In the complex food value chains that are now dominant in many parts of the world, primary production has complex relationships with consumers through processing and marketing companies. The links in the chain are maintained by middlemen, transport companies, and finance groups. Where the value chains become integrated, that is, owned and controlled by one company, the middlemen disappear. In addition, consumer demands have become more sophisticated, with demand rising for processed food and an expectation to purchase foods with zero risk of food-borne diseases (Rushton 2009a). For the intensive poultry systems that are increasingly dominant in the provision of meat across the world, the system is global. Day-old birds and feed are produced in different parts of the world, and the fattening of birds and their slaughter take place some distance from the families that ultimately consume the meat (see Fig. 2). These systems do not allow an individual to gain much direct insight into, or information on, the origin of the meat eaten. Instead, the consumer is given that information through labeling and/or systems of trust on the quality and food safety of the product, for example, through having trusted relationships with a supplier.

The changes in the livestock food systems have been gradual, though there have been jumps associated with major technological changes. These have come at different points in the food system. For example, the ability to freeze meat allowed the slaughter and transport of carcasses from distant places to points of consumption. These changes have also been stimulated by the social and economic shifts in society, the growth of human populations, and the greater proportion of people found in urban, rather than rural areas (Wahba Tadros et al. 2021). The urban-based populations require food to be produced and processed for them, driving food systems globally to become more technologically and economically efficient to provide relatively cheap food in comparison to other goods in society. Overall, this has driven a reduction in the need for labor in primary

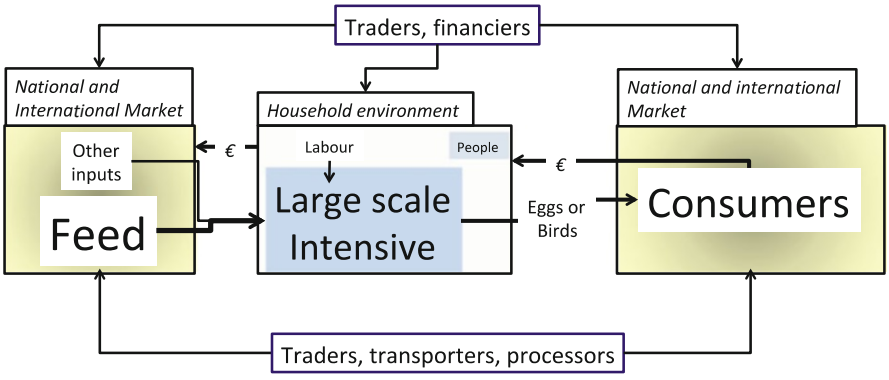

Fig. 2 A schematic diagram of the complex intensive poultry food systems (Rushton 2009a)

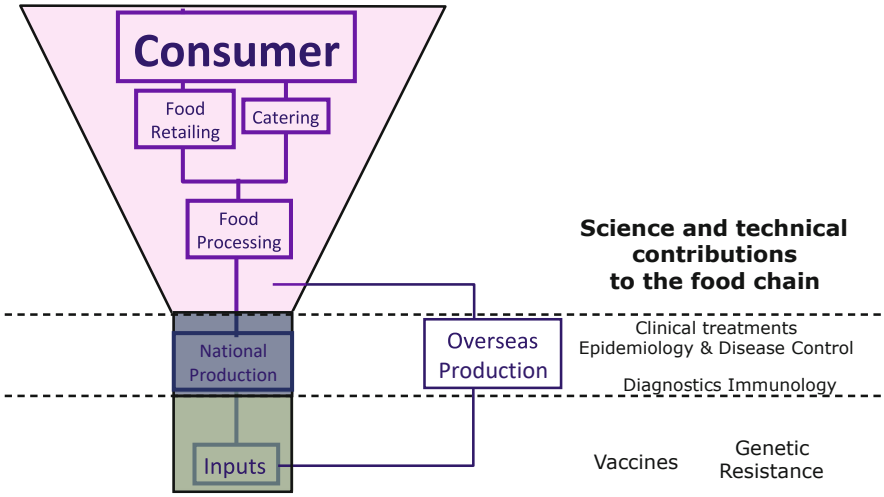

Fig. 3 A schematic diagram of the food systems (Rushton et al. 2012)

production. In the case of livestock, this has meant that animals are managed in larger herds or flocks with a greater animal to human ratio in stewardship. These changes have engendered a shift in the economic activity of the food system, which is now predominantly found in the processing, catering, and retailing areas where food preparation that would have traditionally been done in the home is now carried out by third parties. The shape of the food system in many countries worldwide in terms of numbers of people is therefore like a pyramid with a large number of consumers being supplied with animal source proteins produced by fewer and fewer farmers who are selling to complex food processing, retailing, and catering companies (see Fig. 3). There are still countries where very many farmers supply food to the system (e.g., dairy producers in India), but the trend overall, in particularly in higher income economies, is one of fewer farmers supplying to an increasingly large consumer base.

In the UK, out of the estimated 4.3 million people employed in the agri-food sector in 2018, it is estimated that only 11% were engaged directly in farming. While processing and manufacturing employees accounted for about the same number of employees as farming, most people in the food system were employed in retailing and hospitality. The UK agri-food sector contributed £121 billion or 9.4% to the National Gross Value Added (GVA) in 2018 (Hasnain et al. 2020). This food system relies on imports from other countries and feeds, daily, more than 67 million people. In short, never have so many been fed by so few. While primary production still employs a majority of people in many African and several Asian and Latin American nations (World Bank 2021), similar patterns of consolidation limit the economic impact and international reach of the majority of small-scale producers.

The length, breadth, and density of current food system value chains, and the additional complexity brought on by the resulting increase in number of people and links in the supply chain, suggests that the presence of infectious diseases, including

zoonoses, will have wider and more far-reaching impacts on a greater number and variety of stakeholders, sectors, and people. This alone brings new and complex challenges to disease control. Aside from controlling disease within food production systems, lengthy international value chains are also at risk of disruption from external major crises, including disease outbreaks. A recent example of this is given by the early response to the COVID-19 pandemic-imposed travel restrictions limiting the movement of people and goods between countries (Patterson et al. 2020). These restrictions limited travel for migrant field workers, international shipment of foods and inputs such as livestock feeds, and consumer access to goods. In places reliant on international trade for agricultural inputs, production was slowed or halted. For example, the day-old-chicks, feed, feed additives, and vaccines required as imported inputs in the commercial Ethiopian poultry sector were inaccessible during the early months of the COVID-19 pandemic, causing massive disruption across poultry production systems (Ethiopia-Netherlands Trade for Agricultural Growth, 2020). A telephone survey of commercial poultry producers and stakeholders in Ethiopia found that, in the first few months of the the pandemic in 2020 production rates fell by 92% for feed, 68% for day-old chicks, 100% for pullets, and 87% for broilers totalling losses of ETB 226,485,788 (approximately USD $ 5,186,072). production of feed, day old chicks, pullets, and broilers each fell more than 60%, resulting in significant economic losses for the surveyed producers. Globally, chicken meat systems were disrupted, because of their complex interconnection and dependencies and the ripple effects in the system stemming from disruptions in the hospitality sector, movement restrictions, closure of markets, and negative behaviors such as panic buying or avoidance of products due to food scares (Chapot et al. 2021).

Reduction in the overall number of primary producers and increases in food processing, catering, and retail sectors have also led to an emphasis on quantity over quality to feed a growing global population and keep the price of food low. Fewer international producers are taking up larger portions of the global market share in grains and livestock (Howard 2017). Several transnational corporations wield strong industry influence yet have minimal societal name recognition (Swinburn et al. 2019). Reduction in genetic diversity of livestock breeds and crops has reduced the resilience of plants and livestock to disease (Bennett et al. 2018; Khoury et al. 2014), and in some cases, modern, high yield crop strains have lost the high micronutrient content found in wild progenitor strains (Velu et al. 2019). Researchers are now working to retain and rebuild that lost diversity to maintain average productivity while improving resilience to threats wrought by climate change (drought, flood, and shifting patterns of disease) (Wolfe and Ceccarelli 2020). Modern food systems are often increasingly inequitable on an international scale. Global food demands from countries with greater economic influence can drive economic and environmental externalities related to unsustainable modes of food production that fall disproportionately on communities with less power in the global market (Gonzalez 2010).

The background of food system change is a necessary component of a socio-economic assessment of zoonotic diseases. The food system dictates the costs of production and the price of food, while the public and private rules that govern the food system impact how zoonoses are managed.

55.2.2 Classification of Zoonoses

Zoonoses have been defined as diseases and infections that are naturally transmissible between vertebrate animals and humans (WHO 2021a). This group of diseases is generally classified according to the zoonotic agent itself and the route of disease transmission from animals to humans (Karesh et al. 2012; Lloyd-Smith et al. 2009). This classification offers a means to group zoonoses into diseases that are mainly transmitted to humans through food consumption, such as salmonellosis or campylobacteriosis; those that are mainly transmitted to humans through means other than food, for example, vectors, direct contact, or proximity to infected animals, such as avian influenza, and zoonoses with multiple routes of transmission, such as brucellosis (transmitted through food or direct contact with infected animals) and Rift Valley fever (conferred either through direct contact with an infected animal or the bite of an infected mosquito) (EFSA 2013).

While foodborne zoonoses are particularly important in terms of direct economic ramifications for the food sector, indirect costs of zoonoses transmitted by means other than food can also produce a significant impact on the food industry (McLeod et al. 2006; Rassy and Smith 2012). The designation of a disease as a zoonosis comes with wide-reaching social and political ramifications when considering ownership and leadership of control and management strategies, and while a One Health perspective on disease management has gained considerable traction in recent years, economic ramifications are still often sector-specific. Further, the designation of a disease as a zoonosis is not without ambiguity. A disease such as rabies, which is transmitted to humans through the bite of an infected dog in 99% of global cases, is a clear example of a zoonosis (WHO 2021b). Ambiguity around the appropriateness of the designation of a disease as a zoonosis arises however when human-to-human spread becomes the dominant route of transmission; these diseases (including COVID-19) have been labeled as "infectious disease of probable animal origin" (Haider et al. 2020). Independent of the designation, these pathogens can result in a significant direct and indirect economic impact on animal-source food value chains (Rassy and Smith 2012) – as seen in the case of (H1N1)pdm09 virus.

Zooanthroponosis, or "reverse zoonosis," defined as the human transmission of a disease to animals, must also be regarded as a threat to food systems and the wider economy (Messenger et al. 2014). In the case of COVID-19, its ability to act as a reverse zoonosis has resulted in devasting impacts on select animal populations, most notably, the mass culling of mink in 2020 following human-to-mink transmission of SARS-CoV-2. For instance, porcine cysticercosis (*Taenia solium*), though rightfully designated a zoonotic disease given that humans can become infected through eating undercooked pork, should also be regarded as a zooanthroponotic pathogen when considering that humans are the only definitive host (García et al. 2003), while pigs serve as an intermediate. While it could be argued that increased hygiene and sanitation in the human sector might aid in the reduction of transmission, the pork industry is often held largely responsible for disease prevention from a meat inspection standpoint and frequently shoulders heavy economic losses when

cysts are discovered during the butchering process (Carabin and Traoré 2014). Zooanthroponotic disease transmission can also have negative impacts on conservation initiatives with recent reports of neurocysticercosis (*T. solium*) detected in a wild Bengal tiger and suspected human to elephant spillover of *Mycobacterium tuberculosis* (Miller et al. 2019).

55.3 Understanding the Burden of Zoonoses

The impact of zoonotic diseases results in losses at the human-animal-environment interface and within each of those sectors, individually. Furthermore, the pattern of loss across each sector is widely influenced, both directly and indirectly, by the impacts in other sectors (Grace et al. 2012; Keusch et al. 2009). This is illustrated by the decades-long international battle to control and eradicate brucellosis (see Box 1), a disease with significant direct and indirect costs across livestock and public health.

55.3.1 Pathways for Burden

55.3.1.1 Public Health

The burden of diseases on public health can be seen through a health-related viewpoint, primarily by the assessment of changes in epidemiological parameters, such as prevalence or incidence of disease in the population or mortality rates. Additionally, in human health, the impact of both mortality and morbidity rates can be combined using metrics such as the disability-adjusted life years (DALYs) or quality-adjusted life years (QALYs). From a socio-economic perspective, impact also includes the value of the resources that are utilized as a result of disease, including health sector costs (e.g., visit a physician, laboratory or treatment expenses, or control and surveillance and disease control programs) and the value of decreased or lost productivity by the patient, as well as intangible costs (e.g., psychological costs due to pain or suffering).

The indirect effects mentioned above, stemming from disruptions to food and nutrition security, carry important weight as well, but are more difficult to measure due to their more distal and multistep effects on public health. Consequently, the direct effects on human health can be seen as a minimum burden caused by foodborne disease. In countries where there are no substitution possibilities for foods potentially contaminated with pathogens, consumers may put themselves at risk for foodborne disease when consuming the food due to the lack of alternatives, or they may increase the risk of malnutrition by excluding nutritious foods from their diets. Foodborne disease leading to diarrhea reduces appetite and/or the absorption of nutrients in the body. Malnutrition impairs the immune response and predisposes affected people to infection thereby creating a vicious cycle of malnutrition and infectious disease (Ibrahim et al. 2017).

Box 1 Economic Impact of Zoonoses – Brucellosis

Brucellosis is a highly transmissible disease of livestock, wildlife, and humans causing significant economic losses in livestock due to reduced milk and meat production caused by poor fertility. A 2015 study in India estimated that the livestock industry suffers a median loss of USD $ 3.4 billion in revenue due to brucellosis (Singh et al. 2015). Humans are typically infected via direct contact with infected animals and their products, such as during husbandry, at slaughterhouses, or by drinking unpasteurized milk. In humans, brucellosis infection can cause a recurring undulating fever and joint pain, leading to significant loss of work. In India, annual median losses due to human brucellosis were estimated at USD $10.46 million/year (Singh et al. 2018). Brucellosis also significantly threatens food security by reducing milk output and fertility rates. In 2002, the FAO estimated that eradication of brucellosis in Sub-Saharan Africa (SSA) would have resulted in generation of approximately 371,000 additional tons of meat and 616,000 additional tons of milk in the region (Mangen et al. 2002). Many species of *Brucella* infect livestock, the most important being *B. abortus*, which mainly infects cattle, and *B. melitensis*, which mainly impacts small ruminants (Corbel 2006). *B. melitensis* causes more human cases and more severe disease than *B. abortus*. While vaccines for use in animals exist for both *B. abortus* and *B. melitensis*, they have different safety and effectiveness profiles that contribute to the historical difficulty in controlling *B. melitensis* as compared to *B. abortus* (Corbel 1997). *B. abortus* is more prevalent among livestock, but has proven easier to control than *B. melitensis,* with more countries reaching bovine brucellosis-free status than ovine/caprine brucellosis-free status (Corbel 2006).

Concerted efforts to eradicate or minimize brucellosis began in the early 1900s, but these actions have largely only been accessible to countries with the structural organization and money necessary to sustain vaccination and surveillance for decades. Vaccination, test-and-slaughter, and hybrid campaigns have each been employed with varying levels of success, but this success was contingent on strong, high-level implementation over many years (Zhang et al. 2018). In the US, efforts to eradicate bovine brucellosis cost USD $3.5 billion over 63 years (Dadar et al. 2021), and pockets of brucellosis persist among wildlife in the Greater Yellowstone Ecosystem. Government mistrust, insufficient capital or infrastructure, and social and religious concerns, such as reluctance to cull animals or pasteurize milk, can hamper or totally inhibit control efforts. Nevertheless, if these barriers can be overcome, mass vaccination may be more cost-effective than reactive measures even for developing countries (Zhang et al. 2018). In Mongolia, mass vaccination of small ruminants and cattle against brucellosis was predicted to generate a net positive impact of USD $ 18.3 million (Roth et al. 2003).

(continued)

Box 1 (continued)

Significant trade barriers exist between brucellosis free and brucellosis endemic areas, designated according to OIE guidelines in compliance with the Sanitary and Phytosanitary Agreement of the World Trade Organization (Franc et al. 2018). Other organizations such as the European Union apply additional rules surrounding international surveillance and trade. Consistent risk assessment and monitoring is required to maintain brucellosis free status. In 2010, Great Britain was EU certified as "Officially Brucellosis Free" (OBF), while the Republic of Ireland was not. A risk assessment for import of breeding cattle from Ireland to GB identified a high risk of importing brucellosis. Indeed, in 2003 36 infected heifers were imported into GB from the Republic of Ireland, 10 years after the last reported case of bovine brucellosis in the UK (Jones et al. 2004). For countries with high incidence of brucellosis, animals to be exported must be isolated and tested for disease prior to movement (OIE 2018), making export more costly for producers (Peck and Bruce 2017). Replacement of depopulation policies with quarantine policies cost producers in the USD $ 94,000 for a 400-head herd. However, little work has been done to quantify the overall economic impact of lost trade due to brucellosis status of herds or countries. Investment in veterinary capacity-building can help some nations attain improved brucellosis status, and therefore improved trade prospects (Rossiter and Hammadi 2009). Relaxing restrictions on international trade of low-risk processed meats could also improve equitability of market access for producers in areas endemic for brucellosis.

The true extent of the economic and health impacts of brucellosis on livestock and humans is unknown. Underreporting and poor surveillance, lack of capacity, and mistrust of government intervention all contribute to the persistence of the disease and our inability to quantify it in low and middle-income countries in particular (Franc et al. 2018).

55.3.1.2 Animal Health and Production

The presence of zoonoses in food-producing animals may be associated with losses due to morbidity and mortality, which can lead to a reduction in expected output (e.g., decreased milk yield, lowered body weight) and an increase in expenditures in treatment costs (Bennett and IJpelaar 2005).

Morbidity and mortality of animals due to zoonotic diseases also carry other losses related to the wider social, cultural, and economic value of animals and their health and welfare. Animals can be a source of income and employment, provide draught power and fertilizer, serve as a means of transport, particularly in low-income settings, and serve as guardians of livestock and households and companions to people (Meslin 2006; Torgerson 2013). They also act as a form of insurance and social status. Losses of domestic animals can therefore represent an important socio-economic impact in affected communities. For low-income families

or those with limited wealth, an unexpected loss in earnings may inhibit their ability to seek healthcare when needed (Eckhardt et al. 2018). Among rural households in Kenya that held livestock, the number of cattle owned increased the likelihood of healthcare-seeking when family members fell ill (Thumbi et al. 2015). Zoonoses may also lead to the erosion of the health benefits due to animal interaction, animal ownership, and the human-animal or human-nature bond. More broadly, social value impact that can also be associated with zoonoses, including effects on health equity, may also be significant.

To counteract these losses in the animal health sector, and the potential impact on public health, another economic cost accrues from efforts to prevent, control, or eradicate a disease. In high-income countries, these impacts can be enormous, dwarfing the production losses due to disease. Examples illustrating this are provided by control and prevention measures carried out to tackle some zoonotic events, such as brucellosis (see Box 1), BSE (see Box 2), HPAI (see Box 3), or bovine TB, where control and surveillance activities were estimated to cost GBP £74–99 million/year in the UK (Torgerson and Torgerson 2008).

55.3.1.3 Ecosystem Health

Impacts on the ecosystem can either lead to production losses (e.g., when pollinators such as bees are affected by disease in turn causing harvest losses) or the reduction of ecosystem services to people. For example, if an area cannot be accessed anymore, because of a risk of zoonotic disease transmission, a value loss occurs to people in that they cannot use the area as they usually would.

Land-use change, habitat fragmentation, deforestation, and alteration of biodiverse natural ecosystems for agriculture and infrastructure expansion have long been associated with risks to human health (Myers et al. 2013). While such landscape alterations may offer an opportunity for improved nutrition and livelihoods, there is a growing need to account for the value of natural capital stocks and ecosystem services that are provided by intact, biodiverse environments and consider how disruption and fragmentation through unsustainable practices may impact these wider services.

Box 2 Economic Impact of Zoonoses – *BSE*

The impact of the BSE crisis has been the subject of numerous assessments in several of the countries affected (reviewed by World Bank 2010). The disease has led to important direct and indirect losses. Before the link between BSE in cattle to Creutzfeldt–Jakob disease (CJD) in humans was established, the disease losses were mainly linked to the loss in value of infected carcasses and to the costs of establishing control measures, namely the disposal of specified risk material (Atkinson 1999). The establishment of the link between the two diseases meant the additional emergence of important indirect costs linked to market impacts, including the contraction in domestic demand of beef products, loss of export markets and a fall of beef cattle prices (Atkinson

(continued)

Box 2 (continued)
1999). Beef consumption and domestic prices of cattle, beef and beef products were reported to have substantial drop-offs in many countries (Probst et al. 2013; Serra 2011).

To respond to the crisis, a series of preventive and control measures have been implemented in the countries affected. In the UK, the estimation of the costs associated with control and regulation compliance in the years of 1996/1997 indicated additional costs of around GBP £25–50 million, to which added costs associated with slaughtering and culling of GBP £220 million (Atkinson 1999). In Germany, the total costs associated with prevention, control and surveillance of BSE were estimated to range between EUR €1.8 and 2.0 billion, with approximately 54% of the costs being incurred by the extension of the feed ban for animal protein to all farmed livestock and 21% to active surveillance (Probst et al. 2013). An analysis of the cost-effectiveness of these measures in the Netherlands, indicated a cost of EUR €4.3–17.7 million, from 2002 to 2005, per life year saved (Benedictus et al. 2009).

Exports were also strongly impacted by trade restrictions put in place. For the UK, the export market of beef and trade in live calves, worth GBP £670 million in 1995, was lost with the trade ban imposed in 1996 (Atkinson 1999). These losses associated to a loss in output from beef and associated products, were balanced across the economy through a shift in consumption to substitute products (Wigle et al. 2007). In Europe, for example, poultry, pork, vegetables and milk products benefited from the BSE crisis (Benedictus et al. 2009). In May 2003 the Canadian government reported the detection of a single case of bovine spongiform encephalopathy in a national cattle population of nearly 13.5 million animals. This led to 40 countries banning the import of a large range of live animals and livestock products from Canada. Mitura and Di Piétro (2004) estimated that the impact of the international livestock trade ban was significant for Canada. In 2003, Canadian farm cash receipts from cattle and calves were estimated at CAD $5.2 billion, a sharp drop of CAD $2.5 billion (33%) from 2002. At farm-level it was estimated that on average a family farm with an unincorporated beef unit would have lost CAD $20,000. The more wide-ranging impact of the trade ban was the movement of cattle from Mexico to the USA to fill the demand for store cattle that would have come from Canada. While this has created a positive impact for cattle producers in Mexico, it has meant that beef prices in Mexico have risen affecting Mexican consumers, and that the USA is potentially importing animals from areas with low tuberculosis status (Ayala and Velasco 2005). Later in 2003 the USA also declared the discovery of a single animal with BSE (out of an estimated cattle population of 96 millionc) which led to 53 countries banning the imports of American beef. Coffey et al. (2005) estimated that the losses associated with this trade ban were between USD $3.2 and 4.7 billion. These

(continued)

Box 2 (continued)
authors also estimated that BSE has had considerable costs in terms of increased needs for surveillance at a farm and slaughterhouse level. On an international level the use of BSE cases in Canada and USA as a trade barrier can have a negative impact on disease reporting. Livestock exporting countries, whose economies have far less ability to absorb rapid changes in export demand for livestock products, are unlikely to report minor levels of animal disease where there is a risk of exaggerated and rapid trade bans.

Estimations of losses on the public health sector are not as readily available in the literature as for the animal health sector and food chain. An estimate from the UK points to running costs associated to staff time and expert committees of GBP £2.5 million, in 1988–1996. The cost of patient care for CJD patients were considered too uncertain to be quantified (Phillips 2000).

Zoonotic diseases have a correlative relationship with biodiverse ecosystems. For instance, human-dominated landscapes and unsustainable land management practices are associated with higher zoonotic pathogen diversity and prevalence, while conversely, healthy biodiverse ecosystems and sustainable farming practices are associated with increased human health and decreased pathogen diversity and host prevalence (Gibb et al. 2020). Heightened mixing between domestic animals, humans, and wildlife, particularly at the borders of urban settlements or industrial production settings, can lead to increased transmission of zoonotic disease from domesticated animals to wildlife and negatively impact native ecosystem structures, further threatening endangered wildlife species (Mathews 2009; Reaser et al. 2021). This impacts species conservation initiatives both directly and indirectly through knock-on effects in the wider food and biodiverse functional chain.

"Natural capital" places value on naturally occurring resources such as soil, water, air, geological formations, and biodiversity and positions them as assets to health and the wider economy. These resources are the stocks from which benefits flow to human health, welfare, and the world economy (i.e., ecosystem services). In 2011, these services were given an estimated global value of between USD $125 and $145 trillion, annually (Costanza et al. 2014). Measuring the economic value of naturally occurring systems that facilitate human health and welfare through water filtration, nutrient cycling, erosion control, pollination, and climate regulation is a relatively new practice and does not yet adequately consider the substantial impact that global natural ecosystems have on human health and disease prevention. However, a recent model estimated that the cost of implementation over 10 years of a suite of preventive measures to prevent the next major zoonotic spillover event and pandemic would total merely 2% of the estimated USD $5 trillion global cost of the COVID-19 pandemic. Such actions, including reducing deforestation, routine disease surveillance of domestic and wild animals, and halting the illegal wildlife trade, would also have ancillary environmental benefits in reducing CO_2 emissions (Dobson et al. 2020). While many studies focus on ecosystem services for human health, it should not be forgotten that the same services sustain animals and enable

livestock production around the globe. With livestock being the predominant biomass on the planet (followed by humans), it is important to promote ecosystem health for the benefit of people, animals, plants, and the planet as a whole. Striving for a socio-ecological equilibrium that facilitates the health of multiple populations in the long term sits at the core of modern One Health agendas.

Understanding the value of the relationship between health and the environment is vital to assessing the full impact of zoonotic diseases on society, and when we consider biodiversity of pivotal impact in the prevention of zoonotic disease emergence and potential pandemics, this value serves to contextualize intact ecosystems within the context of the global economy.

55.3.1.4 Trade and Travel

The presence and risks of zoonoses can have substantial impacts on consumption patterns and/or trade and travel restrictions imposed as a consequence of zoonotic disease outbreaks can be extensive and last beyond the duration of an outbreak, depending on the risk perception of trade partners and tourists.

Box 3 Economic Impact of Zoonoses – *Highly Pathogenic Avian Influenza in Chile*

In 2002, Chile reported for the first time an outbreak of HPAI. This was also the first isolation of avian influenza virus in South America (Lupiani and Reddy 2009). The poultry industry in the country produced, at that time, 400,000 tons/year of fresh poultry meat, with exports, mainly to Mexico and the European Union, following an increasing trend (USD $69 million in 2001, $44 million in 2002 and $72 million in 2003) (Orozco 2005). Following the outbreak, the access to export markets was closed (Orozco 2005).

As a response, the national authorities have put in place a series of mitigation measures, including stamping out of affected farms, setting up of surveillance, pre-diagnosis quarantine, depopulation, movement control, and increased biosecurity and to regain access to the export markets as soon as possible, a zooning strategy was adopted (Max et al. 2007; Orozco 2005). The culling of the two infected farms to stamp out the disease resulted in the destruction of 560,000 breeding chicken and turkeys (Rojas 2009). Within 7 months, Chile was declared free from HPAI (Max et al. 2007).

The initial financial impact of the disease was calculated by Verdugo et al., (2006, cited Rojas 2009) to be USD $31.7 million, with costs largely borne by the private sector. An economic impact assessment of HPAI in Chile has been estimated that over the whole economy losses reached USD $250 million (Wright 2004).

The example of the severe acute respiratory syndrome (SARS) epidemic demonstrated the economic impacts of travel restrictions affecting tourism and its contribution to reductions in Gross domestic product (GDP) growth in some countries, through reductions on service exports, particularly tourism-related exports (Keusch et al. 2009; Xiaoqin Fan 2003). For China, Taiwan, Hong Kong, and Singapore, this

impact has been estimated to be USD $13 million, or 0.5–1.1% of the GDP (Keusch et al. 2009). The 1994 plague outbreak in India also led to economic losses due to internal and external travel restrictions (Keusch et al. 2009). The H1N1 emergence in Mexico resulted in a reduction of almost a million overseas visitors and losses of around USD $2.8 billion for the country's economy (Rassy and Smith 2012). More recently, and as mentioned earlier, the ongoing COVID-19 pandemic-imposed travel restrictions limiting the movement of people and goods between countries have also impacted the trade of animal and animal products.

Losses due to changes in consumption patterns and trade disruption can also be highly visible. In the European Union, and following the BSE food scare, more than half of the surveyed consumers were fearful of BSE and unsure as to whether beef was safe for consumption (Bánáti 2011) (see Box 2). This has led to important losses, particularly via trade bans that in 2003 cost CAD $2.5 billion (Mitura and Di Piétro 2004) and cost the USD $3.2–4.7 billion (Coffey et al. 2005). While BSE has led to a significant drop in consumption and a market shock, other scares have been relatively short-lived with consumption returning to previous levels, but disrupting the food system which caused some businesses to go bankrupt and led to the loss of employment and/or restructuring of the industry.

Product recalls have become an important component of the food system as value chains have lengthened. Of the recent major food recall incidents, many have been related to *E. coli* including beef in the USA in 1997 (McKenzie and Thomsen 2001) and salmonella (Roos n.d.). In Europe, the costs of a recall are strongly related to the traceability systems in place. If traceability is poor, then large amounts of products have to be recalled that are likely to be unaffected by the problem. However, the development and implementation of improved traceability systems are onerous and costly. New technologies are emerging, such as blockchain, that may improve traceability by improving transparency and data privacy, reducing manual errors, and increasing the efficiency and speed of identifying contaminated products (Feng et al. 2020). Increasingly advanced traceability systems are a positive step towards food safety and consumer awareness and autonomy. However, the use of advanced traceability technology requires a high degree of collaboration and trust as well as consensus on and implementation of international standards and regulations. As with all cutting-edge technologies, uneven adoption across countries and economies due to lack of resources or infrastructure could limit access of small-scale producers to international markets. Traceability is yet another issue that must be considered in terms of impact not just on food safety, but across domains of equity in a globalized food system.

55.3.2 Assessing the Burden of Zoonoses and the Value of Mitigation Actions

Bringing together the burden of zoonotic diseases across the domains of health of people, animals, and the environment is a large task. Its assessment requires an adequate representation of the complexity of loss across species, sectors, and society.

This in turn requires knowledge of disease levels, morbidity, and mortality of the disease in people and their animals and an assessment of the impacts of the pathogen and its mitigation and transmission patterns in the environment. As such, while some estimates have incorporated aspects of animal and human costs (Bennett and IJpelaar 2005; Budke et al. 2006; Charypkhan et al. 2019; Choudhury et al. 2013), metrics and tools available to measure economic impacts tend to be specific to each sector and difficult to translate across fields, with the different components of impact often considered individually rather than in an integrated way (Grace et al. 2012).

In the field of public health, DALY is one of the most commonly used health gap summary measures and became the key metric for quantifying burden of disease, being used to measure the global burden of disease estimates regularly produced by the World Health Organization (WHO 2021c) and The Global Burden of Disease program (GBD). The DALY captures the loss of life due to reduced life expectancy and reduced quality of life while alive due to impediments in what people can do when affected by a health issue (Murray and Lopez 1996). This framework is relatively simple in its concept, yet complex in its application requiring data and information on disease levels, morbidity, and mortality. The DALY avoids the need to place an economic value on early death and only estimates the disutility to the individual of being ill, not capturing the medical direct and indirect costs of illness to the individual or society. However, the DALY can be used to compare the costs of averting a DALY through a mitigation action.

In health economics, cost burden is commonly assessed using cost-of-illness studies, which cover both the direct and indirect costs of disease and place a monetary value on these costs. There are two aspects in this assessment (Rushton et al. 1999; Rushton 2009b): (i) the expenditure on health care interventions, and mitigation actions such as surveillance, control, and prevention measures – in human health economics referred to as direct costs; and (ii) the loss in health that leads to increased mortality and reduced ability to work in the case of people and generate goods and services in the case of animals – in human health economics referred to as indirect costs.

When assessing morbidity and mortality in animals due to zoonotic disease, units of physical losses (e.g., number of animals that died, number of animals suffering from milk loss, rate of milk loss) can be combined with data on production (e.g., milk yield) and/or market prices (e.g., market value of the animal, milk price). Illustrations of how such losses can be calculated can, for example, be found in Mcdermott et al. (2013) and Herrera et al. (2008). Generally, morbidity and mortality in animals are measurable in monetary units. Frequently used tools include cost-analysis, incorporating the losses mentioned above (Bennett and IJpelaar 2005), and decision tree analysis, which might model different scenarios of production (Carabin et al. 2005; Choudhury et al. 2013). An overview of various techniques suitable to assess the economics of animal disease can be found in Rushton et al. (1999).

There have been attempts to mirror burden estimates for animal diseases, but significant important conceptual difficulties arise (reviewed in Torgerson et al. 2018). In livestock health as the majority of these animals are maintained for economic purposes, the direct and indirect costs can be valued at market prices.

Even where the goods and services these animals generate do not have markets, it is possible to impute a value by estimating what it would cost to generate such goods and services in alternative ways, for example, the use of a tractor rather than oxen for ploughing or the use of artificial fertilizer rather than manure. In addition, it is possible to use contingency or willingness-to-pay valuations. Despite these differences in human and animal health burden estimations, there is still a need to look at the Global Burden of Animal Diseases (GBADs), yet the approach is different from human health. There needs to be an understanding of the gap in production – the difference between current levels of output and input use with the health status as it stands, versus a situation where the animals would have no disease, adequate nutrition and water, and no risks of injury, accidents, or predation. This gap has been termed an Animal Health Loss Envelope (Rushton et al. 2021; Torgerson and Shaw 2021) and is the basis for the estimation of the burden of diseases in livestock.

Willingness-to-pay and the contingent valuation approach have also been used to attribute value to ecosystem services and in animal health to attribute a value to food safety or animal welfare. The concept of "willingness to pay" (WTP) is based on the assumption that the maximum amount an individual is willing to pay for a commodity reflects the value it has for this person. Miller and Unnevehr (2001), for example, conducted a household survey to investigate consumers' WTP for enhanced pork meat safety. They found that roughly 80% of the consumers were willing to pay at least USD $0.10 more per pound of certified safer pork. Another study used a hypothetical market scenario in the UK to investigate people's WTP to support legislation to phase out the use of battery cages in egg production in the EU by 2005 (Bennett 1998). The survey showed a mean WTP of £0.43 increase in price per dozen eggs (with a market price of around £1.40 per dozen), purporting to indicate the value respondents attributed to improved animal welfare. The main criticism of the WTP approach is that it does not give reliable valuations, since the choices are often hypothetical and people tend to overestimate their willingness to pay. Another drawback is that nonusers of a good or service might find it difficult to attribute a value to it because their knowledge of it is very limited. WTP methodologies have had inconsistent success in the valuation of ecosystem services such as water filtration or conservation of a species (Dasgupta 2021). In these instances, people were found at times to vary their answers when asked a question differently or standardize their perceived value of preserving a species regardless of the total number of animals at risk.

As mentioned before, various outbreaks of zoonotic disease in the past have shown that food safety scares can alarm consumers to the extent that they reject consuming certain products. Such a reduction in demand caused by a loss in consumer confidence can lead to a reduction in market prices. Similarly, zoonotic disease outbreaks can lead to movement or export bans, which impact the quantity of products placed on the market and consequently affects prices. The value of these changes in supply and demand can be assessed using surplus models to measure producer, processor, and consumers surplus changes, as illustrated for avian influenza outbreaks in South East Asia and the United States, respectively (Hall et al.

2006; Paarlberg et al. 2007), and BSE (Weerahewa et al. 2007). Furthermore, there is a wide range of different methods available to assess food and nutrition security indicators; a review has been published by Pangaribowo et al. (2013).

When attempting to more holistically assess the effects of disease in different sectors, it can be challenging to capture and effectively pinpoint burden across public health, animal health, and the environment. Recently, Morel et al. (2020) have carefully explained how to incorporate all the data needed for a comprehensive socio-economic assessment of AMR in terms of the cost burden and have placed this under the One Health approach. New methods have also been developed in terms of metrics. The recently developed zDALY metric is an adjusted indicator to estimate the burden of zoonotic diseases that enables DALYs associated with human ill health to be combined with a component measuring losses in animals (Torgerson et al. 2018). This component, termed the animal loss equivalent (ALE), allows for the conversion of losses due to animal disease to an equivalent metric using a local gross national income per capita deflator. The examples of the use of this metric show the importance of measuring both the burden of disease in humans and animals and the actual impact of the losses felt by the population (Torgerson et al. 2018). Other authors suggested a method to monetize the human health benefits derived from zoonotic disease reduction using the annualized value of statistical life to form a "combined" monetary burden (Herrera-Araujo et al. 2020).

Determining the absolute levels of direct and indirect costs of this zoonotic disease burden is necessary yet not sufficient in defining proportionate levels of mitigation actions. The reason is that for every increase in direct costs, there should be an impact on indirect costs as the expenditure on mitigation is aimed at avoiding the losses of health and productivity. A priori, the effectiveness of mitigation actions will be diminished as more money is spent and will reach a point where the incremental levels of indirect costs avoidance will reduce. From an economic perspective, incremental expenditure on mitigation actions should cease when the last dollar spent returns a dollar of avoided health loss.

To assess disease mitigation strategies from an economic perspective, commonly used tools are cost-benefit analyses and cost-effectiveness analysis. Cost-benefit analyses compare the total discounted benefits of a project in monetary units with its total discounted costs and recommend the implementation of the project if the benefits exceed the costs. It includes the definition of the useful life of the project, the estimate in physical units of benefits (losses avoided) and costs (mitigation resources used), translation of the physical units into economic values, the conversion of future values into present values by discounting, and finally the calculation of the net benefit (net present value = total discounted costs − total discounted benefits). Benefit-cost ratios as choice criteria can be misleading when multiple options are compared, and some authors recommend using the net present value instead of the benefit-cost ratio (Howe et al. 2013; McInerney 1991; Tisdell 1995). In any assessment of this nature, it is therefore important to review all measures of project worth, namely, the net present value, the benefit-cost ratio, and internal rate of return and timing permitting an examination of the estimation of the benefit and cost streams.

A similar basic principle is seen in cost-effectiveness analysis, which is commonly used to assess human health interventions but has been less applied to animal health decision-making problems (Babo Martins and Rushton 2014). Cost-effectiveness analysis aims to assess the effect of a program in nonmonetary units in relation to its cost. In human health economics, the effect often refers to the avoidance of illness or death, but the outcome of any objective can – in theory – be measured in various technical terms, for example, reduction of CO_2 emissions or detection of cases of disease. However, the value of the effect in question must reflect a (nonmonetary or monetary) value so that it can be interpreted for decisions on resource allocation. A special case to cost-effectiveness analysis is the least-cost analysis where two or more programs or projects achieve the same effect. The economic assessment then aims to identify the cheaper option.

Importantly, all these fundamental concepts explained above only provide an estimation of the economic efficiency (optimal balance, acceptable combination, and least-cost option) of technically feasible ways of dealing with zoonotic disease. Some authors have proposed frameworks that take into account wider issues, including risk management options and the understanding of the factors impacting those options (Grace et al. 2012; Narrod et al. 2012). It is the case of the framework proposed by Narrod et al. (2012), consisting of a modified risk analysis framework to enhance the reduction of zoonotic disease burden, including the analysis outputs of animal and human disease transmission models and economic impact models.

55.4 Conclusions

Economics provides several tools and frameworks that can be used in the measurement of the impacts of disease and to aid in informing resource allocation for zoonotic disease mitigation. However, the measurement of the impact of zoonotic diseases presents several challenges. The impacts of zoonoses are felt in multiple sectors, in multiple links of increasingly complex value chains, and the interface between sectors and jurisdictions. These multiple dimensions are generally complex to capture as a whole, with many studies focusing on impact assessments per sector and failing to capture the entire realm of effects.

In addition to the need for addressing impacts in a wider context, aspects such as unused human, financial and capital capacity in the food system, reduced confidence in the marketplace, particularly for export markets, and important lags created in terms of confidence and investment – often taking years to recover capacities, skills, and markets – should be incorporated in future, more refined, impact assessments of zoonoses.

Data availability and quality to populate assessments represent a further challenge. Underreporting of cases of zoonotic disease, particularly in low-income settings are, for example, believed to be contributing to the underestimation of the burden of these diseases in the human and animal populations, therefore influencing disease mitigation decisions and contributing to the perpetuation of their impact. However, the use of big data and participatory approaches including citizen science

could improve access to reporting and data availability in the future. The changing context of our food systems should also be considered, including how we as a society move towards a sustainable food system, ensuring that, using a systems approach and stakeholder engagement, gains in one sector or region do not saddle those in other sectors or regions with unmitigated negative consequences.

Zoonoses and Poverty: The Multiple Burdens of Zoonoses in Low- and Middle-Income Countries

56

Delia Grace and Elizabeth Cook

Contents

Abstract

Poor people have greater exposure to zoonoses through livestock keeping; living in agricultural communities; greater exposure to peri-domestic and wild animals; and less access to clean water and sanitation. Although their consumption of animal source products is low, the quality of these products is poor.

In addition to human health burdens, zoonoses reduce livestock productivity and are important barriers to trade in livestock products, as well as causing more difficulty to quantify harms such as spillover to wildlife populations. These

additional impacts also contribute to poverty in developing countries. However, the relation between poverty and zoonoses is complicated.

Assessing the impacts of zoonoses helps prioritize management. Among the most important zoonoses in developing countries are leptospirosis, cysticercosis, brucellosis, tuberculosis, and rabies and zoonoses causing foodborne disease. The COVID-19 pandemic also showed how lack of resilience leads to greater vulnerability of poor people to emerging zoonoses of high economic impact.

Investment and innovation are urgently needed to tackle zoonoses in developing countries where they currently impose massive burdens on human, animal, and ecosystem health.

Zoonoses · Low- and middle-income countries · Poverty

56.1 Introduction

This chapter focuses on links between poverty and zoonoses in low- and middle-income countries (LMICs) and highlights recent developments in our understanding of these links. We first provide a typology of zoonoses according to their epidemiology and next present evidence that the burden of endemic zoonoses falls mainly on the poor, because of greater exposure risk. We describe the endemic zoonoses of greatest impact on poor people. We then discuss how emerging zoonoses can have more harmful impacts on the poor even if health and economic impacts are less, using evidence from the COVID pandemic. We, last, summarize major advances in approaches to understanding and managing the zoonoses of poverty in the last decade.

56.2 Poverty and Endemic Zoonoses

56.2.1 Zoonoses

"The poor you will always have with you" says the Christian Bible, and while wealth disparities are inevitable, are poverty and disease inevitability linked? Over decades and centuries, there has been a positive trend of global reduction in infectious diseases, especially those associated with environmental conditions and food systems as fewer people were directly exposed to the conditions favoring the transmission of disease. However, at the start of the twenty-first century, many people, particularly those in poor, remote, and rural communities, continue to be vulnerable to the avoidable diseases they contract as a result of direct and indirect contact with animals.

Zoonoses are diseases transmissible between animals (livestock and wildlife) and humans. Around 60% of all human diseases and around 75% of emerging infectious diseases are zoonotic (Woolhouse et al. 2005). The first section of the chapter provides an overview of zoonoses and poverty, and the second section provides more details on zoonoses, which have been identified as priorities in poor countries.

Zoonoses threaten human health and well-being in different ways.

- Endemic zoonoses are continually present to a greater or lesser degree in certain animal and human populations. Examples are cysticercosis, brucellosis, bovine tuberculosis, leptospirosis, and foodborne zoonoses. They have mainly been eradicated from wealthy countries but remain common in poor populations. Most at risk are people in LMICs in frequent contact with animals, and perhaps as a result, endemic zoonoses have been neglected by the international donor, standard setting, and research communities.
- Outbreak or epidemic zoonoses typically occur intermittently. Examples are anthrax, rabies, Rift Valley fever, and leishmaniasis. Endemic zoonoses may also occur as outbreaks in naïve populations or when triggered by events such as climate changes, flooding, waning immunity, or concomitant hunger or disease. The overall health impact of epidemic zoonoses is much less than endemic zoonoses, but because they can "shock" systems they reduce resilience. Most are absent from or controlled in HICs, and the burden largely falls on poor rural communities in LMICs. Outbreaks may result in slaughter bans or movement restrictions that have impacts on the wider community including people who are not in contact with livestock. Donors and decision-makers are concerned over epidemic zoonoses because of the risks they pose to trade and economies.
- Emerging zoonoses are those that newly appear in a population or have existed previously but are now rapidly increasing in incidence or geographical range. They are relatively rare, around 300 events in the last 70 years (Grace et al. 2012b). Most are of minimal impact, but some such as COVID-19 have changed the way civilizations operate. Especially if transmission shifts from animal-to-human to human-to-human, people in HICs and LMICs are both at risk. Donors and decision-makers are often concerned about emerging diseases, because of their potentially large impacts on global human health and economies.

Zoonoses do not just threaten human health; they also reduce livestock productivity and impose costs on domestic and international trade (McDermott et al. 2013). Some zoonoses impose a large morbidity and mortality burden in the livestock host (e.g., brucellosis). In other cases, disease impacts in animals may be few (e.g., salmonellosis in chicken), but there may be high costs for the food sector from inspection and intermittent food recalls. Other costs of zoonoses may be more difficult to quantify, for example, the cost of lost biodiversity when animal diseases spill over to wildlife (as when rabies in Ethiopia threatens survival of the Ethiopian wolf, the rarest canid in the world). The environmental impacts are often overlooked, but in the past deforestation and insecticides such as DDT have been used to reduce tsetse fly abundance and hence human African trypanosomiasis with lasting impacts on the ecosystem.

56.2.2 Poverty Context

Poverty can be defined as a pronounced deprivation in well-being. No single indicator exists to measure all dimensions of poverty simultaneously; however,

internationally comparable metrics, such as the "extreme poverty" threshold (less than $2.15 per person per day at 2017 purchasing power parity), are useful for spatial and temporal comparisons. Since 1990, the number of people in extreme poverty was declining, a trend temporarily interrupted by COVID-19 (World Bank 2022). However, the geography of poverty is shifting. While in 1990, 36% of the world lived in extreme poverty and 80% of these were in Asia, by 2030 7% of the world will be in extreme poverty but 85% of these will be in sub-Saharan Africa (Kharas and Dooley 2022).

Livestock keepers, especially pastoralists, are overrepresented among the poor and the poorest of the poor (Grace et al. 2017). The reasons for this are complex: Many livestock-keepers live in rural or remote areas, most are underserved, and many keep livestock because they are poor, rather than to escape poverty (Perry and Grace 2009).

56.2.3 Poverty and Zoonoses

Globally, the greatest burden of infectious disease is borne by poor countries. Since 1990, when systematic efforts first started to estimate the global health burden of disease, estimates have become more granular and precise (Murray 2022). Burden of disease is calculated using the disability-adjusted life year (DALY) which combines years of life lost due to premature mortality and years of life lost due to time lived in states of less than full health.

However, global burden of disease (GBD) estimates have some challenges in assessing zoonoses. First, zoonoses (especially in poor countries) are widely underreported, and underreporting is relatively greater for zoonoses than for non-zoonotic diseases of comparable prevalence (Schelling et al. 2007). Second, no burden estimates exist for several priority zoonoses (di Bari et al. 2022). Third, the GBD is organized around diseases and not pathogens, so assumptions need to be made about the proportion of a disease that is due to zoonotic pathogens, for example, tuberculosis is one category in the GBD, but the proportion that is due to zoonotic diseases is not estimated.

Even with these assumptions, it is clear that poor countries bear the greatest burdens of zoonotic disease (Grace et al. 2012a). The burden of endemic zoonoses falls mainly on the poor and causes at least ten million DALYs annually (di Bari et al. 2022). The great majority of the global foodborne disease burden (33 million DALYs) falls on LMICs, and most of the responsible pathogens are zoonotic (Havelaar et al. 2015). These estimates do not include the burden due to HIV-AIDS (48 million DALYs) (Wu et al. 2021) or COVID-19 (42 million DALYs) which are emerging zoonoses (Fan et al. 2021). Moreover, zoonoses make a substantial contribution (25%) to the estimated 420 million DALYs lost from all infectious diseases (GBD 2020).

We next discuss why people in poor countries may be more vulnerable to zoonotic infections, and why the most poor may be the most vulnerable. There are several reasons why poor people might bear a greater burden of zoonoses. First, they may be exposed to higher levels of pathogens; second, they may be more vulnerable to disease; and third, they may be less able to prevent or treat zoonoses. Finally, even

if they are equally or less vulnerable to disease, the impacts of disease may be relatively greater because of the lower resilience of the poor. This is especially the case for high-impact emerging zoonoses such as COVID-19.

56.2.4 Poverty and Exposure to Zoonoses

This section focuses on the first and most obvious reason poor people are more at risk, which is because they have much greater exposure to pathogens harbored by animals responsible for endemic and epidemic zoonoses.

- Poor people are much more likely to keep or be in contact with animals than rich people. Poorer households are more likely to keep small ruminants and richer households to keep large ruminants. Poultry keeping tends to be evenly distributed across wealth groups. However, poorer people are more likely to keep livestock in the house or close at hand and biosecurity and hygiene practices may be lower.
- Within poor countries, the poorest of the poor often keep less livestock. However, the less poor may keep more livestock than the relatively better off. A 12-country study supports this, finding that on average, around 68% of rural households in the bottom 40% as regards expenditure kept some farm animal compared to 65–58% of those in the top 40%; in urban areas, 22–26% of the poor kept livestock, and 8–12% of the well-off (Pica-Ciamarra et al. 2011). Consumption of bushmeat is also much more common in developing countries.
- Because of poor sanitation and waste disposal, there is greater contact with peridomestic animals such as bats and rodents in poor communities. There are also large numbers of community-owned dogs and cats, which are often semi-scavenging though they may return to one household at night. Poor people are also more exposed to vectors, both through work in agriculture and because they are unable to afford bed nets and other prevention measures.
- Foodborne transmission is a common route for exposure to zoonoses. Overall, livestock consumption is much lower in poor countries than in rich countries. The better off in poor countries have higher consumption of meat, milk, fish, and eggs which are indirect routes for zoonoses transmission and so would be more at risk from infection through this route than poor people. Studies in developing countries typically find that food contains high levels of pathogens; often the majority of samples will exceed international standards (Grace 2015). Waterborne transmission is important from some zoonoses, notably *Cryptosporidium parvum, Escherichia coli* O157, *Salmonella*, *Campylobacter,* and *Taenia solium*). Because poverty is strongly linked to lack of access to clean water, the poor are more at risk by transmission through this pathway.

56.2.5 Poverty and Greater Vulnerability to Zoonoses

People in poor countries may be more biologically vulnerable to endemic and epidemic zoonoses. Compared to rich countries, the proportion of infants, pregnant

or lactating women, and immune-suppressed people is higher. Moreover, high levels of malnutrition and high exposure to toxins (especially mycotoxins) increase vulnerability to infection.

In addition, private and public health services are often under-resourced and underperforming. Common problems include lack of diagnostic facilities; lack of trained personnel; lack of appropriate drugs; high prevalence of fake drugs; and expenses associated with obtaining treatment.

Unlike endemic and epidemic zoonoses which are transmitted by contact with domestic livestock, emerging zoonoses are most serious when they evolve to be transmitted between humans. This was how the Spanish flu, which killed more than 40 million people, is believed to have emerged, and was also the origin of HIV-AIDS, and more recently COVID. Once a disease has become pandemic, the victim profile changes and is more dependent on transmission modalities, virulence properties, immunological status, and treatment and prevention options. For example, the Spanish flu caused greater mortality among younger people, perhaps because older people had some immunity from a previous flu pandemic (Russian flu in 1889–1890) (Gagnon et al. 2013). Because of its transmission through bodily fluids, certain populations are more at risk of HIV-AIDS: In 2021, at-risk groups (sex workers and their clients, men who have sex with men, and people who inject drugs) and their sexual partners accounted for 70% of HIV infections globally (UNAIDs 2023). In the case of COVID-19, LMICs seem to have caused less mortality in LMICs, possibly because of younger age population, fewer comorbidities, cross-immunity from other coronaviruses, and climate conditions (Okonji et al. 2021; Pedersen et al. 2022).

However, while the direct health impacts of emerging zoonoses may be no worse, or even less in LMICs, the indirect livelihood and economic effects may be more severe. Movement restrictions, travel bans, and curfews may prevent opportunities to earn income, purchase food, or access health services for marginalized people.

Although poor people are at greater risk from zoonoses as a result of their greater contact with animals or their lack of resources and hence greater vulnerability, animals and animal source food also bring many benefits. Livestock support livelihoods through generating income, provide nutrient-rich food for household consumption, are assets that can guarantee risks or be monetized to pay for routine or unexpected expenses, may provide manure for soil fertility, fuel, and building materials, may provide power (ploughing, transport), and often have cultural value and provide psychosocial benefits. Livestock can even directly reduce risk of human illness. Zooprophylaxis, the diversion of disease carrying insects from humans to animals, may reduce transmission of diseases such as malaria (Asale et al. 2017).

56.3 Zoonoses of Poverty

56.3.1 Most Important Zoonoses in Poor Countries

In recent years, several prioritization exercises have been developed for zoonoses and animal health, although most did not focus on poor countries. These were summarized by Grace et al. (2012b), finding, in declining order of importance:

- First place: Salmonellosis
- Joint second place: Leptospirosis = rabies
- Joint fourth place: Campylobacteriosis = tuberculosis = West Nile virus infection = toxoplasmosis
- Joint eighth place: Listeriosis = anthrax = echinococcosis = *E. coli* infection = BSE = botulism
- Joint 14th place: Cryptosporidiosis = Japanese encephalitis = Q fever = Rift Valley fever = tetanus

The same study identified 56 priority zoonoses from five different credible sources. These 56 zoonoses were then ranked by five criteria: human mortality; human morbidity; livestock sector impacts; amenability to intervention; and risk of emergence. This produced a short-listing of 12 zoonoses, which were responsible for an estimated 2.2 million human deaths and 2.4 billion cases of illness each year. Total 9 of the 13 top-ranked zoonoses were considered to have high impact on livestock, all have a wildlife interface, and all were amenable to agriculture-based interventions (Table 1).

Another study was carried out for the World Organisation for Animal Health (WOAH) in the WOAH African region on priority diseases (Grace et al. 2015). Questionnaires were sent to the Veterinary Authorities of the 54 OIE Member Countries in Africa. In all, 34 countries responded. As regards zoonoses in general, rabies was most commonly the first priority (44%) followed by anthrax (15%), and then zoonotic influenza, Rift Valley fever, and bovine tuberculosis tied (9% each).

Table 1 Top zoonoses from a literature-based study

Disease	Wildlife interface	Deaths human annual	Affected humans annual
Gastrointestinal (zoonotic)	Important	1,500,000	2,333,000,000
Leptospirosis	Very important	123,000	1,700,000
Tuberculosis (zoonotic)	Some importance	100,000	554,500
Rabies	Important	70,000	70,000
Cysticercosis	Some importance	50,000	50,000,000
Leishmaniasis	Important	47,000	2,000,000
Brucellosis	Some importance	25,000	500,000
Echinococcosis	Important	18,000	300,000
Toxoplasmosis	Important	10,000	2,000,000
Q fever	Important	3000	3,500,000
Trypanosomosis (zoonotic)	Important	2500	15,000
Anthrax	Some importance	1250	11,000

Grace et al. (2012b)

The remaining countries selected brucellosis (n = 2), leptospirosis, or salmonellosis (n = 1). When asked more specifically about the priority emerging zoonoses, avian influenza was selected by 44% of respondents, followed by Rift Valley fever (25%) and Ebola (11%). A few other diseases were selected (anthrax, brucellosis, bovine tuberculosis, monkey pox, and trypanosomosis). Among priority foodborne diseases, two-thirds reported salmonellosis, 11% bovine tuberculosis, and 7% colibacillosis, anthrax, or cysticercosis; the remaining country reported brucellosis.

The last decade has seen dozens of zoonoses prioritization exercises conducted at a national level, summarized in Table 2. Most (n = 22) used the methodology developed by the US Centres for Disease Control and Prevention (CDC), and the One Health Zoonotic Disease Prioritization (OHZDP) Tool, while eight used their own methods.

While these prioritizations were done at different times, and covered different countries, for different purposes, the agreement is striking. The most important zoonoses are the classical zoonoses (rabies, anthrax, brucellosis, leptospirosis, and tuberculosis), foodborne (dominated by salmonellosis, cysticercosis, and campylobacteriosis), viral hemorrhagic fevers (especially Ebola and Rift Valley fever), and emerging (avian influenzas). All of these studies were conducted before the COVID pandemic starting around 2020, but COVID would undoubtedly be near the top of a current list of zoonoses. This shows the need to consider "Disease X" in prioritization and preparedness, that is, a disease currently not

Table 2 The top diseases as ranked by prioritization exercises in 30 countries

	Asian (n = 13)	African (n = 17)	All (n = 30)
Zoonotic influenza/HPAI	12	16	28
Rabies	13	14	27
Anthrax	8	12	20
VHF[a] (any of Ebola, Marburg, Lassa, yellow fever, Crimean-Congo hemorrhagic fever [CCHF], and RVF)	4	14	18
Brucellosis	8	7	15
Zoonotic tuberculosis	2	8	10
Foodborne bacteria	3	4	7
Trypanosomiasis	NA	5	5
Leptospirosis	5	0	5
Q fever	1	0	1
Plague	1	0	1
Streptococcus suis	1	0	1
Echinococcus	1	0	1
Trichinella	1	0	1
Nipah virus	1	NA	1
Dengue	0	1	1
Mpox	NA	1	1

[a]VHF covered different viruses for different countries; here the count is for any mention of any VHF
NA: disease is currently geographically limited to one region (Source: authors)

known but with the potential of being at least as important as current priorities (Van Kerkhove et al. 2021). This results in a short list of ten top zoonoses which will be considered in more depth in the next section. That a small number of zoonoses are considered responsible for the great majority of the problem is compatible with the Pareto principle which states roughly 80% of consequences come from 20% of causes. This phenomenon is commonly observed in disease rankings (Grace et al. 2012b).

56.3.2 Top 11 Zoonoses in Poor Countries

In the last section of the chapter, we consider some of the priority zoonoses in greater depth.

56.3.2.1 Classical Zoonoses

Rabies: Rabies is one of the most feared of all zoonoses. It is a disease of poor and vulnerable communities where deaths are often unreported: More than 95% of human deaths occur in Africa and Asia. Dogs are the most important reservoir, but many domestic and wild animals can be affected. Where rabies is common, it can be of minor importance as a cause of mortality in livestock.

Anthrax: Anthrax is endemic in sub-Saharan Africa and many parts of Asia. It is highly lethal to ruminants, but in humans the most typical manifestation are skin lesions (malignant pustule). However, if spores are inhaled or ingested, death may result. Anthrax is not common in most developing countries, but some areas are prone to outbreaks where localized losses can be high.

Brucellosis: The most important species of *Brucella* are zoonotic: *B. abortus*, responsible for bovine brucellosis; *B. melitensis*, the main etiologic agent of ovine and caprine brucellosis and an increasing cause of cattle brucellosis; and *B. suis,* causing pig brucellosis. The main risks for people are occupational (contact with livestock) and consumption of dairy products. In some areas, brucellosis may be maintained in reservoir wild animal hosts (African buffaloes and North American bison); in other cases, disease spills over to wildlife and, if eliminated in cattle, brucellosis will die out in wildlife. Brucellosis is an important disease of livestock in developing countries because of the impacts on animal fertility and reproduction as well as the public health impacts.

Leptospirosis: Leptospirosis is an infectious disease caused by pathogenic organisms belonging to the genus *Leptospira*. There are many serovars (>250), but typically only around 10–20 are found in a given region. Serovars can be grouped into 25 serogroups. Infected animals often become carriers. Wild animals are affected and can be important reservoir hosts. Although the impact of leptospirosis on animal production has not been quantified, it may be an important cause of disease, particularly abortions, in animals in developing countries. Evidence is especially strong for swine production in Asia. There are occupational risks to dairy farmers, milkers, and abattoir workers in these settings.

Tuberculosis: Worldwide and historically, most human tuberculosis (TB) is caused by *Mycobacterium tuberculosis* (which probably gave rise to cattle TB). *M. bovis* is responsible for cattle tuberculosis. It affects a wide range of animals and is responsible for zoonotic TB in humans. In West Africa, *M. africanum* causes up to half of human tuberculosis. Atypical mycobacteria are found in the soil and environment and can infect both people and animals. Tuberculosis is an important cause of reduced productivity in livestock but is believed to make only a small contribution to the global TB burden (Müller et al. 2013). However, it can be a more serious problem in some high-risk communities (especially cattle-keepers in Africa).

56.3.2.2 Foodborne Zoonoses

Nontyphoidal salmonellosis (NTS): NTS is one of the most frequently isolated foodborne pathogens. Livestock (cattle, swine, and poultry) are the main reservoirs of NTS. Infections are characterized by nonbloody diarrhea, vomiting, nausea, headache, abdominal cramps, and myalgias (hence often called "gastric flu"). Complications can occur such as pancreatitis. Antibiotic-resistant strains have emerged and are often of increased virulence.

Campylobacteriosis: *Campylobacter* species are widely distributed in most warm-blooded animals. Infections are generally mild but can be fatal among very young children, elderly, and immunosuppressed individuals. Although diarrhea is the most common symptom, more severe symptoms such as bacteremia or flaccid paralysis can occur. Subclinical infection has been associated with stunting in children (too short for their age).

Cysticercosis: Cysticercosis is a systemic parasitic infestation caused by the pork tapeworm (*Taenia solium*). Humans are at risk not from consumption of pork with cysts but from consumption of tapeworm eggs shed by themselves or another human carrier. The disease persists in poor, pig-keeping communities where pigs have access to human feces. Cysticercosis is believed to be the most common cause of adult-onset epilepsy in poor, pig-keeping communities. The disease is not an important cause of illness in livestock but reduces the value of meat produced.

56.3.2.3 Viral Hemorrhagic Fevers

Ebola virus disease (EVD). Formerly known as Ebola hemorrhagic fever, EVD is a severe, often fatal illness. It is transmitted to people from wild animals (the natural reservoir is thought to be fruit bats) and spreads in the human population through direct contact with the blood, secretions, organs or other bodily fluids of infected people, and with contaminated surfaces and materials. Antibodies have also been detected in livestock, but the implication is not known. Previously mainly confined to African rainforests, more recently its range has increased and intense transmission has taken place in urban areas.

Rift Valley fever (RVF): This is a viral disease most commonly seen in domesticated animals in sub-Saharan Africa, such as cattle, buffalo, sheep, goats, and camels. People can get RVF through contact with blood, body fluids, or tissues of infected animals, or through bites from infected mosquitoes. Spread from person to person has not been documented. Most symptoms in people are mild, but around 8–10% may develop hemorrhage, eye disease, or encephalitis.

56.3.2.4 Emerging Zoonoses

Zoonotic influenzas: Zoonotic influenza refers to disease caused by animal influenza viruses that cross the animal–human divide to infect people. Avian, swine, and other zoonotic influenza virus infections in humans may cause disease ranging from mild upper respiratory tract infection to death. A major concern is that zoonotic influenzas may mutate to novel influenza with the ability to cause sustained human-to-human transmission. Three worldwide (pandemic) outbreaks of influenza virus with avian origins occurred in the twentieth century: in 1918, 1957, and 1968.

Coronavirus infection: Coronaviruses (CoV) are a family of RNA viruses that typically cause mild respiratory disease in humans. In the twenty-first century, there have been three major emergences capable of causing severe disease in humans. Severe acute respiratory syndrome (SARS) was detected in China in 2003, Middle East respiratory syndrome (MERS) in Saudi Arabia in 2011, and COVID also in China in 2019. The reservoir host is likely bats, but spillover is associated with intermediate hosts: civet cats in the case of SARS and camels in the case of MERS.

56.4 Conclusion

Livestock-keepers in developing countries are not all alike, and there are important differences between isolated and neglected pastoralists in a declining and increasingly climate insecure economy, and the rapidly growing urban centers with their accompanying intensifying livestock systems. The most critical systems where improved understanding on the prevalence, impact, and dynamics of zoonoses are needed include the following: rapidly intensifying agricultural systems; urban systems; and systems where substantial land-use change is occurring especially irrigation in arid areas, and farming on forest margins.

As the importance of zoonoses in poor countries is increasingly recognized, so is the need to generate a stronger evidence-base on problems and solutions to support decision-making. Information is needed on the impacts of zoonoses, the multiple costs and benefits of control, and the sustainability, feasibility, and acceptability of zoonoses management.

History in the developed world shows that the burden of zoonotic diseases can be dramatically reduced. High zoonotic disease prevalence is both a cause and consequence of poverty, and investment and innovation are urgently needed to tackle zoonoses in developing countries where they currently impose massive burdens on human, animal, and ecosystem health.
