Preface to the Second Edition

Zoonoses: Infections Affecting Humans and Animals – A Focus on Public Health Aspects

"Habent sua fata verba" – at least some words have their own history and success stories, even when starting their career with one or more little errors at their coming to life. A striking example is the term "zoonosis." It was coined in 1855 by the German physician Rudolf Virchow, mainly known as father of scientific pathology, but also as an important political figure in nineteenth-century Germany. Prior to the widespread acknowledgment of microorganisms as causative agents of infectious diseases, Virchow introduced the term – without clearly defining it – basically through the back door, when writing a subchapter in the second volume of the "Handbuch der speciellen Pathologie und Therapie" entitled "Intoxicationen, Zoonosen und Syphilis" on "Infectionen durch contagiöse Thiergifte" and putting the term "Zoonosen" as explanation in brackets. Actually, he not even mentioned the term in his chapter except in its heading. Today we know that the underlying pathogenic concept of "Thiergifte," that is, animal poisons or toxins, as disease agents is mostly wrong as is Virchow's very first sentence stating that luckily the number of diseases transmissible from animals to humans is not very large – a gross underestimation since most infectious disease entities and their agents are in fact zoonotic.

Interestingly, the term "zoonosis" is derived from the Ancient Greek word ζῷον (living being, living creature, animal) with its root in ζῷος (living, alive, vivid). Etymologically, Virchow limited the concept of zoonoses to "animals." More than 100 years later in 1958, the Joint WHO/FAO Expert Committee decided to narrow down the scope of "zoonoses" even more by defining these as "diseases and infections which are naturally transmitted between vertebrate animals and man."

On the other hand – and even from the beginning of zoonoses as an object of scientific research – Virchow and his Canadian disciple William Osler, also a physician by training, very early recognized the need for interdisciplinary collaboration between human and veterinary medicine and also – probably even more importantly – the public health, social and political aspects of zoonotic diseases. Researching zoonoses over the decades consequently not only helped to gain deeper insights into infectious diseases – additionally fostered by enormous progress

especially in molecular typing-based techniques – but also changed the research object and broadened the perspective under which zoonoses were seen. In 1984, Calvin Schwabe, a public health-trained veterinarian, introduced the concept of "One Medicine" (as discipline) and the corresponding "One health" approach not only comprising humans and animals but also the environment in all its facets. Thus, the concept of zoonoses had to be expanded by ecological, environmental, even societal, and economical aspects. In this respect, Virchow's etymological rooting of the term "zoonosis" in ζῷον shifts from the narrow "animal" to the much wider "living being," such as in the constructs of "biosphere" or the more mythical "gaia" model (to stay with Ancient Greek-derived expressions or ideas and deities).

"Habent sua fata libelli" (Not only words, but also books have their history). After the publication of its first edition in 2014, the current One Health-based book became rapidly popular among readers worldwide. Since nature never stops creating new infectious challenges for both mankind and the animal kingdom, it became obvious – at latest during the COVID-19 pandemic with one of its very first epicenters being a live wildlife food sale market in China – that a new and completely revised edition of the current book had to be started. New chapters addressing different animal groups (e.g., camels, birds, and reptiles), additional merging and re-emerging pathogens such as Borna Virus, *Borrelia* spp., Coronaviruses, trichinae, *Chlamydia* spp. or staphylococci, or new perspectives, for example, ancient and reverse zoonoses, were incorporated into the second edition.

The authors were chosen from a variety of academic and professional backgrounds, from the fields of human and veterinary medicine, from universities and public health institutions, and from more than 20 countries of all continents except Antarctica. The underlying idea was not to get an encyclopedic review on all known zoonotic disease entities but to have a forum for identifying or discussing urgent issues of zoonoses under a public health perspective.

Accordingly, the main target groups are the respective scientific communities, medical and veterinary practitioners, their students, public health and veterinary public health practitioners as well as decision-makers in the field of public health and veterinary public health.

Finally, I like to thank all authors for their very valuable chapters written with both heart and brain in the midst of a pandemic in which most, if not all of us, were heavily involved in COVID19-related professional work. We all are very grateful to Dr. Silvia Herold from Springer for initiating the new edition and especially to Neha Thapa and her team from Springer Nature India for her tireless, prudent, and extremely dedicated support throughout the whole publication process.

Preface to the First Edition

Zoonoses are infectious diseases caused by microorganisms passing from animals to humans and vice versa. In the last few decades most emerging and re-emerging diseases were in fact either of zoonotic origin or zoonotic potential.

The term "zoonosis" was coined by the German physician Rudolf Virchow, mainly known as father of scientific pathology, but also as an important political figure in nineteenth-century Germany. Although rooted in a classical faculty-based university system, he and his Canadian disciple William Osler, also a physician by training, very early recognized the need for interdisciplinary collaboration between human and veterinary medicine and also – probably even more importantly – the public health, social and political aspects of zoonotic diseases. While the scientific basis for both of them was pathology, the rise of microbiology as a medical discipline allowed to put the focus on microorganisms as the obvious and easiest walkable bridge between human and animal infectious diseases. This is even more true since the advent of especially DNA-based typing techniques for analyzing microorganisms isolated from different species thus allowing to study their real zoonotic potential.

By incorporating life and social science subdisciplines (e.g., immunology or epidemiology) a systemic paradigm was introduced in medical science thus preparing the ground for inter- and transdisciplinary approaches both in human and veterinary medicine. A striking example for the consequences of this paradigm shift on a population level are the concepts of New Public Health.

Not at last driven by the need for global public health efforts to combat both real and anticipated releases from Pandora's box in an interconnected and globalized world the One Health concept rapidly gained momentum in the last decade after the establishment of the 2004 "Manhattan Principles."

This book is based on the One Health concept with a focus on the public health impacts of zoonoses, both medically and societally. Important aspects in understanding zoonoses are not restricted to more classical issues, for example, their epidemiology in both humans and animals or disease symptoms in the respective two-legged, four-, or more-legged, feathered or unfeathered species, but have to take into account molecularly based epidemiological data and systemic, for example, ecological approaches.

To give an impression of the wide range of zoonotic research issues, the authors of this book were chosen from a variety of academic and professional backgrounds, from the fields of human and veterinary medicine, from universities and public health institutions, and from all continents. The underlying ideas were not to get an encyclopedic review on all known zoonotic disease entities but to have a forum for identifying or discussing urgent issues of zoonoses under a public health perspective. Accordingly, the main target groups are the respective scientific communities, medical and veterinary practitioners, their students, public health and veterinary public health practitioners as well as decision-makers in the field of public health and veterinary public health.

About the Editor

Andreas Sing Prof. Andreas Sing, MD, PhD, MA, DTM&H, is currently Head of the Bavarian State Institute of Health and the Department of Public Health Microbiology at the Bavarian Health and Food Safety Authority (LGL). He studied Human Medicine at the Albert-Ludwigs-University of Freiburg/Germany and the University of Massachusetts Medical School in Worcester, MA, USA, as well as Sociology & Political Sciences at the University of Freiburg. He obtained a PhD degree in Sociology at the University of Augsburg/Germany. After a post-doc training at the Department of Innate Immunity/LPS at the Max Planck-Institute of Immunobiology, he obtained his DTM&H at the London School of Hygiene and Tropical Medicine in London, UK, habilitated in Medical Microbiology & Hygiene with studies on Yersinia Innate Immunity at the Max von Pettenkofer-Institute of the Ludwigs-Maximilian-University (LMU) of Munich and became board-certified in Medical Microbiology. He teaches Medical Microbiology at the LMU, is Head of the German National Consiliary Laboratory on Diphtheria as well as Deputy Head of the National Reference Lab on Borreliosis in the Robert Koch-Institute-run German reference lab network. He is a member of ESGBOR (European Study Group of Lyme borreliosis) and founder member of ESGPHM (European Study Group of Public Health Microbiology) of the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) and serves as supervisor for the EPIET and EUPHEM fellowship organized by the ECDC (European Centre for Disease Prevention and Control).

"Les Liaisons Dangereuses"

László Bartosiewicz

Contents

Abstract

Archaeozoology is the study of animal–human relationships using the evidence of archaeological finds. Throughout the history of civilization human and animal welfare have become inseparable from each other. Microbiota found in and on all multicellular organisms include pathogens linking animals and humans not only to their environments but also to individuals of their own and other species. Animal paleopathology is traditionally based on the attempted identification of macromorphological symptoms of various infections on the excavated skeletal remains of various species. Osteological lesions caused by past animal disease reveal situated relations with humans, as many of them may be resulting from zoonoses shared between multiple species, including people. Interactive socio-ecological systems giving rise to zoonoses thus involve humans, animals, and pathogens in specific environments. While many such diseases first emerged with the onset of domestication and increasing social complexity, they are also caused by recent human infringements on the natural habitats of wild animals. Understanding animal disease in the distant past is indispensable in developing a

long-term, holistic perspective on zoonotic infections. Contextualizing scarce archaeozoological evidence for zoonoses in epidemiological terms should help identifying the factors that promote disease and understanding their dynamics.

1.1 Introduction

Human and animal health represent integral aspects of history. An increasing number of modern diseases are zoonotic in nature. Today various forms of the common cold and tuberculosis (TB henceforth) are well-known adaptations of strains originating in species other than humans (Benatar 2007). The historical perspective of co-evolving human and animal diseases cannot be studied without better understanding animal disease in archaeology. This short study is a review of evidence related to animal paleopathology.

Human agency in fostering as well as handling and curing animal disease has recently gained center stage in archaeological research illustrating how ancient people and animals coexisted in their shared environments. A driving force behind pathogen evolution seems to be the general human modification of the environment since many emerging zoonoses have been associated with anthropogenic changes (Pearce-Duvet 2006).

Today, major factors contributing to the emergence of new zoonotic pathogens in human populations are linked to the intensification of agriculture (Jones et al. 2013) as well as increased contacts between humans and wildlife in certain regions (Daszak et al. 2001). Aside from the widely publicized consumption of bushmeat in many parts of the world, zoonoses have recently been exacerbated by the encroachment of human activity into shrinking wilderness areas as well as game straying into ever-expanding human habitats. Contemporary observations in North America show that TB in white-tailed deer is increasingly associated with the proximity of infected cattle herds and/or high areal densities of white-tailed deer (O'Brien et al. 2001). In the *British Isles,* badgers are well adapted as the primary host for bovine TB (Gallagher and Clifton-Hadley 2000).

Throughout history several epidemics have been documented or are hypothesized to have taken place. Most of their causative agents still remain speculative. Archaeological and historical data complemented by robust biomolecular methods can be used to demonstrate the significance of zoonoses in these episodes (Spyrou et al. 2019).

1.2 Research Materials and Methods

"Unlike medical and veterinary work on the living, we usually have calcified tissue and little else. In the future, we can perhaps expect increasing support from immunological and DNA evidence related to specific disease, but for the present we are left with little more than bones and teeth" (Brothwell 2008).

Archaeozoology (or zooarchaeology) is a discipline devoted to the study of relationships between humans and animals, typically using osteological evidence recovered from archaeological excavations. Among archaeological finds, lesions on animal remains have regularly been observed for well over a century, as many diseases cause bone involvement thus allowing research using macromorphological methods (e.g., Steenstrup 1870; Shufeldt 1893).

While human paleopathology can directly benefit from groundbreaking achievements in modern medicine, present-day veterinary research is divided between diverse animal species and is focused on diseases of economic impact rather than odd-looking skeletal disorders. Skeletal manifestations of TB have decreased from 5–9% to 0.5–1% in cattle during the first half of the twentieth century (Lignereux and Peters 1999). In addition to improving prophylaxis, this may be explained by changes in exploitation that reduced longevity (intensive fattening for beef, decreasing draught work). In addition, the spread of modern epidemics is routinely prevented by the mass culling of herds before individuals would develop skeletal lesions. The lack of modern clinical data regarding the appearance and frequency of osteological symptoms of zoonoses in animals thus frequently impedes their detection in archaeozoological assemblages (Bartosiewicz 2021a). Some pathomorphological observations on the human skeleton are thus taken as a proxy in the diagnosis of disease in other mammals.

The sheer nature of archaezoological find assemblages poses additional challenges. Taphonomy is the critical study of information loss caused by fragmentation, poor preservation, and partial recovery in excavated materials. Each of these reduces information of vital significance in archaeozoological inquiry (Bartosiewicz 2008a). The bulk of animal bone deposits were generated through ancient butchery, were prone to scavenging, multiple re-deposition, and other destructive taphonomic forces. Lesions are thus typically noted on isolated bone specimens recovered from fragmented and commingled food refuse. This precludes the reconstruction of diseased individuals in the absence of coherent background information on age, sex, and associated skeletal symptoms. These would be readily available in traditional, undisturbed human burials (Bartosiewicz 2002).

In want of complete skeletons, Upex and Dobney (2012) emphasize the need for large syntheses and detailed analyses in traditional, morphology-based animal paleopathology. Analyses of disarticulated animal bones need to concentrate on the identification, quantification, and mapping of bone lesions associated with infection across the skeleton (Bartosiewicz 2008b) and their correlation with locations of clinically documented skeletal involvement. This work should be supported by advanced biomolecular analyses (Bendrey et al. 2019).

Birds (and likewise mobile bats) present a high risk of zoonotic transmission due to the ease with which they can fly between a variety of habitats, including human settlements. In archaeology, however, their small bones are found in numbers only when targeted, high precision recovery techniques are used in the field (fine screening, water-sieving). Thus, the general underrepresentation of bird remains limits the discovery of pathological cases. Due to these difficulties, traditional, morphology-based animal paleopathology in general and avian paleopathology in particular have seen protracted methodological development compared to archaeozoology as a whole or cutting-edge research in human paleopathology (Thomas 2012; Gál 2013).

By the end of the past millennium, the identification of TB, the probably best researched zoonosis in archaeology, entered a new phase thanks to the identification of mycobacterial DNA and lipid biomarkers in human remains at the eighth century AD site of Bélmegyer–Csömöki domb, Hungary (Haas et al. 2000). The development of high-throughput sequencing has stimulated unforeseen progress in the analysis of ancient DNA and RNA (aDNA and aRNA henceforth), offering a subtle way of identifying causative agents in paleopathology and insights in their microbial evolution (Spyrou et al. 2019).

In aDNA research, there has been a continuing emphasis on the analysis of human samples in the study of zoonotic pathogens. Over two decades ago Lignereux and Peters (1999) lamented the financial limitations of using molecular genetics in routinely identifying TB in archaeozoological assemblages. Studies of aDNA and aRNA necessitate sophisticated analytical procedures using costly infrastructure whose funding is more easily justified in human paleopathology: the long-term evolutionary history of microorganisms is relevant to contemporary challenges in public health (Spyrou et al. 2019). History, however, has been shaped not only by pathogens infecting humans, but also those damaging domestic animals and crops (Balloux and van Dorp 2017). Some groundbreaking work in aRNA research has actually been carried out on plants (e.g., Rollo 1985).

Forces of taphonomy also impact biomolecular methods. The terms aDNA and aRNA refer to the surviving nucleic acids isolated from archaeological samples. *Post mortem* decay takes place both through host enzymes, microbiomes, and abiotic factors. Differential preservation can also distort research results. *Mycobacteria*, for example, have a thicker, hydrophobic, and thus more resistant cell wall than that of *Brucella*. The difference in preservation thus causes a bias in recovery, the *M. tuberculosis* complex (MTBC) being better represented in the archaeological record (Recht et al. 2020). The MTBC includes, among others, *M. tuberculosis*, *M. bovis*, and *M. africanum*. Additional DNA damage may be caused by microbial contaminants (Duchêne et al. 2020). The even faster decomposition of RNA limits the study of aRNA genomes, although recent studies suggest that given favorable conditions even RNA remains can survive for millennia (Smith et al. 2019).

As taphonomic factors determining nucleotide preservation vary dramatically by geological and climatic circumstances, there is no predictable correlation between the level of DNA/RNA damage and the chronological age of archaeological samples. For example, human bone preserved in a shell midden in Latvia yielded identifiable molecular evidence of *Yersinia pestis* after 5000 years of deposition

and 150 years of museum storage in Rudolf Virchow's collection in the *Berliner Gesellschaft für Anthropologie, Ethnologie und Urgeschichte* (Susat et al. 2021).

1.3 History of Zoonoses

During early prehistory, Paleolithic communities of hunter-gatherers tended to be small and probably came into contact rarely with one another. They were indubitably exposed to infections of animal origin, albeit episodically (Sabbatini and Fiorini 2015). Such zoonoses may have occurred through the handling and consumption of infected game, but the spread of disease was likely limited. Isolation would have contained epidemics in localized communities, as the propagation and expansion of pathogens depend on the frequency of contacts between individuals.

In the Old World, this modest conduit for human infection by wildlife was significantly amplified by the onset of domestication (Pearce-Duvet 2006) through increased contact with the vectors of animal illnesses: the ecological entanglements of humans and livestock have resulted in regular somatic exchange (Rosenberg 2020), which became a mutual source of infectious diseases (as well as traumatic injury) for both people and their domesticates. On a broader scale, the combined effects of a higher human population density supported by emerging agriculture, accompanied by close and regular animal–human contacts meant exposure to a much richer pool of dangerous pathogens. Archaeozoological analyses and cases of human TB in late Pre-Pottery Neolithic in the Levant and Northern Syria support the hypothesis that close coexistence between early domesticates and humans has contributed to the emergence of this zoonosis since prehistoric times (Horwitz and Smith 2000; Baker et al. 2017).

Urbanization also increased the risk of mutual infections between animals and humans. Tanga et al. (2022) identified predisposing factors for zoonotic diseases in the Roman cities of Pompeii and Herculaneum. In these crowded urban environments, animals played diverse roles. The intensity of animal-related commercial activities contributed to the risk of infections. The climate also favored the proliferation of parasites and pathogens. Basic hygiene was often ignored in food processing and distribution while the proper disposal of human waste remained to be solved. The contamination of drinking water also became inevitable.

Aside from the immediate physical environment, zoonoses may have been indirectly exacerbated by other natural and social cataclysms. The Black Death (1347–1350 AD), for example, can be seen as part of the Late Medieval Crisis (ca. 1300–1350 AD). Changes occurring until 1350 should be seen within the context of previous catastrophes such as the Great Famine (1315–1322), or the Magdalenian Flood around the end of July in 1342 (Paxinos 2017). Recently, Seetah et al. (2020) have developed an exemplary integrated predictive model of Rift Valley fever virus outbreaks by combining climatic data with those on landscape archaeology, historical sources, and human behavior.

The fact that domestication and urbanization have demonstrably increased the risk of zoonoses should not be treated a *topos*. Contemporary outbreaks have

redirected attention to the role wildlife may play in the evolution of pathogens infecting humans. Paleopathologists should consider wild animals – integral agents in past ecosystems – as sources of health hazard for both humans and their domesticates (Bendrey and Martin 2021).

Paleoparasitological research ought to be increasingly integrated in the study of zoonoses. It would be important to work toward a consistent global coverage in this field (Bendrey and Martin 2021). A recent overview of archaeological finds of zoonotic parasites (identified in association with humans) has demonstrated the key role parasites have played in the evolution and spread of new pathogens, particularly from the Neolithic Period onward (Ledger and Mitchell 2019). An emerging diachronic trend is already evident during prehistory: sediment analyses of the Neolithic Els Trocs cave in Spain show a significant increase in the abundance and diversity of parasites as pastoral resources were increasingly exploited with the advancement of time (Tejedor-Rodríguez et al. 2021).

In order to persist in small, early prehistoric human populations, a pathogen either had to cause chronic infection (surviving in the infected host for a longer time), or it had to spread to other species that served as reservoirs. Some obligate pathogens require more than a single host to fulfill their ontogenetic cycle. The actual host, supporting the adult form of the pathogen, is often a vertebrate, while the intermediate host (referred to as a vector) can also be an arthropod or mollusc (Balloux and van Dorp 2017). In intermediate hosts, pathogens could incubate until susceptible hosts were contacted/infected. Parasite remains are informative in investigating past zoonoses as they have diverse life cycles that often involve both animal and human hosts, while some are not host-specific (Ledger and Mitchell 2019).

In addition to pathogens shared by humans with invertebrates (acting as vectors or intermediate hosts for disease), over 3/4 of reservoir species of zoonoses are mammalian and two thirds of zoonoses have their origins in domesticates (Schwabe 1984; Morse et al. 2012). Risks of infection were multiplied by both human and animal contacts between ancient farming communities (Fournié et al. 2017). In Fig. 1a, the number of diseases shared between humans and common domestic animals (McNeill 1976) are plotted against the approximate time of domestication (calBCE, Zeder 2008). A high correlation between the two variables shows that the longer the shared history between an animal species and humans, the longer the list of bilateral infections.

While we share the greatest numbers of diseases with dog, the first ever domesticate, the four artiodactyl species of the so-called “Neolithic package” (livestock that were first domesticated in addition to dog: sheep, goat, cattle, and pig) form a cluster associated with more zoonoses than expected on the basis of their chronological positions (above the trend line in Fig. 1a). It is important to remember that this diagram shows only bilateral infections between humans and each animal species. In reality the picture is far more complex, following multiple pathways of disease. When various combinations between mammals are considered, humans share the most pathogens with even-toed ungulates (c.f. the “Neolithic package”), followed by rodents, carnivores, and primates (Morse et al. 2012). This is shown by the example of the three most commonly occurring *Mycobacterium* species and their

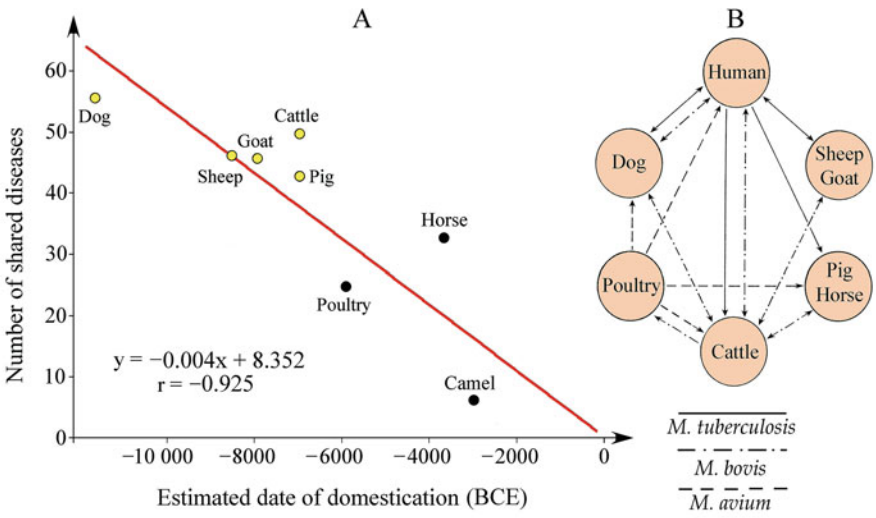

Fig. 1 (**a**) The number of diseases shared between humans and various domestic animals in relation to the time of domestication. Species in the Neolithic Package are marked by light dots; (**b**) Epidemiology of three common forms of *Mycobacterium* infections

hosts (among the best studied in archaeology) summarized in Fig. 1b (Manninger and Mészáros 1975; Lignereux and Peters 1999; Krauss et al. 2003). Based on the worldwide comparison of 14 selected bacterial and viral zoonoses each and four additional (mostly parasitic) zoonoses, Recht and co-workers (2020) warned of inaccuracies and inconsistencies in trying to exactly estimate ever-changing host diversity.

Numerous epidemics, recently recognized as zoonoses, also appear in the documentary record. While a detailed list would be beyond the scope of this chapter discussing archaeolzoological evidence, a few selected examples deserve attention.

In Europe, Thucydides was the first to report, in the *History of the Peloponnesian War*, how the plague of Athens (caused by the bacterium *Yersinia pestis*) devastated the city state in 430 BCE (Balloux and van Dorp 2017). Three major subsequent outbreaks have likewise been documented and even investigated using biomolecular methods on human bone (Wagner et al. 2014).

Cattle plague or *Rinderpest* (*Morbillivirus*) was documented in Asia as early as 3000 BCE, and mentioned in Greek and Roman sources around the beginning of the fourth century BCE (Spinage 2003; Pastoret et al. 2006). Although it is not a zoonotic disease in its modern form, measles likely evolved from cattle plague (Furuse et al. 2010), possibly as early as the fourth millennium BCE (Düx et al. 2020). Viruses seem to mutate at a higher rate than other pathogens thereby adapting to the human host, relying on interpersonal transmission without another reservoir species (Morse et al. 2012). Some experts have suggested that all human viral infections could be originally zoonotic (Benatar 2007).

Another virus infection, rabies (*Rabies lyssavirus*), long known to have spread through dog bites to humans and other animals, was described as early as the thirteenth century by, among others, Albertus Magnus (Walker-Meikle 2012). Archaeological evidence for rapid viral infections in animals is rare as it cannot be visually detected in skeletal remains and their molecular identification is hampered by poor nucleotide preservation.

1.4 Archaeozoological Evidence

Archaeologically, infections can only be identified on animal bones exhibiting a range of secondary macromorphological changes. Several microbes causing zoonoses represent a transition between specific and nonspecific sources of bone inflammation, since after localized beginnings they have a potential to invade the entire skeleton. Within the body, many zoonotic infections are spread by the vascular system through soft tissue foci to the skeleton. This process takes time. Some important zoonoses (e.g., *Erysipelothrix rhusiopathiae* seen mainly in growing pigs) produce acute symptoms rarely visible on the animal skeleton before they cause sudden death. Such diseases cannot be recognized through the visual inspection of archaeological bone finds.

Infections generally affect well-vascularized spongy trabecular bone in vertebral bodies, meta- and epiphyseal ends of long bones, ribs, sternum, and other flat bones, but may also occur under the periosteum (e.g., tuberculous periostitis). Infections by a variety of bacteria can cause tenosynovitis as well as bursitis, leading to osteological changes in the joints affected. However, predilection sites and the character of lesions differ both between pathogens and various host species (Nieberle and Cohrs 1970).

The taphonomic conundrum that symptoms can be observed only on isolated archaeological animal bones limits recognizing ancient MTBC, as only about 5% of known cases are believed to result in osteoarticular changes (Lignereux and Peters 1999; Donoghue et al. 2015). This small proportion shows how intangible even important infectious diseases can remain relying on the evidence of isolated bone finds alone. The macromorphological identification of general zoonotic infections tends to be more reliable in species seldom processed for food, their bodies being buried as a whole. Non-disarticulated skeletons of dogs and horses offer possibilities for better, comprehensive diagnoses.

Studies of human TB show how useful it is to have morphological observations supported by using aDNA (Masson et al. 2013). A case of Pott's disease from Alsónyék-Bátaszék (Köhler et al. 2014) was not only confirmed by the evidence of MTBC aDNA but tests helped detecting three additional humans in the burial group who displayed no visible skeletal lesions (Pósa et al. 2015). As of today, aDNA assays have only been sporadically carried out on animal bone to support macroscopic diagnoses (Rothschild et al. 2001; Bathurst and Barta 2004; Wooding 2010) and the molecular identification of MTBC in archaeozoological assemblages remains elusive. A rare example of testing animal rather than human remains for

microbial aDNA is the Iron Age assemblage from Wetwang Slack, United Kingdom, where aDNA samples from two horses, two cattle, and one pig showing symptoms of infection were tested for both MTBC and Brucella, the primary differential diagnosis for bovine TB (Wooding et al. 2019). Preservation allowing, fetal and neonatal animal bone finds should also be considered for aDNA analyses as possible indicators of abortifacient pathogens (Bendrey and Martin 2021).

1.5 Zoonotic Infections in Archaeology

Tuberculosis, caused by various species of the *Mycobacterium* genus, has been a focal topic in paleopathology. The oldest aDNA evidence for the MTBC in a wild bovine was detected in an American bison dated to ca. 17,000 BP (Rothschild et al. 2001). In the Old World, zoonotic TB infections are at least as old as dairying, a source of food already known in Early Neolithic Europe (Craig et al. 2005; Copley et al. 2003); historically, milk-borne transmission has been responsible for most human *M. bovis* infections (O'Reilly and Daborn 1995). Among livestock it is best known in cattle, its contemporary form being less frequent in sheep and goats. Available aDNA evidence suggests that *M. tuberculosis* in humans and cattle would have gone through a co-evolutionary process. The MTBC genome had a wide time-span to reach a suitable adjustment, co-evolving in geographical environments both at high and low host density (Sabbatini and Fiorini 2015). *M. tuberculosis* is an obligate pathogen that has no environmental reservoir, but numerous mammals and birds can also serve as reservoir hosts. The degree of mutuality and directions of TB infections vary between species as outlined in Fig. 1B. In addition to broadly varying degrees of infection in European livestock (Lignereux and Peters 1999), Mason (1917) reported a 2.8% prevalence of TB in dromedaries at a Cairo abattoir. He concluded that camel TB was caused by *M. bovis* and indicated that the confinement of camels and cattle together may be the source of cross-infection.

In the Americas, mounting pre-Columbian evidence of human TB (Braun et al. 1998; Buikstra 1999) has been indicative of alternative sources for this infection (Lignereux and Peters 1999). The only domestic mammal available to Americans before European contact, dog – as other carnivores – is not highy susceptible to TB (Fröhner and Zwick 1925). Thus it is important that hypertrophic osteopathy caused by TB in a sixteenth century Iroquoian dog skeleton from Southern Ontario, Canada, was directly supported by aDNA evidence (Bathurst and Barta 2004). Pre-Columbian mycobacterial infections in humans also indicate the implication of marine mammals in the zoonotic transmission of the MTBC between continents (Bos et al. 2014).

Avian TB is most often caused by *M. avium* and *M. genovense* (Tell et al. 2001) affecting domestic hen and captive wild birds (Cousins 2008). In the wild it has been observed in wading birds as well as diurnal raptors (Lignereux and Peters 1999). In birds, the lesion first occurs characteristically in the bone marrow, and usually affects the major bones in the leg (Baker and Brothwell 1980).

MTBC is spread through droplet infection and the consumption of infected animal products. When the bacterium is inhaled, pulmonary lesions develop. The aforementioned molecular evidence of TB in several Late Neolithic humans (first half of the fifth millennium BCE; Masson et al. 2013; Pósa et al. 2015) offer the earliest genetically confirmed evidence of TB in Europe. They indirectly support the morphological identification of a "tuberculous" cavern observed macroscopically on a contemporaneous cow metatarsus recovered from the Late Neolithic site of Berettyóújfalu–Herpály in Hungary (Hertelendi et al. 1998).

Human bones from the medieval churchyard of Wharram Percy, England, revealed *M. tuberculosis* aDNA in individuals who also displayed skeletal manifestations of the disease (Mays et al. 2001). Assays aimed at identifying bovine TB (*M. bovis*), however, turned out to be negative, somewhat surprising at this rural settlement where people probably relied on milk and beef. TB infections likely culminated around the industrial revolution when cows were kept even in crowded city centers to provide milk for likewise densely concentrated human populations (Mays 2005). Causing disease in a wide range of mammals, *M. bovis* has the broadest host range of the members of the *MTBC* (O'Reilly and Daborn 1995).

Lignereux and Peters (1999) reviewed the skeletal symptoms attributable to cattle TB, which generally affect well-vascularized trabecular bone in vertebral bodies as primary sites of predilection. Notably, while symptoms of TB commonly occur on both the vertebrae and ribs of animals, they seem unrelated to grave pleural lesions unless infection affects the lymphatic system (Nieberle and Cohrs 1970). In bovids, as in humans, various forms of bone resorption and lysis dominate (e.g., osteomyelitis, osteoporosis, and cavitation). Symptoms of advanced TB also include cavernous, purulent panosteitis with fistulation. Infiltrating TB in cattle may lead to excess bone growth that tends to connect articular surfaces (*arthritis tuberculosa pannosa*; Kardeván 1976) causing ankylosis, as between the three first thoracic vertebrae in a medieval (tenth to eleventh century) horse from Szombathely–Zanat, Hungary (Nyerges 2009). Although TB tends to be manifested in the cervical region in horse (Fröhner and Zwick 1925), this isolated specimen was found among food refuse, thus the involvement of neck vertebrae could not be appraised. The ankylosed vertebrae of this horse also show advanced fistulation (Fig. 2).

A special form, chronic miliary TB results from massive lymphohematogenous dissemination during which bacteria are spread from a single center of infection, producing small tubercles in other parts of the body (Nieberle and Cohrs 1970). A result of this process is the development of tuberculotic fibrous capsules, especially on ribs, reminiscent of callus formation following minor fractures, although these deformations caused by TB have a far softer, spongy structure. In Hungary, such lesions were observed on the ribs of two dogs from the Celtic-Roman village of Balatonlelle–Kenderföld (Daróczi-Szabó 2008) and in a tenth to twelfth century medieval dog in Buda Castle (Csippán and Daróczi-Szabó 2008).

TB usually does not lead to acute arthritis. Its osteological manifestation tends to be infiltrating exudative arthritis rather than acute inflammation in the joints. TB may also be accompanied by osteoporotic inflammation within the bone tissue that is almost always proliferative and leads to the buildup of hypertrophic osseous material

Fig. 3 First century AD Roman Period pig fifth metacarpus from Budapest–Aquincum, Hungary showing hypertrophic osteopathy. Medial, dorsal, and lateral aspects. (Photo: Alice M. Choyke)

(Wooding 2010). Hypertrophic osteopathy seems present on a Roman Period fifth metacarpal bone of pig found in a late first century pit dwelling in Budapest–Aquincum, Hungary (Fig. 3). Although TB is rarely manifested in the pig skeleton, over one third of the infections may cause skeletal symptoms in present-day pigs. Distal extremity segments (metapodia, including those in vestigial dewclaws) appear commonly affected (Kitt 1900). MTBC infections are capable of inducing this symptom in dogs as well (Bathurst and Barta 2004).

In chronic miliary TB the granulation tissue of the synovial membrane and epiphyseal trabecular bone progressively destroys and replaces the articular cartilage (Nieberle and Cohrs 1970). The concomitant necrosis of articular cartilage was observed in the right hip joint of a young pig from the eighth century, Avar Period settlement of Dunaújváros–Alsófoki-patak, Hungary. The originally clear contours of the bone were rearranged in an amorphous mass within the acetabulum. The new tissue buildup was dense enough to develop a secondary articular surface for the dislocated femur as shown by eburnation on the newly formed mass of bone that took over the acetabulum (Bartosiewicz 2013). Less extreme but similar deformations were noted on two pig pelvis fragments from the Eneolithic levels of Poljanitsa,

Bulgaria (Bartosiewicz et al. 2018). Since neither of the latter specimens was found as part of articulated skeletons, differential diagnoses include traumatic luxation compounded by chronic inflammation.

Advanced MTBC infections may be manifested on the diaphyses of long bones. The aforementioned metatarsus of a small cow from Late Neolithic Berettyóújfalu–Herpály, Hungary, shows proliferative/lytic osteomyelitis attributable to microbial infection. Cavitary osteolysis of this type is frequently accompanied by the formation of a wreath-like osteosclerotic ring around the tuberculous lesion (Fig. 4).

Unfortunately, such proliferative deformations are not specific to offending microorganisms, several could cause lytic anomalies similar in appearance. A definitive diagnosis of TB is not possible without confirming the presence of the pathogen microscopically or by biomolecular tests of a typical lesion.

While present-day brucellosis is the most commonly occurring bacterial zoonosis worldwide (Bendrey and Fournié 2020), it is poorly recognizable in the archaeozoological record. This zoonosis is a threat to all important species of livestock, although the risk of infection varies between *Brucella* species. *B. abortus* is a disease of large bovines (cattle, buffalo, bison), horse, and even

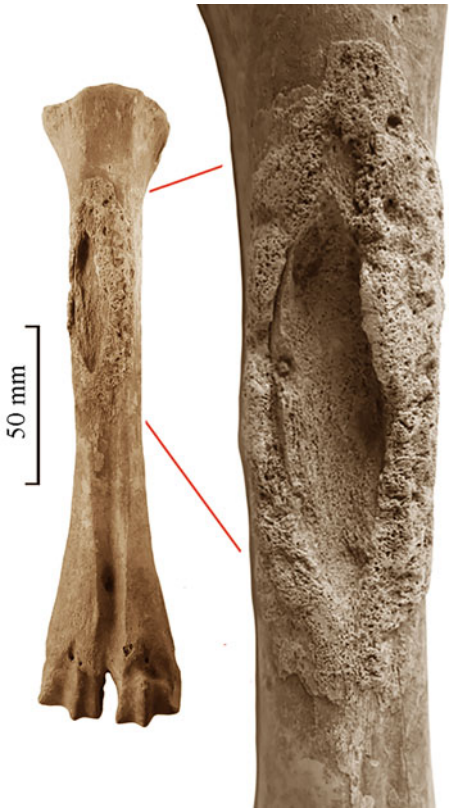

Fig. 4 Osteomyelitic cavern with sclerotic ring on the metatarsus of a gracile Late Neolithic cow from Berettyóújfalu–Herpály, Hungary. Anterior aspect. (Photo: Lajos Sugár)

dog, affecting small stock (pig, sheep and goats) rarely. *B. melitensis* can infect all bovids and camel, but is rarer in horse and pig. *B. suis*, *B. canis*, and *B. ovis* are largely specific to pig, dog, and sheep, respectively. Brucella species generally pathogenic to humans are *B. melitensis, B. abortus*, as well as biovars 1 and 3 of *B. suis* (Corbel 2006).

The impact on bone occurs in the form of focally extensive periosteal formations. Additional bone and joint involvement includes sacroiliitis, spondylitis, peripheral arthritis, osteomyelitis, bursitis, and tenosynovitis. Osteomyelitis frequently affects vertebral bodies, especially in the lumbar section (Corbel 2006). Such lesions, however, may result from numerous other infections, making the study of aDNA evidence especially important. In a recent summary, Bendrey et al. (2019) cited only five human remains with confirmed biomolecular evidence for Brucella infection, and there are no published definitive cases of animal brucellosis from archaeological sites. Known archaeozoological remains for which brucellosis forms part of the differential diagnosis or as a possible cause are exclusively from horses. In the United Kingdom they originate from the site of Dragonby (Baker and Brothwell 1980), the Late Iron Age/Early Roman sites of Viables Farm and Downlands Farm (Bendrey 2008; Bendrey et al. 2008). A horse skull fragment from Arzhan 1, a site of Early Iron Age Scythian burials in the Tuva Republic, Russia, showed inflammation and necrosis following local infection described as "poll-evil" (Bendrey et al. 2011). Reflecting present-day public health concerns focused on humans, however, aDNA research has been quite anthropocentric in archaeology.

Among the most researched ancient zoonoses bubonic plague is caused by the bacterium *Yersinia pestis*. Although this acute disease kills the victim before leaving visible lesions on the bone, it is a zoonosis (Meerburg et al. 2009) archaeologically identifiable through aDNA sequencing. This bacterium has so far caused three genetically identified human pandemics of catastrophic consequences: the Plague of Justinian (sixth to eighth centuries), the Black Death (fourteenth to seventeenth centuries), and a third plague in the Modern Age (nineteenth to twentieth centuries; Wagner et al. 2014). *Y. pestis* is an obligate parasitic bacterium whose life cycle consists of alternating infections of rodents and fleas, but can infect essentially any mammalian host (Balloux and van Dorp 2017). A dramatic 1532 woodcut from Germany shows plague victims equally including people, a stallion, a dog, a cat, poultry, and even a small songbird (Fig. 5). It seems that the lineage of *Y. pestis* inducing the Plague of Justinian differed from the lineage that caused the next pandemic eight centuries later (Wagner et al. 2014). Recently, *Y. pestis* has also been isolated from a prehistoric (5300–5050 calBP) human skull fragment recovered from the shell midden of Riņņukalns, Latvia, in the late nineteenth century (Susat et al. 2021). This case is the first in a series of ancient strains that evolved following the split between *Y. pestis* and its putative predecessor *Y. pseudotuberculosis* 7000 years ago (Susat et al. 2021). It is suggested that this early form of *Y. pestis* was perhaps less transmissible and virulent than later strains. The Riņņukalns case may be attributable to a single zoonotic event rather than an epidemic. *Y. pestis* infected people in Bronze Age Eurasia three millennia before written records of plague, the highly virulent flea-borne bubonic strain emerged only around 1000

Fig. 5 Plague scene in the 1532 German edition of Francesco Petrarca's "*De remediis utriusque fortunae*" (1492) Woodcut by the anonymous Master of Petrarch

calBCE (Rasmussen et al. 2015). Wagner et al. (2014) confirmed that rodents serve as reservoirs in the recurrence of diverse lineages of *Y. pestis* jeopardizing human populations. This falls in line with Rütimeyer's (1877) observation that beaver, a common host of *Y. pseudotuberculosis*, was the best represented game in the Riņņukalns archaeozoological assemblage (Susat et al. 2021). This is yet another example when aDNA tests carried out directly on archaeological animal bone could confirm and expand the interpretive framework of ancient zoonoses.

1.6 Differential Diagnoses

With a few notable exceptions, animal paleopathology has increasingly been studied by archaeologists specialized in osteology rather than veterinarians with clinical experience (Bartosiewicz 2019). Interpretations thus often lack a broader view on animal morbidity.

Differential diagnoses, however, would be of key importance in evaluating ancient zoonoses (Lignereux and Peters 1999; Lawler 2017; Bendrey and Martin 2021). Conditions potentially caused by multiple pathogens always need to be considered. Analogous osteomorphological manifestations of different diseases are the natural consequence of bone tissue having but a limited repertoire of responses to diverse pathological conditions. Typical zoonoses damaging the skeleton, i.e., visible in archaeozoological assemblages, may be understood in terms of inflammatory diseases caused by general infection (Baker and Brothwell 1980; Bartosiewicz 2013).

Inflammation leading to osteological changes such as bacterial arthritis can be caused by several pathogens not falling under the traditional concept of zoonoses as

they can be part of the normal microbiome inhabiting the oral, nasopharyngeal, and digestive tracts of the host. Lesions caused by bacterial vertebral osteomyelitis and septic arthritis are difficult to distinguish in animals as the primary causative pathogens vary both diachronically and by geographical region, affecting differential diagnosis in archaeozoological studies. Many such bacteria (e.g., *Staphylococcus aureus*, *Pasteurella multocida*) are opportunistic pathogens that can cause endemic disease and have recently been increasingly associated with epizootic outbreaks posing a high risk of becoming zoonotic pathogens (Jaffe 1972; Ho 1993; Rao et al. 2017; Wilson and Ho 2020). General inflammations leading to pyogenous osteomyelitis may also be caused by chronic infection by other bacteria (*Corynebacterium* sp., *Streptococcus* sp.; Lignereux and Peters 1999).

In the case of brucellosis, differential diagnoses of various morphological symptoms observed on Iron Age horses included infections caused by *Trueperella pyogenes*, *Mycobacterium bovis*, *Actinomyces bovis*, *Streptococcus zooepidemicus*, and *Aspergillus* sp. (Bendrey et al. 2008, 2011). In animal paleopathology such infections must be considered whenever localized osteological symptoms can be identified. However, it is in such cases when the scarcity of complete skeletal finds makes it impossible to decide whether a lesion encountered on an isolated bone fragment results from localized or general systemic infection.

Of the best known zoonoses in archaeology, MTBC and brucellosis may both cause cavernous, purulent panosteitis with fistulation. From the viewpoint of differential diagnosis it is of interest that paravertebral abscesses are more common in TB than in brucellosis (Aufderheide and Rodríguez-Martín 1998; Corbel 2006). The involvement of the skeleton is late during the pathogenesis of MTBC. Only 0.5–1% of present-day cattle and 8–9.5% of pigs display bone lesions, in part due to early slaughter. (Osteological manifestations are more common in birds, both wild and domestic, than in mammals: Nieberle and Cohrs 1970). In brucellosis, on the other hand, bone and joint involvement (sacroiliitis, spondylitis, peripheral arthritis, osteomyelitis, bursitis, and tenosynovitis) may reach 40% of cases in humans (Corbel 2006). Baker and Brothwell (1980) suggest that there is also a greater incidence of periosteal proliferation in brucellosis than TB. Since pulmonary neoplasia may also induce hypertrophic osteopathy, it should also be considered in differential diagnoses of MTBC on dry bone (Snider 1971; Wooding 2010; Bathurst and Barta 2004).

While these difficulties frequently overshadow the visual evaluation of osseous lesions, they are not limited to the macromorphological study of zoonoses. Lawler et al. (2020) warn that potential contribution by soil microbiota should also be considered in differential diagnoses during the aDNA identification of pathogens.

1.7 Concluding Remarks

As with all historical studies, a better knowledge of ancient zoonoses should support informed decisions made both in the present and future (Bendrey and Martin 2021). During the history of civilization human and animal welfare have become inseparable from each other. The study of animal paleopathology shows a rich diversity of attitudes toward animals (Bartosiewicz and Gál 2018). As Benatar (2007) noted,

even if zoonoses seem inevitable, much suffering and damage caused by zoonotic diseases could probably have been prevented if humans had treated animals better.

While the complexities of public health phenomena are far too subtle to be characterized using the patchwork of archaeological evidence offered by animal paleopathology, contemporary epidemics clearly illustrate the large extent to which the health of people and animals are entangled. Studying archaeological occurrences is indispensable in understanding the emergence of zoonoses on a long-term chronological scale. It can also help nurturing a more objective attitude to such contemporary threats, minimizing defensive overreaction by the broader public (Bendrey and Fournié 2020).

Interdisciplinarity has long been a popular slogan in research. Bendrey and Martin (2021) also stress the importance of a holistic approach in the study of past zoonoses. Interpretations must be aimed at capturing the diverse factors influencing infections. Contextualizing scarce archaeozoological evidence for zoonoses in epidemiological terms should help identifying the factors that promote disease. Understanding the time-depth of ever-changing relationships between animals, humans, and their environment should help in generating hypotheses concerning the dynamics of zoonoses. Such hypotheses can then be tested using carefully compiled paleopathological evidence, both morphological and biomolecular, gained from parallel studies of animal and human remains. Archaeological applications of the One Health perspective (Bendrey et al. 2019) acknowledge the essential link between the well-being of animals, humans, and environment in an interdisciplinary setting. On the other side, in archaeology, the emerging posthumanist approach mirrors this integrative endeavor in the form of a widening spectrum of animal studies in humanities (Bartosiewicz 2021b).

https://doi.org/10.1007/978-3-031-27164-9_59

Abstract

The fundamental premise of the One Health concept is that the collective health of humans, animals, and their shared environments depends upon the interactions between each domain. When it comes to mitigating infectious disease risk at this interface, an integrated approach is necessary. While recognition of the threat of animal-to-human disease transmission (zoonosis) is widely understood, there has been less consideration of the potential harm that humans can have on animal populations through reverse zoonosis. This chapter presents evidence and descriptions of human-to-animal disease transmission spanning viruses, bacteria, parasites, and fungi among companion animals, livestock and poultry, and wildlife as well as recommendations for multidisciplinary strategies for prevention and control. Collaborative efforts between veterinary health, public health, and environmental health professionals are critical to address the anticipated increased risk of reverse zoonotic events.

2.1 Introduction

2.1.1 Healthy Humans, Healthy Animals

Human health and animal health are closely connected. With rapidly growing global human and domestic animal populations, increasing human enchroachment of wildlife habitats, and rapid environmental change, the linkages between human,

animal, and environmental health are becoming more evident. Negative disturbances that impact the health of the environment or biological organisms can affect the equilibrium of their interactions (Alves and Policarpo 2018; Mi et al. 2016). Over the years, many individuals from varied disciplines have worked towards promoting awareness of these risks to mitigate their consequences, which has led to the development of the One Health approach (Europe, A.h. 2017). This multi-disciplinary framework recognizes that the complex relationships that exist at the human-animal-environmental nexus require innovative, holistic, and collaborative approaches to prevent disease threats for all species.

Cross-species transmission of microbes have been observed since humans domesticated animals (Kruse et al. 2004; Reperant et al. 2013). To date, most attention has been placed on the zoonotic movement of pathogens from animals to humans. However, microbes can also move from humans to animals. This reverse zoonosis transmission has two concerns. First, the infected animals can become ill and potentially die; second, the affected population of animals can become a pathogen reservoir from which novel agents may cause spillback into humans resulting in further human disease (Di Marco et al. 2020; Sooksawasdi et al. 2021).

While we have often focused upon zoonotic disease threats to humans, rapidly increasing human population densities and frequent contact with domesticated and wild animals make humans just as likely to be an incubator for pathogens that could be transmitted back to animals. In recent decades, population growth, environmental disruption, and the rise of industrial agriculture have altered the human-animal interface. This change has led to the emergence of several outbreaks of public health and veterinary importance, including influenza A viruses and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Since the 1960s, researchers have documented cases of humans infecting wildlife, companion animals, and livestock with a wide range of pathogens, including viruses, fungi, protozoa, and bacteria. Evolutionary analyses of the 2002–2003 SARS outbreak indicated a bidirectional transmission between humans and animals. Studies of the H1N1 influenza pandemic (H1N1pdm09 2009) in 21 countries confirm that sufficient contact between human and non-human species can facilitate human-to-animal transmission (Scotch et al. 2011). Further, several reverse zoonotic events of SARS-CoV-2 in wildlife and companion animals highlight the risk of transmission via close contact with infected humans such as farmworkers (Forgie et al. 2011; Holyoake et al. 2011; Sweetline Anne et al. 2017), pet owners (Zhang et al. 2020; Zhao et al. 2014; Dundon et al. 2010), caretakers, and veterinarians (Martelli et al. 2019; Crossley et al. 2012). As of August 2022, human-adapted SARS-CoV-2 has infected at least 31 unique animals species in 39 countries (https://vis.csh.ac.at/sars-ani/) (Nerpel et al. 2022).

SARS-CoV-2 has demonstrated the potential of reverse zoonoses while also causing great loss to human life, the global economy, and our social and community networks. Several cases of dogs, cats, domesticated animals, and zoo animals testing positive for SARS-CoV-2 have occurred, primarily due to close

contact with infected humans (Kuchipudi et al. 2022; Munir et al. 2020; Santini and Edwards 2020). Transmission of SARS-CoV-2 from infected animals to humans is also suspected (Munir et al. 2020). In addition to human-to-animal direct transmission (e.g., by physical contact with domestic and wild animals), there remains the potential for animal transmission via indirect contact with contaminated human waste (e.g., nasal discharge, phlegm, saliva, blood, urine, and feces) (Franklin and Bevins 2020; He et al. 2021). Also, improper disposal of contaminated personal protective equipment (masks, face coverings, gloves, tissues, and wipes) constitutes a source of SARS-CoV-2 infection for animals. When not managed properly, these items are subject to open dumping, which pose risks of infection for synanthropic and wild animals in surrounding environments (Han and He 2021). Because animals often suffer a similar spectrum of disease as humans, they can serve as "sentinels" for threats within our living or working environments, just as humans may sometimes serve as sentinels for proximal animal health (Alves and Policarpo 2018). Diseases have an important impact on public health and the economy, as well as conservation of wildlife. Animals are an important resource for food, textiles, companionship, and assistance. Besides serving as a source of dietary protein, animal-based products are fundamental ingredients for both traditional and modern medicines. Healthy animals enable farmers to produce more meat, milk, eggs, and fish, with less environmental impact. Many owners depend on their animals for income; therefore, if an animal falls ill, it can create financial difficulties for the household. The veterinary and daily care expenses associated with animals can be cost-prohibitive for poorer households, making it harder to maintain optimal health and custody of the animals. The loss of food animals on account of poor health or disease can create additional public health issues, such as malnutrition, despite no inherent disease transmission risk.

The more than one billion people worldwide who work daily with food animals, or their products, are at particularly high risk for disease transmission. In addition to their personal risks, animal workers can be a bridge population for zoonotic pathogen transmission between animals and the general human population. For example, the spouses of swine workers have demonstrated elevated rates of seropositivity to swine influenza viruses (Gray et al. 2007). The rise in the global human population is also contributing to an increase in the numbers of companion animals. The significance of companion animals speaks to the strength of the human-animal bond. Studies have suggested positive health effects from such attachments, including improvements in physical and mental well-being (Friedmann and Son 2009). However, just like with food animals, good hygiene is vital to prevent the spread of disease to companion animals as well as to people within shared spaces. Maintaining a healthy diet, providing fresh drinking water, creating clean living conditions, and following recommended vaccination schedules can minimize the risk of animal illness (Leeflang et al. 2008).

2.1.2 What Are Zoonoses and Reverse Zoonoses?

Due to the close contact and proximity that humans and animals have had throughout our common history, many pathogenic microorganisms have co-evolved to successfully infect both types of host (Slingenbergh et al. 2004). Today, more than 200 different diseases are shared between people and animals with 60% of the organisms known to be pathogenic to humans classified as zoonotic (Taylor et al. 2001; Cleaveland et al. 2001). In fact, over 77% of pathogens that infect livestock are multiple species pathogens (Cleaveland et al. 2001). Diseases that can be transmitted between animals and people, or zoonoses, or anthropozoonoses, are found in livestock, poultry, wildlife, and companion animals (FAO-OIE-OMS 2019; Messenger et al. 2014). Although zoonotic diseases are primarily described as transmission occurring from an animal reservoir or host to a human, many of our shared pathogens can be spread bidirectionally, meaning contagion can also occur in animals after exposure to an infected human. This is referred to as reverse zoonoses, or zooanthroponosis (Messenger et al. 2014). Zoonotic microorganisms may cause infection in either or both groups with symptoms and severity of illness dependent upon intensity of pathogen exposure, pathogen virulence, and the immune status and overall health of the host. Types of zoonotic and reverse zoonotic pathogens include bacteria, viruses, protozoa, helminths, fungi, and prions (Slingenbergh et al. 2004; Taylor et al. 2001; Cleaveland et al. 2001). Zoonotic pathogens can be transmitted through indirect contact with the contaminated environment (i.e., soil), items (i.e. fomites), vectors (i.e. ticks), airborne particles or by direct contact with an infected host or host bodily fluids (i.e. petting an animal or droplet spread) (FAO-OIE-OMS 2019).

2.1.3 Why Is Knowledge of Reverse Zoonoses Important?

As human population and livestock production continue to expand, the risk of reverse zoonoses will increase as humans and animals have more frequent and closer contact. Knowledge and understanding of the epidemiological triad, which includes transmission factors associated with the host, pathogen, and environment, is essential for devising public health measures to aid in the prevention and control of infectious disease outbreaks. Most epidemiological studies aim to identify clinical and pathological features in infected species to determine host susceptibility (i.e., which species are capable of being hosts and which are susceptible to natural infections) (Sreenivasan et al. 2021). Early and accurate diagnosis could lead to the timely detection of outbreaks and ultimately decrease the impact of epidemics on human and animal populations (Steele et al. 2016). For public health interventions to be effective, knowledge of risk factors, transmission routes, and virulence factors between different species are crucial for estimating the magnitude of outbreak impacts and transmission rates (Kraemer

et al. 2020; Charu et al. 2017). For example, researchers and health providers should understand the probability of transmission of the pathogen, types of interaction between infected humans and recipient animals, the capability of the animal host factors for producing infection, and the suitability of the animal host population for pathogenic persistence (Sooksawasdi Na Ayudhya and Kuiken 2021).

The recognition of the role of humans as a source of pathogens is pivotal to public health measures as it has redefined vulnerable population groups to include animal species. Interspecies transmission may also contribute to an increase of genetic diversity in pathogens by providing more opportunities for genetic reassortment that could drive the evolution of pathogens (Chastagner et al. 2018; Nelson and Vincent 2015). These evolutionary changes in pathogens pose further challenges to the surveillance and outbreak controls such as reducing the efficacy of vaccines (dos Santos 2021; Lemaire et al. 2012) and increasing the possibility of the emergence of new enzootic strains in animal populations (Watson et al. 2015; Simon et al. 2014). Therefore, genomic sequencing studies help revise our understandings of the dynamics of human-animal transmission and contribute to improved forecasting models of outbreak impacts (Jia et al. 2021). Advancing our knowledge of reverse zoonoses is critical to the development of enhanced outbreak surveillance and biosecurity systems.

2.2 Routes of Transmission

The transmission of an infectious disease depends on the type of interactions that occur between humans, animals, and/or their environments. Compared to the better understood transmission routes of zoonotic diseases, human-to-animal transmission still merits more comprehensive investigation (Al-Tawfiq and Memish 2014). Given a global increase in industrial animal production, increasing proximity between humans and animals across multiple settings provides opportunities for humans to spread shared pathogens to animals through reverse zoonoses. Pathogen transmission generally occurs through the inhalation, ingestion, or contamination of mucous membranes or broken skin by respiratory droplets, bodily fluids, secretions, or other excretions (Pantin-Jackwood et al. 2010). Transmission of pathogens to animals may also occur through the ingestion of contaminated feed. The role of vectors in biologic or mechanical disease exposure has been documented but still requires further research (Patel et al. 2022). Ecological and viral characteristics can directly contribute to the transmission of causative pathogens in a host. Pathogens must be able to evade immune response and colonize the host, be nutritionally compatible with the host, be able to reproduce using host resources, and exit and spread to a new host (Alberts 2015). In addition, anthropogenic activities may facilitate favorable

environments for reverse zoonoses. Increasing intensity of interaction and proximity between humans and animals is found to be associated with disease emergence (Despommier et al. 2006).

2.3 Use of New Technology

While basic PCR measures and viral isolation approaches remain key to the surveillance and detection of pathogens, there have been several innovations that have further enhanced novel disease detection capabilities. A large variety of data mapping techniques are now available with disease tracing, which enable individuals to better visualize the spread of disease, susceptible animals, or infected humans with concurrent time and location tags. Such visualization not only assists epidemiologists in researching the movement of the disease but can also be used to educate policymakers and the public.

Compared to a general analysis of the overlap between host animals and human patients, genomic analysis has become more common to distinguish different pathogen strains. For example, genomic sequencing and phylogenic analysis have been widely used in current anthroponotic research. By building up the phylogeny of a core genome (Linz et al. 2018), the evolutionary relationship between different clones can be laid out for researchers and epidemiologists. These methods help to provide more substantial evidence for the transmission pathways of the disease. Such analysis enables health scientists to distinguish between diseases that co-infect animals and humans, zoonotic transmission, and reverse zoonotic transmission. Further analysis of the phylogenetic relationships between disease strains also aids researchers and health practitioners to better predict possible transmission routes, which can then be used for preventative measures.

Besides increased attention to the general phylogenetic relationships, detailed genetic studies have also been implemented. By comparing the results from DNA fingerprinting and repeated PCR results, researchers can recognize and begin to develop responses to mutations that occur during repeated or prolonged transmission (Hasan et al. 2018). This could provide information on highly conservative sequences or key mutations that could lead to improvements in transmissibility, lethality, and antimicrobial resistance (Hosie et al. 2021; Li et al. 2019). By analyzing the conservative sequences, it is possible for researchers to develop innovative testing methods that could remain effective despite the occurrence of further mutations. Sequence data also helps researchers to develop more effective vaccines. The inclusion of research findings examining possible differences among human and animal strains could drive the expansion of more targeted measures. Such information could also help us to predict the harm of specific pathogens or the impact we could expect from their spread to provide more information and urgency for higher-level policymaking.

2.4 Epidemiology of Zoonotic and Reverse Zoonotic Events (Supported with Heat Map and Frequency Map) (Fig. 1)

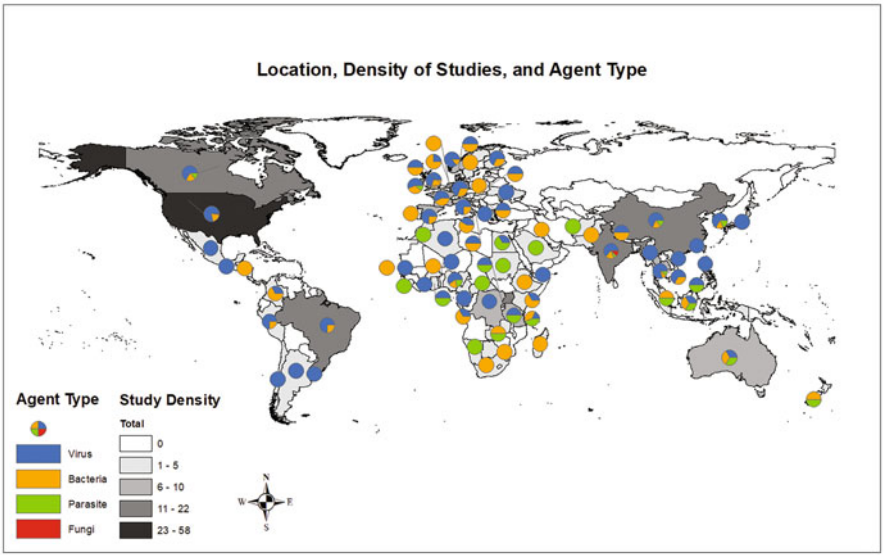

Fig. 1 Map of the density of studies by location and reverse zoonotic agent examined. Study locations without specific country names (ex. Antarctica) were excluded. Country delineation was compiled according to the 2021 World Bank standards. Map created in ArcMap 10.6 (ESRI, Redlands, CA); no copyrighted material was used. ESRI Environmental Systems Research Institute

2.5 Evidence of Reverse Zoonosis of Viruses and Disease Symptoms in Animals and Humans

The rapid increase in the global human population coupled with intensive and frequent traveling for trade, business, and recreational purposes has posed an increased threat regarding the transmission of viruses from humans to animals which may have a negative impact on biodiversity, wildlife conservation, and public health. Human-to-animal virus transmission jeopardizes the health and well-being of wild and domestic animals and the viruses which cause spillback (reverse zoonoses) to animals from humans may cycle back to infect humans again. Several barriers need to be crossed for a virus spillover or species jump between humans and animal species to occur. There must be frequent contact between humans and animals and sufficient compatibility between the virus and the new host to allow for attachment and replication. During the last decade, several reverse zoonoses events among humans, domestic, and wild animals have been reported (Sooksawasdi Na Ayudhya and Kuiken 2021; Messenger et al. 2014; Fagre et al. 2021) (Table 1).

[a]Shrivastava et al. (2020) study included co-infection of viral and parasitic pathogens

Measles is a highly contagious virus that is endemic chiefly among humans. *Measles morbillivirus* (MeV) generally does not occur in monkeys in the wild but can become an important pathogen when nonhuman primates are held in captivity and exposed directly or indirectly with humans (i.e., tourists, visitors, caretakers, etc.) who are infected with the measles virus. Outbreaks of measles in free-living and laboratory primates are known to occur coincidentally with human outbreaks. Several measles outbreaks following shipment of monkeys or introductions into an established colony have been described (Jones-Engel et al. 2006; Levy and Mirkovic 1971; MacArthur et al. 1979; Potkay et al. 1966; Remfry 1976; Shishido 1966; Welshman 1989). The pathogenesis of MeV infection in nonhuman primates is similar to that in humans (Choi et al. 1999). It is known to induce immunosuppression in affected humans and nonhuman primates by disrupting both cellular and humoral immunity, which can result in various secondary opportunistic infections. This pathogen has resulted in significant morbidity and mortality among nonhuman primate populations. Both natural and experimental measles infection can cause disease of varying severity with pathogenesis similar to that of human MeV infection. Erythematous maculopapular skin rash and presence of multinucleated syncytial cells in the lungs are regarded as pathognomonic for measles virus infection. Endometritis, cervicitis, and abortion associated with measles virus have been described in rhesus monkeys (Choi et al. 1999; Willy et al. 1999).

Similarly, herpes virus infections are common in humans and usually result in mild disease characterized by recurrent mucocutaneous lesions. Human simplex herpesvirus (HSV) infections have also been reported in several nonhuman primates along with the domestic rabbit, chinchilla, and the African pygmy hedgehog (Allison et al. 2002; Araujo et al. 2016; Barnes et al. 2016; Bhatt et al. 1966; Bruno et al. 1997; Costa et al. 2011; Eberle and Hilliard 1989; Emmons and Lennette 1970; Gilardi et al. 2014; Gozalo et al. 2008; Heldstab et al. 1981; Huemer et al. 2002; Imura et al. 2014; Juan-Sallés et al. 1997; Kik et al. 2005; Kreutzer et al. 2011; Landolfi et al. 2005; Longa et al. 2011; Marcia Helena Braga Catroxo et al. 2020; Matushima 2014; Mätz-Rensing et al. 2003; McClure et al. 1980; Meléndez et al. 1972; Sakulwira et al. 2002; Schrenzel et al. 2003; Smith et al. 1969; Weissenböck et al. 1997; Wohlsein et al. 2002; Schmitt et al. 2014). New World monkeys are particularly susceptible and often succumb to the disease. Herpes viral interspecific transmission creates significant risk for captive primates and the human handlers working with them. Reverse zoonosis events of HSV have resulted in several outbreaks in various parts of the world. Transmission in nonhuman primates has occurred by direct contact with mucosal surfaces, wounds, and maternal milk or through contaminated feed with HSV. In contrast to infection in humans, significant and often fatal disease occurs with HSV infection in a variety of nonhuman primates and other species. Affected animals have presented with whitish vesicular lesions on the soft palate and ulcerative tongue, as well as enteritis, severe emaciation, vomiting, serous nasal and ocular discharge, dyspnea, neurological signs, prostration, and death (Landolfi et al. 2005).

While the many types of adenoviruses (AdVs) are in general thought to be host-specific, there is increasing evidence that these viruses may infrequently cross

species. In particular, there is evidence that nonhuman primates have been infected from human reservoired AdVs. This risk will likely be higher where contact between species is more prevalent, such as with captive and habituated animals (Dehghan et al. 2019; Medkour et al. 2020; Roy et al. 2009; Shrivastava et al. 2020; Pauly et al. 2015). Recently, similar AdVs in humans and gorillas have been detected and sequences derived from gorillas revealed high similarity to human sequences, suggesting the potential for zoonotic transmission (Medkour et al. 2020). Similar findings have also been shown for feline AdVs, which has been demonstrated to be genetically homologous to human AdV type 1.

Multiple types of hepatitis viruses (HV) are major threats to human and animal health. However, sources of viral infection for many animals are unknown since transmission may occur from animal to animal, human to human, animal to human, and human to animal. Although animal-to-human transmission of HV is relatively well described, pathogen transmission in the opposite direction is poorly understood. For instance, swine function as a reservoir for hepatitis E virus (HEV) infections in humans but there is no clear evidence yet of human HEV spillbacks from humans to swine or other animals. Persons with occupational contact to domestic pigs, such as slaughterhouse workers, pig farmers, or veterinarians, exhibit significantly higher anti-HV antibody prevalence than the general population. Farm animals are transported across wide geographical ranges and often interact with wild species that they would never have encountered naturally. With intensified global animal production and an increase in the movement of both animals and humans, a human-originated pathogen could easily circulate and eventually adapt in different niches/hosts/species (Messenger et al. 2014). Detection of hepatitis B virus (HBV) in old-world primates, neotropical primates, domestic animals, bats, and rodents suggests that transmission from humans to animals or animals to humans is likely to occur wherever there is habitat overlap (Vieira et al. 2019).

Multiple types of rotaviruses (RV) are a major cause of severe gastroenteritis and mortality in young children and animals. The interspecies transmission of animal RV to humans and back to animals is plausible due to the close contact between animals and humans. It may augment interspecies infections and genetic reassortment during co-infection with rotavirus strains from different host species. The reassortment may further result in the evolution of novel or atypical RV. There are several pieces of evidence that demonstrate a potential reverse zoonotic transmission cycle of human RV to animals (Abe et al. 2010; Choudhary et al. 2017; Steyer et al. 2008; Wu et al. 2017; Kumar et al. 2018; Sharma et al. 2013; Ghoneim and K.A.A.-M.a.H.S. 2019).

Human noroviruses (HuNoVs) are the predominant cause of foodborne gastroenteritis worldwide. The possibility of animal transmission of HuNoV is also supported by previous studies, which observed HuNoVs in the feces of cattle, pigs, dogs, birds, and a rat (Caddy et al. 2015; Charoenkul et al. 2020; Summa et al. 2018, 2012; Wolf et al. 2013; Mattison et al. 2007). HuNoV sequences detected in avian fecal samples were identical or nearly identical to previously published sequences from human samples and differed from sequences identified in other avian or murine samples (Summa et al. 2018).

Humans and nonhuman primates are closely related species who share a general predisposition for pathogen exchange and reverse zoonotic transmission risk. Anthroponotic respiratory viruses including human metapneumovirus (hMPV), rhinovirus, respiratory syncytial virus (RSV), and parainfluenza virus (PIV) have caused notable morbidity and mortality among wild apes including chimpanzee, gorilla, and bonobo populations. These infections have heightened concerns about the risk of human pathogen transmission to wild animals and critical effects of anthroponotic transmission on ecosystem biodiversity, conservation efforts, and the economy. HMPV and PIV have been identified as causative agents in morbidity and mortality events in other nonhuman primate populations in the wild and in captivity (Hanamura et al. 2008; Kaur et al. 2008; Köndgen et al. 2010; Patrono et al. 2018a; Scully et al. 2018; Slater et al. 2014; Szentiks et al. 2009; Unwin et al. 2013; Negrey et al. 2019; Sojka et al. 2020; Yoshida et al. 2021; Jones-Engel et al. 2001; Kilbourn et al. 2003). HMPV infections in Tanzania, hMPV and human respirovirus 3 in Uganda, rhinovirus C in Uganda, and coronavirus OC43 have been implicated to have significant mortality in wild chimpanzees (Kaur et al. 2008; Patrono et al. 2018a; Scully et al. 2018; Negrey et al. 2019). In 2009, hMPV contributed to the deaths of two gorillas during an outbreak of severe respiratory infection (Palacios et al. 2011). hRSV has been documented to simultaneously infect lowland, wild bonobos, chimpanzees, and people (Szentiks et al. 2009; Unwin et al. 2013; Grützmacher et al. 2018, 2016; Mazet et al. 2020). Co-infection with other bacterial pathogens could also worsen outcomes of anthroponotic respiratory infections in nonhuman primates. Frequent human contact predisposes wild animals to respiratory viruses of human origin, especially in zoos and wildlife parks (Kilbourn et al. 2003; Buitendijk et al. 2014; Kooriyama et al. 2013).

In addition to human respiratory viruses, Zika virus, dengue virus (DV), Ebola virus (EBOV), and human enterovirus (EV) have also been reported in animals, although routes of transmission are not clear (Kilbourn et al. 2003; Favoretto et al. 2019; Kato et al. 2013; Terzian et al. 2018; Williams et al. 2008; Barrette et al. 2009; Bermejo et al. 2006; Demetria et al. 2018; Fieldhouse et al. 2018). The H1N1pdm09 virus is anthroponotic and has demonstrated cross-species transmission in a variety of animal species, including swine, cats, ferrets, dogs, turkeys, and cheetahs. In all these reported cases, some human owners or animal caretakers were reported to have influenza-like illness and there were frequent contacts and close interaction between the infected animals and humans prior to the detection of the virus in the animal. Human-to-swine transmission of H1N1pdm09 is the most frequently reported reverse zoonoses during the last decade and detection of human-origin H1N1pdm09 in swine herds was reported in many countries (Sooksawasdi Na Ayudhya and Kuiken 2021). In Canada, the first human-to-swine transmission of H1N1pdm09 influenza was observed at a swine farm (Howden et al. 2009). Since then, the H1N1pdm09 virus has transmitted repeatedly from humans to swine spanning six continents (Forgie et al. 2011; Hofshagen et al. 2009; Moreno et al. 2010; Pereda et al. 2010; Sreta et al. 2010; Kim et al. 2011; Deng et al. 2012; Chastagner et al. 2019; Ducatez et al. 2015; Grøntvedt et al. 2013; Njabo et al. 2012; Osoro et al. 2019a; Adeola et al. 2015, 2017; Arunorat et al. 2016; Ayim-Akonor

et al. 2020; Er et al. 2016a, 2020; Rajão et al. 2013; Senthilkumar et al. 2021; Baudon et al. 2015; Meseko et al. 2014; Nagarajan et al. 2010; Ma et al. 2018; Song et al. 2010; Terebuh et al. 2010; Trevennec et al. 2012; Sabale et al. 2013; Nelson et al. 2015; Mon et al. 2020; Pippig et al. 2016; Bálint et al. 2013; McCune et al. 2012). Pigs can act as an active reservoir for H1N1pdm09 virus. Reverse zoonosis events linked to infected farmers with H1N1pdm09 virus have been supported by serological and molecular diagnostics (Forgie et al. 2011; Holyoake et al. 2011). Sequencing analysis has shown that the viruses infecting humans and pigs are highly similar; hence, H1N1pdm09 does not require major changes to adapt and cause replication in swine (Sooksawasdi Na Ayudhya and Kuiken 2021; Forgie et al. 2011; Song et al. 2010). Besides domestic turkeys, reverse zoonosis events of H1N1pdm09 virus infections have not been reported in other avian species over the years. Sporadic infections of H1N1pdm09 have been mainly reported in turkey breeder flocks and sick farm workers potentially transmitted virus to breeder turkeys during artificial insemination (Berhane et al. 2010; Mathieu et al. 2010). The farm workers were showing influenza-like illness symptoms and had antibodies against H1N1pdm09 virus in their serum samples. Viruses from infected farm workers and turkeys revealed highly similar sequences which further supported worker-to-turkey transmission (Sjurseth et al. 2017). Seroconversion against H1N1pdm09, virus isolation, and molecular detection of H1N1pdm09 virus in several organs of infected turkeys confirmed H1N1pdm09 influenza in turkey breeder flocks (Sjurseth et al. 2017; Reid et al. 2012). No mortality was reported among infected turkeys and clinical signs ranged from none to mild (Sooksawasdi Na Ayudhya and Kuiken 2021; Sjurseth et al. 2017; Reid et al. 2012).

Human influenza viruses (H3N2 and H1N1pdm09) isolated from mink strongly suggest human-to-mink virus transmission (Gagnon et al. 2009). Recently, a serological survey revealed that farmed mink were commonly infected with human H3N2 and H1N1pdm09 and transmission of human influenza viruses occurred from humans to mink (Sun et al. 2021). During the pandemic, a mink farm in Norway reported H1N1pdm09 virus infections in American mink and eight striped skunks died on a mink farm in Canada (Åkerstedt et al. 2012; Britton et al. 2010). Phylogenetic analysis revealed highly similar sequences among those derived from infected minks and humans during the same pandemic. Sequences obtained from infected mink were highly similar to human-derived isolates during the H1N1pdm09 pandemic indicating transmission from humans. The source of transmission could be sub-clinically infected humans, fomites, or virus-contaminated feed from infected pig offal. Higher mortality rates were reported among infected minks due to severe respiratory disease.

There are many reports of H1N1pdm09 virus infection in companion animals (e.g., dogs, cats) (Sooksawasdi Na Ayudhya and Kuiken 2021; Sabale et al. 2013; Ali et al. 2011; Damiani et al. 2012; Fiorentini et al. 2011; Ibrahim et al. 2016a; Kwasnik et al. 2020; Löhr et al. 2010; Pigott et al. 2014; Ramírez-Martínez et al. 2013; Said et al. 2011; Seiler et al. 2010; Yin et al. 2014; Kovalenko et al. 2021; Sponseller et al. 2010; Su et al. 2014, 2013; Zhang et al. 2015; Zhao et al. 2014; Jang et al. 2017; Lin et al. 2012; McCullers et al. 2011; Sun et al. 2014; Tangwangvivat

et al. 2019). Molecular diagnostics performed on tissue organs including tonsils, trachea, lungs, and nasal swab and pharyngeal specimens detected H1N1pdm09 viral RNA (Lin et al. 2012; Campagnolo et al. 2013). A sequence analysis revealed a close relationship to H1N1pdm09 virus from infected humans and animals during the pandemic (Fiorentini et al. 2011; Lin et al. 2014). In addition, detection of antibodies against H1N1pdm09 virus in cats and dogs during the period of virus spread in the human population strongly supports the occurrence of reverse zoonoses. Since companion animals often live together in close contact with humans, the mode of transmission could be direct contact between animals and humans during the same time period (Dundon et al. 2010; Zhao et al. 2014). A case of natural H1N1pdm09 infection in a pet ferret was also reported (Campagnolo et al. 2013; Lin et al. 2014; Swenson et al. 2010). Serological studies showed that group housing of animals likely facilitated efficient intraspecies transmission, including cat-to-cat transmission and ferret-to-ferret transmission (Fiorentini et al. 2011; Campagnolo et al. 2013). However, H1N1pdm09 virus transmission between dogs seemed to be limited. Although all of these species were susceptible to H1N1pdm09 virus infection, their clinical signs varied. Cats and ferrets often developed severe respiratory signs, including dyspnea, coughing, and sneezing, and even died from the infection (Sooksawasdi Na Ayudhya and Kuiken 2021; Sponseller et al. 2010; Campagnolo et al. 2013, 2011; Knight et al. 2016). However, dogs either showed no clinical signs or only mild respiratory signs, such as rhinorrhea and coughing (Sooksawasdi Na Ayudhya and Kuiken 2021; Lin et al. 2012).

Evidence of H1N1pdm09 virus reverse zoonoses has been shown among wild animals kept in captivity. This includes cheetah, elephants, a Bornean binturong, an American badger, a black-footed ferret, and giant panda (Crossley et al. 2012; Lin et al. 2014; Goldstein et al. 2013; Paungpin et al. 2017; Schrenzel et al. 2011; Martelli et al. 2019). All animals were housed separately from other wildlife and the source of transmission was not exactly known. It is possible that tourists, caretakers, and veterinarians might have caused a spillback of the virus to zoo animals. The infected giant panda, American badger, and the Bornean binturong showed severe signs of respiratory infection. However, the black-footed ferret did not show any clinical signs (Schrenzel et al. 2011). In addition, H1N1pdm09 has also been reported in Asian elephants. Although the source of infection could not be confirmed, animal caretakers and tourists were implicated as a possible source of transmission (Paungpin et al. 2017).

Like Asian elephants, evidence of H1N1pdm09 virus infection among nonhuman primates has been reported in some studies (Buitendijk et al. 2014; Kooriyama et al. 2013). However, there was no clear association or evidence that H1N1pdm09 was solely responsible for clinical signs of disease or mortality from H1N1pdm09 virus infection in nonhuman primates (Sooksawasdi Na Ayudhya and Kuiken 2021; Buitendijk et al. 2014). There are limited serological and epidemiological studies among captive wild animals and thus it is still largely unknown whether these animals could transmit virus to other closely associated animals or act as a new reservoir for the virus. In addition, H1N1pdm09 virus infections have also been reported in giant anteaters, seals, and sea lions (Goldstein et al. 2013; Boyce et al.

2013; Nofs et al. 2009). The only free-living wild animal species in which H1N1pdm09 virus has been reported is the striped skunk. Sequencing and phylogenetic analysis of virus isolated from affected animals were highly related to H1N1pdm09 virus circulating in humans (Britton et al. 2010, 2019). The source of infection was unclear. In one study, the skunks lived near a mink farm, suggesting that spillover of H1N1pdm09 virus from infected mink farm workers or infected mink may have occurred (Britton et al. 2010). In another study, the skunks were found in an urban park where hand feeding by park visitors normally took place (Britton et al. 2019). Clinical signs were not observed in all infected minks and only fatally infected skunks showed purulent nasal exudate.

Natural infection of SARS-CoV-2 has been reported in domesticated and wild animal species. The frequency of spillover events to other species has been relatively low, despite the high incidence of SARS-CoV-2 human infection. Some studies have reported acute SARS-CoV-2 infection in dogs and cats who had close interaction with SARS-CoV-2-infected individuals, indicating a strong possibility for human-to-pet transmission (Sailleau et al. 2020; Segalés et al. 2020; Sit et al. 2020; Ruiz-Arrondo et al. 2021; Newman et al. 2020; Musso et al. 2020; Barrs et al. 2020; Hamer et al. 2020; Gaudreault et al. 2020; Garigliany et al. 2020; Klaus et al. 2021; Pagani et al. 2021; Patterson et al. 2020). There are several reports which describe natural infection of SARS-CoV-2 infections in zoo animals involving large felids and nonhuman primates. Most zoo animals do not exhibit any clinical signs of infection and remain largely asymptomatic. Conversely, infected companion animals (e.g., dogs, cats) have usually presented with asymptomatic or mild infections involving respiratory and digestive systems. Chicken, ducks, dairy animals, and pigs have shown less susceptibility to SARS-CoV-2 infection. Camels and alpacas are known carriers of Middle East respiratory syndrome virus (MERS-CoV), but show no susceptibility to SARS-CoV-2. Naturally acquired infections of SARS-CoV-2 have been demonstrated in tigers, lions, gorillas and chimpanzees, domesticated ferrets, mink, and white-tailed deer (Kuchipudi et al. 2022; McAloose et al. 2020; Bartlett et al. 2021; Wang et al. 2020a; Mitchell 2021; Karikalan et al. 2021; Mishra et al. 2021; Fernández-Bellon et al. 2021; Glasser et al. 2021; Gortázar et al. 2021; Molenaar et al. 2020; Oreshkova et al. 2020; Oude Munnink et al. 2021; Hammer et al. 2021; Aguiló-Gisbert et al. 2021; Shriner et al. 2021). All such cases of natural infection have been associated with SARS-CoV-2-infected animal caretakers or tourists who transmitted the virus to animals by their direct or indirect contacts. Like other animals, these animals exhibited a wide range of clinical signs from mild-to-severe respiratory and gastrointestinal signs (Oreshkova et al. 2020).

Apart from direct human-to-animal transmission (e.g., by physical contact with domestic and wild animals), transmission to animals via human waste and discarded items is also likely. Contamination of aquatic systems with unmanaged feces and improperly disposed personal protective equipment from infected humans could be a route for spillover into aquatic and wild mammals. Current role of wildlife in the global epidemiology of SARS-CoV-2 seems negligible. However, wildlife could become a potential reservoir for SARS-CoV-2 over time and may further transmit

the virus to humans. Phenotypic variants could also evolve as the virus adapts to new species facilitating continued transmission to humans and other species.

2.6 Evidence of Reverse Zoonosis of Bacteria and Disease Symptoms in Animals and Humans

In recent years, reverse zoonotic transmission of *Mycobacterium tuberculosis* and *Mycobacterium bovis*, human pathogens that cause tuberculosis (TB), have been reported in a wide range of wildlife species. While the actual host range is unknown, between 1974 and 2019, *M. tuberculosis* was isolated from 22 animals. *M. tuberculosis* transmission between human and animals was reported among companion pets in households and among the livestock population (Fernandes et al. 2018; Hackendahl et al. 2004; Kandefer-Gola et al. 2016; Schmidt et al. 2008; Weese et al. 2006; Ackerman et al. 1974; Every et al. 2011; Mittal et al. 2014; Špičić et al. 2012; Thakur et al. 2012). While this finding may accentuate the importance of effective TB detection in human-habituated areas, most reverse zoonotic bacterial infections reported have been among captive wild animals. The pathogens detected in this group include *Staphylococcus aureus, Streptococcus pneumoniae,* and *Campylobacter* spp. (Szentiks et al. 2009; Nagel et al. 2013; Seguin et al. 1999; Senghore et al. 2016; Sørensen et al. 2019; Unwin et al. 2013; On et al. 2019). Close contact, common feeding and drinking sources, and exposure to infected caretakers, veterinarians, and visitors are suspected transmission routes of human-to-animal transmission, which suggests that zoos, research facilities, and wildlife sanctuaries may all serve as reservoirs of infection and spread of the disease.

An extensive study of the prevalence of reverse zoonotic transmission is usually carried out following a report of an outbreak. Prevalence studies in the livestock industry detected several cases of zoonotic bacterial species moving from a farm worker carrying the disease to susceptible livestock. *S. aureus* and *M. tuberculosis* are found in livestock animals like cattle, swine, camels, and goats (Adesokan et al. 2019; Berg et al. 2009; Cobo-Angel et al. 2019; Crestani et al. 2021; Osadebe et al. 2013; Sunde et al. 2011; van de Vijver et al. 2014; Gumi et al. 2012). Other bacterial species were found in livestock and domestic animals such as *Acinetobacter baumannii* in sheep; *Escherichia coli* in chickens, dogs, and horses; *Salmonella* in poultry; and methicillin-resistant staphylococci (MRS) in companion animals living nearby livestock farms (Linz et al. 2018; Li et al. 2019; Nguyen Vinh et al. 2016; Ewers et al. 2010; Post et al. 2019; Loncaric et al. 2016; Kottler et al. 2010). Prevalence studies found bacterial pathogens in several wild animals in zoos, in a sanctuary, and in unprotected natural areas, particularly among primate species such as apes, lemurs, baboons, gorillas, and monkeys (Schaumburg et al. 2012, 2013; Rolland et al. 1985; Nizeyi et al. 2001; Rwego et al. 2008a; Tang et al. 2021). In addition, infections were found in other terrestrial mammals such as banded mongoose and stripe-faced dunnarts (Every et al. 2011; Pesapane et al. 2013). Interestingly, reports of enteric bacteria in Antarctic wildlife suggest a spread of zoonotic agents among seabirds in Antarctica (Cerdà-Cuéllar et al. 2019).

Many studies investigate clinical, microbiological, and molecular characteristics of pathogens in order to determine the epidemiologic origin of novel antimicrobial resistant zoonotic pathogens using genomic approaches. Oftentimes, the strains are found to be of human origin. Methicillin-resistant *Staphylococcus aureus* (MRSA) are prevalent in companion animals, livestock, and wildlife, but oxacillin-resistant *S. aureus* was reported only in Taiwan (Kwon et al. 2006; Morris et al. 2006; Price et al. 2012; Rubin et al. 2011; Feßler et al. 2018; Hsieh et al. 2008). Studies suggest zoonotic pathogens harbor antimicrobial susceptibility of human origin, for example, extended-spectrum beta-lactamases (ESBL) producing enterobacteria in fruit bats, *Clostridium difficile* in farm animals, *Enterococcus faecalis* in poultry, and *E. coli* in chimpanzees (Hasan et al. 2018; Mbehang Nguema et al. 2020; Knetsch et al. 2018; Goldberg et al. 2007). Some studies of *M. tuberculosis* in wildlife unintentionally discovered a genetic similarity between human and animal strains (Goldberg et al. 2008; Michel et al. 2013; Prasad et al. 2005). Studies of human pathogens in aquatic species found the same conclusion such as *Serratia marcescens* in mammals and fish and *Streptococcus agalactiae* in elkhorn coral (Delannoy et al. 2013; Sutherland et al. 2011).

2.7 Evidence of Reverse Zoonosis of Parasites and Disease Symptoms in Animals and Humans

Zoonotic parasites can be transmitted bidirectionally from humans and animals, often via fecal-oral exposure pathways due to contaminated environmental spaces, food, or water. Poorly managed excreta from free-roaming livestock and other animals, inadequate community sanitation services, and areas with open defecation can result in fecal pollution of private and public settings which expose humans and animals to shared pathogens. Safe handling, storage, and treatment of human and animal waste are critical to the prevention of enteric parasites which often follow exposure pathways of contaminated food, water, soil, hands, personal items (i.e., fomites), and filth flies.

For instance, many *Cryptosporidium* spp. are shared between human and animal hosts with several incidents of, or potential for, reverse zoonotic transmission occurring in livestock, companion animals, and wildlife after human contact (Shrivastava et al. 2020; Wang et al. 2020b; Schiller et al. 2016; Ibrahim et al. 2016b; Learmonth et al. 2001; Coklin et al. 2007; Dixon et al. 2011; Graczyk et al. 2001; Guk et al. 2004; Krawczyk et al. 2015; Mynářová et al. 2016; Nizeyi et al. 1999; Nolan et al. 2017; Sak et al. 2014). Likewise, *Giardia duodenalis/Giardia intestinalis* has evidence of probable reverse zoonotic transmission from humans to animals (Coklin et al. 2007; Dixon et al. 2011; Krawczyk et al. 2015; Mynářová et al. 2016; Arafa et al. 2013; Graczyk et al. 2002a; Johnston et al. 2010; Nasher 1988; Sá et al. 2013; Sak et al. 2013; Sleeman et al. 2000; Tangtrongsup et al. 2019; Ash et al. 2010; Teichroeb et al. 2009). *Pentatrichomonas hominis* and *Entamoeba* sp., while considered non-pathogenic to humans, can serve as fecal indicator organisms for proximal water and/or food contamination and have the potential for reverse zoonotic transmission leading to diarrheal disease in animals (Nolan et al. 2017; Arafa et al. 2013; Li et al. 2016).

Gastrointestinal parasites *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, and *Encephalitozoon cuniculi* can cause microsporidiosis, sometimes referred to as a fungal infection, and there is probable evidence of human-to-animal transmission (Sak et al. 2014; Yu et al. 2017; Graczyk et al. 2002b). Additionally, several soil-transmitted helminths like *Ascaris* sp., hookworm, and *Trichuris* spp. can produce infectious particles that are persistent in the environment allowing for reverse zoonoses to occur in animals that live in close proximity to humans and human waste (Arafa et al. 2013; Nasher 1988; Adejinmi 2008; Murray et al. 2000; Mohd-Shaharuddin et al. 2019; Chang et al. 2006).

Alternatively, the parasitic disease of leishmaniasis is a vector-borne zoonoses caused by the bite of an infected female sand fly. This insect vector takes blood meals from both humans and animals and can spread *Leishmania* spp. resulting in multiple disease presentations in humans such as cutaneous, visceral, and mucosal leishmaniasis. Reverse zoonoses of cutaneous and visceral leishmaniasis present a potential exposure risk for animals, particularly dogs, in the vicinity of people and the sand fly vector (Dereure et al. 2003; Faulde et al. 2008a; Ait Kbaich et al. 2017). The human skin mite vector, *Scabies scabiei*, can also be transmitted from humans to animals and cause significant morbidity and mortality among immunocompromised hosts (Kalema-Zikusoka et al. 2002; Pusey 1998).

2.8 Evidence of Reverse Zoonosis of Fungi and Disease Symptoms in Animals and Humans

Over the last 5 years, there have been an increasing number of fungal infections identified among animals and humans. Fungal spores spread in the air and soil of which some are capable of causing infection (Gnat et al. 2021). Reviewing past reports on fungal infections demonstrates cases of reverse zoonoses between a pet owner and their animal(s). One such example is a report of *Trichophyton rubrum*. This fungal species is sometimes found to be related to ringworm in baboons, cats, cattle, and dogs. In one case report, *T. rubrum* was transmitted from the owner to a pet monkey (Pal et al. 1997). In a subsequent report of human-to-animal fungal infection, *Microsporum gypseum* was found to have transmitted from a pet owner to a puppy (Sharma et al. 2009). Beyond those examples of fungal reverse zoonoses due to close contact, an analysis of clades of *Candida albicans* in humans and wildlife has suggested possible reverse zoonoses. The authors suspect that transmission may have occurred due to wildlife having close contact with poorly managed human garbage including dirty diapers or half-eaten food, which could have been the source of infection (Wrobel et al. 2008). These reports have suggested the possibility of transmission of fungal infections from humans to animals. Since a variety of fungal infections are capable of transmission to both human and animal species, more attention is needed to monitor for potential reverse zoonotic events. Despite the limited number of reported cases, this may not be a true indication of low probability for such transmissions.

2.9 The Impact of Zoonosis and Reverse Zoonosis on Animals and Humans

The expenses associated with zoonoses can be measured from related prevention efforts, such as vaccination campaigns, to the health-care costs for treating a human or animal infection (Shaw et al. 2017). However, the costs of zoonoses extend beyond a single case of disease. The impacts and consequences of zoonotic and reverse zoonotic disease encompass more than just physical, social, mental, and emotional health but also the integrity of global economies, agricultural markets, tourism, trade and transportation, gender equality, children's health, international policy, the environment, wildlife conservation, trust in public health and veterinary public health, and more (Jordan et al. 2016; McDonald 2011).

Human effects of zoonotic disease expand beyond the infected person to their household and their communities. For example, if a person is sick from a zoonosis, they may experience pain, social stigma related to the illness, high individual or institutional medical care costs, acute or long-term disability, the inability to participate in normal activities such as childcare, loss of job productivity or lost wages, disruption in education, food insecurity, a risk for additional comorbidities, and even death (Shaw et al. 2017; Jordan et al. 2016). The global socioeconomic burden of zoonotic infections disproportionately impacts lower-income countries and marginalized, vulnerable communities (Grace et al. 2012). Cases of zoonoses are often underreported and categories of neglected zoonotic diseases may not be reflected in national morbidity or mortality statistics (Grace et al. 2012). Estimating the true burden of zoonotic disease for human and animal populations within these regions is challenging.

When an animal is sick from a zoonotic disease, they may also endure pain or death in addition to weight loss, decrease in milk production, infertility, the inability to procure a high trade or sale price, and costs associated with veterinary services (Shaw et al. 2017). Besides the significant harm zoonoses can have on a household's dietary access to animal-based food items or economic opportunity through sale or barter, the region or country may experience a restriction on their ability to export or trade in agricultural goods and food products during an outbreak event (Narrod et al. 2012; Martins et al. 2015). Global livestock production and agriculture is heavily dependent upon biosecurity measures from production to consumption (Waage and Mumford 2008). Without robust sanitation and hygiene measures in place at each farm and packaging facility, the potential for zoonotic disease transmission could be markedly high (Martins et al. 2015). For example, the World Bank has estimated that the economic loss from just six major zoonotic disease outbreaks between 1997 and 2009 was at least $80 billion USD and projected the costs for the global SARS-CoV-2 pandemic to be in the trillions (World 2006). Recognizing and responding to early infections of zoonotic or reverse zoonotic disease in either the human or animal host is critical to prevent further cases or outbreaks.

Spillover events, wherein humans are exposed to zoonotic pathogens largely circulating within wild animal reservoirs, are often due to anthropogenic changes to the land that disrupt the natural wildlife host and disease cycles and create new

opportunities for animal-human contact (Plowright et al. 2020). Since early human movement of people and animals, the spread of zoonotic pathogens into, and out of, previously undisturbed natural wildlife habitats have led to outbreaks and pandemics (May et al. 2021). Reverse zoonotic transmission of virus, bacteria, and parasites to wild animals (i.e., primates) can occur from contact with humans following conflict, land-use changes, and increased housing along conservation areas and national park boundaries (Dunay et al. 2018). As a result, humans could become potential reservoirs or intermediate hosts for some pathogens. Hunters, loggers, livestock herds and herders, farmers, researchers, and visitors have been known to spread emerging and reemerging diseases to and from wild animals through zoonotic spillover and reverse zoonoses (May et al. 2021; Plowright et al. 2017). Therefore, prevention of zoonotic and reverse zoonotic disease is also crucial for the conservation and protection of global biodiversity.

2.10 How to Prevent Occurrence of Reverse Zoonosis

Conventional surveillance measures for infectious disease outbreaks include seroepidemiological studies in outbreak areas, reducing distance (quarantine and physical distancing), vaccinating humans and animals, and conducting serosurveillance (Lee et al. 2021; Gray et al. 2015; Jefferson et al. 2011; Buddle et al. 2013; Bosco-Lauth et al. 2020; Jiles et al. 2014). However, these within-outbreak approaches are principally reactive rather than preventive. As cross-species spillovers result from a multi-level interaction between hosts, pathogens, and environment, ecological interventions to eliminate the environmental conditions that favor human-to-animal transmission could prevent the occurrence of reverse zoonosis. For instance, measures for reducing prevalence in reservoir hosts (i.e., vaccination, treating infections) and manipulating reservoir-host connectivity to reduce contact and spread rates (i.e., fences and translocation) or fertility control of susceptible species could prove effective strategies (Sokolow et al. 2019). In recent years, genomic-based approaches have gained momentum in research as they allow for the accurate identification of potential hotspots and locations with a high density of susceptible groups to make ecological interventions more cost-effective and sustainable.

Geographic proximity may increase the likelihood of cross-species transmission, but successful infection is determined by the biological compatibility of hosts and recipient species, primarily immunological profiles. Phylogenetic studies found that closely related species tend to have similar immunological responses and are of greater risk of interspecies transmission (Woolhouse et al. 2001; Ricklefs and Fallon 2002). Accurate identification of vulnerable species and their habitats can inform policymakers where an escalation in public health intervention may be needed. Further, genomic surveillance data of the pathogen's dissemination patterns can broadly describe outbreak dynamics. Such insights can fill the gap in monitoring epidemics, superspreading events, and differentiating between relapse and reinfection events (Kinganda-Lusamaki et al. 2021). Recently, research focus has been on

infectious disease forecasting models for prediction of characteristics of future outbreaks. The forecasting tools can provide useful guidance for the utility, scale, and timing of prevention and mitigation strategies (Scarpino and Petri 2019; Lutz et al. 2019).

Policy legislation and reinforcement play a vital role in transforming research into practice. In livestock production and wildlife conservation where transmission is more likely, vaccination in both animals and human must be required. Further regulation on regular health checks and disease screening is subject to the geographic area and vulnerability to outbreaks. Besides monitoring the transmission among livestock and wildlife populations, One Health efforts and professionals should pay more attention to the development of education and training related to reverse zoonosis among vulnerable populations to prevent future outbreaks. Owners of companion animals are also the target of such programs to reduce transmission in households where close proximity is often a major concern of secondary infection among close contacts. Importantly, one crucial improvement with the One Health approach is the cohesive cooperation between researchers in epidemiology and public health fields. Within the included titles, there was a lack of well-roundedness and connection in fields of both animal and human disease. Therefore, an adoption of the One Health approach must underlie the importance of transdisciplinary cooperation to achieve a multifaceted understanding of the spread of infectious disease, to better protect the health of humans and animals and their shared environment.

According to the definition given by the CDC, "One Health is a collaborative, multisectoral, and transdisciplinary approach—working at the local, regional, national, and global levels—with the goal of achieving optimal health outcomes recognizing the interconnection between people, animals, plants, and their shared environment" (Alves and Policarpo 2018). With the intent of reducing disease in both human and animals, a One Health approach seeks collaboration between experts in various areas. After reviewing reports on the topic of reverse zoonosis, several aspects of this model should be given more attention.

While human habitat has grown to have more overlap with natural habitat, leading to closer contacts between human and wild animals, the risk of disease transmission between human and domesticated animals should receive more consideration. Among recent reports on transmission of disease between animals and humans, whether zoonotic or reverse zoonotic, most of the cases were reported between farm animals and hosts (Mi et al. 2016; Europe, A.h. 2017; Kruse et al. 2004; Reperant et al. 2013; Di Marco et al. 2020; Sooksawasdi Na Ayudhya and Kuiken 2021). This grouping of animals and humans has provided an optimal environment for fostering disease transmission. However, there still lack a complete education system and preventative policy for most agriculture and food chain workers. This poses a risk not only for the transmission of disease to the host animals but would also endanger the health of the public as infectious agent could move into the larger global chain of food production and distribution.

In addition to consideration of animals within and around farms, more emphasis should be put on the threat of reverse zoonoses among companion animals. As people have close contact with their pets through sharing beds, kissing and

snuggling, and eating and drinking in proximity, the risk of disease transmission between human hosts and their pets also increases (Zhang et al. 2020; Zhao et al. 2014). For example, in recent reports on cases of SARS-CoV-2, there have been several instances of the transmission of the virus from infected people to their household pet animals (Forgie et al. 2011; Holyoake et al. 2011; Sweetline Anne et al. 2017). While early One Health work focused on researching ways to reduce disturbance of wild animals to prevent anthroponotic transmission of human pathogens, the policies and strategies relating to protecting companion animals require improvement. This is of special importance because when people are quarantined in response to a pandemic, the contact between the host and pet(s) is likely increased. In response to One Health's principle of "One Health involves everyone," we should encourage the importance of close observation of pet animals when an infected household member has been identified to prevent possible transmission in the home.

Besides seeking cooperation from stakeholders at the health professional level, we should also encourage more cooperation between researchers. Among the epidemiological reports included in this summary, the publications frequently lacked input from experts in the fields of both animal and human disease. Therefore, such reports usually suggested a possibility of transmission but did not provide tangible evidence that may have been garnered by working with a professional in the parallel areas of animal or human disease. By incorporating the principles of One Health, transdisciplinary cooperation can be enhanced that leads to a more multifaceted understanding of the spread of infectious disease that will better protect the health of all species.

2.11 Conclusions

The threat of disease derives from multiple host species and a variety of exposure pathways. The accelerating human impact on the natural world will likely introduce new opportunities for disease transmission stemming from emerging and reemerging pathogens, likely with zoonotic origins. While we must continue our efforts to discover intervention strategies to prevent, detect, and treat human infection, it is vital that we also devote new and innovative efforts towards the protection and conservation of animals. Intensified farming practices, wildlife habitat encroachment, and an increased desire for companion animals will forge even more intimate human-animal bonds in the coming years. It will take collaboration and communication between researchers and health professionals from both the human and animal fields to prepare, promote, and provide safe and healthy interactions for all.

Zoonoses in Food-Chain Animals with Public Health Relevance

Important Zoonotic Diseases of Cattle and Their Prevention Measures

3

Mo Salman and Katie Steneroden

Contents

Abstract

Cattle production is a vital component of the global food chain. Through meat or milk, animal protein is an essential dietary requirement for most people across the world. Increased cattle production will attempt to meet the need for more protein with both positive and negative impacts. Those impacts may include the spread of disease from livestock to humans directly or indirectly through milk, meat, hide, or manure. The following zoonotic diseases of cattle are included in this chapter due to their potential severity in human or cattle populations and/or their wide distribution or recent emergence: anthrax, bovine spongiform encephalopathy (BSE), bovine cysticercosis, bovine tuberculosis, brucellosis, cryptosporidium,

Cattle production is a vital component of the global food chain. Through meat or milk, animal protein is an essential dietary requirement for most people across the world. The need for animal protein is increasing. An estimated 50% increase in demand is expected by 2030 (Delgado et al. 1999; Jones and Thornton 2009). Increased cattle production will attempt to meet the need for more protein with positive and negative impacts, including the spread of diseases from livestock to people directly or indirectly through milk, meat, hide, or manure.

Threats from old and new pathogens continue to emerge, with contributions from changes in the environment, agriculture and food production systems, food processing, and the demography and connectivity of our world. At one extreme is low-intensity cattle farming, the type traditionally practiced in developing countries and rural households. The impact of disease outbreaks on the lives and livelihoods of these poor farmers is significant (Jones and Thornton 2009). In contrast, intensive farming systems in developed countries may contribute to the large-scale spread of pathogens during disease outbreaks. Zoonotic diseases can have a significant impact on national and international trade and contribute to human illness. We are faced with a changing landscape of infectious disease that affects both humans and animals. This change poses significant threats to the health and food security of the global citizenry (Atkins and Robinson 2013).

The majority of human pathogens now described are linked to animals. An average of three new infections are reported approximately every 2 years, with a new pathogen published every week (Gideon 2013). Nevertheless, good progress continues to be made in controlling several important livestock pathogens, and mechanisms are now in place to bring together the critical scientific expertise and political will to succeed.

The following zoonotic diseases of cattle are included in this chapter due to their potential severity in humans or cattle population and/or their wide distribution or recent emergence: anthrax, bovine spongiform encephalopathy (BSE), bovine cysticercosis, bovine tuberculosis, brucellosis, cryptosporidium, *Escherichia coli* O157:H7, leptospirosis, listeriosis, methicillin resistant *Staphylococcus aureus* (MRSA), Q fever, Rift Valley Fever, and *Salmonella*.

Zoonotic pathogens present considerable challenges to the health and wellbeing of cattle and humans. For some critically important diseases, the first line of defense will be implementing scientific approaches to diagnosis and control. What the future will bring with regard to zoonotic diseases is difficult to predict. A future where human and animal health practitioners work together to discover, control, and prevent zoonotic diseases will surely bring surprising and meaningful results.

Identifying and ultimately addressing emerging cross-species infections will require a "One Health" approach. Adopting and implementing appropriate intervention measures at the farm level will require behavior changes from the farmer (Ellis-Iversen et al. 2010). Some of these measures will require modification of practices and husbandry as well as policy changes. In 1989, the World Health Organization (WHO) promoted a Knowledge, Attitude, Beliefs, and Practices (KABP) framework that was later modified to Knowledge, Attitude, and Practices (KAP) as a tool to improve disease prevention strategies in different cultures around the world. In a recent example, a socio-ecological model that included dairy workers and an external agency in Colorado, USA, was presented by Palomares Velosa et al. (2020).

We attempted in this chapter to identify prevention measures for the underlying diseases with the hope that further assessment of these measures using the KAP approach under the One Health Concept can be applied.

3.1 Anthrax

Bacillus anthracis, the causative agent of anthrax, has a worldwide distribution in animal and human populations. In developing countries, anthrax is a significant problem in livestock and wildlife and among occupationally exposed individuals, including veterinarians, agricultural workers, and butchers (WHO 2013a). Anthrax is no longer a significant livestock disease in developed countries due to appropriate control measures, including prophylactic vaccination. While anthrax does occur sporadically in developed countries, its primary significance lies in its potential use as a bioterrorism agent.

Bacillus anthracis is a Gram-positive bacterium that forms spores when exposed to oxygen, which are highly resistant and long lasting in the environment. Human anthrax cases are associated with infection in livestock or exposure to contaminated products such as carcasses, hides, or wool. Instances of animal anthrax are associated with spore-contaminated pastures. The incidence of anthrax varies with the soil type, climate, animal husbandry, industrial hygiene, and disease reporting status of the country. Globally, anthrax is underreported in both humans and animal populations due to under-diagnosis and lack of internal and international reporting.

Infection can enter the body by ingestion, inhalation, or direct contact. It is generally considered that animals are infected by ingestion of contaminated food or water. In humans, infection mainly occurs by direct contact through a break in the skin. Biting flies and other insects have the ability to transmit the disease mechanically.

In cattle, anthrax usually manifests as peracute or acute disease. The peracute form is most common at the beginning of an outbreak, and animals are found dead without premonitory signs. After death, discharge of blood from the nostrils, mouth, anus, and vulva are common. The acute form runs a course of about 48 h with severe depression, lethargy, abortion, and fever. Necropsy findings include the absence of rigor mortis and gross enlargement of the spleen with natural orifices exuding dark, tarry unclotted blood. If anthrax is suspected, the carcass should not be opened, as

exposure to oxygen will cause spores to form, which may infect individuals and contaminate the environment.

In humans, the three main forms of disease are cutaneous, gastrointestinal, and inhalation anthrax. Cutaneous anthrax is most common and accounts for the vast majority of cases. The gastrointestinal form occurs from eating contaminated meat. Inhalation anthrax occurs through inhalation of the spores and is the most severe form (Decker 2003).

There are different assays for screening and diagnosis of anthrax in cattle. A stained smear of peripheral blood is usually considered the primary screening test to determine the presence of the bacilli in the blood. Confirmation is done by blood culture to identify the bacterial colonies. Fluorescent antibody techniques may also be used to confirm the infection. Animal passage assay may be necessary if antibiotic therapy is used (Dragon et al. 1999).

Two types of vaccines are currently used in cattle. The most known vaccine is the live attenuated strain of *B. anthracis*, resulting in long-term immunity (26 months), but there is a risk of causing the disease. The second vaccine is the cell-free filtrate of a culture of *B. anthracis,* which is incapable of causing anthrax, but it has only a short-term immunity (3–6 months) (WHO 2013a).

Treatment in animals and humans is mainly through the application of antibiotics. In animals, penicillin, streptomycin, and oxytetracycline are used. Anti-anthrax serum may be used in animals during the early stages of the disease, but severely ill animals are unlikely to recover. Human treatment is by penicillin and other antibiotics (Dragon et al. 1999).

Control measures are wide range and include vaccination, appropriate carcass disposal methods and decontamination, quarantine, and movement restrictions on milk and meat.

3.2 Bovine Spongiform Encephalopathy (BSE)

Bovine spongiform encephalopathy (BSE), also known as "mad cow disease," is a degenerative neurological disease of cattle. BSE is caused by misfolded proteins (prions) in the host cell that build up in the central nervous system (CNS) and eventually kill nerve cells. The nature of the transmissible agent is not well understood. The most accepted theory is that the agent is a modified form of a normal protein known as prion protein. For not yet understood reasons, the normal prion protein changes into a pathogenic (harmful) form that then damages the central nervous system.

BSE is one of several rare neurological diseases called transmissible spongiform encephalopathy (TSE). The other TSE diseases include scrapie, which affects sheep and goats, transmissible mink encephalopathy, feline spongiform encephalopathy, and chronic wasting disease of deer and elk. There are six TSE diseases that affect humans: kuru, classical Creutzfeldt-Jakob disease (CJD), variant Creutzfeldt-Jakob disease (vCJD), Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia, and sporadic fatal insomnia.

Variant Creutzfeldt-Jakob disease (vCJD) is a rare human TSE that research from the United Kingdom has associated with consuming products contaminated with CNS tissue from BSE-infected cattle. There have been about 200 cases in the world (most of these in the United Kingdom). Human TSEs also include sporadic Creutzfeldt-Jakob disease (sCJD or CJD), which is not related to BSE. About 85% of CJD cases are sporadic, with an annual incidence of about one case per 1 million people worldwide. The new variant or variant form (vCJD) affects younger people (average age at onset is 26 years) and has different clinical features from CJD.

There is strong epidemiologic and laboratory evidence suggesting that the same infectious agent causes vCJD and BSE. All cases of confirmed vCJD have occurred in people who have lived in geographic areas with BSE cases; the majority occurred in the United Kingdom, which has had the largest number of cases of BSE in cattle. The specific foods, if any, that may be associated with the transmission of this agent from cattle to humans are unknown. However, milk and milk products are unlikely to pose any risk for human exposure to the BSE agent.

Research indicates that the first probable infections of BSE in cows occurred during the 1970s, with the first two cases of BSE being identified in 1986. BSE may have originated from feeding cattle meat-and-bone meal (MBM) that contained BSE-infected products from a spontaneously occurring case of BSE or scrapie-infected sheep products. There is strong evidence and general agreement that the outbreak was amplified and spread throughout the United Kingdom cattle industry by feeding rendered, prion-infected, bovine meat-and-bone meal to young calves.

There is increasing evidence that there are different strains of BSE, the typical BSE strain responsible for the outbreak in the United Kingdom and two atypical strains (H and L strains). The typical BSE strain is responsible for most of the BSE cases in the world. In cattle naturally infected with BSE, the BSE agent has been found in brain tissue, in the spinal cord, and the retina of the eye. Additional experimental studies suggest that the BSE agent may also be present in the small intestine, tonsil, bone marrow, and dorsal root ganglia (lying along the vertebral column).

In response to the BSE epidemic, several countries instituted a series of measures to minimize the risk of disease transmission among both animals and humans. These included a ban on feeding ruminant protein to ruminants and removal of some “high risk” materials (such as brain, spinal cord, and intestines) from cattle at slaughter. Following the institution of these measures, the number of BSE cases has been decreased significantly (USDA-APHIS 2006, 2007).

To prevent BSE from entering the country, several countries prohibited the importation of live ruminants from countries where BSE is known to exist in native cattle. Some countries eliminated the importation of live ruminants and most ruminant products, including meat, meat-and-bone meal, offal, glands, etc., from all of Europe. Most of these countries also prohibited the use of mammalian protein in the manufacture of animal feeds given to ruminants. Testing for BSE under a national surveillance program among slaughtered cattle was implemented in several developed countries. Due to these safeguard measures, the risk of transmitting the BSE agent to humans has become negligible (Salman et al. 2012).

3.3 Bovine Cysticercosis –Taeniasis

Although bovine cysticercosis does not in itself represent an exceptionally serious human health risk, it is a signal of much more serious food safety and public health concerns. A finding of bovine cysticercosis is a signal that the animal feed system is contaminated and that cows are consuming human feces. Aside from *Taenia saginata*, other contaminants that pose threats to bovine and human health would also be expected to be present in human feces. These contaminants include but are not limited to drug-resistant bacteria, such as *E. coli* and *Salmonella*, *Taenia solium* (the pork tapeworm), drug residues, pain killers, hormones, other prescription drugs, illicit drugs, heavy metals, solvents, and other toxicants.

Taenia saginata (T. saginata) is a cestode tapeworm that causes bovine cysticercosis in cattle and taeniasis in humans. *Taenia saginata* is found worldwide, and human disease is highly endemic in Latin America, Africa, Asia, and some Mediterranean countries. Bovine cysticercosis occurs in areas where poor sanitation, poor food inspection, and close contact between humans and livestock are common.

Taenia saginata infection cycles between humans (primary host) and cattle (reservoir host). Humans infected with the tapeworm pass the eggs in their feces. Cattle become infected by ingesting materials contaminated with tapeworm eggs. Larvae form cysticerci in the animal's muscle tissue, humans ingest cysticerci in raw or undercooked beef, and the cycle continues. Tapeworms cannot be passed from person to person or spread between cattle. Clinical signs of cysticercosis in cattle and humans are mild to nonexistent. The most visible sign of tapeworm infection in humans is the active passing of tapeworm segments through the anus and in the feces.

Diagnosis of bovine cysticercosis is largely made during visual inspection of the carcass at slaughter. Serological tests, including ELISA, have been used in epidemiological studies for individual and herd diagnosis (WHO 2005). Taeniasis in humans is diagnosed by finding eggs or cestode segments on the human body or in the feces. Feces microscopy, ELISA, and molecular tests such as PCR may also be used (WHO 2005).

Infection in humans can be prevented by proper meat inspection and handling of meat at slaughter. When the disease is found in cattle, the meat may be condemned or temperature treated by freezing or heating to kill the parasite. Preventing and treating disease in people will prevent disease in cattle. Tapeworm eggs can survive in the environment for many months, depending on humidity and temperature. Infected people can shed hundreds of thousands of eggs each day, so people need to seek treatment to break the cycle.

3.4 Bovine Tuberculosis

Bovine tuberculosis (BTB) is a zoonotic and economically important disease of livestock. The disease was described over 2000 years ago and is responsible for devastating illness and death in humans and animals. Bovine tuberculosis has been

largely controlled in developing countries through government control programs and milk pasteurization. In developing nations where surveillance and control measures are inadequate, humans continue to become infected with BTB through animal contact and ingesting unpasteurized dairy products. Few developing countries have BTB control programs and immune system compromising disease conditions such as HIV allow for co-infection and increased morbidity and mortality (Miller and Sweeney 2013).

Most warm-blooded vertebrates, including humans, are susceptible to the disease-causing agents. Although the principle reservoir of *Mycobacterium bovis* (*M. bovis*) is cattle, this organism has a wide host range capable of producing progressive disease. Ungulates differ somewhat in resistance to *M. bovis* but have similar immune responses and pathological conditions. They all exhibit the classical lesions of tuberculosis.

The infection is caused by the bacterial genus *Mycobacterium.* Mycobacteria are acid-fast, aerobic, non-spore-forming, nonmotile, gram-positive rods containing high lipid content. Some of the lipids possess virulent and immunologic properties. The possible pathogenic role and the effect on the immune response of components of the complex mycobacterial cell wall are the subject of much attention and controversy (Behr 2013).

Bovine tuberculosis occurs throughout the world. The prevalence of *M. bovis* in cattle is low in developed countries due to successful eradication programs. Other countries have experienced increases in the rate of infection due to relaxation in surveillance activities.

Risk factors for cattle include overcrowding, the introduction of tuberculous animals, soil type, wildlife contact in specific geographical regions (UK, Ireland: badger, New Zealand: possum), the purpose of the cattle: dairy vs. beef, and type of management and husbandry – specifically in the type of disposal of the manure.

The most common mode of transmission of BTB is the aerogenous route. Infection can occur by ingestion and other less likely modes such as milk-borne, congenital, or sexually transmitted. Bacteria are excreted in exhaled air, sputum, feces, urine, milk, and discharges from the uterus, vagina, and draining peripheral lymph nodes. Cattle can develop bovine tuberculosis through exposure to other *M. bovis* infected species such as humans, deer, and elk (Bovine TB Advisory Group 2009).

Clinical signs of disease in cattle are variable depending on the location and extent of the lesions. Even with advanced disease, visible signs are frequently absent. If superficial lymph nodes are involved, they may be visibly enlarged and can rupture and drain through the skin. Enlarged internal nodes can cause signs of obstruction. With pulmonary involvement, a chronic cough can develop due to bronchopneumonia. In advanced lung disease, dyspnea occurs with increased respiratory rate and depth. Tuberculosis mastitis causes a marked induration and hypertrophy of the udder. General findings include anorexia, dyspnea, weight loss, weakness, and low-grade fluctuating fever. Often the main sign of tuberculosis is emaciation, despite adequate nutrition and care.

A definitive diagnosis for mycobacterial infection can be made by bacterial isolation and identification, which can be difficult and time-consuming. For example, in M. *bovis*

cultures, visible growth arises following 3–8 weeks of incubation. Conventional mycobacteriological identification procedures on culture media rely on differences in culture growth times, colony morphology, cellular morphology, antimicrobial sensitivity, and various biochemical test reactions. More recent radiometric procedures can expedite mycobacterial detection times, whereas gas-liquid chromatography and DNA probes can accelerate mycobacterial identification from cultures. Research on the use of DNA probes, specifically polymerase chain reaction (PCR), is currently in progress for molecular epidemiology of the disease in livestock species.

The tuberculin skin test is an in vivo diagnostic test that evaluates the cell-mediated immune response to mycobacteria exposure. The test is unable to differentiate between disease and immunity. To determine whether or not an animal is infected with *M. bovis*, tuberculin made from either the human or bovine bacilli (the mammalian tuberculins) is injected intradermally into the animal. Reactivity to tuberculin made from either of these bacilli is similar and is usually the greatest in animals sensitized specifically to these bacilli. The inflammatory response to the injection peaks 24–72 h after tuberculin injection and can linger for several weeks before diminishing. Failure of an animal with observable evidence of tuberculosis to show a palpable skin response to tuberculin at the time of test reading has been defined as anergy. Anergy indicates deficient T lymphocyte function.

Vaccines against *M. bovis* stimulate cell-mediated immunity. BCG (Bacillus of Calmette-Guerin, the modified *M. bovis* vaccine strain named after its two developers) is an attenuated strain of *M. bovis* used in human vaccination. BCG has also been utilized extensively to vaccinate cattle in numerous countries for many years. Protection produced by BCG vaccination of cattle is poor and causes tuberculin sensitivity in the animals, interfering with control and eradication programs based on tuberculin skin testing. By 1968, none of the national control programs for bovine tuberculosis included vaccination.

Treatment of tuberculosis in animals, in general, is discouraged due to possible public health hazards in retaining tuberculous animals. However, numerous procedures have been tried throughout the years without success to treat tuberculous cattle, including injection of live or dead bacilli, specific diets, fresh air, change of climatic conditions, x-ray therapy, serotherapy pneumothorax, and pneumoperitoneum. Chemotherapeutic drugs, including isoniazid, have been used in cattle and were found to only suppress the bacilli during the duration of drug therapy, with shedding of the organism possible after treatment.

Control measures include test and slaughter, active detection of lesion in cattle in slaughterhouses followed by traceback systems, and control of the disease in wildlife populations.

3.5 Brucellosis

Brucellosis is a zoonotic disease of major social and economic importance in most countries of the world. It is caused by several species of *Brucella* bacteria and affects several livestock species – mainly cattle, sheep, and goats. The economic importance

of the disease in cattle is due to a loss of production, primarily decreased milk production, abortion, and infertility. Brucellosis is found worldwide; however, it is limited to a specific *Brucella* species and host species in some geographical areas. Several countries have succeeded in eradicating the disease from specific host species; other countries are engaged in eradication programs. The growing phenomenon of international migration and tourism renews our concern with the prevalence and persistence of human brucellosis.

The *Brucella* spp. have a wide host range; however, they are not readily transmitted from preferential to dissimilar hosts. Nonpreferential hosts may harbor the bacteria, but it is considered an incidental infection. This incidental infection is usually localized and/or shows different clinical and pathological manifestations from those observed in the specific host. The host preferences of this bacterial agent are *Brucella abortus* in cattle, *Brucella melitensis* in sheep and goats, *Brucella suis* in swine, and *Brucella ovis* in sheep (Moreno et al. 2002).

The bacteria is an intracellular organism which is an important factor in its survival in the host and may explain both the transitory titers occurring in some hosts following isolated episodes of bacteremia and the disappearance of titers in hosts with latent infection. The bacteria can survive on grass for variable periods depending on environmental conditions. In temperate climates, infectivity may persist for 100 days in winter and 30 days in summer. The organism is susceptible to heat, sunlight, and standard disinfectants, but freezing is conducive to almost indefinite survival (Blasco and Molina-Flores 2011).

Risk factors associated with infection and the diseases in cattle population include: (1) contact with infected materials – aborted fetus, placenta, semen, secretion, etc.; (2) direct contact with infected animals – including wildlife species; (3) high population density, particularly in dairy farming systems; (4) breeding management and husbandry such as contaminated maternity pens, unregulated breeding time; and (5) poor hygiene/husbandry – particularly during calving seasons.

The infection in humans is nonspecific and manifests as fluctuating fever, joint pain, sweating, and weakness. Transmission to humans occurs through contact with contaminated materials from infected animals, particularly as an occupational hazard, consumption of infected milk and dairy products, nonintentional injection of live animal vaccine, and inhalation of large amounts of bacteria-contaminated aerosols. Human brucellosis is most serious when it results from exposure to *B. melitensis*, which is usually linked to exposure to infected goats and sheep (Corbel 2006).

The disease in animals is transmitted through ingestion of contaminated materials, penetration of intact skin and conjunctiva, and contamination of the udder during milking. Intra-herd spread occurs by both vertical and horizontal transmission. Congenital infection due to in utero infection does occur, but its importance has not been defined. Horizontal transmission can occur both directly and indirectly. Flies, dogs, rats, ticks, contaminated boots, fodder, and other inanimate objects are possible ways for indirect transmission. Preventive measures in cattle populations

are mainly related to early detection of infected cattle with the removal of serologically positive animals (test and culling) and vaccine application.

No reliable vaccine is available for human use. Humans are usually treated prophylactically with antibiotics if exposure is suspected. Preventive measures for human infection include precaution in handling contaminated materials from infected animals and precautions during the use of the vaccine in animals and avoiding consumption of unpasteurized milk or dairy products.

3.6 *Cryptosporidium parvum*

Cryptosporidium parvum is a coccidian protozoan that is an important cause of diarrhea in cattle and humans worldwide. It has emerged since the 1970s as a major cause of calf-hood diarrhea. It is one of the top four agents responsible for moderate to severe gastrointestinal illness in children in developing countries and can be a fatal complication of AIDS (Kotloff et al. 2013; Mosier and Oberst 2000). Cryptosporidiosis is one of the most common causes of waterborne disease among humans in the United States (CDC 2013a).

Cryptosporidium parvum resides in the host's small intestine, where it forms oocysts, which are shed in great numbers in the feces. Transmission occurs through ingestion of food and water contaminated with fecal matter from infected animals or humans, direct contact with infected feces, or ingestion of contaminated water. Large outbreaks have been associated with drinking water, food, swimming pools, and lakes.

Community-wide outbreaks of cryptosporidiosis have been linked to drinking municipal water or recreational water contaminated with *Cryptosporidium*. One large-scale outbreak occurred in Wisconsin, USA, in 1993 when more than 400,000 people became ill from a malfunctioning municipal water filtration system. The total cost of outbreak-associated illness was USD 92 million (Corso et al. 2003). The source of the *Cryptosporidium* oocysts in this outbreak, whether from cattle, slaughterhouse runoff, or human sewage, remains speculative (Mac Kenzie et al. 1994).

In healthy humans, infection is usually asymptomatic and self-limiting. The disease can be severe in immunodeficient people with profuse watery diarrhea and substantial fluid loss. Most animals can become infected with *Cryptosporidium* spp., but clinical signs of diarrhea, tenesmus, anorexia, and weight loss are most commonly observed in calves less than one-month-old.

Cryptosporidiosis is diagnosed by examining fecal samples using acid-fast staining, direct fluorescent antibody, and/or enzyme immunoassays (CDC 2013a). The oocysts are not shed continuously, and repeated sampling may be necessary. Cryptosporidiosis can also be diagnosed in stained biopsy/necropsy specimens or fresh intestinal scrapings. Molecular methods, which can detect *Cryptosporidium* species, are increasingly being used in diagnostic laboratories.

There is no specific treatment available for cryptosporidiosis. Supportive therapy is usually effective. Prevention efforts focus on handwashing, especially after handling or being around animals and before eating or handling food.

3.7 *E. coli* O157:H7

Escherichia coli is in the family *Enterobacteriaceae* and is a normal component of the flora in the large intestine of humans and warm-blooded animals. *E. coli* O157:H7 is a specific pathogenic subset of *E. coli* found worldwide that produces watery diarrhea, hemorrhagic colitis, and rarely, hemolytic-uremia syndrome (HUS) in children.

Cattle are reservoir hosts, harbor the bacteria asymptomatically, and are an important source of infection for humans. Prevalence estimates vary, and it appears that while a large percentage of cattle herds may have infected animals, the actual number of individual infected animals at any one time is relatively low (USDA 2003). The costs associated with attempts to control prevalence in cattle, contaminated food recall, and human healthcare costs make the economic and social burden of *E. coli* O157:H7 high (Callaway 2010).

Transmission of *E. coli* O157:H7 occurs through consumption of contaminated food or water, direct contact with infected animals, their feces, or contaminated soil. Primary sources of *E. coli* O157:H7 outbreaks are raw or undercooked ground meat products, raw milk, and fecal contamination of vegetables. Person-to-person spread can occur during outbreaks (Spickler 2009). Visiting farms and other venues where the general public might directly contact farm animals, particularly calves, has been identified as an important risk factor for *E. coli* O157:H7 infection (WHO 2011a). A low dose of bacteria is sufficient for infection.

E. coli O157:H7 occurs asymptomatically in cattle and is shed intermittently. In humans, illness can range from mild diarrhea to severe hemorrhagic colitis. In most cases, the illness is self-limiting. Hemolytic uremic syndrome, a particularly severe complication, can occur in a small percentage of cases leading to renal failure and death in children and the elderly. Selective and differential culture media have been developed to diagnose *E. coli* O157:H7 in human and bovine fecal samples.

Measures to prevent and control *E. coli* O157:H7 in cattle include management changes (biosecurity, housing, transport, and stress reduction), water and feed management, including additives and probiotics, bacteriophages, and vaccines (Callaway 2010). Preharvest strategies are important but do not eliminate the need for good sanitation in processing plants and households. Good hygienic slaughtering practices reduce contamination of carcasses. Education on hygienic handling of foods is essential for farm workers, abattoir, and food production workers to reduce contamination. Household preventive measures are similar to those recommended for other foodborne diseases (WHO 2011a).

3.8 Leptospirosis

Leptospirosis is a zoonotic disease of worldwide importance. Also a neglected tropical disease, leptospirosis largely affects vulnerable rural and semi-urban populations. The global annual incidence of endemic human leptospirosis is grossly underestimated due to lack of awareness, underdiagnosis, misdiagnosis, and difficulty with diagnostic testing. Efforts to determine the burden of disease are ongoing (WHO 2011b). Leptospirosis is endemic in countries with humid subtropical and tropical climates, and epidemics often occur due to flooding. Individuals at greatest risk include farmers, ranchers, slaughterhouse workers, trappers, loggers, veterinarians, sewer workers, rice field workers, and military personnel.

Leptospirosis is caused by a variety of species of *Leptospira*, a spirochete with more than 250 pathogenic serovars that are adapted to different wild or domestic reservoir hosts. The classification system for *Leptospira* changed in 1989, leading to some confusion, as pathogenic and nonpathogenic serovars are now included in the same species. Serovars vary by geographic region (Spickler 2005a). Host adaptation is not a static situation as serovars adapt to new hosts, vaccine pressures alter serovars in different species, and climate change may alter hosts and serovars. These facts lead to difficulties in the prediction, prevention, and use of vaccines. Reservoir hosts include wild mammals (rats and rodents are the most common) as well as domestic cattle, pigs, pigs, and sheep and dogs. Reservoir hosts experience asymptomatic, mild, or chronic disease and can shed for months to years.

Leptospires reside in the kidneys of infected reservoir hosts and are shed in urine into the environment where they can live for long periods of time, depending on environmental conditions. Freshwater ponds, streams, runoff, and groundwater are common water sources of leptospires. *Leptospira* spp. can also be excreted in vaginal secretions and with aborted fetuses after calving (Spickler 2005a). *Leptospira* spp. can be spread directly between individuals, through skin contact with contaminated water or urine, ingested in contaminated food or water, or spread via aerosol.

At least 13 serovars of *Leptospira* spp. have been isolated from cattle. Clinical signs vary with the serovar and in acutely affected calves include fever, anorexia, conjunctivitis, and diarrhea. In adult cattle, clinical signs may be mild and go undetected. More severe infection may result in abortions, decreased fertility, or decreased milk yields (Spickler 2005a). Clinical signs are associated with kidney disease, liver disease, or reproductive dysfunction; younger animals suffer more severe disease. Differential diagnosis includes brucellosis, neosporosis, bovine viral diarrhea (BVD), and infectious bovine rhinotracheitis (IBR).

In humans, disease ranges from mild to severe depending on the serovar and immune status of the patient. Clinical signs mimic other infectious diseases, including influenza, hepatitis, dengue, hantavirus, yellow fever, malaria, brucellosis, borreliosis, typhoid fever, other enteric diseases, and pneumonia (Spickler 2005a).

Rapid screening tests are available for presumptive diagnosis in humans, but require confirmatory diagnosis by culture, PCR, or microagglutination test (MAT).

The most commonly used test for diagnosis in animals is the MAT test. ELISA tests are also used.

Human vaccines against leptospirosis are available in some countries. Animal vaccines are in use and must contain serovars present in the local environment; most of them require a yearly booster shot. In developed countries, cattle, pigs, and dogs are routinely immunized. In developing countries, vaccines with locally relevant serovars are not as available (Hartskeerl et al. 2011). Prevention programs must be tailor-made and based on predominant serovar and local reservoir hosts. Public health prevention measures include reservoir control through rodent control and vaccination of livestock and dogs, improved sanitation, improvement of water sources that may be contaminated, and outreach and education for high-risk individuals and high-risk areas.

3.9 Listeriosis

Listeriosis, also called Circling disease or Silage sickness, is a disease with worldwide distribution that can affect all ruminants. The etiological agent is usually *Listeria monocytogenes*; however, sheep can also get listeriosis from *Listeria ivanovii* infection (Todar 2003).

The etiological agent *Listeria monocytogenes* is a ubiquitous bacteria characterized as a small, gram-positive, non-spore-forming, catalase-positive, facultative anaerobic, motile rod sometimes arranged in short chains with the ability to produce flagella at room temperatures, but not at 37 °C (Todar 2003). Infection occurs mainly through ingestion of *L. monocytogenes* contaminated soil, vegetation, and silage.

Age and sex are not considered risk factors; however, cattle under 3 years of age are more prone to developing clinical signs of disease. The disease clinically manifests in cattle in one of four forms and is more common during cold weather. These forms are encephalitic, visceral/septicemic, abortion, and ophthalmitic. The encephalitic form is most common in adult cattle, while neonates often suffer from the septicemic or visceral forms. Abortion occurs due to placentitis resulting in fetal death if there is intrauterine infection. The ophthalmitic form is associated with bacterial contamination of the cornea from a feed source. Lactating cows may also contract clinical mastitis associated with listeriosis.

Most animals infected with *L. monocytogenes* show no clinical signs, but can still spread bacteria in the environment and to other animals. Listeriosis is diagnosed by the history of previous cases in the area, accompanied by some clinical signs. A confirmed diagnosis can be made by postmortem examination with histopathology of the pontomedullary region of the brainstem or bacterial culture. Usually, there are no gross lesions seen in the brain at necropsy. Microscopic lesions can include multifocal asymmetrical micro-abscesses and mononuclear cell meningoencephalitis in the brainstem, anterior spinal cord, and, occasionally, cerebellum (George 2002). Treatment of confirmed cases is with either oxytetracycline or penicillin G. Antibiotic therapy works best in animals treated in the early stages of the disease.

Animal to human transmission of *L. monocytogenes* occurs either directly through contact with infected animals or indirectly through ingestion of milk, cheese, meat, eggs, or vegetables. The bacterium is inactivated by pasteurization; however, contamination of pasteurized products with the raw product has been reported as a source of infection. Listeriosis in humans occurs primarily in pregnant women, newborns, the elderly, and immunosuppressed (e.g., transplant recipients or AIDS patients). It has been reported that as many as 5–10% of humans may be asymptomatic carriers of *Listeria* spp. in their feces or vagina. Disease in adult humans is commonly the encephalitic or septicemic/visceral form (Rebhun 1995).

Preventive measures can reduce the spread of infection. In dairy cattle, feeding spoiled silage and other rotting vegetation should be avoided. All cattle showing any signs of disease should be isolated from healthy animals. Good hygiene and sanitation on the farm are essential. Other preventive measures include thoroughly washing raw vegetables, cooking raw meats, proper hygiene during food preparation, and consuming only pasteurized dairy products. Humans should avoid contact with animals that have suffered from abortions as well as with the aborted materials (placenta and fetuses). Livestock and crop producers can help control the spread of *L. monocytogenes* by avoiding the use of untreated manure on vegetable crops. It is almost impossible to produce listeria-free products because infected animals do not always show signs of disease. As a result, people at high risk should avoid exposure to food items commonly associated with listeriosis.

3.10 Methicillin-Resistant *Staphylococcus aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA) are Gram-positive bacteria that are resistant to methicillin and other beta-lactams in this large group of antibiotics that are widely used in veterinary and human medicine. MRSA is found worldwide in humans and animals.

MRSA was first isolated from cattle with mastitis in 1972, which was the first recognition of this emerging disease in animals (Devriese et al. 1972). Since that time, MRSA has been found in many species of animals, including pigs, horses, dogs, cats, pet birds, zoo animals, and marine mammals (Spickler 2011). Most of the strains isolated from animals have been of human origin; this changed, however, in 2003–2005 with the emergence of a new type of MRSA, CC398, isolated from humans and pigs in the Netherlands. This livestock-associated strain appears to be less host-specific than other MRSA strains and has spread to other livestock, including cattle (Vanderhaeghen et al. 2010). The livestock-associated MRSA can cause disease in animals as well as in humans in close contact with them (Vanderhaeghen et al. 2010), and there is evidence of limited human-to-human spread of this strain as well (Voss et al. 2005). The data on this new type of livestock-associated MRSA is limited, and the burden of CC398 in cattle is unclear (Vanderhaeghen et al. 2010).

MRSA is transmitted most commonly through direct contact with colonized or infected individuals (animals or humans) (Spickler 2011). Contaminated

environments, including air in confinement operations, are other potential routes (Gibbs et al. 2006). Human and livestock-associated strains of MRSA can be found in contaminated food (Jones et al. 2002), meat (van Loo et al. 2007; de Boer et al. 2009), and raw milk products (Normanno et al. 2007).

Cattle colonized or infected with MRSA most commonly present with clinical or subclinical mastitis. MRSA colonization has been associated with veal calves (Graveland et al. 2010) and beef calves (Mooij et al. 2007). MRSA can cause a wide variety of infections in humans, including skin and soft tissue infections as well as more invasive infections including pneumonia, endocarditis, septic arthritis, and septicemia; MRSA is one of the most prevalent causes of nosocomial infections worldwide (Spickler 2011).

Diagnosis of infection or colonization with *S. aureus* can be accomplished through culture of the organism. Methicillin-resistant strains can be identified through antibiotic susceptibility or genetic testing. Genetic testing can identify the various human and animal-associated strains.

In general, prevention and control of MRSA include good biosecurity and infection control practices, including hand washing, barrier precautions, and environmental disinfection (Spickler 2011). MRSA is not particularly hardy and can be inactivated by sodium hypochlorite, alcohols, and quaternary ammonium compounds (Spickler 2011). The emerging livestock-associated MRSA urgently requires more research to determine the risk factors and transmission routes (Vanderhaeghen et al. 2010).

3.11 Q Fever

Q fever is a highly contagious zoonotic disease caused by *Coxiella burnetii*, an obligate intracellular bacterium. Livestock are the major source of infection in humans worldwide. Q fever can infect a wide range of hosts, including pets, wildlife, birds, reptiles, and ticks. Because illness can be mild and go undetected, Q fever is under-diagnosed and under-reported globally, and the true burden of disease is unknown. However, a large outbreak with approximately 4000 human cases occurred in the Netherlands during 2007–2010. Dairy goat farms near densely populated areas were the source of the outbreak, which was spread via a windborne route (Schimmer et al. 2009).

Animals that carry this organism usually do not show any signs of disease, but abortions and stillbirths can occur with great quantities of bacteria shed. Both symptomatic and asymptomatic animals shed *C. burnetii* in large quantities at parturition. The bacteria can also be shed in feces, urine, and milk. The organisms persist in the environment for long periods, are highly resistant to disinfectants, and can be spread long distances by the wind (Spickler 2007).

Human infection usually occurs from the inhalation of bacteria from air that is contaminated by the feces of infected animals. Q fever is also rarely transmitted to humans by tick bites and ingestion of unpasteurized milk or milk products (CDC 2013b). Most often, sporadic cases occur in occupationally exposed people, such as

biomedical research facility workers, farmers, ranch-hands, veterinarians, and slaughterhouse workers (CDC 2013b). These cases tend to result from exposure to parturient ruminants; however, cats, dogs, rabbits, and other species have also been implicated. Although Q fever is usually asymptomatic or mild, a small percentage of people develop serious disease. Pneumonia or hepatitis may occur in acute cases, and chronic infections can result in endocarditis or a wide variety of other diseases (Spickler 2007).

In humans, Q fever is usually diagnosed by serology or PCR. Diagnosis of Q fever in aborting animals involves testing of the fetuses and placentas. Veterinary diagnosticians typically identify the organism using special stains applied to microscopic sections of these tissues and/or PCR.

Q fever can be prevented in humans by limiting exposure to livestock during birthing, personal hygiene measures and wearing personal protective equipment, and only eating and drinking pasteurized milk and milk products. In animals, prevention of Q fever is based on herd management and prevention of contact with wildlife and tick vectors. Isolating infected pregnant animals and disposing of reproductive tissues can decrease transmission (Spickler 2007). Prevention in humans and animals can be difficult because Q fever can be transmitted on fomites or in aerosols over great distances. Effective vaccines are available in some countries for both humans and animals.

3.12 Rift Valley Fever

Rift valley fever (RVF) is a zoonotic disease that primarily affects ruminants (cattle, sheep, goats, and camels) and can also infect humans. The disease can be severe in both humans and animals and may cause severe economic losses because of livestock death and abortion. Infection with RVF is caused by a virus in the family Bunyaviridae and is primarily transmitted by mosquitoes. RVF has recently received more attention as a potential agricultural and zoonotic disease threat in Europe and North America due to the increasing numbers of competent vector species in those regions (Salman 2013).

RVF is endemic in much of Africa, with occasional spread to countries in the Arabian Peninsula. Epidemics occur sporadically when climate conditions support breeding of mosquitoes. Rift Valley Fever virus (RVFV) was first isolated from lambs in the Rift Valley of Kenya in the 1930s. Major outbreaks have been recorded in many parts of Africa since that time, and the virus was first detected outside of the African continent in Saudi Arabia and Yemen in 2000. The first report of RVF outside of Africa was attributed to the importation of cattle and small ruminants from the Horn of Africa (Pepin et al. 2010).

Transmission of infection in cattle is mainly via the bites of infected mosquitoes. As an epidemic progress, direct contact transmission by infectious animals or contaminated tissues, including aborted fetuses may occur. Transmission via infected mosquitoes is important for disseminating RVFV between herds over

short distances and over long distances through the movement of infected animals or translocation of infected mosquitoes (Abdo-Salem et al. 2011).

Disease, especially in young animals, may be severe and includes fever, depression, and anorexia. The classic clinical sign of RVF in a herd of cattle is a large number of nearly simultaneous abortions among pregnant animals, regardless of the stage of pregnancy. This abortion storm differentiates RVF from other common infectious causes of abortion in cattle, such as Q fever, chlamydiosis, brucellosis, salmonellosis, listeriosis, or toxoplasmosis. RVF may also cause sudden death in cattle. Aborted fetal materials and placental membranes contain large numbers of virus particles, which can either contaminate the local environment directly or infect animals or humans in close contact. The RVFV may persist for relatively long periods in the environment.

Direct contact and aerosol exposure to infected tissues or bodily fluids constitute the main routes of infection for humans. Certain groups are at increased risk due to occupation, such as herders, farmers, slaughterhouse workers, and veterinarians. There is evidence for virus shedding into milk, so that consumption of unpasteurized milk has major consequences for disease transmission and public health. Most human infections are inapparent or demonstrate mild flu-like symptoms (fever, headache, and myalgia). The infection progresses with severe complications in some cases, including hemorrhagic fever, encephalitis, and acute hepatitis.

RVFV can be diagnosed using several methods, including virus isolation from blood and other tissues and by using serological tests such as ELISA.

There is presently no vaccine licensed for human use, although inactivated vaccines have been in development. Both live attenuated virus vaccines and inactivated virus vaccines are available for use in livestock. The live vaccine produces better immunity and requires only one dose but may induce abortions and congenital defects in pregnant animals. Inactivated vaccines require multiple doses to provide protection making their use problematic in endemic areas.

In endemic areas, sustained animal vaccination programs can help to prevent outbreaks.

To slow the expansion of RVF, livestock movement restrictions may prevent the disease from entering new areas. Outbreaks of RVF in animals precede outbreaks in humans, so sustained surveillance and monitoring systems in animals can act as an early warning system to public health authorities. Raising human awareness of protective measures for mosquito bites and safe handling practices during slaughter, appropriate barrier precautions, and proper pasteurization of milk to prevent spread from animals may prevent human infection. Vector control, RVF forecasting, and climatic models to predict when climate conditions are favorable for RVF outbreaks can also help guide prevention efforts.

3.13 *Salmonella*

Salmonella is a major cause of foodborne disease globally. The global burden of zoonotic disease from *Salmonella* is high. An estimated 93.8 million illnesses and 155,000 deaths result each year from nontyphoidal *Salmonella,* the vast majority of

which are foodborne (Majowicz et al. 2010). Over 100,000 human cases are reported each year in the EU alone, with an estimated overall economic burden as high as EUR 3 billion a year (EFSA 2013). *Salmonella* strains resistant to a range of antimicrobials have emerged since the 1990s and are now a serious public health concern (WHO 2013b). Salmonellosis has a worldwide distribution, but serovars vary geographically. *Salmonella* is most prevalent where livestock are farmed intensively (Spickler 2005a).

Salmonella bacteria are classified into over 2500 different serovars based on surface proteins. *Salmonella* is shed in the feces of various infected animals, including cattle, which are infected by ingestion of contaminated feed, water, or grass. The bacteria are hardy and can survive for months to years in the environment (Spickler 2005a).

Transmission is generally through the fecal-oral route and humans most commonly contract salmonellosis through consumption of contaminated food, including meat, eggs, poultry, and unpasteurized milk products. Less often, *Salmonella* is transmitted through green vegetables contaminated by manure. Person-to-person transmission through the fecal-oral route can also occur. Human cases may also occur through contact with infected livestock, which often do not show signs of disease. Most cases of salmonellosis in humans are mild but can result in severe disease and death depending on host facts and the strain of *Salmonella*. Humans may develop diarrhea, abdominal cramping, and fever, which can be very severe.

Salmonella is often carried asymptomatically in cattle, but young, stressed, or pregnant animals are the most susceptible to infection, which may result in enteritis and septicemia (Spickler 2005a). *Salmonella* infection is diagnosed by isolating the organism from feces. In cases of disseminated disease, bacteria can be isolated from the blood.

To reduce the risk of foodborne transmission, basic food hygiene practices and adequate cooking should be used. To prevent transmission from animals to humans, hand hygiene after touching or working with animals is critical. To reduce the risk of *Salmonella* in cattle, herd management strategies and proactive biosecurity, rodent control, and *Salmonella*-free feed and water sources should be utilized. Fecal contamination of water supplies and feed should be prevented. Vaccines are available in some countries for some serovars and can reduce colonization, shedding, and clinical disease (Spickler 2005a).

3.14 Summary

Zoonotic diseases originating from cattle can cause mild or asymptomatic human infection or severe disease and death. A number of zoonotic diseases were not covered in this chapter but might be considered to depending on geographic location and local circumstances, for example, rabies, ringworm, and Human African Trypanosomiasis. While some diseases are rare, the potential for serious outcomes makes it critical for veterinarians and public health practitioners to provide outreach to those individuals at greatest risk, including farmers – small scale and large.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_2

Abstract

Swine and their products have become a central part of food systems around the world. Global pork production has rapidly increased over the past 30 years, leading to the intensification of the swine industry: though there are fewer farms now, those farms that do persist raise ever-larger numbers of animals. This increases the transmission of pathogens both among animal herds, and between animals and their human caretakers. Furthermore, increased stress to animals and the potential for amplification of pathogens in the farming environment can lead to a higher burden of disease-causing organisms in and on meat products, which then make their way to consumers worldwide. As such, swine and their meat products have the potential to introduce new zoonotic diseases into populations via multiple routes of transmission. Here we discuss several examples of zoonotic diseases of swine origin, reviewing diseases with bacterial, viral, or parasitic causes.

4.1 Background and Introduction

Pork is rapidly becoming the world's source of protein, accounting for approximately 35% of all meat production (FAO 2017). Global pork production increased more than 80% between 1985 and 2010 (Fournie et al. 2012), and this trend has led to the intensification of swine husbandry, with fewer and fewer facilities present, but each raising larger numbers of individual animals. China has been a driver of this market, accounting for approximately 50% of total global pig production (Fournie et al. 2012). As swine production has intensified, so has concern over how these modifications in husbandry may affect the transmission of disease among pigs as well as to human caretakers. It has been estimated that more than 60 % of emerging diseases are zoonotic (Jones et al. 2008). A review (Fournie et al. 2012) identified 77 pathogens that had not been described in swine prior to 1985, including 39 viruses and 32 bacterial species. Not surprisingly, the top 20% of pork-producing countries accounted for 82% of these emerging pathogens. Of these 77 novel species found to infect swine, 30 (39%) are zoonotic, and 26% of these were identified in the context of an outbreak investigation (Fournie et al. 2012). Densely populated South East Asia is the epicenter of emergence of novel zoonotic diseases due to inter-species transmission. However, outbreaks of host specific lethal zoonoses have occurred in industrialized nations as well (Davies 2012). It is plausible that a dramatic change in swine industry demographics in recent decades without adequate biosecurity may have served as a tonic for the emergence of swine zoonosis (Davies 2012). Zoonotic diseases impose significant economic burden with increased morbidity and mortality

globally. A change in ecological niche, climatic change, rapid growth in human population, and socio-economic factors are among the major contributing factors for the emergence of zoonoses (Jones et al. 2008).

Outbreaks of human disease related to swine-origin pathogens, including *Streptococcus suis* in China (Lun et al. 2007), Nipah virus in Malaysia (Chua 2012), and the novel H1N1 variant influenza virus have gained significant media attention in the past decades; along with Hepatitis E virus, these also have shown an increased interest in the scientific literature (VanderWaal and Deen 2018). Here we discuss several examples of zoonotic diseases of swine origin, reviewing diseases with bacterial, viral, or parasitic causes.

4.1.1 Yersinia enterocolitica

Yersinia enterocolitica is a Gram negative bacterium in the family *Enterobacteriaceae. Y. enterocolitica* is widely distributed throughout nature, having many animal and aquatic reservoirs; however, swine are considered the main reservoir for strains that are pathogenic to humans. It is the main causative agent of yersiniosis, a disease that affects animals and humans worldwide (Holt et al. 2000).

Yersinia enterocolitica can be classified into distinct subgroups based on biochemical characteristics (biotypes) and O-antigen specificity (serotypes). There are six biotypes (1A, 1B, 2, 3, 4, and 5) and 60 serotypes, 11 of which are associated with human illness (Nesbakken et al. 2006; Bottone 1997). Biotype 1B is considered the only highly pathogenic strain, while the others are considered moderately pathogenic, except for biotype 1A, which is considered nonpathogenic although this has recently become a contentious topic due to recent reports of 1A infections (Stephan et al. 2013). Biotype 1B is mainly found in North America and Japan and is different from other biotypes in that it can be found in water and other environmental sources, and can also be carried by swine and rodents. Biotypes 2 and 4 are associated with human infections in Europe; their main reservoirs are pigs and cattle. Biotypes 3 and 5 are uncommon, but are also associated with animal reservoirs (EFSA 2009; Fredriksson-Ahomaa et al. 2006a).

Yersiniosis is a gastrointestinal disease, causing fever and watery, occasionally bloody, diarrhea. Rarely, *Y. enterocolitica* can cause septicemia, and in some cases, long-term sequelae can occur. Symptoms generally occur 4–7 days after exposure and may last for up to a month (Bottone 1997; Huovinen et al. 2010), but can be non-specific likely leading to under- or misdiagnosis (Chlebicz and Slizewska 2018). Approximately 16.5 cases per 1000,000 persons occur each year in Europe (EFSA 2009), while in the United States, approximately 3.5 cases per 1000,000 are seen each year (Long et al. 2010). In many developing countries, no sufficient diagnostics are available so less is known about the number of cases in many areas (Carniel and Hinnebusch 2012). Children are infected more frequently than adults, and infections occur most commonly in temperate locations during colder months (Bottone 1997).

Pigs are commonly asymptomatic carriers of pathogenic strains of *Y. enterocolitica*. The bacteria typically reside in the gastrointestinal tract, especially the tonsils, lymph

nodes, intestines, and feces (Fredriksson-Ahomaa et al. 2007; Bhaduri et al. 2005). Cattle and goats have also been found to be carriers (Lanada et al. 2005a, b), and milk products from these animals have been the source of numerous outbreaks in human populations (Black et al. 1978; Shayegani et al. 1983; Morse et al. 1984; Tacket et al. 1984; Ackers et al. 2000). Deer, rabbits, rodents (Quan et al. 1974), dogs (Byun et al. 2011), and cats (Fredriksson-Ahomaa et al. 2001) have also been found to carry as well as to be infected with *Y. enterocolitica*. In addition to livestock, water sources including wells, rivers, and lakes can serve as reservoirs for the bacteria as a result of contamination by feces of carriers or leakage from latrines.

The major risk factors for developing yersiniosis include eating raw or undercooked pork (Boqvist et al. 2009; Fredriksson-Ahomaa et al. 2006b), drinking contaminated milk (Black et al. 1978; Tacket et al. 1984; Ackers et al. 2000), and consuming contaminated drinking water (Thompson and Gravel 1986; Christensen 1979). Porcine sources are frequently associated with the pathogenic serotypes O:3, O:9, and O:5, 27 and sometimes with the highly virulent serotype O:8. Outbreaks in 2006 in Norway were identified as biotype 2 and 4 and indicated a processed pork product to be the likely source (Grahek-Ogden et al. 2007; Stenstad et al. 2007). In the United States, raw pork intestines were found to be the source of an outbreak among infants (Lee et al. 1990; Jones 2003). The occurrence of pathogenic *Y. enterocolitica* in pigs and pork has been established by PCR in several studies (Korte et al. 2003; Fredriksson-Ahomaa et al. 2003). The *ail* gene located within the genome of pathogenic *Y. enterocolitica* strains is the most frequently used target of amplification for positive identification. In Switzerland, the prevalence of *ail*-positive *Y. enterocolitica* in tonsils of slaughter pigs was shown to be 88% by PCR and 34% by culture methods (Fredriksson-Ahomaa et al. 2007). In the USA, *ail*-positive *Y. enterocolitica* were detected in 12% of pig feces sampled by PCR, and in 4% of them using culture methods. Similarly, 40% of the pig lymph nodes were positive by PCR, but none by culturing (Boyapalle et al. 2001). These results indicate that PCR based assays are the most sensitive and accurate means to detect *Y. enterocolitica* colonization.

Clinical presentations of yersiniosis are typical of enteric illness. Infants and children often present with fever, vomiting, and bloody diarrhea that can last from 3–28 days (Metchock et al. 1991; Lee et al. 1991). Adults generally have 1 to 2 weeks of fever, diarrhea, and abdominal pain that can mimic appendicitis. In more severe cases of gastroenteritis, necrotizing enterocolitis, and ulceration may occur. *Y. enterocolitica* can also cause septicemia, leading to abscesses in the liver and spleen, pneumonia, septic arthritis, meningitis, cellulitis, empyema, osteomyelitis, and may evolve into endocarditis. Post-infection sequelae may also occur, particularly after infections with biotype 4, serotype O:3 (Bottone 1999). Reactive arthritis and erythema nodosum are the most common sequelae, but glomerulonephritis and myocarditis have also been reported (Bottone 1997).

Yersiniosis is diagnosed by positive identification of *Y. enterocolitica* in stool samples, although it is not routinely tested for. It can also be recovered from the throat, lymph nodes, joint fluid, urine, bile, or blood. Most cases resolve on their own, although it may take up to 3 weeks to recover. In severe cases, antibiotics such as aminoglycosides, doxycycline, trimethoprim-sulfamethoxazole, or fluoroquinolones

may be prescribed. Prevention is key in avoiding infection. Raw or undercooked pork and unpasteurized milk or milk products should be avoided, as should drinking untreated water. Good hand hygiene when preparing food and after contact with animals should also be practiced to avoid infection.

4.1.2 Staphylococcus aureus

Staphylococcus aureus is a nonmotile, nonspore-forming, Gram positive coccus that occurs singly, in pairs, or in clusters. *S. aureus* produces protein A (*spa*), which is used in molecular testing for strain typing purposes, as well as several other toxins and superantigens (De Vos et al. 2009).

S. aureus is often isolated from the nasal membranes and skin of warm-blooded animals. Approximately 20–30% of the human population is colonized with *S. aureus* in the nose, throat, or both (Smith et al. 2012; Gorwitz et al. 2008; Graham 3rd et al. 2006). The most important site for colonization are the anterior nares (Wertheim et al. 2005). Colonization itself is not harmful; however, it is a risk factor for developing subsequent infections (Graham 3rd et al. 2006; Fritz et al. 2009). Both asymptomatic carriers and infected individuals may transmit the bacterium to others through close contact. *S. aureus* may also be acquired via contact with fomites contaminated with the organism, as well as with animals that are colonized or infected with *S. aureus.*

Skin infections including furuncles, carbuncles, impetigo, and scalded skin syndrome, as well as more severe infections like pneumonia, osteomyelitis, endocarditis, myocarditis, pericarditis, enterocolitis, mastitis, cystitis, prostatitis, cervicitis, cerebritis, meningitis, bacteremia, toxic shock syndrome, and abscesses of muscles, skin, and organs can occur as a result of *S. aureus* infection. Other mammals and birds are also susceptible to infections, including mastitis, synovitis, arthritis, endometritis, furuncles, suppurative dermatitis, pyemia, and septicemia (De Vos et al. 2009). Pigs are common carriers of *S. aureus*; one study in the USA found overall MRSA prevalence was 70% (147/209) from 7 farms in the Midwest (Smith et al. 2009). In the Netherlands, surveillance for MRSA on hog farms has shown that isolates obtained from swine and their human caretakers are frequently indistinguishable, suggesting that the organism is transmitted between the two species (Smith et al. 2009; Huijsdens et al. 2006; Khanna et al. 2007).

S. aureus infections are often resistant to many antibiotics. Approximately 1.5% of the US population carries methicillin-resistant *S. aureus* (MRSA) (Gorwitz et al. 2008). Resistance to methicillin developed within 6 months of the first clinical use and has become a major cause of morbidity and mortality around the world. In the USA in 2011, there were 80,461 invasive MRSA infections, an incidence rate of 25.82 cases per 100,000 persons. In 2017, looking at *Staphyloccocus aureus* more broadly, it was estimated that this organism caused almost 120,000 bloodstream infections and close to 20,000 deaths (Kourtis et al. 2019). Further, many animals, including cows, goats, sheep, rabbits, and poultry, can be infected by *S. aureus,* and these infections can have large economic costs (Fitzgerald 2012).

The epidemiology of MRSA has changed rapidly in the past few decades. After developing resistance in the 1960s following methicillin introduction, MRSA became a superbug that primarily affected hospitalized patients. Due to association with the healthcare environment, these infections were called healthcare-associated MRSA (HA-MRSA). More recently, cases of MRSA infection have been detected in people without prior hospitalization and with no underlying illnesses or healthcare related risk factors; these are referred to as community-associated MRSA (CA-MRSA) infections. Cases of HA-MRSA are usually resistant to several classes of antibiotics and tend to carry the methicillin-resistance gene, *mecA*, on the Staphylococcal Chromosome Cassette (SCC) of type II (SCC*mec* type II). They are often associated with *spa* type t002 and multi-locus sequence type (MLST) ST5. Contrastingly, CA-MRSA infections tend to be resistant to fewer classes of antibiotics, carry the Panton-Valentine leukocidin (PVL) encoding gene, and carry SCC*mec* type IV, *spa* type t008, and MLST ST8. A third group of infections, livestock-associated MRSA (LA-MRSA), has recently been identified (Wulf and Voss 2008) and has typically been associated with swine or cattle. LA-MRSA include strains such as ST398 and ST9, often carry SCC*mec* type V, are typically PVL negative, and (like HA-MRSA) tend to be resistant to multiple classes of antibiotics. However, both CA-MRSA and LA-MRSA have caused nosocomial infections in hospitals (Jenkins et al. 2009; Fanoy et al. 2009; van Rijen et al. 2008, 2009; Wulf et al. 2008; Kourbatova et al. 2005; Seybold et al. 2006; Tattevin et al. 2009).

Livestock-associated MRSA first came to attention in 2005 after its identification in pigs in France (Armand-Lefevre et al. 2005) and in swine farmers in the Netherlands (Wulf and Voss 2008). Dutch researchers found that swine farmers were colonized with MRSA at a rate of 760 times higher than that of the general population (Voss et al. 2005). Since then, LA-MRSA has been found in a number of countries in Europe, Asia, and the Americas (Smith and Pearson 2011; Graveland et al. 2011; Fluit 2012).

Recent reports from Germany and the Netherlands have found a high proportion of ST398 carriage in areas that have a high density of livestock (Kock et al. 2009; Kock et al. 2011; Wulf et al. 2012). While originally thought not to cause severe infections, there have been increasing reports of invasive disease caused by ST398 (Hartmeyer et al. 2010; Mammina et al. 2010; Potel et al. 2010; Aspiroz et al. 2010). Methicillin-sensitive *S. aureus* (MSSA) ST398 isolates have also caused invasive disease in the eastern USA (Mediavilla et al. 2012), Europe (Witte et al. 2007; Declercq et al. 2008; van Belkum et al. 2008), South America (Jimenez et al. 2011), and Canada (Golding et al. 2010), and at least one death in France (Laurent 2009) (reviewed in (Smith and Wardyn 2015).

While the majority of individuals colonized or infected with LA-MRSA have had contact with swine, colonization with ST398 has also occurred in individuals lacking any identified contact with a livestock reservoir (Bhat et al. 2009; Aires-de-Sousa et al. 2006). Genomic analyses of ST398 (Price et al. 2012) and ST9 (Yu et al. 2021) suggest a similar pattern of evolution, from a human origin isolate to animal-adapted strains that have become increasingly antibiotic-resistant.

It has been suggested that one mode of transmission into the community is via contaminated food. Numerous studies in the USA have found MRSA in 5% of 120 meat samples (Pu et al. 2008), MSSA in 16.4% and MRSA in 1.2% of 125 meat samples (Hanson et al. 2011), MSSA in 64.8% and MRSA in 6.6% of 256 pork samples (O'Brien et al. 2012), and multi-drug resistant *S. aureus* in 52% of 136 meat and poultry samples (Waters et al. 2011). Additionally, two studies in the Netherlands found rates of 2.5% of 79 pork and beef samples (van Loo et al. 2007) and 11.9% of 2217 meat and poultry samples, respectively (de Boer et al. 2009). However, to date there have not been any confirmed infections with ST398 caused by contaminated food.

Most MRSA skin infections appear as pustules or boils which often are red, swollen, painful, and have pus or other drainage. They often are mistaken for spider or insect bites. These skin infections commonly occur at sites of visible skin trauma, such as cuts and abrasions, and areas of the body covered by hair. Health professionals may provide antibiotics and drainage if necessary to treat such infections. More severe infections may require hospitalization and intravenous antibiotic therapy. Good hygiene is the key to prevention of MRSA infections.

4.1.3 Salmonella

Salmonella is a genus of Gram-negative, rod shaped, non-spore forming enterobacteria with peritrichous flagella. Originally, classified utilizing serotyping of the somatic lipopolysaccharide (O) and flagellar protein (H) antigens, each serological variant (serovar), was considered its own species under the *Salmonella* genus (White 1926; Kauffmann 1978) as reviewed in (Beltran et al. 1988). This methodology led to misclassifications due to horizontal transfer of cell surface antigens, leading to classification of genetically distinct strains within the same serovar (Beltran et al. 1988; Selander et al. 1990).

In 2005, the Judicial Commission of the International Committee for Systematics and Prokaryotes (JICSP) decided to change the type species of the *Salmonella* genus to *enterica* with subspecies and serovars. (Prokaryotes JCotICoSo 2005). The JICSP indicated *Salmonella enterica* had seven subspecies, *enterica* (type I), *salamae* (type II), *arizonae* (type IIIa), *diarizonae* (type IVb), *bongori* (type V), *houtenae* (type IV), and *indica* (type VI). Subspecies *bongori* was shortly after promoted to species status (Grimont and Weill 2007). *S. bongori* and all subspecies of *S. enterica* besides *S. enterica* subsp. *enterica* are associated mainly with cold-blooded animals (Aleksic et al. 1996; Woodward et al. 1997), but can rarely cause human infection (CDC 2008, 2012a). The primary cause of human infection is *S. enterica* subsp. *enterica* (CDC 2008), as referenced in (Desai et al. 2013).

The CDC defines salmonellosis as an infection with a *Salmonella* spp. bacterium. These infections can often manifest with diarrhea (potentially bloody), fever, and abdominal cramps between 12 and 72 h post infection (CDC 2009). The illness often lasts between 4 and 7 days and is usually self-limiting. *Salmonella* infection can

necessitate hospitalization in a small number of individuals (Mead et al. 1999) and is estimated to cause 150,000 deaths per year globally, most commonly in children infected with serotypes Enteritidis or Typhimurium (Whiley and Ross 2015). Each year, *Salmonella* spp. cause roughly 1.3 billion cases of nontyphoidal salmonellosis worldwide (Chimalizeni et al. 2010). Within the United States, there are estimated to be over one million cases per year, with 95% of these estimated to be caused by foodborne exposure to *Salmonella* (Mead et al. 1999; Jiang et al. 2015; Anderson et al. 2016). The burden on the United States economy from these cases was estimated to be between $0.5 billion and $2.3 billion (Frenzen et al. 2002). These estimates are likely underestimates due to the omission of secondary complications due to *Salmonella* infections. The estimates fail to include complications such as reactive arthritis or costs such as pain and suffering, or travel to obtain medical care.

The most important zoonotic reservoir for *Salmonella* are food animals, with the most important food product being eggs (Ebel and Schlosser 2000). Egg consumption has been shown to be the largest risk factor associated with *Salmonella enterica* infection (Hope et al. 2002). Pork contamination is also a possible source of human infection. In swine, *Salmonella* infection is mainly subclinical, with rare cases manifesting as enterocolitis or septicemia (Barker and Van Dreumel 1985), as referenced in (Fosse et al. 2009). In the United States, the percentage of farms positive for *Salmonella* are estimated to range between 38.2% and 83% with the number of positive pigs in the USA from 6% to 24.6% (Oosterom and Notermans 1983; Davies et al. 1997). Transmission from pig to pig is often due to fecal shedding of the bacteria. Within swine herds, sows were observed to have an increase in *Salmonella* shedding at weaning (Nollet et al. 2005) as well as in their weaned piglets (Kranker et al. 2003). While *Salmonella* is considered primarily fecal borne, swine feed has also been shown to be a potential source of *Salmonella* infection for swine (Harris et al. 1997) with experimental data showing animals may become infected through the consumption of contaminated feed (Smith 1960). Additional risk factors for transmission between herds of swine are: contact with humans, contaminated equipment, or contaminated slurry (Langvad et al. 2006).

Individual outbreaks of *Salmonella* spp. have also been attributed to pork products. In 1989, a small northern England town experienced an outbreak where 206 individuals were infected with serovar Typhimurium (Maguire et al. 1993). Serotyping and antibiotic resistance profiles matched the infective strain to that found in cold cuts of pork purchased from a local butcher shop. In a study by Davies et al., several of the most prevalent serotypes found in swine were also among the most common causes of human infection (Davies et al. 1997).

Attempts to control *Salmonella* spp. prevalence on farms have had mixed outcomes. The use of all-in/all-out systems with multiple sites handling different stages of the rearing process have been shown to have no benefit in reducing *Salmonella* prevalence when compared to farrow-to-finish systems (Davies et al. 1997). These all-in/all-out systems may actually have a greater prevalence of *Salmonella* in finishing pigs than farrow-to-finish systems and fecal shedding of *Salmonella* was higher than observed in farrow-to-finish (Davies et al. 1997). Number of pigs per pen

was also observed to be a risk factor for fecal shedding of *Salmonella* (Linton et al. 1970). Acidification or fermentation of feed is postulated to be protective against *Salmonella* contamination as dry feed and trough feeding have been shown to have an increased contamination risk (Lo Fo Wong et al. 2004; van der Wolf et al. 1999, 2001), but this has not been studied extensively using experimental designs.

In North America, *Salmonella* control programs have been implemented at slaughter to decrease human exposure to *Salmonella* (Funk and Gebreyes 2004). This Pathogen Reduction: Hazard Analysis and Critical Control Point (HACCP) system established slaughter point performance standards for processing plants and has been shown to decrease contamination of pork products with *Salmonella* (Agriculture FSaISUDo 2004). In European Union countries, a farm-to-slaughter program has been implemented to reduce *Salmonella* (Lo Fo Wong et al. 2002). This plan calls for control measures at all production levels and focuses specifically on transportation and handling of the swine to limit the transmission between herds. In addition to prevention methods within the production system, consumer prevention is recommended by the CDC (2010). In addition to recommendations dealing with protecting infants from *Salmonella* exposure, the CDC suggests cooking meat and poultry thoroughly, washing hands, utensils, and kitchen surfaces following contact with raw meat or poultry.

4.1.4 Campylobacter

Campylobacter is a genus of Gram-negative, spiral-spiral shaped bacteria that causes disease in both humans and animals (CDC 2010). *Campylobacter* is the most common cause of gastroenteritis in many developed (Nichols et al. 2012) and developing countries, causing more diarrhea than *Salmonella* globally (WHO 2011) and thought to be the most common food-borne bacterial zoonosis globally, causing up to 500 million yearly infections (Kashoma et al. 2015). In developing countries, infections of those under the age of two are most frequent (WHO 2011). While there are 17 species in the *Campylobacter* genus, *C. jejuni* and *C. coli* are the most frequent causes of infection (WHO 2011). Most cases are sporadic events and not part of outbreaks (CDC 2010). The main route of transmission from animals to humans is through undercooked meat and meat products, contaminated milk, or contaminated water (WHO 2011).

Disease in humans usually occurs 2 to 5 days after infection (WHO 2011) and presents with diarrhea, cramping, abdominal pain, and fever. Most infected individuals recover within 5 to 10 days. In some severe cases, a small amount of people may develop Guillian-Barré syndrome. *Campylobacter* is thought to be responsible for between 20% (Tam et al. 2007) to 40% of cases of Guillian-Barré syndrome (CDC 2010). *Campylobacter* infections tend to be higher in males across all age groups, which suggests a higher susceptibility in males and not participation in at-risk behaviors (Nichols et al. 2012; Louis et al. 2005). In recent years, infections in those over 50 years of age have become more common, especially in men, as has

infection in those between 20 and 32 years (Nichols et al. 2012). The increase in infections in those over 50 may be due to use of proton pump inhibitors (PPI's) (Nichols et al. 2012; Leonard et al. 2007). Seasonality of the infection has been noted, with the greatest impact of seasonality being in young children (Nichols et al. 2012). *Campylobacter* infection rates begin to rise in May and peak between mid-June and mid-July (Nichols et al. 2012; Louis et al. 2005). This seasonality has been observed in many temperate countries (Nylen et al. 2002). Infection rates also tend to be higher in rural compared to urban regions (Strachan et al. 2009; Sibbald and Sharp 1985). This could be reflective of proximity to livestock or differences in access to healthcare (Nichols et al. 2012). Since 1989, there has been a steady increase in the presence of antimicrobial resistant *Campylobacter* isolates. Full and intermediate resistance to ampicillin, ciprofloxacin, nalidixic acid, tetracycline, and erythromycin has been shown (Nichols et al. 2012).

Campylobacter species can be isolated from poultry, cattle, sheep, and goats as well as pigs (Chlebicz and Slizewska 2018); bacteria may be spread to humans via meat products or dairy, especially raw milk products. When swine are infected with *Campylobacter*, it is frequently *C. coli*; however, *C. jejuni* has been seen recently as well (Jensen et al. 2006). *Campylobacter* infections can cause diarrhea in pigs, and often colonizes the intestinal tract. Both *C. jejuni* and *C. coli* have been found in the intestinal tract of pigs and are known to be excreted in their feces (Jensen et al. 2006); studies have suggested that approximately 38–63% of pigs may carry *Campylobacter* in their alimentary tract (Chlebicz and Slizewska 2018). *Campylobacter* has also been identified in the stomach, tonsils, liver, and carcass surfaces of swine. High colonization rates may represent an occupational health hazard, since a low dose of bacteria can cause infection (Nesbakken et al. 2003). Antimicrobial susceptibility to ciprofloxacin and nalidxic acid has been reported in swine strains. It has also been shown that *C. coli* has higher levels of quinolone resistance than *C. jejuni* in swine (von Altrock et al. 2013). However, it is unlikely that swine are a major source of foodborne *Campylobacter*iosis, as *Campylobacter* is rarely detected in retail pork, but may be a source of occupational exposure (Nesbakken et al. 2003). It has also been shown that while there is contamination of pigs in slaughter houses, *Campylobacter* spp. do not spread throughout the operation (von Altrock et al. 2013).

Campylobacter infections do not generally require treatment and are self-limiting (CDC 2010). When disease is severe, electrolyte and fluid replacement may be necessary. Antimicrobials (erythromycin, tetracycline, and quinolones) can be used to treat severe disease or to eliminate carriage (WHO 2011). Several steps can be taken to prevent *Campylobacter* infection. Proper food handling and hand hygiene can help prevent infection. All meats should be thoroughly cooked and measures should be taken to prevent cross contamination. Hands should be washed thoroughly before handling food and persons with diarrhea should wash their hands frequently to reduce the spread of infection (CDC 2010). Improved biosecurity measures and hygienic slaughtering practices will reduce the fecal contamination of carcasses (WHO 2011). Cooling meat with CO_2 has also been shown to kill the bacteria (Nesbakken et al. 2003). Adequate disposal of feces and decontamination of fecal contaminated articles will also help reduce transmission (WHO 2011).

4.1.5 Streptococcus suis

Streptococcus suis (*S. suis*) is a Gram-positive facultative anaerobe bacterium reported to colonize and cause infections primarily in the swine population worldwide (Fulde and Valentin-Weigand 2013; Wertheim et al. 2009). In conjunction with *Actinobacillus suis* and *Haemophilus parasuis*, *S. suis* completes the triad of the "Suis-ide" disease agents given its association with a wide range of severe clinical conditions in the swine population (MacInnes and Desrosiers 1999). *S. suis* causes severe infections in pigs resulting in major economic losses to the porcine industry worldwide (Fittipaldi et al. 2012). Zoonotic infections due to *S. suis* have been reported in countries with a high density of pigs and intensive swine production (Lun et al. 2007; Wertheim et al. 2009). The increasing prevalence of infections due to *S. suis* both in swine and humans over the last few years have urged investigators to better understand the epidemiology and zoonotic potential of this primarily "pig pathogen."

S. suis isolates are verified by serotyping using slide agglutination test, capsular reaction, capillary precipitation or a co-agglutination test (Staats et al. 1997). Serotyping is based on polysaccharide capsular antigen detection . Thirty-five serotypes (1–34 and 1/2) have been identified using these tests (Lun et al. 2007; Higgins and Gottschalk 1990; Gottschalk et al. 1989, 1991a, b, 1999; Higgins et al. 1995). Serotypes 32 and 34 are observed to be closely related to *S. orisratti* (Hill et al. 2005). Serotype 2 is the most frequently reported serotype worldwide and is considered the most pathogenic both in pigs and humans. Other serotypes implicated in diseases are types 1–9 and 14 (Gottschalk et al. 2007). However the presence of "*S. suis*-like strains" which are biochemically similar but genetically distinct have been identified (reviewed in (Hlebowicz et al. 2019)). Therefore, molecular methods including multilocus sequence typing have been increasingly used for typing, with at least 16 sequence types identified to date (Goyette-Desjardins et al. 2014).

Pigs colonized with *S. suis* typically harbor the organism in their tonsils and may never exhibit clinical signs or symptoms (carriers). Some carrier piglets eventually develop bacteremia, septicemia or meningitis due to dissemination of *S. suis* from tonsils and other mucosal surfaces (Fittipaldi et al. 2012; Staats et al. 1997). Disease syndromes in swine also include arthritis, pneumonia, endocarditis, encephalitis, polyserositis, abscesses, and abortion (Wertheim et al. 2009). Death occurs within hours of the onset of clinical signs in pigs with peracute, i.e., very violent or acute forms of infection. Acute disease typically characterized by fever (up to 42 °C), depression, anorexia and lassitude may result in deaths, chronicity, or healthy carriers. In its chronic form, lameness and/or residual central nervous system signs may be apparent (Fulde and Valentin-Weigand 2013). Clinical manifestations of *S. suis* are observed to vary by geographical location (Wangkaew et al. 2006; Yu et al. 2006; Tang et al. 2006). There have been varying reports on the incubation period of *S. suis* ranging from 3 h to 14 days (Yu et al. 2006), and 60 h to 1 week (Mai et al. 2008). Short incubation periods are found to be consistent with direct entry of *S. suis* into the blood stream through skin wounds. There have been no consistent findings in seasonal variation of *S. suis* infection (Wangkaew et al. 2006; Mai et al. 2008; Huang et al. 2005).

S. suis infection is reported in domesticated pigs (Staats et al. 1997). In addition, the organism has been isolated from the intestinal flora of wild boars, dogs, cats, horses, deer and ruminants (Staats et al. 1997; Devriese et al. 1992; Baums et al. 2007; Devriese and Haesebrouck 1992). The rate of asymptomatic carriage in pigs is estimated to be around 80%, representing a potential source of infection to other animals and humans (Lun et al. 2007; Staats et al. 1997; Arends et al. 1984; Ngo et al. 2011). Pigs acquire *S. suis* via vertical and horizontal transmission as the sow is capable of harboring *S. suis* in the genital tract (Fulde and Valentin-Weigand 2013; Fittipaldi et al. 2012; Gottschalk 2011). Carrier rates are highest in pigs between 4 and 10 weeks of age, but infection can occur at any age (Staats et al. 1997; Clifton-Hadley et al. 1984). Environmental contaminants such as feces, dust, water, and feed are considered to be secondary sources of infection (Staats et al. 1997). Vectors such as houseflies (Fulde and Valentin-Weigand 2013; Staats et al. 1997; Enright et al. 1987) and mice (Fulde and Valentin-Weigand 2013; Staats et al. 1997; Williams et al. 1988) are also considered to play a role in disease transmission to pigs. Factors such as stress, crowding, poor ventilation, and concurrent disease could potentially predispose herds to an outbreak of *S. suis* infection (Fulde and Valentin-Weigand 2013; Staats et al. 1997). Morbidity rate in pigs ranges from $<1\%$ to $>50\%$, rarely exceeding 5% (Wertheim et al. 2009). Nevertheless, research has demonstrated that morbidity due to *S. suis* is severely enhanced in the presence of other bacterial and viral infectious agents suggesting the importance of surveillance for *S. suis* (Staats et al. 1997).

Human *S. suis* infection is considered an emerging zoonosis (Lun et al. 2007; Wertheim et al. 2009). Studies observed that longer duration of exposure to pigs and pork affects *S. suis* carriage in the population (Elbers et al. 1999; Smith et al. 2008; Strangmann et al. 2002). Infection rate in individuals with high-risk exposures is estimated to be 1500 times higher than that of the general population (Lun et al. 2007; Arends and Zanen 1988). Pig farmers (Smith et al. 2008; Bartelink and van Kregten 1995; Breton et al. 1986; Sriskandan and Slater 2006; Fowler et al. 2013), abattoir-workers (Arends and Zanen 1988; Bartelink and van Kregten 1995; Breton et al. 1986), veterinarians (Elbers et al. 1999), hunters (Baums et al. 2007; Halaby et al. 2000), and meat-processing workers (Tramontana et al. 2008; Yu et al. 2005) are observed to have a higher risk of *S. suis* infection . Consumption of uncooked or partially cooked pork products is also considered a potential risk factor for *S. suis* infection (Wertheim et al. 2009; Wangsomboonsiri et al. 2008). A mortality rate of 17% was observed in the population and about 2/3 of deaths occurred in the first 24 h after admission (Wangsomboonsiri et al. 2008). Human infections are typically reported as sporadic cases with an exception of two large outbreaks resulting in 25 and 204 cases, and 14 and 38 deaths, respectively (Yu et al. 2006; Tang et al. 2006). Person-to-person transmission is unlikely to occur without very close contact such as with infected blood. Nevertheless, there is strong evidence of *S. suis* transmission from pigs to humans and a great potential for reverse zoonoses, i.e., transmission from humans to animals.

S. suis is sensitive to antibiotics such as penicillin, ampicillin, amoxicillin, ceftriaxone, and cephalosporin (Lun et al. 2007). Clinical disease is known to be suppressed by fortifying feed with antibiotics at therapeutic levels (Staats et al. 1997). However, it

does not eliminate carriers thus negatively impacting transmission of *S. suis.* One of the major drawbacks is the development of antimicrobial resistant *S. suis* isolated from both pigs and humans (Mai et al. 2008; Gottschalk et al. 1991c; Prieto et al. 1994; Aarestrup et al. 1998; Marie et al. 2002; Shneerson et al. 1980; Wisselink et al. 2006; Vela et al. 2005). Vaccines currently in use prevent outbreak in pig herds, but are observed to have varying efficacy (Lun et al. 2007; Haesebrouck et al. 2004). A human vaccine for *S. suis* is not available (Lun et al. 2007; Wertheim et al. 2009).

Prevention of *S. suis* transmission in both humans and pigs depends on control of contact with sick animals. Improving pig-raising and breeding conditions and vaccination of pigs could ensure reduction in *S. suis* infection outbreaks and prevent transmission to humans (Lun et al. 2007). In addition, the potential risk of transmission via contact or consumption of contaminated pork products can be diminished by education and increasing awareness on preventative measures to eliminate this mode of transmission (Lun et al. 2007). World Health Organization (WHO) recommends cooking pork to an internal temperature of 70 °C or until juices appear clear rather than pink (Lun et al. 2007). Use of clean gloves and hand hygiene should also be encouraged when handling raw or undercooked pork products. Review of the current literature exposed a knowledge gap on differences in the virulence capacity and geographical variation of *S. suis* strains. Addition of this information to other available epidemiological data on *S. suis* is warranted to prevent further propagation and losses worldwide due to this pathogen.

4.1.6 Shiga-Toxin Producing Escherchia coli (STEC)

Escherchia coli, a short, rod shaped, Gram-negative, non-sporing, facultative anaerobic bacterium belongs to the family *Enterobacteriacae* (Sussman 1985; Mainil 2013). The gastro-intestinal tract of humans and other warm blooded animals are the primary hosts of this organism (Cheleste et al. 2002; Bell 2002). Although most *E. coli* strains are non-pathogenic, and part of normal microflora, some strains have evolved as pathogenic (Mainil 2013; Bell 2002; CDC 2012b). Pathogenic strains of *E. coli* acquire mobile virulence gene located on pathogenicity islands, integrated bacteriophages, or on plasmids (Bell 2002; FAO/WHO 2011), and are able to cause wide spectrum of diseases in many species including pigs, cattle, rabbits and humans (Mainil 2013; Jay et al. 2007). On the basis of their virulence traits, pathogenic strains of *E.coli* are categorized into at least six groups: entero-pathogenic *E.coli* (EPEC), entero-toxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), entero-haemorrhagic *E. coli* (EHEC), entero-aggregative *E. coli* (EaggEC), and diffusely adherent *E. coli* (DAEC) (Bell 2002; CDC 2012b; Catalina Lopez-Saucedo et al. 2003).

Shiga toxin-producing *E. coli* (STEC), also known as verotoxin-producing *E. coli* (VTEC), are a diverse group of pathogens that has become of significant health concern. These strains of *E. coli* are able to cause disease in both humans and animals. Although EHEC 0157:H7 is recognized as the most prominent STEC, over 200 non-O157:H7 STEC serotypes have been identified, and over 100 strains can cause disease in humans (Bell 2002; Rangel et al. 2005; Fratamico et al. 2004;

Patricia and Griffin 1991). In the United States, most EHEC strains are serotype O157:H7 that accounts for 30–50% of EHEC strains (Johnson and Sears 2006). Infection with non-O157:H7 serotype is more common in other nations including Australia, Argentina, and many European countries, and may account for the majority of haemolytic uremic syndrome (HUS) infections in these countries (Fratamico et al. 2004). Serotypes 026, 045, 0103, 0111, 0121, and 0145 have been associated with human disease and may account for approximately 70% of Non-O157:H7 STEC human infections in the United States (Wells et al. 2012). *E. coli* O157:H7 was first identified as pathogenic strain following two outbreaks of hemorrhagic colitis by consuming undercooked ground beef in 1982 in the United States (Rangel et al. 2005; Patricia and Griffin 1991; Pennington 2010; Beilei Ge et al. 2002; Phillip Tarr and Chandler 2005). Since the discovery of *E. coli* O157:H7, large foodborne outbreaks and sporadic incidence have been documented in the United States and many parts of the world (FAO/WHO 2011; Phillip Tarr and Chandler 2005; Tiiomas et al. 1995). Annually, EHEC O157:H7 and other serotypes of STEC accounts approximately 110,000 cases of illness in the United States (Cornick and Helgerson 2004).

STEC is a worldwide public health threat. Over 100 different serotypes can cause human illness (Acheson 1999). The exact global prevalence of STEC infection is unknown since there is no uniform surveillance and reporting system. Annually, an estimated 73,000 cases are caused by *E. coli* O157:H7 in the United States leading to estimated 2,168 hospitalizations and 61 deaths (Rangel et al. 2005; Beilei Ge et al. 2002). Non-O157:H7 accounts for 37,740 cases and 30 deaths annually in the United States (Beilei Ge et al. 2002). Studies have indicated that STEC infection is more prevalent in the northern regions of the United States, and is more common in summer season (Phillip Tarr and Chandler 2005; Tiiomas et al. 1995). *E. coli* O157:H7 can infect people of any age. However, children and elderly are more prone to develop severe illness and HUS compared to any other age groups (Phillip Tarr and Chandler 2005; FAO/WHO 2011). Various studies have suggested that animals including cattle, sheep, goats, and pigs are reservoirs for different STEC strains (Cheleste et al. 2002; Bell 2002; Fratamico et al. 2004). Although cattle are considered to be the primary reservoir of *E. coli* O157:H7, it is implicated in fecal shedding of other domestic livestock and wildlife (Jay et al. 2007). Evidence from epidemiological studies suggests that domestic pigs are potential reservoirs and biologically competent hosts of *E.coli* O157:H7 (Jay et al. 2007; Fratamico et al. 2004; Cornick and Helgerson 2004). In 2006, a spinach associated outbreak of *E. coli* in the United States caused 205 cases of illness and six deaths. A successful isolation of the outbreak strain from feral swine living close to spinach field provides insight on swine-to-swine transmission and transmission between cattle and swine. A study conducted by Jay et al. was able to recover related *E. coli* O157: H7 subtypes from feral swine, cattle, surface water, soil, and sediment that were contaminated with spinach causing the outbreak (Jay et al. 2007). *E. coli* O157: H7-infected swine can shed the bacteria in feces for about 2 months thus serving as a reservoir host (Cornick and Helgerson 2004). Rios et al. isolated enterohemorrhagic STEC subgroup 026 and 0111 from the intestinal content of pigs. These strains had

virulence genes (*stx1, stx2*) suggesting they were potential human pathogens (Fratamico et al. 2004; Maritza Rios et al. 1999). Fratamico et al. isolated STEC serogroup O2, O5, O7, O8, O9, O15, O65, O91, O101, O120, O121, O163, and several others from fecal samples of pigs (Fratamico et al. 2004). Other studies have indicated that STEC strains can be isolated from both healthy pigs and pigs with diarrhea and edema disease (Fratamico et al. 2004; Cornick and Helgerson 2004).

Various O, H, and K antigens of *E.coli* are identified (Kauffmann 1947). Virulent strains have gens for fimbriae, adhesions, and wide varieties of exotoxins that help pathogenic *E. coli* to colonize human tissues (Mainil 2013). *E. coli* O157:H7 produces a type III secretion system that injects two types of proteins, which disrupt the cells metabolism and provide surface for attachment (Mainil 2013; Pennington 2010). Shiga toxin is the key virulence factor of STEC (Patricia and Griffin 1991; Werner Brunder and Karch 1997), and it causes necrosis of host cells and tissues (Pennington 2010). Although several virulence factors encoded by a 60-MDa plasmid such as a bifuctional catalase-peroxidase, secreted serine protease (EspP), α-hemolysin (EHEC-Hly), and chromosomally encoded enterotoxin EAST1 have been found, their role in pathogenicity still remains unclear (Cheleste et al. 2002; Werner Brunder and Karch 1997; Paul and Mead 1998). All *E. coli* belonging to STEC strains can produce Shiga toxin1 (*Stx1*) and/or Shiga toxin 2 (*Stx2*) or variants of *Stx1 or Stx2*. *Stx2e* variant strain of STEC cause edema disease in swine (Fratamico et al. 2004; Patricia and Griffin 1991).

The incubation period of STEC infection is 2–4 days, but may vary from 1–5 days (Acheson 1999). Many people infected with STEC remain asymptomatic (Pennington 2010); others suffer from mild to severe gastro-intestinal symptoms. STEC infection ranges from mild to life threatening. Symptoms include watery diarrhea which can be bloody as the disease progresses), severe abdominal pain, low to mild-grade fever and nausea and vomiting. Fecal and peripheral leukocytosis is often present. Most people recover within 5–7 days of the onset of infection (Cheleste et al. 2002; Bell 2002; Patricia and Griffin 1991; Acheson 1999). Hemolytic uremic syndrome (HUS) is developed in 5–10% of STEC cases (Acheson 1999). HUS is a serious complication characterized by hemolytic anemia, thrombocytopenia, fever, and kidney damage (Cheleste et al. 2002; Rangel et al. 2005; Acheson 1999; Frederick Koster et al. 1978). HUS often develops in children below age 5 as a complication of *E. coli* infection. HUS accounts 15% of EHEC infection in children below 10 years old. HUS is seen as a complication in 6–9% of overall infections (Bell 2002; Phillip Tarr and Chandler 2005; Tiiomas et al. 1995). 5–10% of HUS patient may die or develop further complications (stroke) (Cheleste et al. 2002). An estimated 50% of HUS patients may have permanent kidney damage. Since patients with HUS are in risk of renal failure, they should be hospitalized (Cheleste et al. 2002; Acheson 1999). The mortality of HUS is approximately 5% (Acheson 1999), and the case fatality rate of HUS is approximately 10% (Bell 2002).

The use of antibiotics could aid in Shiga toxin production thus exacerbating the disease; as such, this treatment is not recommended in the United States. Symptomatic treatment along with maintaining hydration is very important to prevent further complications. Prevention is the most important aspect of STEC infection (Acheson

1999; Paul and Mead 1998). Frequent hand-washing is the most effective tools to avoid person-to-person transmission. Proper handling of foods, preventing temperature abuse and cross-contamination of foods, as well as maintaining a proper storage temperature is essential. Boiling water before drinking can help to stop waterborne transmission in developing countries where drinking water system is poor. The practice of using animal fecal as manure for crops used for human consumption should be stopped. Foods should be cooked to the optimum temperature. Undercooked meat and unpasteurized milk should not be consumed (Bell 2002; CDC 2012b; Acheson 1999).

4.2 Colistin-Resistant Organisms

While not a single species, the emergence of transmissible colistin resistance (a polymixin antibiotic) in important food-borne organisms has been a key concern in recent years. A novel plasmid-mediated colistin resistance gene, *mcr-1*, was reported in animals and humans in China (Liu et al. 2016), potentially emergent due to use of polymixins in livestock farming in the country. The initial report examined *E. coli* previously collected from pigs at slaughter and retail meat products, and *E. coli* and *Klebsiella pneumoniae* obtained from human patients; isolates were collected between 2011 and 2014. *mcr-1* was detected in a portion of all samples tested, ranging from 0.7% (human samples of *K. pneumoniae,* 2014) to 28.0% (*E. coli* in retail chicken meat samples, 2014). Pigs at slaughter and pork product positivity ranged from 6.3% positive (2011, retail pork) to 25.4% (pigs at slaughter, 2013). Since this time, *mcr-1* has been found in samples dating back to at least 2002 and on 5 continents (Wang et al. 2018); while most were in *E. coli*, other food-borne pathogens including *Salmonella enterica* were also positive. Related colistin genes *mcr-2*, *mcr-3*, *mcr-4*, and *mcr-5* have also been identified (Rebelo et al. 2018).

Colistin is an antibiotic of last resort for multi-drug resistant infections by Gram-negative bacteria; as such, transmissible resistance to this drug is concerning. Colistin was used in animal production for both treatment and growth promotion purposes in some countries in Europe and Asia (Rhouma et al. 2016). However, this does not appear to be the only potential reason for emergence, as *mcr-1*-positive organisms have been identified in countries even where colistin has not been used in animal populations (such as the United States).

4.3 Hepatitis E Virus (HEV)

Hepatitis E virus (HEV) belongs to the *Hepeviridae* family, and is the most common cause of acute viral hepatitis globally. A single-stranded positive-sense RNA virus, it was first visualized in 1983 (Balayan et al. 1983).

There are four genotypes of HEV that appear to infect humans: HEV1, HEV2, HEV3, and HEV4. While HEV1 and HEV2 do not appear to be spread between humans and animals, zoonotic transmission is common with HEV3 and HEV4. Pigs

are the main reservoir, but infection has also been documented in wild boars (De Sabato et al. 2020) and a variety of other wild and domestic species, including cats, dogs, horses, deer, sheep, cattle, and rabbits (Izopet et al. 2012; Schlosser et al. 2014; Doceul et al. 2016; Yan et al. 2016).

While large epidemics of HEV1 and HEV2 can occur among human populations due to fecal contamination of water supplies (especially during flooding and heavy rainfall), transmission of HEV3/HEV4 from animals to humans seem to occur more commonly due to close contact with infected animals or animal products. This can include contact with animal feces or other secretions (including milk of infected animals), or handling/consumption of under-cooked meat products. As such, farmers, veterinarians, and slaughterhouse workers are more prone to zoonotic HEV infections than the general population (Aslan and Balaban 2020).

Symptoms of HEV infection are generally mild; infections may be asymptomatic. Symptoms may include nausea, vomiting, malaise, and fever, which in some patients continue to jaundice and other hepatic symptoms (Lhomme et al. 2020), which tend to be more severe in those infected with HEV1/HEV2 than the zoonotic HEV strains (Pischke and Wedemeyer 2013). Infection is generally cleared without treatment, but in severe cases, therapy with the antiviral ribavirin may be helpful (Peron et al. 2011). There is currently no vaccine to prevent infection, although vaccines are in development (Zhu et al. 2010); as such, safety during animal contact and consumption of animal products are the primary ways to prevent zoonotic HEV infections at this time.

4.4 Japanese Encephalitis Virus (JEV)

Japanese encephalitis virus (JEV) belongs to the genus *Flavivirus*, family *Flaviviridae* (Weaver and Barrett 2004; van den Hurk et al. 2009; Solomon 2004). This virus was first isolated from a fatal human encephalitis case in Japan in 1935 (Weaver and Barrett 2004) and from *Culex tritaeniorhynchus* mosquitoes in 1938 (van den Hurk et al. 2009). This arbovirus (arthropod-transmitted) (Weaver and Barrett 2004; Igarashi 2002) is the leading cause of worldwide epidemics of viral encephalitis (Weaver and Barrett 2004; Tom Solomon et al. 2000). This single stranded positive sense RNA virus with a genome length of 11 kilobases (Weaver and Barrett 2004; Solomon 2004) consists of a spherical virion with a 30 nm core that is surrounded by a lipid envelop. The RNA genome of JEV encodes a single polypeptide that is cleaved into non-structural proteins such as NSI, 2A, 2B, 3, 4A, 4B, and 5, and structural capsid, member (M) and envelope (E) proteins (Tiroumourougane et al. 2002; Spickler 2007). The E protein plays vital antigenic role as it is important for viral attachment and entry into host cells (Solomon 2004; Mouhamadou Diagana and Dumas 2007). This virus has only one serotype and two subtypes, and is closely related to St. Louis encephalitis virus, Murray Valley encephalitis virus, West Nile virus, and dengue fever virus (Solomon 2004; Tiroumourougane et al. 2002; Spickler 2007). On the basis of nucleotide sequencing of the viral pre-membrane (prM), JEV can be categorized into four different genotypes. Moreover, the phylogenic analysis of the viral envelop 'E' gene has classified JEV strains into five genotypes (Health WOfA 2009). A wide

range of host species might be infected by JEV including cattle, snakes, birds, pigs, horses, and other farm animals (Weaver and Barrett 2004; van den Hurk et al. 2009; Spickler 2007). High heat (56 °C for 30 min), acidic environment (pH 1–3), and various chemicals and disinfectants such as iodine, phenol, and formaldehyde also inactivate the virus. JEV is quite sensitive to ultraviolet light and gamma irradiation (Health WOfA 2009).

JEV is transmitted between wild and domestic birds and pigs by *Culex* species mosquitoes (Tom Solomon et al. 2000; van-den-Hurk et al. 2008). *Culex tritaeniorhynchus* plays a major role, because many animals such as horses, swine, humans, and birds are susceptible hosts. It is also the most important vector for human infections (Weaver and Barrett 2004; Tom Solomon et al. 2000). These mosquitoes particularly breed in pools of stagnant water, especially in flooded rice fields (Tom Solomon et al. 2000; Erlanger et al. 2009). JEV has also been isolated from other species of mosquitoes (Tiroumourougane et al. 2002). Ardeid or wading birds (herons and egrets) are considered as the primary maintenance hosts (Igarashi 2002; van-den-Hurk et al. 2008; Erlanger et al. 2009) and pigs are the main amplifying hosts (Weaver and Barrett 2004; van-den-Hurk et al. 2008, 2009; Tom Solomon et al. 2000; Spickler 2007; Erlanger et al. 2009), which are necessary for pre-epizootic amplification of the virus. Pigs can act as maintenance hosts in endemic regions (van den Hurk et al. 2009). Pigs in close proximity to humans are the most important natural hosts for transmission of JEV to humans (Weaver and Barrett 2004; Solomon 2004; Tom Solomon et al. 2000; Tiroumourougane et al. 2002). Pigs have a prolonged and high viraemia and a high natural infection rate of 98–100% (van den Hurk et al. 2009). Domestic pig rearing aids in the transmission to humans (Erlanger et al. 2009). Humans and horses are dead-end or incidental hosts (van den Hurk et al. 2009; Tiroumourougane et al. 2002). Human-to-human transmission of JEV has not been reported yet (Tiroumourougane et al. 2002).

JEV remains the major cause of viral encephalitis in Southeast Asia (van-den-Hurk et al. 2008), but it is widely spread in eastern and south-eastern Asian countries, the Pacific Rim, and in Northern Australia. However, related neurotropic flaviviruses are found worldwide (Tom Solomon et al. 2000; Erlanger et al. 2009). Japanese encephalitis claims about 50,000 human cases and 15,000 deaths annually (Weaver and Barrett 2004; Tom Solomon et al. 2000). Due to lack of surveillance and inadequate data collection, the actual incidence rate might be a lot higher. It is estimated that 175,000 cases of Japanese encephalitis occurs annually worldwide. 11,000 cases and more than 2000 deaths resulted from JEV outbreaks in Nepal and Northern India between 2005 and 2007 (van den Hurk et al. 2009). Children under 15 years of age are mainly affected by JEV in endemic areas (Tiroumourougane et al. 2002). Pediatric encephalitis is caused by this virus in many Asian countries including India, Korea, and China. More than one third of world populations are at risk of infection of JEV. The epidemiological patterns of JEV involve endemic and epidemic activities in tropical regions and temperate and subtropical areas, respectively. There is no seasonal pattern in endemic areas, but epidemic activity is observed in summer and autumn months in temperate and subtropical areas. Migratory birds help the virus to travel large distances (Weaver and Barrett 2004).

Japanese encephalitis is mainly a disease of rural areas. It is endemic in tropical regions and often associated with irrigated rice agriculture (van den Hurk et al. 2009). The annual incidence of Japanese encephalitis is between 10 and 100 per 100,000 population in endemic areas (Tiroumourougane et al. 2002).

The incubation period of Japanese encephalitis in man is not exactly known. It varies from 1–6 days, and can be as long as 14 days (Tiroumourougane et al. 2002). Incubation period in horses is 8–10 days (Spickler 2007). Most infections of Japanese encephalitis are asymptomatic. Clinical features are developed only in 1 in 50 to 1 in 1000 infections. The clinical manifestations range from mild flu-like illness to severe and lethal meningoencephalomyelitis (van den Hurk et al. 2009; Tom Solomon et al. 2000). High grade of fever with or without rigors, headache, general malaise, and vomiting are present in the prodromal stage. It is followed by the encephalitis stage which is characterized by abnormal movements, muscular rigidity, neck stiffness, convulsions, altered neurological functions, and other CNS signs (Tiroumourougane et al. 2002). Convulsion often occurs and it is reported in about 85% of children and 10% of adults (Tom Solomon et al. 2000). The recovery stage may be accompanied by signs of CNS injury. Thick, slow speech, aphasia, and paresis are seen as residual neurological impairments. Complications include secondary bacterial infection, urinary tract infection, and stasis ulcers (Tiroumourougane et al. 2002). Abnormal mental behaviours may exist in some patients leading to misdiagnosis of mental illness (Tom Solomon et al. 2000). Poliomyelitis-like acute flaccid paralysis and "fever associated seizure disorder" has also been identified in some cases (Tiroumourougane et al. 2002). Almost one third of patients admitted to hospital with Japanese encephalitis die (Tom Solomon et al. 2000), and 45% to 70% of survivors suffer from neurological sequelae that last for months. The case fatality rate of Japanese encephalitis can be as high as 67%. Higher fatality rates are seen in children and the elderly population (van den Hurk et al. 2009). The mortality rate varies in a range of 8.5–72% (Tiroumourougane et al. 2002). Pigs with Japanese encephalitis exhibit reproductive disease with stillbirth as the most common symptom (van den Hurk et al. 2009).

JEV can be detected using reverse transcriptase polymerase chain reaction in human CSF samples. But the reliability of this test still remains unconfirmed. Serological tests such as IgM and IgG ELISA are widely used for the detection of antibodies to JEV in human and swine (CDC 2021). However, this type of testing requires complex equipment and it is not feasible in the rural areas of developing countries. A recent modification of this test to a simple nitrocellulose membrane based format is more useful in rural areas, since it does not require any sophisticated equipment and can be interpreted by eye vision (Tom Solomon et al. 2000). Virus neutralization and epitope blocking ELISAs can help to differentiate if cross-reactions have been occurred in serological tests due to the presence of other viruses of the JEV serogroup (Kitai et al. 2007; Jacobson et al. 2007). Various other serological tests such as haemagglutination inhibition, the complement fixation test, single radial hemolysis, and neutralisation are still in practice in some laboratories. Other antigen detection techniques in CSF include reverse passive

hemagglutination, immunofluorescence, and staphylococcal coagglutination tests using polyclonal or monoclonal antibodies (Tom Solomon et al. 2000).

Treatment of Japanese encephalitis involves supportive and symptomatic care. Although isoquinolone compounds and monoclonal antibodies are effective in vitro and animal models, respectively, there is no specific treatment available for this disease. Controlling convulsion and raised intracranial pressure are crucial. Physical therapy and excellent nursing care are important to prevent further complications (Solomon 2004; Tom Solomon et al. 2000; Spickler 2007).

Prevention strategies should be focused on control of mosquito vectors, improvement in animal husbandry practices, changing agricultural practices, preventing amplification of the virus in pigs and birds, measures against reservoirs, and immunizing of species at risk (van-den-Hurk et al. 2008, 2009; Tom Solomon et al. 2000; Tiroumourougane et al. 2002; Spickler 2007; Erlanger et al. 2009). Prevention of mosquitoes from biting human is essential (Tiroumourougane et al. 2002). Use of bed nets, wearing long sleeved shirts and long trousers, and application of insect repellent on exposed body surfaces, avoidance of outdoor sleeping, and decreasing outdoor activity during twilight and dawn would be beneficial (Spickler 2007; Mackenzie and Smith 2006). Relocation of piggeries away from residential areas and making them mosquito proof could decrease the risk of JEV. Vaccine is recommended to people, especially for high-risk group such as laboratory workers with potential risk of exposure to JEV, travelers who spend more than a month in endemic areas, and residents of endemic areas. Travelers who spend less than 30 days during epidemics and carry out extensive outdoor activity should also get vaccinated. Vaccinations of pigs also yield positive results (Tiroumourougane et al. 2002). Vero cell-derived JEV vaccine is currently used in the United States (Fischer et al. 2010).

4.5 Nipah virus

The first cases of Nipah virus (NiV) infection were identified during an outbreak in Malaysia in September 1998 and involved pig farmers who had contact with pigs on a regular basis (Luby and Gurley 2012). JEV was initially suspected due to the similar clinical presentation in humans and because it is endemic in the outbreak area in Malaysia (Chua 2012). Although known measures to control JEV were taken, such as vaccination, the number of cases did not decrease (Chua 2012). The cause of the outbreak was eventually discovered to be a novel paramyxovirus (Chua et al. 1999, 2000). Humans with direct contact with pigs were at an increased risk of contracting the virus (Chua 2003). During March 1999 in Singapore, there was an outbreak of NiV-associated encephalitis and/or pneumonia in abattoir workers (Paton et al. 1999) who were more likely to have exposures to the urine or feces of imported Malaysian pigs during the corresponding outbreak (Luby and Gurley 2012). An isolate obtained from a deceased abattoir worker in Singapore was identified as having the identical nucleotide sequence as the isolates collected from human and pig cases in Malaysia (Paton et al. 1999). This provides evidence that the

same strain infected human and pig cases in Malaysia and that the outbreak had spread to a different country.

Isolates collected from the lungs and respiratory secretions from infected pigs revealed the presence of NiV and this taken in conjunction with the observation that many of the NiV human cases were in contact with pigs has led to the suspicion that NiV may be transmitted from pigs to humans through infected saliva and potentially infected urine (Uppal 2000).

When officials could no longer ignore the potential of a novel agent as the culprit, they began further diagnostic tests that identified a novel paramyxovirus (Chua et al. 1999, 2000, 2007) that was closely related to Hendra virus (Ksiazek et al. 2011). This novel virus was named Nipah virus after Kampung Sungei Nipah, the residential village of the patient from whom the first virus was isolated (Ksiazek et al. 2011). Since this initial outbreak in 1998–1999, the exact geographical distribution of NiV remains unknown, but it appears to occur in Asia Pacific and South East Asia (Young et al. 1996) with Singapore, Bangladesh, and India as countries specifically encountering NiV outbreaks (Luby and Gurley 2012). Nipah virus outbreaks have been reported nearly every year beginning in 2001 in the western and northwestern regions of Bangladesh and in West Bengal, India (Luby and Gurley 2012).

Through surveillance efforts, fruit bats, from the genus *Pteropus*, have been found to be the reservoir of NiV (Arif et al. 2012). This virus can then be spread to humans through pigs acting as an intermediate host (Arif et al. 2012). The distribution of this genus of fruit bats encompasses areas from the eastern coast of Africa to the South East of Asia, to the Philippines and Pacific Islands, and as far south as Australia (Young et al. 1996). The distribution of this genus of bats suggests that it may be possible for NiV to be spread across the regions inhabited by these fruit bats; public health officials need to be aware of the potential for NiV to spread to these susceptible areas that may not have seen this disease before. A study performed in Goalondo of Rajbari district in central Bangladesh during a 2004 outbreak found that NiV was found in 14% of blood samples contained antibodies from clinically healthy bats (Arif et al. 2012).

It is suspected that pigs may contract the virus from ingesting fruits that have been nibbled on by NiV infected fruit bats living near pig farms (Arif et al. 2012). Moreover, the virus has been isolated from fruits that have been half eaten by bats in Malaysia (Chua et al. 2000). The majority of NiV-infected pigs develop mild illness (Parashar et al. 2000), while some pigs never develop clinical signs of disease. In infected adult pigs, the case fatality rate is less than 1–5% (Mohd Nor et al. 2000). Some mathematical models suggest that in order for NiV to be sustained at epidemic levels in pigs, multiple spillover events are necessary for the development of a dynamic population with numbers of susceptible pigs above the needed threshold level to maintain transmission within pigs for months (Pulliam et al. 2012).

There is evidence that various husbandry practices may play a role in determining how long an epidemic will last and in influencing the characteristics of an outbreak (Luby and Gurley 2012). In large factory farms, thousands of pigs are raised together in more compact conditions and have an increased risk of interacting with pigs from other farms, so longer transmission chains in pigs will be more likely to occur (Luby

and Gurley 2012). However, in rural areas with fewer pigs kept on individual farms that may have limited contact with pigs from other farms, a shorter transmission chain may be seen, because the number of susceptible pigs will decrease more slowly overtime since fewer will be in contact with each other. This second type of husbandry practice has not been linked to an outbreak to date; however, human cases have been linked to animal infections with this form of husbandry (Luby and Gurley 2012).

The majority of infected pigs present with a mild illness, if an apparent illness is detected at all. Those which develop clinical symptoms present most often with fever, agitation, trembling, and twitching (Mohd Nor et al. 2000). These symptoms appear along with labored and rapid respirations, increased drooling, and a loud, nonproductive barking cough (Mohd Nor et al. 2000). Almost all of the pigs with symptoms are often diagnosed with acute respiratory syndrome (Kay-Sin Tan and Goh 1999; Chua 2003). Necropsies revealed that pigs with severe disease have had extensive lung damage with giant cell pneumonia; NiV antigen can be detected in lung tissue as well as in the epithelial cells lining the upper airways, respiratory secretions, and in renal tubular epithelial cells (Chua et al. 2000; Middleton et al. 2002).

Symptoms in humans may vary from severe to mild to asymptomatic (O'Sullivan et al. 1997), may lead to debilitating chronic neurologic conditions, and can be fatal (Arif et al. 2012). The incubation period has been reported to be between 4 and 18 days, but occasionally clinical symptoms may not develop until an average of 8 months after an exposure (Holmes 2001). Clinical symptoms in humans usually present as severe acute encephalitis with individual symptoms that include fever, headache, vomiting, breathing difficulty, seizures, and progression into coma (Luby and Gurley 2012; Arif et al. 2012). Patients may also develop pneumonia from an accumulation of respiratory secretions in the lungs, which has been noted to occur in up to 25% of cases (Chua et al. 1999; Chadha et al. 2006).

Cases with NiV infection may also develop chronic illness leading to severe neurologic conditions later in life, even if the case did not present with acute symptoms shortly after exposure (Luby and Gurley 2012; Tan et al. 2002). Patients who had developed acute encephalitis and appeared to have recovered may also develop neurologic conditions and relapses of encephalitis months to years after their initial infection, with NiV antigen being found in the neurons of those who died after a case of late-onset encephalitis (Tan et al. 2002).

In many situations, patients are more likely to be in direct contact with pigs that appeared to be sick when compared to farm controls (Parashar et al. 2000). Direct contact with pigs involves activities such as feeding pigs, processing piglets, aiding in breeding and birthing, injecting and medicating pigs, and handling dead pigs (Parashar et al. 2000). The case fatality rate may be high for humans. During the 1998–1999 Malaysia outbreak, of the 283 reported cases, 39% or 109 cases died (Chua 2003). Although contact with pigs increases the risk of contracting NiV, there have been reported cases of disease in humans without pig contact or without direct pig contact such as cleaning a crate that was used to house infected pigs (Parashar et al. 2000; Kay-Sin Tan and Goh 1999). This suggests that it may be possible for pig secretions or excretions to be infectious for hours, if not days (Kay-Sin Tan and Goh 1999).

Human-to-human transmission has been reported, but the rates vary geographically (Luby and Gurley 2012). Numerous outbreaks involving human-to-human transmission have been recognized in Bangladesh and India, while only very few reports on human-to-human transmission exist from Malaysia (Luby and Gurley 2012) and the Philippines (Ching et al. 2015), where horses rather than pigs were implicated. In a 2004 Bangladesh outbreak, a chain of NiV transmission was sustained through five generations, which is the longest reported chain of human-to-human transmission (Gurley et al. 2007). Through reviewing human NiV cases from 2001–2007 in Bangladesh, Luby et al. (2009) found that 51%, or 63 out of 122 cases, contracted NiV after being in close contact with a patient. Various investigations in Bangladesh suggest that the primary mode of transmission between humans is through respiratory secretions and that those who did have difficulty breathing as one of their symptoms were more likely to spread the virus than those who did not (12% compared to 0%, $p = 0.03$) (Luby et al. 2009). During the 2004 Bangladesh outbreak referred to earlier, people caring for human cases who shared utensils, ate the patients' leftover food, slept in the same bed with a coughing patient, and fed and/or hugged dying patients were more likely to contract NiV (Blum et al. 2009).

Since direct contact with pigs has shown to increase the risk of contracting NiV, the use of personal protective equipment (PPE) is imperative in reducing the risk of contracting the virus (Uppal 2000). General safety measures that should be taken when contact with suspected NiV infected pigs occurs is changing needles between every pig, using soap or detergent to wash the hands and body, disinfecting abattoir and veterinary equipment, spraying disinfectant on trucks every time they leave a farm, disinfecting dead pigs before burying them, and avoiding contact with blood, urine, and feces (Uppal 2000). Recommendations for PPE to protect individuals are goggles and face masks for eye protection, masks that cover the nose and mouth, rubber gloves, a long sleeved shirt, a long apron, long pants, and rubber boots (Uppal 2000). Measures in addition to PPE use have been implemented to control the spread of the disease. In Malaysia, when PPE was employed to those who are in direct contact with pigs, especially sick pigs, along with the implementation of livestock transportation restrictions, and culling of a large number of pigs (over 900 thousand), the amount of human cases drastically declined (Uppal 2000). The importance of control must be stressed because during an outbreak there is a large social impact due to the potential closure of schools, loss of human life leading to fewer community members able to work and earn money, loss of pig populations (especially when culling is implemented) which minimizes farmer's wages (even if marginal compensation occurs for their lost revenue), and decreases a community's moral while increasing a sense of panic (Uppal 2000).

4.6 Swine Influenza virus

Influenza is an acute respiratory disease caused by viruses of the family *Orthomyxoviridae* (Capua and Munoz 2013; Thacker and Janke 2008). The virus was first isolated in 1930 in the United States (Kothalawala et al. 2006). Estimated 36,000

human deaths and 200,000 hospitalizations are due to influenza virus infections in the United States per year (Ramirez et al. 2006). The genome of the virus is composed of eight negative-strand RNA segments. This allows both for a high mutation rate (as an RNA virus) leading to antigenic drift and for mixing of genomic segments via recombination causing antigenic shift of the virus. Two major surface glycoprotein, hemagglutin (HA), and neuraminidase (N) are important tools for subtype classification, and determination of antigenicity and pathogenicity (Thacker and Janke 2008; Kothalawala et al. 2006). With the recent discovery of a new influenza viral subtypes in bats (Tong et al. 2012, 2013; Campos et al. 2019), influenza viruses are now grouped according to the expression of 18 HA (H1-H18) and 10 NA (N1-N10) subtypes (Capua and Munoz 2013).

Influenza viruses may be subject to antigenic drift and antigenic shift, which impose major challenges in vaccine development. Antigenic drift is a minor genetic variation within subtypes due to a series of point mutations. Antigenic shift is caused by reassortment of genes from two different viruses that result in a new combination of H or N segments (Kothalawala et al. 2006). For example, the 2009 pandemic H1N1 virus (H1N1pdm09) was the result of a virus reassortment event in swine (Skowronski et al. 2013). The H1N1 virus contains segments from North American-like triple reassortant swine H1 viruses (6 genes) and Eurasian avian-like swine viruses (neuraminidase and matrix genes) (Pascua et al. 2012).

The ultimate host of all influenza viruses appears to be wild birds, specifically waterfowl (Thacker and Janke 2008), where the viruses replicate in the respiratory tract and intestine typically without any signs and symptoms of disease. Although mammalian species are all derived from birds, studies have shown interspecies transmission of influenza virus (e.g., H3N8 from horses to dogs) (Kothalawala et al. 2006; Pascua et al. 2012; Myers et al. 2006). Interspecies transmission of influenza virus A is the principal mechanism of emergence of novel strains, and pigs likely play an important role in such transmission (Myers et al. 2006; Bowman et al. 2012).

Viral attachment on host cells was thought to depend on the specificity of binding to particular sialic acids (SAs). Prior research suggested that avian influenza viruses bind to α2–3 SAs, while influenza viruses infecting mammals preferentially attach to α2–6 SAs. However, recent research (reviewed in (Capua and Munoz 2013)) suggests that it is more complicated than that. Nevertheless, the cells of pigs can bind both "avian" and "human" types of influenza viruses suggesting that they may be important in the generation of novel variants that could go on to infect humans and spread zoonotically (Scholtissek 1990).

Influenza viruses become a pandemic threat when they become capable of being transmitted efficiently from human to human and if limited protective immunity exists in the human population. There are three major interfaces for human-to-pig contact: commercial swine production, abattoirs, and agricultural fairs (in the United States). Agricultural fairs provide common ground for the transmission of influenza viruses between humans and pigs. Fairs are unique because "they facilitate prolonged comingling of pigs from numerous sources raised under varied management programs with millions of persons who have widely disparate histories of exposure to various influenza viruses" (Bowman et al. 2012).

Prior to the 2009 pandemic, a review article identified 37 civilian and 13 military cases of swine influenza in humans in the literature from 1958–2005 (Myers et al. 2007), of which 19 cases were reported in the United States, 6 in Czechoslovakia, 4 in the Netherlands, 3 in Russia, 3 in Switzerland, 1 in Canada, and 1 in Hong Kong. The majority of the cases had some kind of exposure to live swine. There were no unique clinical features to distinguish swine from human influenza; healthy people and those with underlying conditions were both at risk (Myers et al. 2007). In a 2006 study of farmers, meat processing workers, veterinarians, and individuals lacking swine exposure, elevated titers to swine viruses were found in individuals with occupational exposure (Myers et al. 2006). Thus, it appears that even prior to 2009, transmission of swine influenza viruses to humans was not a rare event. In one paper examining the 2009 pandemic, evidence was found of at least 49 discrete introductions of H1N1pdm09 influenza virus from humans into swine in 2009 (Nelson et al. 2012), suggesting bidirectional spread of these viruses from swine to humans and backwards.

"Classic" swine influenza A (H1N1) virus (cH1N1) was the predominant subtype of swine influenza viruses in North America for nearly 80 years. The entry of the H3N2 virus in 1998 that was composed of avian, human, and swine influenza genes into the US swine population resulted in the emergence of multiple reassortment influenza viruses (Thacker and Janke 2008). The true incidence of swine-to-human transmission of influenza virus A is unknown. During the period of December 2005 to April 2012, 36 human infections with variant influenza virus A were reported by the Centers for Disease Control and Prevention in the United States. There might be far more cases than what is actually reported (CDC 2013a). The US national swine influenza virus surveillance program is passive and focuses on swine showing signs of influenza-like illness and on reacting to reports of variant influenza A cases in humans. Thus, subclinical infections are unlikely to be reported. Surveillance should instead be carried out in both healthy and sick animals (Bowman et al. 2012), but this is a costly proposal.

4.7 H1N1 2009 (Influenza A H1N1pdm09)

The earliest reports of H1N1 swine infections in the USA occurred at state fairs in Minnesota and South Dakota. An estimated 150 million people attend at fairs in North America (Bowman et al. 2012) which can be a conduit to introduce influenza viruses into swine herds or vice versa (Bowman et al. 2012; Gray et al. 2012). Eleven of fifty-seven (19%) of swine tested in Minnesota in 2009 were found to be influenza positive by rRT-PCR; four of them harbored influenza viruses similar to H1N1pdm09. This occurred during the second wave of the 2009 pandemic. It is possible that these show pigs were infected by their owners or others prior to arrival at the fair. Notably, all pigs found to be positive exhibited infections which were subclinical in nature (Gray et al. 2012), again emphasizing the need for surveillance even of animals which appear to be healthy.

4.8 H3N2 variant

H3N2 variant viruses contain the matrix gene from the 2009 H1N1 pandemic virus. These triple-reassortant swine viruses (A/Sw/OH/511445/2007, A/Ohio/01/2007, and A/Ohio/02/2007) were found both in pigs and humans in a 2007 fair in Ohio (Killian et al. 2013). In 2011, 12 cases of H3N2v were found in Indiana, Iowa, Maine, Pennsylvania, and West Virginia. In 2012, 309 cases H3N2v infections were found across 12 states. This virus had been seen in human since July 2011 and in swine in "many states." Fifteen of the sixteen cases had recent contact with pigs at a fair, and person-to-person spread was seen in at least three cases. Most cases were mild (CDC 2013b, c). Another outbreak of H3N2v occurred at a Pennsylvania fair in August of 2011. In this outbreak, one confirmed infection in a child was identified; serological studies determined that 82 additional suspected, 4 probable, and 3 confirmed cases also had attended the fair. The highest risk of transmission was in those who touched swine during their fair visit. Some reports of symptomatic pigs were noted, but all of these animals were sold or slaughtered before they could be tested (Wong et al. 2012). In 2012, 11 patients of H3N2v were hospitalized in Ohio; sporadic infections have been detected since that time (CDC 2013). Of the reported 11 cases hospitalized, 10 had direct or indirect contact with pigs. One patient, a 61-year-old woman with type 2 diabetes, died as a result of H3N2v infection (Centers for Disease C, Prevention 2012). Additional novel H3N2 viruses were detected in swine in Oklahoma in 2017, likely transmitted to pigs from humans (Zeller et al. 2018). Compared to many of the common H1 lineages, swine H3 lineages tend to be more geographically restricted (Anderson et al. 2021).

A recent study using a ferret model found that the zoonotic potential of four representative triple-reassortant swine influenza viruses caused mild disease and were inefficiently transferred via air, but one (an H1N2 virus) replicated well the upper and lower respiratory tract of ferrets, was efficiently transmitted via respiratory droplets, and showed high lethality. As such, some field isolates from swine may show zoonotic potential (Pascua et al. 2012). Although there have been multiple outbreaks of H3N2v in recent years, a recent analysis suggests that the current pandemic potential of H3N2v is low (Skowronski et al. 2013).

Individuals working with swine or visiting swine fairs are urged to practice good hygiene and the use of proper personal protective equipment (PPE) while working with pig or pig facilities. Isolation of sick or infected pigs, partial depopulation and segregation of early weaned piglets would help to prevent the transmission of swine influenza. Inactivated, whole virus and subunit influenza virus vaccines are available for humans, horses, birds, and pigs (Kothalawala et al. 2006). However, due to ongoing mutations in the HA and NA genes via antigenic drift, these vaccines need to be revised annually. Due to its ability to elicit both humoral and cellular immune responses, a live attenuated influenza virus vaccine is considered relatively better compared with an inactivated vaccine; it is currently licensed in the United States (Schnitzler and Schnitzler 2009). Researchers have been studying DNA vaccines as a novel alternative to the conventional vaccines using chicken, mouse, ferret, and

primate models. Nonetheless, so far it has not been successful in pigs (Thacker and Janke 2008; Kothalawala et al. 2006).

4.9 Swine Parasitic Zoonoses: *Trichinella* and *Taenia*

Parasites with zoonotic potential such as *Trichinella* spp. and *Taenia* spp. are public health hazards affecting both animals and humans. Global eradication of these pathogens is a challenge due to limitations in implementation of strict regulations and policies, methodological issues in early diagnosis and treatment, and above all varying cultural and social practices that govern the propagation of these parasites.

Trichinella spp. are nematode worms that are one of the most widespread food-borne zoonotic pathogens in the world (Pozio 2007). Strains of *Trichinella* have been isolated from domestic and wild animals in 66 countries (Pozio 2007). This parasite was first discovered in 1835, but was linked to food-consumption and disease only in 1860 (Dupouy-Camet 2000). The main source of human infection is pork and pork products, game meat, and horse meat. Nevertheless, *Trichinella* spp. has been reported to infect other animals such as wild boars, rats, cats, dogs, bear, walrus, jackals, raccoon, foxes, warthogs, crocodiles, lizards, and even birds (Pozio et al. 2009). Due to its vast host range and difficulties in identification of the pathogen or establishing an early diagnosis, *Trichinella* is one of the most resilient and persistent zoonotic parasites.

Taeniasis caused by *Taenia* spp. (tapeworm) is a food-borne infection commonly observed in developing or less developed countries and adds to the global public health burden of parasitic infections. To meet the scope of this chapter, we will discuss only *Taenia solium* (*T. solium*), since this parasite is commonly observed in pigs. *T. solium* (pork tapeworm) infections are commonly referred to as the taeniasis/cysticercosis complex (Garcia et al. 2003a). Cysticercosis is endemic in Central and South America, sub-Saharan Africa, most of Asia, and parts of Oceania (Garcia et al. 2003b). Neurocysticercosis is the most common cause of late adult-onset seizures in the developing world (Epilepsy CoTDotILA 1994). More than 1000 new cases of neurocysticercosis (Hawk et al. 2005) are diagnosed in the United States each year, and it is the most prevalent infection of the brain, worldwide (Garcia et al. 2003b; Shandera et al. 1994).

4.9.1 Trichinella

The genus *Trichinella* has a broad range of host species. Nevertheless, clinical infection is apparent only in humans (Gottstein et al. 2009). *Trichinella* spp. are found in animals all over the world, except Antarctica possibly due to absence of surveillance (Pozio 2007). Parasites in the genus *Trichinella* are classified by the presence of a collagen capsule: encapsulated and nonencapsulated. Within the genus, *T. spiralis* is the species most adapted to domestic and wild pigs and is also most

commonly isolated from human infections (Pozio and Darwin Murrell 2006). Other *Trichinella* spp. found in pigs are *T. britovi* (wild boar), *T. nelsoni* (bush pigs), *T. pseudospiralis* (domestic and wild pigs). Horses fattened with pork scraps are known to be infected with *Trichinella*.

Prevalence estimates depend on the geographical region and the detection methods used: *Trichinella* antibodies were found in 0.35% of pigs in the Netherlands (van der Giessen et al. 2007), 0.2% of wild boar muscle samples contained *Trichinella* in Spain (Boadella et al. 2012), a 0.37% prevalence was estimated in pigs in the northeastern United States (Gamble et al. 1999), in China prevalence data ranged from 0.01% to 29.95% by serological testing to 0–5.75% in pigs slaughtered at abattoirs, respectively (Cui and Wang 2011), 19.9% Vietnam pigs tested positive by E/S ELISA (Vu Thi et al. 2010), antibody prevalence was 0.0002–0.0003% in wild boars in France (Pozio et al. 1996), a prevalence of 1.3% was established for wild boars in Finland (Oivanen et al. 2002), and of 11.4% wild boars in Argentina by artificial digestion (Cohen et al. 2010). Despite a broad spectrum of hosts, *Trichinella* spp. are most common in porcine omnivores, mainly in domestic pigs, different races of wild pigs, wild boars, bush pigs, and warthogs (Pozio 2005).

Human trichinellosis has been documented in 55 countries and is most often linked to established food-consumption behaviors including consumption of raw or undercooked pork or pork products. A 2011 study observed about 261 reports of trichinellosis outbreaks worldwide (Murrell and Pozio 2011). This study estimated 65,818 cases and 42 deaths reported from 41 countries between 1989 and 2009 (Murrell and Pozio 2011). About 87% of the cases were reported from the WHO-European region, of these 50% were reported from Romania alone (Murrell and Pozio 2011).

Trichinellosis is the infection caused by *Trichinella* spp. in humans. Severity of trichinellosis depends on the load of ingested parasite, frequency of consumption of infected meat, method of cooking and treating meat before consumption, species involved in reproduction of larvae, and the amount of alcohol consumed at the time of meat consumption, with alcohol acting as a protective factor (Murrell and Pozio 2011; Xu et al. 1995). The estimated minimum dose necessary for causing symptomatic trichinellosis ranges from 70 to 150 larvae (Murrell and Bruschi 1994; Dupouy-Camet et al. 2002). The major signs of classical trichinellosis are myalgia, diarrhea, fever, periorbital and facial edema, and headaches as per an algorithm used to diagnose acute trichinellosis (Murrell and Pozio 2011). Complications usually develop within 2 weeks of infection (Ancelle et al. 2005; Lachkar et al. 2008; Dupouy-Camet 2007; Bessoudo et al. 1981; Compton et al. 1993; Ellrodt et al. 1987; Fourestie et al. 1993). Mortality due to trichinellosis is very rare and is estimated to be around 0.4% (Murrell and Pozio 2011; Dupouy-Camet 2007; Kociecka 2000; Ancelle et al. 1988). Humans are observed to be asymptomatic while being chronically infected with the larvae (Dupouy-Camet et al. 2002). Children are found to be more resilient to *Trichinella* infection, while it may result in abortion or premature delivery in pregnant women (Dupouy-Camet et al. 2002).

Globalization and migration of population with culturally unique food practices and illegal introduction of *Trichinella* infected meat from endemic to non-endemic

countries are some of the risk factors for human trichinellosis particularly in countries with low-incidence (Pozio and Marucci 2003; Gallardo et al. 2007; Nockler et al. 2007; Stensvold et al. 2007). Impact of food-consumption practices are reflected by the low incidence of trichinellosis in the Muslim population worldwide (Pozio 2007; Haim et al. 1997; Marva et al. 2005). International travelers and hunters are two high-risk groups observed to acquire *Trichinella* infection from endemic countries and exposure to *Trichinella* infected animals, respectively (Ancelle et al. 2005; Moller et al. 2005a; Wang et al. 2006; Shiota et al. 1999; Nakamura et al. 2003; Centers for Disease Control & Prevention 2004). This population also plays a major role in propagation of *Trichinella* to a naïve population.

Diagnosis of *Trichinella* infection in animals is conducted by direct methods such as meat inspection using conventional trichinoscopy (Epizooties OId 2004; Kapel 2005; Nockler and CMO 2007). Other methods used in animal detection are artificial digestion using the magnetic stirrer method (Kapel et al. 2005), multiplex PCR (Pozio and La Rosa 2003), and serological tests for IgG antibodies (Nockler et al. 2005). Enzyme-linked immunosorbent assay (ELISA) using metabolic E/S antigens or tyvelose ELISA are the most commonly used methods for the detection and confirmation of *Trichinella* infection (Moller et al. 2005b; Gamble and Graham 1984; Gamble et al. 1983). Diagnosis in humans is based on clinical, epidemiological and laboratory criteria, as outlined by the European Center for Disease Control (Dupouy-Camet 2007).

Initiation of anthelminthic therapy such as albendazole and mebendazole early in the infection is recommended and observed to be beneficial for the cure of trichinellosis (Dupouy-Camet et al. 2002). Other treatment options are available based on the severity of infection (Gottstein et al. 2009; Dupouy-Camet et al. 2002; Dupouy-Camet 2007). Prognosis is reported to be poor for severe cases with cardiac or cerebral complications and fatality was found to be about 5% in severe infections despite therapy (Gottstein et al. 2009).

4.10 Taenia (*T. solium*)

The life cycle of *T. solium* is divided between two hosts. Humans are the definitive host for the adult *T. solium*, while both pigs and humans may harbor the larvae or cysticerci with pigs being the typical intermediate host. Human infection due to *T. solium* occurs when larvae are consumed by eating poorly cooked or raw pork products. Larvae attach to the mucosa of the human small intestine using their scolex (head) and grow into adult tapeworms (Flisser 1994). Eggs from these adult worms are shed in human feces. Contamination of pig feed with such human feces results in ingestion of eggs by the pigs. Ingested eggs develop into a larval stage, travel through the intestinal wall, enter the bloodstream, and lodge in various pig tissues eventually forming cysts (porcine cysticercosis) (Garcia et al. 2003a). Ingestion of such infected pig or pork products by humans result in intestinal infection or taeniasis. Humans can also ingest *T. solium* eggs through the fecal-oral route or by auto-infection (Hawk et al. 2005). Autoinfection is the retrograde transmission of

taenia segments from human intestine back into the stomach, followed by release of eggs into the gut (Garcia et al. 2003b; Hawk et al. 2005; Flisser et al. 2006). Fecal-oral contamination occurs in infected food handlers who do not practice good hand hygiene. Even vegetarians who do not consume pork may acquire cysticercosis via wind, water, flies, and other indirect means of transmission (Martinez et al. 2000).

Clinical manifestation of cysticercosis depends on the organ affected (Garcia et al. 2003b). The most common clinical manifestation is neurocysticercosis that develops once the viable cysticerci enter the central nervous system. Epileptic seizures are the most common presentation of neurocysticercosis. Neurocysticercosis and ocular cysticercosis are associated with significant morbidity (Garcia et al. 2005). Other types of extraneural cysticercosis are subcutaneous, muscular, cardiac, and – in rare cases – limb enlargement due to massive parasite burdens (muscular pseudohypertrophy) (Garcia et al. 2003a).

T. solium is one of the major public health hazards and causes of economic problems in pig husbandry (Flisser et al. 2005). Transmission of adult tapeworms and larvae are associated with poor hygiene and sanitation, low living standards, lack of meat inspection and control, and lack of education and awareness (Flisser et al. 2006). In addition, immigrants, overseas domestic workers, international travelers, and transport of infected pigs have spread the disease to non-endemic areas (Hira et al. 2004; Rajshekhar et al. 2003). *T. solium* is widely prevalent in regions where pigs are reared in free ranging systems and raw or undercooked pork is consumed. In most endemic villages, more than 10% of the population is observed to be seropositive for *T. solium* with an observed maximum of 25% (Garcia et al. 2003b). Studies have found that up to 6% of the general population in endemic countries may harbor adult tapeworms (Allan et al. 1996a). A recent meta-analysis on the prevalence of neurocysticercosis in people with epilepsy including studies from Latin America, India, and sub-Saharan Africa found that neurocysticercosis was the cause of epilepsy in 30% of the population with epilepsy (Ndimubanzi et al. 2010). Cases of intestinal taeniasis are consistently observed to cluster in families possibly due to food consumption habits (Allan et al. 1996b). Rate of porcine infection varies and seropositivity has been observed in 30–60% pigs (Garcia et al. 1999; Gonzalez et al. 1990).

Diagnosis of cysticercosis is based on a set of criteria developed using clinical, radiologic, histologic, and epidemiologic findings (Garcia and Del Brutto 2003; Kraft 2007). Neurocysticercosis is diagnosed using a computed tomography (CT) scan and performing a cerebrospinal fluid (CSF) examination (Garcia et al. 2005; Garcia and Del Brutto 2003; Kraft 2007). The MRI is a better tool in detecting certain pathological changes (Garcia et al. 2003a). Antibodies against *T. solium* generally persist even after the cyst dies, hence serology should be used as a confirmatory test secondary to clinical signs and imaging studies (Garcia et al. 2005). Frequency of stool examination for *T. solium* eggs vary among patients and may be related to the severity of infection (Garcia and Del Brutto 1999; Gilman et al. 2000). In addition, ELISA and PCR tests for coproantigen detection may be useful in screening for *T. solium* carriers in endemic regions (Mahanty et al. 2010).

Antiparasitic treatment such as albendazole and praziquantel in conjunction with steroids are the treatment of choice in most types of cysticercosis (Baranwal et al.

1998, 2001; Carpio et al. 1995; Padma et al. 1994; Padma et al. 1995; Corona et al. 1996; Pretell et al. 2001). Studies have shown 100% effectiveness using the TSOL18 vaccine developed against *T. solium* in pigs (Gonzalez et al. 2005; Flisser et al. 2004; Lightowlers 2004). The vaccine requires at least two doses to be effective.

Some preventative strategies for parasitic infections such as *Trichinella* and *T. solium* are improved living conditions by better sanitation, education and commercial pig production, regular monitoring and mandatory reporting for the pathogen (Nockler and Kapel 2007; Community E 2005), strict regulations in pig-farms and slaughterhouses (Gottstein et al. 2009), adequate vaccination of pigs, health education and human mass chemotherapy (Gottstein et al. 2009), pig corralling, and regulations for processing pork and pork products (Garcia et al. 2007; Hill et al. 2010). However, these preventative practices are not implemented in high-risk countries such as Eastern Europe, Asia, parts of South America, and in the African subcontinent. These regions have the potential for exponential increase in transmission of pathogens due to the dense pig population, interaction between humans and pigs, and the vast reservoir for *Trichinella* in regional wildlife. Human cultural and social practices are one of the greatest challenges in prevention of transmission of food-borne parasites such as *Trichinella* and *T. solium* on a global basis.

4.11 Discussion

In recent decades, the global emergence of infectious diseases in human, domestic animals, and wildlife have attracted a greater attention of researchers and agencies. As a result, studies have now demonstrated zoonotic pathogens by quantitative analysis as risk factors for emergence in humans (Cleaveland et al. 2001). Rapid growth of human population and globalization of trade are considered to be main factors responsible for emergence of zoonotic diseases. However, several other direct and indirect factors such as ecological disruption, increasing movement of animal species, uncultivatable organisms, and terrorism play potential role in disease expansion (Brown 2004). A study by Jones *et al.* found a significant correlation between emerging infectious disease origin and socio-economic, environmental, and ecological factors (Jones et al. 2008).

Zoonotic diseases account for 75% of all emerging diseases affecting the human population in the last two decades (Brown 2004). Almost two-thirds (61%) of human infectious diseases are zoonotic in nature. A database of disease causing pathogens of humans and domestic mammals constructed by Cleaveland *et al.* showed that 61.6% of 1415 pathogens able to cause human diseases have an animal origin. A high prevalence of multi-host pathogens were observed in both human and domestic mammal pathogens, suggesting cross-species transmission (Cleaveland et al. 2001). The COVID-19 pandemic demonstrates once again how vulnerable we are to such emerging zoonotic pathogens, and susceptibility of pigs to the virus seems to be low but with mixed results to date (Pickering et al. 2021; Vergara-Alert et al. 2021).

Recent decades have witnessed the rapid growth of pork industry (Pappas 2013). In fact, pork is the most widely eaten meat in the world, leading to the production of 1.3

billion pigs each year globally (Health CfFSaP 2013). Global increase in pork production and predicted increase in annual pork demand have reached 80% and 7%, respectively (Pappas 2013). However, the projected human population growth still outcompetes the meat supply. This increase in demand of pork production has led to intensification and industrialization of production systems. Production modifications with larger herds in a contained area have the potential to make pigs and their caretakers increasingly vulnerable to inter-species pathogen transmission (Pappas 2013).

A recent review of emerging pig pathogens revealed at least 77 novel emerging species, of which 35 were pig-specific zoonotic (Pappas 2013) suggesting an urgent need of considering pigs as a potential vehicle for zoonotic disease transmission. The pig may also serve as an amplifying host, as is the case for both Japanese encephalitis virus and Nipah viruses discussed above (Weaver and Barrett 2004; Pappas 2013).

The economic burden imposed by zoonotic diseases is paramount. It has been estimated that the zoonotic epidemics between the period of 1995 and 2008 caused more than 120 billion dollars in economic loss. Major recent infectious disease outbreaks have been zoonotic, leading to unprecedented human morbidity and mortality causing greater human productivity loss (Cascio et al. 2011). For example, cysticercosis alone, a parasitic infection that is caused by uncooked or undercooked pork, imposes an estimated economic burden between US $18.6 million and US$34.2 million in the eastern cape of South Africa (Carabin et al. 2006).

As zoonotic infections go beyond the individual and affect the household, especially in agricultural settings, the economic impact is even more pronounced. Animal loss due to disease or mandatory regulations adds more to the economic burden of zoonoses. For example, the slaughter of more than one million pigs in Malaysia in 1999 in the wake of Nipah virus outbreak caused destruction of the local swine industry. It is predicted that the majority of future infectious disease outbreaks will be zoonotic in origin (Cascio et al. 2011), potentially amplifying this cycle.

4.12 Conclusions/Recommendations

Zoonotic diseases directly impact human morbidity and mortality. An indirect impact of zoonotic diseases is via disruption of the food chain, thus causing grave economic loss. The globe is under the threat of emergence of new species of zoonotic pathogens and their pandemic potential, such as the H1N1 pandemic of 2009 and the COVID-19 pandemic. Public health intervention programs to tackle the rapid emergence of zoonoses are essential, but underfunded and understaffed. Public health interventions should be designed in the light of evidence-based practices to address the zoonotic diseases that are often neglected and associated with poverty such as zoonotic helminthes, protozoan, viral and bacterial infections. Disease-specific research priorities to support zoonotic disease control are crucial to combat the epidemics and pandemics of zoonoses (World Health Organization 2012). What was effective in the mitigation of zoonotic diseases epidemics or pandemics a decade ago could be antediluvian in the current era largely due to rapid human growth, transportation, movement, and human migration. Early detection, rapid and enhanced surveillance,

and ongoing research for the discovery of new knowledge are warranted for the effective mitigation of emerging zoonotic infectious diseases. A long-term socio-political and economic commitment by government and private agencies across the globe is essential to combat the global threat of zoonotic diseases. Policy-makers should consider prioritizing for improved surveillance, multi-sectorial interactions between public health, livestock, agriculture, natural resource and wildlife, and a measure to precisely assess the burden of zoonoses (World Health Organization 2012).

Practice of good personal hygiene such as proper hand washing after working with animal and animal products, use of proper personal protective equipment (PPE) while working with animal or animal facilities, isolation of sick or infected animal, and good practice of cleaning and disinfection would help to prevent the zoonotic disease infection and transmission. High-risk-groups should get vaccinated if one is available.

Abstract

Sheep and goat can be infected with several pathogens. While some may have a great impact on the small ruminant industry, others are more important as zoonotic agents. Human infections can occur from contact with both live and dead animals, animal products, and wastes, whereas some are well known while others have only recently been discovered. Several microorganisms may cause severe infection if transmitted to vulnerable people, such as pregnant and immune-comprised persons. Climate change, increased globalization, loss of natural habitats, improved diagnostics, and an active surveillance will increase records of zoonotic infections. The present chapter will briefly deal with a selected number of zoonotic microorganisms where small ruminants may play an important role as hosts for human infection.

Keywords

Sheep · Goats · Zoonosis · Review

5.1 Introduction

Sheep and goats, which were domesticated by humans as early as 9.000 years ago, are distributed worldwide and their products, such as milk, meat, wool, and skin are used extensively. Microorganisms have therefore been shared between humans and small ruminants for a long period of time. In this context, small ruminants may carry zoonotic pathogens, either transiently or permanently. The risk of transmission to humans varies considerably due to geographical area, seasons, climatic conditions, and management systems. The impact on human health will also depend on pathogen species/subspecies, virulence of the pathogen, level of exposure, presence of co-infections, susceptibility of the host, the host immune status, and the transmission route.

In general, microorganisms can be transmitted from small ruminants to humans by direct contact, aerosols, milk, meat, or indirectly by manure, feces, urine, and wool. For instance, the development of zoonotic infections through exposure to manure, either directly or indirectly, constitutes a real and significant risk of human health. Contamination of ground, irrigation or drinking water provides not only a source of infection, but also a means to spread the pathogens (Milinovich and Klieve 2011).

Water and foodborne zoonotic pathogens, such as *Campylobacter jejuni*, *Cryptosporidium parvum*, *Escherichia coli* (EHEC), *Giardia duodenalis*, and *Salmonella* spp. are widespread and have a wide host range. *Salmonella* spp., for instance, are ubiquitous in nature and have been isolated from a wide variety of vertebrate hosts. *Salmonella* is also commonly found in farm animals, their environments, and is one of the most important foodborne zoonotic microorganisms (Milinovich and Klieve 2011). Infections from goat products due to consumption of raw or uncooked goat meat, milk, and cheese have been documented. Severe gastroenteritis and even fatalities may occur (Desenclos et al.1996; Espié and Vaillant 2005). However, human salmonellosis may not normally arise as a result of contact with small ruminants, since this transmission pathway seems to be less frequent than that from other animals such as cattle and poultry (Kirby 1985; Rabinowitz and Conti 2010). Although *S. enterica* subsp. *diarizonae* is commonly found in sheep, the impact on human health seems to be limited (Sören et al. 2015). Similarly, all the mentioned pathogens are important zoonotic agents, but small ruminants play normally a less important role as reservoir for human infection compared to other species (Palmer et al. 1998). These microorganisms will therefore not be described further in this condensed review.

Some links between diseases in humans and animals are still debated. For instance, *Mycobacterium avium* subspecies *paratuberculosis* (MAP) causing Johne´s disease in ruminants has been isolated from some humans with Crohn´s disease, a chronic granulomatous infection of the human intestine (Sharp 2007; Smith and Sherman 2009). The association between this bacterium and the disease is still unclear (Agrawal et al. 2020). The presence of MAP in a percentage of Crohn´s disease patients is either associated with the pathogenesis of the disease or these patients may be more likely to be colonized by these organisms. The unanswered question raises the issue of meat, milk, and water contamination by MAP and human health (West et al. 2009; Singh and Gopinath 2011). Transmissible spongiform encephalopathies such as classical scrapie is an old, widespread, and well-known disease in small ruminants, but its zoonotic potential has not yet been verified, although bovine spongiform encephalopathies, another prion disease, may cause human disease (Ganter 2015). It has also been questioned if Borna disease virus infection in sheep, one of the principle species affected could be transmitted to humans (Chalmers et al. 2005; Dürrwald et al. 2007). However, recent investigation indicates that sheep only represent an accidental dead-end host, with no contribution to the spread of the virus (Rubbenstroth et al. 2019). The issues mentioned above will not be discussed further in this chapter.

5.2 Specific Infections

Zoonotic pathogens detected in small ruminants of which several may cause severe infection in humans, are listed in Tables 1, 2 and 3. These lists, however, are not complete. Microorganisms may, for instance, be transmitted to humans due to the lack of normal hygiene procedures when handling infectious material. Common pathogens, such as *Staphylococus aureus* and *Trueperella pyogenes*, which regularly cause infections in small ruminants, are not covered by this chapter. In this short

Table 1 Zoonotic bacteria, rickettsia, and chlamydia detected in small ruminants

Pathogen	Host	Distribution	Transmission	Clinical symptoms (small ruminants)	Clinical symptoms (human)	References
Anaplasma capra	Wild deer, small ruminants	Asia, Europe	Ticks	Mild - subclinical	Flu-like CNS-symptoms	Peng et al. (2021)
Anaplamsa ovis	Small ruminants	Worldwide	Ticks	Mild- severe, Anemia	Flu-like (only one case)	Chochlakis et al. (2010) Stuen (2020)
Anaplasma phagocytophilum (several variants)	Several mammals	Northern Hemisphere (Ixodes-tick)	Ticks	Mild - subclinical Mild- severe, Anemia Fever, abortion (secondary infections)	Variable, flu-like – severe infection	Woldehiwet (2010) Stuen (2020)
Bacillus anthracis	Several mammals	Worldwide	Aerosols, cutaneous, oral (spores)	Found dead	Variable, cutaneous, pulmonary, and intestinal form	Turnbull (1998)
Borrelia burgdorferi sensu lato	Several, incl. small rodents, birds	Northern Hemisphere (Ixodes-tick)	Ticks	Subclinical, arthritis	Variable Acute - subacute -chronic form	Stanek et al. (2002)
Brucella melitensis (*B. abortus*)	Several, mainly small ruminants	Widespread, especially Mediterranean, Middle East	Oral (aerosols, cutaneous)	Abortion, arthritis	Variable, undulating fever chronic	See text
Burkholderia pseudomallei	Several	Widespread, mainly tropical areas	Oral, insects, vertical transmission	Abscesses, weight loss, polyarthritis meningoencephalitis	Pneumonia, septis, genitourinary infection, abscesses, suppurative parotitis, encephalomyelitis	Cheng and Currie (2005) Smith and Sherman (2009)

(continued)

Table 1 (continued)

Pathogen	Host	Distribution	Transmission	Clinical symptoms (small ruminants)	Clinical symptoms (human)	References
Camphylobacter jejuni	Several, esp. poultry	Widespread	Oral	Abortion, watery diarrhea	Flu-like, Diarrhea	Skirrow (1998)
Chlamydopila abortus	Several, mainly small ruminants	Widespread	Aerosols	Abortion	Abortion, stillbirth, puerperal sepsis, renal failure, hepatic dysfunction, DIC	See text
Corynebacterium pseudotuberculosis	Several, incl. domestic animals	Widespread	Cutaneous, oral	Caseous lymphadenitis	Suppurative granulomatous lymphadenitis	Thomas (1998) Smith and Sherman (2009)
Coxiella burnetii	Several, incl. livestock	Widespread	Aerosols, oral (cutaneous, ticks)	Abortion, stillbirth, weak offspring	Flu-like, pneumonia, endocarditis, hepatitis	See text
Dermatophilus congolensis	Several species	Worldwide	Cutaneous	Dermatitis (exudate)	Dermatitis	Stewart (1972a, b) Hyslop (1980)
Ehrlichia ruminantium	Ruminants	Africa, Caribbean	Ticks	Heartwater	Severe, encephalitis, vasculitis	Allsopp (2010)
Escherichia coli (EHEC)	Several	Worldwide	Oral	Heartwater	Variable Diarrhea, hemorrahagic colitis HUS	Nelson et al. (1998) Smith and Sherman (2009)

Francisella tularensis	Several hosts, esp. rodents	Worldwide	Aerosols, oral, cutaneous, ticks	Sepsis	Variable Bubonic - intestinal - pneumonic form	Pearson (1998) Genchi et al. (2015)
Leptospira spp. serovar Pomona (serovar Hardjo-bovis)	Several mammals, incl. cattle, pig	Unknown	Oral, cutaneous	Fever, depression, dyspnea,weakness, anemia, icterus, hemoglobinuria	Flu-like, encephalitis	See text
Listeria monocytogenes (L. ivanovii)	Several	Worldwide	Oral, cutaneous	Abortion, encephalitis, septicemia, mastitis, diarrhea, ocular disease	Meningitis, encephalitis, septicemia	See text
Mycobacterium avium subspecies paratuberculosis (Johnés disease)	Several, esp. ruminants and rabbits	Widespread	Oral	Progressive weight loss, diarrhea, intermandibular edema	Chronic bronchitis, cervical lymphadenopathy, disseminated disease (Crohn´s disease?)	Gallagher and Jenkins (1998) Smith and Sherman (2009)
Panola Mountain Ehrlichia *Salmonella* spp.	Small runinants Several	USA, Africa Worldwide	Ticks Oral	Unknown Gastroenteritis, septicemia, abortion	Mild, sore neck Enteric fever, gastroenteritis, diarrhea, septocemia	Stuen (2020) Humphrey et al. (1998) Mearns (2007) Smith and Sherman (2009)
Yersinia enterocolitica *Y. paratuberculosis*	Several	Widespread	Oral	Enteritis, mastitis, abortion, ill-thrift	Enterocolitis, polyarthritis, erythema nodosum, exudative pharyngitis, sepsis	Butler (1998) Smith and Sherman (2009)

Table 2 Zoonotic virus detected in small ruminants

Pathogen	Host	Distribution	Transmission	Clinical symptoms (small ruminants)	Clinical symptoms (human)	References
Crimean-Congo hemorragic fever (genus *Nairovirus*)	Several, including wild and domestic animals	Asia, Africa, southeastern Europe	Ticks, especially *Hyalomma* spp.	Unknown	Variable, high fever, hemorrhages, multiorgan failure, high fatality rate	Bente et al. (2014)
Louping-ill (genus *Flavivirus*)	Several, especially sheep and grouse	Scandinavia, United Kingdom	Ticks, (*Ixodes ricinus*) (Aerosols, oral, cutaneous)	Variable, subclinical - incoordination - paralysis	Tick-borne encephalitis	Reid and Chianini (2007)
Nairobi sheep disease (genus *Nairovirus*)	Small ruminants	Africa	Ticks (mainly *Rhipicephalus appendiculatus*)	Fever, diarrhea, gastroenteritis, death	Rare.benign illness	Swanepoel (1998) Smith and Sherman (2009)
Orf (genus *Parapoxvirus*)	Several, mainly small ruminants	Worldwide	Cutaneous (oral)	Wart-like outgrows	Skin lesions	See text
Rabies (genus *Lyssavirus*)	Several	Widespread	Bite, (Aerosols, oral)	Behavior changes, paralysis, paralytic/ furious condition, death	Nonspecific (prodromal period) Paralysis, aggression, unconsciousness, paralysis	King (1998)
Rift Valley Fever (genus *Phlebovirus*)	Ungulates	Africa, Arabian Peninsula	Mosquitoes (Aedes spp.) . Other insects	Abortion, fever, listlessness, recumbency	Flu-like Menigoencephalitis, hemorrhagic fever, photophobia, retinitis	See text

Severe fever with thrombocytopenia syndrome (SFTS)	Several species	Asia, especially China	Ticks, especially *Hemophysalis longicornis*	Unknown	Fever, gastrointestinal symptoms, thrombocytopenia, leukocytopenia, lymphadenopathy	Chen et al. (2019)
Tick-borne encephalitis	Several, mainly small rodents, ticks	Asia, Europe	Ticks, oral	Mild, subclinical	Biphasic fever, tick-borne encephalitis Fever, rash, arthralgia	Ruzek et al. (2019)
Wesselsbron disease (genus *Flavivirus*)	Several, incl. domestic ruminants and rodents	South Africa	Mosquitos (Aedes), (Aerosols, oral)	Abortion, sudden death	Fever, rash, arthralgia	Leake (1998) Smith and Sherman (2009)

Table 3 Zoonotic parasites and fungi detected in small ruminants

Pathogen	Host	Distribution	Transmission	Clinical symptoms (small ruminants)	Clinical symptoms (human)	References
Babesia venatorum	Wild deer, especially roe deer	Europe	Ticks Oral	Unknown	Anemia, fever, dark urine	Azagi et al. (2020) Gray et al. (2019)
Cryptosporidium parvum	Several, esp. cattle	Worldwide	Oral	Subclinical (adults) Watery diarrhea (young animals)	Diarrhea	Wright and Coop (2007) Smith and Sherman (2009)
Dicrocoelium dendriticum	Several, esp. domestic ruminants	Widespread	Oral	Subclinical Weight loss, Anemia	Subclinical Constipation / diarrhea, hepatomegaly	Smith and Sherman (2009)
Echinococcus granulosus	Several (intermediate hosts) Canids (end host)	Widespread	Oral	Mainly subclinical	Variable (localization/size) Shock/pulmonary edema	See text

Eurytrema pancreaticum	Several domestic animals, esp. ruminants	Asia, South America	Oral	Subclinical, ill-thrift, weight loss emaciation	Nonspecific	Lloyd and Soulsby (1998) Taylor et al. (2007) Smith and Sherman (2009)
Fasciola hepatica	Several ruminant Snail: (intermediate hosts)	Worldwide	Oral	Acute, subacute, chronic (anemia, icterus, submandibular edema, death)	Variable Acute (hepatic) - chronic (biliary) phase	Mas-Coma (2005) Smith and Sherman (2009) Fried and Abruzzi (2010)
Giardia duodenalis	Several species	Worldwide	Oral	Subclinical, enteritis, diarrhea	Variable, diarrhea, chronic syndrome	Thompson (1998) Taylor et al. (2007)
Oestrus ovis	Small ruminants	Unknown	Flies	Nasal discharge, sneezing, rubbing (noses) (unthriftiness/incoordination),	Catarrhal conjunctivitis, stomatitis	Beesley (1998) Taylor et al. (2007)

(continued)

Table 3 (continued)

Pathogen	Host	Distribution	Transmission	Clinical symptoms (small ruminants)	Clinical symptoms (human)	References
Schistosoma spp.	Several	Widespread, esp. tropics, subtropics)	Cutaneous	Rhinitis, enteritis, hepatitis, pneumonia	Multisystemic Nonspecific Dermatitis	Taylor (1998) Smith and Sherman (2009)
Taenia multiceps (*Coenurosis cerebralis*)	Sheep	Unknown,	Oral	Depression, blindness, convulsions	Variable, (localization)	Lloyd (1998)
Toxoplama gondii	Multiple intermediate hosts, Felid family (end host)	Worldwide	Oral (tissue cysts)	Abortion, stillborn, weak offspring	Mild – transient - serious Abortion, congenital lesions	See text
Tricophyton verrucosum	Several, mainly cattle	Worldwide	Cutaneous	Alopecia, scaling, crusting, folliculitis	Dermatophytosis	Sparkes (1998)

review, the focus is on the distribution, hosts, disease manifestations, transmission, diagnosis, treatment, and control measures on a selected number of zoonotic micro-organisms where small ruminants may play an important role as reservoir hosts for human infection. Focus will be on the following pathogens: *Brucella melitensis*, *Chlamydophila abortus*, *Coxiella burnetii*, *Echinococcus granulosus*, *Leptospira interrogans*, *Listeria monocytogenes*, Orf-virus, Rift Valley fever virus, tick-borne pathogens (several), and *Toxoplasma gondii*.

5.3 Brucellosis

5.3.1 The Pathogen

Bacteria of the genus *Brucella* are Gram-negative coccobacilli. There are four important species that may cause infection in humans, whereas *B. melitensis* is considered as the most invasive producing the most severe disease in humans (Godfroid et al. 2005; El-Koumi et al. 2013). *B. melitensis* is associated with small ruminants, although *B. abortus* may occasionally cause infection in sheep and goats.

5.3.2 Occurrence

Worldwide, particularly in the Mediterranean region, Middle East, parts of Asia and Africa, and Central and South America (Corbel 1997; Castrucci 2007).

5.3.3 Hosts

B. melitensis is primarily found in sheep, goats, and camels, but cattle, dogs, and rats can also acquire the infection (Castrucci 2007).

5.3.4 Disease in Small Ruminants

B. melitensis may cause abortion, and occasionally orchitis and arthritis. Usually, abortion occurs from mid to late pregnancy. The infection may persist in the udder to the following pregnancies. Excretion of bacteria may last for 2 months in vaginal discharges and up to 180 days in milk after delivery or abortion (Castrucci 2007; Scott 2007; Smith and Sherman 2009).

5.3.5 Disease in Humans

It has been estimated that around 500.000 cases of human brucellosis occur annually (Franco et al. 2007). The incubation period varies from 1 week to several months.

Human brucellosis can be both an acute and a chronic febrile illness with a variety of clinical manifestations. The patient may show fever, chills, headache, muscle and joint pains, malaise, nausea, night sweats, and lack of appetite for 3–6 weeks. The condition may also show a variety of nonspecific hematological changes, such as anemia and leucopenia (Plommet et al. 1998; El-Koumi et al. 2013).

5.3.6 Transmission (Small Ruminants-Human)

The main route of entry is via the nasopharynx, although a cutaneous route of infection does also exist. Material from abortions represents the main source of transmission in ruminants, with the excretion of enormous numbers of bacteria in the placenta, fetal fluids, and fetus (Castrucci 2007). Humans, however, are mainly infected through ingestion of fresh (unpasteurized) milk, cheese, and meat, but also through direct contact with infected animals, semen, vaginal fluids, or infectious aerosols (Castrucci 2007; Smith and Sherman 2009). The environmental resistance of the pathogens varies; the organisms can, for instance, survive in dust for 3–44 days, in tap water for 30 days, on pasture between 15 and 35 days, and in liquid manure at 15 °C or below for up to 8 months (Plommet et al. 1998; Castrucci 2007).

5.3.7 Diagnosis in Small Ruminants

If abortion occurs, *B. meliensis* infection can be confirmed by bacteriological methods (aborted fetus and placenta) or serology (aborted ewe/doe). The diagnosis in the chronic stage of the infection is difficult, since the infection may become non-apparent. In nonpregnant ewes, the bacterium is not excreted from the vagina. However, during pregnancy, excretion starts at the time of delivery or abortion and could continue for several months (Castrucci 2007). There are several serological tests available, such as the standard agglutination test (SAT), Rose Bengal test, complement fixation test, and ELISA.

Although all organs may be infected, microscopic examination should focus on material with suspected large amounts of bacteria, such as placenta, fetus, and vaginal discharges in case of abortion. Stained tissue smears, bacterial culture, or PCR can be used for identification (Plommet et al. 1998; Redkar et al. 2001).

5.3.8 Treatment and Control

Brucellosis has been controlled in many countries, however it remains an important health issue in many developing countries. *B. melitensis* is considered as an important food safety concern in human because it may be present in dairy products made from milk of infected small ruminants. The bacteria survive for days in fresh milk,

weeks in ice cream, and months in butter, although the bacteria are killed by pasteurization and are sensitive to common disinfectants (Godfroid et al. 2005).

Chemotherapy is not 100 % effective, so little is accomplished with the control and eradication of brucellosis in small ruminants. The best scheme is to identify and cull the infected animals (Castrucci 2007). Vaccination of sheep and goats with an attenuated strain of *B. melitensis* is considered to be the main control strategy. Vaccination prevents abortion and reduces pathogen shedding from immunized animals, although the vaccine may retain some degree of virulence, which may result in abortion and excretion in milk. The vaccine may also interfere with serological testing (Godfroid et al. 2005). In addition, vaccination of replacement animals is not sufficient to control the disease, especially in countries with high prevalence, uncontrolled animal movements, nomadic and low socioeconomic conditions, and illegal import of animals (Ebrahimi et al. 2012).

Surveillance, testing, and massive immunization of animals, and national brucellosis control are necessary to eradicate the disease (El-Koumi et al. 2013). For human consumption, unpasteurized milk and milk products should be avoided. No human vaccine exists, however recent results are promising in developing a recombinant vaccine against *B. melitensis* (Gomez et al. 2013).

5.4 Chlamydophilosis (Ovine Enzootic Abortion (OEA)

5.4.1 The Pathogen

Ovine enzootic abortion (OEA) is caused by the obligate intracellular Gram-negative bacterium *Chlamydophila (*former *Chlamydia) abortus*. The organism belongs to the family *Chlamydiaceae* and genus *Chlamydophila*, which comprise two distinct developmental forms, a small extracellular infectious elementary body (EB) and a larger intracellular noninfectious, metabolically active reticulate body (Longbottom and Coulter 2003).

5.4.2 Occurrence

C. abortus is recognized as a major cause of reproductive loss in sheep and goats worldwide, although the disease does not appear to be a problem in either Australia or New Zealand (Aitken and Longbottom 2007).

5.4.3 Hosts

Main hosts are small ruminants, but the organism can also infect cattle, pigs, horses, and deer, although such infections are thought to be less common (Aitken and Longbottom 2007).

5.4.4 Disease in Small Ruminants

Chlamydophilosis is an important cause of abortion worldwide. In previously uninfected farms, up to 60% abortion rate of pregnant ewes or does has been reported (Ganter 2015). Infection in animals is usually asymptomatic, except for abortion, although some behavioral changes or a vaginal discharge may be observed. Ewes/does may deliver stillborn or weakly offspring that fail to survive. The majority of infected placentas will have thickened red intercotyledonary membranes, dark red cotyledons, and a creamy-yellow colored exudate on the surface. An infectious vaginal discharge may be observed for several days following abortion, but otherwise the ewes/does are clinically normal and are considered immune to further disease (Longbottom and Coulter 2003; Aitken and Longbottom 2007; Smith and Sherman 2009).

5.4.5 Disease in Humans

Human infections with *C. abortus* are rarely reported or remain underdiagnosed, as the organism normally induces asymptomatic or mild flu-like illness (Ganter 2015). The greatest threat of human infection seems to exist for pregnant women, where the outcome of infection in the first trimester of pregnancy is likely spontaneous abortion, while later infection causes stillbirths or preterm labor (Hyde and Benirschke 1997). Several cases of abortion, puerperal sepsis, and shock, including renal failure, hepatic dysfunction, and disseminated intravascular coagulation, as well as death have been reported (Buxton 1986; Bloodworth et al. 1987).

5.4.6 Transmission (Small Ruminants-Human)

Most cases in humans infection are associated with direct exposure to infected sheep or goats via inhalation of dust and aerosols during abortion or normal parturition. The major sources of infection are contact with placental membranes, dead fetuses, live lambs/kids born to infected mothers, and vaginal discharges (Aitken and Longbottom 2007; Smith and Sherman 2009).

5.4.7 Diagnosis in Small Ruminants

A presumptive diagnosis of infection can be made based on abortion in the last 2–3 weeks of gestation and examination of the placenta. Pathological changes involve both the intercotyledonary membranes and the cotyledons. This is usually confirmed by the identification of large numbers of EBs in stained smears prepared from the placental membranes and cotyledons using, for instance, a modified Ziehl-Nielsen procedure. Other methods of antigen detection include immunohistochemical staining of tissue sections, immunoassays, DNA amplification methods, and isolation in cell-culture. Serological testing is normally performed by the complement fixation test on paired blood samples. However, none of the current serological tests

have been proven to be suitable for detecting infection prior to abortion and are not able to differentiate vaccinated animals from those infected with wild-type strains (Longbottom 2008; Sachse et al. 2009).

5.4.8 Treatment and Control

If OEA is suspected to be present in a flock or herd, the administration of long-acting oxytetracyclines will reduce the severity of infection and losses resulting from abortion. Although such treatment will reduce losses and limit the shedding of infectious organisms, it does not eliminate the infection nor reverse any pathological placental damage already done; thus abortions or the delivery of stillborn or weakly lambs can still occur and the shed organisms are a source of infection for naïve animals (Longbottom and Coulter 2003; Aitken and Longbottom 2007). Animals that have aborted are considered immune to further disease. Ewes, however, may become persistently infected carriers and continue to excrete infectious organisms at the next oestrus (Papp et al. 1994; Papp and Shewen 1996).

In humans, early therapeutic intervention is important, whereas tetracycline, erythromycin, and clarithromycin should be used. Severely ill patients require supportive therapy (Sillis and Longbottom 2010).

During an OEA outbreak the primary aim is to limit the spread of infection to other naïve animals. Affected animals should be identified and isolated as quickly as possible. All dead fetuses, placental membranes, and bedding should be carefully destroyed and lambing pens cleaned and disinfected. Pregnant women and immune-compromised individuals are advised not to work with sheep, particularly during the lambing period and should avoid all contact with possible sources of infection. Basic hygiene procedures, including thorough washing of hands and the use of disposable gloves are essential when handling potentially infected materials (Winter and Charnley 1999; Longbottom and Coulter 2003).

Live-attenuated vaccines based on a temperature-sensitive mutant *C. abortus* strain have been used for several years. These vaccines must be administered at least 4 weeks prior to mating and cannot be used in combination with antibiotic treatment. Good protection from abortion is obtained, but does not completely eradicate the shedding of infectious organisms at parturition. Moreover, some vaccinated animals still abort as a result of wild-type infections. Vaccine development to produce the next generation OEA vaccine continues to progress. This is likely to be a subunit vaccine based on protective recombinant antigens identified through comparative genomic and proteomic approaches (Longbottom et al. 2013; Entrican et al. 2012).

5.5 Contagious Ecthyma (orf)

5.5.1 The Pathogen

Contagious ecthyma is caused by orf-virus, a DNA- and poxvirus belonging to the genus *Parapoxvirus*.

5.5.2 Occurrence

Orf-virus is distributed worldwide.

5.5.3 Hosts

Several ruminants may be affected by orf-virus, especially small ruminants.

5.5.4 Disease in Small Ruminants

Orf-virus affects the skin primarily around the mouth and udder. There is considerable heterogenicity between virus isolates, but it is still not confirmed if different virulence exists. A correlation between genetic variability and virulence has to be further elucidated. Genetic differences in orf virus strains seem to be due to geographic locations and animal hosts involved (Reid and Rodger 2007; Li et al. 2012).

The clinical manifestation is variable. Symptoms are seen most frequently in young lambs, normally in two peaks, first in spring shortly after lambing and then 3–4 months later. Morbidity usually approaches 100%, while in most outbreaks the mortality is low. However, occasionally up to 80% mortality has been recorded. Severity of outbreaks seems to be attributed to environmental factors (Reid and Rodger 2007).

The lesions usually develop at sites where the skin or the mucous membranes are traumatized. The first clinical signs are local erythema, followed by formation of papules, vesicles, and pustules ending in scab formation. Without secondary infections the lesions resolve within approximately four weeks. In natural cases, proliferation often gives rise to wart-like outgrows, which may develop into extensive cauliflower-like structures that persist for a long period. Lesions are normally found around the mouth and nostrils, but may also develop on the buccal cavity, esophagus, ears, axilla, poll, lower limbs, and coronet. The infection can also spread to the udder thus increasing the risk of mastitis (Reid and Rodger 2007; Smith and Sherman 2009; Li et al. 2012).

5.5.5 Disease in Humans

In humans, after an incubation period of 3–7 days, a macropustular reaction occurs, most commonly found on one finger. As in small ruminants, the development stages comprise erythema, papules, vesicles, pustules, and scabs. Several lesions may be present on hand and arm, but single lesions are more common. These are usually raised, circular, or oval and about 0.5–1.5 cm in diameter, often with central vesiculation and pustulation. The lesions will normally heal and detach after 6–8 weeks without leaving a scar. However, secondary bacterial infection can cause complications, especially lymphangitis and lymphadenitis of the draining lymph nodes, which may be associated with flu-like symptoms. Infection may in some cases develop into a generalized reaction, including widespread maculopapular

eruption and Erythema multiforme. Extensive lesions have especially been seen in immunosuppressed people (Martin 1991a; Reid and Rodger 2007).

5.5.6 Transmission (Small Ruminants-Human)

Humans are mainly infected by direct contact with lesions from live animals. Infection can also be transmitted by fomites. Persons directly handling infected animals, particularly when bottle-feeding lambs, shearing, and slaughtering sheep are especially at risk (Reid and Rodger 2007).

5.5.7 Diagnosis in Small Ruminants

Diagnosis is mainly based on clinical signs, such as papillomatous lesions around the lips and nostrils. However, the clinical picture may be atypical and laboratory confirmation is necessary. Electron microscopy has earlier been used to verify the diagnosis, but PCR-methods are now available (Reid and Rodger 2007).

5.5.8 Treatment and Control

Outbreaks spread rapidly in a flock, with most animals becoming affected within a few weeks. Such outbreaks will last for 6–8 weeks. No specific treatment is available. The main treatment is to avoid secondary infections. A live vaccine is available in some countries. If vaccination during an outbreak is considered necessary, an autogenous vaccine can also be prepared (Reid and Rodger 2007). Vaccine development using a DNA-vaccine has showed promising results (Zhao et al. 2011).

Persistently infected animals with no clinical symptoms have been described. The importance of these animals in the epidemiology of the infection is unknown. The virus may survive in buildings and handling facilities between epidemics. Orf-virus is known to survive in dry scabs for a long period, up to 23 years at 7 °C, but the infectivity is lost more rapidly at higher temperature and at more moist conditions. Disinfection of the actual pens should be performed. Infection in humans can normally be avoided through good hygienic procedures. Protective gloves should be used when handling infectious animals or infective material (Reid and Rodger 2007; Smith and Sherman 2009).

5.6 Echinococcosis (hydatidosis)

5.6.1 The Pathogen

E. granulosus is a tapeworm that belongs to the class *Cestoda* and the family *Taeniidae*. Several species of genus *Echinococcus* exist, but it is mainly *E. granulosus* that involves small ruminants as intermediate hosts. Ten genotypes (G1-G10) including five species

have been characterized, of which three (G1 to G3) are "sheep" strains belonging to *E. granulosus* sensu stricto (Moro and Schantz 2009), while G1 and G6 (*E. canadensis*) affect goats (Smith and Sherman 2009; Moro and Schantz 2009; Wen et al. 2019).

5.6.2 Occurrence

E. granulosus is widespread in areas where sheep are reared (Brunetti and White 2012).

5.6.3 Hosts

The definite host are domestic dogs and some wild canids. There are several intermediate hosts such as sheep, goats, cattle, swine, camelids, cervids, lagomorphs, and humans. The sheep strain G1 is most commonly associated with human infection (Moro and Schantz 2009).

5.6.4 Disease in Small Ruminants

Cestode eggs, which contain oncospheres must be ingested in order to continue the life cycle of the parasite. After ingestion, the larval stage will develop to cysts (hydatid cyst) in different organs, most commonly in liver and lungs. No definite clinical symptoms have been observed in small ruminants, even in cases with multiple cysts in either liver or lungs (Taylor et al. 2007).

5.6.5 Disease in Humans

E. granulosus cysts in humans may take years to develop and produce clinical symptoms. Many cysts remain asymptomatic throughout life and are only discovered by accident. However, the infection can result in respiratory distress and abdominal enlargement depending on which organ is affected. Clinical symptoms depend on the location and size of the *E. granulosus* cyst, and are mainly due to the pressure on the actual organ and on surrounding tissues. In man, the hydatid cysts may be 5–10 cm in diameter or even larger (Martin 1991b). The most common localization is the liver (70%), followed by the lungs. Rupture of the cyst is often fatal, due to anaphylactic shock or pulmonary edema (Moro and Schantz 2009; Brunetti and White 2012).

5.6.6 Transmission (Small Ruminants-Human)

The dog-sheep-dog cycle is the most important cycle in several endemic areas. Small ruminants normally contract *E. granulococus* by gracing on pasture contaminated by dog feces containing cestode eggs. The dogs are again infected by ingestion of viscera with fertile cysts (Moro and Schantz 2009).

Man can be infected by direct contact to dogs or indirectly through contaminated food, water, and infected objects. Dogs may carry eggs on the body surface and a person can become infected by touching the animal. Close contact with dogs and lack of hygiene are important factors for transmission. Another important source of human infection is through vegetables and water contaminated with eggs. Ingestion of infected flies may also transmit the infection (Lawson and Gemmell 1990). However, direct transmission from small ruminants to man has not been observed (Moro and Schantz 2009; Smith and Sherman 2009).

5.6.7 Diagnosis in Small Ruminants

Numerous tests have been developed for the diagnosis in humans, although few reliable serological tests are available for small ruminants. Various imaging techniques can be used to identify the hydatid cysts, but postmortem examination is still the most reliable method for diagnosis in intermediate hosts (Moro and Schantz 2009; Smith and Sherman 2009), although molecular diagnosis may also be used to identify infected animals (Wen et al. 2019).

5.6.8 Treatment and Control

The main control measurement is to interrupt the transmission cycle from the intermediate to the definite host. The infection cycle would be halted if dogs lack access to the viscera of intermediate hosts. In addition, the number of dogs might be reduced or treated with efficient anthelmintics. Treatment of infected sheep/goat in order to stop the infectivity of the cysts is not yet possible. Recombinant vaccines have been developed both for sheep and dogs with promising results (Lightowlers et al. 1999; Zhang and McManus 2008).

Oncospheres have little resistance to desiccation and high temperature; however they may survive in water/damp sand for 225 days at 6 °C (Lawson and Gemmell 1983). Hygiene is important to prevent human infection, as eggs may be swallowed with uncooked vegetables contaminated with dog feces or from fingers contaminated from soil or the fur of an infected dog. Close contact with possibly infected dogs should therefore be avoided. Early diagnosis in human is important to avoid complications and rupture of the cysts. Surgery was earlier the traditional approach for treatment in humans, but anthelmintics, percutaneous procedures, and a watch-and-wait approach are now more commonly used (Brunetti and White 2012).

5.7 Leptospirosis

5.7.1 The Pathogen

Leptospirosis is caused by helical Gram-negative organisms of the family *Leptospiracea* and the genus *Leptospira*. More than 250 serovariants have been detected (Cerqueira and Picardeau 2009). The main serovariants infecting small

ruminants seem to be *L. borgpetersenii* serovar Hardjobovis and *L. interrogans* serovar Pomona (West et al. 2009).

5.7.2 Occurrence

Leptospira involving small ruminants have a worldwide distribution.

5.7.3 Hosts

Several hosts are involved, including cattle and swine.

5.7.4 Disease in Small Ruminants

Small ruminants have been found infected with the three species of the genus *Leptospira*, namely, *L interrogans*, *L. borgpetersenii*, and *L. kirschneri* (Levett 2001; West et al. 2009; Smith and Sherman 2009). There are several serovariants within each species, such as *L. interrogans* serovar Pomona. Virulence of these strains varies, whereas the majority of leptospiral infections in small ruminants are subclinical and disease seems to be uncommon. However, septicemia, depression, anorexia, and in some cases hematuria may occur. Severe illness is characterized by jaundice, hematuria, and hemoglobinuria, which may progress to a fatal outcome. Abortion has also been reported (Smith and Sherman 2009; West et al. 2009).

Sheep could be infected with *L. interrogans* Hardjobovis, but are usually asymptomatic and studies indicate that sheep are only transiently infected with this serovariant (West et al. 2009). In addition, serovar *L. grippotyphosa*, *L. icterohemorrhagiae*, and *L. serjoe* have been involved in clinical leptospirosis in goats (Smith and Sherman 2009).

5.7.5 Disease in Humans

Human disease varies widely according to the serovar of *Leptospira* involved. The incubation period varies from 2 to 30 days. In the acute febrile stage, the clinical symptoms are related to a generalized vasculitis, such as severe headache, muscle pain, conjunctival suffusion, rash, and photophobia. Intrauterine infection and fetal death may occur in pregnant women. The infection may proceed to aseptic meningitis and renal failure (Ellis 1998).

5.7.6 Transmission (Small Ruminants-Human)

Human infection may be acquired through occupational, recreational, or avocational exposures. Leptospires persist in the kidney and genital tracks of carrier animals and

are excreted in the urine and genital fluids. Survival outside the host is favored by warm and moist conditions. Transmission is mainly due to direct or indirect contact with persistently infected animals and occurs through contact with infected urine, products of abortion, handling of infected kidneys, and ingestion of infected milk. However, a recent study excludes raw milk as a source of human infection (Fratini et al. 2016). Leptospires gain access to the host mainly through mucous membranes and abraded and water-softened skin (Ellis 1998).

5.7.7 Diagnosis in Small Ruminants

The diagnosis is based on laboratory confirmation, such as PCR analyses of blood, CSF or tissue biopsy, and serology (such as Microscopic agglutination test (MAT) and ELISA). Leptospires in the urine is, however, not a common feature of serovar Pomona infection in sheep (West et al. 2009). No reliable method exists for detection of carrier animals.

5.7.8 Treatment and Control

Leptospira are important pathogens in developing countries, where poor work and living conditions increase the opportunity for transmission from animals to man. The infection often occurs after heavy rainfall when surface water accumulates in the paddocks. Clinical cases should be treated with antibiotics (West et al. 2009). Vaccines based on killed whole leptospiral cells have been available for several years. Recent vaccine developments based on recombinant proteins showed promising results (Yan et al. 2010; Félix et al. 2011).

To avoid spread of the infection, infected animals should be identified and contact with carrier animals should be minimized. A potential for venereal transmission of *Leptospira* strains in small ruminants have been reported (Lilenbaum et al. 2008; Arent et al. 2013). Prevention should be based on environmental control, such as rodent control, elimination of standing water, and avoidance of damp beddings. In addition, contact with infected herds and import of infected animals should be avoided. In order to prevent the human infections, common water sources or potentially contaminated water supplies should be restricted. Farmers, milkers, slaughterhouse, and meat-processing workers as well as veterinarians have an increased risk for exposure (Dorjee et al. 2008; Smith and Sherman 2009).

5.8 Listeriosis

5.8.1 The Pathogen

Listeria monocytogenes is a Gram-positive coccobacillus within the genus *Listeria*. At least 16 serotypes with numerous subtypes of *L. monocytogenes* exist. *L. ivanovii* may occasionally cause abortion in small ruminants, but this bacterium rarely infects

humans causing bacteremia, fetal loss, or gastroenteritis (Smith and Sherman 2009; Guillet et al. 2010).

5.8.2 Occurrence

L. monocytogenes is ubiquitious in the environment.

5.8.3 Hosts

Several animals including small ruminants can be infected with *L. monocytogenes*. The natural reservoir appears to be the mammalian gastrointestinal tract. Grazing animals may ingest the bacteria and further contaminate vegetation and soil (Scott 2007).

5.8.4 Disease in Small Ruminants

There are mainly six manifestations of the disease: abortion, septicemia, encephalitis, diarrhea, mastitis, and ocular infections. Clinical manifestations vary according to the route of infection. *L. monocytogenes* often affects the pregnant uterus and the central nervous system. During pregnancy, infection spreads to the fetus, which will either be born severely ill or die *in utero* (Scott 2007).

Listeriosis is one of the most common neurological diseases in adult sheep. Sheep aged 18–24 months are often affected due to molar teeth eruption, which may facilitate infection. Lesions are normally localized in the brainstem and clinical signs indicate unilateral dysfunction of the third to seventh cranial nerves. Facial nerve paralysis with dropping ear, muzzle pulled to one side, and lowered upper eyelids are typical symptoms. Profuse salivation and retained food material in the cheek is also typical. Keratoconjunctivitis and iritis may occur, in addition to partial paralysis of the pharynx. The clinical course in sheep and goats is often rapid, and death may occur 4–48 h after onset of clinical symptoms (Scott 2007; Smith and Sherman 2009).

5.8.5 Disease in Humans

Systemic *L. monocytogenes* infection is a serious, but usually sporadic, invasive disease that primarily affects pregnant women, neonates, and immune-compromised persons (Cork and Checkley 2011). Infections can be treated successfully with antibiotics, but 20–40% of human cases are fatal (McLauchlin and Van der Mee-Marquit 1998).

The infective dose of *L. monocytogenes* is not known. The incubation period from foodborne infection varies widely from 3 up to 70 days, with a medium

incubation period estimated to be around 3 weeks. There may be strain variation in pathogenicity, but this has to be unraveled more closely. Outbreaks of listeriosis are usually spread via the fecal-oral route, resulting in a self-limiting gastroenteritis in healthy persons. However, cutaneous infection has also been observed in people during deliveries of listeria-infected animals. During pregnancy, infection spreads to the fetus. In nonpregnant humans, listeriosis usually presents as meningitis, encephalitis, or septicemia in the immune-compromised and elderly (McLauchlin and Van der Mee-Marquit 1998; Swaminathan and Gerner-Smidt 2007; Cork 2011).

5.8.6 Transmission (Small Ruminants-Human)

Foodborne transmission of *L. monocytogenes* is the main route of infection, whereas unpasteurized dairy products are the main source of human infection. Other sources include uncooked food of animal origin and contaminated raw vegetables. *L. monocytogenes* may also be transmitted by direct contact with infected animals or animal products. In such cases, the disease occurs principally as papular or cutaneous lesions, usually on the arms or the wrist 1–4 days after attending a listeria-abortion. This manifestation, however, has mainly been seen after contact with cattle (McLauchlin and Van der Mee-Marquit 1998; Smith and Sherman 2009).

5.8.7 Diagnosis in Small Ruminants

Unilateral cranial nerve paralysis affecting the eye, eyelid, ear, and lips with ataxia are typical for listeriosis. Samples from cerebrospinal fluid can support the diagnosis. At postmortem examination, histological lesions such as microabscesses and perivascular cuffing in the brainstem and medulla are pathognomonic of listeriosis. Aborted fetuses due to *L. monocytogenes* are usually autolytic with miliary necrotic foci scattered throughout the liver and spleen, while listeria-septicemia is often accomplished by focal hepatic necrosis. Listeriosis, however, can only be confirmed by isolation or identification of *L. monocytogenes* (Low and Donachie 1991; Scott 2007).

5.8.8 Treatment and Control

Infection can be treated with antibiotics. The drug of choice is high-dosed penicillin. Supportive therapy including fluids and electrolytes are required for animals having difficulty eating and drinking (Scott 2007).

In an outbreak, affected animals should be segregated. In silage-fed ruminants, listeriosis is mainly a winter-spring disease and is normally seen in animals fed with poorly conserved silage. Outbreaks may occur within 10 days of feeding poor silage. Use of the particular roughage should be discontinued. However, due to an incubation period of 1–3 weeks, most of the *Listeria*-infected silage may not be

longer available. Animal to animal transmission may occur via the fecal-oral route. A live attenuated vaccine for use in sheep has been developed, but the results from field trial vaccinations are equivocal (Scott 2007). However, new vaccine technologies seem promising in developing a protective immune response against *L. monocytogenes* (Carrasco-Marin et al. 2012; Kim et al. 2012; Luo and Cai 2012; Mohamed et al. 2012).

To avoid infection in humans, hygiene during food preparation and storage as well as avoidance of unpasteurized dairy products are preventive measures. However, *L. monocytogenes* can survive in soil or silage for more than 2 years. It is also found in excreta from apparently healthy animals, although carriage in the gut is likely to be transitory. Control measures should be focused on avoiding *Listeria*-contaminated food, especially since the bacteria maintain to grow during refrigeration. Pregnant women and immune-compromised individuals are at increased risk for developing listeriosis (McLauchlin and Van der Mee-Marquet 1998).

5.9 Q-Fever (Coxiella burnetii)

5.9.1 The Pathogen

Q-fever is caused by the intracellular organism *Coxiella burnetii* within the genus *Coxiella* and the order *Legionellales* (Seshadri et al. 2003). The organism exists in two different antigenic phases. In nature, *C. burnetii* exists in phase 1 form, which is virulent. However, when cultivated in cell cultures or hen eggs the organism mutates irreversibly to the phase II form, which is less virulent (Quevedo Diaz and Lukacova 1998). *C. burnetii* has mainly two different morphologic forms, a large and a small form. In addition, an endospore-like structure is observed in the large form, which is highly resistant to environmental degradation, such as high temperatures, ultraviolet light, and osmotic shock (Mearns 2007).

5.9.2 Occurrence

Q fever is a worldwide zoonosis that occurs in all geographic and climate zones, with the exception of Antarctica and possibly New Zealand (Hilbink et al. 1993; West et al. 2009). However, Q fever is not a reportable disease in many countries, so it is difficult to know exactly where it occurs.

5.9.3 Hosts

C. burnetii is able to infect many animal species including mammals, birds and several arthropods. However, cattle, sheep, and goat seem to be the primary animal reservoirs for human infection (Maurin and Raoult 1999).

5.9.4 Disease in Small Ruminants

In animals, *C. burnetii* infections are generally asymptomatic, except for abortion, stillbirth, and the delivery of weak offspring. However, *C. burnetii* may induce pneumonia, conjunctivitis, and hepatitis (Arricau-Bouvery and Rodolakis 2005). High abortion rates are rarely observed, although abortion storms in some caprine herds have been described (Sanford et al. 1994). In the outbreak of Q-fever in the Netherlands (2007–2009), abortion rate up to 60%, mainly in the final month of pregnancy, was reported in goats (Roest et al. 2011). Aborted fetuses appear normal, but infected placentas exhibit intercotyledonary fibrous thickening and discolored exudates that may be mineralized (Moore et al. 1991).

5.9.5 Disease in Humans

In humans, acute Q fever is rarely diagnosed, because of nonspecific initial clinical signs, such as fever, pneumonia, headache, and weakness. However, 1–2% of infected individuals can develop chronic infection that may result in severe granulomatous hepatitis, osteomyelitis and valvular endocarditis. Chronic infection can manifest itself within a few months or even years after the acute infection (Fournier et al. 1998; Ganter 2015).

5.9.6 Transmission (Small Ruminants-Human)

Contaminated aerosols generated from desiccation of infected placentas, body fluids, or dust from contaminated manure are the main sources of both animal and human infection, and the control of fecal excretion and placental bacterial discharge is essential (Arricau-Bouvery and Rodolakis 2005). Grazing contaminated pasture and tick bites are other modes of transmission. Single animals may shed large amount of *C. burnetii*, the so-called super-spreaders, within infected flocks (Bauer et al. 2020). The organism is also highly infectious, with an infective dose of 1–10 bacteria (Tigertt et al. 1961). Because *C. burnetii* is extremely resistant to desiccation and to physical and chemical agents, it survives in the environment for long periods. The endospore-like form survives in dust for 120 days, in tick feces for 568 days and in wool for 12–16 months at 4–6 °C (Mearns 2007).

5.9.7 Diagnosis in Small Ruminants

Current alternatives to diagnose *C. burnetii* infection in ruminants include serological analysis, isolation by cell culture, live animal inoculation, immunohistochemical, and PCR-based detection. In the acute phase of the infection, *C. burnetii* can be detected in lungs, spleen, liver, and blood (Fournier et al. 1998; Maurin and Raoult 1999).

Placental smear or impression of placentas can be stained, for instance, by using a modified Ziehl-Nielsen procedure (Mearns 2007). Several serologic tests are available, such as complement fixation test, ELISA, and a fluorescent antibody test. However, carrier animals may also have an antibody titer increase in late pregnancy (Kovacova et al. 1998; Smith and Sherman 2009). For Q fever diagnosis, it has been recommended to use PCR and immunofluorescence tests of *Coxiella* on parturition products and vaginal secretions at abortion (Arricau Bouvery et al. 2003).

5.9.8 Treatment and Control

If Q fever is suspected, aborting animals and animals in late pregnancy should be treated with tetracycline, although this treatment does not totally suppress the abortions and shedding of *C. burnetii* at lambing (Berri et al. 2005). Placentas and aborted fetuses should be destroyed properly and aborted animals should be isolated. In addition, materials such as bedding and straw contaminated with birth fluids and other secretions from affected animals should be destroyed (Smith and Sherman 2009).

The spread of *C. burnetii* infection in domestic animals depends on many factors, such as population density of animals, the system of rearing and management at parturition. Because the environment can remain infected for a long time and many species can be carriers, test and cull strategies are not appropriate for infected herds (Smith and Sherman 2009). However, during the recent outbreak of Q fever in humans in the Netherlands, the Dutch Government decided to cull more than 50.000 pregnant ewes and goats in order to halter the worst outbreak of Q fever ever known where more than 4000 human cases have been recorded from 2007–2010. The reason for this strategy was that dairy goats were believed to be the main source of human infection (van der Hoek et al. 2012).

In animals, the uterus and mammary gland of females are sites for persistent *C. burnetii* infection. Reactivation of the bacterium during pregnancy results in shedding of a great amount of infectious agent into the environment during abortion or via birth fluids, placenta, and fetal membranes (Sawyer et al. 1987). Over 10^9 bacteria per gram of placenta may be released at the time of delivery (Babudieri 1959). Studies indicate that ewes shed the bacterium mostly in feces and vaginal mucus, while in goats shedding in milk seems to be the most frequent route (Rodolakis et al. 2007; Rodolakis 2009).

In animals, the most effective vaccines are those composed of inactivated whole phase I bacteria. Bacterial shedding in placentas and milk was strongly reduced in experimental infection or in natural Q fever infection in ewes vaccinated with phase I vaccines (Sampere et al. 2003). Since phase I vaccine are dangerous to produce, a subunit vaccine has been investigated (Arricau-Bouvery and Rodolakis 2005).

To prevent human infection, drinking raw milk or consumption of raw milk products should be restricted. For inactivation, pasteurization of milk at 62.8 °C for

30 min or at 71.7 °C for 15 s is required (Kazar 1999). Q fever often occurs as an occupational disease. Persons at particular risk are livestock handlers, processors of animal products, abattoir workers, those in contact with dairy products, veterinarians, and laboratory personnel working with *C. burnetii*-infected animals (Maurin and Raoult 1999). In addition, it is necessary to inform vulnerable persons such as immunosuppressed patients or those suffering from cardiac valvopathy and pregnant women that they must avoid contact with animals during lambing and kidding (Arricau-Bouvery and Rodolakis 2005).

5.10 Rift Valley Fever (RVF)

5.10.1 The Pathogen

RVFV (Rift Valley fever virus) is a single-stranded RNA-virus in the genus *Phlebovirus* of the family *Bunyaviridae*.

5.10.2 Distribution

RVFV is mainly distributed in sub-Saharan Africa, but has also been identified in Northern Africa and on the Arabian Peninsula (Bath 2007).

5.10.3 Hosts

RVFV may cause infection in several ungulate species, although their importance as reservoir host has to be unraveled. Mosquito vectors, such as in the genus *Aedes*, may maintain the virus in endemic areas by transovarial transmission. Other insects, such as *Culex* species, may also be involved in epidemics (Bath 2007). Vertical transmission occurs in all livestock species, even in pregnant ewes with no detectable viremia (Antonis et al. 2013).

5.10.4 Disease in Small Ruminants

RVFV can infect a wide variety of tissues, such as liver, lymphoid, and nervous tissue. The incubation period is short, as little as 12 h in young lambs and up to 72 h in adult sheep. High fever, anorexia, listlessness, and recumbency are common in young lambs. However, clinical signs are not always observed, since young animals may die rapidly. Mortality rate may exceed 90% in lambs under 2 weeks old. Abortion is a common sign in adult animals, and this may occur at any time during pregnancy and reach up to 100%. Infection in older animals is often subclinical (Bath 2007).

5.10.5 Disease in Humans

Human infection can result in a variety of clinical outcome, while most cases induce a self-limited febrile illness (Wright et al. 2019). Fatality rate is normally less than 1%, but the death toll can mount to several hundreds in severe outbreaks (Swanepoel 1998; Bath 2007). The largest recorded outbreak in humans was in 1997–1998 in East Africa where approximately 89.000 human cases and 478 fatalities were recorded (CDCP 1998). Typical symptoms in humans are flu-like illness after a short incubation period of 2–6 days. Other symptoms are photophobia, retinitis, meningoencephalitis, and hemorrhagic fever. The symptoms may be severe in patients with a preexisting liver disease. Sequelae may include widespread hemorrhages, jaundice, shock, liver, and kidney failure and death.

5.10.6 Transmission (Small Ruminants-Human)

The route of transmission in animals is via different mosquitoes. The virus has been isolated from more than 30 mosquito species. In addition, RVFV has also been isolated from flies and midges (*Culicoides*). Both biological and mechanical vector transmission may occur. In Sub-Saharan areas the main vector seems to be mosquitoes within the genus *Aedes* (Bath 2007; Smith and Sherman 2009). Heavy rainfall often precedes a RVF outbreak, where an increase in vector population may increase transmission potential (Wright et al. 2019).

The main transmission route in humans is via direct or indirect exposure to infected blood, tissues, or body fluids of infected animals, for instance, in connection with slaughtering, butchering, obstetrical procedures, or treatment of infected animals. Infection may also occur via vectors, aerosols, and consumption of unpasteurized milk. Direct person-to-person transmission has not been reported. Persons at risk are veterinarians, farmers, shepherds and abattoir workers (Swanepoel 1998; Smith and Sherman 2009).

5.10.7 Diagnosis in Small Ruminants

The diagnosis is based on clinical symptoms and postmortem examination. In young lambs, widespread hemorrhages and liver necrosis are often recorded. Disseminated intravascular coagulopathy may occur in several internal organs. Samples from spleen, liver, and brain should be used for histological examination. The diagnosis, however, has to be verified by PCR, virus isolation, and serological investigations (such as ELISA and hemagglutination-inhibition test) (Bath 2007).

5.10.8 Treatment and Control

Outbreak of RVF occurs at irregular intervals. The virus may persist in a vector/natural host cycle and low level of virus activity is found between outbreaks.

Infected eggs from *Aedes* species may survive in the soil for years. The single most important responsible factor for an outbreak of RVF is heavy rainfall and widespread flooding, which favors multiplication of the vectors. Movement of infected animals or winds that transport infected mosquitoes over long distances may spread the disease to non-endemic areas (Sellers 1980). The development of early warning systems and surveillance in and around endemic areas in order to recognize animal and human cases as early as possible are crucial in order to control the infection.

There is no treatment available for infected animals, since the disease is usually very acute and the lesions too severe. Control measures rely on the use of efficient vaccines. A live attenuated vaccine is available for nonpregnant animals, while an inactivated whole virus vaccine can be used for pregnant animals. The last vaccine requires a booster and annual revaccination. A recombinant vaccine has recently been developed, but it must be tested in appropriate animal models before being used as a livestock and human vaccine (Indran and Ikegami 2012; Morrill et al. 2013). When handling suspicious animals, wearing of eye protection, protective clothing, gloves, and masks should be mandatory (Swanepoel 1998). Only general supportive treatment is available for human cases of RVF and no licensed vaccine is yet available (Wright et al. 2019).

5.11 Tick-Borne Pathogens

5.11.1 The Pathogens

Around 900 species of ticks have been described (Guglielmone et al. 2014), of which several are associated to small ruminants especially in the genera *Amblyomma*, *Haemophysalis*, *Hyalomma*, and *Rhipicephalus*, although *Dermacentor* and *Ixodes* ticks may also infest sheep and goats (Stuen 2020). Tick-borne infections detected in small ruminants may again affect humans, such as *Anaplasma phagocytophilum*, *A. ovis*, *A. capra*, *Borrelia burgdorferi* sensu lato, Crimean-Congo hemorrhagic fever (CCHF)-virus, *Ehrlichia ruminantium,* Panola Mountain *Ehrlichia* (PME), tick-borne encephalitis (TBE)-virus, Louping ill (LI)-virus, and *Babesia venatorium* (Bente et al. 2014; Böhm et al. 2017; Gray et al. 2019; Stuen 2020).

In addition, a recently described serious virus infection in humans caused by severe fever with thrombocytopenia syndrome virus (SFTSV) has been detected in China, were *Haemaphysalis longicornis* seems to be the main vector species. A lot of animal species may be involved as potential hosts, including small ruminants. However, whether SFTSV causes clinical symptoms in sheep and goats or undergoes animal to human transmission requires further studies (Chen et al. 2019).

Only a few human cases have been reported from *A. ovis*, *E. ruminantium*, and PME, and *B. venatorum* infection in sheep has so far only been reported once (Allsopp 2010; Chochlakis et al. 2010; Böhm et al. 2017; Stuen 2020). *Coxiella burnetii*, and *Francisella tularensis* may also be transmitted by ticks, although other transmission routes are normally more important (Arricau-Bouvery and Rodolakis 2005; Mailles and Vaillant 2014; Borde et al. 2017). In addition, *B. burgdorferi* s.l. infection in sheep seems to be rare (Stanek et al. 2002).

Although small ruminants can be infected with different zoonotic pathogens, small ruminants are seldom important hosts for these infections, although they could be important accidental hosts. The most important zoonotic tick-borne pathogens in this context seem to be *A. capra, A. phagocytophilum,* CCHF-, TBE-, and LI-*virus* (Stuen 2020).

5.11.2 Occurrence

Tick-borne pathogens related to small ruminants may occur on all continents. *A. phagoctophilum*, known as a sheep infection for more than two centuries, is reported worldwide, especially in Europe (Stuen 2020). Only scattered information from Asia and Europe is available concerning the distribution of *A. capra*, since it was first described in 2015 (Peng et al. 2021). Human CCHF is widespread in Asia, Africa, and south-eastern Europe (Bente et al. 2014), while TBE-virus is spread in Europe and Asia with mainly three genetically distinguishable subtypes within partly overlapping geographical areas: Western European TBEV (mainly transmitted by *I. ricinus*), and Siberian and Far Eastern TBEV (predominantly transmitted by *I. persulcatus*) (Ruzek et al. 2019). In contrast, LI virus is localized only in north-western Europe, especially in the UK (Jeffries et al. 2014).

However, distribution of these infections changes continuously due to migration and transportation of vectors and animals, and an increased globalization of animals and their products, driven directly or indirectly by climate changes. These changes will have a huge effect on the distribution and establishment of both hosts, pathogens and vectors (Shope 1991).

5.11.3 Hosts

Small ruminants are important hosts for *A. phagocytophilum*, and LI-virus, while only accidental hosts for CCHM- and TBE-virus. Several enzootic cycles of *A. phagocytophilum* occur in nature, whereas variants with a more important zoonotic potential seem mainly to involve small rodents, hedgehogs (*Erinaceus europaeus*), and wild boar (*Sus scrofa*) (Stuen 2020). *A. carpa* seems to be related to domestic and wild ruminants, but the importance of small ruminants as hosts has still to be unraveled (Peng et al. 2021). CCHM-virus is maintained in several genera of ixodid ticks, especially *Hyalomma* ticks, and through transient viremia in a variety of wild and domestic mammals (Bente et al. 2014). Small rodents and *Ixodes* spp. ticks are important reservoir hosts for TBE-virus, while red grouse (*Lagopus lagopus scotica*), mountain hare (*Lepus timidus*), and sheep are the main reservoirs for LI virus (Reid and Chianini 2007; Salat and Ruzek 2020).

5.11.4 Disease in Small Ruminants

The tick-borne pathogens mentioned above may cause a variable degree of clinical signs in small ruminants, although only *A. phagocytophilum* and LI-virus seem to introduce severe clinical illness. *A. phagocytophilum* causes tick-borne fever (TBF) in ruminants, a febrile disease. TBF by itself is seldom fatal, but the infection induces immunosuppression that makes affected animals vulnerable to secondary infections, such as pyemia and septicemia. TBF may therefore cause severe economic and welfare challenges in the sheep industry (Stuen and Longbottom 2011). LI virus may also cause severe fever illness in sheep, with CNS-symptoms that may progress into fatal encephalitis. High death rate occurs by simultaneous infection with *A. phagocytophilum* (Jeffries et al. 2014).

In contrast, *A. capra,* CCHF- and TBE-virus may cause mild or subclinical symptoms in small ruminants (Bente et al. 2014; Salat and Ruzek 2020; Stuen 2020), although there has been a report on clinical symptoms in sheep after natural infection with TBE-virus (Böhm et al. 2017).

5.11.5 Disease in Humans

Several tick-borne infections cause severe disease in human, such as anaplasmosis, CCHF, and TBE. *A. phagocytophilum* causes flu-like symptoms, but severe complications have been reported involving septic shock like syndrome and acute respiratory distress symptoms. The mortality rate is around 1% (Bakken and Dumler 2015). More than 15.000 human cases have so far been reported, mainly in the USA (Stuen 2020). However, phylogentic studies show that strains/variants of *A. phagocytophilum* isolated from sheep differ from isolates normally affecting humans, indicating that sheep are an uncommon reservoir host for clinical cases in humans (Scharf et al. 2011; Jahfari et al. 2014).

A. capra may cause flu-like symptoms, but also rash, eschar, and gastrointestinal symptoms that may progress to central nervous involvement. Several hundred cases have so far been reported, mainly from China (Peng et al. 2021).

CCHF show a variety of symptoms, from a mild, unspecific febrile syndrome to a multiorgan failure, shock, and hemorrhages with up to 20–30% or even higher fatality rates. Several thousand cases have so far been reported, with an increasing number in several countries (Bente et al. 2014).

Signs of TBE are typically divided into two phases, first a viremic phase with flu-like symptoms that may progress into a neurological (second) phase, with meningitis, meningoencephalitis, and meningoencephalomyelitis (Ruzek et al. 2019). The western and Sibirian subtypes usually result in a rather mild form of TBE with a morality rate less than 2%, while the Far-Eastern subtype is associated with higher fatality rates, although viral subtypes are not the sole determinant of TBE

severity (Ruzek et al. 2019). Between 10.000 and 15.000 cases of TBF are reported in Europe and Asia each year (Salat and Ruzek 2020).

LI-virus may cause the same symptoms, although milder, as TBE-virus. Several LI-cases were diagnosed earlier, but no human patients suffering from LI-virus encephalitis have been definitively diagnosed over the past 20 years (Jeffries et al. 2014).

5.11.6 Transmission (Small Ruminants-Human)

A. phagocytophilum and LI-virus are mainly transmitted to humans by tick bites, although other routes of transmission have been reported, such as through contact with infected animals (Jeffries et al. 2014; Stuen 2020).

CCHF infections occur via tick bites or exposure to blood or body fluids of an infected animal through occupational exposure to infected livestock, such as farmers, abattoir workers, butchers, veterinarians, and laboratory scientists. However, infected animals seem only to develop a transient viremia (Bente et al. 2014).

TBE-virus is mainly transmitted from small ruminants to humans by consumption of unpasteurized milk or milk products from infected animals (Salat and Ruzek 2020). It has been estimated that around 1% of all TBE cases are caused by foodborne infections (Ruzek et al. 2019).

5.11.7 Diagnosis (Small Ruminants)

Diagnosis of tick-borne infections may be based on clinics, stained blood smear (especially *A. phagocytophilum*), serology, or molecular methods. Postmortem analysis may support the diagnosis. However, clinical symptoms or pathological changes may not be observed or may even be absent. Serological tests are available for most of the pathogens mentioned above. Although in order to verify the diagnosis, PCR-methods are often necessary, the infection can be difficult to detect in persistently infected animals (Reid and Chianini 2007; Stuen and Longbottom 2011; Bente et al. 2014; Ruzek et al. 2019).

5.11.8 Treatment and Control

Tick control measures are necessary in order to reduce tick exposure and to limit tick distribution and expansion. Different methods are available, such as draining, fencing, mechanical clearing of bushes, control burning, removal of leaf litter, partial removal of forest canopy, reduction of hosts, and use of herbicides and acaricides. Current control strategies are mainly based on the reduction of tick infestation by application of chemical acaricides, mostly done by dipping or pour on-application of pyrethroids. However, several of these treatments are not environmentally friendly and may cause chemical residues in

animal products (Samish et al. 2004; Stuen and Longbottom 2011). Anti-tick vaccine development is a solution, but still not available, except for vaccine against *Rhipicephalus microplus* (Stuen and Longbottom 2011).

Infection may occur through occupational exposure to infected livestock. Infected animals should therefore be handled with care. The drug of choice in treatment against *A. phagocytophilum* infection is tetracycline. Fluoroquinolone antibiotics and rifampin may be alternative drugs, especially in humans, in patients with intolerance to tetracycline. No vaccine is yet available against *A. phagocytophilum,* mainly due to the challenge in choosing conserved antigens, especially since antigenic variation of surface proteins occurs during the infection (Stuen and Longbottom 2011).

A formalin-inactivated CCHF vaccine is available for humans, although lack of proper animal models has hampered the effort to develop a more efficient vaccine. Several TBE-vaccines are also available for humans, which are widely used in TBE endemic areas. However, there is no specific treatment against these virus infections; supportive and symptomatic therapies are therefore the mainstay of TBE and CCHF management (Bente et al. 2014; Ruzek et al. 2019).

There is no specific treatment for LI in animals, although an inactivated virus vaccine is currently available for animals. There is no commercial LI vaccine licensed for human use, although neutralization antibodies from commercial TBE vaccines may provide some cross-protection against LI-virus infection (Jeffries et al. 2014).

5.12 Toxoplasmosis

5.12.1 The Pathogen

Toxoplasma gondii is a protozooan parasite within the family *Sarcocystiidae* and genus *Toxoplasma*. The life cycle can be divided into two parts, a sexual cycle, restricted to enteroepithelial cells in cats and the production of oocysts, and an asexual cycle (forming tissue cysts), which occurs in a wide range of warm-blooded intermediate hosts. Six major clades of *T. gondii* have been characterized (Buxton and Rodger 2007; Su et al. 2012).

5.12.2 Occurrence

T. gondii has a worldwide distribution.

5.12.3 Hosts

Multiple intermediate hosts seem to exist, but the most important domestic hosts are pigs, sheep, and goats. The final host is in the felid family.

5.12.4 Disease in Small Ruminants

Clinical toxoplasmosis causes abortion and neonatal mortality in small ruminants, especially in sheep. Mummified fetuses, stillborn or weak offspring are common features. However, infection in early pregnancy (< 55 days) may result in death or expulsion of a small fetus. Clinical signs in aborting animals are usually not observed. Abortion is associated with primary infection during pregnancy in non-immune animals and is most commonly seen in young animals. A long-lasting immunity develops following primary exposure and animals are unlikely to abort again due to toxoplasmosis (Buxton and Rodger 2007; Smith and Sherman 2009).

5.12.5 Disease in Humans

In most cases, toxoplasmosis in human is a disease with relatively mild and transient symptoms. However, primary infection during pregnancy may lead to intrauterine infection, and result in abortion or congenital lesions in the fetus. In addition, in patients with impaired immunity, *T. gondii* may lead to serious and even fatal infection (Dubey and Beattie 1988).

5.12.6 Transmission (Small Ruminants-Human)

The proportion of the human population infected with *T. gondii* depends on the age, area, and environment. Most human infection appears to result either from exposure to oocysts from a contaminated environment or from ingestion of raw or lightly cooked meat containing tissue cysts. The most common way for infection from small ruminants to humans is by ingestion of tissue cysts. In addition, human infection through drinking of unpasteurized goat milk has been reported. A low risk may also apply when assisting infected animals at lambing or kidding. However, both these last modes of transmission are probably of low significance (Dubey and Beattie 1988; Smith 1991).

5.12.7 Diagnosis in Small Ruminants

Abortion due to *T. gondii* occurs mainly in young animals. Typical clinical signs of abortion result following infection in mid-gestation, with ewes and does producing stillborn and/or weekly offspring often accompanied by a mummified fetus. Cotyledons will also show characteristic lesions, such as white foci of necrosis 2–3mm in diameter, which may become mineralized. Diagnosis may include serology (such as Sabin dye test, IFAT, MAT, and ELISA), histology, immune-histochemistry, and PCR methods (Buxton and Rodger 2007; Taylor et al. 2007; Smith and Sherman 2009).

5.12.8 Treatment and Control

Susceptible animal gets infected by ingestion feed or water contaminated with oocysts. The oocysts are highly resistant and survive for a long period (> 500 days) at room temperature in moist conditions. The main source of *Toxoplasma* infection in small ruminants are oocysts excreted from cats. Susceptible cats become infected with *T. gondii* after ingestion of tissue cysts from, for instance, small rodents and may excrete a large numbers of oocysts, which then sporulate and become infective within a few days and remain so for several months. Infected feces will then contaminate beddings, stores of hay, concentrates, water supplies, and pasture. It has been estimated that although < 1% of the cat population may excrete oocysts at any time, contamination of the environment is readily maintained (Dubey and Beattie 1988; Buxton and Rodger 2007).

During an outbreak of toxoplasma-caused abortion little can be done. Infected placentas and dead lambs or kids should be buried or disposed to prevent their ingestion by other animals. Animal to animal transmission during lambing or kidding does not appear to occur to any significant extent. More direct preventive measures include chemoprophylaxis, chemotherapy, and vaccination. A live vaccine based on an attenuated strain of *T. gondii* has been developed for sheep (Buxton and Rodger 2007; Smith and Sherman 2009).

In humans, as already mentioned, the most common way for infection from small ruminants is by ingestion of raw or lightly cooked meat. Tissue cysts may be viable for the lifetime of infected sheep (Dubey and Beattie 1988). Treatment of meat by curing, smoking, freezing at -20 °C is usually sufficient to kill the encysted *T. gondii*. However, cysts can survive insufficient microwave cooking (Lundén and Uggla 1992). Treatment of tissue cysts in infected sheep to prevent human exposure to meat-borne toxoplasmosis has shown promising results (Kul et al. 2013). Shepherds, veterinary surgeons, slaughterhouse staff, and butchers are especially at risk for contracting infection from small ruminants.

5.13 Concluding Remarks

Only a limited number of topics are covered by this brief review and important issues such as differential diagnoses are not included or discussed. A correct and swift diagnosis is a prerequisite for proper treatment and control. This may not always be available due to long incubation periods, unspecific clinical symptoms, and imprecise diagnostic tests. Some pathogens may survive unnoticed in animals or animal products for a long period of time. Anthrax in humans, for instance, has occurred when handling imported goat skins for drum making, skins contaminated with spores of *B. anthracis* (Anaraki et al. 2008).

Microbial transmission will always occur between species, but the risk of transmission can be reduced with proper hygiene, management, husbandry, and prophylactic treatment. Climate change, increased population, and globalization will have a

huge impact on the occurrence and distribution of these infections. In this context, recent vaccine developments against several zoonotic pathogens through genomic, transcriptomic, and proteomic approaches are promising.

Conflict of Interest Statement The author has nothing to disclose.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_4

Abstract

Many factors and problems influence poultry production worldwide. These include strong global competition, continuous changes of consumer perceptions regarding food safety, animal welfare, and environmental protection. Poultry share a number of infectious diseases with humans, and most of the zoonotic diseases in poultry have additional reservoirs in other mammals than humans, which complicates their control. Roughly, there are three groups of zoonoses that humans can acquire from poultry:

The **first group** includes **food-borne diseases**, mainly caused by *Salmonella* serovars and *Campylobacter spp.,* which are the most common causes of human food-borne bacterial diseases linked to poultry. There are indications that *Escherichia coli* from poultry can cause disease in humans, in which case *E. coli* would have to be considered a potential food-borne pathogen. In addition, the development of antibiotic-resistant bacteria will also continue to be a hazard to public health.

The second group comprises diseases that are **transmitted by direct contact** between birds and humans. These include avian influenza, Newcastle disease, and chlamydiosis. Erysipelas has an exceptional position as it mainly infects people working in processing plants via skin injuries.

The third group comprises diseases **transmitted by insects**, especially ticks from mammals and birds, including poultry, to humans. These include West Nile Virus and Eastern and Western Equine Encephalitis.

Keywords

Chicken · Turkeys · Poultry · Birds · Salmonella · Campylobacter · *Escherichia coli* · Antimicrobial resistances · Avian influenza · Newcastle disease · Chlamydiosis · *Chlamydia psittaci* · Ornithosis · Erysipelas · Erysipeloid · *Erysipelothrix rhusiopathiae*

6.1 Introduction

In developed countries, most poultry is kept in large flocks on specialized farms. These husbandry conditions offer a high level of biosecurity, and only few humans or other animals have direct contact with the birds. Thus, the main transmission route from poultry to humans is via contaminated food, namely meat and eggs. *Salmonella* and Campylobacter are the two most important zoonotic agents in poultry causing food-borne infections. Despite significant improvements in technology and hygienic practice at all stages of the poultry production, these pathogens remain a persistent threat to human health. There have also been indications that Avian Pathogenic *Escherichia coli* (APEC) might have zoonotic properties, but more substantial evidence is needed. Furthermore, bacterial isolates from chicken can be resistant against antimicrobials and cause infections in humans that are difficult to treat or pass the resistance genes on to other bacteria.

In developing countries, where smaller backyard flocks are more common and where many of the birds raised for meat production are traded live to the consumer, direct contact between poultry and humans is more frequent. Thus, diseases are transmitted more often directly from poultry to humans. Avian influenza is the most important example and has received major attention in the media despite a relatively low number of infected humans. Other pathogens transmitted from poultry to humans by direct contact include Newcastle disease and chlamydiosis.

Erysipelas has an exceptional position since it mainly infects humans through skin injuries. Thus, besides persons handling infected birds, personnel at processing plants have an elevated risk of infection.

Further zoonotic diseases, which have lesser importance either, because they occur only infrequently or because they have a low virulence for humans, are listed in Table 1.

Table 1 Zoonotic pathogens detected in poultry

Pathogen	Host	Distribution	Transmission	Clinical symptoms (poultry)	Clinical symptoms (human)	Further information
Crimean Congo Hemorrhagic Fever Virus	Ostriches, migratory birds, several mammals	Asia, Africa	Ticks	Asymptomatic	Hemorrhagic fever	Estrada-Peña et al. (2012)

6.2 Salmonella

6.2.1 Epidemiology of Salmonella Infections in Poultry

Salmonellosis and *Salmonella* infections in poultry occur worldwide. The more than 2500 serovars of *Salmonella enterica* can roughly be classified into three categories or groups: **Group 1: highly host adapted and invasive serovars.** This group includes species restricted and invasive salmonella such as S. Pullorum and S. Gallinarum in poultry and S. Typhi in humans. **Group 2: nonhost-adapted and invasive serovars.** This group consists of approximately 10 to 20 serovars that can cause an invasive infection in poultry and may be capable of infecting humans. Currently, the most important serovars are S. Typhimurium, S. Enteritidis, S. Heidelberg, and S. Kentucky. Some serovars may be predominant for a few years in a region or country before they disappear and are replaced by another serovar. In the past, the dominant type worldwide of salmonella food poisoning was S. Typhimurium, but since the early 1980s, S. Enteritidis has become more important. S. Heidelberg and S. Kentucky are two serovars associated with poultry that are currently causing problems. **Group 3: nonhost-adapted and noninvasive serovars.** This group is the by far the largest but poses no or only a very low risk for human health. However, *Salmonella* of this group are detected when flocks are monitored. Laws and regulations may or may not apply to them.

The prevalence of *Salmonella*-infected flocks and the serovars involved varies widely between different countries. Current data obtained by monitoring programs in the European Union are published in regular intervals. Within an infected flock, the prevalence of infected birds can be well below 10%.

Transmission and spread of *Salmonella* in poultry occur by horizontal and/or vertical routes. Horizontal spread of infection takes place through contaminated feed, water, equipment, and the rearing environment. Significant reservoirs for these microorganisms are asymptomatically infected chickens, other avian species including pigeons and wild birds, and other farm animals and pets. Rodents are potential reservoirs transmitting infection between houses and contaminating stored feeding stuffs. In addition, insects are a potential source of *Salmonella* infection in chicken. Some invasive *Salmonella* can be transmitted vertically within the eggs, i.e., true vertical transmission. True vertical transmission occurs primarily by infection of the ovaries and the follicles, which become the yolks, by contact of the follicles with infected peritoneum or air sacs or alternatively in the oviduct where the egg white is produced. Pseudovertical transmission happens by contamination of the eggshell as a result of fecal contamination from cloaca and/or contaminated nests, floor, or incubators. Subsequently, Salmonella can penetrate the eggshell into the eggs.

6.2.2 Epidemiology of Salmonella Infections in Humans

Despite significant improvement in technology and hygienic practices at all stages of food production accompanied with advanced improvement in public sanitation,

Salmonellosis and *Salmonella* infections remain a persistent threat to human and animal health.

During the slaughter process, carcasses can become contaminated with *Salmonella*, if the equipment is contaminated from the same or a previous flock. Feather pickers and chilling of carcasses are among the processing steps with the highest risk of cross-contamination. Air-chilling or antimicrobial compounds like trichloroacetic acid in water chillers can decrease the risk. Eggs can be contaminated with *Salmonella* as described above. Egg-washing is a controversial preventative measure. While it removes fecal contaminations from the eggshell, it also removes the cuticle, a protective layer that reduces penetration of the eggshell by bacteria. Humans can contract the disease if they consume meat or eggs that are not thoroughly cooked. In addition to food-borne transmission, direct transmission from birds in pet- and backyard flocks to humans has been well documented and can be a major risk for children.

Humans will shed the bacteria in the feces and can infect other humans under unhygienic conditions.

6.2.3 Evidence of Zoonotic Transmission

Samples for the detection of *Salmonella* spp. in poultry flocks are crop, ceca, yolk sac, liver, or spleen from diseased birds. Samples for monitoring healthy flocks include composite samples of feces, boot swabs, or dust. In many countries, the sampling protocols for *Salmonella* monitoring are regulated by legislation. The laboratory procedure to detect *Salmonella enterica* serovars is described in ISO 6579.

There is ample evidence of zoonotic transmission from poultry to humans. Historically, the identity of strains was determined by restriction enzyme digestion of the genome and visualization after pulsed field gel electrophoresis (PFGE). Today, the whole genome is sequenced on a routine base to trace back outbreaks.

6.2.4 Disease Symptoms in Poultry

The course of the infection of salmonellosis in poultry depends on a number of factors such as the involved *Salmonella* serovar, age of birds, infectious dose, and route of infection. More often than not, infections of chickens with *Salmonella* are subclinical. In cases with disease, the incubation periods range between 2 and 5 days. Mortality in young birds varies from negligible to 10% to 20% and in severe outbreaks may reach 80% or higher.

Symptoms include an increased number of un-pipped and pipped hatching eggs with dead embryos, if infection was egg transmitted or occurred in the hatchers. Signs usually seen in young birds are somnolence, weakness, drooping wings, ruffled feathers, and huddling together near heat sources. Many birds that survive for several days will become emaciated, and the feathers around the vent will be soiled with fecal material (“pasty vent”). Furthermore, respiratory distress as well as

lameness as a result of arthritis may be present. Adult birds serve mostly as intestinal or internal organ carriers over longer periods with little or no clinical signs, but a drop in egg production can occur.

Birds that die in the acute phase of the disease show a persistent or inflamed yolk sac, catarrhal and hemorrhagic enteritis, necrotic foci in liver, spleen heart muscle, or granuloma in the lungs. Furthermore, congestion of the liver, kidney, gall bladder, and heart muscle is the most constant postmortem finding. Ceca may contain a caseous core and sometimes are filled with blood. In adult birds, lesions most frequently found in chronic carrier hens are misshapen, pedunculated, discolored cystic ova. The involved ova usually contain oily and caseous material enclosed in a thickened capsule. Ovarian and oviduct dysfunction may lead to abdominal ovulation or impassable oviduct, which in turn bring about extensive peritonitis and adhesions of the abdominal viscera. In male birds, the testes may be atrophied with thickening of tunica albuginea and multiple abscesses.

After recovery, salmonellae can persist in the intestines, especially in the ceca and the cecal tonsils, and birds continue to excrete *Salmonella* intermittently in their feces.

6.2.5 Disease Symptoms in Humans

Infections with S. Enterica serovars may cause intestinal inflammation with mucopurulent or bloody diarrhea accompanied by fever, vomiting, and abdominal cramps for several days. Incubation time is between less than 1 day and 3 days. If high amounts of water and electrolytes are lost, a hypovolemic shock can result. In severe cases, especially in infants and immunocompromised persons, sepsis and spread to other organs may occur, leading to a septic shock.

6.2.6 Unresolved Issues

Salmonellosis and *Salmonella* infections remain a persistent threat to human and animal health. According to the European Food Safety Agency, the proportion of human salmonellosis cases due to S. Enteritidis acquired in the EU remained at a similar level in recent years.

The EU prevalence of Salmonella target serovar-positive poultry flocks has been stable since 2015. The EU has set targets to reduce the prevalence of *Salmonella* in commercial poultry flocks; however, of the 26 member states reporting their data, only 18 met the reduction targets, whereas 8 failed to meet at least one.

In general, the major strategy to control salmonella should include cleaning the production chain from the top in aim to prevent the vertical transmission, hygienic measures throughout the production chain, vaccination, therapy, and eradication/reduction by legislations. In all cases, agent surveillance and monitoring programs must be adapted and followed strictly in aim to allow early intervention. In addition, since the success of any disease control program depends on farm and personal sanitation, it is essential to educate people involved in poultry production about

microorganisms, to educate people about modes of transmission, and to raise general awareness for the reasons behind such control programs. Finally, legislations, on its own, can never be sufficient to ensure the production of safe food. Rather, the industry itself, from producer to retailer, has a responsibility to ensure the safety of its products.

6.3 Campylobacteriosis

6.3.1 Epidemiology of Campylobacter Infections in Poultry

Campylobacter are curved, rod-shaped bacteria. Thermophilic *Campylobacter* has been found worldwide in poultry flocks. In most countries, prevalence in broiler, layer, and turkey flocks is higher than 50%. Of the 17 species and 6 subspecies, thermophilic species are the ones infecting avians and mammals. *C. jejuni* is predominant in poultry, while *C. coli* is less common, and *C. lari* is rare. Flocks younger than 3 weeks are rarely affected. Additionally, there is a seasonal variation with higher infection rates in spring and fall than in winter and summer.

In poultry, the highest prevalence of thermophilic *Campylobacter* has been detected in gallinaceous birds, but wild and commercial aquatic birds are also frequently affected. In addition, various mammalian species including cattle, sheep, pigs, pets, or rodents can be carriers.

It is not fully understood how thermophilic *Campylobacter* spp. are introduced into flocks. Due to their low tenacity, they probably depend strongly on living avian or mammalian vectors. Furthermore, various insects can serve as vectors for *Campylobacter* spp.

However, water supply sources, farm equipment such as trucks, forklifts, pallets, crates, and footwear have also been identified as potential sources of *Campylobacter* infection of poultry. Outside personnel like thinning crews pose a major risk for the introduction of *Campylobacter* into flocks. Furthermore, biofilms in water pipes offer *Campylobacter* an opportunity to survive for several weeks. It is very controversial if *Campylobacter* can be vertically transmitted.

6.3.2 Epidemiology of Campylobacter Infections in Humans

Globally, *Campylobacter* are one of the most frequent causes of diarrhea. In the EU, about 200,000 human cases of campylobacteriosis are diagnosed every year, making it the most frequently reported food-borne disease. Its incidence together with its duration and potential complications make it an important disease with a high socioeconomic impact. In the EU, the cumulative cost including direct cost to health systems as well as lost productivity is estimated to be around EUR 2.4 billion annually. In developing countries, *Campylobacter* infections in children under the age of 2 years are especially frequent.

Infection of humans generally occurs by the consumption of raw or undercooked meat, which originated from infected flocks and/or was contaminated during the

slaughter process. Contamination of carcasses or meat with *Campylobacter* during processing usually happens from feces.

Of the 17 *Campylobacter* spp. and 6 subspecies *C. jejuni* ssp. jejuni and *C. coli* are most frequent in humans. Other species such as *C. lari* and *C. upsaliensis* are found less frequently but have also been associated with diarrhea.

6.3.3 Evidence of Zoonotic Transmission

For the detection of thermophilic *Campylobacter,* various selective media are used. A standardized procedure for the isolation of *Campylobacter* from food and feed has been published in ISO 10272-1:2006. This method may be adapted for the investigation of clinical samples from birds.

As with *Salmonella*, there are many examples where the same clones were detected in live birds, poultry products, and infected humans. Isolates are typed by restriction enzyme digestion of the genome and visualization after pulsed field gel electrophoresis, multilocus sequence typing, or whole-genome sequencing, respectively.

An indirect indication is that in countries with specific strategies to reduce the prevalence of *Campylobacter* in live poultry, a similar reduction in human cases is observed.

6.3.4 Disease Symptoms in Poultry

Virtually all infections of poultry with thermophilic *Campylobacter* are without clinical signs or pathological lesions. Only chickens infected with virulent isolates at the time of hatch may develop enteritis with accumulation of mucus and fluid or focal hepatic focal necrosis and some mortality.

Avian vibrionic hepatitis was a disease that occurred in laying hens in the 1950s and 1960s. The hepatitis was characterized by small grayish-white focal lesions. *Campylobacter* spp. were regarded as the causative organisms, but for unknown reasons, the disease has not been observed in recent times.

6.3.5 Disease Symptoms in Humans

After an incubation period of 1 to 7 days, the most common clinical symptom of infections of humans with thermophilic *Campylobacter* is diarrhea. Other symptoms may be abdominal cramps, nausea, vomiting, fever, or headache.

Some postinfectious complications may be associated with *Campylobacter* infections. The most important of them is Guillain–Barré syndrome. The Guillain–Barré syndrome is a rapidly evolving paralysis without fever or other systemic symptoms and apparent causes. The symptoms are the consequence of an acute inflammatory demyelinating polyneuropathy. It is thought that antibodies against gangliosides are

involved in the pathogenesis, and that these autoantibodies are originally formed against *C. jejuni* strains possessing ganglioside-like epitopes or other pathogens.

6.3.6 Unresolved Issues

It is rarely known how *Campylobacter* are introduced into poultry flocks. Epidemiological investigations hardly ever provide a smoking gun, and estimation of the relative importance of the known sources is extremely difficult. In addition, epidemiological data also show circulation of multiple strains in the same farm or flock indicating repeated infections. This makes clear how difficult it is to prevent introduction into flocks with conventional biosecurity measures. Furthermore, *Campylobacter* are not easily isolated because they are fragile in the environment, forming viable-but-not-culturable stages, and are easily overgrown by other bacteria.

In addition, due to the high prevalence of *Campylobacter*, it is difficult to implement control strategies throughout the food chain. Processing plants receive birds from multiple farms. A single positive flock can contaminate carcasses from subsequent flocks, significantly increasing the risk of *Campylobacter* contamination of chicken meat. The different processing steps can all contribute to cross-contamination of *Campylobacter* until packaging.

6.4 *Escherichia coli*

6.4.1 Epidemiology of *Escherichia coli* in Poultry

E. coli are a ubiquitous, potentially beneficial part of the intestinal microbiota of chickens and turkeys. Chicks and poults can get infected right after hatch with environmental *E. coli* or *E. coli* from the eggshell surface. There is no true vertical transmission of *E. coli*.

Several diverse strains are present in each host, including strains of serotypes that are regarded as potentially pathogenic. Diseases in poultry are either caused by commensal *E. coli*, when predisposing factors weaken the birds, or by avian pathogenic *E. coli* (APEC) that can cause disease in uncompromised birds. There is no clear-cut criterion for APEC; APEC belong predominantly to serotypes O2, O18, and O78, but not all *E. coli* of these serotypes are APEC, and some APEC isolates belong to other serotypes. Detection of virulence genes and genes that enhance extraintestinal survival in the host allows a more etiological diagnosis.

6.4.2 Epidemiology of *Escherichia coli* in Humans

Epidemiology of *E. coli* in humans resembles epidemiology of *E. coli* in poultry. *E. coli* is a ubiquitous, mostly benign part of the intestinal microbiota, and only some strains, often belonging to serotypes O157, O4, or O18 are primary pathogens. These strains carry one or several of the known virulence genes. Based on the toxins and

course of the disease, a variety of pathotypes like Shiga toxin producing *E. coli* (STEC), enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli* (EHEC), or extraintestinal pathogenic *E. coli* (ExPEC) are differentiated.

6.4.3 Evidence of Zoonotic Transmission

Poultry and poultry products have been found to be a source of *E. coli* possessing or expressing the genes for various toxins or virulence factors associated with human disease like Shiga toxin or intimin, respectively.

In addition, ExPEC causing disease in humans and APEC, i.e., avian ExPEC, can share traits and are closely related. These traits include serogroups and phylogenetic groups. Some human ExPEC, especially of serogroups O1, O2, and O18, seem to be closer related to APEC strains than other human ExPEC strains. More importantly, the same virulence and fitness genes, e.g., adhesins, toxins, iron acquisition mechanisms, and invasins, can be found in APEC and human ExPEC isolates.

Considering the relatedness between APEC strains and some human ExPEC strains, it is not surprising that *E. coli* isolates similar to ExPEC and even isolates that were able to cause ExPEC-associated illnesses in animal models have been found on poultry products.

6.4.4 Disease Symptoms in Poultry

The most important diseases caused by *E. coli* in poultry are colisepticemia, inflammation of the upper and lower airways, omphalitis and yolk sac inflammation, as well as coliform cellulitis. Inflammation of the airways with involvement of *E. coli* is also known as swollen head syndrome, which is recognizable by edema of the skin of the head, or chronic respiratory disease causing respiratory distress. Coliform cellulitis is characterized by thickened and hard skin with a dark yellow to brown discoloration at the lower abdominal region and at the shanks. Mortality is usually under 5%, but can rise to more than 50%.

Pathological lesions of colisepticemia are polyserositis and swollen spleen, kidneys, and liver. Inflammation of the airways is visible by the accumulation of fibrinous exudate in the lungs and air sacs. Inflamed yolk sacs have fluid or past, greenish to brownish, and smelly contents. Salpingitis is characterized by oviducts that are thin-walled, dilated, and filled with fibrinous, scrambled egg-like material.

6.4.5 Disease Symptoms in Humans

E. coli strains can cause several diseases in humans. Infections with enteric *E. coli* can manifest themselves in various types of diarrheal disease, depending on the toxins. The most serious of these is hemolytic–uremic syndrome (HUS) caused by EHEC and characterized by bloody diarrhea, fever, and kidney failure. HUS can be a life-threatening disease.

Urinary tract infections (UTI), neonatal meningitis, and neonatal sepsis are the major diseases caused by ExPEC, but ExPEC can also be involved in infections of other organs. More than 50% of all UTI are caused by uropathogenic *E. coli* (UPEC). Neonatal meningitis occurs mostly in newborns between 6 and 9 days of age with 20% to 30% of infected babies dying. Signs of neonatal sepsis are lethargy, hypothermia, and poor feeding, and case fatality rates differ depending on age, but can be up to 25%.

6.4.6 Unresolved Issues

There is no smoking gun connecting *E. coli* in poultry with disease in humans yet. So far, all evidence is based on genetic and other similarities between APEC and ExPEC. Future research is needed to prove that poultry can be a reservoir for *E. coli* causing disease in humans, and how this risk can be minimized.

6.5 Antibacterial Resistances

6.5.1 Epidemiology of Antibacterial Resistances in Poultry

Many ad-hoc investigations and regularly conducted monitoring programs, e.g., the Canadian Integrated Program for Antimicrobial Resistance Surveillance (CIPARS) in Canada, Germ-Vet in Germany, or the National Antimicrobial Resistance Monitoring System (NARMS) in the United States, report data about the prevalence of antimicrobial-resistant bacteria in poultry flocks and on poultry products. On the European level, the Summary Report on Antimicrobial Resistance in Zoonotic and Indicator Bacteria from Humans, Animals, and Food in 2018/2019 focused on poultry and poultry carcasses. The results vary widely between geographic regions, years, bacterial species, and antimicrobials. Antimicrobial resistances are more common in meat-type poultry, which is more likely to receive antimicrobials, than in laying hens because withdrawal periods on eggs result in major economic losses unless one of the few products with no withdrawal time is used.

There is the common tendency that a reduced use of antibiotics in poultry flocks decreases the incidence of bacteria-resistant against these antibiotics. However, it is also important to note that a reduction in the use of antimicrobials does not necessarily lead to a decrease of antimicrobial resistances. The most common reason is the localization of several resistance genes on the same plasmid causing coresistance. At best, there will be a lag of several years between the end to using an antimicrobial and the decrease of resistance rates.

6.5.2 Evidence of Zoonotic Transmission

While it is controversial to what extent the use of antimicrobials in food producing animals contributes to infections of humans with antimicrobial-resistant bacteria,

there is good evidence that resistant bacteria can be transmitted from animals to humans. Several studies found that bacteria, including *Salmonella* and *Campylobacter*, isolated from certified organic poultry meat, i.e. from flocks that had not received antimicrobials, had a lower prevalence of antimicrobial resistances than bacteria from conventional broiler meat.

In contrast, the detection of the same resistance genes in bacteria isolated from meat and in bacteria from human patients is no conclusive evidence because the direction of the transmission is unclear. This is especially true when genes coding for resistances against antimicrobials that are not used in poultry are detected in live birds or on food products. Further indications without being final evidence are correlations between prevalences of resistance against several antimicrobials in bacterial isolates from poultry and human patients.

6.5.3 Unresolved Issues

Even though the extent to which antimicrobial usage in food producing animals contributes to resistances in bacteria infecting humans remains controversial, there is a broad consensus that the use of antimicrobials that are important for human medicine needs to be minimized in animals.

Laying hen flocks have historically received fewer antimicrobial treatments, so efforts concentrate on meat-producing birds. Recently, improvements have been made in raising broilers without antibiotics; in the United States, 60% of broiler flocks are now raised without receiving prophylactic or therapeutic antibiotics, including ionophores, which are not used in human medicine. The challenge of the coming years will be to further reduce the need for antimicrobials through improved management and vaccines, while balancing this aim with animal welfare and economic constraints.

6.6 Avian Influenza

6.6.1 Epidemiology of Avian Influenza in Poultry

Influenza viruses can infect virtually all bird species. Wild aquatic birds like duck and geese have the highest prevalence of infection. When they are subclinically infected and migrate, they can transport the virus around the globe.

Avian influenza (AI) is caused by influenza A viruses of the subtypes H5 and H7 and occurs worldwide. Prevalence of infection in poultry varies widely between countries. Regions with high infection rates include Mexico, Egypt, and Southeast Asia. In Europe, North America except Mexico, and Australia, infections of domestic poultry with AI are comparatively rare, but their frequency has increased in recent years resulting in a series of smaller outbreaks in Europe and an epizootic causing about 3 billion US dollar economic damage in the United States in 2015.

The virus can be transmitted directly through contact with infected birds or indirectly through contaminated equipment. Contact with infected wild birds, especially waterfowl, is the major route how AI is introduced into flocks. A distinct relation between the proximity of poultry-rearing areas and migratory waterfowl routes as well as the method of rearing can be observed. Spread between commercial flocks seems to be less important but can happen by mechanical transfer of infective feces through movement of man and contaminated equipment. Rodents and insects may also mechanically carry the virus from infected to susceptible poultry.

There is little or no evidence of vertical transmission. However, eggshell surfaces can be contaminated with the virus.

6.6.2 Epidemiology of Avian Influenza in Humans

Transmission from birds to humans occurs only after close contact with infected live birds. This happens most frequently in rural Southeast Asia and in Egypt, where poultry is kept close to living quarters. Food-borne infections of humans have not been reported. However, this possibility should not be ruled out completely, since some felids like tigers and cats got infected this way.

AIV has been transmitted only in rare cases between humans. In the last 20 years, the World Health Organization registered less than 1000 cases of humans infected with H5 AIV, and since 2013, less than 200 cases of human infections with H7 subtypes. Human-to-human transmission seems to be exceedingly rare.

6.6.3 Evidence of Zoonotic Transmission

Influenza virus may be isolated in embryonated chicken eggs followed by typing by hemagglutination inhibition assay and classifying as highly or low pathogenic AI (HPAI or LPAI) in infection studies or by sequencing of the hemagglutinin gene. Alternatively, molecular biological detection and characterization can be done. Methods are described in detail by the OIE and are part of the legislation in many countries.

H5 and H7 influenza types do not usually infect humans, so detection of these subtypes is indicative of transmission from poultry. Sequencing of the hemagglutinin gene and the whole genome has shown that isolates from humans were identical to strains from poultry.

6.6.4 Disease Symptoms in Poultry

The severity of clinical signs, course of the disease, and mortality in poultry after infection with AI are extremely variable from highly acute to a very mild or even

inapparent form with few or no clinical signs. The most virulent form of AI in poultry is called Highly Pathogenic Avian Influenza (HPAI). Currently, only viruses of H5 and H7 subtype have been shown to cause HPAI in susceptible species, but not all H5 and H7 viruses cause HPAI. H5 and H7 influenza viruses not meeting the criteria of HPAI are designated Low Pathogenic Avian Influenza (LPAI). Infection of poultry with other influenza subtypes occurs, but is legally not defined as AI.

Clinical signs of HPAI may include high mortality, ruffled feathers, depression, diarrhea, sudden drop in egg production, cyanosis of comb and wattles, edema and swelling of head, blood-tinged discharge from nostrils, respiratory distress, incoordination, and pin-point hemorrhages mostly seen on the feet and shanks.

Lesions at postmortem may include swelling of the face. Removing skin from the carcass will show a clear straw-colored fluid in the subcutaneous tissues. Blood vessels are usually engorged. Hemorrhage may be seen in the trachea, proventriculus, and throughout the intestines. Young broilers may show signs of severe dehydration with other lesions less pronounced or entirely absent.

LPAI as well as some non-H5 or H7 influenza strains cause mild to severe respiratory disease.

6.6.5 Disease Symptoms in Humans

Infection of humans with AI causes disease of the lower respiratory tract, leading to cough, sore throat, breathing problems, and pneumonia. Other flu-like symptoms that may be caused by AI include fever and muscle aches. In atypical cases, respiratory symptoms may be absent, and diarrhea or neurologic signs have been reported in infected humans.

Lethality in confirmed cases is well above 50%; however, many nonfatal cases of the disease with milder symptoms may be undiagnosed.

6.6.6 Unresolved Issues

Control of AI is regulated at the national and international level, but most of the legislation is motivated by the disastrous consequences of the disease for infected poultry rather than by its public health significance. In countries with a low prevalence of AI, infected flocks usually are destroyed. This means that they are not slaughtered, and their meat cannot be used for human consumption. In the EU, table eggs laid during the presumed incubation period are also not to be used for human consumption unless they have been properly disinfected.

Countries with a high prevalence have adopted vaccination strategies which have led to frequent emergence of new variants. Before the emergence of COVID, it was feared that an AIV strain would mutate to be transmissible

between humans and cause a pandemic. The risk still exists with increasing case numbers of AI in Europe, partially due to increased free range husbandry of poultry and continuing close and frequent contact between poultry and humans in developing countries.

6.7 Newcastle Disease

6.7.1 Epidemiology of Newcastle Disease in Poultry

Newcastle disease (ND) is ranked as the major virus disease of poultry in many countries worldwide. In developed countries with established poultry industries, outbreaks with very virulent (velogenic) ND are comparatively rare or neglected. Due to widespread vaccination of commercial flocks against ND, it is difficult to assess its prevalence because clinical signs are rare. If NDV is tested for and detected, the isolate must be typed to determine if it is virulent or a circulating nonvirulent or vaccine strain. In developing countries, ND is one of the leading causes of mortality in small flocks.

Infections with NDV have been reported worldwide in at least 241 bird species from 27 different orders. It has been suggested that virtually all birds are susceptible to infection with NDV. Infections have also been reported in some nonavian species.

The infection can be transmitted primarily through direct contact between healthy and infected birds. The disease can also be spread by mechanical means and by vaccination and debeaking crews, manure haulers, rendering-truck drivers, or feed delivery personnel.

6.7.2 Epidemiology of Newcastle Disease in Humans

Transmission to humans requires close contact to infected birds that allows the virus to come into contact with the eye. Most cases in humans occur in persons working on poultry farms or in processing plants. Spray vaccination of poultry flocks poses a particular risk if no appropriate eye protection is worn, since lesions in humans can also be caused by vaccine strains. Additionally, laboratory accidents when working with isolated NDV have been reported.

6.7.3 Evidence of Zoonotic Transmission

The virus can be isolated in embryonated chicken eggs and identified by hemagglutination inhibition assay. Pathotyping can be done in infection studies in order to discriminate very virulent strains from less virulent strains, especially live vaccines. However, virulence, or lack thereof, for poultry is not connected to virulence for humans. The classical methods can be replaced by molecular biological detection and characterization. The methods are described in detail by the OIE.

Whenever NDV is detected in humans, zoonotic transmission can be assumed because human-to-human transmission has not been described.

6.7.4 Disease Symptoms in Poultry

The course of the disease is mainly determined by the virulence of the involved strain. Age and immune status of the birds as well as general health and environmental conditions play a comparatively minor role. Infection with velogenic and viscerotropic strains is accompanied with a high, peracute mortality rate without specific disease symptoms. Very virulent and neurotropic strains also cause high mortality, but birds show nervous signs such as tremors, twisting of the head and neck, abnormal movement like circling, rearing, somersaulting as well as paresis, and paralysis.

Clinical signs after infection with strains of lesser virulence include ruffled feathers, depression, diarrhea, and respiratory signs in form of nasal discharge, coughing, rales, and dyspnea.

Gross lesions may be absent or include hemorrhagic lesions on the heart, in the proventriculus, in the intestine, and in cecal tonsils. In addition, tracheitis and airsacculitis can be observed.

6.7.5 Disease Symptoms in Humans

The most common symptom of NDV infection of humans is conjunctivitis, which does not affect the cornea and is characterized by swollen and reddened eye lids and lacrimation. In rare cases, a generalized infection with sneezing, dyspnea headaches, and fever may occur after exposure to a high amount of virus.

6.7.6 Unresolved Issues

ND remains a problem in poultry. In commercial poultry, infections pose a significant economic risk masked by widely applied vaccines, while in small unvaccinated flocks, infections are frequent and cause severe losses. In contrast, because of the high infection doses and the usually mild course of the disease, infection of humans has a low priority for public health.

6.8 Chlamydiosis

6.8.1 Epidemiology of Chlamydiosis in Poultry

Infections of birds with *Chlamydia psittaci* occur worldwide, but incidence and distribution vary widely. Infections with *C. psittaci* have been described in more than 500 bird species.

Table 2 Association between *C. psittaci* genotypes and avian hosts

Genotypes							
	A	B	C	D	E	E/B	F
Psittacines	++[a]	+[b]			+		+
Pigeons, doves	+	++			++	+	
Waterfowl	+	+	++		+	++	
Turkeys	+	+	+	++	+	+	+
Chickens		++	+	++	+	+	
Passerines	+	++					
Ratites					++		
Wild birds		++			++		

[a]++ = Genotype most commonly associated with this bird species or group
[b]+ = Genotype less commonly associated with this bird species or group

C. psittaci has been classified based on genetic differences in the *omp1* gene into nine genotypes. Seven of them (A, B, C, D, E, E/B, and F) are found in avian species. Host species are mainly infected with one certain serotype, and each serotype seems to have a main host, but these connections are not absolute (Table 2). Infections have also been reported in more than 30 mammalian species, including mice and men.

In poultry, the infection is especially prevalent among turkey flocks, where outbreaks are mostly caused by isolates of serotype B or D. Outbreaks in turkeys usually involve several flocks, and free ranging flocks are at considerably greater risk. Clinically apparent and inapparent chlamydiosis in turkeys is more common than in chickens.

Occasional outbreaks in ducks as well as in geese have been caused by isolates of serotype C, and ducks and geese are considered the main host of serotype C. Outbreaks of Chlamydiosis in commercially reared ducks in North America are rare and were considered a problem in Europe. Serotypes A and F are mostly associated with psittacines and serotype E with pigeons.

C. psittaci is shed in large numbers in respiratory exudate, especially in the nasal secretions, and in the feces. The primary route of infection is inhalation of aerosols containing the bacterium, but infection by ingestion can also occur. Arthropods have been implicated as vectors, but indirect transmission does not seem to play an important role. The most important way *C. psittaci* is introduced into flocks seems to be by wild birds. Vertical transmission may happen at a low frequency in turkeys, chickens, and ducks. Birds may shed the bacterium intermittently.

6.8.2 Epidemiology of Chlamydiosis in Humans

Humans can get infected by direct contact with infected birds, mostly by inhalation of infectious aerosols, but infections through bite wounds have occurred. Humans contract infections most frequently from psittacines, but persons handling infected birds at the farm and personnel at processing plants have been infected from poultry. Consequently, mostly veterinarians, owners of pet birds, pet shop staff, and persons working in poultry processing plants are at risk.

Infections by consumption of contaminated meat or eggs are not known. Spread among humans is rare.

6.8.3 Evidence of Zoonotic Transmission

For a quick diagnosis, organ smears or smears of swabs from conjunctiva, oropharynx, or cloaca can be stained with Giemsa or related methods and investigated for red or purple chlamydial elementary bodies within infected cells. Staining of fixed tissues or immunohistochemistry is also possible.

For isolation in cell culture or embryonated chicken eggs, samples should be placed in special transport medium if they cannot be processed immediately.

At present, tests for the detection of chlamydial antigens lack sensitivity as well as specificity and are not recommended, while detection of chlamydial genes by PCR is the method of choice for routine diagnosis. Several protocols for different genes have been published.

Detection of antibodies against *C. psittaci* may identify inapparently infected birds and flocks. This can be done by complement fixation test, indirect immunofluorescence, or ELISA.

Because transmission between humans is rare, zoonotic infection is usually assumed whenever the disease is diagnosed in humans.

6.8.4 Disease Symptoms in Poultry

Generally, infections caused by isolates of serotype B have a longer incubation time of up to several weeks and are less severe than infections with isolates of serotype D, which have an incubation time of less than 10 days and cause more severe disease. Additionally, there are differences between different isolates of the same serovar.

Clinical symptoms of infected turkeys include severe respiratory disease with nasal and ocular discharges, conjunctivitis, and green droppings. Diseased birds are lethargic and anorectic and may become cachectic. Egg production in breeder hens is reduced. Morbidity may be up to 80% and mortality up to 30%. Gross lesions at postmortem are enlarged spleen, liver, and heart due to vascular congestions, congested, and inflamed lungs as well as fibrinous airsacculitis, pericarditis, and peritonitis.

Clinical signs and postmortem lesions in ducks are similar. Additionally, nervous signs can be observed. As in turkeys, morbidity may be up to 80% and mortality up to 30%.

6.8.5 Disease Symptoms in Humans

Historically, the disease in humans was called either psittacosis or ornithosis depending on the source of the infection, and it was assumed that ornithosis was a

less severe disease. Nowadays, this differentiation is no longer considered to be correct, and the disease is generally called chlamydiosis.

Incubation time usually is between 1 and 2 weeks. The outcome of infections depends on infection dose and route besides other factors. The disease may be inapparent or characterized by pneumonia accompanied by fever, headache, and myalgia. Symptoms may continue for several weeks. The disease is rarely fatal if treated correctly with antibiotics.

6.8.6 Unresolved Issues

Chlamydiosis in chickens causes only unspecific clinical signs and postmortem lesions. Diagnosis requires detection or isolation of the bacterium, and the tests are not part of routine procedures in diagnostic laboratories receiving poultry for necropsy. Detection of the intracellular inclusion bodies requires special stains. For this reason, the prevalence of chlamydiosis is likely to be underestimated, which puts poultry workers at risk of infections. At the same time, due to the underestimation and the unspecific signs, chlamydiosis might not be considered as differential diagnosis in poultry workers.

Infected flocks should be treated with chlortetracycline to reduce mortality. They will not clear the birds from the infection but reduce clinical symptoms and shedding. Therapy should continue until shortly before slaughter to prevent relapses and to minimize the risk for the workers at the processing plant. Personnel handling the birds and at processing plants must wear appropriate personal protective equipment. If an infected flock is allowed to be processed at all, it must be determined on a case-to-case base.

6.9 Erysipelas

6.9.1 Epidemiology of Erysipelas in Poultry

Erysipelas is an acute infection caused by *Erysipelothrix rhusiopathiae*, a ubiquitous gram-positive bacterial organism. The genus *Erysipelothrix* is classified into two species: *E. rhusiopathiae* and *E. tonsillarum*. Among them, 26 different serotypes are recognized. Some serotypes of *E. rhusiopathiae* are pathogenic for poultry, whereas *E. tonsillarum* strains are nonpathogenic. In poultry, serotypes 1, 2, and 5 are most prevalent; all of them belong to *E. rhusiopathiae*.

Infections of poultry with *E. rhusiopathiae* occur sporadically worldwide. In some regions, the disease is considered endemic. At risk are mostly free-range and older, i.e., laying hen and breeder flocks. The host spectrum of *E. rhusiopathiae* is extremely wide, comprising various species of mammals, birds, reptiles, and fish. All species of domestic poultry are susceptible to infection, even though the susceptibility differs between them.

The natural route(s) of infection are not entirely certain. It is assumed that the bacterium enters the host through injuries of the skin or mucous membranes. Experimental infections are done either subcutaneously or orally. *E. rhusiopathiae* can survive several weeks in soil, and this may be the main source of infection.

Turkey hens can become infected through lesions caused by artificial insemination. The infection can be introduced into flocks by the red fowl mite as potential mechanical vector of *E. rhusiopathiae*. In addition, infected rodents, pigs or sheep, as well as contaminated fish meal have been implicated as a source of infection.

6.9.2 Epidemiology of Erysipelas in Humans

Humans get infected through skin injuries. Particularly at risk are animal caretakers, veterinarians, and butchers. Infection by consumption of contaminated food or transmission between humans has not been reported.

6.9.3 Evidence of Zoonotic Transmission

Presumptive diagnosis can be done by detection of Gram-positive rod-shaped bacteria in smears of infected organs. *E. rhusiopathiae* can readily be isolated from heart, liver, spleen, and bone marrow of dead birds, but the small colonies are easily overlooked or overgrown by other bacteria. If dead birds have already started to decompose, culturing bone marrow samples will make it easier to obtain cultures.

PCR assays have been described that will detect almost all serotypes and differentiate *E. rhusiopathiae* from *E. tonsillarum*. Detection of antibodies against *E. rhusiopathiae* is not done in routine practice.

When *E. rhusiopathiae* infections are detected in humans, zoonotic transmission can be assumed because human-to-human transmission has not been described. If possible, serotypes of isolates from humans can be matched with isolates from birds.

6.9.4 Disease Symptoms in Poultry

The course of the disease is especially fulminant in turkeys, regardless of age and sex. However, outbreaks with high mortality have also occurred in chickens (especially layer flocks), ducks, and geese. Incubation time depends on the infection dose and on the infection route. In animal studies, it is shorter after subcutaneous infection than after oral infection. In turkeys, first signs may be observed 2 or 3 days after oral infection.

Older birds are more sensitive to the infection than the younger birds. Mortality in laying hens is age related and, just as the incubation time, dependent on the route of the infection with subcutaneous infection causing more severe disease.

Infected birds show unspecific signs like moderate general depression or decreased egg production in laying hens. Furthermore, diarrhea or cutaneous lesions, especially swollen, purple snoods in turkeys, can be observed. Unvaccinated birds showing clinical signs usually die, and some infected turkeys may suddenly die without previous clinical signs. Mortality in turkeys may be up to 50% over the course of several weeks.

The most prominent gross lesion at postmortem is generalized congestion of internal organs with hemorrhage in several organs. Liver, spleen, and kidneys are enlarged and may have areas of necrosis. Other lesions may be enteritis, endocarditis, or fibrinopurulent exudate in joints and pericardial sac. Histopathology shows vascular congestion in all organs with intravascular aggregations of bacteria and fibrin thrombi. Parenchymal cells may be damaged in liver, spleen, and kidney.

6.9.5 Disease Symptoms in Humans

Infections of humans with *E. rhusiopathiae* are called erysipeloid, while erysipelas in humans refers to infections with *Streptococci*. This is a potential source of confusion in conversations between veterinarians and medical doctors or when studying literature.

E. rhusiopathiae infections in humans most often are local infections of the skin at infection site characterized by swelling and purple discoloration. Usually, the hands are affected. Rarely infections become septicemic. In these cases, symptoms and lesions may be very diverse and include polyarthralgia, septic arthritis, renal failure, endocarditis, encephalitis, and peritonitis. Infections are usually successfully treated with penicillin.

6.9.6 Unresolved Issues

Infections of humans with *E. rhusiopathiae* have traditionally been regarded a problem in fish mongers and other persons handling raw fish. Due to the sporadic nature of the disease in poultry and the symptoms that resemble other infections, medical doctors might not consider infections with *E. rhusiopathiae* a differential diagnosis in poultry workers.

Treatment of infected flocks does not clear the infection so that infected flocks have to be processed. Extra precautions to prevent and cover skin injuries of workers processing flocks that are positive with *E. rhusiopathiae* should be taken.

6.10 Conclusions

Poultry share a number of infectious diseases with humans, and most of the zoonotic diseases in poultry have additional reservoirs in other mammals than humans, which complicates their control and makes eradication all but impossible.

Diseases that are transmitted from poultry to humans by the consumption of contaminated meat and eggs and diseases that are transmitted from poultry to humans by close contact have been described in some detail in this chapter. Food-borne pathogens, namely *Salmonella* and *Campylobacter*, receive much attention, and extensive control programs against *Salmonella* are in place that have contributed to a decrease of *Salmonella* infections of poultry and humans in the recent two decades. Prevention of campylobacteriosis will for the foreseeable future depend on hygiene during processing because control in live flocks seems not to be feasible. Because by far fewer humans have close contact with poultry, diseases that are directly transmitted from birds to humans are considered to be of minor importance.

A third group of diseases comprises pathogens transmitted by insects, especially ticks from mammals and birds, including poultry, to humans. Examples for these pathogens are West Nile Virus, which has rapidly spread in North America and is occasionally detected in migratory birds in Europe, as well as Eastern and Western Equine Encephalitis. Until now the importance of poultry in the epidemiology of these diseases is low, but the situation may change, especially in the light of climate change and a wider dissemination of insect vectors.

Bacterial Pathogens Associated with Aquaculture Products

7

Iddya Karunasagar

Contents

Abstract

According to FAO statistics, aquaculture is contributing to nearly half the global food fish production. Fish contributes to both nutritional and food security in many developing economies. Fish is also one of the extensively traded food commodities, and most of global aquaculture production takes place in developing countries and the major markets are in the developed world. European Union, Japan, and the USA together account for 70% of global fish imports. Generally, fish and fishery products have a very good safety record. But there are some bacterial hazards associated with aquaculture products. The chapter discusses the bacterial pathogens that may be associated with products of aquaculture, pathways of contamination, and risk management measures reported for these bacterial hazards. In terms of antibiotic usage, there is limited data from developing countries, and a number of studies have looked at antimicrobial resistance in bacterial pathogens associated with fish and fishery products. Aspects related to antimicrobial resistance in aquaculture products are also presented in this chapter.

7.1 Introduction

Fish constitute a highly nutritious food providing proteins, polyunsaturated fatty acids (PUFA), micronutrients, and vitamins. Though it is commonly believed that mostly marine fish like salmon are the major source of PUFA, particularly omega-3 fatty acids, it has been found that even fresh water farmed fish like carps that are widely produced and consumed in Asia provide much more omega-3 fatty acids than poultry or beef. Globally, fish contribute about 17% of animal protein intake of human population and this proportion is even higher in low-income food-deficit countries, reaching over 50% in some countries like Cambodia, Sierra Leone, Bangladesh, and Indonesia (FAO 2022). During 2020, the global fish production was 178 million tons of which 87.5 million tons came from aquaculture (FAO 2022). Global fish production by capture has been stagnating for last two decades and most of the fish stocks are either fully exploited or even over-exploited. Hence, to meet the increasing demand for fish as food, it is important to increase fish production by aquaculture. Diverse species of finfish and shellfish are produced by aquaculture. Fact sheets of 62 species of fish, crustaceans, and mollusks that are cultured in different parts of the world are available from FAO website (FAO 2023). Asia accounted for 89% of global aquaculture production by volume in 2020, and this was dominated by the contribution of China, which accounted for more than 64% of global aquaculture production by volume. Farmed finfishes dominate global aquaculture production (57.5 million tons), followed by mollusks (17.7 million tons), and crustaceans (11.2 million tons).

In general, fish is considered a safe food and there are very few epidemiological record illness associated with farmed fish. In the USA, during 1998–2015, 857 seafood-associated outbreaks occurred resulting in 4815 illnesses, 359 hospitalizations, and 4 deaths were recorded (Barrett et al. 2017). Of these, etiology could be confirmed in 637 outbreaks, and of these, scombrotoxin accounted for 349 outbreaks (55%) and ciguatoxin for 227 outbreaks (36%). Both these were associated with captured finfish such as tuna and mahi mahi. The bacterial pathogen, *Salmonella* was associated with 978 illness (26%) and 97% hospitalizations (31%). Norovirus was associated with 418 illnesses (11%). Illness due to Norovirus may be associated with cultured bivalves, but often, there could also be person-to-person spread and actual number of illness due to bivalve consumption is difficult to estimate. Data from the European Union (EU) show that in 2018, there were 113 outbreaks associated with fish and shellfish involving 1196 cases (EFSA and ECDC 2019) but data for aquaculture is not available separately. During 2011, 78.9% of the 71 outbreaks associated with finfish were due to scombrotoxin, and 4.2% due to ciguatoxin. *Salmonella* accounted for 4.2% of the illness. In case of shellfish (crustaceans, mollusks), 40.5% of the 42 outbreaks in 2011 were due to calciviruses (noroviruses) and 16.7% due to algal biotoxins

(EFSA and ECDC 2013). *Salmonella* and *Escherichia coli* each accounted for 4.8% illness. In some parts of Asia, where there is the practice of consuming raw fish, a large number of parasitic diseases caused by the fish-borne trematodes have been reported to be prevalent. For example, about 1.5 million people in Korea, six million people in China, and over five million in Thailand are reported to be infected with the liver flukes, either *Clonorchis sinensis*, *Opisthorchis viverrini*, or *O. felineus* (Chai et al. 2005). However, this chapter deals only with pathogenic bacteria that may be associated with farmed aquatic species.

7.2 Bacterial Hazards Associated with Aquaculture Products

Farmed fish live in an environment, where there are significant levels of aquatic bacteria and the microflora associated with fish are greatly influenced by the microflora in the surrounding environment. When fish are alive, aquatic bacteria may be associated with the skin surface, in the gill surface and in gut. Most of the bacteria that are associated naturally with aquatic environment are generally not pathogenic to humans with the exception of few *Vibrio* species that are discussed in later sections. Once the fish are harvested, they are handled, transported, and processed, and during this period, they will come in contact with human hands and various surfaces (containers, equipment), ice and water, which could influence the microflora associated with fishery products that reach the consumers. Bacteria of zoonotic potential that may be associated with fish and fishery products are discussed in the following sections.

7.2.1 *Vibrio* spp.

Vibrio spp. are autochthonous inhabitants of the aquatic environment, and of over 80 species included in the genus *Vibrio*, at least 12 are capable of causing human infections (Oliver and Kaper 2007). Most of the pathogenic species have environmental non-pathogenic strains. *Vibrio* spp. are commonly isolated from estuarine, coastal marine environments (some species like *Vibrio cholerae* are found in fresh waters) all over the world, and seafood-borne illnesses are primarily caused by *Vibrio parahaemolyticus*, *V. vulnificus,* and *V. cholerae* (FAO/WHO 2003). Of these, *V. parahaemolyticus* and *V. cholerae* cause gastrointestinal disease, while *V. vulnificus* causes septicemia. There are very few pathogens of fish that can also affect humans. For example, some strains of *V. vulnificus* cause infection in eels and can also infect humans. Most of the other *Vibrio* spp. pathogenic to aquaculture species, e.g., *V. harveyi* (causing disease in shrimp) and *V. anguillarum* (pathogenic to marine fish), are not human pathogens.

7.2.1.1 *V. cholerae*

V. cholerae is a heterogeneous species consisting of over 220 serotypes, of which only serotypes O1 and O139 are known to cause the disease cholera and these are

generally referred to as choleragenic *V. cholerae* (FAO/WHO 2005a). Strains belonging to non 01/non-0139 serotypes of *V. cholerae* are widely distributed in the aquatic environment including aquaculture systems (Gopal et al. 2005) and are mostly not pathogenic to humans, though occasionally, they may be associated with sporadic cases of gastroenteritis (Oliver and Kaper 2007). None of the *V. cholerae* serotypes are known to be pathogens of farmed aquatic animals. The O1 serovar is known to possess three antigenic forms: Inaba, Ogawa, and Hikojima. Based on their phenotypic characteristics, *V. cholerae* O1 strains are classified into two biotypes, Classical and El Tor (Kaper et al. 1995). Since the seventh pandemic of cholera, most outbreaks have been caused by El Tor strains and the Classical biotype strains are rarely isolated from any part of the world (Sack et al. 2003). The choleragenic El Tor biotype strains of *V. cholerae* are grouped in four major clonal groups: (i) the seventh pandemic, (ii) the US Gulf Coast, (iii) Australia, and (iv) Latin America, which seem to reflect broad demographic and epidemiological associations (Wachsmuth et al. 1994). When the O139 emerged in early 1990s and almost replaced O1 serotype in Southeast Asia, it was thought that it might represent a new pandemic, but this strain did not spread beyond Southeast Asia and even there, the cases due to O139 serotype have declined and O1 serotype has become dominant again (Oliver and Kaper 2007). The disease cholera is characterized by the passage of voluminous stools of rice water consistency leading to dehydration, hypovolemic shock, acidosis, and if appropriate treatment is not initiated, death. However, it has been estimated that only 2% of those infected with ElT or biotype and 11% of those infected with classical biotype develop severe disease. Five percent of El Tor infections and 15% of classical infections may result in moderate illness that can be managed in outpatient clinics (Kaper et al. 1995). Infected individuals shed the pathogen in their feces for 7–14 days. Symptoms due to O1 and O139 serotypes appear to be identical. About 80% of patients can be treated adequately through oral rehydration salts (ORS) or intravenous fluids depending on severity of symptoms. Antibiotic treatment can reduce the volume of diarrhea in patients with severe symptoms and reduce the period of fecal shedding. Doxycycline, tetracycline, trimethoprim-sulfamethaxazole and erythromycin are some of the antibiotics used. Antibiotic resistance in *V. cholerae* O1 El Tor has been reported from a number of countries (Kitaoka et al. 2011), but there are no such documented outbreaks associated with consumption of aquaculture products.

For differentiation of choleragenic *V. cholerae* from non-choleragenic types, serotyping has been commonly used, but some environmental stains could cross-react with O1 or O139 antisera (FAO/WHO 2005a). The most important virulence factor associated with *V. cholerae* O1 and O139 is the cholera toxin, which has two subunits, A and B. The *ctx* genes (*ctx*A and *ctx*B) encoding the production of the cholera toxin are present in a filamentous bacteriophage that is integrated into the genome of *V. cholerae* O1 and O139 (Faruque et al. 1998). Loss of bacteriophage may explain the presence of non-toxigenic O1 *V. cholerae* in the environment. Molecular identification methods based on probes or PCR primers binding to *ctx* gene have been widely used to detect toxigenic O1 or O139 *V. cholerae* in the environment and in foods (FAO/WHO 2005a). FDA Bacteriological Analytical

Manual recommends *ctx*-based PCR for determining toxigenicity of *V. cholerae* (Kaysner and DePaola 2004). Detection of choleragenic *V. cholerae* in fish homogenates containing less than 10 cells/ml was possible when PCR was performed after 6 h enrichment in alkaline peptone water (Karunasagar et al. 1995).

Toxigenic *V. cholerae* may persist in the environment for long periods of time in the absence of clinical cases and this explains the presence of *V. cholerae* O1 in waters in areas where cholera is not an endemic disease, e.g., US Gulf Coast and in Australia (Oliver and Kaper 2007). Adhesion to chitin has been shown to influence strongly the ecology of *V. cholerae* and strong association between levels of zooplankton like copepods, and incidence of *V. cholerae* has been observed in the aquatic environment. Choleragenic *V. cholerae* has also been reported to attach to the hindgut of crabs and it is noted that the hindgut of crustaceans is an extension of the exoskeleton and is lined with chitin (FAO/WHO 2005a). However, there are very few records of isolation of *V. cholera* O1 and O139 from aquaculture ponds and with shrimp. This could be because shrimp are benthic organisms. Studies from Southeast Asia indicate absence of *V. cholera* O1 from raw shrimp (Karunasagar et al. 1990, 1992; Fonseka 1990; Rattagool et al. 1990). Several studies on shrimp farms in India indicated an absence of choleragenic *V. cholerae* in shrimp culture ponds (Otta et al. 1999; Gopal et al. 2005). Dalsgaard et al. (1995a) found that *V. cholerae* O1 was present in 2% (2/107) of water, sediment, and shrimp samples collected from a major shrimp culture area in Southeast Asia. However, subsequent testing of the isolates indicated absence of the *ctx* genes in both the O1 strains (Dalsgaard et al. 1995b). Ravi Kiran (1992) and Dalsgaard et al. (1995a) analyzed shrimp gut content for the presence of potential human pathogens and noted the absence of *V. cholerae* O1.

Farmed fish could be contaminated with choleragenic *V. cholerae* due to improper hygiene during postharvest handling. Saravanan et al. (2007) noted the absence of choleragenic *V. cholerae* in shrimp processed under HACCP (Hazard Analysis Critical Control Point) conditions in India, but detected the organism in one shrimp sample in a domestic market. Chen et al. (2004) isolated *V. cholerae* O1 and O139 from shrimp in domestic market in Malaysia and possibly this could be due to postharvest contamination. During the Peruvian cholera epidemic, high levels of contamination (100%) were observed in a small number of raw seafood samples from street vendors, but only one out of 1011 seafood samples intended for export and processed under HACCP conditions was positive (DePaola et al. 1993). FAO/WHO risk assessment for choleragenic *V. cholerae* in warm water shrimp in international trade looked at the data from testing laboratories in shrimp importing countries during the period 1995–2000. Of a total of 21,857 samples tested, only two samples originating from an Asian country in 1995 (early days of HACCP) were positive for choleragenic *V. cholerae* (FAO/WHO 2005a).

Epidemiological data indicates that a variety of fish and fishery products have been involved in outbreaks of cholera in different parts of the world (FAO/WHO 2005a). Transmission of *V. cholerae* by seafood can be acute where fish and shellfish are consumed raw (DePaola 1981). Seventy-five of 336 passengers in an airline were affected in the Americas in 1992 in which cold seafood salad was implicated (Eberhart-Phillips et al. 1996). The shellfish most often associated with cholera

cases are molluscan shellfish (oysters) and crabs. Oysters are consumed raw in many countries, but crabs are generally cooked. However, studies (Blake et al. 1980) have shown that even after boiling crabs for up to 10 min or steaming for up to 30 min, *V. cholerae* O1 may still retain viability due to issues related to heat penetration. There are very few outbreaks linked to crustacean shellfish. In an outbreak linked to the consumption of raw shrimp in the USA in 1986, the source was found to be domestic. Contaminated crab salad served in an airplane flying from Peru to California caused 75 cases. An outbreak in Japan in 1978 was associated with lobsters imported from Indonesia and another outbreak was linked to the consumption of raw shrimp in the Philippines in 1962. However, in most cases it is not possible to assess whether *V. cholerae* O1 was naturally present or cross-contaminated after harvest (FAO/WHO 2005a). Kim et al. (2018) reported three cases of cholera in Korea associated with raw seafood and the source of contamination was traced to be seawater in the area.

There is very little data on the level of *V. cholerae* associated with aquatic animals and most studies reporting isolations were done following enrichment. Hence, it is expected that levels are generally very low. The dose–response model developed in FAO/WHO risk assessment (FAO/WHO 2005a) indicates that 10^6 choleragenic *V. cholerae* is required to produce disease. This suggests that if products of aquaculture are contaminated with *V. cholerae*, multiplication of the organism has to occur before infective dose is reached. In raw shrimp, *V. cholerae* has to compete with other organisms for growth. The optimum temperature for growth of *V. cholerae* is 37 °C with a range of 10–43 °C (ICMSF 1996). Kolvin and Roberts (1982) measured growth of *V. cholerae* O1 in raw and cooked seafood. No growth was observed in raw prawns, mussels and oysters, but growth occurred in cooked shellfish. Levels of 10^{10} cells/g were reported in cooked prawns and mussels stored at 37 °C. At 22 °C, there was a lag phase of 8 h for classical biotype and 4 h for the El Tor biotype. The organism is sensitive to desiccation and to heat with a D value of 2.65 min at 60 °C (ICMSF 1996). *V. cholerae* survives refrigeration, though some decline in numbers is seen. Viable cells could be recovered from raw shrimp spiked with 10^5 cells/g *V. cholerae* O1 after 4–9 days at 5–10 °C (ICMSF 1996). Similarly, though freezing causes initial decline in numbers, the organism may survive over 180 days in fish (ICMSF 1996).

FAO/WHO risk assessment of choleragenic *V. cholerae* in warm water shrimp in international trade indicated that the risk of transmission cholera through this commodity is very low (FAO/WHO 2005a). Use of a spread sheet-based risk assessment tool (Ross and Sumner 2002) for quantitative risk assessment predicted the likelihood of illness to be 1–2 cases in a decade in Japan and the USA, considering the volumes of warm water shrimp imported and consumed, and one case in 25 years in other shrimp importing countries (FAO/WHO 2005a). Quantitative approach using model based on import to consumption pathway (prevalence estimated based on data from testing laboratories in importing countries – 2 samples in 1995 positive out of 21,857 samples tested between 1995 and 2000) predicted the illness to be 1–5 cases every 5 years, based on the assumption that 10% shrimp are consumed raw and 90% after cooking (FAO/WHO 2005a). Thus,

quantitative risk assessment indicates a very low risk, and there are no epidemiological records of illness linked to imported warm water shrimp supporting the very low risk predicted.

7.2.1.2 *V. parahaemolyticus*

Vibrio parahaemolyticus is found in the estuarine and coastal environments in the tropical to temperate zones (Joseph et al. 1982) where it is considered to be part of the autochthonous microflora. There is no correlation between the presence of this organism and fecal contamination of the environments (Joseph et al. 1982; Oliver and Kaper 2007). *V. parahaemolyticus* has been isolated from seawater, sediment, marine animals, plankton, various fish and shellfish species (Joseph et al. 1982). Thus, *V. parahaemolyticus* is naturally present in shellfish (shrimp and molluscan shellfish) growing and harvesting areas. The level of this organism in various fish and shellfish may vary. Certain areas may have more favorable environmental conditions that support establishment, survival, and growth of the organism such as temperature, salinity, zooplankton, tidal flushing, and dissolved oxygen (Garay et al. 1985; Kaneko and Colwell 1977; Venkateswaran et al. 1990). In temperate waters, the ecology is strongly influenced by temperature and salinity. In these environments, *V. parahaemolyticus* is often detected in warmer months and the organism has been reported to survive in the sediment during winter (Kaneko and Colwell 1977; DePaola et al. 2003); however, in tropical waters, *V. parahaemolyticus* can be detected throughout the year (Natarajan et al. 1980; Deepanjali et al. 2005). Salinity may influence the levels in tropical waters, low counts being recording during post-monsoon period (Deepanjali et al. 2005). *V. parahaemolyticus* can grow in sodium chloride concentrations ranging from 0.5% to 10% with optimum levels between 1% and 3% (Colwell et al. 1984). Adsorption of *V. parahaemolyticus* on to plankton or chitin containing materials occurs with higher efficiency under conditions of estuarine salinity (Kaneko and Colwell 1977). In tropical shrimp culture environments, *V. parahaemolyticus* is often present. This organism accounted for 0–27% of the flora in water and sediment of shrimp ponds in India (Otta et al. 1999; Gopal et al. 2005). The level of *V. parahaemolyticus* in seafood may vary depending on the type of seafood and geographical location. In US Gulf Coast oysters, during warm months, levels such as 1.1×10^4/100 g have been reported, but in Pacific oysters that are at lower temperatures, the levels were 2.1×10^3/100 g (Drake et al. 2007). In Indian oysters, the levels range from 10^2 to 10^4/g (Deepanjali et al. 2005). In shrimp, the levels range from undetectable to 10^4/g, high counts being rare (Cann et al. 1981; Karunasagar et al. 1984) and in finfish levels of ~88/g have been reported (Chan et al. 1989).

Most of the environmental strains may not be pathogenic to man. Early studies in Japan showed that 96% of clinical strains produce a thermostable direct hemolysin (TDH), while only 1% of the environmental strains produce this hemolysin (Joseph et al. 1982). Low prevalence of TDH positive strains in the environment has been confirmed from different geographical regions. In the Gulf Coast in the USA, the percentage has been generally less than 1%, but in Pacific North west, up to 3.2% strains could be TDH positive (FAO/WHO 2007). Six to 10% of oysters from India were positive for *V. parahaemolyticus* carrying *tdh* gene (Karunasagar et al.

1996; Deepanjali et al. 2005; Raghunath et al. 2008). Some TDH negative strains from clinical cases were found to produce a TDH-related hemolysin, TRH (Honda et al. 1988). Presently, strains producing TDH and TRH are considered pathogenic to man. But there may be strain variations. There are five sequence variants of the *tdh* gene (*tdh*1 – *tdh*5) and two sequence variants of the *trh* gene (*trh*1 – *trh*2) (Nishibuchi and Kaper 1990, 1995). Some strains carry both *tdh* and *trh* genes. Most clinical strains carry *tdh*-2 gene. Diverse serotypes may be associated with human infections, but recently, strains belonging to O3:K6 serotype and its variants have been found to be the causative agent of several outbreaks in different countries (Nair et al. 2007). Though several publications refer to these strains as "pandemic" strains, Nair et al. (2007) pointed out that this is misleading in the epidemiological sense, because outbreaks have not affected exceptionally high proportion of the population. Nevertheless, strains belonging to this group show clonality in molecular typing methods like arbitrarily primed (AP) PCR, ribotyping, or pulse field gel electrophoresis (PFGE) and are characterized by the presence of only *tdh* gene (and not *trh* gene), some mismatches in nucleotides in the *tox*RS gene, an open reading frame ORF8 derived from a filamentous bacteriophage f237 (Nair et al. 2007).

Outbreaks of shrimp mortality at early stage (<30 days) were reported from China in 2009, which spread to Vietnam, Thailand, and Mexico during following years. The disease was called "Early Mortality Syndrome (EMS)" and a case definition was adopted in 2012 (NACA 2012). The causative agent was identified as specific types of *V. parahaemolyticus* (Tran et al. 2013) possessing a unique virulence plasmid bearing genes encoding a *Photorhabdus* insect-related (PIR) toxin (Yang et al. 2014). The disease is now called Acute Hepatopancreatic Necrosis Disease (AHPND) and all *V. parahaemolyticus* strains causing AHPND tested so far contain the virulence plasmid and are negative for *tdh* and *trh* genes (Kumar et al. 2021). This shows that *V. parahaemolyticus*$_{AHPND}$ is not of food safety concern.

Based on data from human volunteer studies and using beta-Poisson model, a dose–response relationship has been established in FAO/WHO risk assessment of *V. parahaemolyticus* in seafood (FAO/WHO 2011). This suggests that there is a low risk (0.001%) of illness following consumption of 10^4 *tdh* + *V. parahaemolyticus* and high risk (50%) when 10^8 cells are consumed. Since the levels of this pathogen found in freshly harvested or frozen seafood are generally low, growth of the organism due to mishandling at temperatures permitting growth would be necessary before the organism reaches infective dose. *V. parahaemolyticus* can grow at a temperature range of 5–43 °C and optimum temperature for growth is 37 °C (ICMSF 1996). At optimum temperature, the doubling time in shrimp was 9–10 min and at 18.3 °C, it was 144 min (Katoh 1965). At 20 °C, the doubling time was 34 min in raw shrimp and 28 min in cooked shrimp (Liston 1974). Growth rates in a range of seafoods and tryptic soy broth with 2.5% salt (NaCl) have been recorded and these data indicate that moderate populations of 10^2–10^3 organisms/g on seafood can increase to $>10^5$ organisms/g in 2–3 h at ambient temperatures between 20 °C and 35 °C (ICMSF 1996). A number of studies indicate that *V. parahaemolyticus* dies when exposed to temperatures <5–7 °C, with highest mortality rate being in the range 0–5 °C (ICMSF 1996). A 1–2 $\log_{10}$ drop in numbers

occur during freezing, but the organism can persist in frozen seafood for long periods of time (ICMSF 1996). Both pathogenic and non-pathogenic strains have been observed to respond similarly to freezing (FDA 2005). *V. parahaemolyticus* is very sensitive to heat with a D value of <1.0 min at 65 °C in crab homogenate with an initial inoculum of 10^6 cells (ICMSF 1996), hence cooking would greatly reduce the hazard due to this pathogen.

Symptoms of *V. parahaemolyticus* infection include watery diarrhea, nausea, vomiting, abdominal cramps, and less frequently headache, fever, and chills (FAO/WHO 2011). Generally, the gastroenteritis is self-limiting and severe cases requiring hospitalization are rare. Depending on seafood consumption habits, the source of infection could vary, but mostly involving consumption of raw products and cooked products subjected to postprocess contamination. Oysters are the most common source in outbreaks in the USA and South America, but there have been reports of involvement of other types of seafood including clams, shrimp, lobster, crayfish, scallops, crabs, and finfish (Daniels et al. 2000; Oliver and Kaper 2007). In Japan (Anonymous 2000), implicated foods include *sashimi*, pieces of raw fish fillet (responsible for 26% of outbreaks), followed by *sushi,* vinegary rice ball with pieces of raw fish fillet (23%), shellfish (16%), and cooked seafood (12%). A large outbreak linked to shrimp occurred in Louisiana in 1978 in which 1133 of the 1700 persons attending a dinner were affected and this appears to have been caused by cross contamination between raw and boiled shrimp. Shrimp boiled in the morning were kept in the same wooden seafood box used to transport raw shrimp and transported 40 miles in an unrefrigerated truck and held additional 7–8 h before serving for dinner (Oliver and Kaper 2007). In Japan, *V. parahaemolyticus* is one of the most common causes of gastroenteritis and annually 500–800 outbreaks affecting 10,000 people are reported annually (FAO/WHO 2011). This organism is the leading cause of food-borne illness in Taiwan causing 197 outbreaks during 1986–1995 (Pan et al. 1997) and accounted for 69% of the food-borne cases between 1981 and 2003 (Su and Liu 2007). *V. parahaemolyticus* accounted for 31.1% of 5770 food-borne outbreaks that occurred in China from 1991 to 2001 (Liu et al. 2004).

FDA (2005) carried out quantitative risk assessment of *Vibrio parahaemolyticus* in raw oysters in which a model for predicting *V. parahaemolyticus* levels in oyster based on water temperature was developed. The postharvest oyster handling practices in the USA and the effect of these practices on levels of *V. parahaemolyticus* were modelled. Data from two regions in the USA (Pacific Northwest and Gulf Coast) were used to estimate the proportion of strains that are pathogenic. It was estimated that about 50% of oysters are consumed raw and each serving would be about 200 g. The risk assessment suggested that in the absence of subsequent post-harvest mitigations, "at-harvest" guidance levels of 10^5, 10^3, 10^2 total *V. parahaemolyticus* per g could potentially reduce the illness rate by 1.6, 68, and 98% with corresponding impact of 0.25, 21, and 66% of the harvest, respectively. If the control is applied on the basis of *V. parahaemolyticus* levels at retail, a standard to 10^4/g would reduce illness by 99% and 43% of the harvest would have to be diverted from the raw market. A 5000/g standard could almost eliminate almost 100% of illness, with 70% of the harvest having to be diverted from the raw market (FDA 2005).

The FAO/WHO risk assessment of *V. parahaemolyticus* in raw oysters used a similar approach to estimate risk of illness in Australia, New Zealand, Canada, and Japan (FAO/WHO 2011). Local data on water and air temperature, local harvest practices and prevalence of *V. parahaemolyticus* in oysters in these countries was used. The US data on proportion of pathogenic *V. parahaemolyticus*, multiplication of *V. parahaemolyticus* in oysters, consumption patterns, and underreporting of illness was used. The risk assessment also looked at the impact of applying microbiological criteria, e.g., 100/g, 1000/g, and 10,000/g. The data showed that a criterion of 100/g would lead to 99% reduction in illness in Australia, but this would lead to rejection of 67% of product currently going to the market. Considering that epidemiological records of illness are very rare in Australia, risk management based on microbiological criterion would not be a reasonable approach there. Noting wide variations in the occurrence of *V. parahaemolyticus* in different geographical regions, adopting a global microbiological criterion could not be recommended. This led the Codex Alimentarius Commission to develop a Code of Practice (CAC/GL 73-2010) for minimizing the risk rather than adopt a microbiological criterion.

Since the illness caused by *V. parahaemolyticus* is generally mild, it does not require antibiotic treatment. In severe or prolonged cases, tetracycline, ampicillin, or ciprofloxacin may be used. Though antimicrobial resistance has been detected in environmental strains (Baker-Austin et al. 2008), there is very little evidence that this is an issue with clinical strains. A study of *V. parahaemolyticus* strains isolated from outbreaks of illness in Chile during 2005 and 2007 showed that they were sensitive to tetracycline, sulfamethaxazole-trimethoprim, and ciprofloxacin, but were resistant to ampicillin (Dauros et al. 2011).

7.2.1.3 *Vibrio vulnificus*

Vibrio vulnificus is a common inhabitant of warm water estuarine environments all over the world. The organism has been isolated from coastal marine and estuarine waters, sediment, plankton, and various shellfish (both molluscan and crustacean) and finfish species in areas where the temperatures range from 9 °C to 31 °C. *V. vulnificus* proliferates in waters where temperature exceeds 18 °C (Kaspar and Tamplin 1993; Strom and Paranjpaye 2000; FAO/WHO 2005b; Drake et al. 2007). The abundance varies considerably and is greatly influenced by temperature and salinity. In North America, higher densities are observed in mid-Atlantic, Chesapeake Bay, and Gulf Coast waters, where temperatures are warmer throughout the year, while densities are lower in Pacific, Canadian, and North Atlantic waters (FAO/WHO 2005b). The lowest temperature at which *V. vulnificus* has been isolated varies geographically, being 8 °C at Chesapeake Bay (Wright et al. 1996) and < 12.5 °C in Gulf Coast (Simonson and Siebeling 1986) and the organism survives in sediment during winter. In tropical waters, where temperature does not go below 18 °C, abundance of *V. vulnificus* is influenced by salinity (Parvathi et al. 2004). In south India, highest *V. vulnificus* levels were found during monsoon season when the salinities were less than 5 ppt, and at salinities exceeding 25 ppt, these organisms were not detectable (Parvathi et al. 2004). Salinity has a significant effect on the abundance of the organism even in temperate waters. In the waters of the USA,

numbers of *V. vulnificus* were high at salinity between 5 and 25 ppt, but dropped by 58–88% at salinities over 30 ppt (FAO/WHO 2005b). *V. vulnificus* produces chitinase, which might help the organism to colonize zooplankton (Strom and Paranjpaye 2000) and can colonize plankton and fish gut (FAO/WHO 2005b). Through fish, the organism even reaches the gut of birds since Miyasaka et al. (2006) found 14.1% aquatic birds in Japan to be positive for *V. vulnificus*.

Presently three biotypes are recognized based on a combination of phenotypic, serologic, and host range characters (Drake et al. 2007). Biotype 1 strains are indole positive, serologically diverse, and are associated with human infections. Biotype 2 strains are indole negative and considered mainly as eel pathogens, but may also be opportunistic human pathogens, being associated with infections in eel handlers. This biotype has three serotypes and strains associated with eel and human infections belong to serotype E (Sanjuan and Amaro 2004). Biotype 3 has five atypical biochemical characters, genetically clonal, and has been isolated from 62 Israeli patients with wound infection or septicemia. This biotype has not been associated with food-borne infections (Drake et al. 2007). The virulence of this organism seems to be related to multiple factors such as presence of a polysaccharide capsule, ability to obtain iron from transferrin, and ability to produce extracellular enzymes and exotoxin (Drake et al. 2007). Most of the virulence-associated factors are present in over 95% of environmental strains. Rosche et al. (2005) using nucleotide sequence analysis showed that Biotype 1 strains can be distinguished into two types that strongly correlate with clinical (C) or environmental (E) origin. C-genotypes showed greater resistance to human serum than E-genotypes and had lower LD_{50} suggesting that C-genotype strains may be more virulent (Rosche et al. 2010). While similar levels of C- and E-genotypes were found in estuarine waters, oysters had 85% E-genotypes (Warner and Oliver 2008).

V. vulnificus can cause primary septicemia and wound infections. The disease rarely (<5%) occurs in healthy individuals and risk factors for *V. vulnificus* infection include liver disease, cirrhosis due to alcohol consumption, diabetes, gastrointestinal disorders (ulcer, surgery), hematological conditions, and immunocompromised condition associated with cancer and therapy with immunosuppressive drugs. Epidemiological data suggests that men are more susceptible than women to *V. vulnificus* infection. The fatality rate (about 50%) is the highest among food-borne pathogens (FAO/WHO 2005b) while the attack rate is low with one illness occurring per 10,000 meals of raw US Gulf Coast oysters (containing *V. vulnificus*) served to the highest risk population, i.e., people with liver diseases (FAO/WHO 2005b). The incubation period ranges from 7 h to 10 days, with symptoms appearing in 36 h in most cases (Oliver and Kaper 2007). The symptoms include sudden onset of fever and chills, generally accompanied with nausea, vomiting, abdominal pain, hypotension (systolic pressure < 85 mm) and in over 60% cases, secondary lesions appear, mostly on the legs that often develop necrotizing fasciitis or vasculitis that may require surgical debridement or amputation (Strom and Paranjapaye 2000; Oliver and Kaper 2007). *V. vulnificus* can be isolated from blood and cutaneous lesions. Rare cases of atypical infections have been reported and these include septic arthritis, meningoencephalitis, and ocular infection following consumption of raw oysters or raw fish. Sixty-nine

percent of wound infections were associated with occupational exposures among oyster shuckers and commercial fishermen (Strom and Paranjapye 2000). Wound infections may progress to echymoses, cellulitis, bullae, and necrotizing fasciitis, but mortality rate (25%) is much lower than in case of primary septicemia, though 50% of cases may require surgical debridement or amputation (Jones and Oliver 2009).

Antibiotic therapy is important for both wound infections and septicemia. While tetracycline has been the most effective drug, in some cases, this has been used in combination with third-generation cephalosporin or gentamycin or chloramphenicol (Strom and Paranjapye 2000; Liu et al. 2006). Roig et al. (2009) noted that the *V. vulnificus* biotype 2 serovar E eel pathogenic strains can develop resistance to quinolones by spontaneous mutation of *gyr*A gene and suggested avoiding quinolones for treatment of vibriosis in eel farms. Baker-Austin et al. (2009) screened 151 environmental isolates and 10 primary septicemia isolates for antimicrobial susceptibility. Several isolates showed resistance to antibiotics routinely prescribed for *V. vulnificus* infections such as tetracycline, doxycycline, aminoglycosides, and cephalosporins. The resistance was seen at similar frequencies in C-type and E-type strains. Among environmental isolates, there was no consistent difference in the frequency of resistance between strains from pristine and anthropologically impacted areas suggesting natural rather than human-derived source of resistance traits.

Epidemiological data suggests that about 100 cases of primary septicemia due to *V. vulnificus* occur per year in the USA (Drake et al. 2007). The Korean Centres for Disease Control estimates 40–70 confirmed cases per year and this high rate is suspected to be due to consumption of raw seafood or higher prevalence of predisposing factors (Drake et al. 2007). However, in Japan, Inoue et al. (2008) estimated 12–24 cases per year and in Taiwan, there was a peak occurrence in 2000 with 26 cases per million population (Hsueh et al. 2004). While in the USA, oysters are the main source, this is not the case in Japan since raw oysters are eaten only in winter and most infections occur during June–November with a peak in July. A mud shrimp *Upogebia major* was the common agent associated with *V. vulnificus* infections (Inoue et al. 2008). 72.3 percent of infections had septicemia and mortality rate was 75%. Most patients (86.5%) had liver function impairment with 56.9% having liver cirrhosis and 10.1% liver cancer (Inoue et al. 2008). In Europe, *V. vulnificus* infections are rare and mostly wound infections (Baker-Austin et al. 2010). Rare cases of septicemia have been reported from Thailand (Thamlikitkul 1990) and India (Saraswathi et al. 1989).

V. vulnificus is a natural inhabitant of the estuarine environment and hence fecal coliforms/*Escherichia coli* cannot be used as indicator organism for this pathogen. Since molluscan shellfish are filter feeding organisms, when environmental conditions are favorable, they may harbor high levels of *V. vulnificus* with levels in oysters being 100 times higher than in water surrounding them. On the US Gulf Coast, the levels in oysters may reach 10^4cfu/g during summer months (Drake et al. 2007), and in tropical waters of India, similar levels were reached in oysters when salinities were less than 10 ppt (Parvathi et al. 2004). *V. vulnificus* counts exceeding 10^6/g have been reported from the intestines of benthic fish inhabiting oyster reefs (DePaola et al.

1994). If the temperature of oysters is not controlled immediately after harvest, growth of *V. vulnificus* could occur. Cook (1997) demonstrated that *V. vulnificus* levels in oyster shell stock held without refrigeration for 3.5, 7, 10.5, and 14 h increased 0.75, 1.3, 1.74, and 1.94 log units. It has also been reported that *V. vulnificus* levels in retail oysters originating from Gulf of Mexico were 1–2 log units greater than at harvest (Cook et al. 2002). The organism does not grow in oysters at temperatures below 13 °C and prolonged refrigeration could lead to reduction in numbers and the levels could become non-detectable (<3/g) in 14–21 days (Cook 1994; Cook and Ruple 1992). However, Kaysner et al. (1989) observed survival in artificially contaminated oysters for 14 days at 2 °C, suggesting that refrigeration cannot be relied upon for elimination of this pathogen in oysters. The rate of decline in refrigerated oyster shell stock has been estimated to be 0.041log unit per day (Cook et al. 2002). It has been estimated that commercial cooling of oyster stocks could take an average of 5.5 h (FDA 2005) and therefore the time shell stock is unrefrigerated on boat deck is an issue in control plans.

Freezing could reduce levels of *V. vulnificus* in oysters, but this cannot eliminate the organisms completely. Four to five $\log_{10}$ reductions in numbers of natural *V. vulnificus* population in oysters occur when frozen to −40 °C and stored for 3 weeks (Cook and Ruple 1992). A combination of vacuum packaging and freezing can bring down *V. vulnificus* counts by 3–4 $\log_{10}$ units in 7 days but complete elimination cannot be achieved (Parker et al. 1994). *V. vulnificus* is sensitive to heat with 6 $\log_{10}$ reduction in numbers occurring when subjected to 50 °C for 5 min in shucked oyster meat (Cook and Ruple 1992). Natural populations of *V. vulnificus* (4.3×10^3cfu/g) could be reduced to non-detectable levels by exposing them to 50 °C for 10 min (Cook and Ruple 1992). In North and South Carolina, commercial shell stock is subjected to heat shock by submerging about 70 chilled oysters in wire baskets into a heat-shock tank containing about 850 L of potable water at a temperature of 67 °C for about 5 min depending on oyster size and condition. This process has been shown to reduce *V. vulnificus* levels by 2–4 $\log_{10}$ units (Drake et al. 2007). *V. vulnificus* cells are acid-sensitive and can be inactivated at pH 2.0 (Koo et al. 2000). *V. vulnificus* is sensitive to ionizing radiation and irradiation doses of 1.0 kGy applied on whole shell oysters can reduce the cell numbers from 10^7cfu/g to undetectable levels (Andrews et al. 2003). Hydrostatic pressure of 250 Mpa for 120 s reduced *V. vulnificus* >5 $\log_{10}$ units in oyster (Cook 2003).

Joint FAO/WHO Expert Meeting on Microbiological Risk Assessment (JEMRA) carried out a quantitative risk assessment for *V. vulnificus* in raw oysters (FAO/WHO 2005b) and this study modified the FDA *V. parahaemolyticus* risk assessment model to assess the risk of *V. vulnificus* primary septicemia in the USA. The geographical coverage was limited because quantitative data for *V. vulnificus* levels in oysters at the point of consumption and the data for the susceptible population was available only for the USA (FAO/WHO 2005b). The risk assessment model used the data on *V. vulnificus* levels in oysters from four Gulf States and assumed that all strains were equally virulent. Harvest and postharvest module used for exposure assessment was based on postharvest practices (duration oysters in harvest vessel in water, time to first refrigeration, cool down time) derived based on surveys conducted in Gulf

Coast. *V. vulnificus* growth in oysters, survival during refrigeration, and levels at consumption were estimated based on data from studies along the US Gulf Coast (FAO/WHO 2005b). The model predicted that the mean *V. vulnificus* levels in oysters would be 5.7×10^4/g in summer and 8.0×10^1/g in winter. At a serving size of 196 g, the ingested dose would be 1.1×10^7 *V. vulnificus* in summer and 1.6×10^4 in winter. FDA data on the prevalence of risk factors in the US population and oyster consumption data from surveys was used in the model (FAO/WHO 2005b). The dose–response relationship was modeled by estimating the exposure per eating occasion and number of eating occasions for oyster-associated *V. vulnificus* cases reported to the US Centers for Disease Control and Prevention (CDC) during 1995–2001. The risk assessment also predicted the reductions in illness that could be achieved by postharvest treatments to reduce *V. vulnificus* levels to target values such as 3/g or 30/g or 300/g. In the USA, there are three validated methods to achieve end-point criterion of <3 MPN/g *V. vulnificus* and these include mild heat treatment (50 °C), freezing with extended frozen storage and high hydrostatic pressure. If all oysters are treated to achieve target level of 3/g, the model predicted that the number of cases could be reduced from current 32 reported cases per year to one case every 6 years. If the target is shifted to 30 or 300/g, then the predicted cases would increase to 1.2 and 7.7 cases per year, respectively (FAO/WHO 2005b).

The FAO/WHO risk assessment model suggested that immediate cooling of oysters alone is not adequate to achieve substantial reduction in the number of *V. vulnificus* illnesses. The predicted illness ranged from 17.7 to 59.3 at a time to refrigeration range of 0–20 h. Since *V. vulnificus* levels in oysters harvested from waters with a salinity of >30 ppt is greatly reduced, it is predicted that if all oysters are harvested from waters at salinity of >30 ppt, irrespective of the water temperature, *V. vulnificus* illness would be <1 case per year (FAO/WHO 2005b). Relaying oysters to high salinity waters (>32 ppt) has been shown to reduce *V. vulnificus* levels by 3–4 log units (<10/g) within 2 weeks. Based on FAO/WHO risk assessment, Codex Committee on Food Hygiene developed Code of Hygienic practice for control of *Vibrio* spp. in seafood with an annex on control measures for *V. parahaemolyticus* and *V. vulnificus* in bivalve mollusks. This Code recommends assessment of the need for control measures based on (a) number of sporadic illnesses associated with bivalve mollusks in the area, (b) water temperature at harvest, air temperature, and harvest and post-harvest practices, and (c) water salinity at harvest. Since there is wide geographical variation in prevalence and levels of *V. vulnificus* in bivalves, control measures that have been validated and appropriate for the region may be adopted by the competent authority having jurisdiction and implemented under HACCP system. Validation of control measure should be carried out in accordance with the Codex Guidelines for the validation of food safety control measures (CAC/GL 69-2008).

V. vulnificus resides inside various tissues of oysters, hence depuration is ineffective in elimination of this pathogen, but relaying oysters in high salinity (>30 ppt) waters for 17–49 days caused a decrease in population from 10^3cfu/g to <10 MPN/g (Motes and De Paola 1996). The US National Shellfish Sanitation Programme (NSSP) guide

(2011) includes the following strategies for minimizing the risk due to *V. vulnificus* in molluscan shellfish in states reporting two or more cases of *V. vulnificus* illness per year: (a) increased educational efforts targeted toward the population at risk to improve their awareness of the risks of eating raw molluscan shellfish and to change their eating behavior to reduce or stop eating raw or untreated molluscan shellfish, (b) limited harvest restrictions on areas incriminated in outbreaks, (c) requirement for the temperature of shell stock to be brought down to 10 °C or less by using ice, mechanical refrigeration, or other means within specified period (12 h when water temperature is >28 °C; 18 h when water temperature is 15 and 27 °C; 14 h when water temperature is 18–23 °C; and 36 h when water temperature is <18 °C), and (d) phased-in postharvest treatment requirements or other controls.

7.2.2 *Salmonella*

Currently, two species are recognized in the genus *Salmonella,* a member of the family Enterobacteriaceae (Tindall et al. 2005): *Salmonella enterica* and *Salmonella bongori*. Six subspecies are recognized in *S. enterica*, viz. subsp. *enterica*, subsp. *salamae*, subsp. *arizone*, subsp. *diarizonae,* subsp. *Houtenae,* and subsp. *indica*. More than 2500 serotypes have been recorded, of which majority (59%) belong to *S. enterica* subsp. *enterica*, which are also responsible for 99% of *Salmonella* infections in humans and warm-blooded animals (Brenner et al. 2000). Other subspecies may also be associated with cold-blooded animals and environment, but isolates from both species and all subspecies have occurred in humans (Brenner et al. 2000).

The clinical outcomes of *Salmonella* can be considered as two separate groups: (a) Typhoid fever (enteric fever) caused by *Salmonella* Typhi/Paratyphi strains is a serious systemic illness. Incubation period ranges from 7 to 28 days. Symptoms include malaise, headache, fever, cough, nausea, vomiting, constipation, abdominal pain, chills, rose spots, and bloody stools. Typhoid fever is generally transmitted through water. (b) Non-typhoid *Salmonella* caused by other strains and characterized by gastroenteritis in humans. Incubation period ranges from 8 to 72 h. The symptoms include abdominal pain, diarrhea, chills, fever, nausea, vomiting and malaise. Systemic infection such as septicemia may occur especially in susceptible patients such as the very young, very old, and immunocompromised. The available data measuring illness as the endpoint suggests that no response is observed until a dose of 10^6 is reached (Coleman and Marks 1998). However, outbreak investigations show that lower number of cells can cause infection depending upon the food matrix. There is no data with seafood matrix alone but in an outbreak of *S. enteritidis* associated with scallop and egg yolk, a 56% attack rate was observed at a dose of 6.3 log CFU (FAO/WHO 2002). Severe dehydration due to diarrhea can on occasion require medical intervention through the administration of intravenous fluids and antibiotic treatment. However, occasionally some serovars of this pathogen may cause sepsis after entering the blood stream from the intestine and require intense medical intervention. Mortality is rare if patient is promptly hydrated and provided antibiotic treatment.

Though the normal habitat of *S. enterica* subspecies *enterica* is the gut of warm-blooded animals, very few serovars are host adapted and others may be found in the environment for long periods of time. The habitat for other subspecies is cold-blooded animals and environment. *Salmonella* has been isolated from several aquatic environments in different parts of the world (FAO 2010). Water bodies contaminated with fecal matter from humans, animals including birds and aquatic mammals may contain this pathogen. *Salmonella* can survive in human waste for 10–15 days in septic system and through seepage from septic tanks, sewage and storm runoff, reach surface waters. It can survive and even multiply in aquatic environment, e.g. it can adhere to soil particles and survive and multiply in this ecosystem for at least 1 year (Winfield and Groisman 2003). In Tech River (France), 574 isolates of *Salmonella* belonging to 41 serotypes were obtained during 1996–1997, some serotypes being specific to flood events (Baudart et al. 2000). In a 4-year study of coastal waters of Galecia, North western Spain, a prevalence of 2.4% in mollusks and seawater was found with *S.* Senftenberg being the most predominant (42%) among 20 different serotypes (Martinez-Urtaza et al. 2004a). The presence of S. Senftenberg could not be correlated with environmental parameters, while presence of other serotypes was associated with wind and rainfall events. *S.* Senftenberg has been very rarely reported in human infections and is halotolerant since it has been isolated from brines with a salt concentration of 30% (Martinez-Urtaza et al. 2004b). *Salmonella* Senftenberg has been one of the predominant serovars detected in the coastal waters of Portugal (Catalao Dionisio et al. 2000). This serovar has been isolated from crustaceans from India (Hatha and Lakshmanperumalsay 1995), seafood imported into the USA especially from tropical countries (Heinitz et al. 2000), and from environmental samples in France and Brazil (Baudart et al. 2000; Tavechio et al. 2002). Detection of *Salmonella* in 16% shrimp and 22.1% in mud/water in Southeast Asia led Reilly and Twiddy (1992) to suggest that *Salmonella* are part of the normal aquatic flora in tropical environments. But recent reports of detection of *Salmonella* in fish gut in natural river system in Texas (Gaertner et al. 2008) suggest that *Salmonella* are more widely present in aquatic systems than earlier thought to be. Seventeen to thirty-three percent of fish sampled in San Marcos River, Texas were positive for *Salmonella* and presence in fish gut has been attributed to ingestion of *Salmonella* present in detritus. Byappanahally et al. (2009) reported that the filamentous alga, *Cladospora* in Lake Michigan is a reservoir for *Salmonella*, a 3-year study during 2005–2007 indicating presence in 23–72% samples at densities ranging from 0.16 to 89.46 the most probable number (MPN) per gram. This alga can be found in fresh and marine waters. Therefore, present evidence suggests that *Salmonella* are widely distributed in the aquatic environment and could be part of normal flora in aquaculture systems.

Specific seasonal patterns or climate characteristics have been reported to affect the dynamics of contamination of *Salmonella* in natural environments. The presence of *Salmonella* in the environment in both temperate and tropical regions has been linked to the periods of rains, and more specifically, after the days of the first heavy rains signaling the washing effect of torrential rains as one of the principal environmental drivers of *Salmonella* contamination in coastal areas (FAO 2010). There may

also be other sources in the marine environment. For example, *Salmonella* may colonize marine mammals like killer whale, bottlenose dolphins, seals, sea lions, elephant seals and porpoises (Higgins 2000; Old et al. 2001; Fenwick et al. 2004; Stoddard et al. 2005) and the organisms shed by these mammals may contaminate other marine fish. 21.7% of harbor porpoises in England and Wales were positive for *Salmonella* during 1990–2002. In San Miguel Island, California, 33% of fur seal pups and 40% of sea lion pups were positive for *Salmonella* (Higgins 2000).

Most of the studies looking at the presence of *Salmonella* in aquatic environments have evidenced two main observations: only a small but constant number of serovars have been found in these environments and, in most cases, these do not coincide with the main zoonotic serovars identified in the surrounding areas (FAO 2010). In spite of the variability in sampling size ($n = 37$ to 251), in most of these studies the maximum number of serotypes identified has been around 20 (FAO 2010). Among the clinically important serovars, typhimurium has been shown to be the most common but mostly this accounted for only a small percentage of serotyped strains (FAO 2010); nevertheless, this attests to their capacity of adaptation survival in external environments (Baudart et al. 2000). *Salmonella* Weltevreden has been identified in recent years as one of the prevailing serovars in seafood products from Asian countries. Serovar Weltevreden has been detected as the dominant *Salmonella* serotype in fish and shrimps samples collected in India (Shabarinath et al. 2007), and in other Asian countries (Reilly and Twiddy 1992; Koonse et al. 2005) and this serovar has been involved in several clinical cases in Asia (Bangtrakulnonth et al. 2004; Phan et al. 2005).

Salmonella has been isolated from aquaculture systems in both developing countries and developed countries and the prevalence rates reported vary depending on the methodology used for detection. In aquaculture systems of Southeast Asia, 16.1% of shrimp and 22.2% of water/mud samples were positive for *Salmonella* (Reilly and Twiddy 1992). In US fresh water catfish ponds, Wyatt et al. (1979) reported a prevalence of 5% while a relatively high percentage of 33% in US catfish and 50% in Vietnamese catfish were reported by Pal and Marshall (2009) and this may be due to the methodology used for isolation. From eel culture ponds in Japan, a prevalence of 21% (Saheki et al. 1989) has been documented. *Salmonella* has also been isolated from pond water in a trout farm in Spain (Cesar-Javier et al. 1999). Long-term persistence of *Salmonella* in fish feed plants in Norway has been reported (Nesse et al. 2003). During 2000–2004, 3.78% of environmental samples from Norwegian fish feed production facilities were positive for *Salmonella*. But the serovars recovered were mostly *S*. Senftenberg and *S*. Montevedeo that account for 2% of human cases in Norway (Lunestad et al. 2007). Thus, fish feed could be a source of *Salmonella* in aquaculture systems. These studies provide evidence for the rather common prevalence of *Salmonella* in aquaculture systems across the globe. Contamination of aquaculture systems with *Salmonella* could involve multiple pathways such as runoff of organic matter into ponds during rainfall events, animal wastes introduced directly through bird droppings, frogs living in ponds or indirectly through runoff, fertilization using no-composted manures, integrated aquaculture systems, where animals such as poultry are housed directly over aquaculture pond,

toilets discharging into ponds, contaminated source water through wildlife runoff, untreated domestic sewage, discharge from animal farms, contaminated feed or unhygienic handling practices in farm (FAO 2010). Noor Uddin et al. (2015) reported that *Salmonella* could be detected in both extensive and intensive shrimp culture systems in Vietnam and isolates of *S*. Weltevreden from these systems were clonal in nature. They suggested that *S*. Weltevreden could survive and possibly even multiply in shrimp culture systems. Studies of Hounmanou et al. (2020) indicated occurrence of *S*. Weltevreden as the most common *Salmonella* associated with shrimp culture systems in China and the isolates are genetically related. Though detection of *Salmonella* in aquaculture products has been reported, this has not led to any major public health problem.

Salmonella are often detected in seafood in markets and the prevalence rates reported vary widely. In Malaysia, 25% raw prawns in market were positive, the serovars found being *S*. Blockley, *S*. Weltevreden, *S*. Agona (Armugaswamy et al. 1995), and in India, 1% of the 500 market prawns tested were positive the serovars being *S*. Newport and *S*. *infantis* (Prasad and Pandurangarao 1995). *Salmonella* present in seafood at market level could be a result of postharvest contamination. *Salmonella* including serovar Weltevreden can form biofilms on food contact surfaces and resist sanitizer treatment in biofilms (Joseph et al. 2001). In a study of 353 imported seafood in Japan, 2/47 black tiger shrimp were positive, both with *S*. Weltevreden, and contamination level in seafood were <30–40 MPN/100 g (Asai et al. 2008). Analysis of 11,312 imported and 768 domestic seafood in the USA during 1990–1998 revealed that 10% of imported and 2.8% domestic raw seafood was positive for *Salmonella* and the overall incidence was 7.2% for imported and 1.3% for domestic seafood (Heinitz et al. 2000). The most frequent serotypes in imported seafood were *S*. Weltevreden, *S*. Senftenberg, *S*. Lexington, and *S*. Paratyphi B. These most common serotypes were rarely (<0.5%) observed in human illness in the USA (Helfrick et al. 1997). *S. enteritidis* ranked fifth and *S. typhimurium* ranked 12th (Heinitz et al. 2000). S. Weltevreden was also the most common serotype isolated from imported food including seafood in USA in 2000 (24/187) followed by *S*. Thompson (13/187), *S*. Lexington (12/187), and number of other serotypes (Zhao et al. 2003). Though *S*. Weltevreden is rarely associated with human cases in the USA, it is frequently isolated from human cases in Thailand (Bangtrakulnonth et al. 2004).

Most studies on *Salmonella* in foods including seafood have been carried out using enrichment procedure and quantitative estimation of the concentration of *Salmonella* in foods has rarely been reported. One study of imported seafood (353 samples of 29 types of seafood) in Japan found two samples of black tiger shrimp and the levels estimated by Most Probable Number (MPN) were < 30 to 40/100 g (Asai et al. 2008). Considering that $>10^5$ cells are required to cause infection (FAO/WHO 2002), it can be suggested that multiplication in fish would be necessary before the food is consumed. *Salmonella* being a mesophilic organism, the growth rate of this organism is markedly reduced at temperatures <15 °C while the growth of most strains is prevented at <7 °C (ICMSF 1996). In raw seafoods containing a variety of bacteria, *Salmonella*, if present has to compete with other

flora for growth. *S*. Heidelberg had a generation time of 28 h and 31 h in the fish English sole and sterile crab, respectively, at 8 °C (ICMSF 1996). Ingham et al. (1990) reported proliferation of *Salmonella* in cooked crab inoculated with *Salmonella* and stored at 8–11 °C under modified atmospheres containing low levels of CO_2 (20–50%). The optimum pH for the proliferation of *Salmonella* is 7.0–7.5 though the organism can grow at pH values ranging from 3.8 to 9.5 with (ICMSF 1996). The minimum water activity for growth is 0.94 (ICMSF 1996) and the growth is generally inhibited at 3–4% NaCl, but salt tolerance increases with increasing temperature in the range 10–30 °C (D'Aoust and Maurer 2007). Though the resistance of *Salmonella* to drying varies, this organism may survive for months or even years in dried products and has been frequently isolated from fish meal, meat and bone meal, maize and soy products (Lunestad et al. 2007). *Salmonella* is sensitive to lower temperatures causing decrease in numbers during freezing and frozen storage, but this process does not guarantee elimination of salmonellae in foods (ICMSF 1996). *Salmonella* are heat-sensitive and typical D-values reported are 0.176 min in chicken at 70 °C, 0.36 min in ground beef at 63 °C (FAO/WHO 2002). Some strains of *Salmonella* like *S*. Senftenberg 775 W may show higher heat resistance (ICMSF 1996). Interestingly, *S*. Senftenberg is the serovar often isolated from fish feed (Lunestad et al. 2007). D-values are influenced by the water activity, nature of the solutes, and pH of the suspending medium (ICMSF 1996).

Though *Salmonella* has been isolated from seafood at both farm level and retail level, seafood account for only a small proportion of salmonellosis outbreaks. Greig and Ravel (2009) analyzed food-borne outbreaks reported in International literature between 1988 and 2007, for which a source could be identified ($n = 4093$). This study indicated that 46.9% outbreaks were due to *Salmonella* of which, seafood accounted for 1.7% compared to 14% associated with eggs. In the USA over a three-decade period (1973–2006), *Salmonella* accounted for 18 of a total of 188 outbreaks involving seafood. Three hundred seventy four illness were associated with *Salmonella* in seafood out of 4020 seafood associated illnesses (Iwamoto et al. 2010). In EU, during 2011, there were 1501 food-borne outbreaks of salmonellosis, and these were grouped as 283 outbreaks with strong evidence and 1218 outbreaks with weak evidence (EFSA and ECDC 2013). Of the outbreaks with strong evidence, 17 (6%) were due to seafood.

Considering that *Salmonella* in aquatic systems are derived from human or animal source, antibiotic resistance in seafood would be reflective of the situation in other sectors. Antimicrobial resistance was detected in 9% of the total of strains isolated from environmental sources and shellfish over different studies in Spain (Martinez-Urtaza et al. 2004b; Martinez-Urtaza and Liebana 2005). On the other hand, the presence of antimicrobial resistant strains among strains isolated from the marine environment in Morocco reached 49.1% of the strains (Setti et al. 2009), whereas in Mexico, 50.4% of the strains recovered from water samples showed resistance to antimicrobials (FAO 2010). In a study carried in Cochin, India, 82% of the strains isolated from seafood product presented antimicrobial resistance (Kumar et al. 2009), whereas in Vietnam, antimicrobial resistance was observed in 11.1% of strains (Van et al. 2007). It should however be noted that the methodology and

spectrum of antibiotics used by different investigators vary and this may contribute to the high degree of variation observed. Khan et al. (2006, 2009) recorded varying antibiotic resistance in *Salmonella* strains belonging to several serovars isolated from imported seafood in the USA, but the frequency of resistance in the serovar Weltevreden was low (Ponce et al. 2008).

Biosecurity and control measures to minimize the risk of Salmonella contamination of aquaculture products have been elaborated by FAO (2010). A number of aspects covering farm design, layout, source of water, hygiene of equipment, personnel, feed as well as good hygienic practices during harvesting, transport, and processing would be important.

7.2.3 *Listeria monocytogenes*

The genus *Listeria* has seven species, of which only *L. monocytogenes* is considered as a pathogen to human, and *L. ivanovii* is considered an animal pathogen (Swaminathan et al. 2007). *L. monocytogenes* is a common inhabitant of moist environments like decaying vegetation, soil and can be isolated from various aquatic environments and therefore, the organism is commonly associated with aquaculture environments and in freshly harvest fish (Reilly and Kaferstein 1997) and fish in retail markets (Dhanashree et al. 2003; Parihar et al. 2008). In the US catfish industry, *L. monocytogenes* has been found at a frequency of 76.7% in chilled fresh catfish fillets and 43.3% in unchilled fillets. The organism was also detected in fish contact surfaces such as deheading machine, trimming board, chiller water, and conveyor belts at different stages (Chen et al. 2010). In some studies, raw fish have been found to be a source of contamination of fish processing plants (Gudmundsdóttir et al. 2005). Prevalence of *L. monocytogenes* in fish processing environments has been a particular problem, particularly for the fish smoking industry. To understand the source of contamination of the final product, various molecular techniques such as Pulse Field Gel Electrophoresis (PFGE) and Multi Locus Sequence Typing (MLST) have been used. Chen et al. (2010) noted that in the US catfish industry, chiller water and processing table are important sources of contamination for the final fillets rather than the raw material. Ciccio et al. (2012) noted that though raw fish could be source of contamination of the processing environment, certain strains can persist longer than others and the strains found in the final product are generally these persistent strains. *L. monocytogenes* has been reported to form biofilms and survive in fish processing environment for years (Wilks et al. 2006). PEGE studies on isolates provide evidence for the persistence of strains for 11 years (Vongkamjan et al. 2013).

Unlike most other food-borne pathogens, *L. monocytogenes* is psychrotrophic and capable of growing at refrigerator temperatures. The temperature range at which growth can occur is between 0 °C and 45 °C with an optimum temperature of 37 °C. The organism is resistant to environmental conditions such as high salinity or acidity, which enables its survival for long periods in the environment. Possibly, due to its

psychrotrophic nature, the organism seems to be more prevalent in seafood from temperate environments compared to that from tropical regions. For example, in India, the reported prevalence ranges from absence to 8.6% (Karunasagar and Karunasagar 2000; Parihar et al. 2008), while in cold water shrimp, the prevalence could be 20.9% (Gudmundsdottir et al. 2006).

Despite the wide prevalence of *Listeria monocytogenes* in foods, natural and food processing environments, and its asymptomatic carriage in 5–10% of humans and domestic animals, listeriosis is a rare disease. The incidence is typically in the range of 0.1–11 cases per million people per year (FAO/WHO 2004). A severe form of listeriosis is characterized by an invasive infection often leading to septicemia with or without infections of the central nervous system such as meningitis, meningoencephalitis, rhomboencephalitis or brain abscess. In the case of pregnant women, while the mother will often experience mild flu-like symptoms, her fetus may be stillborn, aborted or be born with generalized infections. Less common symptoms include localized infections including endocarditis, peritonitis, and arthritis. Skin infections may also occur in some patients. The incubation period is very variable ranging from 3 to 70 days, and since most people do not remember their food consumption from months earlier, it is often difficult to trace the source of infection. The median incubation period is approximately 3 weeks. If diagnosed, the disease can usually be treated effectively with a range of common antibiotics. Severe form of listeriosis occurs mostly in susceptible population that includes elderly, pregnant women, people with underlying illness (chronic conditions such as cardiovascular disease, congestive heart failure, diabetes, cirrhosis, and alcoholism) and immunocompromised individuals. Fatality rate of 20–30% is common in severe form of listeriosis (FAO/WHO 2004).

L. monocytogenes may also cause a non-invasive febrile gastroenteritis in healthy individuals. An outbreak of gastrointestinal illness from a tuna and corn salad, affecting >1500 schoolchildren and adults in Italy, provided conclusive evidence for the existence of a febrile gastroenteritis form of listeriosis (Drevets and Bronze 2008; Allerberger and Wagner 2009). The incubation period for this form of the disease ranges from 6 to 50 h, and symptoms usually resolve without treatment after 1 to 2 days. Symptoms are described as "mild flu-like," including diarrhea, abdominal pain, fever, muscle pain, and headaches.

Most outbreaks of listeriosis are associated with ready-to-eat foods that can support the growth of *L. monocytogenes,* have a long refrigerated shelf life and are consumed without further listericidal treatment. Even in products that receive listericidal treatment, post-process contamination, cross contamination at distribution level and home level is an important issue (FAO/WHO 2004). This applies to a range of seafood products, including marinated fish and mussels, prawns, pasteurized crustacea, and smoked fish products. Cold-smoked products have received particular attention in this regard due to a high prevalence of *L. monocytogenes* in such products and persistent contamination of fish processing plants. Contamination rates range from 0.4% to 78.7% but more typically in the range of 4–30%. Studies by Jørgensen and Huss (1998) suggest that at the point of production, 34% of samples are positive with 28% having <10 CFU/g, 5% having 10–100 CFU/g, and 1%

having >100 CFU/g. After 14–20 days of storage at 5C, 40% were positive and the level exceeded 100 CFU/g in 10.5% samples and the levels were 10–100 CFU/g in 20% cases. Epidemiological evidence suggests that listeriosis has been associated with consumption of shrimps, smoked mussels, "gravid" trout and smoked trout (FAO/WHO 2004). Many of these outbreaks, however, involved the gastrointestinal form of the disease and, despite the interest in RTE smoked fish as a source of listeriosis, there are very few documented cases of *systemic* listeriosis due to seafood.

Based on somatic (O) and flagellar (H) antigens *L. monocytogenes* has been differentiated into 13 serovars (1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4b, 4c, 4d, 4e, 6a, 6b). Most isolates involved in human disease belong to four serotypes, 1/2a, 1/2b, 1/2c, and 4b. Dose–response models for *L. monocytogenes* inferred from epidemiological data and estimates of total food-borne exposure (FAO/WHO 2004) have generated ID_{50} estimates for immunocompromised people of $>10^{10}$ cells. Since the levels of *L. monocytogenes* found in seafood are generally low, multiplication of the organism would have occurred in products involved in outbreaks. Therefore, prevention of growth in the products would be an important risk management strategy. A number of hurdles are employed to increase the shelf life of lightly preserved seafood, often in combination, including refrigeration, salt, phenolic (smoke) compounds, acidification with organic acids including lactate, acetate, sorbate, benzoate, citrate, or addition of salts of organic acids, addition of nitrite and modified atmosphere packaging including CO_2. Models to predict the effect of these hurdles on the growth of *L. monocytogenes* have been developed and evaluated (Mejlholm et al. 2010).

When *L. monocytogenes* was identified as a food-borne pathogen, the first response of regulatory agencies was to establish a "zero tolerance" policy, i.e., the organism should be absent in 25 g sample of the product. This caused trade disruptions and the issue came up before the Codex Alimentarius Commission, which asked FAO/WHO to perform risk assessment of *L. monocytogenes* in foods and specifically to "estimate the risk of serious illness from *L. monocytogenes* in food when the number of organisms ranges from absence in 25 grams to 1000 colony forming units (CFU) per gram or millilitre, or does not exceed specified levels at the point of consumption." The risk assessment report (FAO/WHO 2004) noted that in areas where a regulatory level of "absence in 25g" or 0.04 CFU/g is applied and all products in market comply with the requirement, the listeriosis cases would be less than 1 case per year, but in the USA, where such regulatory limit is applied, cases were still being seen and this indicated that a portion of ready-to-eat food contained a substantially greater number of the pathogen than the regulatory limit. Thus, the public health impact of *L. monocytogenes* is almost exclusively a function of the foods that greatly exceed the "absence in 25g" limit. The report also examined "what if scenario" using two often discussed regulatory limits – 0.04 CFU/g and 100 CFU/g. The risk assessment model indicated that at 100% compliance, the number of predicted cases is low for both limits, with an approximate tenfold difference between them, that is, 0.5 cases versus 5.7 cases. But as the number of "defectives" (proportion of products not meeting the criteria) increased, the difference narrowed. For example, at a presumed defective level of 0.0001%, the predicted number of cases would be 12.3 and 17.4. The model predicted that if a microbiological limit of 0.04 CFU/g with

a 0.018% defect rate (2133 cases) was replaced with a 100 CFU/g limit and a 0.001% defect rate (124 cases), the predicted result based on the scenario is an approximate 95% reduction in food-borne listeriosis. In view of the widespread occurrence of *L. monocytogenes* in fish processing environments, there would be significant percentage of "defectives," if "absence in 25 g" is used as criterion. Considering these findings, the Codex Alimentaruis Commission agreed to have a criterion of 100 CFU/g for ready-to-eat products that do not support the growth of *L. monocytogenes* and absence in 25 g for products that support the growth of the organism.

Ampicillin is the antibiotic of choice for treatment of listeriosis. Many investigators have screened clinical as well as food isolates of *L. monocytogenes* for antimicrobial susceptibility and generally the reported prevalence of resistance is very low (Walsh et al. 2001; Hansen et al. 2005). Lungu et al. (2011) compiled data regarding reported antibiotic resistance in *L. monocytogenes* isolated from food. Resistance to a variety of antimicrobials including tetracyclines, cephalosporins, β Lactams, aminoglycosides, and quinolones has been noted in many food-borne strains. Interestingly, there were no such strains reported from fish or seafood.

7.2.4 *Streptococcus agalactiae*

Group B Streptococci (GBS) have been known to cause neonatal septicemia and have been involved in sepsis in adults with co-morbidities. In 2015, *S. agalactiae* were implicated in an outbreak involving over 140 apparently healthy adults in Singapore. The affected individuals had serious systemic disease like septic arthritis and meningitis. Epidemiological investigations indicated strong link to consumption of raw freshwater fish. Multilocus sequence typing (MLST) of the isolates involved in the outbreak showed that they belong to Sequence Type 283 (FAO 2021). Based on capsular polysaccharide, GBS have been assigned to ten serotypes Ia, Ib, II to IX. All ST283 isolates belong to serotype III-4.

GBS have also been reported to cause fish infections, particularly in fresh water fish like tilapia in aquaculture. The affected fish show anorexia, abdominal distension, exophthalmia (protruding eyes), hemorrhages, and meningoencephalitis. Three major serotypes of *S. agalactiae* have been detected in fish, serotype Ia, Ib, and III. Isolates of serotype Ia belong to ST7, isolates of serotype Ib belong to ST 260, and isolates of serotype III belong to ST283 or closely related STs.

Betalactams have been the drug of choice for treatment of GBS in humans. GBS ST283 have been reported to be generally susceptible to erythromycin, tetracycline, and penicillins (FAO 2021).

7.3 Antimicrobial Resistance Microorganisms Associated with Products of Aquaculture

The importance of antimicrobial agents in protection of animal health has been widely acknowledged, but the negative impacts of the use of these agents in animals raised for food have been a cause of concern. The use of antimicrobials in

agriculture, animal husbandry, and aquaculture in many developing countries is often unregulated and there is very little data on their usage. Schar et al. (2020) estimated that aquaculture accounts for 5.7% of global consumption of antimicrobials. In 2017, the consumption was 10,259 t and the consumption intensity varied in different species, e.g., 157 mg/kg for catfish, 103 mg/kg for tilapia, 59 mg/kg for tilapia, 46 mg/kg for shrimp, and 27 mg/kg for salmon.

The current risk management strategy for antimicrobial residues in aquaculture products is based on the precautionary principle, and there are no epidemiological records of illnesses in fish consumers due to residues. The FAO/OIE/WHO consultation on scientific issues related to non-human usage of antimicrobials held in Geneva, in December 2003, concluded that residues of antimicrobials in foods, under present regulatory regimes, represent a significantly less important human health risk than the risk related to antimicrobial resistant bacteria in food. Resistance of bacteria to antimicrobial agents is a complex issue. Some bacteria have intrinsic resistance to certain antibiotics, e.g., most gram-negative bacteria have intrinsic resistance against penicillin G, due to the nature of cell wall in this group of bacteria. Resistance to antimicrobial compounds is a very ancient trait in environmental bacteria. Genes conferring resistance to antibiotics that are critical for human medicine today have been found in bacteria billions of years before antimicrobial usage (D'Costa et al. 2011). Bacteria resistant to β-lactams, aminoglycosides, and macrolides, as well as newer drugs such as daptomycin, linezolid, telithromycin, and tigecycline, have been isolated from the Lechuguilla caves in New Mexico that were totally isolated for >4 million years (Bhullar et al. 2012). Recent molecular biological studies on antibiotic resistance genes provide very interesting insights into the evolution and ecology of antibiotic resistance genes. It is estimated that Class A β-lactamases evolved approximately 2.4 billion years ago and were horizontally transferred into the gram-positive bacteria about 800 million years ago. The family of genes, including the progenitors of CTX-Ms (cefotaxime resistance genes), diverged 200–300 million years ago. In addition to being involved in hydrolysis of the β lactam ring, metallo-β lactamases are involved in various basic cellular processes such as hydrolysis, DNA repair, and RNA processing and these enzymes can be found in all the three domains of life, i.e., Bacteria, Archaea, and Eucarya (Garau et al. 2005). Ribosomal protection proteins (RPP) that mediate resistance to tetracyclines were derived through duplication and divergence of GTPase, before the divergence of the three superkingdoms: Bacteria, Archaea, and Eucarya (Kobayashi et al. 2007).

There is evidence to show that clinical bacteria have acquired resistance genes from environmental bacteria. The *qnr* gene responsible for resistance to quinolones are widely distributed in aquatic bacteria such as members of Vibrionaceae, Aeromonas, and Shewanella species (Poirel et al. 2012). $bla_{CTX\text{-}M}$ gene coding for resistance to extended spectrum β-lactamases (ESBL) have originated from the environmental bacteria belonging to *Kluyvera* species (Canton et al. 2012).

Though antibiotic resistance genes may emerge as a process of natural genetic changes occurring in bacteria, presence of antibiotics would exert selective pressure favoring resistant bacteria and their spread. Multiple antibiotic resistance in bacteria causing human infections is a great public health concern. The widespread use of

antibiotics in different sectors such as animal husbandry, agriculture, and human medicine has contributed to selection and spread of antibiotic-resistant bacteria in the environment. Antibiotic resistance genes can spread among unrelated bacteria without any phylogenetic, ecological, or geographical barriers. The Joint FAO/OIE/WHO Expert Consultation on Antimicrobial Use in Aquaculture and Antimicrobial Resistance held in 2006 identified two types of hazards with respect of antimicrobial resistance:

(a) Development of acquired resistance in bacteria in aquatic environments that can infect humans – This can be regarded as a direct spread of resistance from aquatic environments to humans; and
(b) Development of acquired resistance in bacteria in aquatic environments whereby such resistant bacteria can act as a reservoir of resistance genes from which the genes can be further disseminated and ultimately end up in human pathogens – This can be viewed as an indirect spread of resistance from aquatic environments to humans caused by horizontal gene transfer.

The consequences of antimicrobial resistance in bacteria causing human infections could include increased severity of infection and increased frequency of treatment failures (FAO/OIE/WHO 2006). However, there are no recorded cases of human infections caused by antibiotic-resistant bacteria from aquaculture products.

There are few human pathogenic bacteria that are commonly found in the aquatic environment (e.g., *Vibrio parahaemolyticus*, *V. vulnificus*, *V. cholerae*, motile *Aeromonas* spp., *Edwardsiella tarda*). Antibiotic resistance that cannot be linked to the use of antimicrobials in aquaculture may be found in these aquatic bacteria. Baker-Austin et al. (2008) found antibiotic resistance in *V. parahaemolyticus* isolated from water and sediment along the coasts of Georgia and South Carolina, and resistance frequency was slightly reduced among virulent strains compared to non-virulent strains. Study of antibiotic resistance in *V. vulnificus* from different sites found no difference in antibiotic resistance frequency in isolates from pristine and anthropologically impacted areas and suggested that the resistance traits are naturally derived, rather than from human-derived sources (Baker-Austin et al. 2009). A recent FAO/WHO risk assessment has shown that the risk of transmission of cholera through warm water shrimp in international trade is very low (FAO/WHO 2005a). Motile *Aeromonas* spp. and non-O1 *V. cholerae* are rarely involved in gastrointestinal infections that are mostly self-limiting, and such infections do not require antibiotic therapy.

Indirect spread of antibiotic resistance from aquatic bacteria and human pathogens has been considered a possible hazard. A number of investigators have reported increased prevalence of bacteria carrying antibiotic resistance genes in fish/shrimp ponds and in water and sediments surrounding aquaculture sites in Japan (Kim et al. 2004), Europe (Schmidt et al. 2000), the USA (Chuah et al. 2016), South America (Miranda and Zemelman 2002), China (Dang et al. 2009), and Southeast Asia (Karunasagar et al. 1984; Lee et al. 2005). Though experimental transfer of antibiotic resistance from fish pathogenic bacteria to human gut-associated *E. coli* has been

demonstrated (Kruse and Sorum 1994), the link between antibiotic resistance in aquatic bacteria and human pathogens in nature is yet to be clearly established. Often, similarity in genetic elements is taken as evidence of transfer, but one cannot be sure in which direction the gene flow has occurred, considering that hospital effluents also discharge antibiotic resistant bacteria to the aquatic environment. Although some authors (e.g., Cabello 2006) have tried to link the antibiotic resistance seen in *V. cholerae* involved in the cholera outbreak in Latin America in 1991 with bacteria present in shrimp farms in Ecuador, Smith (2007) presented evidence that resistance plasmids found in these bacteria were earlier reported from pandemic *V. cholerae* strains in other countries and concluded that no link to the pool of resistance genes in the aquaculture environment could be established. Conclusions based on similarity of genetic determinants found in aquatic bacteria and human pathogens need to be evaluated carefully due to the fact that the aquatic environment receives effluents from various sectors of antimicrobial use, e.g., human medicine (hospital effluents), agricultural use, animal husbandry, and aquaculture (fish farm effluents). Thus, the water source used in aquaculture may be contaminated with antibiotic residues or antibiotic-resistant bacteria derived from different sectors (Karunasagar 2012, Fig. 1). Complexities involved in source attribution of antimicrobial resistance in aquaculture have been discussed recently by Karunasagar et al. (2020).

FAO (2008) noted that a risk analysis of the release of human and animal effluents into aquatic environments serving as water sources for aquaculture needs to be performed, particularly with respect to the antimicrobials identified as critically

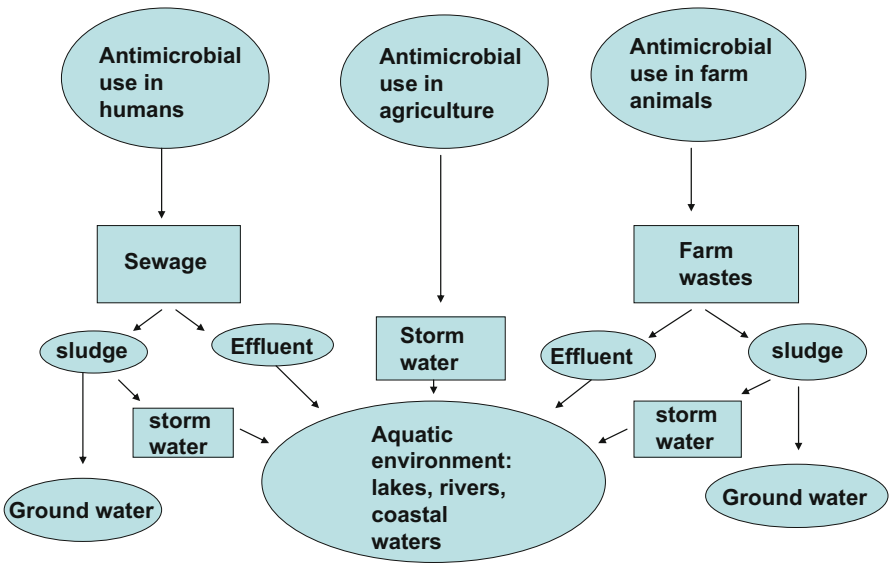

Fig. 1 Pathways for spread of antimicrobial residues and resistant bacteria in the aquatic environment

important by WHO and OIE. Such a risk analysis would determine the appropriate management options through which improved effluent management measures should be implemented (e.g., measures dealing with hospital effluents). Thus, the issue of antimicrobial resistance cannot be addressed for one sector (e.g., aquaculture) alone, but requires a comprehensive approach involving all sectors of antimicrobial usage.

Abstract

Campylobacteriosis is a frequently diagnosed disease in humans. Most infections are considered foodborne and are caused by *Campylobacter jejuni* and *C. coli*. The animal reservoirs of these *Campylobacter* species, and the sources and routes of transmission, are described and discussed in this chapter. Most warm-blooded animals can be colonized by *Campylobacter,* but avian species, and in particular poultry, are preferred hosts. Much of the world's poultry production is colonized by *Campylobacter.* Source attribution studies estimate that 20–40% of cases are attributed to the handling and consumption of chicken meat, while up to 80% of cases are due to *Campylobacter* found in the chicken reservoir. The difference suggests that routes other than through the food chain, i.e., environmental contamination, are important. The epidemiology of infections in humans differs between industrialized and low- and middle-income countries. Thus, the most effective interventions would be targeted to primary production. To date, only improved biosecurity is available. If effectively implemented, strict biosecurity can reduce the number of *Campylobacter*-positive flocks, but implementation to this level has proved difficult for the poultry industry. Available interventions in chicken processing plants can substantially reduce *Campylobacter* numbers on carcasses and consequently reduce the risk to humans. Public health strategies therefore utilize control programs, which aim at reducing the level of *Campylobacter* by measures along the food chain. It is now recognized that commercially acceptable complementary interventions for primary production, such as vaccines and feed additives, are urgently needed. Once *Campylobacter* in poultry is controlled then other minor sources of *Campylobacter* including contaminated drinking water, direct contact with (pet) animals, and other food items (e.g., red meat and milk) can be addressed.

8.1 Campylobacteriosis: The Disease and Its Burden in Humans

Human campylobacteriosis is primarily caused by *Campylobacter jejuni* (*C. jejuni*) and to a much lesser extent by its close relative *Campylobacter coli* (*C. coli*). Human infection with either pathogen largely presents as gastrointestinal illness (Gillespie et al. 2002). *C. jejuni* and *C. coli* together account for more than 90% of all cases of

human campylobacteriosis. Infections with other *Campylobacter* species may also occur, but they occur in either specific risk groups, for example, people with impaired immunity (e.g., *C. fetus*) (Wagenaar et al. 2014), or are very rare (e.g., *C. lari*), or cluster in specific geographical areas (e.g., *C. upsaliensis*) (Man 2011). This chapter will focus on *C. jejuni* and *C. coli*, and hereafter *Campylobacter* refers to these two species only.

Campylobacter is the most commonly reported cause of bacterial infectious intestinal disease (IID). However, disease surveillance programs, which include campylobacteriosis, are largely limited to industrialized countries, such as the United States (USA) and Member States of the European Union (EU) (EFSA and ECDC 2021; CDC 2022a). In industrialized countries, *Campylobacter* is isolated 3–4 times more frequently from patients with IID than *Salmonella* or *Escherichia coli*. However, it is well recognized that underreporting of such diseases is frequent. Adjusting for this, the true prevalence of campylobacteriosis was estimated to be 9.2 million in the EU in 2009 (Havelaar et al. 2013) and 1.3 million in the USA in 2011 (Scallan et al. 2011). Nevertheless, serological evidence suggests that exposure to this pathogen is substantially more frequent (Teunis et al. 2013), such that based on serological data virtually all individuals have been exposed to the organism by 20 years of age (Ang et al. 2011) and that the average infection pressure is estimated at around 1.6 *Campylobacter* infections per person/year (Monge et al. 2018). Such exposure can lead to protective immunity, which might affect the outcome and impact on disease incidence and could explain the low reported prevalence of disease in developing countries despite obvious regular exposure (Havelaar et al. 2009).

There are some additional interesting epidemiological features of campylobacteriosis, many of which have yet to be fully explained. These include a seasonal peak, which varies between countries and seems to be inconsistent with seasonal peaks observed in potential sources (Djennad et al. 2019).

In the past campylobacteriosis was largely considered a mild illness, but the severity of this disease is clearly reflected in the relatively high rate of *Campylobacter*-infected individuals seeking medical attention. Surveys show that one in four cases in the Netherlands and one in seven cases in the United Kingdom (UK) visit a general practitioner and approximately 1% of these individuals are hospitalized (Tam et al. 2012; Havelaar et al. 2012). In the acute phase, campylobacteriosis is primarily characterized by gastrointestinal symptoms, such as watery (sometimes bloody) diarrhea, abdominal cramps, nausea, vomiting, and fever. The disease is usually self-limiting, lasting a week or less. Antimicrobial treatment is only indicated in severe cases (e.g., bloody diarrhea or systemic infection). However, *Campylobacter* infections can also have serious sequelae, including Guillain-Barré and Miller-Fisher syndromes, reactive arthritis, and functional gastrointestinal disorders, including irritable bowel syndrome (Helms et al. 2006; Doorduyn et al. 2008; Haagsma et al. 2010; Berumen et al. 2021).

The burden of campylobacteriosis has been quantified in terms of disability-adjusted life-years (DALYs), which is a metric of health loss caused by the disease comprising years of life lost by the population due to disability and premature death. The different manifestations of campylobacteriosis were estimated to cause an

average disease burden of 3300 DALYs in the Netherlands in 2019, with sequelae accounting for approximately 80% of this burden (Lagerweij et al. 2020). Among foodborne pathogens investigated in the Netherlands, this DALY estimate was the highest. Similar studies in the USA in 2011 showed *Campylobacter* to cause a burden second only to *Salmonella*, with a cost of illness of $1.7 billion annually (Hoffmann et al. 2012).

Despite the relative importance of campylobacteriosis, unlike for salmonellosis, there have been no effective intervention programs implemented, with the exception of Iceland and New Zealand where very specific conditions prevailed (Stern et al. 2003; Sears et al. 2011). This is all the more surprising given that the incidence of human campylobacteriosis increased significantly during the 1980s–1990s, stabilized around the start of this century, and has tended to increase again in the second decade of this century in the USA, while remaining stable in Europe (EFSA and ECDC 2021; CDC 2022b). There has been a remarkable sudden decrease in human campylobacteriosis associated with the COVID-19 pandemic in the USA and Europe, as observed also, for example *Salmonella* (Mughini Gras et al. 2021a). The reasons for the lack of specific intervention for *Campylobacter* are debatable, but include the complexity of foodborne and environmental sources and transmission routes, the financial imbalance accruing from interventions where the cost is to the poultry industry while the benefit is to the public health sector, and lack of consumer/political acceptance of effective measures like irradiation or chemical decontamination. In addition, there is a general lack of public interest, which is in part due to the scarcity of major outbreaks.

8.2 Characteristics of *Campylobacter*

Campylobacter comprises a genus of Gram-negative, motile, non-spore forming, mostly microaerophilic, spiral bacteria (diameter 0.2–0.5 μm, length 0.5–8 μm). To date (January 2023), the genus includes 43 species (https://lpsn.dsmz.de/genus/campylobacter) and with the use of molecular approaches, this number is rapidly expanding. Both *C. jejuni* and *C. coli* are thermophilic, showing optimal growth at 42 °C. For the purposes of isolation this thermotolerance, especially in combination with resistance to cephalosporin, is often used to reduce contaminating flora and improve recovery, particularly from fecal material.

Campylobacter readily generates resistance against an increasing number of classes of antimicrobials. Although antimicrobials are infrequently prescribed for campylobacteriosis, such resistance can have clinical consequences. There are clear differences in antimicrobial resistance in different geographical areas. Generally, resistance is higher in Asia and Africa compared to Europe, the USA, and Australia and New Zealand (Nhung et al. 2016; Gahamanyi et al. 2020; EFSA 2021). This parallels the amount of antimicrobials used in animals and humans in these regions. Resistance to fluoroquinolones and tetracyclines is increasing in most regions of the world. An association between the licensed use of fluoroquinolones in poultry and increased fluoroquinolone resistance in strains isolated from humans was noticed in the 1980s

(Endtz et al. 1990). This association was strengthened by a low fluoroquinolone resistance in *C. jejuni* isolates from humans in Australia, a country where fluoroquinolones were never licensed for use in production animals (Cheng et al. 2012).

Campylobacter is sensitive to many environmental stresses, including desiccation, heat, ultraviolet radiation, atmospheric oxygen, and high salinity. As a consequence, *Campylobacter* is unable to grow naturally outside a host and is considered generally fragile compared with, for example, *Salmonella*. Nevertheless, *Campylobacter* can survive in the environment for prolonged periods, especially in moist conditions. Survival has been recorded for up to 3 months in slurries and water contaminated with organic materials (Nicholson et al. 2005) and up to 10 months in manure compost (Douglas Inglis et al. 2010).

The fastidious nature of the organism is reflected in its demanding requirements at culture. Diagnosis of infection is usually based on isolation from fecal samples using selective media, containing appropriate antimicrobials, and incubated under reduced oxygen tension, at 42 °C for 48–72 h. However, the isolation technique and media constituents may vary depending on the matrix under investigation and may affect both the efficacy of recovery and the species and/or strain types recovered (Newell et al. 2001). Numerous rapid detection tests, using a variety of technologies, are now commercially available. For application in food chain settings, e.g., slaughterhouses or chicken farms, such tests need to be cheap and user-friendly as well as sensitive and specific (Llarena et al. 2022).

The typing of *Campylobacter* has proved challenging. The organisms demonstrate considerable variation at both the phenotypic and genotypic levels and many attempts have been used to exploit this diversity to characterize *Campylobacter* for epidemiological studies. Initial typing methods included serotyping and phage typing. However, these methods were largely superseded by molecular techniques, such as *fla*-typing and Pulsed Field Gel Electrophoresis (PFGE) (Wassenaar and Newell 2000). Subsequently, as DNA sequencing became cheaper and quicker, Multi Locus Sequence Typing (MLST), based on variations in the sequences of seven housekeeping genes, was used to establish the population structures of *C. jejuni* and *C. coli* (Dingle et al. 2001). The significant advantage of this technique was its portability due to the use of globally available internet-based databases, which allowed easy strain comparison. Not surprisingly, this technique was quickly exploited for epidemiological purposes and, with the application of highly sophisticated statistical methods, its use was expanded to determine potential infection sources and to provide a global public health tool. Many *C. jejuni* MLST sequence types (STs) have been cataloged to date. Most STs are generalists and can colonize several hosts but some are specialized to defined hosts, such as cattle and chicken (Mourkas et al. 2020). However, the use of just the sequences of seven housekeeping genes has raised issues regarding resolution for the purpose of source identification. With continued improvements in DNA sequencing, rapid whole-genome sequencing (WGS) of campylobacters has become routine (Didelot et al. 2012). However, due to the high genome diversity of *Campylobacter*, SNP-based comparisons are problematic. In 2017, a core-genome MLST (cgMLST) approach was proposed expanding the number of gene sequences analyzed to 1343 (Cody et al. 2017). The cgMLST

typing approach has now been validated and types present in a wide range of animals identified (Hsu et al. 2020) and compared with those found causing human disease using increasingly sophisticated analytical techniques, including machine learning techniques (Arning et al. 2021). Nevertheless, the large number of "generalist" sequence types continue to elude source attribution. As a consequence, efforts to further improve the resolution by incorporating additional sequences, for example, from potential host-associated genes, continue.

8.3 The Disease and Carriage in Animals

The primary habitat of *Campylobacter* and its main amplification site is the intestinal tract of warm-blooded animals. Both *C. jejuni* and *C. coli* are normal inhabitants of the guts of healthy livestock, pets, and wild animals. There appears to be some host preference with *C. jejuni* more commonly isolated from most animals, like cattle, dogs. and cats, while pigs predominantly carry *C. coli*. The reason for this is unclear. Certainly, a significant proportion of livestock animals is colonized and the prevalence varies with factors like age, husbandry, country, etc. (Plishka et al. 2021; Mota-Gutierrez et al. 2022; Knipper et al. 2022). Similarly, up to 45% of dogs are colonized (Marks et al. 2011).

The role of *C. jejuni* and *C. coli* as pathogens in these animals is considered of relatively minor importance. They can cause abortion in cattle and sheep, but are usually less frequently isolated from aborted fetuses than *C. fetus*. An exception is the spread of a single tetracycline-resistant *C. jejuni* clone causing abortion in sheep throughout the USA (Wu et al. 2014). This hypervirulent clone is also reported in other countries such as the UK, Japan, and China (Stone et al. 2014; Wu et al. 2016, 2020; Sahin et al. 2017; Tang et al. 2017; Hsu et al. 2020; Yaeger et al. 2021a, b). Interestingly, this clone has also been recovered from diarrheic humans in the USA, but the route of transmission has not yet been identified. The role of *Campylobacter* as a pathogen in dogs remains debatable (Burch 2005; Marks et al. 2011). The high level of asymptomatic carriage (Marks et al. 2011) suggests that any association with disease is coincidental rather than causative. Nevertheless, there is certainly evidence of such companion animals as a source for human infections (Mughini Gras et al. 2013, 2021b).

Poultry, in particular and (wild) avian species in general, are the preferred hosts for these organisms. This is a reflection of the bacterium's thermophilic character, as 41–42 °C is the normal body temperature of a bird. Colonization occurs throughout the gut, but primarily in the cecum of a broiler, where levels of up to 10^9 colony forming units per gram have been reported. All the evidence indicates that *Campylobacter* act as a commensal in the avian gut, although this is occasionally disputed. The prevalence of *Campylobacter*-positive broiler flocks varies considerably, for example, with age, season of the year, latitude, extensive or intensive rearing, etc. In an EU-wide survey of broiler flocks undertaken in 2008, the prevalence of *C. jejuni*/*C. coli* colonization varied between 5% and 100% among Member States (EFSA 2010). The prevalence is particularly high if the flocks are free-ranging

(Vandeplas et al. 2010). The organism is highly infectious and in each colonized flock up to 100% of birds can be *Campylobacter*-positive. Thus, overall, it is reasonable to assume that a significant proportion of broilers produced worldwide are colonized with these organisms.

8.4 *Campylobacter* Epidemiology in Low- and Middle-Income Countries

Country-specific epidemiological data on infectious enteric diseases, especially those transmitted through the food chain, has been sparse in Low- and Middle-Income Countries (LMIC) but the effects of these diseases, as leading causes of morbidity and mortality, has long been recognized.

Campylobacteriosis is generally considered to be a major contributor to those diseases, especially in young children, but evidence from large global case-controlled studies has been poorly available. There have been multiple barriers to such investigations, including costs, organizational structures, perceptions of importance, etc. One barrier has been access to modern rapid diagnostic/surveillance technologies. For example, qPCR can have twice the sensitivity of *Campylobacter* detection than the more conventional culture methods generally available in laboratories in LMIC (Liu et al. 2016). Recently, the microbiological causes of diarrheal diseases in LMIC have been investigated in two such global studies using improved diagnostic and statistical tools. In the Global Enteric Multicentre Study (GEMS), the etiology and population-based burden of pediatric diarrheal disease in Sub-Saharan Africa and South Asia were investigated (Kotloff et al. 2013) in 9439 children with moderate-to-severe diarrhea and 13,129 children without diarrhea. Interestingly *C. jejuni* was only identified as a statistically significant cause of pediatric diarrhea in children of 0–11 months and 24–59 months in sites in India. Five other enteropathogens, including rotavirus and *Cryptosporidia*, were considered substantially more important targets for intervention. However, when qPCR was applied rather than more conventional methods, *Campylobacter* was identified as the sixth most common cause of illness. Similarly, the Malnutrition and Consequences for Child Health and Development (MAL-ED) consortium study (Platts-Mills et al. 2015), comparing 7318 diarrheal and 24,310 non-diarrheal stools from 2145 children (aged 0–24 months) from eight sites in South America, Sub-Saharan Africa, and Asia indicated that *Campylobacter* was among the most important causes of pediatric diarrhea, especially in the second year of life. These recent epidemiological surveys support reports from the WHO's Foodborne Disease Burden Epidemiology Reference Group (FERG), which considers *Campylobacter* one of the most common organisms causing diarrhea, especially in children (Havelaar et al. 2015), with the geographical regions most highly affected by campylobacteriosis in LMIC.

These recent large epidemiological studies have also confirmed some differences in the presentation of campylobacteriosis between high- and low- and middle-income countries. For example, although it had been previously well recognized that in LMIC adults excreting *Campylobacter* are usually asymptomatic, many

infected children also show no symptoms. In addition, the seasonal distribution in *Campylobacter* infections generally seen in the higher income world is not observed elsewhere (Havelaar et al. 2015; Platts-Mills et al. 2015).

The extent of the public health burden due to campylobacteriosis in LMIC is only just begun to be understood. Not only are symptomatic *Campylobacter* infections associated with poor linear growth in children over the first 2 years of life (Amour et al. 2016; Rogawski et al. 2018), but repeated exposure to such enteropathogens, even if subclinical, can cause substantial enteric dysfunction and malnutrition (Walson and Pavlinac 2018). Such life changing effects reinforce calls for interventions against foodborne enteropathogens, including *Campylobacter*, in LMIC (WHO 2017). Another potentially significant health issue is Guillain–Barré syndrome (GBS), which is most commonly caused by a preceding *Campylobacter* infection. Unfortunately, data on post-infectious GBS in LMIC is sparce and largely confined to South Asia (Bangladesh and India) (Papri et al. 2021).

Worldwide, the control and prevention of the public health burden of campylobacteriosis requires surveillance and monitoring especially of *Campylobacter* throughout the food chain. Unfortunately, LMIC rarely include foodborne enteropathogens, such as *Campylobacter,* in disease surveillance (Deolalikar et al. 2021). As a consequence, the national prevalence of such diseases in the population is generally unknown. Among South-East Asian countries in 2017, apparently only Singapore included campylobacteriosis in its national disease surveillance program (Premarathne et al. 2017).

The sources and routes of *Campylobacter* transmission in LMIC are poorly understood. Although epidemiological data from Africa, Asia, and the Middle East are incomplete, it is widely accepted that infection with *Campylobacter* is endemic in these regions, and traveling to Asia, Africa, Latin America and the Caribbean, and Southern Europe poses an increased risk of campylobacteriosis compared to traveling within Western Europe (Mughini Gras et al. 2014). It is generally believed that in such countries, campylobacteriosis is limited to children, because exposure in early life leads to protective immunity (Havelaar et al. 2009), which would also be consistent with endemicity.

The prevalence of human campylobacteriosis in LMIC may be attributed to many factors, including poor food hygiene, environmental contamination, animal rearing and handling practices, wet markets, etc. In high-income countries, human-to-human transmission is not considered an important route of *Campylobacter* infection, except in some institutional situations. Nevertheless, high levels of asymptomatic infections in those locations where sanitary facilities are inadequate could contribute to environmental contamination and result in higher exposure.

Campylobacter is generally considered a foodborne enteropathogen. To date, there is very little information available on potential sources of infection in LMIC and the little available data comes primarily from poultry, presumably because this is considered the primary source in high-income countries. Poultry production is thriving in South-East Asia, with livestock production in these regions being largely extensive (Gilbert et al. 2015), but frequently also as backyard or small local units for economic reasons (Alders et al. 2018). In such systems, biosecurity is either unfeasible or very difficult to apply (Kalupahana et al. 2013; Wang et al. 2015). Even commercial poultry production will use deep litter open-house systems where

biosecurity is minimal and the birds are constantly in contact with the outdoor environment, wild animals, and insects. Moreover, new flocks, including day-old chicks, are generally exposed to already *Campylobacter*-colonized chickens in the same farms (Kottawatta et al. 2017). Therefore, a high prevalence of *Campylobacter* colonization of broilers at slaughter in LMIC should be expected. Consistent with this, surveys conducted in Sri Lanka have reported >65% *Campylobacter* prevalence in broilers at slaughter (Kottawatta et al. 2017; Kalupahana et al. 2018).

Published surveys of *Campylobacter* contamination in retail poultry meats and their by-products (such as ground or frozen poultry meats) indicate that in most countries, regardless of social-economic status, the majority of samples are contaminated with *Campylobacter* (Suzuki and Yamamoto 2009) and there is no obvious difference between countries in the prevalence of sample contamination. However, few such retail surveys have been undertaken in LMIC compared to high-income countries.

Because *Campylobacter* is a common gut colonizer of many domestic animal species, not just poultry, multiple attributable sources and routes of transmission can occur especially in those countries where animal-to-human contact levels might be high. For example, in India *Campylobacter* colonization is frequent in dogs and calves, as well as poultry (Begum et al. 2015), though whether these strains can cause human disease is not known (Begum et al. 2015). To understand the attributable role of potential sources, time-related strain collections from humans and animals/environment need to be compared using typing techniques of appropriate discriminatory power, such as WGS. Unfortunately, such techniques may not be widely available in LMIC and, because of their low discriminatory power, little if any, useful conclusions can be drawn on sources from the use of low-technology techniques, such as serotyping (Bodhidatta et al. 2013).

Effective cheap and easy-to-apply interventions for the control and prevention of campylobacteriosis remain a major challenge for LMIC, where food chain regulations would be difficult to implement. Nevertheless, the eating and handling of raw or improperly cooked poultry meat has been shown to be the most common source of human campylobacteriosis throughout the world. One (apparently) simple approach, therefore, is education to encourage the effective cooking of poultry meat. In Sri Lanka, the absence of *Campylobacter* contamination in chicken curries (Kulasooriya et al. 2019) indicated that such approaches were effective. However, *Campylobacter* contamination of chicken dishes identified in, both local and branded, Pakistani restaurants (Arshad and Zahoor 2019) indicate that kitchen hygiene is also important.

Overall, the paucity of information available on the epidemiology of campylobacteriosis in LMIC highlights the need for active food safety surveillance in these countries using state-of-art technologies and approaches.

8.5 Sources and Transmission Pathways of Human Campylobacteriosis

Although *Campylobacter* is considered mainly a foodborne pathogen, there is evidence for other transmission pathways, including contact with colonized animals and environments contaminated by their waste products, as well as, rarely, infected

people in conditions of poor hygiene (Mughini Gras et al. 2012, 2013, 2014, 2021b). It is well recognized that *Campylobacter*-containing gut contents can enter the food chain by contaminating various food products of animal origin, including meats and dairy products. Cross-contamination during food preparation at home is also an important transmission route (Bai et al. 2021). Alternative routes with animals as sources include exposure to environments contaminated by primary production (e.g., run-off from livestock in farms and at pasture, water used for cleaning animal-containment areas, stockpiled sewage, etc.). *Campylobacter* survives for long periods in surface waters, so such contamination might pose a risk to humans through the drinking of untreated water, recreational activities, or the consumption of fresh produce irrigated or washed with manure-contaminated water.

8.5.1 *Campylobacter* Source Attribution

A general framework for source attribution of campylobacteriosis has been designed (Wagenaar et al. 2013). Based on this framework, animals (e.g., cattle, sheep, poultry, etc.) are defined as *reservoirs* or *amplifying hosts*; the environment, the food chain, and direct contact with animals are given as examples of *pathways*; drinking water, meat, milk, and occupation are given as examples of *exposure*; and examples of *risk factors* include swimming in rivers, eating chicken meat, beef, etc. In a typical example, cattle (reservoir) may contaminate the food chain (pathway) resulting in a hazard in the milk supply (exposure), which manifests itself as an increased risk associated with the consumption of unpasteurized milk (risk factor) (Wagenaar et al. 2013).

Source attribution models provide an estimate of the relative contribution of the different known reservoirs to the burden of human illness. They can be used to inform decision makers in order to target the most effective intervention strategies and are, therefore, an important tool for risk management (Pires et al. 2009). Several approaches can be used for source attribution, including microbiological (e.g., microbial subtyping) and epidemiological (e.g., outbreak investigations and case-control studies) approaches and intervention studies (Pires et al. 2009). Structured expert opinions and comparative exposure assessment can also be used for source attribution, but will not be considered here.

8.5.1.1 Source Attribution Based on Outbreak Data

Most *Campylobacter* infections are sporadic. As an example, in Europe in 2019, the total number of reported campylobacteriosis cases was 220,682, of which only 1254 were related to outbreaks (EFSA and ECDC 2021). Outbreak data is, therefore, generally considered of limited value for campylobacteriosis because of the rarity of reported outbreaks (Pires et al. 2010). *Campylobacter* outbreaks, however, may occur more frequently, but are often unreported due to the generally intermittent typing of clinical isolates. Indeed, the added value of high-throughput sequencing methods for campylobacteriosis outbreak investigation has been shown in several occasions, such as during the large waterborne campylobacteriosis outbreaks that

occurred in New Zealand, in 2016 (Gilpin et al. 2020). An estimated 6260–8320 campylobacteriosis cases were linked to the contamination of an untreated, groundwater-derived drinking water supply. Of the 12 different *Campylobacter* genotypes observed in the clinical cases, four were also retrieved from water, three from sheep, and one from both water and sheep. The outbreak was traced back to contamination of the water supply after a heavy rainfall event that caused drainage of sheep feces into a shallow aquifer. The existence of a routine clinical surveillance for campylobacteriosis, coupled with early testing of water for pathogens and genotyping of *Campylobacter* isolates from human cases and potential sources, facilitated outbreak detection and helped define its source, as well as confirm outbreak periods and cases. Similar experiences are increasingly being documented for foodborne campylobacteriosis outbreaks as well (Sorgentone et al. 2021). Moreover, using data of the New Zealand outbreak, it has been shown that alternative data sources (i.e., general practitioner consultations, consumer helpline, Google Trends, Twitter microblogs, and school absenteeism) can provide earlier indications of the outbreak as compared to conventional case notifications (Adnan et al. 2020). Routine application of WGS to *Campylobacter* isolates is already a reality in several governmental agencies, industry, and academia. The ever-growing availability of sequencing data as well as the creative exploitation of alternative data sources are expected to improve our ability to detect and characterize *Campylobacter* outbreaks, including source tracing and root cause determination of contamination events (Franz et al. 2016).

Although scarce, campylobacteriosis outbreak data is collected annually in Europe and has been used to estimate the causative vehicles for the years 2005–2006 (Pires et al. 2010). Putative sources rank differently depending on whether the data was analyzed in terms of either the proportion of outbreaks or the proportion of infected individuals reported. The majority (~64%) of outbreaks had no identified source, while ~12% were attributed to meat products as a whole and ~10% specifically to chicken. In contrast, in terms of ill individuals, the majority (~44%) was attributed to travel, ~17% to putatively contaminated drinking water, 10% each to meat and chicken, and 36% were of unknown source. Although the ranking of source importance seems different, chicken remains an important source regardless of the approach taken. Indeed, the authors report that "among illnesses that could be attributed to a source, 29% of campylobacteriosis cases were attributed to chicken" (Pires et al. 2010).

8.5.1.2 Source Attribution Based on Case-Control Studies

Case-control studies have been used in several countries to identify those risk factors associated with sporadic *Campylobacter* infections. Overall, these studies indicate that the handling and consumption of chicken meat is a very important risk factor (Doorduyn et al. 2010; Domingues et al. 2012; MacDonald et al. 2015; Mossong et al. 2016; Rosner et al. 2017; Kuhn et al. 2018). Other frequently identified risk factors include the consumption of unpasteurized milk (Friedman et al. 2004; Mughini Gras et al. 2021b), eating in restaurants (Friedman et al. 2004; Danis et al. 2009), contact with pet dogs (especially puppies) (Friedman et al. 2004;

Doorduyn et al. 2010; Mughini Gras et al. 2013; MacDonald et al. 2015; Mossong et al. 2016; Kuhn et al. 2018), contact with livestock (Friedman et al. 2004; Danis et al. 2009; Mughini Gras et al. 2012; Rosner et al. 2017), and foreign travel (Friedman et al. 2004; Doorduyn et al. 2010). The calculations of the attributable fractions for each risk factor also indicate that, like the outbreak data, chicken consumption accounts for 28–31% of sporadic cases (Doorduyn et al. 2010; MacDonald et al. 2015; Rosner et al. 2017; Kuhn et al. 2018). In contrast, the contribution of dog ownership is 4–8% (Doorduyn et al. 2010; MacDonald et al. 2015), but it can go up to 21% in children under 5 years (Kuhn et al. 2018). Of course, many factors can influence source attribution studies using case-control data. For instance, individuals taking proton-pump inhibitors or having a chronic gastrointestinal disease have increased risk of campylobacteriosis (Doorduyn et al. 2010; Mughini Gras et al. 2012; Rosner et al. 2017; Kuhn et al. 2018; Fravalo et al. 2021), probably as a consequence of reduced gastric acidity allowing the survival of *Campylobacter* during passage through the stomach and/or disturbed gut function facilitating intestinal infection.

A recent systematic review and meta-analysis (Fravalo et al. 2021), which synthesized the evidence provided by 71 eligible case-control studies on risk factors for sporadic *Campylobacter* infection, highlighted the importance of other, less common risk factors beyond chicken consumption. These include consumption of food products like beef, eggs, and dairy, especially when consumed raw/undercooked, but also non-foodborne transmission routes like contact with animals and environmental sources. For example, occupational exposure to animals or products thereof, such as working in a slaughterhouse, farm, pet shop, or zoo, as well as working in food handling/preparation, emerged as significant risk factors. The same applied to (non-occupational) contact with farm animals, wild animals and pets, and environmental exposure to playground sandpits, rural environments, or recreational waters, with these non-foodborne risk factors, as well as person-to-person transmission, being particularly important among children (Fravalo et al. 2021).

Specific immunity against *Campylobacter,* acquired as a result of prior exposure, is another very important confounder of case-control studies (Havelaar and Swart 2016). Certainly, repeated exposure to pathogens, such as *Campylobacter*, may lead to sufficient immunity to provide protection against severe clinical illness (Swift and Hunter 2004). Such immunity can lead to individuals being protected from disease, even when colonized (Havelaar et al. 2009; Havelaar and Swart 2016), and this has been proposed as an explanation of why, in some instances, the regular consumption of poultry meat (at home) is identified as a protective, rather than a risk factor (Friedman et al. 2004). Acquired immunity also provides an explanation of why either the very frequent consumption of chicken meat or never consuming it, are risk factors for campylobacteriosis (Mughini Gras et al. 2021b). Indeed, people who frequently consume chicken are highly exposed to chicken-associated *Campylobacter* strains and therefore are at increased risk of falling ill with these strains because the levels of exposure to these strains are too high to allow acquired immunity to exert any protective effect. Conversely, people who do not eat chicken meat would not be exposed to these strains at all, and therefore would be unable to develop any

immunity against them, thereby falling ill more easily upon incidental exposure to them via, e.g., cross-contamination of other food items or non-foodborne transmission. It has also been shown that consumption of chicken meat is a risk factor for campylobacteriosis only or predominantly when this is consumed outside the household (Swift and Hunter 2004; Friedman et al. 2004; Mossong et al. 2016; Lake et al. 2021), which indicates that exposure to chicken-associated *Campylobacter* strains outside the household (e.g., at restaurants, catering events, etc.) would increase the chance of being exposed to (possibly higher doses of) specific *Campylobacter* strains different from those to which people are (usually) exposed at home (Mughini Gras et al. 2021b).

8.5.1.3 Source Attribution Based on Microbial Subtyping

As previously indicated, *Campylobacter* are highly phenotypically and genotypically variable. This variability has been exploited to develop subtyping strategies with the aim of determining sources of human infection. However, for various reasons including the high plasticity of the *Campylobacter* genome, the lateral transfer of genetic material among strains, the time delay to diagnosis, and the poor recovery from putative sources, the direct tracking of strains from source to human has not been feasible. However, the widespread application of MLST, as well as other genotyping methods with higher discriminatory power like cgMLST, allowed for the study of *Campylobacter* population structures and the conduction of source attribution analyses. Studies of the evolutionary relationships within populations reported that some *Campylobacter* strain features are preferentially associated with certain animal hosts. Thus, using complex statistical methods, the probable sources can be inferred by comparison of the *Campylobacter* strains recovered from diseased humans with those recovered from a range of animal, food, and environmental sources. Several MLST-based studies, reviewed by Cody et al. (2019), have provided in the past the first source attribution results for campylobacteriosis, showing that most (50–80%) strains infecting humans come from the chicken reservoir, 20–30% from cattle, and the remainder from other reservoirs (e.g., sheep, pigs, wild animals, etc.) (EFSA BIOHAZ 2010). However, in more recent years, the growing availability of WGS data allowed for genomic data with a much higher discriminatory power than MLST, such as cgMLST and wgMLST, to be used in source attribution studies (Pérez-Reche et al. 2020; Lake et al. 2021; Mughini Gras et al. 2021b; Harrison et al. 2021; Arning et al. 2021). While most human cases are still attributed to poultry, followed by cattle, the ability to better differentiate isolates based upon more than just seven MLST genes, coupled with the use of more powerful models, allow for more accurate attribution estimates. This includes better differentiation of host generalist, commonly occurring or clonally related strains.

While there is an apparent conflict between the importance of poultry as a source from case-control studies (20–40%) and from the genotyping studies (50–80%), this is explained by case-control studies being able to trace human cases back only to the level of exposure (e.g., food items consumed, contact with animals, etc.), while genotyping data indicates the original host reservoir. It has been hypothesized that

the difference reflects that *Campylobacter* strains may reach humans through pathways other than food, for example, through environmental exposure (EFSA BIOHAZ 2010) (section "Role of the Environment").

8.5.1.4 Intervention Studies

On the presumption that poultry is the major source of sporadic campylobacteriosis, there have been several incidents that have acted as "natural experiments," which have been investigated to determine the effect of reduced population exposure to *Campylobacter* in the food chain. For example, in 1999, contamination of animal feed with dioxin in Belgium resulted in a nationwide withdrawal of broiler meat from the market, which was concomitant with a 40% decrease in campylobacteriosis, countrywide (Vellinga and Van Loock 2002). Similarly, in 2003 in the Netherlands, an avian influenza outbreak led to a massive poultry cull, which was associated with a subsequent 30% decrease overall in campylobacteriosis (Friesema et al. 2012). This disease reduction varied between regions from 10% to 70%, with the largest fall reported in those laboratories' serving areas where the flocks were actually culled. This observation supports the hypothesis that there were important transmission routes other than the handling and consuming poultry meat (EFSA BIOHAZ 2010; Friesema et al. 2012). As yet, the transmission routes of such alternative pathways are unclear.

Other interventions targeted at the poultry production sector and/or to the poultry meat consumer, resulted in reduced exposure to national populations in Iceland and New Zealand. Following these interventions, the number of reported campylobacteriosis cases fell by 72% in Iceland (Stern et al. 2003) and by 54% in New Zealand (Sears et al. 2011). Furthermore, in New Zealand there was a concurrent 74% reduction in the proportion of poultry-associated campylobacteriosis cases as determined by source attribution using MLST (Sears et al. 2011) and 13% decline in hospitalizations for Guillain-Barré syndrome (Baker et al. 2012).

8.5.2 Role of the Environment

Campylobacter is often found in the environment, including surface water, where it usually indicates recent fecal contamination from animals, sewage, or agricultural run-off. *Campylobacter*'s fate in the environment is typically the one of die-off rather than growth. Although *Campylobacter* survives poorly outside the host, some specialist strains can survive better in certain sylvatic (Hepworth et al. 2011), farmland (French et al. 2005), and environmental (French et al. 2005; Sopwith et al. 2008; Colles et al. 2011) niches. These strains are generally more resistant to physical stress (Sopwith et al. 2008). *Campylobacter* can also assume a viable, but non-culturable state in response to advert conditions outside the host (Murphy et al. 2006).

Human *Campylobacter* infections of environmental origin exhibit strong seasonality (Mughini Gras et al. 2012). Indeed, *Campylobacter* survival in the environment is compromised by factors like high temperatures and sunlight, among others, and shedding from animals varies seasonally depending on stress, changes in diet,

housing conditions, rearing period, etc. Moreover, the pattern of human exposure to environmental sources (e.g., outdoor activities) is largely weather-dependent. Although the primary transmission route for human *Campylobacter* infection is contaminated food, source attribution studies have estimated that on top of the contributions of livestock and wild animals, the environment may account for a further 5–10% of human campylobacteriosis morbidity, with open water swimming, consuming game meat, and exposure to storm water overflows being a source of environment-borne campylobacteriosis (Mughini Gras et al. 2012, 2021b; Sales-Ortells et al. 2015; Mossong et al. 2016). Studies have also shown that heavy rainfall may lead to *Campylobacter* entering the drinking water supply system (Gilpin et al. 2020). Perhaps more importantly, water may act as a source for *Campylobacter* (re)colonization in livestock (Bull et al. 2006). Yet, the environment at large serves more as a vehicle of transmission for *Campylobacter* among animals, from animals to humans and vice versa, rather than as an amplifying reservoir per se.

Surface water represents a "sink" that collects *Campylobacter* strains from different (animal) hosts, whose individual contributions have been quantified in source attributions studies based on MLST (Mughini Gras et al. 2016) and cgMLST (Mulder et al. 2020). This latter study, conducted in the Netherlands, provides the most comprehensive data on the prevalence, genotypes, and animal sources of *Campylobacter* in surface water. Prevalence is the highest in agricultural waters (77%) and in autumn and winter (74%), and lowest in recreational (swimming) waters (46%) and in summer (54%), which concurs with *Campylobacter* being highly sensitive to sunlight and high temperatures. Overall, water isolates are mainly attributed to wild birds (84%) and poultry (10%). However, the probability for water isolates to originate from poultry is significantly higher in high poultry density areas, i.e., a geographical association exists between the magnitude of the local poultry industry and its role as source of microbial contamination of the environment. Similarly in the USA, it has been shown that communities with high-density poultry operations have higher incidences of campylobacteriosis and infectious diarrhea (Poulsen et al. 2018).

8.6 *Campylobacter* in Poultry and Intervention in Primary Production

Given that the majority of the infecting strains in humans come from chicken, targeting *Campylobacter* in poultry production has become the preferred public health measure (Koutsoumanis et al. 2020). The poultry meat chain can be viewed as two distinct stages: chicken rearing and production (largely on-farm to entry to the slaughter house) and poultry meat processing (largely lairage to retail). Theoretically, control measures focused on the primary production stage will prevent up to 80% of human cases, by preventing or reducing *Campylobacter* entering the food chain and the environment, while those measures targeted at the processing stage, can prevent only an estimated 42% of cases (Mughini Gras et al. 2012). Control of

Campylobacter in primary poultry production, however, has proved to be very difficult (Wagenaar et al. 2013).

Campylobacter colonization occurs in all types of commercially produced poultry (e.g., broilers, turkeys, ducks) (Wagenaar et al. 2006), but clearly the focus for intervention is broiler, as it forms the largest source of human infections. The prevention of *Campylobacter* in poultry is solely targeted at meat-producing birds. This is because vertical transmission is extremely rare, if at all (Callicott et al. 2006; Cox et al. 2012). Thus, each new broiler production cycle starts with *Campylobacter*-free chicken. In all-in/all-out production systems, poultry houses are cleaned, disinfected, and dried before the arrival of a new flock. Such preparation seems to be largely effective at preventing the carry-over of *Campylobacter* from previous flocks (Newell et al. 2011; Georgiev et al. 2017). Nevertheless, birds subsequently become colonized with the bacteria. Experimental studies indicate that the ingestion of as few as 40 organisms can cause colonization (Cawthraw et al. 1996). Once the first bird has been colonized, it sheds large numbers of bacteria in its feces (up to 10^7 cfu per gram), and most, if not all, the other birds in the flock become colonized within a few days. Thus, preventing the first bird becoming colonized seems to be a prerequisite for a *Campylobacter*-negative flock.

Broiler flocks are frequently exposed to the *Campylobacter* from their external environment throughout their limited lifespan (Newell et al. 2011). However, colonization does not usually become detectable until 2–3 weeks of age of the flock. This so-called "lag-phase" appears to be due to an inherent resistance in young chickens (Kalupahana et al. 2013) which is, at least in part, a result of maternal immunity (Cawthraw and Newell 2010).

By comparing *Campylobacter*-negative with -positive flocks, many risk factors and farm practices have been identified, which increase the chance of flock positivity (Newell et al. 2011; Sibanda et al. 2018). One major risk factor is the age of broilers at slaughter, which is most likely associated with exposure to external contamination over time and is a measure of the effectiveness of biosecurity. Other biosecurity-associated risk factors, such as multiple broiler houses on the farm, the presence of other livestock, partial depopulation (thinning), pets on the farm, etc., are also important. Nevertheless, no one biosecurity-related factor seems to predominate. Moreover, although improved biosecurity can decrease the risk of a flock becoming *Campylobacter*-positive, it seems that even strict biosecurity cannot guarantee a *Campylobacter*-free flock at the time of slaughter (Newell et al. 2011). In many countries, the biosecurity challenge seems even more difficult in the summer months, when the prevalence of *Campylobacter*-positive flocks increases significantly in response to some temperature-related factors (Jore et al. 2010). Some of this seasonal increase may be associated with transmission by flies. In Denmark, this risk has been significantly reduced by the application of fly-screens around broiler house ventilation systems (Bahrndorff et al. 2013). The efficacy may be country-dependent, i.e., related to weather conditions, as well as dependent on the biosecurity level already applied.

In Europe, improved biosecurity has been strongly recommended as the only currently available intervention measure to reduce flock positivity (Koutsoumanis

et al. 2020). However, the appropriate targeting of biosecurity measures has proved very frustrating for the poultry industry. Anecdotal evidence suggests the compliance of farmers with general biosecurity measures is essential and such compliance would be even more important in summer months (Koutsoumanis et al. 2020). The challenge is likely to become even greater in the future given consumer-driven concerns for animal welfare leading to an increasing trend toward the production of slower-growing animals with a longer lifespan and with outdoor access. Under such conditions good biosecurity is impractical (Kalupahana et al. 2013).

It is widely recognized that biosecurity alone cannot produce *Campylobacter*-negative flocks and that complementary measures will be required to increase the resistance to, or reduce the colonization of, birds with the bacterium (Koutsoumanis et al. 2020; Lu et al. 2020). Research into vaccination against *Campylobacter* is progressing, but not yet ready for practice (de Zoete et al. 2007; Nothaft et al. 2021). Neither is it yet possible to influence the intestinal flora to generate a *Campylobacter*-resistant avian gut (Schneitz 2005). The use of bacteriophages and bacteriocins looks promising (Wagenaar et al. 2005), but research to solve key issues in safety, efficacy, and sustainability is still needed (Olson et al. 2021). The use of medium chain fatty acids has been reported to have at least some effect on *Campylobacter* colonization (van Gerwe et al. 2010; Hermans et al. 2012; Jansen et al. 2014; Guyard-Nicodème et al. 2016), but the results require validation in the field.

Thus, it currently seems that improved biosecurity is the only credible measure available to decrease the prevalence of *Campylobacter*-positive flocks. However, as indicated above, the identification of specific and effective biosecurity approaches has proved very difficult. Thus, a wide range of high-level biosecurity measures need to be consistently maintained throughout the life of intensively reared flocks. This is often impractical, especially when *Campylobacter* colonization is asymptomatic, and therefore with no consequent economic loss to providing an incentive for the poultry farmer.

8.7 Post-Harvest Control Measures in Poultry

When *Campylobacter* colonization cannot be prevented at the farm level, post-harvest treatment becomes very important. Such treatments include the prevention of cross-contamination and the application of chemical or physical methods of decontamination in the slaughterhouse. The availability and effectiveness of such methods, with particular relevance to Europe, have been reviewed previously (Koutsoumanis et al. 2020).

Cross-contamination can be a significant problem associated with the huge throughput of carcasses (circa 13,000 per hour in many processing plants), slaughter line automation, and the high concentrations of *Campylobacter* in cecal contents. Any leakage of fecal material, or rupture of the gut during evisceration, can lead to surface contamination of the meat. Interestingly, there are statistically significant differences, in the level of carcass contamination between slaughterhouses (EFSA 2010), suggesting that some processing plants are better than others at controlling

this problem. However, the basis of these differences has yet to be determined (Koutsoumanis et al. 2020).

The decontamination of carcasses with chemicals is allowed in the USA and currently practiced using several chemicals, such as organic acids, quaternary ammonium compounds, acidified sodium chlorite, and trisodium phosphate. Although the decontamination of carcasses with chemicals is allowed in the EU, specific approval is required and currently no chemic decontaminants have been approved for use on chicken carcasses.

Some physical treatments (e.g. ,ultraviolet, ultrasound, etc.) have been specifically applied to reduce *Campylobacter* on chicken carcasses, but their effectiveness is usually limited to a reduction of only 1–2 $\log_{10}$. Highly effective irradiation procedures are poorly accepted by consumers and difficult to implement under high throughput conditions. The freezing of carcasses from positive flocks can reduce *Campylobacter* concentrations by 2–3 $\log_{10}$ and this strategy has been effectively used in Iceland as part of a program to reduce human campylobacteriosis (Stern et al. 2003). However, from both the logistic and the economic (i.e., the preference of consumers for fresh meat) viewpoints, such a strategy would be difficult to implement, especially in those countries with high prevalence of *Campylobacter*-positive flocks (Havelaar et al. 2007).

8.8 Interventions and Public Health Impact

The potential public health impact of intervention measures in the poultry production chain are clearly demonstrated in two successful examples from Iceland and New Zealand (see section "Intervention Studies").

In Iceland, multiple-level measures were implemented (including producer and consumer education, enhanced biosecurity, changes in poultry processing, and the identification and freezing of products from *Campylobacter*-positive flocks) in response to a sharp increase in campylobacteriosis in 1999 (Tustin et al. 2011). As mentioned before, this spectrum of measures resulted in a 72% reduction in the incidence of campylobacteriosis (Stern et al. 2003). Of all these measures, the freezing of contaminated products is considered the most important (Tustin et al. 2011). In New Zealand, a 54% reduction in the incidence of campylobacteriosis was similarly achieved as a consequence of the introduction of a range of voluntary and regulatory measures (Müllner et al. 2010; Sears et al. 2011; Baker et al. 2012).

Given these successes, it is tempting to extrapolate those approaches implemented in New Zealand and Iceland to other countries. However, in both cases, specific conditions prevailed and, therefore, success in disease reduction in other countries may not be predictable. While highly effective interventions against *Campylobacter* in broiler farms remain elusive, slaughterhouses in the EU have been set up to keep *Campylobacter* contamination in broiler carcasses under control. Indeed, since 2018, a process hygiene criterion (Commission Regulation EU 2017/1495), with a limit of 1000 CFU/g of neck skin, has been implemented among EU Member States. This limit was based on a Scientific Opinion of the European Food

Safety Agency (EFSA) on control options for *Campylobacter* along the poultry meat production chain and their estimated impact on the reduction of the number of human campylobacteriosis cases (EFSA BIOHAZ 2011). The EFSA estimated a public health risk reduction of more than 50% if carcases complied with the aforementioned process hygiene criterion. Moreover, a cost-benefit analysis indicated that a process hygiene criterion for *Campylobacter* in broiler carcases would provide one of the best balances between reduction of human campylobacteriosis cases attributed to broiler meat and the economic consequences of the application of such criterion (EC Europe 2012). A step-by-step approach would also be recommendable, making the process hygiene criteria gradually stricter over time.

8.9 *Campylobacter* in Poultry – The Future

Given that *Campylobacter* is a part of the normal gut flora of birds (and is a highly successful colonizer of that site), the increasing consumer demand worldwide for low cost chicken meat (while expecting higher animal welfare during production) and the steady reduction in human populations with acquired immunity (either due to lack of natural exposure or to increased susceptibility through age, disease or medication), campylobacteriosis will remain a major foodborne pathogen in most countries (Newell et al. 2010). At the moment, the reliable production of *Campylobacter*-negative flocks, through best-practice biosecurity alone, seems unlikely. In the future, effective vaccines and/or other complementary measures should be achievable outcomes of current research. Although, such measures may not totally eliminate colonization, significant reductions in colonization levels may be feasible. In this case, risk assessment studies show that a significant reduction in public health risk can still be achieved (Nauta and Havelaar 2008). Once chicken is no longer a major source of *Campylobacter*, the importance of other animal reservoirs and transmission routes can be identified and tackled.

Acknowledgments This study was supported by the Netherlands' Organization for Health Research and Development (ZonMw) with grant number 50-52200-98-316 (project name: "DEPiCT – Discerning Environmental Pathways of Campylobacter Transmission").

Abstract

Salmonella are ubiquitous and robust pathogens, which are often transmitted via food. Especially poultry and poultry products, but also pork and plant-based foods, play an important role as vehicles. They are widely distributed and often spread unnoticed along the farm to fork continuum. Their entry can take place at various points along the food chain ending up in animal and nonanimal derived, *Salmonella*-contaminated food. *Salmonella* can be host-restricted, host-adapted, or of broad host range, but only a relatively small proportion of the about 2600 described serovars have significant clinical relevance. Among these, serovars *S.* Enteritidis and *S.* Typhimurium represent the most prevalent serovars worldwide, together accounting for about 75% of all reported cases with a specified serovar in Germany. Both have a broad host range and likewise infect humans and various animal species (including invertebrates). Depending on serovar, ingested dose, and immunocompetence of the host, *Salmonella* infections differ substantially in their clinical manifestations, ranging from an asymptomatic state to severe illness. Foodborne outbreaks provoked by *Salmonella* are frequently described and range from temporally restricted regional occurrences to protracted, multinational events with hundreds of cases. Whole-genome sequencing (WGS) data is an important tool for bacterial typing, outbreak investigation, source tracking, and surveillance, and its application is highly encouraged by international authorities. By now, numerous examples of the utile application of WGS have been given in different countries and contexts for *Salmonella,* emphasizing its capacity to identify potential outbreak vehicles, support epidemiological studies, and food safety activities, finally aiming for the prevention of further cases.

Keywords

Salmonella enterica · Salmonellosis

9.1 The Zoonotic Agent *Salmonella*

Salmonella is a facultatively anaerobic, rod-shaped, and flagellated gram-negative bacterium. Based on the currently applied nomenclature for the genus *Salmonella,* two species have been described: *Salmonella (S.) bongori* and *Salmonella (S.) enterica*, with *S. enterica* further divided into six subspecies by biochemical characteristics (Tindall et al. 2005). Recent genome-based studies even propose 11 subspecies (Alikhan et al. 2018; Pearce et al. 2021). In total, both species comprise more than 2600 serovars (Issenhuth-Jeanjean et al. 2014). While *S. bongori* and the *S. enterica subspecies II (salamae), IIIa (arizonae), IIIb (diarizonae), IV (houtenae)*, and *VI (indica)* are predominantly related to cold-blooded animals and considered to be of minor clinical relevance (Brenner et al. 2000), *S. enterica subspecies I (enterica)* is responsible for about 99% of human salmonellosis cases (Lamas et al. 2018). The >1500 *subspecies I* serovars form a group of pathogens that differ widely

in their host range within mammals, birds, and reptiles. They can also differ substantially in clinical manifestations, ranging from an asymptomatic state to severe illness (Jones et al. 2008). Serovars can be host-restricted (e.g., *S.* Typhi in humans and higher primates), host-adapted (e.g., *S.* Choleraesuis in pigs and infrequently in humans), or of broad host range (e.g., *S.* Typhimurium, *S.* Enteritidis), infecting various avian and mammalian hosts with a wide spectrum of diseases. Up to now, the traditional *Salmonella* serotyping scheme according to White-Kauffmann-Le Minor (Grimont and Weill 2007) is accepted worldwide as the "gold standard" for the classification of *Salmonella* below the subspecies level. However, this phenotypic approach has been challenged by the emergence of molecular typing methods (Achtman et al. 2012b) and will be presumably replaced by whole genome-based methods in the near future (Ashton et al. 2015). The majority of human cases are caused by only a few non-typhoidal serovars and the overall number of reported human *Salmonella* infections in Germany dropped dramatically during the last three decades from 195,000 in 1992 (Bundesamt 1993) and still 77,000 in 2001 (Robert Koch-Institut 2002) to 13,500 cases in 2019 (Robert Koch-Institut 2020). Among these, *S.* Enteritidis and *S.* Typhimurium represent the most prevalent serovars, together counting for about 75% of all reported cases with specified serovars (Robert Koch-Institut 2020). In accordance to this, meat/meat products and eggs/egg products are still regarded as the most common vehicles of transmission (EFSA and ECDC 2013). However, in recent years, transmission through foods of nonanimal origin has been increasingly reported (Da Silva Felício et al. 2015; Dyda et al. 2020; Krtinić et al. 2010) and typically rare serovars account for a considerable number of large foodborne outbreaks (see Table 1). In this chapter, we focus on the zoonotic potential of *Salmonella enterica,* emphasizing its prevalence in different animal hosts, various foods, and humans, and the shift of surveillance tools to next-generation sequencing as new standard.

9.2 *Salmonella* in Animal and Food

Salmonella is widely spread and often unnoticed along the farm to fork continuum. Their entry can take place at various points along the food chain ending up in animal- and nonanimal derived, *Salmonella*-contaminated food (Hazards 2013).

Salmonella are ubiquitous and are able to withstand harsh conditions in the environment. Growth requirements of *Salmonella* are low, compared to other bacteria. They are able to grow in temperature ranges from 10 °C to 48 °C or even 6–8 °C, at pH values of 4.5–9, and a minimal a_w value (depending on substrate and temperature) of >0.93 (Alvarez-Ordóñez et al. 2010; Alvseike et al. 2000; Dewanti and Doyle 1992; Himathongkham et al. 1999; Matches and Liston 1972; Oscar 2003). However, survival in dried food was even possible at far less water activity levels ($a_w < 0.6$) (Santillana Farakos et al. 2013). Thus, *Salmonella* is able to survive extended time in farm surroundings, dust, soil, feed, or food processing plants. This allows horizontal transmission to the livestock sector and productions systems of

food of nonanimal origin (FoNAO) (Finn et al. 2013; Habimana et al. 2014; Jechalke et al. 2019; Liljebjelke et al. 2005; Marin et al. 2009; Skov et al. 2008). *Salmonella* are also found in cold-blooded animals such as reptiles or insects, which may act as vectors to reach or spread from their main reservoir, the gastrointestinal tract of warm-blooded animals (Corrente et al. 2017; Pulford et al. 2019; Vandeweyer et al. 2021). Wildlife animals are also frequently reported to carry *Salmonella* (Skov et al. 2008; Uelze et al. 2021b). However, the main focus is set on livestock animals, due to the risk of subsequent transmission to derived foodstuff. In this context, vertical transmission from parents to progeny (e.g., from chicken to eggs) plays an important role (Liljebjelke et al. 2005). Infected farm animals can be asymptomatic, healthy-looking carriers, but acute and chronical disease symptoms or dying animals due to a *Salmonella* infection are possible as well (Gutema et al. 2019; Suzuki 1994). Animals can shed relatively large numbers of *Salmonella* in the feces over a long period of time. Infection with host-adapted serovars, such as *S.* Gallinarum (in poultry) or *S.* Dublin (in cattle), can severely affect the livestock production with high mortality rates (Mcdonough et al. 1999; Schat et al. 2021). Meanwhile, non-adapted serovars – among them the most relevant ones in human infections: Enteritidis and Typhimurium – often spread asymptomatically within herds replacing the eradicated host-specific serovars as matter of concern. Although causing no symptoms in animals, those non-adapted serovars cause severe health issues in humans. The incidence of *Salmonella* in livestock depends on several factors such as the conditions for intensive animal husbandry, hygiene measures, and climate conditions. The incidence of *Salmonella* in Northern countries is often lower than in those located in warmer climate zones. Furthermore, *Salmonella* cases are subject to a seasonal variation with higher rates in the summer and autumn, and a decline in the winter months (EFSA and ECDC 2021c).

Consequently, the control of *Salmonella* in food-producing animals preharvest is imperative to avoid the transmission along the food chain to humans. Usually, in

developed countries, livestock is regularly monitored in order to estimate the prevalence of the pathogen and serovars and to perform control measures. Such control measures include the application of vaccine strains of relevant serovars to herds of livestock to improve subsequent foodstuff safety, rather than the prevention of salmonellosis in animals.

Food processing, such as the slaughter process of the animals, raw fruits and vegetables, or infant formula processing lines are further possible points of contamination (Bolton et al. 2003; Ehuwa et al. 2021; Kent et al. 2015; Artes et al. 2007). Therefore, at the food processing and retail levels, *Salmonella* surveillance is continued, and, e.g., food safety criteria are laid down in the context of the EU Commission Regulation (EC) No 2073/2005. Here, i.e., the absence of *Salmonella* in 25 g of most listed food types is regulated. This includes a variety of foods such as meat products, eggs, infant formula, milk products, ready-to-eat-food, seafood and snails, sprouts, as well as cut fruits and vegetables. In the last few years, *Salmonella*-associated outbreaks have additionally shed a light on uncommon *Salmonella* serovars. These are often associated with "new" vehicles that attracted attention and should be considered in food safety management, notably for foodstuffs with low water activity (tahini, chocolate, dried fruits, food supplements, and tea) (EFSA 2021; EFSA and ECDC 2018).

9.2.1 Salmonella in Poultry and Poultry Products

Poultry represents the major putative source for non-typhoidal salmonellosis infections in humans (CDC and FDA 2021; Thomas et al. 2020). Especially, *S.* Enteritidis, which had been found since the 1980s to contaminate poultry flocks worldwide (often asymptomatically), is today a dominant serovar in, e.g., laying hens and broilers in the EU and still remains a global problem for public health (Baumler et al. 2000; Ferrari et al. 2019; Li et al. 2021). Contamination in poultry production might take place via horizontal transmission through feed, the farm environment, and live vectors (e.g., rodents or insects), as well as via vertical transfer in hen reproduction (Liljebjelke et al. 2005; Okamura et al. 2001).

In Europe, baseline surveys (2004–2005) on the prevalence of *Salmonella* in, e.g., commercial large-scale laying hen holdings showed that 30.8% of the flocks of *Gallus gallus* were *Salmonella* positive (EFSA 2007). Subsequently, control programs were established in Europe (Directive 2003/99/EC and Regulation (EC) No 2160/2003) aiming at reducing the prevalence of predominant target serovars such as *S.* Enteritidis and *S.* Typhimurium in poultry (i.e., in laying hens (Commission regulation (EU) No 517/2011) and broiler flocks (Commission regulation (EU) No 200/2012) of *Gallus gallus* and in breeding and fattening flocks of turkeys (Commission regulation (EU) No 1190/2012). In breeding hen, further target serovars were included, namely *S.* Infantis, *S.* Hadar, and *S.* Virchow (Commission Regulation (EU) No 200/2010).

Since the beginning of the control programs in 2008, target serovar prevalence has shown an overall decreasing trend since 2009. Target prevalence for breeding (target prevalence of 1%) and laying hen (target prevalence of 2%) has been met,

with a few states missing the criteria (e.g., in 2019, up to 5 out of 27 states reported data for breeding flocks of *Gallus gallus*). Otherwise, the trends in prevalence of *Salmonella* target serovar-positive flocks were rather stable from 2015 for all poultry categories. However, increasing *Salmonella* prevalence trends point at the issue of certain successful clonal lineages with high fitness spreading in different animal populations, such as *S.* Infantis in broiler flocks (EFSA and ECDC 2021b). Predominant serovars in poultry all over the world are reported to vary among different regions. For example, in the USA, *S.* Kentucky is often isolated, as well as *S.* Heidelberg, which is also common in, e.g., Brazil (Foley et al. 2013; Golden and Mishra 2020; Shah et al. 2017). Poultry-adapted serovars *S.* Gallinarum and *S.* Pullorum, which in the last century have caused great damage to the poultry industry, are, in contrast to, e.g., Asia, no longer an issue in European and North American poultry flocks nowadays due to past eradication programs (Kumar et al. 2019; Wang et al. 2020).

In the USA, data from 2017 and 2018 show a prevalence of *Salmonella* in chicken (cecal) of 38% and 46% and 14% and 15% in turkey (cecal content) (FDA 2022). Thomas et al. (2020) reported an adjusted *Salmonella* prevalence of 13.9% in poultry samples in Africa.

While eggs and egg products account for most of the strong-evidence salmonellosis foodborne outbreaks in the EU (EFSA 2018–2020), findings of *Salmonella* in eggs in the EU are rare. From 2016 to 2019, 78 (0.28%) out of 28,190 eggs and egg product samples (non-ready-to-eat-food) were *Salmonella*-positive. Nevertheless, several *Salmonella* outbreaks linked to eggs have caught attention in recent years (EFSA 2014a; EFSA and ECDC 2020, 2022). Despite control programs on poultry primary production levels in the EU, percentage of *Salmonella* positive samples is still the highest in poultry meat, e.g., fresh broiler meat at 6.79% or turkey at 5.99% between 2016 and 2019. TOP serovars found in both matrices are *S.* Infantis and *S.* Enteritidis (EFSA and ECDC 2021c).

9.2.2 Salmonella in Pork and Pork Products

Pork is regarded as another important source for human salmonellosis (EFSA and ECDC 2021c; Pires et al. 2011). Pig meat and products thereof range second in the EU TOP food vehicle (following egg and egg products) causing strong-evidence *Salmonella* outbreaks, while in the USA, pork is the third food category (first chicken, second fruits) attributed to *Salmonella* illnesses (CDC and FDA 2021; EFSA and ECDC 2021c). In animal production, European data from 2019 and 2020 revealed 36% (17 states, 66,624 samples) and 27.9% (10 states, 56,008 samples) positive pig samples (EFSA and ECDC 2021b, c). In the USA, data from the NARMS Update listed up to 50% of market swine cecal samples in 2017 (1008 samples) and up to 61% of sows cecal samples in 2018 *Salmonella*-positive (FDA 2022). *S.* Typhimurium together with its monophasic variant 4,[5],12:i:- is one of the most common serovars isolated from pigs in both, Europe and the USA (EFSA and ECDC 2021c; Morningstar-Shaw et al. 2016). The monophasic variant started to

emerge in Europe in the mid-1990s beginning from Spain (Echeita et al. 1999). In the EU, *S.* Typhimurium 4,[5],12:i:- meanwhile became one of the most frequently isolated serovars from pigs and pork. Noteworthy, the dominant host-adapted serovar Choleraesuis in Europe (Sojka et al. 1977) decreased dramatically since the 1950s and 1960s and is today very rarely isolated in European pig production. However, it remains predominant in wild boars. The second predominant serovar in pigs is *S.* Derby, which causes mainly asymptomatic infections in pigs (EFSA and ECDC 2021c). In pigs and pig meat, *Salmonella* Derby ranks in the top two in Europe (EFSA and ECDC 2021c). Similarly, *S.* Derby is the third most frequently isolated in clinical and nonclinical cases of pigs in the USA, while *S.* Typhimurium monophasic and biphasic variants ranked separately first and second in 2016 (Morningstar-Shaw et al. 2016). In fresh pig meat, the rate of *Salmonella*-positive tested samples in Europe from 2016 to 2019 was 1.94% (EFSA and ECDC 2021c). The serovar distribution in pig meat is similar compared to pigs at the primary production level, reflecting the transmission of the serovars along the food chain.

9.2.3 Salmonella in Cattle and Bovine Products

Although foodborne illness due to contaminated beef products is less often reported compared to poultry or pork, bovine-associated *Salmonella* outbreaks have caught attention in the past. In cattle, the prevalence of *Salmonella* is generally significantly lower than in poultry or pigs. A rate of 3.3% and 3.4% in 2019 and 2020, respectively, on animals and 7.6% (2019) at the slaughterhouse level (animals) was detected in the EU (EFSA and ECDC 2021c). In North America, *Salmonella* pooled prevalence in healthy cattle was determined in a meta-analysis at 16% (2000–2017), while in the USA, 9% of cecal beef samples were *Salmonella*-positive in 2018 (Gutema et al. 2019; FDA 2022). Bovine salmonellosis is often associated with cattle-host-adapted serovar *S.* Dublin, but *S.* Typhimurium (including the monophasic variant) infection may also cause bovine *Salmonella* symptoms (Wallis and Barrow 2005). In the EU, the overall prevalence of bovine foodstuffs was low. Between 2016 and 2019, it was 0.34% in non-ready-to-eat meat and meat products from bovine animals, and in fresh meat from bovine animals 0.28% (EFSA and ECDC 2021c). In the USA, ground beef was analyzed at 1% positive for *Salmonella* in 2018 (FDA 2022).

9.2.4 Salmonella in Plant-Based Food

Salmonella infections are increasingly reported to be linked to the consumption of food of nonanimal origin (FoNAO) (Olaimat and Holley 2012; Lynch et al. 2009; CDC and FDA 2021). In the EU, *Salmonella* ranked as the most common causative agent causing outbreaks linked to FoNAO. Leafy greens eaten raw as salads, bulb and stem vegetables, tomatoes, and melons were the most common FoNAO products involved in outbreaks (2013). In the USA, fruits are estimated to be the main cause

of plant-based foodborne salmonellosis, responsible for 13.5% of human *Salmonella* infections in 2019 (CDC and FDA 2021). *Salmonella* is detected in further FoNAO matrices, such as spices and herbs, bakery products, sprouts, cereals, and nuts, but at very low levels (0.1–0.8%) in the EU (EFSA and ECDC 2021c). Various serovars could be detected in diverse spice matrices in the USA, from domestic as well as imported products. Worldwide, different studies on the prevalence of *Salmonella* in spices and herbs ranged from 0% to 5.6% (Zweifel and Stephan 2012).

Worldwide trade, large-scale productions, and changing consumption behaviors aiming at a convenient and healthy diet (ready-to-eat products, increasing demand for fresh produce) contribute to the rising infection risk. Epidemic outbreaks of foodborne infections are not only a threat to public health but also erode consumer confidence in the causal food product and thus affect the economic viability of the industry. Contamination of plant-based food with *Salmonella* might occur at various production stages. Applications of manure or compost, fertilizers, pesticides, or the use of contaminated irrigation water are described as the main risk factors (2013). Furthermore, environmental factors, such as proximity to animal rearing operations, seasonality, and associated climatic conditions might increase the transfer of *Salmonella* from those reservoirs. Further contact with animal reservoirs such as wild life or insects poses another contamination source. Post-harvest cross-contamination on the farm or by food handlers and equipment can occur through washing, packaging, and transport processes (Zweifel and Stephan 2012; Park et al. 2012; Beuchat 2002).

Although the low water activity of spices or dried herbs does not support *Salmonella* growth and many spices have inhibitory compounds that show antibacterial activity against *Salmonella*, contamination levels of up to 10% could be detected. The survival of *Salmonella* in those dried products for an extended period of time is promoted by its resistance against desiccation (Keller et al. 2013). In general, concentrations of *Salmonella* in spices are low, and due to the low amount of spices used for food preparation, the dose of *Salmonella* intake might be smaller than in other foodstuffs with similar *Salmonella* contamination levels (Chitrakar et al. 2019).

Colonization of crop plants with *Salmonella* are mainly due to surface (cross-) contaminations, but internalization of *Salmonella* into plant tissues was also proven and poses a concern for public health (Zarkani and Schikora 2021; Park et al. 2012). Consequently, cleaning and disinfection can be ineffective to remove the pathogen before consumption. The identification of routes of plant contamination by *Salmonella* is crucial to the design of intervention strategies to prevent contamination from taking place (Brandl and Sundin 2014). Zarkani and Schikora (2021) summarized mechanisms implicated in *Salmonella* interactions with crop plants that enable *Salmonella* colonization or persistence on or in plant tissues. Different strategies based on *Salmonella* adaptation mechanisms, avoidance, or suppression of the plant's immune system are described in the literature, considering the genetic variation of both the plant and the microorganism in determining the efficiency of colonization and persistence (Zarkani and Schikora 2021). Further external influences like the co-colonization of other established epiphytic bacteria such as *Pseudomonas fluorescens* and *Erwinia herbicola* (*Pantoea agglomerans*) influence the ability of *Salmonella* to persist on plants (Poza-Carrion et al. 2013).

9.2.5 Salmonella in Seafood

Salmonella in seafood is rarely detected in the EU and is only reported from single Member States, underlining that seafood is not a common reservoir for *Salmonella*. However, occurrence of *Salmonella* from seafood is described worldwide with different serovars dominating in different continents, such as the serovar *S.* Hadar in Latin America and Africa, *S.* Typhimurium in Europe, *S.* Weltevreden in Asia, and *S.* Newport in North America (Ferrari et al. 2019). In some countries, especially India and African countries, *Salmonella* may reach contamination levels of up to 24% at retail markets (Olgunoğlu 2012; Prabhakar et al. 2020). *Salmonella*-related foodborne outbreaks related to seafood consumption occur occasionally and were reported from the USA, Japan, and the EU (Ferrari et al. 2019; Barrett et al. 2017; Li et al. 2013). In the USA, *Salmonella* is the most common bacterial causative agent in fish and fishery products, leading to large human outbreaks. The percentage of foodborne *Salmonella* illnesses caused by fish or other seafood in the USA was estimated as 2.6% or 1.4%, respectively, with tuna being one of the main sources of infection (Barrett et al. 2017). Shrimp can be another major source of *Salmonella*. The prevalence of *Salmonella* in fresh shrimp at processing plants can reach 10–14%, and in the USA, seafood was described as the product with the most violations for *Salmonella* (Barrett et al. 2017; Wan Norhana et al. 2010). The occurrence of *Salmonella* in fish and shellfish is often a sign of low control measurement at the primary production level and poor standards of hygiene and sanitation during processing, handling, and transport and might be intensified by anthropogenic contamination of coastal waters (Olgunoğlu 2012; Prabhakar et al. 2020).

9.2.6 Salmonella in Insects

Nowadays, insect-based food is discussed intensively and might capture the European market due to insects as alternative protein sources to combat issues coming up with growing world population and increasing demands on an optimized nutrient composition in food, enabling simultaneously sustainable food and feed production systems and the reduction of greenhouse gases (Bessa et al. 2020). Although *Salmonella* in edible insects are considered being a lower risk, occurrence of different *Salmonella* serovars with public health relevance, such as *S.* Agona, but also *S.* Stanley and *S.* Wandsworth being endemic in Asian countries (Frentzel et al., not yet published) have been detected in edible insects or insects rearing residues (Wynants et al. 2019; Vandeweyer et al. 2021). Transfer from substrate to insects and survivability or transmission of main *Salmonella* serovars in or via insects are known to occur (EFSA 2015; Wynants et al. 2019). On the other hand, several studies have shown that, for example, black soldier flies possess antimicrobial potential to reduce *Salmonella* and other pathogenic bacteria from their substrate (Vandeweyer et al. 2021). This open gap in the knowledge of *Salmonella* contamination during mass produced insects needs to be filled in the future (Vandeweyer et al. 2021).

9.2.7 Salmonella in Wild Animals

Occurrence of *Salmonella* in wildlife animals is generally not of human health relevance. However, several broad host range *Salmonella* serovars or sequence types including those most often associated with disease in humans are detected among diverse wildlife species and also whole-genome sequencing analysis reveal isolates from wildlife being genetically highly similar to isolates from infected humans, foodstuff, or livestock animals (Hilbert et al. 2012; Uelze et al. 2021b). Apart from human infections caused by consumption of wildlife-derived meat, transmission of *Salmonella* isolates from wildlife to humans may occur by direct contact with wild animals and their natural environment, with children being predominantly affected (Hauser et al. 2009; Williams et al. 2015; Lawson et al. 2018). Indirect transmission of *Salmonella* from wildlife to food-producing animal housings or consumption of crop plants contaminated by wildlife animals is further possible transmission pathways (EFSA 2014b; Hilbert et al. 2012). However, transmission from contaminated animal farms to surrounding wildlife was proven (Skov et al. 2008). Besides birds and rodents, the continuous expansion of omnivorous wildlife species like foxes, raccoons, and wild boars into urban settings, where they to a considerable extent feed on waste and ort and verifiably contaminate public zones like sunbathing areas or playgrounds, may pose a risk for pathogen transmission (including *Salmonella*) to humans, especially young children. Some *Salmonella* sequence types are described to be associated with certain animal species, such as *S.* Typhimurium ST128 with pigeons, *S.* Enteritidis ST183 with hedgehogs, or *S.* Choleraesuis ST145 with wild boars (Uelze et al. 2021b; Longo et al. 2019; Leekitcharoenphon et al. 2019).

9.3 Human Salmonellosis

9.3.1 Transmission and Symptoms

Salmonella enterica can provoke gastrointestinal as well as systemic disease. Bloodstream infections are regularly caused by the typhoid serovars *S.* Typhi and *S.* Paratyphi A, B, and C. These infections are mostly related to people coming or returning from areas with poor sanitary conditions where typhoid and paratyphoid are still endemic. Typhoid serovars are host-restricted to humans and higher primates; they have no reservoir in other wildlife or livestock animals. Transmission occurs via fecal contamination of food/water or through (chronic) carriers. Due to their lack of zoonotic potential, typhoid serovars are not further discussed here.

Non-typhoid *Salmonella* (NTS) typically remain restricted to the gastrointestinal tract, where they cause self-limiting gastroenteritis characterized by diarrhea, abdominal pain, and fever (Velge et al. 2012). Symptoms like nausea, vomiting, and headache may also occur. Illness usually lasts 4–7 days and does not require antibiotic treatment. Nevertheless, dysfunction of the mucosal barrier can result in life threating infections, especially in vulnerable groups like infants, elderly, and

immunocompromised people (Santos et al. 2009). Severe infections, like bacteremia, meningitis, osteomyelitis, and bronchopulmonary salmonellosis have been described (Gilchrist and Maclennan 2019; Gordon 2008; Fabrega and Vila 2013).

The main reservoir for NTS is warm-blooded animals, including livestock. Food of animal origin is still supposed to be the most common source of human infections, but infections due to plant-derived foods have been increasingly reported. Direct or indirect animal contact also bears a potential risk for infection, and although fecal-oral human-to-human transmission rarely occurs in industrialized countries, it poses a problem in areas with poor hygiene conditions.

Surveillance programs that detect *Salmonella* contaminations in a timely manner in the entire food chain (crop plants, animal feed, breeding, rearing and fattening plants, hatcheries, layer flocks, slaughterhouses, food processing plants, whole sale, and retail sector) together with sanitary measures are essential for preventing human *Salmonella* infections (Newell et al. 2010; Wattiau et al. 2011).

9.3.2 Pathogenesis

The incubation time for NTS mostly varies from 6 to 72 h, but in cases with low-dose exposure, symptom onset may be delayed for up to 16 days (Abe et al. 2004; Siira et al. 2019). Infections with NTS lead to an acute intestinal inflammation in human and animal hosts. Following ingestion via contaminated food, the bacteria need to overcome the highly acidic pH of the stomach as well as the adverse conditions in the intestine (high bile concentration, competition with commensal bacteria) to reach their infection site. It is proposed that foods with a high fat or protein content may protect *Salmonella* from digestion in the stomach or that the uptake with liquid foods facilitates survival due to a shorter passaging time. But more importantly, *Salmonella* has developed complex strategies to survive in these hostile environments (Álvarez-Ordóñez et al. 2011). Crucial to *Salmonella* virulence is its ability to invade and break through the intestinal mucosal barrier. Adhesins and fimbriae are necessary to mediate attachment to epithelial cells in the gut. Once in the lower intestine, the bacteria adhere to enterocytes or M cells. From there, they translocate to the lamina propria, where they are taken up by phagocytes, disseminate from the gastrointestinal tract to mesenteric lymph nodes, and colonize systemic sites, like the liver and spleen (Agbor and Mccormick 2011; Dong et al. 2022).

Therefore, *Salmonella enterica* has developed ingenious virulence mechanisms to manipulate host cell functions to its own benefit (Agbor and Mccormick 2011). Two type III secretion systems (T3SS) encoded within the ***S****almonella* **p**athogenicity **i**slands SPI-1 (Mills et al. 1995) and SPI-2 (Shea et al. 1996) are responsible for the delivery of a series of bacterial effectors into host cells with the intention to reprogram eukaryotic cell functions. While the T3SS apparatus is highly conserved across bacterial genera, the translocated effectors are unique proteins with very specialized functions critical to virulence. Moreover, considerable evidence indicates that individual effectors secreted by the T3SS are modular proteins composed

of functionally distinct domains that may act in different stages of the infection process (Agbor and Mccormick 2011).

SPI-1 effectors play a fundamental role in the early stages of mammalian infection mediating the remodeling of the actin cytoskeleton of the host cell, thus leading to internalization of the bacteria and subsequent penetration of the ileal mucosa. SPI-1 effectors also have pro-inflammatory potential via activation of the host cell inflammasome, and they cause a very strong proapoptotic effect in monocytic cells (Hautefort et al. 2008; Kaiser and Hardt 2011; Bierschenk et al. 2017).

The SPI-2-encoded T3SS and its effectors allow the intracellular survival of *Salmonella enterica* within phagocytic cells, creating a niche where the bacteria are inaccessible for the host cell defense mechanisms. Within this so-called *Salmonella* containing vacuole (SCV), the bacteria replicate and translocate various effectors into and across the SCV membrane, thereby interfering with host cell functions like antimicrobial defense mechanisms, intracellular transport processes, integrity of the cytoskeleton, and host cell death (Kuhle and Hensel 2004).

Besides these two major pathogenicity islands altogether 24 SPIs have been identified in *Salmonella enterica* so far. Some of them are widespread, others are restricted to certain subspecies or even serovars and contribute to virulence processes in different hosts (Cheng et al. 2019).

Like other enterobacteria, *Salmonella* can exchange genetic material via horizontal gene transfer. The acquisition or loss of plasmids, prophages, and other mobile genetic elements may result in changes to the antibiotic resistance profile or affect the virulence or fitness properties of these strains.

9.3.3 Salmonellosis Worldwide

9.3.3.1 Global Burden of Disease

Assessing the burden of foodborne disease is a complex task because many different pathogens can be transmitted by food, leading to different health outcomes. But doubtlessly, human salmonellosis has a very high economical and public health impact worldwide (Majowicz et al. 2010), and burden-of-disease estimates combining indicators of mortality, morbidity, and health care costs are increasingly used to instruct public health officials and politicians. Based on WHO data, in 2010, the estimated number of foodborne illnesses caused worldwide by NTS was 78.7 Mio. They accounted for 59,000 fatal casualties and about 4 Mio. years of life lost (YLL) (Havelaar et al. 2015). The public health burden of non-typhoidal *Salmonella* infections is exceptionally high in low-income countries and urban settings with high population density and poor sanitary conditions, especially in areas where other severe infectious diseases (e.g., Malaria and AIDS) are endemic. Data collected between 2009 and 2012 from the World Health Organization (WHO) Foodborne Disease Burden Epidemiology Reference Group (FERG) showed that of all foodborne diseases, diarrheal and invasive infections due to non-typhoidal *S. enterica* infections resulted in the highest burden. They cause 4.07 million (95% UI 2.49–6.27 million) disability adjusted life years (DALYs), with a most

considerable burden of foodborne disease in children less than 5 years of age. In addition, as major cause of global morbidity and mortality an increasing number of invasive non-typhoidal salmonellosis (iNTS) was observed in recent years worldwide, but mostly in the sub-Sahara region. Especially patients infected with HIV are at risk. Improved access to antiretroviral therapy (ART) has probably helped to reduce the burden of iNTS disease among those persons (Havelaar et al. 2015).

9.3.3.2 Salmonellosis in Germany and the European Union

In Germany and the European Union (EU), salmonellosis is the second most commonly reported bacterial foodborne infection in humans after campylobacteriosis with about 13,500 and 88,000 reported cases in 2019, respectively (Robert Koch-Institut 2020; EFSA and ECDC 2021a). After a long period of remarkable decline, the number of salmonellosis cases in humans has been stable for several years now, and *Salmonella enterica* still represents an important cause of foodborne outbreaks (Robert Koch-Institut 2020; EFSA and ECDC 2021a).

In Germany, salmonellosis ranked fourth among six major enteric pathogens considering YPLL (years of potential life lost) with the highest mortality rate (Werber et al. 2013).

In Europe, salmonellosis is a largely seasonal disease with most cases reported during the summer months (EFSA and ECDC 2021b).

S. Enteritidis and *S*. Typhimurium represent the far most prevalent serovars, together counting for >70% of all reported cases with specified serovars in Germany and also in the EU. Although eggs and egg products are still considered as the main source for *S*. Enteritidis infections while pork and pork products are regarded as the most common food vehicles for *S*. Typhimurium, other food categories (also of nonanimal origin) may as well be contaminated with these serovars.

Although the main focus of this chapter is on foodborne *Salmonella* infections, it should be mentioned that infections are also acquired through direct or indirect animal contact in homes, veterinary clinics, zoological gardens, farm environments, or other public, professional, or private settings. Clinically affected animals may exhibit a higher prevalence of shedding than apparently healthy animals, but both can shed *Salmonella* over long periods of time. The public health risk varies by mammals, birds, and reptile species, age group, husbandry practice, and health status (Hoelzer et al. 2011). Numerous reports exist on the prevalence of *Salmonella* sp. in reptiles, and many different serovars have been described, usually rarely isolated from humans or livestock. Publications demonstrate a higher prevalence in lizards in comparison to tortoises and turtles: in a study in captive lizards, *Salmonella* spp. were isolated from 76% of all cloacal swabs, including 44 serovars (Pasmans et al. 2005).

While most reports of reptile-associated salmonellosis are from infants and children, adults, especially immunocompromised individuals and patients with impaired gastric acid production (Stam et al. 2003), may also be affected. Clinical symptoms include mainly gastroenteritis, but severe outcomes such as septicemia, meningitis, and subdural empyema (Chiodini and Sundberg 1981) have been described, especially in children younger than 5 years (Tabarani et al. 2010; Van

Meervenne et al. 2009). Fatalities due to reptile-associated salmonellosis in infants have been reported, for instance, from Austria.

A study exploring the evidence for transmission of *Salmonella* from pet reptiles to children in Germany showed that almost 50% of the interviewed households kept at least one reptile. Sixty-eight percent of the examined reptiles were bearded dragons (*Pogona vitticeps*). Altogether, 319 *Salmonella* isolates were recovered and 44 different serovars were identified (Pees et al. 2013).

9.4 *Salmonella* Outbreaks

Salmonella enterica is an important and frequent cause for foodborne outbreaks on regional, national, or international level and a leading cause for outbreak-related hospitalization. In the EU, *S. enterica* accounts for the largest proportion of bacterial foodborne outbreaks: In 2019, 926 foodborne salmonellosis outbreaks were reported to the ECDC, representing 17.9% of all foodborne outbreaks but counting for 50.5% of all outbreak-related hospitalizations (EFSA and ECDC 2021b). In Germany, 277 *Salmonella* outbreaks were reported in 2019. On EU level, almost three-fourths of *Salmonella* outbreaks were caused by the predominant serovar *S.* Enteritidis, followed by *S.* Typhimurium (bi- or monophasic). Commonly associated food vehicles for *Salmonella* Enteritidis outbreaks were eggs, egg products, egg dishes, and bakery products. Implicated food vehicle for *S.* Typhimurium outbreaks were commonly pork products, such as ground pork or different types of raw sausage. Further serovars observed in more than one outbreak in the EU member states in 2019 were: *S.* Infantis, *S.* Newport, *S.* Coeln, *S.* Mikawasima, *S.* Agona, *S.* Muenchen, and *S.* Poona. However, many different serovars were observed in foodborne outbreaks over the last years. In addition to classical food vehicles for *Salmonella* outbreaks, food of plant origin, like fresh vegetables and fruits, but also herbal infusions, spices, and sweets have been identified as sources for foodborne illness and associated with (multinational) outbreaks (Table 1).

9.4.1 Molecular Tools for Outbreak Investigations

The ability to distinguish strains or clonal lineages of a bacterial pathogen is essential for addressing many questions in food microbiology, epidemiology, infection prevention, and control. Traditional typing systems were based on phenotypic characteristics, such as serotype, phage type, or phenotypic antibiotic resistance profiles. However, phage typing schemes had been developed only for a few *S. enterica* serotypes, and the discriminatory power of these phenotypic methods was quite limited. Genotyping methods had been successfully established within the past decades to characterize subsets of defined strains. They provided better discriminatory power to differentiate closely related *Salmonella* strains and give more information with respect to the genetic relatedness within the population (Wattiau et al. 2011).

The detection of sequence variation within housekeeping genes is highly suitable for such studies because they are considered to be neutral in evolution and generally their function is well understood. This concept is utilized by multilocus sequence typing (MLST). Following PCR amplification and sequencing of seven housekeeping genes, MLST generates allelic profiles from these genes and can thus identify phylogenetic lineages. Further, MLST has shown that certain serovars originate from more than one common ancestor (termed as polyphyletic serovar), meaning that different lineages of the same serovar are only distantly related (Achtman et al. 2012b). However, due to its limited resolution 7-locus MLST is not an appropriate tool for outbreak investigations.

Methods for outbreak investigations and for tracing contamination within the food chain should be highly discriminative. This had been achieved by digesting the DNA from the strain(s) of interest with specific restriction endonucleases and separating the fragments, e.g., using pulsed-field gel electrophoresis (PFGE), fluorescent amplified fragment length polymorphism (fAFLP), or ribotyping, each providing distinct band patterns. PFGE fingerprinting was the gold standard for molecular subtyping of *Salmonella* serovars (especially for outbreak investigations) for about two decades because it had been internationally standardized and provided the highest level of strain discrimination in the pre-NGS era (Gerner-Smidt and Scheutz 2006; Swaminathan et al. 2006).

Another molecular approach was the multilocus variable number of tandem repeat analysis (MLVA), which is based on the determination of short repetitive tandem DNA units within defined loci by capillary electrophoresis. The more differences in the number of tandem repeat units within the set of analyzed loci are detected, the more distantly related the strains are interpreted to be. Although, MLVA schemes had been developed for a couple of serovars such as *S.* Typhimurium (Lindstedt et al. 2004), *S.* Enteritidis (Boxrud et al. 2007; Malorny et al. 2008), *S.* Infantis (Ross and Heuzenroeder 2008), *S.* Typhi (Ramisse et al. 2004), *S.* Newport (Davis et al. 2009), and *S.* Heidelberg (Young et al. 2012), only those for the epidemiologically most important serovars *S.* Typhimurium and (to a smaller degree) *S.* Enteritidis achieved international standardization and acceptance. In several countries, MLVA was applied instead (or in addition to) phage typing for strain characterization below serotype level and as a tracing tool (with limited discriminatory power) in outbreak studies (Heck 2009; Hopkins et al. 2011; Sintchenko et al. 2012).

Also another family of DNA repeats named CRISPR (clustered regularly interspaced short palindromic repeats) is highly polymorphic in *Salmonella spp.* (Fabre et al. 2012). CRISPR are supposed to confer resistance to foreign DNA, such as plasmids and phages. The spacer content of a strain reflects previous DNA insertions and therefore can provide evolutionary information. It strongly correlates with both, serovar and multilocus sequence types. The discriminatory power based on variations in the spacer content (loss, acquisition, duplication of spacers, or point mutations within spacers) is regarded similar to that of former gold standard methods, such as PFGE. CRISPR strain characterization was therefore regarded as a potential alternative to both serotyping and PFGE (Fabre et al. 2012).

9.4.2 Whole-Genome Sequencing: A Game Changer for Molecular Typing and Outbreak Investigation of Foodborne Disease

In recent decades, a variety of immunological, biochemical, and molecular techniques have been developed for the detection, characterization, and typing of foodborne bacteria (Li et al. 2009). However, especially the introduction of whole-genome sequencing (WGS) in routine diagnostics in public health, veterinary, and food safety laboratories has revolutionized the surveillance of foodborne pathogens and microbial food safety (Ronholm 2018; Taboada et al. 2017).

Bacterial whole-genome sequencing data can be used for bacterial typing, outbreak investigation, source tracking, and surveillance, and its application is highly encouraged by international authorities (EFSA et al. 2019; ECDC 2016).

By now, there are several examples for the valued application of WGS for outbreak investigation and routine surveillance typing in different countries and contexts (Leekitcharoenphon et al. 2019; Hoffmann et al. 2020; Simon et al. 2018; Meinen et al. 2019). For WGS of bacteria such as *Salmonella*, genomic DNA extracted from a bacterial isolate culture is yet the basis for the routine utilization of sequencing data. However, with new technologies rising, metagenomic approaches will also soon find their way into routine applications (EFSA et al. 2019). The isolated DNA is the starting point for the device-dependent sequencing preparation procedure (also called library preparation process). After preparation, the DNA is sequenced using a suitable sequencing platform (EFSA et al. 2019) (Fig. 1). While short-read sequencing is

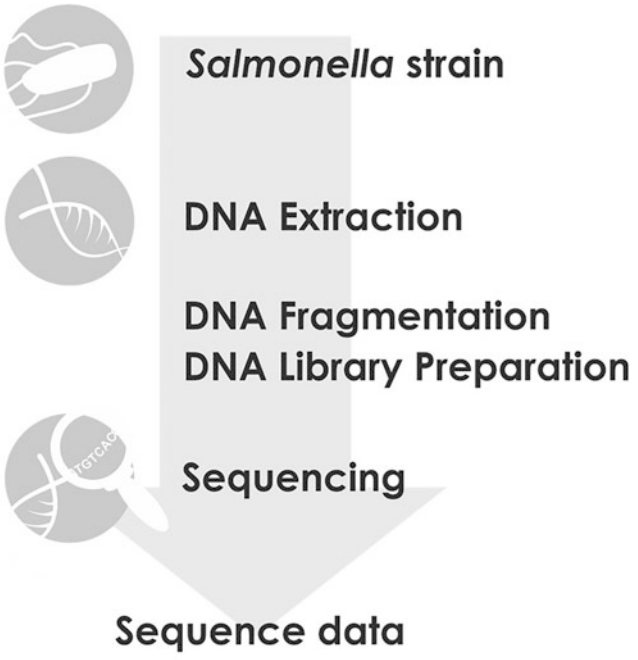

Fig. 1 Whole genome sequencing workflow

standard procedure for routine application today, long-read procedures are developed to generate complete bacterial genomes. These long-read sequencing approaches have specific application areas including the reconstruction of gene order and orientation and localization of virulence factors and antimicrobial resistance genes on mobile elements for the evaluation of potential transmission risks (Ben Khedher et al. 2022).

International standardization efforts to define universally applicable quality criteria are currently developed (EFSA et al. 2019, DIN EN ISO 23418:2020). These are needed not only for quality-assured data generation and metadata sharing but also for data evaluation software and pipelines. This is necessary in order to share and compare the generated WGS data nationally and globally across the food safety, environmental and public health sectors (EFSA et al. 2019).

9.4.2.1 WGS-Based *Salmonella* Typing

With the entire genetic information of the organism at hand, the analysis of WGS data is able to replace or extend classical methods used in *Salmonella* typing. *Salmonella* serovars can be predicted using bioinformatics software such as SeqSero (Zhang et al. 2015, 2019) or the *Salmonella* in silico *typing resource* SISTR (Yoshida et al. 2016). Classical 7-gene multilocus sequencing typing (MLST) used to further discriminate *Salmonella* isolates (Achtman et al. 2012a) was previously assessed by means of PCR and can be now determined in silico by comparing WGS data against the Enterobase MLST database also available at PubMLST (Jolley et al. 2018; Jolley and Maiden 2010).

Additionally, conventional phenotypic screening methods can be complemented. Antibiotic resistance markers and corresponding phenotypic traits of *Salmonella* can be predicted by directly searching *Salmonella* WGS data for the presence of antimicrobial resistance genes (Anjum 2015). For this purpose, bioinformatics tools searching comprehensive databases containing sequence data of resistance genes and chromosomal point mutations associated with resistance phenotypes are provided to the scientific community. Examples are the ResFinder tool, searching the ResFinder and PointFinder databases (Bortolaia et al. 2020; Zankari et al. 2017), and AMRFinderPlus, searching the NCBI Pathogen Detection Reference Gene Catalog (Feldgarden et al. 2021). The latter can also be used to identify acid, biocide, metal, and stress resistance and virulence genes (Feldgarden et al. 2021). Moreover, mobile genetic elements (plasmids, transposons, phages, pathogenicity islands), which often carry resistance or virulence genes and are transmissible between bacterial hosts, can be classified. This allows to investigate the epidemiology of plasmid-mediated antibiotic resistance and virulence (Orlek et al. 2017). To further analyze genomes, genome annotation programs are available to predict genes and get a deeper insight into the microbial gene content, genomic organization, and metabolic traits (Ruiz-Perez et al. 2021).

Users can choose to install bioinformatics tools locally, if they have a suitable computer infrastructure available. However, there are also possibilities to use web-based typing and characterization tools as provided by the Center of Genomic Epidemiology (CGE) (https://www.genomicepidemiology.org/) or the Pathosystems Resource Integration Center (PATRIC) (https://www.patricbrc.org/).

9.4.2.2 WGS-Based *Salmonella* Outbreak Detection

Thanks to the high resolution and rapid data provision of WGS methods, outbreaks can be analyzed in a much higher discriminatory manner and quicker as with previously applied subtyping methods, like phage typing or pulsed-field gel electrophoresis (PFGE). This helps to carry out intervention in a more targeted and rapid way (U.N., Food and Agriculture Organization 2016). To determine the phylogenetic relationship of isolates based on WGS data, two main approaches exist: (a) reference-based mapping approach with subsequent variant identification and (b) whole or core genome multilocus sequence typing (wg/cgMLST) (Fig. 2).

In the reference-based mapping approach, sequencing reads are aligned against a reference genome to identify single nucleotide polymorphisms (SNPs). By alignment of sequence reads of different isolates against the same reference genome and comparison of the detected SNP positions, distance matrices can be calculated and/or phylogenetic trees can be constructed to investigate the relatedness of different *Salmonella* isolates (WHO 2018) (Fig. 3).

In cgMLST, de novo assembled WGS data is used to determine the allelic variation of a predefined set of genes from the *Salmonella* core genome. Based on the allelic differences of the analyzed isolates, a distance matrix can be calculated and a phylogenetic tree can be inferred (Schürch et al. 2018; Alikhan et al. 2018).

Both, SNP analysis and cgMLST can be applied for *Salmonella* outbreak analysis by individual laboratories using available commercial or open source software. Due to their different approaches, each method comes with its own advantages: Fitted with the best possible reference genome for the data set, the mapping-based

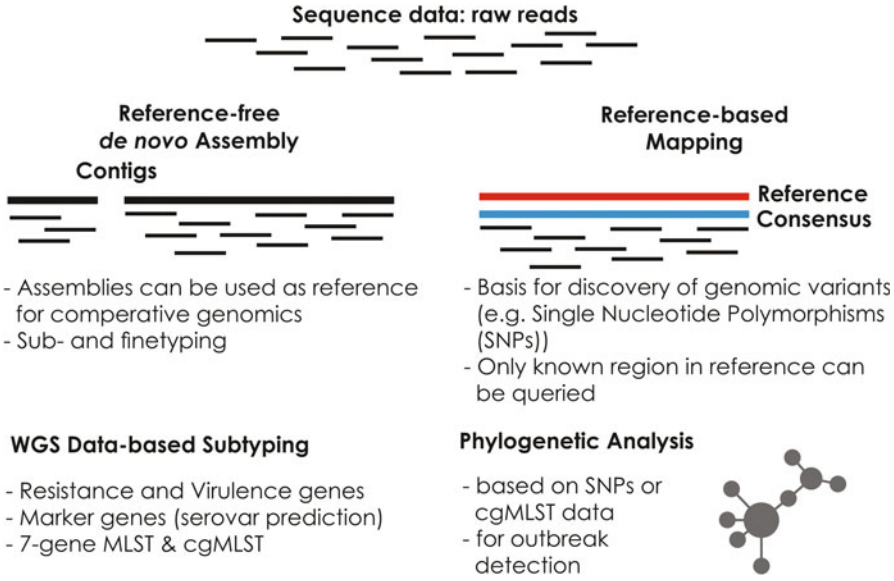

Fig. 2 Bioinformatic analysis of sequence data: *De novo* assembly and reference-based mapping are exemplary bioinformatics approaches for the determination of phylogenetic relationships

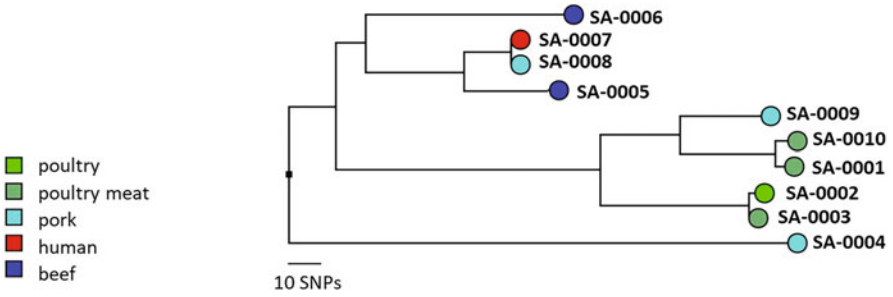

Fig. 3 Schematic SNP-based phylogenetic tree of *Salmonella* Infantis from human, animal and food samples. Isolates SA-0007 from human and SA-0008 from pork are indistinguishable (0 SNPs)

approach enables the highest possible resolution by including intergenic regions into the analysis. However, an interlaboratory comparison with SNP-based analysis is more difficult as well as time and computing intensive to achieve. The cgMLST approach on the other hand offers a sufficiently high (but not so in depth as the SNP approach) resolution for outbreak analyses and comes (usually) with the advantage of a common nomenclature (likewise to STs) and easier data sharing possibilities due to the stable core genome set.

WGS is already used for *Salmonella* outbreak analysis by government agencies in several countries on routine basis (Uelze et al. 2021a; Brown et al. 2019; Gymoese et al. 2017; Simon et al. 2018).

In order to take the full advantage offered by WGS, the data must be placed in an international context to perform real-time outbreak investigation in a global manner. Therefore, different public online platforms and surveillance networks have been established. The GenomeTrakr network and the NCBI Pathogen Detection Browser use SNP-based approaches, which allow participating laboratories to compare their *Salmonella* isolate data to the international NCBI pathogen detection database, which already includes data for more than 400,000 *Salmonella* isolates (Timme et al. 2019) (https://www.ncbi.nlm.nih.gov/pathogens/isolates/#taxgroup_name:"Salmonella enterica" 18.03.2022). Similarly, Enterobase allows international outbreak investigation based on cgMLST by providing a public and stable *Salmonella* cgMLST scheme, a public allele database and a *Salmonella* isolate database including already more than 300,000 *Salmonella* isolates (Alikhan et al. 2018) (https://enterobase.warwick.ac.uk/, 18.03.2022).

9.4.2.3 WGS-Based Salmonella Surveillance and Source Tracking

Moreover, WGS-based Salmonella surveillance allows to globally monitor the emergence and spread of Salmonella lineages (Li et al. 2021; Rantsiou et al. 2018) and thus the emergence and spread of novel serovars (Meinen et al. 2019) or of multidrug-resistant or highly virulent Salmonella lineages (EFSA et al. 2019).

As WGS data offers numerous of characteristic markers of an organism and enables phylogenetic differentiation in depth, the data can be used to trace the

transmission routes of foodborne bacterial pathogens and develop source attribution models extending classical source attribution approaches. So far, only few pilot and benchmarking studies in this field were conducted (Merlotti et al. 2020; Munck et al. 2020; Sévellec et al. 2020). However, these source attribution models for Salmonella are promising for future development in the context of identifying contamination source in the food chain (Brown et al. 2021; EFSA 2019; Rantsiou et al. 2018).

Abstract

Yersinia enterocolitica and *Yersinia pseudotuberculosis* can cause enteric yersiniosis among humans and animals. The infection is typically acquired through contaminated food or water. Common symptoms among humans are diarrhea, abdominal pain, and fever, but sometimes sequelae such as joint pain and skin rash occur. Yersiniosis is usually self-limiting and no treatment with

antimicrobials is needed. Animals are often asymptomatic carriers of pathogenic *Yersinia*. Yersiniosis usually occurs in animals under stress. *Y. enterocolitica* and *Y. pseudotuberculosis* differ clearly from each other both phenotypically and genotypically. *Y. enterocolitica* species consists of a very heterogeneous group of bacteria and not all strains are pathogenic. *Y. pseudotuberculosis* strains show only little variation in their biochemical reactions and correctly identified strains are considered pathogenic. Several plasmid and chromosomal encoded virulence factors are needed for *Yersinia* pathogenicity, and all pathogenic strains carry a virulence plasmid, which is essential for the bacteria to multiply and disseminate in the host. Isolation and identification of enteropathogenic *Yersinia*, especially from non-human sources, is challenging and time-consuming.

Keywords

Yersinia enterocolitica · Yersinia pseudotuberculosis · Yersiniosis, virulence, detection, transmission

10.1 Introduction

Yersinia enterocolitica and *Yersinia pseudotuberculosis* are two species belonging to the enteropathogenic *Yersinia* spp. They cause enteric yersiniosis, which was the fourth most frequently reported foodborne bacterial enteritis in the EU in 2019, with a stable trend in 2015–2019 (EFSA and ECDC 2021). Both species have animal reservoirs and a fecal-oral transmission route (Fredriksson-Ahomaa et al. 2018). The infection is usually acquired through contaminated food, especially raw or undercooked meat or vegetables. It can also be acquired through contact with infected humans or animals. Diarrhea, abdominal pain, and fever are common symptoms. Sequelae as joint pain and skin rash occur occasionally (Rosner et al. 2013; Rivas et al. 2021). Isolation and identification of *Yersinia* spp. is challenging and time-consuming (Fredriksson-Ahomaa et al. 2018). The pathogenicity of *Y. enterocolitica* strains vary from nonpathogenic to highly pathogenic, thus the detection of virulence markers is also necessary for determining the clinical significance of isolated strains.

10.2 *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*

10.2.1 Characteristics

10.2.1.1 The Genus *Yersinia* Includes Two Enteropathogenic *Yersinia* spp.

The genus *Yersinia* is classified in the *Yersiniaceae* family of the order *Enterobacteriaceales* (Adeolu et al. 2016). The taxonomy is constantly evolving, and 25 *Yersinia* spp. have been reported at the time of writing (Le Guern et al. 2020).

The genus *Yersinia* includes a heterogeneous group of gram-negative, oxidase-negative, and facultative anaerobic rod-shaped bacteria that do not possess a capsule or spores. *Y. enterocolitica* and *Y. pseudotuberculosis* are the two *Yersinia* species that can cause an enteric infection in humans and animals. They are zoonotic bacterial pathogens that can be transmitted from animals to humans through a fecal-oral route (Laukkanen-Ninios et al. 2014). *Y. enterocolitica* and *Y. pseudotuberculosis* differ clearly from each other, especially genotypically (McNally et al. 2016). *Y. pseudotuberculosis* is genetically closely related to the highly virulent agent of plague, *Yersinia pestis,* which is transmitted from animals to humans by fleas or in aerosols.

10.2.1.2 Not All *Y. enterocolitica* Strains Are Considered Pathogenic

The *Y. enterocolitica* species consists of a very heterogeneous group of bacteria: it comprises over 30 serotypes based on variation of the O antigen dependent on cell wall lipopolysaccharides (Wauters et al. 1991) and six biotypes (1A, 1B 2–5) based on biochemical reactions (Wauters et al. 1987). Certain biotype and serotype combinations have been associated with human and animal infections. Bioserotype 4/O:3 (phylogroup 3), which has a worldwide distribution, is the most common type associated with human disease, followed by bioserotypes 2/O:5,27 (phylogroup 4) and 2/O:9 (phylogroup 5) (Reuter et al. 2015; Hunter et al. 2019; Rivas et al. 2021). Infections due to bioserotype 3/O:3 have frequently been reported, especially in China (Duan et al. 2017). Bioserotype 1B/O:8, which is the most highly pathogenic type, has mainly been found in Northern America (Savin et al. 2018). In recent years, this pathogenic type has also been identified in human yersiniosis in Europe, especially in Poland (Radziszewski et al. 2019). Biotype 1B (phylogroup 2) strains have been associated with high pathogenicity and strains of biotypes 2–5 with moderate or low pathogenicity (Reuter et al. 2015). All pathogenic strains carry the virulence plasmid. Strains belonging to biotype 1A (phylogroup 1) are usually regarded as nonpathogenic because they lack the most important virulence genes. Discussions have been raised of the potential pathogenicity of certain biotype 1A strains (Huovinen et al. 2010). However, no clear difference between *Y. enterocolitica* 1A strains isolated from humans with and without diarrhea could be found in Switzerland (Stephan et al. 2013).

10.2.1.3 Two Clear Lineages Exist Among *Y. pseudotuberculosis* Strains

The genetic diversity of *Y. pseudotuberculosis* strains is quite limited (Laukkanen-Ninios et al. 2011). Two lineages with different geographical locations have been observed: European and Asian clades (Seecharran et al. 2017). Only little variation occurs in their biochemical reactions. The strains can be divided into four biotypes using melibiose, raffinose, and citrate (Tsubokura and Aleksić 1995). Biotyping has been rarely used, and it correlates quite poorly with the pathogenicity and geographical distribution of the strains (Reinhardt et al. 2018). *Y. pseudotuberculosis* strains can be classified into 21 serotypes according to their varying lipopolysaccharide O-antigen structure: O:1–O:15 and three subtypes (a–c) in O:1 and O:2, and two subtypes (a and b) in O:4 and O:5 (Seecharran et al. 2017). Most of the strains in humans belong to

only a few serotypes: O:1a, O:1b, and O:3 in Europe and in the Far East, also O:4b and O:5b (Amphlett 2016). Correctly identified *Y. pseudotuberculosis* strains are considered pathogenic (Le Guern et al. 2016; Fredriksson-Ahomaa et al. 2018). High-pathogenic *Y. pseudotuberculosis* strains, mostly originating from the Far East, can cause a systemic infection called Far East scarlet-like fever (FESLF).

10.2.1.4 Enteropathogenic *Yersinia* Strains Can Grow at Low Temperatures

Yersinia bacteria are able to grow at temperatures ranging from 4 °C to 43 °C; however, slow growth has been reported to occur even below 4 °C (Yehualaeshet et al. 2013; Keto-Timonen et al. 2018). The optimal temperature for growth and metabolic activity is around 30°C. The ability to grow at low temperatures allows *Y. enterocolitica* and *Y. pseudotuberculosis* to multiply in refrigerated foods. *Yersinia* strains typically tolerate freezing for a prolonged time and even repeated cycles of freezing and thawing (Bhaduri 2005). However, *Yersinia* is heat-sensitive and can thus be easily destroyed by heat treatment (Bursová et al. 2017). Pasteurization at 72 °C for 15–20 s kills *Yersinia* bacteria. As a facultative anaerobic bacterium, *Yersinia* can multiply under both aerobic and anaerobic conditions, and under a modified atmosphere. Pathogenic *Y. enterocolitica* has been shown to grow well on pig cheek meat in a modified atmosphere with high oxygen (70% O_2) and carbon dioxide (30% CO_2) concentrations during cold storage at 6°C, even in the presence of large numbers of lactic acid bacteria (Fredriksson-Ahomaa et al. 2012). *Yersinia* bacteria are also able to grow over a wide pH range (pH 4–10). Alkalotolerance of *Yersinia* has been used to separate *Yersinia* strains from background organisms by enrichment broth treatment with potassium hydroxide (0.5%) before streaking onto agar plates (Hallanvuo et al. 2019).

10.2.2 Virulence

10.2.2.1 Several Plasmid and Chromosomal Encoded Virulence Factors Are Needed for *Yersinia* Pathogenicity

Several virulence factors have been identified among *Y. enterocolitica* and *Y. pseudotuberculosis* strains, some of which are common in both species (Table 1). The most important factor is the presence of an approximately 70-kb plasmid, which is termed pYV (plasmid for *Yersinia* virulence) and is present in pathogenic *Yersinia* spp., including *Y. enterocolitica* and *Y. pseudotuberculosis* (Moorman and Cohen 2021). However, *Y. enterocolitica* strains belonging to biotype 1A do not carry pYV and are thus considered nonpathogenic (Reuter et al. 2014). This virulence plasmid is essential for bacterial replication in host tissue, and *Yersinia* strains without pYV are rapidly eliminated from the gut. In addition to pYV-encoded virulence factors, chromosomal encoded factors are also needed for pathogenicity.

Table 1 Virulence factors present in *Y. enterocolitica* and *Y. pseudotuberculosis* strains

Species		pYV	Chromosomal							
			Inv	Ail	YstA	YstB	HPI	MyfA	PsaA	YPM
Y. enterocolitica										
Biotype	1A	–	+	–	–	+	–	–	–	–
	1B	+	+	+	+	–	+	+	–	–
	2–5	+	+	+	+	–	–	+	–	–
Y. pseudotuberculosis										
		+	+	+	–	–	+[a]	–	+	+[b]

[a] Serotypes O:1 (complete HPI) and O:3 (truncated HPI)
[b] Found frequently in Far Eastern strains, which also often carry a large plasmid called pVM82

10.2.2.2 *Y. enterocolitica* and *Y. pseudotuberculosis* Can Be Divided into Different Groups Correlating with Pathogenicity

Y. enterocolitica strains can be divided into six phylogroups (PGs), which correlate with the biotypes and pathogenicity (Reuter et al. 2015). High-pathogenic strains belong to PG2 and biotype 1B, and they all carry the high-pathogenicity island (HPI) in their chromosomes (Table 1). Low-pathogenic strains belong to PG3–6, including biotypes 2–5, and nonpathogenic strains belong to PG1and biotype 1A. *Y. pseudotuberculosis* strains, which are considered pathogenic, can be divided into five genetic groups (G1–3, G4–5) based on the presence of three key virulence factors: pYV, HPI, and the *Y. pseudotuberculosis* – derived mitogen (YPM) toxin (Amphlett 2016). The most common clinical genetic group in Europe is G2. These strains carry pYV and a complete HPI (Table 2). High-pathogenic strains, which belong to G3, can cause a systemic infection associated with FESLF, mainly reported in Japan and Russia. Most FESLF strains synthesize the superantigen toxin YPMa, which is seldom detected in European strains. FESLF strains have lost the HPI, and they often carry an additional pVM82 plasmid (Timchenko et al. 2016).

10.2.2.3 Virulence Factors Encoded by the pYV Virulence Plasmid Are Essential for Pathogenicity

The pYV encodes the Ysc-Yop type 3 secretion system (T3SS), which allows pathogenic *Yersinia* to escape phagocytosis (Tan et al. 2016). *Yersinia* outer proteins (Yops), which are necessary for downregulating antibacterial responses, are translocated directly from the bacterial cytosol into the target cell cytosol by the T3SS (Grabowski et al. 2017). The T3SS is a molecular syringe (injectisome) that delivers Yop cytotoxic effector proteins into the host cell (Berger et al. 2021; Moorman and Cohen 2021). The expression of T3SS genes are controlled primarily by temperature and calcium concentration (Bancerz-Kisiel et al. 2018). With this system, *Yersinia* can replicate extracellularly in lymphatic tissue and encounter the immune defenses of the host. Additionally, pYV encodes the non-fimbrial, outer-membrane protein YadA (*Yersinia* adhesin A) (Mühlenkamp et al. 2015). This protein is a multifunctional protein that, e.g., promotes the attachment of bacteria to the intestinal

Table 2 Distribution of pYV, HPI, and YPM among *Y. pseudotuberculosis* strains of different genetic groups

Genetic group	Presence of			Pathogenicity	O-serotype	Geographical distribution
	pYV	HPI	YPM			
G1	+	Complete	YPMa	High	1, 3, 5	Far East
G2	+	Complete	–	Medium	1	Europe
					1, 3, 5, 13, 14	Far East
G3	+	–	YPMa	High, systemic	4	Europe
					1–7, 10	Far East
G5	+	Truncated	YPMc	Low	3	Europe, Far East
G6	+	–	–	Medium	1–3, 5	Europe
					1–7, 10, 11, 13	Far East

brush border. In *Y. enterocolitica*, YadA also confers resistance to human serum (Chung and Bliska 2016). YadA is optimally expressed at 37 °C. The pYV-encoded proteins VirF of *Y. enterocolitica* and LcrF of *Y. pseudotuberculosis*, respectively, are important thermo-activated transcriptional regulators that activate Yops production (Grabowski et al. 2017). Both *yad*A and *vir*F genes are frequently used as targets to detect and identify pathogenic *Yersinia* strains (Petsios et al. 2016).

10.2.2.4 Chromosomally Encoded Virulence Factors Are Also Needed

Two chromosomal genes, *inv* and *ail*, are important for mammalian cell invasion (Tan et al. 2016). The *inv* gene codes for an outer-membrane invasion (Inv) protein, which plays an important role in promoting the entry into epithelial M cells of the ileum during initial stages of infection. All *Yersinia* spp. have *inv* homologs, but they are only functional in pathogenic strains (Tan et al. 2016). Epithelial cell penetration of *Y. enterocolitica* is also enhanced by the outer membrane attachment invasion locus (Ail) protein encoded by the *ail* gene. In *Y. pseudotuberculosis*, Ail is the primary serum resistance factor (Chung and Bliska 2016). The *ail* gene is suggested to be laterally transferred from *Y. pseudotuberculosis* to *Y. enterocolitica* (Tan et al. 2016). It is generally found only in pathogenic *Y. enterocolitica* strains belonging to biotypes 1B and 2–5. Some strains of biotype 1A have been shown to carry *ail* homologs, and these *ail* homologs have also sporadically been detected in *Y. kristensenii* strains (Joutsen et al. 2020). The *yst* gene in the chromosome of *Y. enterocolitica* encodes a heat-stable enterotoxin called *Yersinia* stable toxin (Yst), which may play a role in diarrhea (Bancerz-Kisiel et al. 2018). YstA is produced by pathogenic *Y. enterocolitica* strains belonging to biotypes 1B and 2–5, and most biotype 1A strains produce YstB; however, not all *yst*-positive strains produce enterotoxins (Bancerz-Kisiel et al. 2018). The HPI pathogenicity island, which is a large integrative and conjugative element, can generally only be found in the chromosome of *Y. enterocolitica* biotype 1B strains and *Y. pseudotuberculosis* O:1 and O:3 strains (McNally et al. 2016). However, it is truncated in *Y. pseudotuberculosis* O:3 strains. HPI codes the yersiniabactin, which is a siderophore facilitating iron uptake. Some *Y. pseudotuberculosis* strains can also

synthesize the superantigen toxin YPM, which plays an important role in systemic infections (Amphlett 2016). Additionally, *Y. enterocolitica* strains elaborate a mucoid *Yersinia* factor (Myf) and *Y. pseudotuberculosis* strains elaborate the pH6 antigen (Psa), which are surface (fimbrial) structures with high sequence similarity (Pakharukova et al. 2016). The Psa is an adhesin, which has an important role in the pathogenesis of *Y. pseudotuberculosis* infections by inhibiting the phagocytosis when the function of MyfA in the *Y. enterocolitica* infection is still unknown.

10.3 Yersiniosis – The disease

10.3.1 Pathogenesis

10.3.1.1 *Y. enterocolitica* and *Y. pseudotuberculosis* Are Transmitted Through the Intestinal Tract

Yersiniosis due to *Y. enterocolitica* or *Y. pseudotuberculosis* is usually acquired through oral ingestion of contaminated food or water. Enteropathogenic *Yersinia* strains produce urease, which is vital for bacteria to survive in acidic environments (Righetto et al. 2020). This is important during an infection, where *Yersinia* must survive the low pH of the stomach. *Yersinia* binds to the mucus layer that covers the epithelial cells, preferably in the terminal ileum. It attaches to M cells, which overlay the Peyer's patches and are specialized in the uptake of intestinal antigens (Bancerz-Kisiel et al. 2018). Subsequently, *Yersinia* penetrates the tissue. Attachment and invasion of the M cells are mediated by chromosomal determinants, including the Inv and Ail proteins, and the pYV-encoded YadA. After penetration of the intestinal epithelium, *Yersinia* colonizes the Peyer's patches. Subsequently, *Yersinia* may spread via the lymphatic system or the blood into the mesenteric lymph nodes and to the internal organs, such as the spleen and liver, where they may form micro-abscesses (Drechsler-Hake et al. 2016). The survival ability within these tissues is dependent on the pYV-encoded Yops, which downregulate the antibacterial response (Grabowski et al. 2017). The multiplication of *Yersinia* in the Peyer's patches may cause severe abdominal pain that may be confused with appendicitis (Bottone 2015). *Y. enterocolitica* and *Y. pseudotuberculosis* are resistant to human serum. In *Y. enterocolitica*, serum resistance requires the YadA adhesin when Ail is the primary serum resistance factor in *Y. pseudotuberculosis* (Chung and Bliska 2016). Most infections are usually localized and self-limiting due the host's inflammatory response, which finally leads to elimination of the pathogen.

10.3.1.2 Some Patients Develop Post-Infective Reactive Arthritis (ReA)

ReA is a form of peripheral spondyloarthritis that can develop after an intestinal infection. In *Yersinia*-triggered ReA, the primary infection is in the gut; however, how the intestine-joint connection operates in the disease remains unclear (Silva et al. 2020). The synovial fluid from the affected joints of patients is usually culture-negative but contains bacterial antigens in the joint (Granfors et al. 1989). Most individuals with post-infective ReA are positive for human leukocyte antigen

HLA-B27 (Vasala et al. 2014). It seems that HLA-B27-positive individuals are more prone to develop severe symptoms and to show a more prolonged disease course than HLA-B27-negative patients.

10.3.2 Yersiniosis in Humans

10.3.2.1 Intestinal Symptoms Are Variable

Yersiniosis due to *Y. enterocolitica* and *Y. pseudotuberculosis* is mostly an uncomplicated enteric disease with diarrhea and abdominal pain (Borud et al. 2020; Rivas et al. 2021). Fever and blood in the feces may also occur. The incubation period typically ranges from 3 days to approximately 1 week, and symptoms may persist for weeks (Espenhain et al. 2019; Borud et al. 2020). The minimal infectious dose is unknown. The severity of the infection depends on the age and immunity of the infected person, the virulence of the strain, and the infection dose. Acute diarrhea, which may be bloody, and high fever occur most frequently in infants and children under 5 years of age (Rivas et al. 2021). Abdominal pain in the right lower quadrant due to mesenteric lymphadenitis and terminal ileitis is a common symptom in older children and adolescents. The abdominal pain resembles the symptoms of appendicitis and may lead to unnecessary surgery (Rosner et al. 2013).

10.3.2.2 Extraintestinal Sequels May Occur

In some cases, *Yersinia* infections may lead to extraintestinal complications such as joint pain (ReA), skin rash (erythema nodosum), and conjunctivitis/iritis (Rosner et al. 2013). *Y. pseudotuberculosis* has also been implicated in the etiology of Kawasaki diseases, which is a febrile vasculitis (Horinouchi et al. 2015). ReA is the most common sequelae of enteric yersiniosis, occurring especially among adults (Borud et al. 2020). ReA, which typically develops 1 week to 1 month after primary infection, usually affects the knees, ankles, elbows, and wrists. Symptoms may last for several months. ReA is usually self-limiting and only rarely remains chronic (Leirisalo-Repo and Suoranta 1988). A skin rash with painful red lesions along the trunk and legs may also occur 2 weeks after infection. The symptoms typically resolve themselves spontaneously within 1 month (Rivas et al. 2021).

10.3.2.3 Far East Scarlet-Like Fever (FESLF) Is a Rare and Poorly Investigated Disease

FESLF is an acute disease caused by certain *Y. pseudotuberculosis* strains (Amphlett 2016). Typical symptoms are severe fever and a rash that covers the body, particularly the face, neck, toes, and hands (Timchenko et al. 2016). A raspberry-like tongue is an additional manifestation. Gastrointestinal manifestations are variable, and abdominal pain mimicking appendicitis is common. Many patients also develop hepatic lesions (Amphlett 2016). The disease typically lasts around 2 weeks, after which the rash and jaundice also disappear. FESLF has mainly been reported in the Far East. Incidence is seasonal, increasing in winter. It is mostly associated with

serotype O:1b (ST2 sequence type), which circulates among rodents (Timchenko et al. 2016).

10.3.2.4 Systemic Infections Are Rare

Septicemic and systemic infections are mainly associated with immunocompromised individuals or in patients with underlying disease such as diabetes mellitus, liver cirrhosis, or hemochromatosis (Guinet et al. 2011; Amphlett 2016). During sepsis, *Yersinia* spreads preferentially to the liver, spleen, kidneys, and lungs, where they can form small tuberculosis-like abscesses. Transfusion-associated sepsis due to asymptomatic bacteremia in blood donors has also been reported (Rivas et al. 2021). Severe sepsis and rapid septic shock are typical symptoms, and older age is more often associated with a fatal outcome.

10.3.2.5 Yersiniosis Is Usually Self-Limiting and No Treatment with Antimicrobials Is Needed

Treatment is only warranted in severe cases such as in systemic infections and sepsis, (Guinet et al. 2011). Antimicrobials should also be considered for patients who are immunocompromised and for patients with iron overload. Most *Y. enterocolitica* strains produce β-lactamases and are thus resistant to penicillins, aminopenicillins, and first-generation cephalosporins (Bonardi et al. 2016; Peng et al. 2018). Third-generation cephalosporin, trimethoprim-sulfamethoxazole, tetracyclines, and fluoroquinolones are the antimicrobials of choice for severe infections (Guinet et al. 2011). *Y. pseudotuberculosis* is usually sensitive to all antimicrobials active against gram-negative bacteria; however, multiresistant strains have also been reported despite being rare (Cabanel et al. 2017). Multidrug-resistant strains are shown to be resistant to β-lactams, streptomycin, tetracycline, chloramphenicol, and gentamicin. Also, colistin resistance occurs among *Y. pseudotuberculosis* strains (Rivas et al. 2021).

10.3.3 Yersiniosis in Animals

10.3.3.1 *Yersinia* Infections Are Most Commonly Latent in Animals

Yersiniosis is quite a rare disease in animals. Animals are often asymptomatic carriers of enteropathogenic *Yersinia* strains. Sporadic infections usually occur in animals under stress, e.g., due to suboptimal weather, poor nutrition, host parasitism, and young age (Stanger et al. 2018a; Ceccolini et al. 2020). Most common symptoms are apathy, diarrhea, and weight loss, but also abortion and mastitis, and septicemia with sudden death has been reported (Magistrali et al. 2015; Stoute et al. 2016). Enterocolitis and military necrotic foci in the liver, spleen, kidneys, and lungs are typical postmortem findings (Stoute et al. 2016; Hammerl et al. 2021). *Y. pseudotuberculosis* has been identified in sick animals more often than *Y. enterocolitica,* especially in wild animals with clear symptoms (Le Guern et al. 2016). Zoo animals have also been more frequently infected with *Y. pseudotuberculosis* than *Y. enterocolitica* (Hammerl et al. 2021). However, a clonal spread of *Y. enterocolitica* bioserotype 1B/O:8 in multiple zoo species has recently been reported in the USA (Nebraska) (Hicks et al. 2020). The

symptoms varied from mild clinical signs to death, while some animals were latent without any signs. *Y. enterocolitica* has more commonly been found in asymptomatic farm animals, especially in pigs, than *Y. pseudotuberculosis* (Le Guern et al. 2016; Rivas et al. 2021). *Y. enterocolitica* strains belonging to pathogenic bioserotypes have been isolated from dogs and cats with diarrhea (Stamm et al. 2013).

10.3.3.2 Outbreaks Due to *Y. pseudotuberculosis* Infections Are Common in Zoo Animals

Several *Y. pseudotuberculosis* outbreaks have been reported in captive nonhuman primates, large rodents, bats, and birds (Ceccolini et al. 2020; Hahn et al. 2021; Hammerl et al. 2021). Lethargy and sudden death typically occur after a period of stress, but sometimes clinical signs, such as diarrhea and anorexia, can be seen (Ceccolini et al. 2020). *Y. pseudotuberculosis* can often be isolated from lung, heart, kidney, liver, spleen, and intestine samples. Recently, an outbreak causing osteomyelitis in a male turkey flock in Finland was reported, and *Y. pseudotuberculosis* was isolated from leg bone samples (Blomvall et al. 2021). Recurrent diarrhea outbreaks caused by pathogenic *Y. enterocolitica* and *Y. pseudotuberculosis* have been reported among weaned sheep in Australia (Stanger et al. 2018b). In Canada, a *Y. enterocolitica* outbreak with a high mortality rate (19%) has been reported on an alpaca farm (Ragno et al. 2019). In this study, *Y. enterocolitica* was isolated from the intestine, liver, spleen, and kidneys.

10.4 Epidemiology

10.4.1 Incidence in Humans

10.4.1.1 Notification Rates in Europe Have Been Stable from 2015 to 2019

In 2019, yersiniosis was the fourth most common reported bacterial enteric infection after campylobacteriosis, salmonellosis, and STEC infections in Europe (EFSA and ECDC 2021). *Y. enterocolitica* was the most common species (99%) of the confirmed cases with species information. In total, 7048 confirmed human yersiniosis cases (1.7 cases per 100 000 inhabitants) were reported by 20 European countries in 2019. The highest country-specific notification rates were reported in Finland, Lithuania, and Czechia) (> 5 cases per 100 000 inhabitants). Due to inconsistency of the surveillance systems in various countries, a comparison of yersiniosis incidence between countries is only suggestive. In Europe, incidence is highest among infants and children under 5 years of age. The majority of yersiniosis cases are sporadic and domestically acquired, and no seasonal distribution has been reported (EFSA and ECDC 2021).

10.4.1.2 The Incidence of *Yersinia* Infections Is Underestimated if Culture Methods Only Are Used

The incidence of yersiniosis in the USA was 1.4 cases per 100 000 inhabitants in 2019 (Tack et al. 2020). It has increased significantly (158%) in 2019 compared with

2016–2018. However, 57% of the cases were diagnosed using culture-independent diagnostic methods (CIDM) such as PCR and antigen-based methods. One reason for the high incidence rate may be that many laboratories have begun using PCR methods to avoid problems with time-consuming and insensitive isolation methods (Fredriksson-Ahomaa and Korkeala 2003). From 2015, diagnostic laboratories in New Zealand have progressively introduced CIDM for fecal samples. This may have influenced the incidence of human yersiniosis, which significantly increased between 2015 and 2018. The current rate of yersiniosis in New Zealand is 24.1 cases per 100 000 inhabitants, which is very high compared to other industrialized countries (Rivas et al. 2021). Introduction of PCR screening for fecal samples has also significantly increased the annual incidence rate of yersinosis in England (Clarke et al. 2020).

10.4.2 Foodborne Outbreaks

10.4.2.1 Foodborne *Yersinia* Infections Are Mainly Sporadic Infections and Outbreaks Are Rare

Foodborne yersiniosis is mostly caused by *Y. enterocolitica* (EFSA and ECDC 2021). Although *Y. pseudotuberculosis* is a rare cause of sporadic human foodborne infections, it has caused several foodborne outbreaks in Finland, Japan, and Russia. During past years, several foodborne *Y. enterocolitica* outbreaks have been reported in Nordic countries (Table 3).

10.4.2.2 *Y. enterocolitica* O:3 Outbreaks Have Recently Been Linked to Vegetables in Nordic Countries

In Sweden, a *Y. enterocolitica* O:3 (ST18) outbreak with 53 cases was linked to imported iceberg lettuce in 2021 (https://www.foodsafetynews.com/2021/03/yersinia-outbreak-linked-to-imported-iceberg-lettuce/). In 2020, pre-cut lettuce was associated with *Y. enterocolitica* O:3 outbreaks in Norway (Promed, Archive number: 20201227.8050413). The most common symptoms were diarrhea, fever, and abdominal pain, which lasted 1–3 weeks. A *Y. enterocolitica* O:3 cross-border outbreak was identified in Denmark and Sweden in 2019 (Espenhain et al. 2019). This outbreak was confirmed with whole-genome sequencing (WGS) and the sequence type was ST18, which is a typical type found in pigs. Imported fresh spinach was identified as the vehicle by combining epidemiological and trace-back investigations. Symptoms such as fever, diarrhea, and abdominal pain in the right lower part of the abdomen occurred after an incubation period of 3–7 days. Earlier in the same year, another *Y. enterocolitica* O:3 outbreak was linked to imported spinach in Sweden. Outbreaks due to serotype O:9 have also been reported (Table 3). Three *Y. enterocolitica* O:9 outbreaks have been reported in Norway, all linked to fresh produce. The largest *Y. enterocolitica* O:9 outbreak, which was linked to mixed salad, was reported in military camps in 2014 (MacDonald et al. 2016). In total, 133 cases with identical genotypes were found. The same year, sushi was linked to an outbreak caused by *Y. enterocolitica* O:9 (ST12) in New Zealand (Strydom et al. 2019). Outbreaks due to serotype O:8, which is a quite rare serotype and is regarded

Table 3 Reported outbreaks due to *Y. enterocolitica* (YE) and *Y. pseudotuberculosis* (YP) during the past decade

Year of outbreak	Country	Serotype of causing agent		Confirmed cases	Suspected sources
		YE	YP		
2021	Norway	O:3		15	Unknown
2021	Sweden	O:3		53	Iceberg lettuce
2020	Norway	O:3		10	Mixed salad
2020	Norway	O:3		23	Spinach
2019	Sweden	O:3		30	Spinach
2019	Denmark + Sweden	O:3		20+37	Spinach
2019	USA (Pennsylvania)	O:8		48	Milk
2018	Norway	O:9		18	Mixed salad
2016	New Zealand	O:9		24	Sushi
2014	Finland		O:1	55	Raw milk
2014	New Zealand		O:1	220	Vegetables
2014	Norway	O:9		133	Mixed salad
2013	Japan	O:8		52	Salad
2012	Japan	O:8		39	Unknown
2011	Norway	O:9		21	Mixed salad
2011	USA (Pennsylvania)	O:8		109	Milk

highly pathogenic, have been reported in Japan and the USA (Table 3). The two US outbreaks were associated with pasteurized milk, which was most probably contaminated after pasteurization (Longenberger et al. 2014; Gruber et al. 2021).

10.4.2.3 *Y. pseudotuberculosis* Outbreaks Have Been Associated with Vegetables and Raw Milk

A large *Y. pseudotuberculosis* outbreak was reported in New Zealand in 2014. In total, 220 laboratory-confirmed cases were infected by a novel *Y. pseudotuberculosis* O:1 clone belonging to sequence type ST42 (Williamson et al. 2016). The case-control study implicated contaminated carrots and lettuce as the most probable infection source. In Finland, an outbreak of *Y. pseudotuberculosis* O:1 infection with 55 cases was reported in 2014 (Pärn et al. 2015). The same strain was found in humans and raw milk, which was also associated with the outbreak using a case-control study. In Finland, *Y. pseudotuberculosis* infection is a notifiable disease, and outbreaks cause large variation in the annual incidence. Most cases are sporadic, but ten outbreaks were reported between 1997 and 2008 (Rimhanen-Finne et al. 2009). These outbreaks were caused by serotypes O:1 and O:3 and were linked to contaminated carrots and iceberg lettuce. Several large *Y. pseudotuberculosis* outbreaks linked to raw vegetables (cabbage, onions, and carrots) have been reported in Russia (Tseneva et al. 2012). Outbreaks have been registered mostly in schools and day-care

centers. The number of children hospitalized has been large. Multiple FESLF outbreaks due to serotypes O:1b and O:3 have also been linked to contaminated vegetable (Timchenko et al. 2016). The vegetables have probably been contaminated by rodents. Incidences are highest in winter, possibly due to the need to store vegetables for a prolonged period, with a subsequent higher risk of being contaminated by rodents (Amphlett 2016). In Japan, surface water has also been linked to outbreaks (Tsubokura et al. 1989).

10.4.3 Prevalence in Animals

10.4.3.1 Nonpathogenic *Y. enterocolitica* Are Common in Animals

Numerous works have been carried out to study the presence of enteropathogenic *Yersinia* in a variety of animals, including farm, pet, wild, and zoo animals (Fredriksson-Ahomaa et al. 2018). *Y. enterocolitica* strains have frequently been isolated from animal sources; however, these strains mainly belong to biotype 1A, regarded as nonpathogenic (Joutsen et al. 2017; Lucero-Estrada et al. 2020). Human pathogenic *Y. enterocolitica* strains have mostly been found in slaughtered fattening pigs (Laukkanen-Ninios et al. 2014; Morka et al. 2018).

10.4.3.2 *Y. enterocolitica* of Bioserotype 4/O:3 Is Frequently Isolated from Pigs

Pigs are asymptomatic carriers of human pathogenic *Yersinia* strains. High seroprevalence (60–90%) of enteropathogenic *Yersinia* has been reported in pigs at slaughter (Bonardi et al. 2016; Lorencova et al. 2016; Felin et al. 2019). *Y. enterocolitica* belonging to bioserotype 4/O:3, the most common type associated with human disease, has mainly been identified in pigs (Råsbäck et al. 2018). This pathogenic type has frequently been isolated from the oral cavity of pigs at slaughter in Europe, especially from the tonsils, but also from the submaxillar lymph nodes and intestinal content (Laukkanen-Ninios et al. 2014; Fois et al. 2018). It has also been isolated from surface swabs of pig carcasses and edible offal at the slaughterhouse. *Y. pseudotuberculosis* has also been isolated from the tonsils and feces of pigs at slaughter, but much more rarely than *Y. enterocolitica* (Laukkanen-Ninios et al. 2014; Bonardi et al. 2016).

10.4.3.3 *Y. enterocolitica* O:9 Has Sporadically Been Found in Ruminants

Y. enterocolitica O:9, which is the second most frequently reported serotype among human *Yersinia* infections in many countries, has mainly been isolated from ruminants, cattle, and deer but also from sheep and goats (Le Guern et al. 2016; Rivas et al. 2021). *Y. enterocolitica* O:9-positive animals can give false-positive results for *Brucella* when using serological tests (O'Grady et al. 2016). *Y. enterocolitica* bioserotype 5/O:3, which is a rare pathogenic type mainly associated with hares, has quite recently been isolated from Finnish sheep at slaughter (Joutsen et al. 2016). High seroprevalences of *Y. enterocolitica* and *Y. pseudotuberculosis* in sheep and *Y. enterocolitica* in goats were recently reported in Pakistan (Ullah et al. 2019).

10.4.3.4 Dogs and Cats Are a Source of Human Pathogenic *Y. enterocolitica* Strains

Human pathogenic *Y. enterocolitica* strains have sporadically been isolated from dogs and cats in Europe (Stamm et al. 2013). Dogs were shown to excrete pathogenic *Y. enterocolitica* more frequently in their feces than cats. The most dominant *Y. enterocolitica* type in dogs in Europe is biotype 4, followed by biotypes 2 and 3 (Stamm et al. 2013; Le Guern et al. 2016). Bioserotype 3/O:3, which is the dominant type among human infections in China, is the dominant type found in the tonsils and feces of dogs in China (Wang et al. 2014). *Y. pseudotuberculosis* has more frequently been detected in cats than in dogs in France (Le Guern et al. 2016). In China, *Y. pseudotuberculosis* strains of various serotypes have been found in dog tonsils and feces.

10.4.3.5 *Y. pseudotuberculosis* Is a Common Finding in Wildlife

Y. pseudotuberculosis has mostly been isolated from wildlife, especially from birds, rodents, and lagomorphs, which are therefore considered the most important reservoirs of this pathogen (Le Guern et al. 2016). *Y. pseudotuberculosis* of various serotypes has also been isolated from wild boar tonsils (Reinhardt et al. 2018; Sannö et al. 2018). Pathogenic *Y. enterocolitica* has quite rarely been found in wild animals (Joutsen et al. 2017). However, in Sweden, pathogenic *Y. enterocolitica* was isolated from the tonsils of hunted wild boars (Sannö et al. 2018). A high seroprevalence (>50%) of enteropathogenic *Yersinia* has also been reported in wild boars in Europe, indicating that wild boars are an important reservoir of *Y. enterocolitica* and *Y. pseudotuberculosis* (Arrausi-Subiza et al. 2015; Lorencova et al. 2016; Fredriksson-Ahomaa et al. 2020). High pathogenic *Y. enterocolitica* 1B/O:8 and *Y. pseudotuberculosis* have recently been reported in deer in Japan (Takahashi et al. 2020). In Belgium, *Y. enterocolitica* bioserotypes, 2/O:5,27 and 3/O:1,2,3, which are very seldom identified in human infection, have been reported in brown rats (Rouffaer et al. 2017). Bioserotype 4/O:3, the most common *Y. enterocolitica* type found in human infections and pigs, has been isolated from brown rats near pig farms in Sweden (Backhans et al. 2011). The genotypes of rat and pig strains were indistinguishable, indicating that rats may spread this pathogen within a farm.

10.4.4 Prevalence in Food and Water

10.4.4.1 A High Prevalence of *Y. enterocolitica* Has Been Detected in Pork Products by PCR

Pathogenic *Y. enterocolitica* strains have frequently been detected by PCR in pork products, but also sporadically in game meat, dairy products, vegetables, and surface water (Cheyne et al. 2010; Fredriksson-Ahomaa 2017; Bonardi et al. 2018; Verbikova et al. 2018). Using culture methods, most of the *Y. enterocolitica* isolates found in food and water have belonged to nonpathogenic biotype 1A. Pathogenic *Y. enterocolitica,* mainly belonging to bioserotype 4/O:3, has been isolated from pork, especially from pig head meat and tongues in Europe (Laukkanen-Ninios et al. 2014). In China, pathogenic *Y. enterocolitica* bioserotype 3/O:3 (ST135), which is a

typical bioserotype in pigs in China, was quite recently isolated for the first time from raw chicken (Peng et al. 2018). *Y. pseudotuberculosis* has only rarely been found in meat. It has more commonly been isolated from vegetables (Tseneva et al. 2012) but also from surface water (Fukushima et al. 1995; Le Guern et al. 2016). Recently, *Y. pseudotuberculosis* was isolated from raw milk associated in a *Y. pseudotuberculosis* outbreak in Finland (Castro et al. 2019).

10.4.5 Transmission Routes

10.4.5.1 Several Transmission Routes Exist for Enteropathogenic *Yersinia*

Both *Y. enterocolitica* and *Y. pseudotuberculosis* are primarily transmitted fecal-orally from animal reservoirs to humans through contaminated food and water, but direct animal contact is also a possible transmission route (Fig. 1). Transmission of enteropathogenic *Yersinia* may also occur directly from human to human or indirectly by blood transfusion.

10.4.5.2 Consumption of Pork Is a Significant Risk Factor for Sporadic *Y. enterocolitica* Infections

In a recent review, pork consumption and occupational contact with pigs were significantly associated with sporadic *Y. enterocolitica* infections (Guillier et al. 2020). In the same study, untreated water was also a risk factor for sporadic yersiniosis. Consumption of raw minced pork has been identified as the main risk factor for sporadic *Y. enterocolitica* in Germany using a population-based case-control study (Rosner et al. 2012). Raw pork consumption may play an important role in countries such as Belgium, Germany, and the Netherlands, where raw minced pork with pepper and onion is a delicacy that can be purchased as ready-to-eat food from butcher shops. However, in most countries, transmission is more likely to occur via cross-contamination of cooked pork or foods not normally harboring *Y. enterocolitica*.

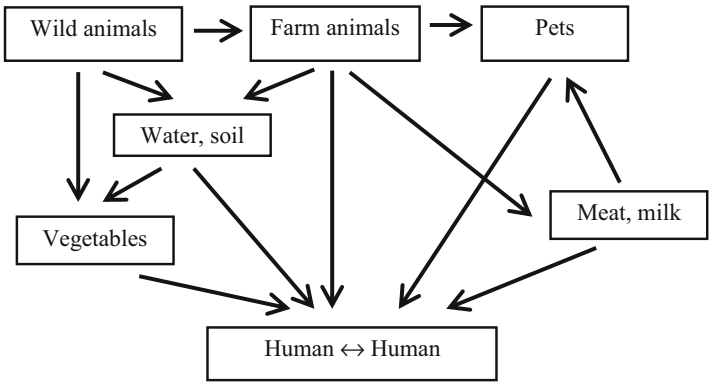

Fig. 1 Transmission routes of enteropathogenic *Yersinia*

10.4.5.3 *Y. pseudotuberculosis* Is Transmitted by Contaminated Vegetables

Both fresh produce and untreated surface water are important infection sources for *Y. pseudotuberculosis* infections. Wildlife feces may have contaminated the vegetables during storage, or the vegetables have already been contaminated at the farm through contaminated irrigation water or soil (Rimhanen-Finne et al. 2009). Untreated drinking water from wells, springs, and streams contaminated with wildlife feces has been associated with *Y. pseudotuberculosis* infections in Japan (Tsubokura et al. 1989).

10.4.5.4 Enteropathogenic *Yersinia* Can Be Transmitted to Humans via Pets

Companion animals, such as dogs and cats, are suspected sources of human yersiniosis through close contact, especially for young children (Boqvist et al. 2009). In China, indistinguishable *Y. enterocolitica* bioserotype 3/O:3 strains have been found in humans, dogs, and pigs, indicating a link between human infections, dogs, and pigs (Wang et al. 2014). Pathogenic *Y. enterocolitica* 4/O:3 may be transmitted to dogs and cats via raw pork and offal (Fredriksson-Ahomaa et al. 2001).

10.4.5.5 Human-to-Human Transmission Has Rarely Been Reported

Enteropathogenic *Yersinia* can be transmitted from human-to-human either by direct contact or indirectly through blood transfusion. Direct transmission may occur when basic hygiene and handwashing habits are inadequate (Ong et al. 2012). Transmission of *Y. enterocolitica* from chitterlings (prepared pig intestine, which is a traditional dish in African-American households) to infants occurs through contact with their caretakers preparing chitterlings (Jones et al. 2003). Indirect transmission may occur by transfusion of contaminated blood products (Guinet et al. 2011). A blood donor with subclinical bacteremia is the most likely source of *Yersinia* contamination (Rivas et al. 2021).

10.5 Detection and Typing

10.5.1 Detection Methods

10.5.1.1 Culturing Is Still Commonly Used to Find Enteropathogenic *Yersinia* from Various Sample Types

The isolation of enteropathogenic *Yersinia* is time-consuming, especially when samples with low levels of *Yersinia* and high levels of other bacteria are studied (Fredriksson-Ahomaa and Korkeala 2003; Petsios et al. 2016). Isolation methods for food and environmental samples are based on (1) direct culturing on selective agar media, (2) a short selective enrichment step before culturing on agar plates, and/or (3) cold enrichment at 4°C for 2–3 weeks (Hallanvuo et al. 2019; Weagant and Feng 2017). Direct culturing on selective agar plates without any pre-enrichment is

usually successful only for samples containing a large number of *Yersinia,* such as clinical samples from humans and animals with acute yersiniosis. The most widely used commercially available selective agar plate is CIN (cefsulodin-igasan-novobiocin) agar (Petsios et al. 2016). In parallel to CIN agar, commercially available chromogenic agar is used for *Y. enterocolitica* isolation (Hallanvuo et al. 2019). No chromogenic agar for *Y. pseudotuberculosis* is currently available commercially, and a low-selective MacConkey agar is therefore used along with CIN (Weagant and Feng 2017). The isolation of *Y. pseudotuberculosis* is very challenging because it grows slowly, thus being easily overgrown by other bacterial species present in the sample.

10.5.1.2 PCR Is Increasingly Used to Screen for the Presence of Pathogenic *Yersinia* in Various Sample Types

PCR is a very practical method that is both cost- and time-effective to screen for the presence of pathogenic *Yersinia* before culturing. There is still no sensitive and accurate isolation method available for detecting enteropathogenic *Yersinia* in food and environmental samples, thus several PCR methods have been designed for this purpose (Petsios et al. 2016). Currently, PCR is also used to screen for the presence of enteropathogenic *Yersinia* in the fecal samples of humans (Clarke et al. 2020). The *ail* gene located in the chromosome of *Y. enterocolitica* and *Y. pseudotuberculosis* is the most commonly used target in the PCR methods. The chromosomal *ail* gene is preferred over the virulence genes located on the pYV plasmid because pYV may be lost during culturing, giving a false-negative result. However, false-positive results are possible using *ail* because it has also been detected in nonpathogenic *Y. enterocolitica* and *Y. kristensenii* strains (Joutsen et al. 2020). PCR methods are rapid and have a superior sensitivity compared to culture methods; however, they may also detect nonviable bacteria and do not yield bacterial isolates that are essential for further epidemiological studies. Therefore, isolation methods should be used together with PCR.

10.5.1.3 MALDI-TOF (Matrix-Assisted Laser Desorption/Ionization-Time of Flight) Is Used for Rapid Identification of *Yersinia*

Commercially available identification kits, especially the API 20E test, have been widely used for identifying *Y. enterocolitica* and *Y. pseudotuberculosis* (Petsios et al. 2016). However, tests based on biochemical reactions easily misidentify *Yersinia* spp. (Fredriksson-Ahomaa et al. 2018). Identification of *Yersinia* spp. using MALDI-TOF has increased recently. It is a rapid and accurate method that provides protein profiles for identifying *Yersinia* at the species and subspecies levels (Stephan et al. 2011). However, rare and untypical strains cannot be identified if the protein profiles are missing from the database (Morka et al. 2018). Also, PCR methods using species- and virulence-specific genes are commonly used for rapid and accurate identification of enteropathogenic *Yersinia*.

10.5.1.4 Serological Tests Are Used to Screen the Prevalence of Yersiniosis in Animal Reservoirs

There are several commercial serological tests available to detect anti-*Yersinia* antibodies in humans and animals (Dalby et al. 2017; Wielkoszynski et al. 2018; Ullah et al. 2019). Serological tests are very practical for monitoring yersiniosis in animal reservoirs and for estimating the prevalence of pathogenic *Yersinia* in livestock at the herd level, as these tests are not as expensive and time-consuming as traditional culture methods (Vanantwerpen et al. 2017; Felin et al. 2019). Serological testing can be performed from the serum or muscle fluid, which can conveniently be collected at the slaughterhouse. Serological diagnosis is not equivalent to classical microbiological detection of the organism, as the serological response is delayed with respect to the time of infection. Serological tests are also valuable when *Yersinia* has not been isolated from an asymptomatic patient and when clinical symptoms indicate a previous infection. The diagnosis is especially important for diagnosing sequelae after gastroenteritis, such as arthritis.

10.5.2 Typing Methods

10.5.2.1 Biotyping Is Still Used to Assess the Potential Pathogenicity of the *Y. enterocolitica* Isolates

Phenotyping methods based on biotyping and serotyping are still used for characterization of *Y. enterocolitica* isolates (Fredriksson-Ahomaa et al. 2018). The potentially pathogenic *Y. enterocolitica* isolates can be identified by the pyrazinamidase test, which is one of the key tests included in the biotyping scheme (Hallanvuo et al. 2019). Information of biotype and/or serotype alone often lacks the discriminatory power needed to differentiate *Y. enterocolitica* isolates that belong to the same bioserotype. Therefore, in addition to bio- and serotyping, more discriminatory typing methods are needed. Correctly identified *Y. pseudotuberculosis* isolates are considered pathogenic. However, *Y. similis* and *Y. wautersii* are impossible to differentiate from *Y. pseudotuberculosis* using biochemical tests, and they may also share the same serotypes (Savin et al. 2014). Therefore, the presence of certain virulence genes in presumptive *Y. pseudotuberculosis* isolates should be studied.

10.5.2.2 Whole-Genome Sequencing (WGS) Is Replacing Other Typing Methods

Bacterial WGS can now be obtained rapidly and affordably. Nowadays, WGS is increasingly used for identifying *Yersinia* strains and in epidemiological studies, including outbreak studies (Williamson et al. 2016; Fredriksson-Ahomaa et al. 2018; Inns et al. 2018). Currently, two seven-gene multilocus sequence typing (MLST) schemes are available for enteropathogenic *Yersinia*. The first one was designed for identifying and typing *Y. pseudotuberculosis* isolates (Laukkanen-Ninios et al. 2011). The newer scheme was a pan-*Yersinia* scheme for accurate identification of *Yersinia* spp. (Hall et al. 2015). Increasingly, MLST based on core genes (cgMLST) is used for more discriminatory typing (Inns et al. 2018; Hunter et al. 2019; Hammerl et al. 2021). Currently, there are two databases for MLST and cgMLST typing of *Yersinia* isolates

available online: EnteroBase (https://enterobase.warwick.ac.uk/species/index/yersinia) (Zhou et al. 2020) and BIGSdb-Pasteur (https://bigsdb.pasteur.fr/yersinia/) (Savin et al. 2019). cgMLST is an accurate and reliable high-throughput typing method that is suited for surveillance, outbreak studies and other epidemiological studies. In addition to sequence types, i.e., serotypes, virulence and resistance genes can be derived from the WGS data (Hammerl et al. 2021). Pulsed-field gel electrophoresis (PFGE) and multiple locus variable-number tandem repeat analysis (MLVA), which have shown to be quite discriminatory methods for *Yersinia* typing, are also used in epidemiological studies (Saraka et al. 2017; Raymond et al. 2019; Strydom et al. 2019; Hammerl et al. 2021). However, they may be replaced by WGS in the future.

10.6 Conclusions

Y. enterocolitica and *Y. pseudotuberculosis* are important pathogens that cause enteric yersiniosis in humans and animals. These pathogens differ phenotypically and genotypically from each other. However, while they cause a disease with similar symptoms, their animal reservoirs and transmission routes may be different. PCR is increasingly used to screen the presence of enteropathogenic *Yersinia* in human and nonhuman samples usually combined with culture methods. Efforts should be made to develop better and standardized isolation methods for these pathogens. Identification of enteropathogenic *Yersinia* is challenging because *Yersinia* spp. are easily misidentified. This can be overcome by using methods based on WGS, which enables accurate identification of pathogenic *Yersinia* spp.

Enterohemorrhagic *E. coli* (EHEC): Environmental-Vehicle-Human Interface

11

Carlos L. Correa-Martinez, Shana R. Leopold, Robin Köck, Annelene Kossow, Andreas Bauwens, and Alexander Mellmann

Contents

Abstract

Enterohemorrhagic *Escherichia coli* (EHEC) are a pathogenic subgroup of Shiga toxin-producing *E. coli* (STEC) that can cause severe intestinal disease and hemolytic uremic syndrome (HUS) in humans, the latter of which is of significant clinical concern. Cattle are the major reservoir of EHEC, where host-related factors allow bacteria to persist asymptomatically for years. Of particular concern are a small percentage of animals in herds that shed extremely high numbers of

EHEC ($\geq 10^4$ CFU/g of feces), termed "supershedders," and are responsible for the majority of EHEC spread and contamination in a farm environment. Another transmission route is through the environment, where EHEC can express genetically encoded factors of bacterial fitness, enabling the bacteria to remain viable in bovine feces, soil, and water for weeks, up to several months. Contamination of meat during slaughter or processing and contamination of plants via EHEC-containing water or manure are major routes of entry into the food chain. The predominant EHEC-serotype O157 as well as non-O157 strains caused several hundred outbreaks in industrialized countries worldwide. Current and future research efforts are focused on rapid outbreak identification, development of therapeutics to treat HUS, and implementation of measures to reduce colonization of herds as well as prevent spread from animal reservoirs.

Keywords

Enterohemorrhagic Escherichia coli (EHEC) · Shiga toxin-producing E. coli (STEC) · Food-bornd outbreak · Transmission · Supershedder

11.1 Introduction

Most members of the species *E. coli* are part of the physiological flora in the gastrointestinal tracts of humans and animals. In addition to these commensal bacteria, there are pathogenic *E. coli* that cause extraintestinal and intestinal disease. Intestinal pathogenic *E. coli* presently include seven pathogroups: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), enteropathogenic *E. coli* (EPEC), adherent invasive *E. coli* (AIEC), diffusely adherent *E. coli* (DAEC), and enterohemorrhagic *E. coli* (EHEC) (Croxen et al. 2013). Each pathotype is associated with unique epidemiological characteristics and specific forms of disease that cause significant morbidity and mortality. Zoonotic *E. coli*, of which EHEC are the prototype, are a major cause of foodborne disease, thus posing complex challenges to the food industry. Due to their public health relevance, EHEC are intensively studied in human and veterinary medicine. Ongoing investigations are addressing ecology of EHEC in animals, persistence and survival in the environment, and how these factors affect entry into, or dissemination along, the food chain. Other areas of research include the epidemiology of EHEC infections in humans, diagnostics, pathogenic mechanisms of these bacteria, and treatment as there is currently no specific therapy.

EHEC can cause a broad clinical spectrum of disease which includes watery or bloody diarrhea and hemolytic uremic syndrome (HUS), a leading cause of acute renal failure in children (Tarr et al. 2005). Since the first isolation of an EHEC outbreak strain in the USA in 1982 (Riley et al. 1983), which was identified as *E. coli* serotype O157:H7, EHEC has emerged as an important public health concern worldwide. The large EHEC O104:H4 outbreak in Germany in 2011 with 3842 cases, 855 HUS patients, and 53 deaths demonstrates the significant impact of an

EHEC outbreak on human health (RKI 2011) and also the challenges in source tracing due to growing globalization of food production (Karch et al. 2012; Kampmeier et al. 2018).

11.2 Expression of Shiga Toxins in EHEC

A key characteristic of the EHEC pathotype is the presence of bacteriophage-encoded Shiga toxins (Stx). Stx, also known as verocytotoxins (VTs), are members of a large family of cytotoxins that are characterized by a high degree of sequence diversity. The Stx family is divided into two major branches, Stx1 and Stx2, and many toxin subtypes and variants have been described (Karch et al. 2009; Bergan et al. 2012; Scheutz et al. 2012). Classification of Stx subtypes is used not only for taxonomic purposes, but also serves as an important clinical predictor, because Stx found in strains associated with HUS differ from those Stx subtypes that are carried by strains causing a milder course of disease (Scheutz et al. 2012). More specifically, a significant association has been established between strains producing Stx2 and the development of hemorrhagic colitis and HUS. The subtypes Stx2a, Stx2c, and Stx2d are most relevant in human infection (Joseph et al. 2020), while Stx2e is associated with edema disease of pigs, one of the rare veterinary clinical manifestations of EHEC infections (Moxley 2000).

A sequence-based protocol for characterization of the Stx genes has been described (Scheutz et al. 2012) and includes three levels of classification: types, subtypes, and variants (see Table 1).

1. Types: The two major branches Stx1 and Stx2 share structure and function but are not cross-neutralized with heterologous antibodies. The terms Stx1 and Stx2 should only be used when the subtype is unknown.
2. Subtypes: Currently the antigenically related members of Stx1 (Stx1a, Stx1c, and Stx1d) and Stx2 (Stx2a, Stx2b, Stx2c, Stx2d, Stx2e, Stx2f, and Stx2g) are distinguished.

Table 1 Types, subtypes, and variants of Shiga toxins according to Scheutz et al. (2012)

Types	Subtypes	Variants (examples)
Stx1	Stx1a	Stx1a-O157-EDL933
	Stx1c	Stx1c-O174-DG131-3
	Stx1d	Stx1d-ONT-MHI813
Stx2	Stx2a	Stx2a-O104-G5506
	Stx2b	Stx2b-O111-S-3
	Stx2c	Stx2c-O157-A75
	Stx2d	Stx2d-O91-B2F1
	Stx2e	Stx2e-O26-R107
	Stx2f	Stx2f-O128-T4-97
	Stx2g	Stx2g-O2-S86

3. Variants: Variants include the subtype-specific prototypic toxins or related toxins within a subtype (that differ by one or more amino acids from the prototype). The variants are designated by toxin subtype, O-antigen group of the host *E. coli* strain, followed by the strain name or number from which that toxin was initially described, for example, Stx1a-O157-EDL933 or Stx2a-O104-G5506 (Scheutz et al. 2012) (see Table 1). Nucleotide variants within a given Stx subtype are italicized.

All Stx consist of a single A subunit and five identical B subunits (AB_5). The A subunit is the enzymatically active component, and the Stx B pentamer binds to endothelial cellular ligand glycosphingolipids (GSLs): with high affinity to globotriaosylceramide (Gb3Cer) and less effective binding to globotetraosylceramide (Gb4Cer) (Müthing et al. 2009). Stx1 and Stx2 share identical binding specificity (Müthing et al. 2009). After binding to the cell surface, the AB_5-Gb3Cer complex is internalized by various endocytic mechanisms and routed from the early endosomes through the *trans*-Golgi-network and the Golgi stacks to the endoplasmic reticulum (Sandvig et al. 2010; Bauwens et al. 2013). Moreover, evidence suggests that Stx (like other ribosome-inactivating proteins) not only remove adenine moieties from rRNA, but also efficiently depurinate DNA. Stx genes are found within the genomes of temperate bacteriophages, which are mobile elements that can easily integrate at specific sites in the bacterial chromosome. In vitro and in vivo studies have demonstrated that most EHEC can lose the Stx-encoding gene by bacteriophage excision during infection, isolation, or subculture, resulting in *stx*-negative isolates (Mellmann et al. 2009). This finding is also important for the diagnostics of EHEC infections: If stool samples from patients, especially those suffering from HUS, which usually develops >7 days after the onset of infection, lack the detection of *stx*, EHEC-associated HUS still cannot be ruled out.

A close genetic relationship between *stx*-positive and *stx*-negative EHEC O157:H7 isolates has been recently described using next-generation sequencing (NGS). The loss of *stx* genes poses an additional diagnostic challenge, since routine detection of EHEC relies on the identification of *stx* genes. This could potentially lead to misidentification, with the therapeutic and epidemiologic consequences that this entails (Ferdous et al. 2015; Bielaszewska et al. 2007; Mellmann et al. 2005).

11.3 Epidemiology of EHEC in Animals

Several studies have demonstrated that cattle are the main reservoir of human pathogenic EHEC O157:H7, in addition to many pathogenic non-O157 EHEC serotypes (Naylor et al. 2005a). These bacteria have adapted to an oral-fecal cycle in cattle, where EHEC colonization begins with ingestion and subsequent entrance to the rumen and gastrointestinal tract, but they generally do not have a pathogenic effect on adult animals. Systemic disease similar to that observed in humans does not occur in cattle due to the absence of Stx receptors in bovine endothelial cells; however, EHEC may cause diarrhea and enterocolitis in calves (Dean-Nystrom et al. 1997). Although

certain non-O157 serogroups (O26, O111, O118) (Naylor et al. 2005a) have been reported to cause disease in young calves, their role in diarrheal disease among these animals remains controversial, as EHEC has been more commonly detected in healthy calves than in symptomatic ones (Kolenda et al. 2015). Prevalence among cattle varies widely and may be due to several circumstances including the geographical region, animal age, or the specific farm conditions (Ferens and Hovde 2011). Published prevalence rates vary dramatically, from 0% to 36% among animals studied in different countries and farm types (Naylor et al. 2005a), with highest prevalence values described in Africa and North America (Islam et al. 2014). Studies have also shown that EHEC prevalence is related to the type of farm (i.e., beef, dairy, or mixed) and may be influenced by factors such as cattle movement, hygiene management, diet, husbandry, as well as the type of specimen analyzed (Menrath et al. 2010; Cobbaut et al. 2009; Ferens and Hovde 2011; Islam et al. 2014). While cattle are the major known reservoir of EHEC, other minor reservoirs include sheep, goats, pigs, horses, dogs, poultry, and deer (Naylor et al. 2005a).

The persistence of EHEC O157:H7 in cattle may be due to its ability to colonize a particular niche within the lower gastrointestinal tract (Grauke et al. 2002). Tissue tropism for the colon has been demonstrated by immunofluorescent detection of microcolonies on the lymphoid follicle-dense mucosa at the terminal rectum within 3–5 cm proximal to the recto-anal junction (Grauke et al. 2002; Naylor et al. 2003, 2005b). A correlation between recto-anal junction colonization and supershedder status has been described (Cobbold et al. 2007; Low et al. 2005). Supershedding is thought to be caused, in part, by an impaired innate and adaptive immune response in rectal tissue due to the downregulation of relevant genes. EHEC's ability to form a biofilm on the bovine intestinal epithelium may be an additional factor contributing to the supershedding phenomenon as portions of the biofilm may detach during defecation, allowing for the sporadic shedding of high numbers of bacteria (Munns et al. 2015). Furthermore, several fimbrial and afimbrial proteins expressed by EHEC O157 and non-O157 strains likely play a role in ruminant reservoir persistence (Farfan and Torres 2012). In studies that used bovine terminal rectal primary epithelial cells, the H7 flagellum was demonstrated to act as an adhesin to bovine intestinal epithelium, supporting its involvement in initiating colonization of the cattle reservoir (Mahajan et al. 2009). Additionally, proteins such as EhaB, ELF, HCP, and UpaG have been shown to enhance intestinal adhesion by binding to laminin, an extracellular matrix protein (Segura et al. 2018). Stx may also play a role in colonization and persistence by blocking bovine lymphocyte activation and thus suppressing the bovine host's immune response to the intestinal colonization (Moussay et al. 2006).

11.4 EHEC in the Environment

EHEC can survive in bovine feces for a long time making feces (or manure) a likely vehicle for transmission to cattle, food, and the environment. Survival in feces can range from 1 to 18 weeks depending on the temperature (5–25 °C) (Fukushima et al. 1999). Several factors contributing to a prolonged survival of specific EHEC O157:

H7 strains have been identified, including biofilm-formation and the ability to activate genes promoting bacterial fitness in adverse environmental conditions (Segura et al. 2018). Entry of EHEC to the environment may occur directly through deposit of feces onto land or through drainage runoff of fecal material in soil, especially after heavy rainfalls (Thurston-Enriquez et al. 2005). Moreover, under experimental conditions, EHEC can even survive for more than 1 year in various manure-amended soils at different temperatures (Fremaux et al. 2008). Long-term survival of EHEC in lake water (13 weeks) and in cold river water (27 days) has also been demonstrated (Wang and Doyle 1998; Maule 2000). This extended persistence in the environment likely plays a significant role in the colonization of cattle and subsequent human infection (Fremaux et al. 2008).

EHEC O157:H7 is also able to colonize various types of plants and fruits. For example, EHEC O157:H7 has been shown to form bacterial aggregates on apples (Janes et al. 2005) as well as on the surface of lettuce leaves (Seo and Frank 1999; Auty et al. 2005). Furthermore, studies have found EHEC in the internal inner tissues of plants, including radishes, carrots, and lettuce (Itoh et al. 1998; Solomon et al. 2002). These subsurface localizations may be protective to the bacteria as they are inaccessible to other competitive bacteria as well as surface treatments and washing. The growth rate of EHEC in leafy vegetables, sprouts, and soil has been found to depend on the type of plant; however, growth was detected irrespective of the serotype or the Stx carriage (Merget et al. 2020). Once attached to food items, EHEC can remain viable for long periods of time, such as up to 9 months at room temperature in wheat flour (Forghani et al. 2018) and over 6 months in meat products frozen at −18 °C, even surviving freeze-thaw cycles (Ro et al. 2015).

11.5 EHEC Infections in Humans

After ingestion of EHEC, a 3- to 12-day incubation period is typically followed by development of watery diarrhea accompanied with abdominal cramping and pain. Approximately 90% of patients with culture-positive infection will subsequently suffer from bloody diarrhea resulting from a hemorrhagic colitis caused by EHEC (Karch et al. 2005). About 1 week after the initial onset of diarrhea, HUS develops in a variable proportion of cases, depending on the causative EHEC strain serotype and Stx subtype (Tarr et al. 2005). HUS patients present with widespread thrombotic microvascular lesions in the kidneys, the gastrointestinal tract, and other organs (Richardson et al. 1988). Since EHEC infections are rarely bacteremic, that is, bacteria do not penetrate the circulatory system and are not found in patient blood cultures (Bielaszewska and Karch 2005), it is hypothesized that HUS results from vascular endothelial injury by circulating Stx. According to the generally accepted model of HUS pathogenesis, Stx is released by EHEC in the intestine, absorbed across the gut epithelium into the circulation (Hurley et al. 2001; Müthing et al. 2009), and transported to small vessel endothelial cells.

HUS is the most common cause of acute renal failure in children, with a 1–4% mortality rate (Spinale et al. 2013; Karch et al. 2005). While 70% of EHEC-infected

patients were fully recovered within 5 years after diagnosis, the remaining 30% still experienced hypertension (9%), neurological symptoms (4%), decreased glomerular filtration rate (7%), and/or proteinuria (18%) (Rosales et al. 2012). The occurrence of extra-renal sequelae has also been reported, including colonic strictures, diabetes mellitus, cholelithiasis, and neurological disorders (Spinale et al. 2013). There is currently no effective therapy, and antibiotic treatment is mostly discouraged, as in vitro data suggested that antibiotics used in an early phase of the infection might increase the release of Stx by EHEC bacteria and thus induce HUS (Wong et al. 2000; Davis et al. 2013). In children, the risk of HUS development associated with antibiotic treatment has been shown to reach up to 25% (Wong et al. 2012). In a first round of a meta-analysis including all available studies, the association between antibiotics and the development of HUS was initially questioned with a pooled Odds Ratio (OR) of 1.33 (95% confidence interval [CI], 0.89–1.99). The re-analysis, however, focusing only on studies with less bias risks and appropriate HUS-definitions, yielded a significant association with an OR of 2.24 (95% CI, 1.45–3.46) (Freedman et al. 2016). In contrast to cattle, EHEC O157:H7 colonizes humans only for a limited time of about 4 weeks (Karch 1996) (Fig. 1). Moreover, in cattle many different EHEC O157:H7 subtypes can co-exist in a single animal (Jacob et al. 2011), while human patients are infected mostly by a distinct O157:H7 subtype.

EHEC O157:H7 is the most prevalent EHEC serotype identified as causative of sporadic HUS cases (Tarr et al. 2005; Karch et al. 2005), though non-O157:H7 EHEC (especially O26:H11, O103:H2, O111:H8, O145:H28/H25 and sorbitol-fermenting (SF) O157:H$^-$) represent a significant portion of EHEC infections leading to HUS complications (Karch et al. 2005; Mellmann et al. 2008; Bielaszewska et al. 2013). In Europe, O26 is the serotype most commonly associated with HUS development, accounting for 39% of all cases, followed by O157 with 23% (EFSA/ECDC 2021). Although EHEC strains are often considered as a pathogroup, there may be important differences between serotypes (CDC 2006).

SF EHEC O157:H$^-$ represent a significant serotype in Europe which has not yet been detected in North America. These strains are characterized by a specific

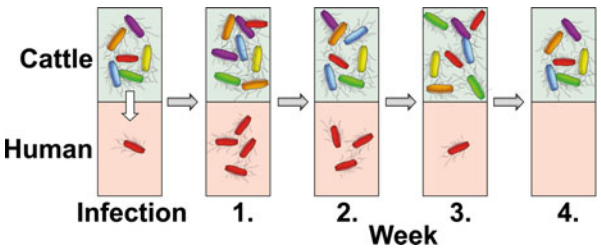

Fig. 1 Schematic illustration of EHEC O157:H7 infection in cattle and humans. In contrast to cattle, EHEC O157:H7 colonizes humans only for a limited time of about 4 weeks. Moreover, whereas in cattle many different EHEC O157:H7 subtypes can co-exist in a single animal, human patients are infected mostly by a distinct O157:H7 subtype. Different EHEC O157:H7 subtypes are indicated by different colors

combination of their phenotypic and virulence characteristics that differentiates them from classical non-SF EHEC O157:H7, including the ability to ferment sorbitol overnight and produce β-D-glucuronidase (Karch and Bielaszewska 2001; Bauwens et al. 2017). The *sfp* gene cluster, which encodes fimbriae and mediates mannose-resistant hemagglutination, has been identified on the large plasmid of SF STEC O157:H$^-$ and is notably absent in EHEC O157:H7 (Brunder et al. 2001).

The minimum infectious dose of EHEC in humans is extremely low, with approximately 10–50 bacteria needed for colonization (Teunis et al. 2004). In meat implicated as an outbreak source in the USA in 1993, there were less than 700 EHEC O157:H7 bacterial cells per hamburger patty prior to cooking (Tuttle et al. 1999). Moreover, a high degree of tolerance to acid and drying enables EHEC to survive even in food items that rarely cause foodborne illness (e.g., apple cider, semi-dry fermented sausage). Nonmeat products such as cookie dough, flour, and soy nut butter have also been identified as sources of EHEC outbreaks, demonstrating the complexity of transmission chains between animals and humans (Neil et al. 2012; Hassan et al. 2019; Crowe et al. 2017). Three principal routes of transmission of EHEC infection have been identified: (1) contaminated food and contaminated water used for drinking or swimming, (2) person-to-person transmission, and (3) direct animal contact. The latter was described for contact in petting zoos, on farms, and within homes (e.g., housing domesticated sheep, goats, and other small animals like cats and dogs) (Crump et al. 2002; Karch et al. 2005; Neil et al. 2012).

11.6 EHEC Outbreaks

EHEC is the cause of hundreds of outbreaks worldwide (Griffin et al. 1988; Michino et al. 1999; Karch et al. 1999; Tack et al. 2021). Examples of large outbreaks caused by EHEC O157:H7 and non-O157 are described in Tables 2 and 3, respectively.

After its discovery in 1982 as the causative agent of two unprecedented outbreaks related to consumption of undercooked meat in the United States (Riley et al. 1983), EHEC O157:H7 increasingly became acknowledged as a public health threat. As observed in these early outbreaks, consumption of raw or undercooked food items of bovine origin, particularly ground beef (hamburger), is a common mode of EHEC O157:H7 transmission. Moreover, contaminated sprouted seeds, fruits, and leafy greens, such as radish sprouts, lettuce, spinach, strawberries, as well as contaminated water have been implicated in transmitting EHEC O157:H7 (Kintz et al. 2019; Saxena et al. 2015).

One of the largest outbreaks occurred in 1996 in Sakai City, Japan (Watanabe et al. 1996; Michino et al. 1999), where thousands were affected, mostly school children. White radish sprouts served during school lunches were the most probable vehicle of the infection. In the winter of 1992–1993, the largest outbreak of EHEC O157:H7 in the United States affected 501 persons in four western states including Washington, Idaho, Nevada, and California (Bell et al. 1994) where 45 persons, mostly children, developed HUS and three children died. Hamburgers from a single fast-food restaurant chain were identified as the vehicle of the infection (Bell et al.

Table 2 Example of outbreaks caused by EHEC O157:H7

1994). The largest outbreak caused by EHEC O157:H7 contaminated drinking water occurred in Canada in 2000. Approximately 2300 people became seriously ill and seven died. In Europe, a large EHEC O157:H7 outbreak occurred in Central Scotland in 1996; 345 people contracted an infection after consuming meat from a single butcher's shop and 16 died (Dundas et al. 2001). Foodborne transmission of EHEC O157:H7 also plays an important role in healthcare facilities, as shown by an outbreak in Japan associated with consumption of contaminated pickles from one manufacturer, affecting a total of 94 residents in 10 different nursing homes (Tabuchi et al. 2015). Similarly, outbreaks in childcare facilities have also been reported (Kanayama et al. 2015).

Non-O157 EHEC strains representing a wide range of serotypes have caused numerous large outbreaks, with the largest to-date occurring in Germany in 2011 associated with EHEC O104:H4 contaminated fenugreek sprouts (RKI 2011; Karch et al. 2012). Here, the proportion of patients who developed HUS was significantly higher than in O157-associated outbreaks (Tables 2 and 3). Similarly, 40% of 86 individuals affected by an EHEC O111 outbreak in 2015 in Japan involving raw meat consumption became severely ill with HUS (Yahata et al. 2015).

11.7 Future Strategies and Unresolved Issues

Advances in rapid alert systems for the early detection of EHEC outbreaks have created greater awareness for both the public and the clinical community. Moreover, an increasing number of clinical microbiological laboratories routinely screen for EHEC by detection of Stx-encoding genes and/or toxin production in cases of

bloody diarrhea or clinical HUS. Diagnosed cases are now legally required to be reported in nearly every country. New high-resolution techniques including NGS are becoming more accessible, which enable the rapid identification of outbreaks at the earliest stages (Mellmann et al. 2011). In recent years, new approaches that integrate NGS data and epidemiological information to establish national genomic surveillance networks have been implemented in countries such as the USA, England, and Germany to keep track of EHEC cases, enhancing outbreak detection (FDA 2021; Jenkins et al. 2019; WWU/RKI/FZB 2021). With strain linkage analyses, common sources of infection can be identified accurately and rapidly. Moreover, microevolutionary models of important non-O157 EHEC could already be developed (Eichhorn et al. 2018). This is especially important nowadays when foodborne outbreaks less frequently follow the "church picnic" model, in which small isolated

clusters of illness can easily be identified with case interviews and more frequently result from the dissemination of (industrially produced) vehicles that are contaminated by relatively low levels of pathogens. In a globalized world, food safety has also gained a global dimension. Livestock and food production crosses regional and national borders, which facilitates large-scale EHEC outbreaks across vast geographical areas. In this context, NGS is a valuable tool to understand complex transmission chains (Fung et al. 2018; Jagadeesan et al. 2019).

Another area where considerable efforts are being expended is improvement of farming practices and environmental factors that affect colonization of animals with EHEC. EHEC transmits readily between ruminants in the farm setting and wild animals can represent important vectors. For many years, the cattle industry and researchers have focused on improving the safety of meat products after slaughter. Post-slaughter antiseptic treatments of carcasses and HACCP policies in slaughter plants have been shown to significantly reduce meat contamination (Elder et al. 2000). Alternatively, probiotic bacteria could contribute to colonization control in cattle by producing metabolites that are inhibitory to EHEC. The addition of probiotics, such as *Lactobacillus acidophilus* (Sargeant et al. 2007; Stephens et al. 2007; Peterson et al. 2007; Younts-Dahl et al. 2005) and *Propionibacterium freudenreichii* (Sargeant et al. 2007), to animal feeds has been shown to effectively reduce fecal EHEC O157 shedding. Environmental contamination has been attained by applying soil solarization, with studies describing a >3.0-log reduction of EHEC O157 after 6 weeks of soil treatment (Berry and Wells 2012).

Due to the widespread distribution of EHEC O157 and non-O157 in cattle, its control will require intervention at the individual farm level. Vaccination approaches could be useful in controlling EHEC colonization among cattle, thus reducing the risk of human infection. Statistical models estimate that a vaccine efficacy of 60% would be required to effectively reduce infection rates in a herd (Wood et al. 2006). While use of these vaccines could reduce the risk of EHEC in cattle by 50%, this translates to approximately 85% reduction in human cases (Matthews et al. 2013). Different vaccine candidates have been developed, including compounds based on antibodies against Stx, as well as bacterial components such as proteins, peptides, DNA, and polysaccharides (Rojas-Lopez et al. 2018). Furthermore, plant-based vaccines have shown to effectively reduce EHEC shedding in animal models (Miletic et al. 2017). Two vaccines against EHEC O157:H7, which have been approved for use in cattle in Canada and the USA, have demonstrated a significant decrease in EHEC colonization and fecal load (O'Ryan et al. 2015). These vaccines have not yet been widely accepted by farmers, however, due to several factors including burden of responsibility and lack of economic return as vaccinated cattle has no added value over unvaccinated animals in the market (Matthews et al. 2013; Smith 2014). Still, more research is needed to develop viable strategies targeting the different factors that contribute to EHEC transmission (cattle, food, person-to-person spread, etc.) to work towards better control of EHEC.

Further research is also needed to address effective therapies for humans upon EHEC infection. Experimental investigations have focused on the use of Stx receptor analogs and Stx-specific antibodies. Pharmacokinetic and clinical factors,

limitations with extrapolation of results from research in animal models to human cases, and the low availability of patients for phase III clinical trials continue to significantly hinder the development of EHEC-specific therapeutic agents (Mühlen and Dersch 2020).

Listeria monocytogenes · Epidemiology of Listeriosis · Listeriosis in Humans and Animals

12.1 Introduction

The genus *Listeria* is presently composed of 21 species: *L. monocytogenes, L. ivanovii, L. seeligeri, L. welshimeri, L. grayi, L. innocua, L. marthii, L. rocourtiae, L. weihenstephaniensis, L. fleishmanii, L. floridensis, L. aquatica, L. cornellensis, L. riparia, L. grandensis, L. booriae, L. newyorkensis, L. costaricensis, L. goaensis, L. thailandensis,* and *L. valentina* (Leclercq et al. 2010; Bertsch et al. 2012; Den Bakker et al. 2014; Weller et al. 2015; Núñez-Montero et al. 2018; Doijad et al. 2018; Leclercq et al. 2019; Nwaiwu 2020; Quereda et al. 2020). Although *Listeria* spp. are basically environmental bacteria, two species—*L. monocytogenes* and *L. ivanovii*—are pathogenic for animals and humans. In the genus, *L. monocytogenes* is the most commonly isolated member responsible for listeriosis in humans and animals. Occasional human infections are also due to *L. ivanovii*, which is mainly responsible for abortion in sheep. In contrast to most pathogenic bacteria, listeria are *psychrotrophic,* capable of multiplying at low temperatures as applied in refrigeration. In an era when food production and food storage heavily rely on refrigeration, this ability to grow (albeit slowly) at low temperatures has opened a new ecological niche to a pathogen that previously had mediocre relevance only. Industrialized food manufacturing also constitutes an ecological niche due to the ability of *L. monocytogenes* to form biofilms for colonization of surfaces (Jemmi and Stephan 2006). Not only surfaces but also raw materials seem to play a role in contamination of finished products. Molecular analyses have shown that some clonal types are stable over time and are persisting in food and food-related environment (Andrade et al. 2020). The evolvement of silage as a dominant feed for ruminants during the mid-twentieth century constitutes another key factor, responsible for the emergence of listeriosis as a relevant animal disease. H.P.R. Seeliger even dubbed this zoonosis a "man-made disease" (Allerberger et al. 1997).

Listeria monocytogenes is a facultative anaerobic, rod-shaped Gram-positive bacterium that is motile when cultured at 20 °C and immotile when grown at 36 °C (Figs. 1 and 2). It is able to produce severe sepsis, meningoencephalitis, and a wide variety of focal infections in animals and in humans. *L. monocytogenes*, the causative agent of listeriosis, was discovered in 1927 by Murray and Pirie, working

independently of each other on outbreaks among laboratory rabbits and guinea pigs (Rocourt 1999). The first-documented case on human listeriosis involved a soldier who suffered from meningitis at the end of World War I (McLauchlin 1997). *L. monocytogenes* was not considered a significant animal pathogen until the late 1970s and early 1980s when it was recognized as a major foodborne pathogen (Paoli et al. 2005). Because of the severity of certain clinical manifestations (infections of

the central nervous system, septicemia, and abortion), the high case-fatality rate (up to 30% of cases), and the long incubation time, human listeriosis is now a zoonosis of major public health concern (LeMonnier and Natas 2012; Halbedel et al. 2020). Outbreaks in humans were associated with the consumption of a wide range of foods such as contaminated coleslaw, soft cheese, ready-to-eat meat products like jellied pork or cold cuts, fish and seafood products, chocolate milk, ice cream, rice salad, corn salad, (frozen) vegetables, sprouts, precut celery and melons (Allerberger 2007; Pichler et al. 2011; Szymczak et al. 2020). It is now recognized that most cases of listeriosis, both sporadic cases and common-source outbreak cases, are caused by *L. monocytogenes*-contaminated food or feed. Although rare, infection can also be transmitted directly from infected animals to humans as well as between humans and between animals.

12.2 Pathogenicity

Although Murray recognized the oral route of infection in his original isolation of *L. monocytogenes* in the 1930s, the key to recognizing the organism as a food-borne pathogen came nearly 60 years later, when an outbreak of listeriosis was epidemiologically linked to the consumption of contaminated coleslaw (Paoli et al. 2005).

L. monocytogenes has the capacity to cross three important barriers in humans: intestinal epithelium, blood–brain barrier, and placenta (Chen et al. 2009). After ingestion of *L. monocytogenes*-contaminated food or feed, bacteria pass through the stomach and cross the intestinal barrier, presumably via M cells. Entry into mammalian cells is mediated by surface invasion proteins such as internalin A (InlA), internalin B (InlB), and internalin C (InlC) (Lee et al. 2012b). The listerial protein internalin (InlA) mediates bacterial adhesion and invasion of enterocytes in the human intestine through specific interaction with its host cell receptor E-cadherin, an adhesion molecule located at adherens junctions between epithelial cells (Lecuit et al. 2001). E-cadherin was identified as InlA receptor in 1996 (Mengaud et al. 1996). The importance of InlA for the entry of *L. monocytogenes* into nonphagocytic cells was demonstrated in 1991, when *L. monocytogenes* InlA was shown to confer to *L. innocua* the ability to enter human Caco-2 cells, cells originating from a human epithelial colorectal adenocarcinoma (Cossart et al. 2003). Internalin B (InlB) is another surface protein of *L. monocytogenes*. It contributes to invasion into a wider range of cell types such as endothelial cells, hepatocytes, and fibroblasts owing to the ubiquitous nature of its receptor, the hepatocyte growth factor receptor Met (Lee et al. 2012b). InlB is responsible for internalization into Vero cells (originating from African green monkey kidneys), HeLa cells (originating from a human cervical adenocarcinoma), and CHO cells (originating from Chinese hamster ovary) (Lecuit et al. 1997). Internalin C (InlC) contributes to cell-to-cell dissemination between polarized epithelial cells by decreasing cortical tension at apical junctions (Rajabian et al. 2009) and damps the host's immune system in preventing the proinflammatory pathway via NF-kB (Matle et al. 2020).

The intestine is the primary port of entry for *L. monocytogenes*, but questions about the exact mechanisms by which *L. monocytogenes* transgresses the intestinal barrier remain, and clear differences among host species exist (Hoelzer et al. 2012). In host species deficient of functional E-cadherin such as mice, *L. monocytogenes* is thought to translocate through the intestinal wall by gaining access into M cells, phagocytic cells in the Peyer's patches of the ileum. In species such as humans or guinea pigs that possess functional E-cadherin, *L. monocytogenes* is thought primarily to invade the epithelium of the intestinal villi, followed by bacterial replication in the underlying lamina propria. *L. monocytogenes* then rapidly translocates across the intestinal barrier, without a need for bacterial replication in the intestinal wall (Hoelzer et al. 2012).

After crossing the intestinal barrier, *Listeria* spp. are—within minutes of oral inoculation—transported by lymph or blood to the mesenteric lymph nodes, the spleen, and the liver. *L. monocytogenes* and *L. ivanovii* are facultative intracellular pathogens, which are able to replicate in macrophages and a variety of non-phagocytic cells, such as epithelial and endothelial cells, and in hepatocytes. After entering these cells, listeria escape early from the phagocytic vacuole, multiply in the host cell cytosol, and then move through the cell by induction of actin polymerization. The bacteria then protrude into cytoplasmic evaginations, and these pseudopod-like structures are phagocytosed by the neighboring cells (Schmid and Hensel 2004). When listeria enter cells, they not only trigger actin and membrane rearrangements, but they also use clathrin (Lebreton et al. 2011).

All major virulence factors of *L. monocytogenes* and *L. ivanovii* are involved in a single process: the cell-to-cell spread. By this function, the pathogen can avoid extracellular environments and can escape humoral efforts of the immune system during their dissemination in the host. In *Listeria* species, four virulence gene clusters have been identified to date and termed *Listeria* pathogenicity islands 1, 2, 3, and 4 (LIPI-1, LIPI-2, LIPI-3 and LIPI-4). *Listeria* pathogenicity island 1 (LIPI-1) refers to a genomic region flanked by *prs* and *ldh* and harboring several well-known virulence genes (*prfA*, *plcA*, *hly*, *mpl*, *actA*, *plcB*) in a 9-kb gene cluster (Vazquez-Boland et al. 2001). LIPI-1 was identified in *L. monocytogenes*, *L. seeligeri*, and *L. ivanovii*. The *hly* gene encodes the pore-forming listeriolysin O (LLO), a thiol-activated hemolysin, which is able to lyse erythrocytes and other cells in a cholesterol-dependent manner. LLO is an essential virulence factor of *L. monocytogenes*, and its inactivation leads to avirulence. It has been shown that LLO has several modes of action-promoting infection and evasion of the immune system, including the support of internalization of *L. monocytogenes* into phagosomes as well as disruption of the phagocytic vacuole for release of bacteria into the cytoplasm, which enables intracellular replication (Matereke and Okoh 2020, Maury et al. 2017). Ribet et al. showed that *L. monocytogenes* is able to dampen the host response by decreasing the SUMOylation level of proteins critical for infection (Ribet et al. 2010). Also this event is triggered by the bacterial virulence factor LLO.

A second island of 22 kb was termed LIPI-2. LIPI-2 is specific for *L. ivanovii* and may play a role in the tropism of this pathogen for ruminants (Gonzalez-Zorn et al. 2000). LIPI-3 contains the eight-gene cluster (*llsA*, *llsG*, *llsH*, *llsX*, *llsB*, *llsY*, *llsD*,

and *llsP*) encoding listeriolysin S (LLS), a bacteriocin-like modified peptide exhibiting hemolytic and cytotoxic activities (Clayton et al. 2011). In contrast to LIPI-1, which is found in all strains of *L. monocytogenes* as well as in other *Listeria* species, LIPI-3 is present only in a subset of *L. monocytogenes* lineage I (Lee et al. 2012b). LIPI-4, a cluster of six genes annotated as cellobiose family phosphotransferase system (PTS)—identified through whole-genome sequencing (Matle et al. 2020)—confers hypervirulence (Hurley et al. 2019). Selective tropism of *L. monocytogenes* for CNS and fetal-placental infections is associated with LIPI-4 that enhances invasion, leading to CNS and maternal-neonatal (MN) listeriosis (Maury et al. 2016).

European-wide cluster analyses of food and human isolates demonstrated a high degree of EU-wide dissemination of certain strains, but not all widespread food isolates match with any human cases, indicating a virulence variation among *L. monocytogenes* strains (ECDC, ELiTE. 2021).

12.3 Epidemiology of Listeriosis in Animals

L. monocytogenes has been isolated from numerous species of mammals, birds, fish, crustaceans, and insects. Nevertheless, the primary habitats of *L. monocytogenes* are considered to be the soil and decaying vegetable matter, in which it survives and grows saprophytically (Bille 2007).

Animal models have played fundamental roles in elucidating the pathophysiology and immunology of human listeriosis (Lecuit 2007). Such tests include intraperitoneal inoculation of mice, inoculation of the chorioallantoic membranes of embryonated eggs, and inoculation of the conjunctivae of rabbits (Anton test). Data derived from animal studies helped to characterize the importance of cell-mediated immunity in controlling infection, allowed evaluation of antimicrobial treatments for listeriosis, and contributed to quantitative assessments of the public health risk associated with *L. monocytogenes* contaminated food commodities (Hoelzer et al. 2012). However, data about species-specific differences have raised severe concern about the validity of most traditional animal models of listeriosis (Disson et al. 2008).

Even though *L. monocytogenes* can infect a wide variety of animal species, listeriosis is primarily a clinical disease of ruminants. Sheep appear to be particularly susceptible to infection, but listeriosis is also common in a variety of other polygastric species, and *L. monocytogenes* has for instance been isolated from cattle, goats, llamas, alpacas, deer, reindeer, antelopes, water buffalos, and moose (Hoelzer et al. 2012). Listeriosis represents one of the most common etiologies for encephalitis among adult ruminants. Ruminants affected by encephalitis generally show marked neurological symptoms including ataxia, circling, opisthotonus, and paralysis of cranial nerves, combined with hyperthermia, anorexia, and depression. Large epidemics of third trimester abortions, typically manifested as stillbirth, as well as atypical manifestations such as conjunctivitis have also repeatedly been described (Ryser and Marth 2007). With the exception of neonates and young ruminants, septicemia is unusual, but can result in mastitis, gastroenteritis, hepatitis, or

pneumonitis. Notably, in a given affected herd, listeriosis usually exhibits a single clinical manifestation (Ryser and Marth 2007).

Clinical listeriosis is relatively rare in most monogastric mammals such as dogs, cats, horses, and pigs, but appears more common in rodents and lagomorpha. Listeriosis in monogastric mammals is predominantly manifested as septicemia. Abortion, meningoencephalitis, and other manifestations such as conjunctivitis are also possible, but their relative frequency differs by animal species. Large outbreaks of listeriosis have been reported among colonies of captive rodents and lagomorpha, including chinchillas, rabbits, rats, and guinea pigs (Ryser and Marth 2007). Contaminated feed such as silage or sugar beets was implicated as the outbreak vehicle in many of these outbreaks, and coprophagy may have contributed to some of these events (Ryser and Marth 2007). In a pregnant primate model, oral administration of *L. monocytogenes* resulted in stillbirth with isolation of the bacterium from placental and fetal tissues (Smith et al. 2003).

Among ruminants, listeriosis occurs seasonally with the highest incidence in winter and spring, and appears strongly associated with ingestion of spoiled silage, although cases do occur where silage feeding has not been used (Ryser and Marth 2007; Sanaa et al. 1993). Silage is high-moisture fodder that can be fed to ruminants. It is fermented and stored in a process called ensiling, and is usually made from grass crops, using the entire green plant (not just the grain) [http://en.wikipedia.org/wiki/Silage]. The ensiled product retains a much larger proportion of its nutrients than if the crop had been dried and stored as hay. Silage undergoes anaerobic fermentation, which starts about 48 hours after the silo is filled. While properly produced silage is largely free of listeria, spoiled silage, often at the end of the silage-feeding period, can harbor high numbers of *L. monocytogenes*. Poor quality is often due to insufficient herbage quality or to contamination by soil or feces. The change to production of silage in polythene bales ("big bales") corresponded to increases in ovine listeriosis in the United Kingdom (McLauchlin 2011). According to McLauchlin, the "big bale" method is more prone to spoilage and growth of *L. monocytogenes*: High numbers are often associated with sites where the damage to the bags has occurred or at the tied end. Figure 3 gives the number of listeriosis cases diagnosed in farm ruminants submitted for necropsy to the Institutes for Veterinary Disease Control of the Austrian Agency for Health and Food Safety, based on data from 2007 to 2020 by month of reporting, again showing strong seasonality for animal listeriosis. The peak in the numbers of animal listeriosis in winter (goats) and in spring (cattle and sheep) may reflect a seasonal decrease in the quality of silage used for feed.

Animals may also be asymptomatic intestinal carriers and can shed the organism in significant numbers, contaminating the environment (Ho et al. 2007). The European Union summary report on trends and sources of zoonoses, zoonotic agents, and food-borne outbreaks in 2010 lists the following rates of fecal carriage of *L. monocytogenes*: cattle 5.5%; pigs 0.0%; sheep 7.0%; goats 10.5%; fowl (*Gallus gallus*) 0.4%; water buffalo 3.7%; and wild rodents 5.3% (EFSA 2012). As observed in 2009, the highest proportions of positive findings were found in decreasing order in goats, sheep, and cattle. In comparison to 76 cattle- and 39 sheep isolates of *L. monocytogenes, L. ivanovii* was cultured from only one cattle and two sheep

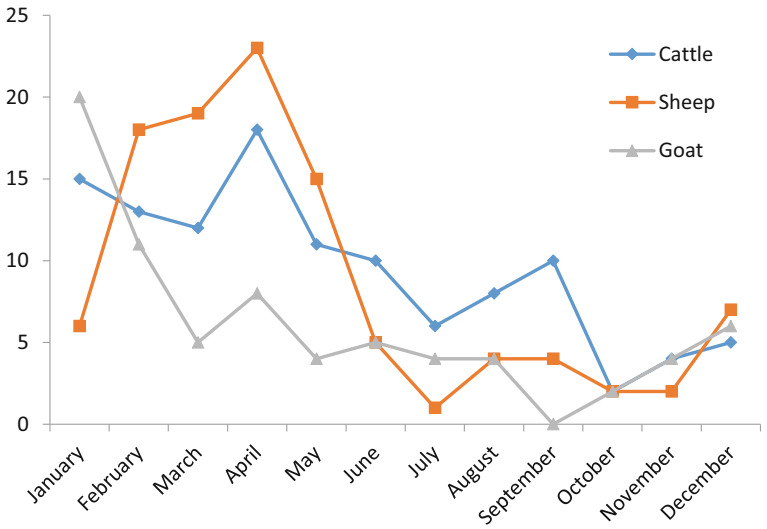

Fig. 3 Number of listeriosis cases in farm ruminants (n = 434), diagnosed by bacterial isolation and/or morphologically at the Austrian Agency for Health and Food Safety from 2007 till 2012 stratified by month of reporting

(Allerberger 2007). The 2001 report also reported rates of fecal carriage of *L. monocytogenes* for horses (fecal carriage rate: 2.1%), red deer (8.3%); farmed rabbit (0.7%), cats (0.7%), and dogs (0.0%) (Allerberger 2007).

In most countries, listeriosis in animals is not a notifiable disease. In Europe, listeriosis in animals is notifiable only in Germany, Finland, Sweden, and Norway. Usually, surveillance in animals is based on clinicopathological observations.

12.4 Epidemiology of Listeriosis in Humans

The large majority of listeriosis cases (sporadic and outbreak-related) are caused by food-borne transmission, which—according to Scallan et al. (2011)—accounts for 99% of human cases. In neonatal infections, *L. monocytogenes* can be transmitted from mother to child in utero, during passage through the infected birth canal or possibly via ascending infections from vaginal colonization. There are rare reports of nosocomial transmission in the nursery attributed to contaminated material or patient-to-patient transmission via healthcare workers (Hof and Lampidis 2001; Roberts et al. 1994; Heymann 2015). Hospital cross-infection between newborn infants occurs, usually originating form an infant born with congenital listeriosis. There is little evidence for cross-infection or person-to-person transmission outside the neonatal period. Rarely listeriosis may be transmitted by direct contact with infected animals or animal material. Usually, such local infections present as cutaneous lesions on the upper arms or wrists of farmers or veterinarian one to four days

after attending bovine abortions but not in association with sheep (McLauchlin 2011).

Invasive illness mainly manifests in certain well-defined high-risk groups, including immunocompromised persons, pregnant women, neonates, and the elderly. However, listeriosis can occur in otherwise healthy individuals, particularly during an outbreak.

Investigation of several outbreaks has demonstrated that all epidemic listeriosis was caused by food-borne transmission of *L. monocytogenes.* Outbreaks of listeriosis have been associated with the ingestion of raw milk, soft cheeses, contaminated vegetables, and ready-to-eat meat products such as paté. Also the sporadic cases of listeriosis mostly result from food-borne transmission. In several cases, by tracing a strain of *L. monocytogenes* isolated from a patient to a food item in the patient's refrigerator, and then to the retail source, public health officials were even able to provide microbiological confirmation of foodborne transmission of sporadic listeriosis (Pinner et al. 1992; Huhulescu 2012). Eating soft cheeses or food purchased from store delicatessen counters and eating undercooked chicken have been shown to increase the risk of sporadic listeriosis (Schuchat et al. 1992; Pinner et al. 1992).

Figure 4 presents the number of human invasive *L. monocytogenes* isolates registered at the Austrian National Reference Centre from 2015 to 2020, showing up- and downturns during the year. The European Union One Health Zoonoses Report 2019 observed high summer peaks followed by smaller winter peaks over a five-year period (2010–2019) (EFSA 2021), whereas only one clear slight seasonal peak during the late summer into the fall was described elsewhere (Wagner and MacLauchlin 2008, McLauchlin 2011; Feng et al. 2013).

In 2019, 28 member states reported 2621 confirmed invasive human cases of listeriosis. The overall EU notification rate was 0.46 cases per 100,000 population,

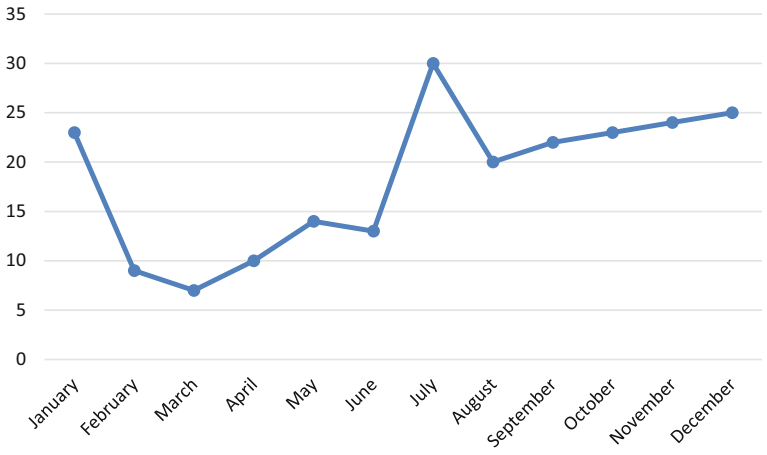

Fig. 4 Number of *L. monocytogenes* isolates (n = 220) from invasive cases registered at the Austrian National Reference Centre, based on data from the years 2015 to 2020 (by month of receipt of isolate)

with the highest country-specific notification rates observed in Estonia (1.59 cases per 100,000 population) followed by Sweden and Denmark (1.10 and 1.05 cases per 100,000 population, respectively). After an increasing trend over a long period, the EU trend of confirmed listeriosis cases remained stable from 2015 on. Particularly, the proportion of elderly has steadily increased over the last ten years until 2017, especially in those aged over 84. The proportion of cases in this age group slightly decreased in 2018 till 2019. Nevertheless, according to the European Union One Health Zoonoses Report, the notification rate in 2019 was highest in those aged over 65, covering 64.5% of all reported cases. Looking at the data of each reporting member state, ongoing statistically significant increasing trends in listeriosis notification rates from 2015 to 2019 were noted in Estonia, Poland, and Portugal. Statistically significant decreasing trends from 2015 to 2019 were noted in Greece (EFSA 2021).

The reason for the increased incidence and the upsurge in septicemia cases remain unknown. It has been hypothesized, however, that the higher incidence of listeriosis might be related to higher exposure to *L. monocytogenes* (Gillespie et al. 2006; Goulet et al. 2008). Increasing use of acid inhibitors (H_2 receptor antagonists) was also postulated to contribute to increased vulnerability to *L. monocytogenes* infection (Gillespie et al. 2009).

Sisó et al. studied the incidence of listeriosis during pregnancy over a 25-year period based on data compiled in a tertiary referral hospital in Spain. Whereas between 1985 and 2000 the incidence remained almost constant at 0.24%, an increasing incidence was observed from then on, reaching 0.86% during the last years until 2010 (Sisó et al. 2012). According to their findings, a four-fold increase in listeriosis rate during pregnancy has occurred in recent years in Spain. No such increase has been reported for pregnancy-associated cases from other countries. In Austria in 2020, listeriosis occurred in 3 of approximately 83,000 deliveries (0.04%).

Despite the high contamination rates of certain food, listeriosis is a relatively rare disease compared to other common food-borne illnesses such as campylobacteriosis or salmonellosis. However, because of its high case fatality rate of approximately 20%, human listeriosis ranks among the most frequent causes of food-borne death (Allerberger and Wagner 2010). Listeriosis has the highest number of fatal cases among food-borne diseases in the EU, with a continuous increase in reported deaths among cases and has, with more than 90%, the highest proportion of hospitalization among zoonoses under EU surveillance (EFSA 2021). Therefore, besides the economic consequences, listeriosis remains of great public health concern. The substantial burden of listeriosis in Europe is anticipated to increase in line with the projected growth of the elderly population. The proportion of people aged at least 65 is 20% by 2016 and expected to reach almost 30% by 2070 (European Commission 2018).

Control of listeriosis requires action from public health agencies and from the food industry. Important control strategies from public health agencies include developing and maintaining timely and effective disease surveillance programs, as well as promptly investigating clusters of listeriosis cases. Routine characterization of human, animal, food, and environmental isolates, and utilization of large-scale subtype databases facilitate Europe-wide outbreak detection and control. Outbreak

investigations provide a unique source of information to improve our understanding of transmission of listeria and to identify gaps in industry and regulatory measures to safeguard against contamination of the food and feed supply. In this respect, the importance of isolating the pathogen as a prerequisite for an accurate epidemiological investigation and ultimately stopping transmission cannot be overemphasized (Cartwright et al. 2013; Lachmann et al. 2021).

12.5 Epidemiology of *Listeria monocytogenes* in Food

Listeria monocytogenes is a particularly important cause of illness, mainly found in foods that are packaged and prepared commercially, rather than those prepared in the home (Carpentier and Cerf 2011). During the last decades, consumer lifestyles have changed with less time for food preparation and more ready-to-eat (RTE) and take-away foods. Changes in food production and technology have led to the production of foods with a long shelf life that are typical "listeria risk foods," because the bacteria have time to multiply, and the food does not undergo a listericidal process such as cooking before consumption. Main factors propagating the incidence of listeriosis are the high degree of centralization and consolidation of food production and processing, the increased use of refrigerators as the primary means of preserving food, and the above-mentioned changes in food consumption habits (increased consumer demand for convenient food) (Swaminathan et al. 2007). Gillespie et al. studied the food exposures of listeriosis cases aged $\geq$60 years reported in England from 2005 to 2008 and compared them to those of market research panel members representing the same population (i.e., residents of England aged $\geq$60 years) and time period. Cases were more likely than panel members to report the consumption of cooked meats (beef and ham/pork, but not poultry), cooked fish (specifically smoked salmon) and shellfish (prawns), dairy products (most noticeably milk, but also certain cheeses), and mixed salads. They were less likely to report the consumption of other forms of seafood, dairy spreads, other dairy products, sandwiches, and fresh vegetables. The diversity of high-risk food exposures reflects the ubiquity of the microorganism in the environment and the susceptibility of those at risk, and suggests that a wide variety of foods can give rise to listeriosis (Gillespie et al. 2010a, 2010b). In the United States, two case–control studies on risk factors for sporadic listeriosis found that cases were most likely to have eaten melons, hummus prepared in a commercial establishment, and soft cheeses or food purchases from store delicatessen counters (Schuchat et al. 1992; Varma et al. 2007).

L. monocytogenes is widespread in nature and has been isolated from soil, dust, food products for humans (both of animal and vegetable origin), feed, water, and sewage, and it can be carried by almost any animal species, including asymptomatic humans. The principal reservoir of the organism is said to be in soil, forage, water, mud, livestock food, and silage (Heymann 2015). Due to this environmental ubiquity, listeria strains are also frequently detected in food products. In addition, growth and survival of these psychrotrophic bacteria are favored particularly due to the above-mentioned increasing use of refrigeration in food production, food distribution, and

food storage. Unlike most other food-borne pathogens, *L. monocytogenes* tends to multiply in refrigerated foods that are contaminated. To understand why *L. monocytogenes* may persist in food industry equipment and premises, notably at low temperature, scientific studies have so far focused on adhesion potential, biofilm-forming ability, resistance to desiccation, acid and heat, tolerance to increased sublethal concentration of disinfectants, or resistance to lethal concentrations. Carpentier and Cerf postulated that the main factor associated with the presence of *L. monocytogenes* in production plants is growth promotion (Carpentier and Cerf 2011). Good growth conditions can be found in so-called harborage sites, i.e., shelters due to unhygienic design of equipment and premises or unhygienic or damaged materials. These sites are hard to eliminate. Carpentier and Cerf stipulated that there are no strains of *L. monocytogenes* with unique properties that lead to persistence, but harborage sites in food industry premises and equipment where *L. monocytogenes* can persist (Carpentier and Cerf 2011). In the European Union, foods that contain less than 100 colony-forming-units (cfu)/g are considered to pose a negligible risk for a healthy human population (EFSA 2012). EU legislation defines different criteria for three categories of foods (25 g samples) (European Commission 2005). In Europe, only food products for vulnerable populations (e.g., infants) have to be entirely free from *L. monocytogenes*. For food products enabling growth of *L. monocytogenes*, total absence is required for products sampled at the production plant, and a level of 100 cfu *L. monocytogenes* per gram food is tolerated at the consumption stage. For food products unable to support the growth (e.g., "hard cheese" or "fermented sausages") of *L. monocytogenes,* a limit of 100 cfu *L. monocytogenes* per gram food is accepted, when sampled on the market during their shelf life. Foods were defined as unable to support the growth of *L. monocytogenes* by pH $\leq$ 4.4; $a_w \leq 0.92$; pH $\leq$5.0 and $a_w \leq 0.94$; and shelf life less than 5 days.

In the United States, regulations require food companies to guarantee zero *L. monocytogenes* levels in all ready-to-eat products. The achievement of this objective is probably impractical, and it is clearly unattainable for raw foods or those which have not undergone a listericidal process (McLauchlin 2011).

Microbiological surveys have documented that *L. monocytogenes* may be present in a wide range of retail foods (Schuchat et al. 1992; Pinner et al. 1992). Wagner et al. studied samples of ready-to-eat (RTE) foodstuffs in Vienna, Austria, in 2007. They found 4.8% of 946 samples collected from 103 supermarkets positive for *L. monocytogenes*, with 5 smoked fish samples exceeding the tolerated limit of 100 cfu/g food (Wagner et al. 2007). Products showing the highest contamination rates were fish and seafood (19.4%), followed by raw meat sausages (6.3%), soft cheese (5.5%), and cooked meat products or patés (4.5%). Pulsed field gel electrophoresis (PFGE) typing of the collected *L. monocytogenes* isolates revealed a high degree of diversity between the isolates. Also evidence from EU-wide routine food safety investigations indicates that a substantial proportion of RTE products is contaminated by *L. monocytogenes* (EFSA 2021). No major changes compared with previous years were recently detected in the proportions of RTE foods not in compliance with the EU microbiological criteria. Once again the highest proportions exceeding the limit were observed in RTE fish products and RTE meat products. *L. monocytogenes* was detected in 2.8% of RTE meat products and meat preparations

of beef tested in 2019, in 2.1% of RTE products and meat preparations of pork, in 0.9% respectively 1.6% of RTE products and meat preparations of meat from broilers and turkeys, in 1.2% of soft and semisoft cheeses made from raw or low heat-treated milk from cows, in 1.5% respectively 0.0% of soft and semisoft cheeses made from raw or low heat-treated milk from sheep and goats, in 0.8% of hard cheeses made from raw or low heat-treated milk from cows, in 2.7% respectively 3.5% of hard cheeses made from raw or low heat-treated milk from sheep and goats, and in 4.4% respectively 4.3% of RTE fish products and fishery products (EFSA 2021).

Painter et al. studied the attribution of deaths from food-borne diseases to food commodities by using outbreak data (United States, 1998–2008) and found that more deaths were attributed to poultry (19%) than to any other commodity, and that most poultry-associated deaths were caused by listeria (Painter et al. 2013).

From 1998 to 2002, three large listeriosis outbreaks were linked to turkey delicatessen meat contaminated in the processing plant after cooking (Gottlieb et al. 2006; Mead et al. 2006; Olsen et al. 2005). However, pork paté ("rillettes"), a beef meat dish and horse minced meat, were also involved in outbreaks (Goulet et al. 1998; Smith et al. 2011; Goulet et al. 2013). A risk-ranking model for listeriosis among RTE foods identified delicatessen meat as the highest risk food (FDA 2003).

Soft cheeses, especially soft cheeses made with unpasteurized milk (Mexican-style), red smeared cheeses, brie, camembert, and sour milk curd cheese "Quargel" were responsible for large outbreaks in Europe and in the United States (Pichler et al. 2011; Goulet et al. 1995; Johnson et al. 2010). In Australia, 29 cases (including three fatal cases) were linked to brie, blue cheese, and camembert from one company in 2013 (Anonymous 2013).

Agricultural commodities are increasingly identified as a source of listeriosis outbreaks: In the United States, sprouts caused an outbreak in 2009, and precut celery caused an outbreak in 2010 (CDC 2012). A total of 147 persons infected with any of five subtypes of *L. monocytogenes* were reported to the Centers for Disease Control and Prevention from 28 states in connection within an outbreak associated with cantaloupes (melons) in 2011, including 33 outbreak-associated deaths (CDC 2012).

Although fish and seafood are very often found to be contaminated with *L. monocytogenes*, this food only occasionally was involved in outbreaks. Five cases with gastroenteritis related to consumption of cold smoked trout were reported from Finland (Miettinen et al. 1999). Shrimp was implicated as food source in two pregnancy-associated cases with bacteremia in the United States in 1989 (Riedo et al. 1994).

In China, an outbreak of gastroenteritis involving 82 cases was traced back to a vacuum-sealed product of cooked, unshelled eggs served to children as a meal during school break (Feng et al. 2013). In Italy, 1566 cases of listeria gastroenteritis were traced to consumption of corn salad in 1997, and 14 cases to rice salad in 1993 (Salamina et al. 1996; Aureli et al. 2000).

The discovery of *L. monocytogenes* mainly in raw and RTE meat, poultry, seafood, and dairy products has prompted numerous product recalls leading to large financial losses for the industry and to numerous health scares. In the European Union, a rapid alert system for food and feed (RASFF) was put in place to provide food and feed control authorities with an effective tool to exchange information about measures taken responding to serious risks detected in relation

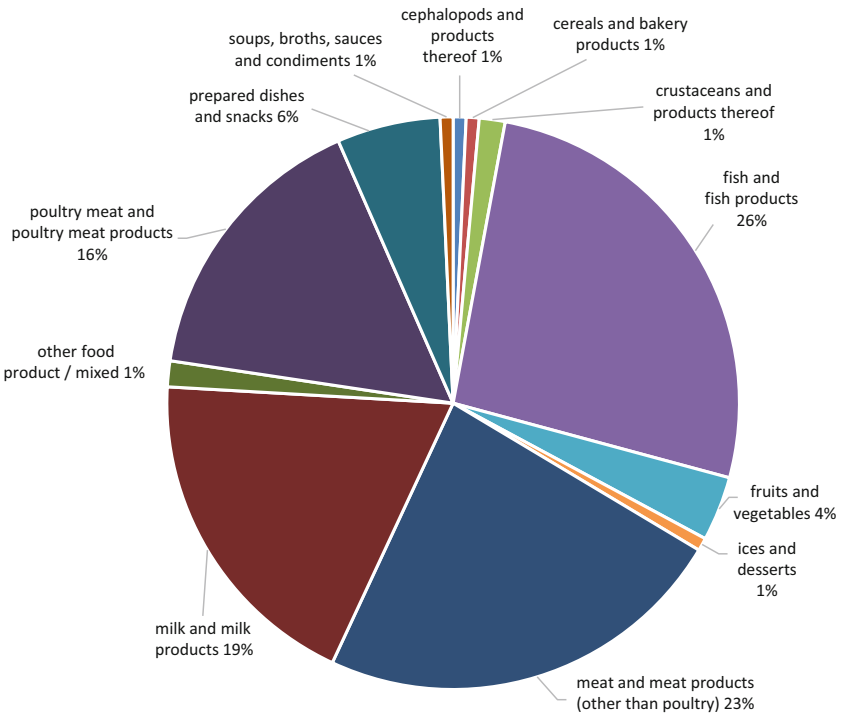

Fig. 5 Rapid Alert System for Food and Feed (RASFF) notifications concerning *Listeria monocytogenes*, 2020

to food or feed. This exchange of information helps member states to act more rapidly and to respond to a health threat caused by food or feed in a coordinated manner. During the last two decades, RASFF messages with information concerning listeria have increased by the factor of four. While in 2020, 137 notifications concerned *L. monocytogenes* (2019:138, 2018:122, 2017: 92, 2016: 81, 2015: 99, 2014: 98, 2013: 72, 2012: 90, 2011: 107, 2010: 108, 2009: 85, 2008: 51, 2007: 37, 2006: 26, 2005: 117, 2004: 122, 2003: 58, 2002: 51, 2001: 36), only 33 alerts were issued in the year 2000. This increase seems to reflect increased awareness about listeria contamination as a potential public health risk. In 2020, fish, meat, and milk products accounted for 85% (n = 116) of the 137 RASFF notifications (Fig. 5).

12.6 Molecular Typing and Interpretation of Typing Results

12.6.1 Typing Methods

Typing of bacterial isolates is essential for active surveillance and outbreak investigation. If a typing method shows isolates to be very similar to each other, transmission is likely, and we speak of "making" a cluster ("rule in"). If a typing method

shows isolates to be different, transmission is unlikely, and we speak of "breaking" a cluster ("rule out"). However, there are various caveats like occurrence of genetic recombinations (falsely ruling out) and occurrence of epidemiologically independent sources (falsely ruling in). Typing results can miss epidemiological relations due to underdiscrimination and due to overdiscrimination. The resolution can be too crude and too fine, so transmission chains can be overlooked. The challenge is to find a typing method with a resolution that correlates with epidemiological events. In the last years, molecular typing methods have become more and more important and have displaced classical methods step by step.

Molecular typing refers to any technique and method that is used to characterize microorganisms at the nucleotide level. It supports studies to trace back the source of an outbreak and to identify new risk factors as the strains can be linked more accurately to epidemiological and clinical data. All of this information can be applied toward improving and better targeting existing infectious disease prevention and control measures and thus presents a clear and immense benefit for the public health and public health policies (Allerberger 2012).

Early studies identified two genomic divisions ("lineages") by means of a variety of genotyping tools (Lee et al. 2012b). An additional lineage, lineage III, was first discovered in 1995 (Rasmussen et al. 1995). More recently, four lineages of *L. monocytogenes* were proposed by dividing lineage III into two separate evolutionary groups (den Bakker et al. 2010). Lineage I includes strains of serotypes 4b, 4d, 4e, 1/2b, and 3b. Serotype 4b is implicated in many outbreaks and sporadic cases resulting in lineage I being overrepresented among clinical samples (Lee et al. 2012b). Lineage II encompasses serotypes 1/2a, 1/2c, 3a, and 3c. Isolates belonging to this lineage are frequently found in foods and natural environments, although serotype 1/2a is also frequently identified among clinical isolates and sometimes implicated in outbreaks. Lineages III originally consisted of serotypes 4a and 4c. It was divided into two subgroups, one subgroup with strains of serotype 4a and the other with strains of serotype 4c (Doumith et al. 2004b). Even though these "new" lineages III and IV have been implicated in occasional sporadic cases, they are markedly less common in human listeriosis than strains of lineage I or II.

Molecular typing of *L. monocytogenes* splendidly complements traditional epidemiological surveillance by providing appropriate discriminatory analyses to foster rapid and early detection of dispersed clusters or outbreaks and to facilitate detection and investigation of transmission chains.

In the following, we would like to give an overview of the typing methods used so far.

12.6.1.1 Serotyping

Serotyping was the first method available for subtyping *L. monocytogenes* isolates. Serotyping is based on somatic (O) and flagellar (H) antigens. Published references define 13 *L. monocytogenes* serotypes: 1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4ab, 4b, 4c, 4d, 4e, and 7 (Allerberger 2003; Chen 2012). Serotypes are determined by reactivity with antisera. Commercially available serotyping sera (available from BD Diagnostics, USA, and Denka Seiken Co. Ltd., Japan) include a serotyping scheme for these 13 serotypes. Listeria handbooks do not agree on this issue; for example, the latest

edition of "Listeria, Listeriosis, and Food Safety" (Graves et al. 2007) does not list the *L. monocytogenes* serotype 4ab, whereas the "Handbook of *Listeria monocytogenes*" (Chen and Knabel 2008) does. In light of our experience, we question the existence of *L. monocytogenes* serotype 4ab. Taking into consideration the significance of reliable and unambiguous serotyping, especially in epidemiological tracking, an official revision of the *L. monocytogenes* serotyping scheme might be advised. In epidemiological investigations, bacterial serotyping usually is unable to estimate the relatedness of different isolates, as both invasive listeriosis and febrile gastroenteritis are caused mostly by serotypes 1/2a, 1/2b, and 4b strains. Serotyping of *L. monocytogenes* therefore has only limited practical value for investigating chains of transmission.

Doumith et al. developed a PCR-based serotyping method. Their multiplex PCR divides *L. monocytogenes* isolates into four groups employing primers annealing to *Listeria* genus-specific *prs* and genes specific to serotype-associated phylogenetic lineages of *L. monocytogenes*; this method can differentiate between strains of serotype 1/2a or 3a, 1/2c or 3 c, 1/2b or 3b, and the serotype 4b complex (4b, 4d, 4e) (Doumith et al. 2004a). The *prs* primers are specific for the putative phosphoribosyl pyrophosphate synthetase (*prs*) gene of *Listeria* spp.

Using whole-genome sequence (WGS) based methods, serogroup information can be extracted directly from the sequence data (Hyden et al. 2016).

12.6.1.2 High-Resolution Melting Curve-PCR (HRM-PCR) Analysis

High-resolution melting (HRM) curve-PCR analysis for *L. monocytogenes* was developed by Pietzka et al. (2011). Genomic bacterial DNA (gDNA) is extracted from bacterial cells grown overnight at 37 °C on blood agar plates, and a 500-bp fragment located in the virulence gene internalin B (*inlB*) is amplified for subsequent HRM analysis. HRM curve analysis constitutes an inexpensive assay and represents an improvement in typing relative to classical serotyping. This method provides a rapid and powerful screening tool for simultaneous preliminary typing of up to 384 samples in approximately 2 hours.

12.6.1.3 Pulsed-Field Gel Electrophoresis (PFGE)

DNA macrorestriction analysis by pulsed field gel electrophoresis (PFGE) has been the gold standard for typing of food-borne pathogens like Listeria, Salmonella, Campylobacter, and *Bacillus cereus* for many years (Allerberger 2012).

Electrophoresis as an analytical method separates macromolecules such as nucleic acid by their size, charge, conformation, and reactivity (Lee et al. 2012a). Classical electrophoresis employs a steady electric field orientated in one direction. This procedure, relying on a single paired electrode, permits the movement of DNA molecules only to a maximal size of 50 kb (Fangman 1978). PFGE is able to separate molecules as large as 12 Mb in size (Orbach et al. 1988). D.C. Schwartz and C.R. Cantor developed this variation of agarose gel electrophoresis, which revolutionized precise separation of DNA fragments greater than 40 to 50 kb. In PFGE, the orientation of the electric field across the gel is changed periodically ("pulsed") rather than kept constant as it was in conventional agarose gel electrophoresis

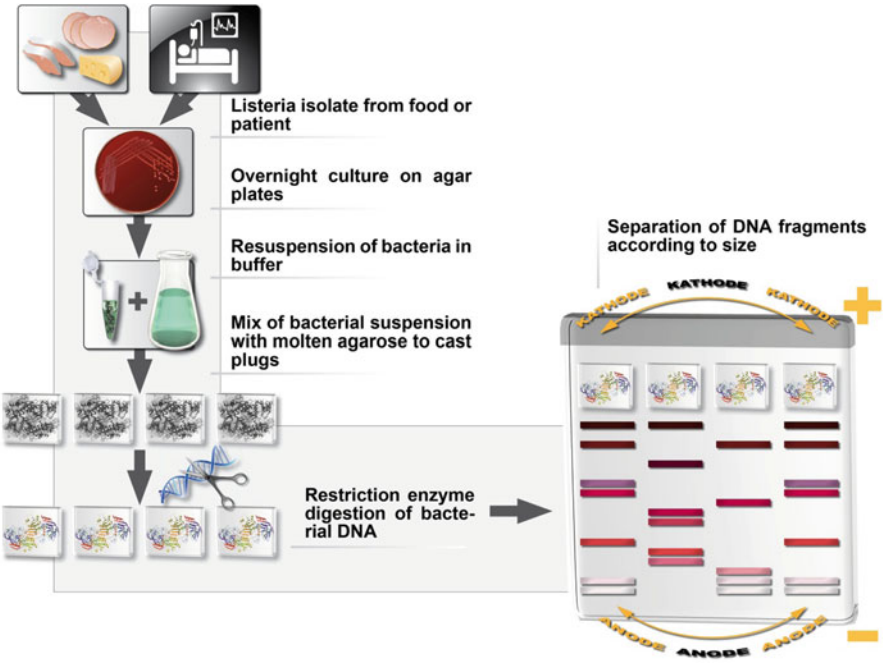

Fig. 6 Schematic principles of pulsed field gel electrophoresis (PFGE)

(Schwartz and Cantor 1984). This technology separates large fragments of unsheared microbial chromosomal DNA obtained by embedding intact bacteria in agarose gel plugs, enzymatically lysing the cell wall, and digesting the cellular proteins. The intact DNA is digested with an infrequently cutting restriction enzyme. Subsequent restriction fragment length polymorphism analysis allows differentiation of clonal isolates from unrelated ones. PFGE relies on a direct current electric field that changes orientation and intensity relative to the agarose gel. The rate of the changes is called pulse time, and its duration is an important factor to determine what molecular size range can be separated. The DNA molecules migrate through the agarose gel in a zigzag way, responding to the changes of the electric field. For larger molecules, the reorientation takes more time. They become trapped in the matrix if the pulse time is too short (Birren et al. 1988). Figure 6 depicts the basic principles of pulsed field gel electrophoresis (PFGE).

12.6.1.4 Amplified Fragment Length Polymorphism (AFLP)

Amplified fragment length polymorphism (AFLP) analysis was developed in the early 1990s by Vos et al. and is a registered trademark of KeyGene (Vos et al. 1995). It is based on PCR amplification of restriction fragments of a complete genomic digest. AFLP represents a relatively simple, low-cost, rapid, and highly discriminatory method which covers a larger portion of the genome than other typing techniques. In principle, the method scans the genome for sequence polymorphisms

producing DNA fragments, mainly between 50 base pairs and 700 base pairs in size. The fragments are separated on a denaturing acrylamide gel. The presence and absence of fragments produce a band pattern or AFLP profile comparable to bar codes used for product identification in commerce (Rupptisch 2013). Here, it determines a genetic fingerprint. For subsequent data analysis, the resulting AFLP profile can be converted into a binary presence–absence (1/0) code, a process known as "scoring" (Kück et al. 2012).

The national *Listeria*-reference laboratory for England and Wales had used fluorescent Amplified Fragment Length Polymorphism (fAFLP) analysis with *Hind*III/*Hha*I as subtyping method for *L. monocytogenes* since 2008. In fAFLP, the *L. monocytogenes* genome is digested with a rare cutting restriction enzyme such as *Hind*III and a more frequently cutting enzyme like *Hha*I. In a second step, adapters containing about 15 bp are ligated to the restriction fragments. These adapters serve as targets for two different primers, one of which has a fluorescent label. Usually, a FAM-labeled *Hind*III and a nonlabeled *Hha*I primer are used. Both primers contain the adapter sequence, the specific restriction site sequence, and one additional base pair on the 3′ end which extend into the restriction fragment. PCR amplifies only one fourth of the fragments containing the corresponding additional base pair and only hybrid fragments with two different restriction sites. Electrophoretic separation of amplicons on a gel matrix is followed by visualization of the band pattern. While PFGE is known to be a very time-consuming and work-intensive method (starting with a pure culture, first results can be achieved within 3 to 4 days), fAFLP can be completed within 48 h and is easier to perform. Roussel et al. analyzed 109 different *L. monocytogenes* isolates by both methods (Roussel et al. 2013). The isolates were divided by fAFLP and PFGE into three distinguished lineages. Strains known to be epidemiologically associated with one another were found to have unique PFGE and fAFLP types. fAFLP and PFGE divided the strains into 76 and 82 distinct profiles, or types, respectively. The discriminatory index calculated was 0.993 and 0.996 for fAFLP and PFGE, respectively. The authors concluded that the discriminatory ability of fAFLP was similar to that of PFGE for the subtyping of *L. monocytogenes* isolates and that, "as a less labour intensive technique, fAFLP may be a better method to use than PFGE in investigating outbreaks of human listeriosis and tracking the source of contamination in food processing facilities in real time."

12.6.1.5 Multiple-Locus Variable Number Tandem Repeat Analysis (MLVA)

The availability of whole-genome sequences had facilitated the discovery of variable number tandem repeats (VNTRs), loci that contain short strings of nucleotides that are repeated, from a few to many times, and which are scattered throughout the bacterial genome. This has led to the birth of Multi-Locus Variable Number Tandem Repeat (VNTR) Analysis (MLVA) (Lindstedt 2005). Different organisms show variations in the number of these tandem repeated DNA sequences stashed in different loci. These loci can be multiplexed via PCR and separated by capillary gel electrophoresis. The size of the fragments varies according to the number of repeats in each locus. Results are depicted by numerical codes, giving the number of

alleles at each locus tested. These numbers consisting of integers are the MVLA profile and can be compared to those in an existing profile database (Sperry et al. 2008; Jadhav et al. 2012). Murphy et al. called this approach "a valuable tool, which has the capability to provide comparable results when compared with other more established typing methods, including pulsed-field gel electrophoresis" (Murphy et al. 2007). We consider MLVA less discriminatory than PFGE or AFLP.

12.6.1.6 Whole-Genome Sequencing

The "endpoint" of typing techniques is sequencing the whole genome, a method to determine the complete DNA sequence of a single organism. To construct the complete nucleotide sequence of a genome, multiple short sequence reads must be assembled based on overlapping regions (de novo assembly), or comparisons with previously sequenced "reference" genomes (resequencing). The emergence of benchtop sequencers using next-generation sequencing (NGS) technology makes bacterial whole-genome sequencing (WGS) feasible even in small research and clinical laboratories.

The progress in technology from automated Sanger sequencing (first-generation sequencing) to next-generation sequencing has revolutionized the field of molecular epidemiology. Sequencing methods still become faster and more affordable from year to year Ng and Kirkness 2010). According to this development, genome sequencing has become the method of choice for characterization of *Listeria monocytogenes*.

Regardless of the respective sequencing method, NGS can be divided into the process of DNA extraction, library preparation, sequencing, and data interpretation using bioinformatics tools (Hess et al. 2020).

Sequencing requires a high quality of DNA; therefore, high-molecular-weight DNA has to be prepared. The first step after DNA extraction is the preparation of a so-called library. Sequencing libraries are typically created by fragmenting DNA followed by ligation of adapter sequences and index sequences on both ends (Giani et al. 2020). During the sequencing steps, the library is loaded onto a flow cell, where an amplification process takes place. Chemically modified nucleotides (containing fluorescent tags) are used to bind to the DNA template strand. The fluorescent tag indicates which nucleotide has been added. Short sequences with a defined range of length, the so-called reads, are generated. These reads are overlapping and were set together in an assembly process (de novo genome assembly). The added index sequences allow a correct assembly of the generated reads. After sequencing, the data can be analyzed using bioinformatics tools (Hess et al. 2020). Figure 7 depicts the basic principles of the whole-genome sequencing process.

For the characterization of *L. monocytogenes* strains, high-resolution typing schemes using WGS technology have been developed (Ruppitsch et al. 2015a; Pightling et al. 2015; Kwong et al. 2016; Moura et al. 2016). Core genome (cg) MLST scheme-based typing of *L. monocytogenes* represents an expansion of the classical seven-gene MLST scheme (Salcedo et al. 2003) and is in all aspects superior for tracking and source identification, as compared to PFGE and fAFLP

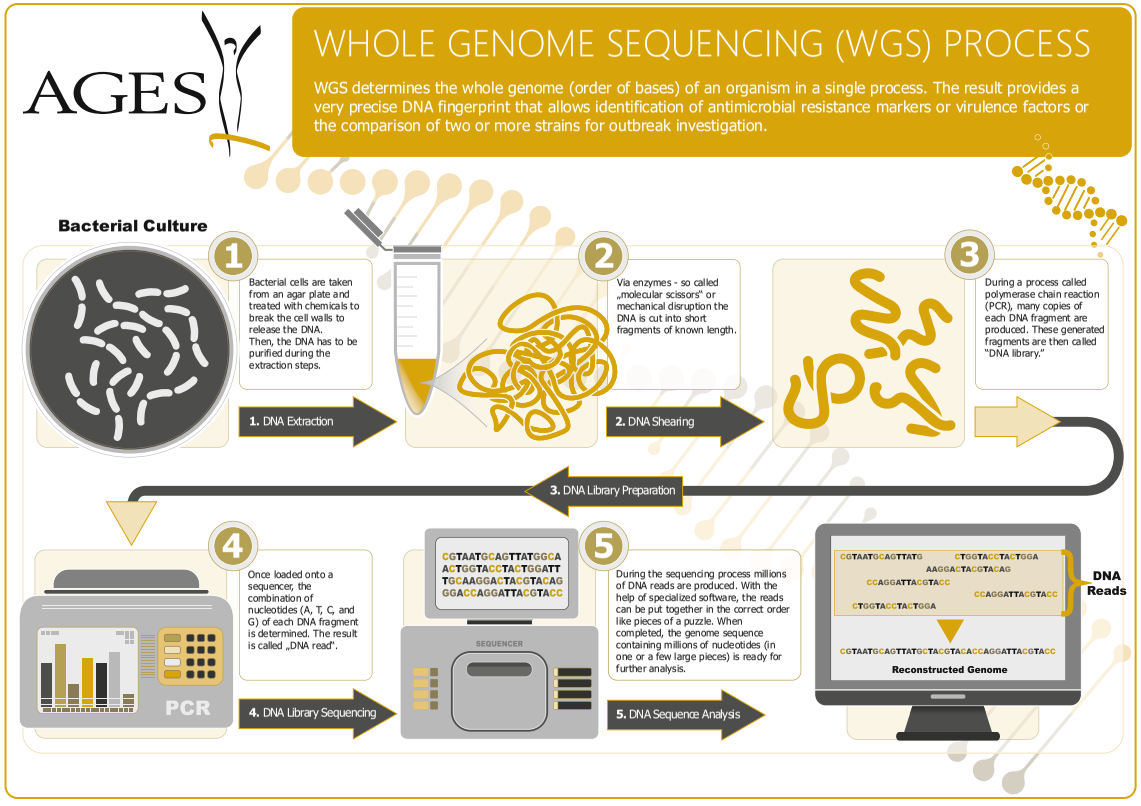

Fig. 7 Schematic principles of whole-genome sequencing (WGS)

(Schmid and Hensel 2004; Ruppitsch et al. 2015b). cgMLST-based typing results can be easily shared between different laboratories all over the world.

Due to the high informative value and the good comparability of the results, the European Centre for Disease Prevention and Control (ECDC) and the European Food Safety Authority (EFSA) have recommended to introduce routine WGS-based typing of human and nonhuman *L. monocytogenes* isolates across Europe (ECDC-EFSA 2019).

12.6.2 Interpretation of Typing Results

Adequate molecular typing enables linking pathogen data from human, food, animal, and environmental sources (provided the discrimination correlates epidemiologically). If applied routinely in real time, molecular typing allows for an early detection of national and international clusters and thus facilitates the early identification of potential sources of outbreaks (ECDC 2013). However, the use of analytical studies to investigate outbreaks of listeriosis has had only mixed success (McLauchlin 2011).

According to the World Health Organization (WHO), "foodborne illness is almost 100 % preventable" (WHO 2003). In order to achieve that position, an overview of the sources of infection and transmission routes is essential. If thoroughly investigated, food-borne outbreaks of listeriosis provide an opportunity to identify the food vehicle involved and the factors in the food preparation and handling that contributed to the outbreak. Within the European Union, reporting on food-borne outbreaks is mandatory under the framework of DIRECTIVE 2003/99/EC OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL of November 17, 2003, on the monitoring of zoonoses and zoonotic agents. According to this directive, a food-borne outbreak is defined as an incidence, observed under given circumstances, of two or more human cases of the same disease and/or infection, or a situation in which the observed number of cases exceeds the expected number and where the cases are linked, or are probably linked, to the same food source.

While it is clear what constitutes a food-borne outbreak, there is no consensus on criteria for defining a *L. monocytogenes* cluster as a possible food-borne outbreak. Even the term cluster is still under controversial discussion: Within the European Centre for Disease Prevention and Control, a cluster is considered for *Listeria monocytogenes* having $\leq$7 cgMLST allelic differences from another or an outbreak reference isolate. The cgMLST scheme should be either that of Moura et al. (2016), Ruppitsch et al. (2015a), or a country respective cgMLST scheme.

In Austria (unlike in Germany or in Switzerland), medical laboratories have a legal obligation to forward human *L. monocytogenes* isolates to the National Reference Centre. From 2009 to 2016, when PFGE was the gold-standard method routinely used in Austria, more than 50% of human isolates yielded PFGE patterns that fell into clusters (more than one isolate showing a unique PFGE pattern).

Lay persons often urge to define a possible food-borne outbreak by the occurrence of just two indistinguishable human isolates, ignoring the fact that many

two-isolate clusters are due to chance and ignoring that any pregnancy-related pair of isolates (mother/child isolates yield identical DNA fingerprinting patterns) would incorrectly be deemed a possible food-borne outbreak. In contrast to the situation in forensic human genetics, where—with the exception of monozygotic twins—indistinguishable DNA sequences prove epidemiological relatedness, in bacteriology, epidemiologically unrelated *L. monocytogenes* isolates can yield DNA fingerprinting patterns or sequences indistinguishable from each other. Therefore, pure chance yields pairs of epidemiologically unrelated human *L. monocytogenes* isolates with PFGE patterns indistinguishable from each other or closely related DNA sequences and pairs of contemporary isolates of human and of food origin, without any causal relation. Figure 8 shows PFGE patterns of seven food isolates received by the Austrian reference center for *L. monocytogenes* in 2012, isolates not linked to one food or food producer. The occurrence of indistinguishable DNA sequences in different food products—epidemiologically unrelated to each other or to human cases—also hampers attribution of human illness to certain food. Since 2017, WGS-based typing methods are routinely used in Austria, only a few human isolates were assigned to a single cluster. This is mainly due to the superiority of WGS in contrast to the former used PFGE fingerprinting technique.

While much has been learned about food sources for epidemic listeriosis, little is known about food sources of sporadic listeriosis, which, in fact, represents the majority of cases. In Austria, when $\geq$2 *L. monocytogenes* isolates show closely related DNA sequences ($\leq$7 allelic differences, using the cgMLST by Ruppitsch et al. 2015a) within the actual year, this cluster is evaluated. If these isolates were detected within the last three to six months, the cluster is deemed a possible food-borne outbreak. If already typed *L. monocytogenes* isolates from food or food-associated sources cluster with patient isolates within a similar timeframe, the national Public Health (PH) authority is informed. At the discretion of the national authority, the local authorities are requested to check the food safety measures at the site of the related producers. The occurrence of a phylogenetically related case of listeriosis within 3 months prompts epidemiological investigations including food exposure analysis, tracing analyses, and targeted sampling of the incriminated food processor(s) to test the hypothesis on the outbreak source. Clusters containing only nonhuman isolates are reported quarterly to the national PH authority (Cabal et al. 2019).

An EFSA-ECDC collaboration on typing of listeria in RTE products and clinical cases of human listeriosis started in 2010 called the European Listeria typing exercise (ELiTE) (ECDC-EFSA 2021). This was a joint study of ECDC, EFSA, and the European Union Reference Laboratory for *Listeria monocytogenes* hosted by the French Agency for Food, Environmental and Occupational Health & Safety—ANSES. This collaborative study was initiated in 2010 as a multisectoral, multicenter exercise and was based on a dataset of certain RTE food isolates from the EU base line study (BLS) and a dataset of human isolates collected from clinical cases around the same time period as the food BLS. The molecular typing method mainly used in this study was PFGE, which has been the gold-standard molecular typing method for several food-borne pathogens for many years, with an improved discriminatory power compared to phenotyping methods. At the time of the study, this method was still the

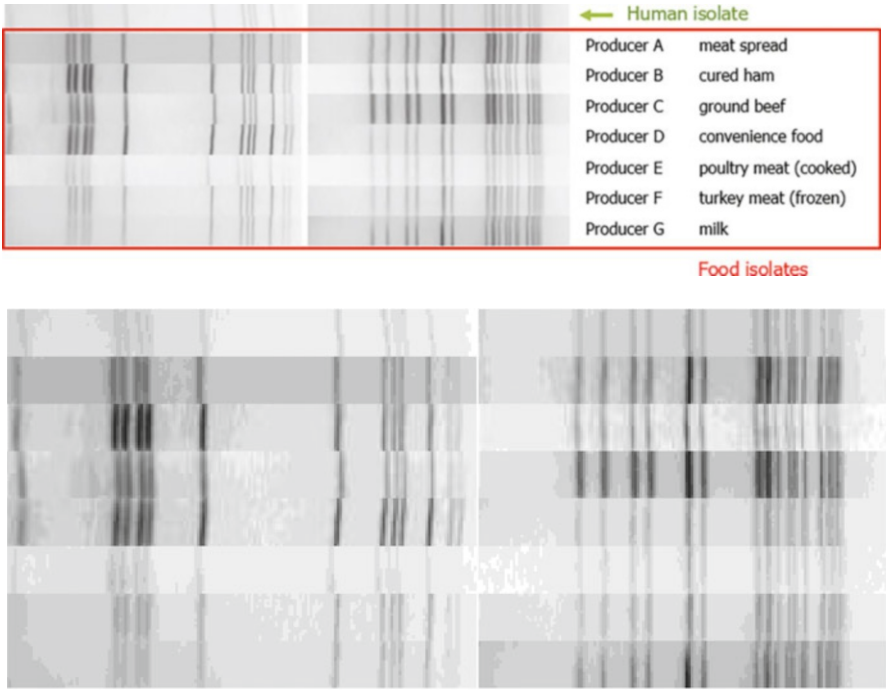

Fig. 8 Indistinguishable pulsed field gel electrophoresis (PFGE) patterns from seven different food items from seven individual (geographically and economically unrelated) food producers in comparison with a contemporary isolate from a sporadic human case (source of infection unknown), Austria 2012 (RTE = ready to eat)

best available standard method for *L. monocytogenes* genotyping. While the WGS technique is currently the recommended method for real-time surveillance of listeriosis and is increasingly used by reference laboratories, the EU public health and food safety value of PFGE has been bridging the historical national and EU-wide PFGE databases to WGS typing for the investigation of multicountry *L. monocytogenes* outbreaks during the transition period. The results provided by this study contributed to a better understanding of listeriosis epidemiology in the EU and helped to target effective

control and preventive measures within both food safety and public health as the presence of commonly circulating *L. monocytogenes* strains in food and humans has been demonstrated. The study has been a good example of a successful joint scientific exercise in the spirit of One Health.

12.7 Disease Symptoms in Both Animals and Humans

12.7.1 Disease Symptoms in Animals

In general, listeriosis in animals can be classified as six different forms (Selbitz 2011): (a) latent intestinal colonization with shedding via feces, (b) encephalitic listeriosis, (c) septicemic form, (d) metrogenic form, (e) mastitis, and (f) ocular manifestation. Table 1 summarizes the listeriosis cases in animals, submitted for necropsy and diagnosed at the Institutes for Veterinary Disease Control of the Austrian Agency for Health and Food Safety from 2007 to 2020 (total: 450). The simultaneous incidence of several distinct forms (b–f) in one animal is possible, but constitutes a rare event. Several factors influence the development of these manifestations: site of bacterial entry (oral or nasal mucosa, eye, gastrointestinal mucosa, navel), microbial virulence, host immune competence, and way of dissemination (lympho-hematogenous or neurogenic) (Selbitz 2011). Therefore, incubation periods can vary between a few days and 4 weeks.

The most frequent encephalitic form (and other organic manifestations as well) can readily be diagnosed by histological examination with subsequent immunohistochemical detection (i.e., avidin–biotin–peroxidase complex (ABC) technique) of the pathogen. Suspicion of listerial infection is usually raised by typical morphological features, in a high number of cases upon sole examination of H&E sections. In a retrospective study of 178 encephalitis cases in ruminants, Bagó et al. (2001) found morphological characteristics of listerial encephalitis in 52 cases, which were all confirmed by immunohistochemistry. Moreover, immunohistochemical examination

Table 1 Cases of listeriosis in animals submitted for necropsy and diagnosed at the Institutes for Veterinary Disease Control (Austrian Agency for Health and Food Safety) from 2007 to 2020 (total: 450)

revealed two additional cases of listeriosis, formerly classified as nonpurulent encephalitis of unknown etiology. These findings underline the value of immunohistochemistry in the diagnosis of encephalitic listeriosis. Figures 9 and 10 display two histological features of listerial rhombencephalitis in ovine brain with different detection intensity of *L. monocytogenes* (Bagó et al. 2001).

Ruminants are most frequently affected by the encephalitic form (Selbitz 2011) with histological features of a characteristic, predominantly purulent rhombencephalitis and nonpurulent leptomeningitis. Symptoms include elevated temperature (initially), depression, exaggerated forward or sideward stance, vestibular ataxia, circling, paresis of cranial nerves (nervus facialis, nervus glossopharyngeus, nervus trigeminus), salivation, strabismus, nystagmus, nasal and ocular discharge, reduced pupillary reflex, reduced tongue movement, and head tilt (Schweizer et al. 2006; Selbitz 2011; Weiss and Amtsberg 1995; Braun et al. 2002). Young animals during dentition are particularly susceptible for neurogenic dissemination via the trigeminal and glossopharyngeal nerves due to the increased vulnerability of the oral mucosa. The metrogenic form is characterized by late abortions, premature delivery, and frailty of the offspring displaying liver necrosis, abomasal erosions, and multifocal accumulations of *Listeria* in parenchymatous organs of the fetus/neonates with or without inflammatory reaction. Metritis or placentitis of the dame is rarely encountered (Dennis 1975; Wagner et al. 2005; Weiss and Amtsberg 1995). The septicemic form primarily affects juveniles (predominantly lambs) and is characterized by fever,

(Reprint by permission of Österreichische Gesellschaft der Tierärzte (ÖGT))

general discomfort, and diarrhea (Weiss and Amtsberg 1995). The pathomorphological findings are dominated by multifocal necrosis in parenchymatous organs and occasionally fibrinopurulent meningitis. Listerial mastitis is a rare form that usually presents with subclinical chronic interstitial mastitis resulting in parenchymal atrophy (Winter et al. 2004). The ocular manifestation of listeriosis is characterized by a granulomatous to purulent keratoconjunctivitis and uveitis/iridocyclitis (Evans et al. 2004; Selbitz 2011). The so-called exposition keratitis is interpreted as a result of cranial nerve paresis and cannot be attributed to the infection itself. Special manifestations like listerial gastroenteritis and granulomatous-suppurative lymphadenitis have also been described (Fairley et al. 2012; Otter et al. 2004; Thompson et al. 2009).

In **swine**, listeriosis usually presents as abortion, septicemia of suckling and fattening pigs as well as encephalitis. Fattening pigs frequently develop hemorrhagic enteritis in the septicemic phase. Animals suffering from cerebral affection display incoordination, torticollis, circling, tremor, and paresis of hind legs (Wendt and Bickhardt 2001).

Listeria infection is occasionally detected in **horses**. Few cases of encephalitic (Rütten et al. 2006), abortive (Welsh 1983), ocular (Evans et al. 2004), and septicemic (Jose-Cunilleras and Hinchcliff 2001; Warner et al. 2012) forms have been reported. The septicemic form is characterized by necrotizing hepatitis and typhlocolitis.

Listeriosis of **dogs** and **cats** is exceptionally rare: Septicemic form (Schroeder and van Rensburg 1993; Weiss 2005), tonsillitis (Läikkö et al. 2004), cutaneous manifestation (Weiss 2005), and abortion (Sturgess 1989) have been described.

In **poultry**, septicemic listeriosis leading to acute death and encephalitic listeriosis with central nervous system disturbances such as torticollis and drowsiness has been described. Pathomorphologically, granulomatous, and purulent (heterophilic)

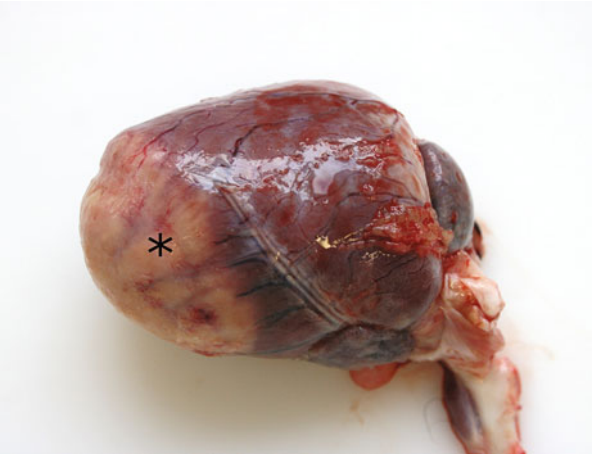

Fig. 11 Myocardial listeriosis in a red panda. Note the acute myocardial necrosis (*). In this case, we detected listeria intralesionally by immunohistochemistry. (Image courtesy Dr. S. Merbach)

inflammation of the central nervous system could be demonstrated (Kurazono et al. 2003; Ramos et al. 1988).

Lagomorpha and **rodents** are susceptible to listeriosis as well, usually developing septicemic, metritic, and ocular forms (Hoelzer et al. 2012; Peters and Scheele 1996; Selbitz 2011).

In addition, listeriosis has been reported in a multitude of **wild mammalian species**, whereas the above-described courses of disease and lesions can be transmitted to related genera of domesticated species (Hoelzer et al. 2012).

Recently, a very rare event of myocardial listeriosis in a red panda (Fig. 11) could be detected by bacteriological examination and immunohistochemistry (Merbach et al. 2019).

The increased frequency of raising/holding **reptiles and amphibians** as pets draws additional attention to the zoonotic potential of listeria, as these animals provide good examples for latent intestinal colonization of listeria with shedding via feces (Weber et al. 1993). Nevertheless, some case reports about fatal clinical disease, e.g., myocarditis in these species exist (Matt et al. 2019).

12.7.2 Disease Symptoms in Humans

L. monocytogenes is prevalent in many different foods for human consumption, and exposure to this pathogen by the consumption of contaminated food would be considered fairly common. However, clinical disease is rare and mainly occurs among the immunocompromised, the pregnant, and the elderly (age $\geq$ 60 years). Clinical manifestations range from febrile gastroenteritis to more severe invasive forms including sepsis, meningitis, rhombencephalitis, abortion, and perinatal infections.

The median incubation period is estimated to be 3 weeks. Outbreak cases have occurred 3 to 70 days following a single exposure to an implicated product (Heymann 2015). Noninvasive listeriosis (commonly manifested as febrile self-limited gastroenteritis) usually has a shorter incubation period, which ranges between six hours and ten days (American Medical Association et al. 2001). Invasive listeriosis generally needs a much longer incubation period, usually about 20 to 30 days (Linnan et al. 1988). Goulet et al. (2013) calculated the incubation period of listeriosis by reviewing published literature on patients with a single exposure to a confirmed food source contaminated by *L. monocytogenes*. For gastroenteritis cases, the median incubation period was 24 hours with variation from 6 hours to 30 days. For invasive listeriosis, the overall median incubation period was 8 days (range: 1–67 days); it differed significantly by clinical form of the disease: pregnancy-related cases showed a median incubation period of 27.5 days (range: 17–67 days), cases with central nervous system (CNS) manifestation a median of 9 days (range: 1–14 days) and for bacteremia cases a median of 2 days (range: 1–12 days).

Ten to twenty percent of clinical cases are pregnancy-associated (including neonates within the first 3 weeks after birth), and the majority of the rest occurs in nonpregnant immunocompromised individuals or in the elderly. While listeriosis during pregnancy usually presents with flu-like symptoms, which can lead to infection of the fetus causing abortion, premature birth, or stillbirth, in nonpregnancy-associated cases, it mainly manifests as meningoencephalitis or septicemia. The onset of meningoencephalitis (rare in pregnant women) can be sudden, with fever, intense headache, nausea, vomiting, and signs of meningeal irritation, or may be subacute, particularly in an immunocompromised or an elderly host (Heymann 2015; Tunkel et al. 2004).

Rhombencephalitis is an unusual form of listeriosis (Armstrong and Fung 1993). This brain stem encephalitis occurs in previously healthy adults. It is analogous to "circling disease" in sheep. Clinical features are biphasic: fever, headache, nausea, and vomiting, lasting several days and then cerebellar signs: cranial nerve deficits and hemiparesis. Cerebrospinal fluid shows increased protein and white blood cell counts; culture is positive in only 50%.

Kasper et al. studied a total of 150 human cases of listeriosis reported in Austria between 1997 and 2007 and found 9.3% to be pregnancy-associated (mother/child illness considered as a single case) (Kasper et al. 2009). Among the 136 nonpregnancy-associated cases, 55.2% were male and 44.9% female. Overall, 131 of 150 human cases (87%) had some type of risk factor or underlying disease associated with contracting listeriosis. The majority of cases (90.7%) were caused by systemic infections, only 9.3% of cases were local infections. Among nonpregnancy-associated cases, the 30-day all-cause fatality rate was 28.7% (39/136) and among the pregnancy-associated cases 35.7% (5/14; miscarriage x3, stillbirth x1, death in a newborn within 15 days of birth x1).

The widespread use of immunosuppressive medications for treatment of malignancy and management of organ transplantation has expanded the immunocompromised population at increased risk of listeriosis. The estimated risk for contracting listeriosis is 300 to 1000 times higher for AIDS patients than for the

general population. However, relatively few cases have been reported worldwide among HIV-positive or AIDS patients; in Austria, listeriosis in HIV-positive patients is a rare event (da Silva et al. 1992; Kasper et al. 2009). The preventive dietary recommendations to avoid the high-risk foods in HIV-positive persons and the repeated antimicrobial therapy for opportunistic infections may explain the relatively low incidence rate of listeriosis in AIDS patients (Vazquez-Boland et al. 2001).

L. monocytogenes can produce a wide variety of focal infections: conjunctivitis, skin infection, lymphadenitis, hepatic abscess, cholecystitis, endocarditis, peritonitis, splenic abscess, pleuropulmonary infection, joint infection, osteomyelitis, pericarditis, myocarditis, arteritis, tonsillitis, and endophthalmitis (Lorber 2010; Guerrero et al. 2004, Allerberger et al. 1989; Allerberger et al. 1992; unpublished data). Cutaneous listeriosis usually presents as papular or pustular lesions on the arms or hands (of veterinarians). Cutaneous listeriosis is observed extremely rarely and is most often acquired as an occupational hazard from infected animals (McLauchlin and Low 1994; Regan et al. 2005; McLauchlin 2011).

In healthy adults, exposure to *L. monocytogenes*-contaminated food usually causes only a short period of fecal shedding without illness. Foodborne transmission of *L. monocytogenes* can also cause a self-limiting acute gastroenteritis (in immunocompetent persons). From the data available in normal hosts in Italy, Illinois (USA), and Austria, it appears that febrile gastroenteritis in normal hosts requires the ingestion of a high dose of several million bacteria (Aureli et al. 2000; Dalton et al. 1977; Pichler et al. 2009). Majority of invasive listeriosis cases are caused by consumption of food containing more than 2000 CFU (colony-forming units)/g. Growth of *L. monocytogenes* during storage at costumer's home is responsible for diseases in about one third of cases (EFSA BIOHAZ Panel 2018). Grif et al. studied the incidence of fecal carriage of *L. monocytogenes* in healthy volunteers (Grif et al. 2003). The PCR results of the subjects indicated an incidence of five to nine exposures to *L. monocytogenes* per person/year. On an average, the incidence of culture-confirmed fecal carriage in healthy adults was two episodes of *L. monocytogenes* carriage per person/year. Fecal shedding was of short duration (maximum four days). The discrepancy between PCR results and the results from conventional culture could be explained by protective host effects. In particular, secretion of gastric acid provides an important protective factor against the passage of potentially pathogenic organisms. Cobb et al. have shown a drastically increased prevalence of *L. monocytogenes* in the feces of patients receiving long-term H_2-antagonists compared to the prevalence in patients with normal gastric secretion (Cobb et al. 1996).

12.8 Conclusion

Although invasive listeriosis occurs primarily in patients with underlying diseases, there are also reports on a rise of listeriosis in previously health persons (Goulet et al. 1998). The mechanism of this appearance has not yet been elucidated. Mainly affected from invasive listeriosis are elderly, immunocompromised individuals and

pregnant women. After a long period of increasing rate of invasive listeriosis, cases remained stable since 2015 but this trend placed listeriosis on place five of foodborne diseases, still with the highest rate of hospitalization and death (EFSA 2021). Goulet et al. hypothesized that the reduced salt content in ready-to-eat food (RTE) products may contribute to the growth of the organism, if present as a contaminant, and increase the likelihood of infection when these products are consumed by susceptible individuals (Goulet et al. 2008). The food industry reduced the salt content of selected products, such as RTE meat products, in response to recommendations in 2002 from food safety agencies, asking for a 20 % reduction in average salt intake, spread over five years, in order to prevent disease attributable to hypertension-related conditions. The influence of salt content in food on the general incidence of human listeriosis is unclear.

Changes in the way food is produced and distributed have increased the potential for widespread outbreaks involving many countries as a result of contamination of widely distributed commercial food products. Results of the European Listeria typing exercise (ELiTE) demonstrated a high degree of dissemination of certain *L. monocytogenes* strains (ECDC-EFSA 2021).

In 2008, ECDC (European Centre for Disease Prevention and Control) established a surveillance of invasive listeriosis and reporting to the European Surveillance System (ECDC-EFSA 2021). A rapid alert system (RAFFS System) allows prompt action and recall of contaminated products, and rapid exchange of whole-genome sequencing data is an important mechanism for collaborative outbreak investigation.

The dose–response relationship of *L. monocytogenes*, which represents an essential component of risk assessment, is still a pivotal question (Hoelzer et al. 2012). Presumably, it depends upon the serotype, concentration, virulence, and pathogenicity of the involved strain and also on host risk factors (Vázquez-Boland et al. 2001). The infectious dose for systemic listeriosis has not yet been determined. Recently, EFSA published a scientific opinion on *L. monocytogenes* contamination of RTE foods and the risks for human health: The majority of invasive listeriosis cases are attributable to ingestion of $>$10,000 cfu (EFSA BIOHAZ Panel 2018).

The emergence of human listeriosis is the result of complex interactions between various factors that may reflect changes in social patterns. Gillespie et al. (2010a, 2010b) studied the association of human listeriosis with neighborhood deprivation and found that listeriosis incidence was highest in the most deprived areas of England when compared with the most affluent, and those affected were more likely to purchase foods from small convenience stores or from local services (bakers, butchers, fishmongers, and greengrocers) than were the general population. They hypothesized that small businesses do not have access to the same level of food safety expertise as do larger retail companies, that increased deprivation could be associated with conditions where refrigeration may be inadequate or unavailable, and that financial pressures may encourage individuals to store food longer than the food product's safe shelf-life. The exact role of changes in social patterns is still an unresolved issue.

Morvan et al. have analyzed the evolution of susceptibility to antibiotics in 4186 clinical isolates of *L. monocytogenes* through several decades and found the prevalence of resistant strains in humans at a stable low level of 1.3% (Morvan et al. 2010). Marco et al. tested the in vitro activity of 22 antimicrobial agents against *L. monocytogenes* isolated in Spain (Marco et al. 2000) and found no increase in resistance with sequential analysis over the study period. Yan et al. studied 2862 food-borne *L. monocytogenes* isolates and detected 28 resistant isolates, 11 of them multiresistant, demonstrating the ability of *L. monocytogenes* to acquire antimicrobial resistance (2019). The question why *L. monocytogenes*, in contrast to all other zoonotic agents, is not showing an increase in antimicrobial resistance to drugs widely used in animal production and in human medicine remains unresolved. Baquero et al. stated that rare exposure of *L. monocytogenes* population to antibiotics as well as the large core genome and therefore limited need for acquisition of foreign genes might play a role (2020).

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_63

Abstract

Human brucellosis belongs to the most common bacterial zoonotic diseases with about 500,000 reported cases per year and is one of the most widespread zoonoses according to the World Health Organization. The disease is caused by *Brucella* species, a highly contagious bacterial agent causing severe infection in humans and economic loss in livestock. It is considered to be a bioterrorism organism due to its low infectious doses of 10 to 100 bacteria and its ease of transmission as an aerosol. Brucellosis is endemic worldwide but the Mediterranean region has been particularly affected. The species of the genus *Brucella* with the greatest importance as zoonotic pathogens are *Brucella* (*B*.) *melitensis*, *B. abortus*, and *B. suis*. Some species are further subdivided into biovars. The species differ in their animal host specificity and epidemiological occurrence depending on the livestock or the prevalence of the corresponding wild animals in the respective country. In addition, the species and, in the case of *B. suis*, even the biovars differ in their pathogenicity und thereby in the clinical picture caused in humans which is complex and often characterized by relapses or chronification and termed by the syndrome Mediterranean fever, among others. Since 2007, the genus *Brucella* has changed fundamentally. A series of new "atypical" species and *Brucella*-like organisms have been described infecting humans, rodents, amphibians, fish, and even reptiles, like the panther chameleon. The significance as a zoonosis of these rare species remains still unclear, but first cases caused by atypical *Brucella* spp. in humans have been reported. Diagnosis is based on the detection of the pathogen by means of cultivation and the detection of genus-specific nucleic acids in patient or animal samples. Unambiguous species differentiation and genotyping in case of outbreaks are challenging due to the close relationship between the species and can be achieved by multiplex PCRs, sequencing of single genes as well as by whole genome sequencing. The serological diagnosis in humans and livestock is based on the detection of antibodies against the *Brucella* lipopolysaccharide. It is hampered by different lipopolysaccharide types among the species and by cross-reactivities to other zoonotic Gram-negative bacteria. Prevention and control in livestock are achieved by regular testing and vaccination with live vaccines and in humans by avoiding contaminated food products and protection from infected animals and their secretions.

Brucellosis · Zoonosis · Mediterranean fever · Bioterrorism

13.1 Introduction

Brucellosis is recognized as a significant public health challenge, with a major economic and financial burden in countries where the disease remains endemic like the Mediterranean region, the Middle East, parts of Central and South America, Africa, and Asia. Over the last 10 years, the infection has re-emerged, with high prevalence in sheep and goats in particular, in Eastern Europe, Central Asia, and Eurasia and single autochthonous cases from countries officially free of bovine brucellosis (Beauvais et al. 2017; Kracalik et al. 2016; Mailles et al. 2012; Gwida et al. 2012a; Schaeffer et al. 2021). Economic losses from *Brucella* infections include decreased productivity as a result of abortion, weak offspring, and decreased milk production, as well as lost trade opportunities. The agent is highly contagious for humans, and the disease, unless diagnosed and treated both promptly and effectively, can become chronic, affecting multiple parts of the body. It is acquired by ingestion of contaminated dairy foods and from occupational exposure to infected live animals or carcasses during slaughter. Furthermore, *B. melitensis*, *B. abortus*, and *B. suis* are on the CDC list of selected agents and toxins (http://www.selectagents.gov) and are considered to be a bioterrorism organism due to its low infectious doses of 10 to 100 bacteria. The latter is also responsible for laboratory infections described for *Brucella*. Brucellosis is the most common bacterial laboratory-acquired infection. Laboratory exposure is regularly reported from both endemic and non-endemic countries, and up to 43% of exposed laboratory workers may develop active infection (Traxler et al. 2013).

The bacteria causing brucellosis, *Brucella*, are small (0.5 to 0.7 × 0.6 to 1.5 μm), nonmotile (with some exceptions among atypical species), facultative intracellular, Gram-negative, nonspore-forming, rod-shaped bacteria. They are catalase positive, oxidase variable, and most species show fast and strong urease activity. The optimal temperature for growth is 37 °C (between 20 °C and 40 °C), and the optimal pH for growth is 6.6 to 7.4, and it occurs within 48 to 72 h (Scholz et al. 2018). The bacteria are named after Sir David Bruce, who first recognized the organism as causing undulant fever in the 1850s in Malta during the Crimean War and was referred to as Malta Fever. Isolates from all *Brucella* species should be regarded as potentially pathogenic for man. In many countries, they are classified as risk group 3 agents, requiring a biosafety level 3 (BSL3) containment for handling of bacterial cultures (Scholz et al. 2018).

Based on the 16S rRNA gene sequence phylogeny the family *Brucellaceae* forms a monophyletic cluster within the *Alphaproteobacteria* including all species of the genera *Brucella*, *Ochrobactrum*, *Paenochrobactrum*, *Pseudochrobactrum*, and *Falsochrobactrum*. The closest phylogenetic neighbour within the family *Brucellaceae* are the members of the genus *Ochrobactrum*, specifically *Ochrobactrum intermedium*, a saprophyte that occasionally infects humans. Notably, *Ochrobactrum* spp. share a wide series of serologically cross-reactive proteins and exhibit 16S rRNA gene similarities of up to 98.6% compared with *Brucella*, indicating the close relationship of both genera (Scholz et al. 2008a, 2018). Because

of this close genetic relationship, the genera *Ochrobactrum* and *Brucella* had been unified to a single genus (Hördt et al. 2020) with *Brucella* as combined genus name. Consequently, all *Ochrobactrum* species now belong taxonomically to the genus *Brucella*.

The genus *Brucella* currently comprises 12 validly published species (30 species together with all formerly *Ochrobactrum* species, see https://lpsn.dsmz.de/genus/brucella) which are genetically highly related to each other. Many of the twelve recognized *Brucella* species are important facultative intracellular human pathogens, infecting a broad spectrum of animal species, mostly isolated from clinical specimen or contaminated food products. Only *B. microti* has been isolated directly from soil (Scholz et al. 2008c). *B. melitensis* is by far the most frequently observed causative agent of human infection, followed by *B. abortus*, *B. suis*, and *B. canis*. Based on DNA-DNA hybridization studies with DNA-DNA similarities of >80%, all species would belong to a single species with several biovars. However, due to historic reasons, predilection for particular animal hosts, biochemical features, etc., the subcommittee on the taxonomy of *Brucella* agreed in 2003 on a return to the pre-1986 taxonomic opinion with a six species concept including the "classical" *Brucella* species (the type species *B. melitensis* and *B. abortus*, *B. canis*, *B. neotomae*, *B. ovis*, *B. suis*) (Osterman 2006). Further *Brucella* species with no or rare associations to human infections were isolated from marine mammals (*B. ceti*, *B. pinnipedalis*), rodents (*B. microti*), primates (*B. papionis*), Canidae (*B. vulpis*), or humans (*B. inopinata*). A number of further atypical strains have been isolated in the past decade from amphibians, fish, and reptiles (see Table 1) and are awaiting their species description. The term "atypical" hereby refers to either a clearly different phenotype when compared to the classical species (*B. microti* and *B. inopinata*) and/or species with a higher degree of genetic diversity (*B. inopinata* and in particular *B. vulpis*). In contrast to classical *Brucella* species, most atypical species or *Brucella* isolates are metabolically very active, fast growing, and biochemically resemble *Ochrobactrum* rather than *Brucella* (Al Dahouk et al. 2017).

The genome of *B. melitensis* consists of two chromosomes, a larger one with 2.1 M bases and a smaller one with 1.2 M bases. The GC content adds up to 57%. Although more than 3,000 genes are predicted, the organism lacks the typical virulence factors, such as exotoxins, capsule, flagella, fimbriae, plasmids, lysogenic phage, antigenic variation, cytolysins, or type I, II, or III secretion systems (Purcell et al. 2007). The most important virulence factors identified in *Brucella* species are, among others, the type IV secretion system (T4SS) and the lipopolysaccharide (LPS). The T4SS, encoded by the *virB* region, is essential for survival and multiplication in macrophages and persistent infection in mice models of infection. The VirB T4SS permits the injection of a large variety of bacterial effectors inside host cell's cytosol, leading to subversion of signaling pathways and favouring bacterial growth and pathogenesis. Studies of the VirB System in different *Brucella* species indicate that the T4SS plays crucial roles in the inhibition of the host innate immune response and in intracellular survival during infection and might be required for chronic persistence during infection (Boschiroli et al. 2002; Lacerda et al. 2013; Ke et al. 2015).

Table 1 Host tropism and zoonotic potential of *Brucella* species and their biovars

Brucella species	Biovar (bv) or strain ID	Animal host	Zoonosis	References
Classical *Brucella* species				
B. melitensis	bv 1, 2, 3	Goat, sheep, camels	Yes	Meyer and Shaw 1920
B. abortus	bv 1–7, 9	Cattle, bison, buffalo, elk	Yes	Meyer and Shaw 1920
B. suis	bv 1	Pig (domestic and feral), dogs	Yes	Huddleson 1924; Meyer and Cameron 1963
	bv 2	European brown hare (*Lepus europaeus)*, wild boar (*Sus scrofa scrofa)*	Yes	Melzer et al. 2007; Mailles et al. 2017
	bv 3	Pig (domestic and feral), wild boar (*Sus scrofa*)	Yes	Jiang et al. 2012
	bv 4	Reindeer (*Rangifer tarandus tarandus*), wild caribou (*Rangifer tarandus groenlandicus*)	Yes	Rausch and Huntley 1978
	bv 5	Rodents (*Apodemus agrarius*, *A. sylvaticus*, *Mus musculus*, *Microtus arvalis*, and *Cricetulus migratorius*)	Unknown	Vershilova et al. 1983
B. canis	Reference strain RM6/66	Dog (*Canis lupus familiaris*), *canidae*	Yes	Carmichael et al. 1968
B. ovis	Reference strain 63/290	Sheep	No	Buddle 1956
B. neotomae	Reference strain 5 K33	Rodents, desert rat (*Neotomae lepida*)	2 cases reported	Stoenner et al. 1957; Villalobos-Vindas et al. 2017
B. ceti	Reference strain B1/94	Cetaceans	1 case report	Jahans et al. 1997; Foster et al. 2007

Brucella sp.	Strain 191011898	Panther chameleon (*Furcifer pardalis*)	Unknown	Eisenberg et al. 2020

The *Brucella* cell wall is composed of an outer membrane comprising an external layer of lipopolysaccharide, a range of outer membrane proteins including some with porin activity, lipoproteins, and phospholipids. Colony morphologies have been classified into smooth and rough forms, based on the respective presence or absence of the most external antigen, O-polysaccharide (O-PS), within the LPS of the cell wall, which constitutes the hydrophilic part of the LPS. *B. melitensis*, *B. abortus*, and *B. suis* are examples for smooth species, and the respective LPS occurs as smooth lipopolysaccharide (S-LPS). In rough species, such as *B. canis* and *B. ovis*, the LPS occurs as rough lipopolysaccharide (R-LPS). R-LPS is devoid of the O-chain or O-polysaccharide, which is the most exposed part of S-LPS in the outer membrane of smooth organisms. The LPSs of *Brucella* present biological properties distinct from enterobacterial LPSs, such as low endotoxicity, high resistance to macrophage degradation, and protection against immune responses (Lapaque et al. 2005;

Cardoso et al. 2006). Taken together, these properties may constitute key virulence mechanisms of *Brucella* spp. for intracellular survival and replication and for persistence inside the animal host. The O-PS is critical in this regard for smooth strains, as rough mutants that lack O-PS do not survive as well as their smooth counterparts in macrophages or in animal models of infection. The O-chain of *Brucella* S-LPS carries the major antigenic determinants involved in the humoral immune responses in animals and humans infected by smooth *Brucella* strains (Fernández-Lago and Díaz 1986; Díaz-Aparicio et al. 1993; Alonso-Urmeneta et al. 1998), while immunodominant antigens in rough *Brucella* strains are R-LPS and outer membrane proteins (Riezu-Boj et al. 1986). The genes identified to be involved in O-PS biosynthesis were located in two major separate chromosomal loci termed the *wbk* locus and the *wbo* locus. Part of the *wbk* locus is closely related to that found in *Y. enterocolitica* O:9, which partly explains the common O-PS structure between *Brucella* spp. and *Y. enterocolitica* O:9 and consequent O-PS antigenic relatedness and serological cross-reactions (Godfroid et al. 2000). Recent research suggests that the loss of O-PS results from the spontaneous excision of the *wbkA* glycosyltransferase gene (Mancilla et al. 2012). This phenomenon is referred to as smooth to rough dissociation (Mancilla 2016; Mancilla et al. 2012). The significance of colony morphology and *Brucella* LPS genetics remains controversial, but a potential link to virulence is discussed. Defects in LPS structure that eliminate O-antigen was shown to result in a number of attenuated phenotypes, including sensitivity to complement-mediated killing, increased sensitivity to killing by antimicrobial peptides, increased maturation of dendritic cells, and attenuation in tissue culture and animal infection models.

13.2 Pathogenicity

The genus *Brucella* contains zoonotic pathogens originally associated predominantly with terrestrial livestock and wildlife sources. They are pathogenic for a wide variety of animals, frequently producing generalized infections with a bacteremic phase followed by localization in the reproductive organs and the reticuloendothelial system. Infection in the pregnant animal often results in placental and fetal infection, and this frequently causes abortion at third trimester of gestation. Because fetal membranes and placenta are highly contaminated by bulk of free bacteria, abortion is a major mechanism of *Brucella* transmission in nature (Alexander et al. 1981). The organisms may localize in mammary tissue and can be excreted in the milk. Because all the main species of meat- and milk-producing domesticated animals are susceptible to brucellosis and act as sources of human infection, the economic impact of the disease is enormous. Typically, growth in vivo is intracellular and the organisms can survive within both granulocytes and monocytes. Infections in the natural host are rarely lethal and often mild, with clinical manifestations occurring mainly in the pregnant animal. Nevertheless, localization can occur in a wide range of organs with production of a variety of lesions. All the *Brucella* species may produce infection, but the severity of the infection varies considerably

with the virulence of the infecting *Brucella* species (Braude 1951; Isayama et al. 1977). The more pathogenic strains usually produce a local abscess at the site of inoculation, followed by bacteremia of varying duration. The regional lymph nodes may become enlarged and granulomatous changes develop. Similar changes occur in the liver and spleen and frequently in other organs, particularly the testes and epididymides. *B. melitensis* and *B. suis* biovars sometimes produce fatal infections (Braude 1951). The other species rarely produce severe disease, and infection is usually self-limiting within a period varying from a few weeks to more than six months. Pathogenic effects of these nomenspecies are limited to slight-to-moderate splenic enlargement.

Infection among the nomadic population arises from direct or indirect contact with infected animals. Urban populations mostly contract the disease by consumption of contaminated milk or meat products, establishing cluster infection among family and tribe members, respectively. Person-to-person transmission is extremely rare. It has been described by vertical and sexual route as well as by blood transfusion, but it plays no part in the natural history of the disease (Tuon et al. 2017). Entry of the organisms may be via the respiratory or gastrointestinal mucosa, or the percutaneous route. The subsequent pathogenesis is believed to follow a similar pattern to that observed in experimental animals, with proliferation in lymphoid tissue succeeded followed by a bacteremic phase of variable duration with, in some cases, localization in specific organs. The infection may be completely subclinical, or it can produce a subacute or acute febrile illness. In the absence of adequate antibiotic therapy, this can persist for many months and may be accompanied by the development of severe complications such as endocarditis, meningoencephalitis, arthritis, spondylitis, and orchitis. A postinfectious, chronic, debilitating syndrome may also result. *B. melitensis* accounts for the majority of severe infections (Pappas et al. 2006), followed by *B. suis*. *B. abortus* and *B. canis* are usually associated with milder disease. Infection elicits both antibodies and cell-mediated immunity. The LPS is the dominant antigen in the serological response, but antibodies and delayed hypersensitivity to a variety of proteins can develop.

13.3 Epidemiology of Brucellosis in Animals

Some species and their biovars show distinct host tropism. In general, infection with *Brucella* sp. in animals is characterized by one or more of the following signs: abortion, retained placenta, orchitis, epididymitis and, rarely, arthritis, with excretion of the organisms in uterine discharges and in milk. In some animal species and for some *Brucella* species, the animals show no symptoms.

13.3.1 *B. melitensis*

B. melitensis is the most significant species in terms of both animal and human disease impact, and this refers to all three phenotypically differentiated biovars (bv 1, 2, 3).

The three biovars of *B. melitensis* can be found globally; however, in some geographical regions, a certain biovar may dominate. As an example, in the Mediterranean region (e.g., Tunisia, Greece, Italy), *B. melitensis* bv 3 occurs most frequently. The main animal hosts of *B. melitensis* are goats and sheep and with much less frequency cattle and camels, as well as yaks (*Bos grunniens*), water buffalo, alpacas, dogs, horses, and pigs. *B. melitensis* is rarely reported from wildlife. However, sporadic cases have been reported in terrestrial wild animals in the alpine ibex (*Capra ibex ibex)*, chamois (*Rupicapra rupicapra*), and wild boar in France (Marreros et al. 2011; Mick et al. 2014; Gennero et al. 2004) and in Arabian oryx (*Oryx leucoryx*) in Saudi Arabia (Ostrowski et al. 2002). Interestingly, *B. melitensis* was also isolated from wild catfish (*Clarias gariepinus*) captured from the Nile Delta region of Egypt. In this case, fish might have been infected due to disposing of animal waste into the canals (El-Tras et al. 2010). Whether fish are a possible reservoir for *B. melitensis* and may have a role in the epidemiology of the disease remains unclear.

The characteristic clinical signs of caprine brucellosis caused by *B. melitensis* are middle- to late-term abortion, stillbirths, the delivery of weak offspring, and association with an extensive negative impact in a flock's productivity leading to economic losses in livestock sector. Historical observations indicate that goats have been the hosts of *B. melitensis* for centuries; but around 1905, the Greek physician Themistokles Zammit was able to build the epidemiological link between "Malta fever" and the consumption of goat milk (Wyat 2005). While the disease has been successfully eradicated in sheep, goats, and cattle in most industrialized countries, it remains a significant burden on animal and human health in the Mediterranean region, the Middle East, Central and Southeast Asia (including India and China), sub-Saharan Africa, and certain areas in Latin America, where approximately 3.5 billion people live at risk (Rossetti et al. 2017). Despite intense joint efforts to eliminate *B. melitensis* from livestock in Europe, the disease still occurs in Portugal, Spain, France, Italy, the Balkans, Bulgaria, and Greece. Northern and Central European countries like the United Kingdom, Belgium, the Netherlands, Denmark, Germany, Austria, Switzerland, the Czech Republic, Hungary, Poland, Romania, Sweden, Norway, and Finland, among others, are officially free of the disease. Case reports from these countries are imported infections or due to imported (contaminated) food. Only single events with only a small number of cases of *B. melitensis* infections among domestic animals occurred. One was, e.g., in Austria, where a small autochthonous outbreak occurred in 2018 with three infections in humans and four in cattle (Schaeffer et al. 2021). Another outbreak in France, where a *B. melitensis* spillover between the alpine ibex and a 21-head dairy herd producing raw milk cheese in the French Alps, occurred in 2012 (Mick et al. 2014).

Camel brucellosis was first reported in 1931 and has since been found in all camel-keeping countries particularly well documented in Africa and the Arabian Peninsula (Gwida et al. 2012b). Infections with *B. melitensis* in camels occur due to the comingling of camels and ruminant livestock (Sprague et al. 2012) and among the highest prevalence rates in camels have been documented when camel herds are intermixed with ruminants (Musa et al. 2008). Prevalence rates of brucellosis in camels vary widely based on several factors, especially animal

husbandry practices (Gwida et al. 2012b). The pathology of brucellosis infection in camels is poorly known as well. Consistent with findings from other livestock, the bacteria appear to localize in reproductive tissues, lymph nodes, and spleen, causing inflammation, edema, and necrosis (Wernery 2014). Infection of pregnant camels can result in placental and fetal pathologies resulting in abortion (Narnaware et al. 2017). As with brucellosis in other animals, these abortion events likely disseminate the bacteria broadly and allow for transmission to other livestock and to animal handlers.

13.3.2 *B. abortus*

B. abortus is worldwide the main cause of brucellosis in cattle and is differentiated into eight biovars (bv 1 to 7 and bv 9). Biovar 3 is further divided into two genetically disparate subgroups 3a and 3b (Whatmore et al. 2016). The predominant biovars in livestock worldwide are bv 1 and bv 2. Biovars 3 and 4 are less frequent, although bv 4 has been reported in South America (Torres Higuera et al. 2019; Matle et al. 2021). Biovar 3 has been isolated from cattle in several European countries and in Africa, whereas the subgroup 3b of *B. abortus* bv 3 is more commonly of European origin than subgroup 3a which is associated with African origins (Ica et al. 2008; Muendo et al. 2012). *B. abortus* is usually transmitted from animal to animal by contact following an abortion. The organisms are mostly acquired by ingestion of contaminated pasture or animal barn. Additionally, inhalation, conjunctival inoculation, skin contamination, and udder inoculation from infected milking cups are other possible routes of infection. Cattle can remain infected for years. They can shed *B. abortus* whether they abort or carry the pregnancy to term, and reinvasion of the uterus can occur during subsequent pregnancies. *B. abortus* is also shed in milk, urine, and semen. Camels can also be infected with *B. abortus*, likely due to the commingling of camel herds with infected cattle (Sprague et al. 2012; Narnaware et al. 2017).

Eradication programs in a number of European nations, Canada, Australia, New Zealand, Japan, and Israel have eliminated this organism from domesticated animals with single exceptions. In terrestrial wildlife, *B. abortus* has been detected in the Greater Yellowstone Ecosystem in the USA and in the Canadian Wood Buffalo National Park from American bison (*Bison bison*) and the Rocky Mountain elk (*Cervus elaphus nelsoni*) (Cross et al. 2010). In Africa, the African buffalo is considered as a reservoir of *B. abortus* (Alexander et al. 2012). In Latin America *B. abortus* was detected, additionally to already listed animals, from foxes, grey weasels, horse capybaras, and ferrets (Lucero et al. 2008). In Europe, it was detected in chamois from large areas of the Western Italian Alps (Ferroglio et al. 2000), and in one case, it was isolated from a single red deer, probably as a spillover from infected cattle. However, in Europe, wild ruminants seem to be occasional victims of brucellosis transmitted from infected livestock, rather than true reservoirs of the infection for livestock (Muñoz et al. 2010).

13.3.3 *B. suis*

B. suis was first isolated from aborted porcine fetuses in Indiana in 1914. Additional isolates obtained from swine fetuses in 1916 were used to demonstrate pathogenicity of the bacterial isolates in swine (Huddleson 1924). Although *B. suis* is the causative agent of brucellosis in pigs, the agent is able to infect several different hosts, including rabbits, reindeer, caribou cattle, dogs, and horses. Swine brucellosis is considered to be one of the main diseases affecting the pig industry. Data from numerous countries indicate widespread distribution of *B. suis* in both domestic livestock and wildlife populations. In some parts of the world, prevalence of swine brucellosis appears to be influenced by religious or cultural preferences that influence consumption of pork and impact populations of the preferred host species. The most common manifestations of the disease are abortion at any stage of gestation, stillbirth, weak piglets in sows, and orchitis in boars. Arthritis with lameness and occasional posterior paralysis may also be seen in both sexes. *B. suis* is currently subdivided into five biovars (bv 1 to bv 5) with different animal hosts and differences in their pathogenicity. *B. suis* bv 1 is the most frequently found biovar in South America isolated from pigs, hares, and dogs (Lucero et al. 2008) and in the People's Republic of China due to high levels of swine production (Deqiu et al. 2002). Furthermore, there are single cases of dogs suffering from *B. suis* bv 1 infections, at which the risk of infection was determined to be a raw meat-based diet of hares from Argentina (van Dijk et al. 2018) or participation in wild boar hunting (Ramamoorthy et al. 2011). In Europe, porcine brucellosis almost exclusively results from transmission of *B. suis* bv 2 from Eurasian wild boar (*Sus scrofa scrofa*) and European brown hare (*Lepus europaeus*) reservoirs (Melzer et al. 2007; Mailles et al. 2017; Muñoz et al. 2010); also *B. suis* bv 1 has been detected in wild boar in the Piedmont region in France (Gennero et al. 2004). Reemergence of swine brucellosis in continental Europe is predominantly related to production systems in which swine are raised outdoors under conditions where contact with wildlife reservoirs may occur (Olsen and Tatum 2017). Venereal transmission is proposed as the main route of transmission of *B. suis* bv 2 from wild boars to domestic swine, whereas transmission from brown hares is probably through oral consumption. Although in the European Union most of the Member States are recognized as "officially free from bovine brucellosis," single cases of *B. suis* bv 2 were reported from cows (Szulowski et al. 2013; Fretin et al. 2013). *B. suis* biovar 3 has been isolated from swine and wild boar in Europe, the USA, Australia, and the People's Democratic Republic of China (Cvetnić et al. 2005, Cvetnić et al. 2009; Cornell et al. 1989; Deqiu et al. 2002). The distribution of *B. suis* bv 4 is exclusively limited to subarctic areas (Alaska, Canada and Russia) where they primarily infect reindeer (*Rangifer tarandus tarandus*) and wild caribou (*Rangifer tarandus groenlandicus*). It was also isolated from wolves, the native relative of dogs, and other carnivores like foxes and wolverines in subarctic areas. (Rausch and Huntley 1978). Isolates of *B. suis* bv 5 also have very limited geographic distribution as they have only been recovered from rodents (*Apodemus agrarius*, *A. sylvaticus*, *Mus musculus*, *Microtus arvalis*, and *Cricetulus migratorius*) in southern Ukraine and southeastern European Russia including the northern Caucasus (Vershilova et al. 1983; Hubalek et al. 2007).

13.3.4 *B. canis*

Brucella canis was discovered in 1966–1967 during an investigation of abortion in beagles, in which the organism was isolated from aborted tissues and vaginal discharge (Carmichael et al. 1968). The host range for *Brucella canis* is predominantly domestic dogs, but other species have been investigated. Serologic studies of wild canids have documented positive antibody titers also in foxes and coyotes (Cosford 2018). Dogs get infected by oronasal contact and ingestion of contaminated tissue or fluid. Transmission between dogs occurs during reproductive, social, and grooming activities. The primary sources of transmission are reproductive fluids: vaginal discharges and semen. Large numbers of infectious bacteria are shed into the environment after abortions or through vaginal or seminal secretions. Clinical signs in dogs range from asymptomatic, lymphadenopathy, orchitis and epididymitis, and embryonic loss to abortion and testicular atrophy (Hollett 2006).

Breeding kennels show high prevalence rates all over the world. In most countries, clinical disease attributed to *B. canis* infection occurs sporadically, but the dog trade leads to spread of the infection. With the unprecedented rates of animals moving across international borders and the lack of federal regulation, canine brucellosis changes its geographical distribution. Reports indicating the infection is endemic by serosurveys or detection of the agent itself are available from Central and South America, southern USA, Canada (Lucero et al. 2008; Lovejoy et al. 1976; Bosu and Prescott 1980); in Asia from Japan, India, the Philippines, Korea, China, Malaysia and Taiwan; and in Africa from Nigeria (Holst et al. 2012). In central Europe, stray dogs in the Mediterranean area are suggested to serve as a reservoir. Published reports of canine brucellosis in Europe are from imported cases due to dog imports or serosurveys from outbreaks in kennels (Holst et al. 2012). Although the literature supports the notion that *B. canis* infection has a worldwide distribution, there are no consistent epidemiological studies assessing the prevalence of canine brucellosis.

13.3.5 *B. ovis*

B. ovis infections in animals affect sheep exclusively, causing genital lesions and overall reproductive failure. It was reported in sheep farming worldwide, but to date, the real distribution of *B. ovis* infection in the world is unknown. It was isolated for the first time in 1952 from a ram in New Zealand (Buddle 1956). Since then, large outbreaks as well as prevalence of the agent are, e.g., described from the Mediterranean region, Australia, and South America (Galuzzo et al. 2021; Sergeant 1994; Costa et al. 2016). The disease is often subclinical and could circulate in the flock without suspicion. The main clinical manifestation in rams is epididymitis (either uni or bilateral), orchitis, resulting in testicular atrophy and infertility. *B. ovis* infection can also induce clinical signs in ewes such as placentitis and abortion in pregnant ewes. The disease is mainly transmitted via mating. Ewes act as a passive reservoir. Rams generally develop a subacute or chronic infection and shed *B. ovis* intermittently with semen, genital secretions, and urine for at least two to four years.

13.3.6 *B. neotomae*

B. neotomae has been isolated from the organs of wood rats in North America (Stoenner and Lackman 1957). It has been shown to display pathogenicity for experimentally infected mice and guinea pigs (Gybby and Gibby 1965; Stoenner 1963) as well as intracellular invasion and survival in macrophages and epithelial cells in vitro (Waldrop and Sriranganathan 2019).

13.3.7 *Brucella* Strains of Marine Origin (*B. ceti* and *B. pinnipedialis*)

Since 1994, *Brucella* strains have been isolated from a wide range of marine mammals. In 2007, the sea mammal *Brucella* isolates were subdivided into two novel *Brucella* species named *B. ceti* and *B. pinnipedialis* with cetaceans and seals as their preferred hosts (Foster et al. 2007). Most marine mammal isolates described have been isolated form the Atlantic, but also from the Pacific (Maquart et al. 2009) as well as from the German North Sea (Prenger-Berninghoff et al. 2008). Transmission of *Brucella* is poorly understood in marine Mammals. *B. ceti* and/or *B. pinnipedialis* has been isolated from the male and female reproductive organs, birth products (including the placenta, fetal fluids, and fetal organs) and the milk or mammary gland. A number of strains has also been detected from lung tissue of marine mammals. The isolation of marine *Brucella* sp. from lungworms (*Parafilaroides* spp.) as well as from marine mammals with bronchopneumonia suggests that transmission of marine *Brucella* strains by lungworms is possible (Prenger-Berninghoff et al. 2008). Experimental infections with marine mammal isolates have been described in cattle, sheep, pigs, and laboratory animals (mice, guinea pigs) with varying outcome (Rhyan et al. 2001; Perrett et al. 2004). In the Arctic, 5 to 10% of polar bears (*Ursus maritimus*) were found to have antibodies against *Brucella*, probably from eating infected seals (Tryland et al. 2001). Whether these infections result in any clinical signs is uncertain.

13.3.8 *B. microti*

Brucella microti was first isolated from systemically diseased common voles (*Microtus arvalis*) in the Czech Republic in Central Europe in 2007 (Hubalek et al. 2007). Natural acute infection was characterized by edema of extremities, arthritis, lymphadenitis, and perforations of the skin resulting from colliquated abscesses, orchitis, and peritoneal granulomas. It has also been isolated from mandibular lymph nodes of red foxes in Lower Austria (Scholz et al. 2009) and even directly from soil (Scholz et al. 2008c). Long-time persistence in the soil suggests that *B. microti* might at least have a transient reservoir in the environment and that common voles (and other animals) become infected by (aerosolized) contaminated soil. Foxes are presumably infected by the ingestion of diseased rodents. In Hungary, *B. microti* was isolated from a wild boar (*Sus scrofa*) in September 2014 (Rónai et al. 2015). It was isolated from lymph nodes. The (female) wild boar did not develop any clinical disease. In

2017, *B. microti* was isolated from domestic marsh frogs (*Pelophylax ridibundus*) of a French farm producing frogs for human consumption (Jaý et al. 2018). Later it was shown that *B. microti* was highly prevalent in these frogs and also in the environment, suggesting long-term persistence (Jaý et al. 2020). It was speculated that its presence could constitute a possible risk for consumers. The prevalence of *B. microti* in other animal species needs further investigation.

13.3.9 Rare *Brucella* Species Recently Described from Animal Hosts

B. vulpis was isolated in 2008 from mandibular lymph nodes of red foxes in Austria and described as a novel *Brucella* species in 2016 (Scholz et al. 2016a). Up to now, only two strains, the type strain F60T and strain F965, both isolated from a single fox, exist. In contrast to most other atypical *Brucella*, *B. vulpis* is slowly growing, similar to *B. melitensis*. Currently, *B. vulpis* is the genetically most diverse *Brucella* species when compared to classical *Brucella* species.

In 2014 *B. papionis*, isolated from baboons (*Papio* spp.), was described as a novel *Brucella* species (Whatmore et al. 2014). The two available strains (F8/08-60T and F8/08-61) were isolated in 2006 and 2007 from two cases of stillbirth and retained placenta that had delivered stillborn offspring at a primate research center in Texas, USA (Schlabritz-Loutsevitch et al. 2009). Phylogenetically *B. papionis* is most closely related to *B. ovis*. Genetically and phenotypically, *B. papionis* belongs to the group of classical *Brucella* species.

In the last few years, many further atypical *Brucella* have been isolated from cold-blooded vertebrates, mainly from exotic frogs kept in zoos and private housings (Table 1). The presence in frog species native to Africa, Asia, America, and Australia indicates that they might be endemic in these regions. The case history of *Brucella* infections in amphibians reveals a variety of pathologies ranging from localized manifestations to systemic infections. Some isolates seem to be capable of causing high mortality in zoological exhibitions putting higher demands on the management of endangered frog species. In 2020, the isolation of an atypical *Brucella* isolate from a reptile, the panther chameleon (*Furcifer pardalis*), was described the first time the (Eisenberg et al. 2020). The detection of *Brucella* in amphibians and reptiles significantly broadens the host range of this medically important genus.

13.4 Epidemiology of Brucellosis in Humans

B. melitensis is the predominant species causing human brucellosis in most endemic regions, but *B. abortus* or *B. suis* might significantly contribute to the number of human infections in areas with extensive cattle or swine livestock farming, and therefore, the occurrence of the different *Brucella* species varies among geographic regions. In the European Union, brucellosis cases stayed stable over the last years. Highest case numbers (between 40 and 200 cases per year, https://www.ecdc.europa.eu/sites/default/files/documents/zoonoses-EU-one-health-2018-report.pdf) are found

in Italy, Greece, Spain, Portugal and Germany. In these countries, cases are linked to imported brucellosis, but also local outbreaks due to unpasteurized dairy products occurred (Control 2018; Nenova et al. 2015).

13.4.1 *B. melitensis*

B. melitensis is the species with highest zoonotic potential causing most human infections among all *Brucella* species. All three recognized biovars (bv1, bv2, bv3) are pathogenic to humans. The live attenuated Rev-1 vaccine for the vaccination of small ruminants is also pathogenic for humans. Although there are single reports of occurrence in wild animals, the main source for *B. melitensis* infections in humans are domestic animals, in particular sheep and goat and with less frequency camels and cattle and their dairy products (Shimol et al. 2012; Garcell et al. 2016). It is the causative agent of Malta fever and the type species of the genus; that was named after the region where the disease has been described for the first time (*melitensis* is the Latin name for the island Malta).

At highest risk for occupational transmission of *B. melitensis* are abattoir workers, rural workers (animal breeders, farmers), and laboratory workers. The latter are at highest risk for *B. melitensis*, especially when miss-identification occurred and/or cultures were processed outside a safety cabinet or due to accidents in the laboratory (Pereira et al. 2020).

13.4.2 *B. abortus*

B. abortus is also zoonotic. It is the etiological agent of bovine brucellosis characterized by abortion in animals and is an occupational disease among people in contact with ruminants or their tissues, such as farmers, butchers, abattoir workers, veterinarians, and laboratory personnel. In addition to wild-type strains of *B. abortus* bv 1 to bv 7 and bv 9, the live attenuated vaccines containing organisms of strain 19 or RB51 are also pathogenic for humans. They must be handled with caution to avoid accidental injection or contamination of mucous membranes or abraded skin. Human exposure can be reduced by controlling brucellosis in livestock and by wearing personal protective equipment when handling infected animals. In milk *B. abortus* is killed off by pasteurization. The consumption of raw milk and dairy products derived from raw milk are among the potential sources of brucellosis. Their persistence in unpasteurized cheese is influenced by factors such as the type of fermentation, temperature, water content, pH, and ripening time.

13.4.3 *B. suis*

Swine brucellosis in humans is most frequently a disease of farm workers, veterinarians, and abattoir workers, but it can also be contracted through other activities

such as hunting or other associations with feral swine. *B. suis* bv 1 and bv 3 are pathogenic in humans, whereas bv 2 appears to be a very rare cause of human infection. The usual route of transmission to humans is the ingestion of contaminated food, e.g., unpasteurized dairy products or undercooked meat from infected animals. The disease may also be acquired by handling infected animals or inhalation of infectious aerosols. High numbers of *B. suis* bv 1 transmissions were described from Argentina in slaughterhouse workers. Affected employees were infected by injuries when processing pork meat, contaminated aerosols, conjunctival splashes, or direct bacterial entry through skin lesions (Wallach et al. 2017; Escobar et al. 2013). Infections from processing meat are described even outside endemic regions (Zange et al. 2019). From other countries (the USA, Australia, Turkey), *B. suis* bv 1 infections have been also reported in humans who hunt and handle feral pigs and are associated with dressing the killed animals or processing their meat (Kutlu et al. 2016; Carrington et al. 2012; Starnes et al. 2004). From China, *B. suis* bv 3 has been reported as the causative pathogen in human brucellosis in Hainan Province (Jiang et al. 2012). Although the current prevalence of *B. suis* bv 4 in people is unknown, case reports from Alaska and Canada's Arctic highlight that rangiferine brucellosis has occurred among northern peoples who consumed caribou (Chan et al. 1989; Forbes 1991).

13.4.4 *B. canis*

The pathogenicity of *B. canis* is considered to be relatively low, making it less of a perceived public health concern than other *Brucella* species. Mild clinical symptoms, such as fever, headache, anorexia, and fatigue, have been reported in patients suffering from *B. canis* infections, but also single severe cases and/or chronic manifestations, such as peritonitis, endocarditis, aneurysms, osteomyelitis, and arthralgia were described (Javeri et al. 2014; Ying et al. 1999; Wallach et al. 2004; Piampiano et al. 2000). Furthermore, infections in patients with underlying disease like HIV infection even with appropriate CD4 counts and negative viral loads have also been diagnosed and successfully treated for *B. canis* infections (Lawaczeck et al. 2011; Dong et al. 2020). The M-strain of *B. canis*, which is used for the serological diagnosis of canine brucellosis and avirulent in dogs, is described to be pathogenic to humans (Wallach et al. 2004). The most common route of infection is through contact with infected dogs, which disseminate the disease with their secretions. Urine and vaginal fluid from canines suffering from brucellosis may contaminate the environment, leading to human disease. Infections occurs via inhalation of aerosols or direct contact with mucosa or non-intact skin, furthermore, after ingestion, either by contaminated hands or by allowing an infected dog to lick around the face and mouth area. Of high risk are people living in close contact with infected dogs especially in overcrowded living conditions, dog breeders, laboratory personnel handling positive samples, and animal technicians (Boeri et al. 2008; Dentinger et al. 2015; Lucero et al. 2005). The true incidence of *B. canis* in humans is unknown, due to a general lack of reliable serological detection methods and as

not in all countries *Brucella* is routinely tracked beyond the genus level as well as due to misidentification as *B. suis* as a consequence of the similar banding pattern in the *Brucella* bruce-ladder PCR. This points out the zoonotic potential of this disease and the importance of pet owner education as well as public health initiatives to ensure appropriate animal treatment and control.

13.4.5 *B. ovis*

B. ovis is not classified as a zoonosis. Although large outbreaks are described from livestock (sheeps), there are no human cases reported so far.

13.4.6 *B. neotomae*

In 2008 and 2011, *B. neotomae* was detected in two patients with neurobrucellosis in Costa Rica. In both cases, the agent was cultured from blood and cerebrospinal fluid. After antibiotic treatment, the patients recovered with normal mental activities. The source of infection could not be identified (Villalobos-Vindas et al. 2017). In Costa Rica, there are no rats of the genus *Neotomae*, but other Neotominae species are endemic. In the described cases, the bacterium was identified as *B. neotomae* by multiple-locus variable number tandem repeat analysis of 16 sequences (MLVA16) and whole genome sequencing (Suárez-Esquivel et al. 2017). Whole genome analysis of *B. neotomae* has also revealed that this bacterium possesses the same virulence arsenal as the classic zoonotic *Brucella* spp. In vitro, invasion and replication in epithelial cells and macrophages by *B. neotomae* has been shown (Waldrop and Sriranganathan 2019). This demonstrates the zoonotic potential of *B. neotomae*.

13.4.7 *Brucella* Strains of Marine Origin (*B. ceti* and *B. pinnipedialis*)

Three human cases with naturally acquired infection by *Brucella* strains presumably of marine origin have been reported, one case of spinal osteomyelitis from a patient in New Zealand (Mc Donald et al. 2006) and two neurobrucellosis cases from Peruvian patients (Sohn et al. 2003). Potential routes of exposure in these three cases included eating raw fish or shellfish, handling raw fish and bait, and swimming in the ocean. None of the people had been directly exposed to marine mammals. Interestingly, these human isolates presented the same genotype as strains from cetaceans from the Pacific (Whatmore et al. 2008). In MLVA-typing, the human isolates share homologies with *B. pinnipedialis* but might also be a third marine mammal *Brucella* species (Maquart et al. 2009). Another clinical case occurred in a person who was working with *B. ceti* in the laboratory (Brew et al. 1999). Altogether, this may point towards a zoonotic potential of these marine mammal *Brucella* species.

13.4.8 *B. microti*

No human infection with *B. microti* has been reported so far. Nevertheless, *B. microti* was shown to replicate in human macrophages and in human and murine macrophage-like cells. It is highly virulent in murine models of infection in which 10^5 colony-forming units of *B. microti* killed 82% of Balb/c mice within seven days (Jiménez de Bagüés et al. 2010). In a mouse model using wild-type and immunodeficient mice that either lacked B, T and B, or T, B, and NK cells, *B. microti* was able to cause disease in the immunocompromised mice but was cleared completely in wild-type mice after three weeks (Jimenez de Bagüés et al. 2011). Histopathology analysis of diseased mice showed extensive areas of necrotic tissue and thrombosis in livers after one week postinfection. *B. microti* was also shown to cause fatal infection in experimentally infected chicken embryos where it provoked marked gross lesions, i.e., hemorrhages and necroses with a killing rate of 100% (Wareth et al. 2015).

13.4.9 The Role of Atypical *Brucella* Species as Human Pathogens

Only little is known about the virulence and zoonotic potential of atypical *Brucella* species. The first atypical *Brucella* isolated from a patient was strain BO1 (De et al. 2008). It was isolated from an inflamed breast implant of a 71-year-old immunocompetent woman without underlying diseases in the USA, presenting with repeating fever attacks and breast pain. Later this strain was described as a novel *Brucella* species, *B. inopinata* (Scholz et al. 2010). Besides fever and local inflammation of the breast, no complications were observed, and the patient responded well to standard antibiotic treatment. The source of infection could not be verified and remained speculative.

The second case was described in a patient from Australia with chronic destructive pneumonia (Tiller et al. 2010). The strain isolated from a lung biopsy was phenotypically and genetically closely related to *B. inopinata* BO1T and therefore was termed BO2. Like for *B. inopinata*, the source of infection could not be determined. The most recent reported infection with atypical *Brucella* species was reported from a 28-year-old patient in France who was hospitalized for an exploration of polyadenopathies associated with multiple pulmonary condensations (Rouzic et al. 2021). The patient had reported a left cervical lymphadenopathy, associated with general degradation in condition and weight loss (8 kg in 3 months). The patient also reported fever and intense night sweats. A cervicothoracic and abdominal computed tomography (CT) scan revealed multiple mediastinal adenopathies, pulmonary parenchymal condensations, and cystic emphysematous lesions in the right upper lobe and splenomegaly (Rouzic et al. 2021). From a cervical lymph node, an atypical *Brucella* strain (BO3) was isolated. In-depth molecular analysis using comparative genome analysis revealed that strain BO3 was identical to strain B13-0095 recently isolated from a Pac-Man frog in Texas (Soler-Lloréns et al. 2016). Indeed, the patient declared having been in close contact with Pac-Man

frogs during his previous activities as exotic animal keeper. The clinical picture was compatible with severe brucellosis, and the patient required prolonged antibiotic therapy of 3 months.

Besides reported human cases, the virulence of atypical *Brucellae* had been investigated in cell culture experiments and by using animal models. In a murine model of infection, some strains caused death (Jiménez de Bagüés et al. 2014). In vitro, strains including isolates from amphibians were found to effectively multiply in different cell lines (Al Dahouk et al. 2017; Soler-Lloréns et al. 2016), and most strains were capable to persist in mammalian hosts over a period of up to three months (Al Dahouk et al. 2017). Furthermore, they share identical virulence genes compared to classical *Brucellae* (Al Dahouk et al. 2017; Soler Lloréns et al. 2016) and have been associated with significant morbidity and mortality in common voles and amphibians (Hubalek et al. 2007; Mühldorfer et al. 2016). On the other hand, one may argue that only weak pathological signs were observed in mice that cleared infections more efficiently and with fewer signs of inflammation compared to classical *Brucella* species (Al Dahouk et al. 2017).

Summarizing, despite the low number of human case**s**, current reports show that atypical *Brucella* are able to infect humans and may induce a clinical picture resembling brucellosis.

The animal reservoirs of *Brucella inopinata*-like strains for human infections still have to be identified, but the high similarity to strains isolated from exotic frogs suggests this as a possibility. Since *B. inopinata*-like strains have also been isolated from fish and reptiles, all cold-blooded vertebrates may serve as a potential source for human infection.

13.5 Laboratory Diagnosis and Typing

The diagnosis of human brucellosis relies on three different modalities: culture, nucleic acid amplification tests, and serology. Bacterial culture is essential for performing strain typing.

13.5.1 Bacterial Culture

Although the diagnosis of brucellosis by bacterial culture is hampered by the slow-growing features of members of the genus *Brucella*, laboratory safety concerns, and reduced sensitivity in prolonged disease and focal infections, isolation of the bacterium is indisputable evidence of the disease. Culture, when positive, provides the definitive diagnosis and is considered to be the gold standard in the laboratory diagnosis of brucellosis. It is essential for determining antimicrobial susceptibility and performing strain typing. Since the pathogenesis of human brucellosis always involves a bacteremic stage, cultures of peripheral blood represent a suitable tool for confirming the disease, although their sensitivity shows a broad range (10–90%) in different reports (Pappas et al. 2005). As bacteremia is low-grade,

sensitivity can be easily improved by drawing two or three separate blood culture sets. In addition to blood samples, *Brucella* can be cultured from clinical samples from affected organs. Automated continuously monitored blood culture systems and the corresponding culture broths are suitable for cultivation of all *Brucella* species from bacteremic patients. The latter could also be applied for puncture fluids from infected tissue or joints. The incubation of liquid culture media, such as blood culture bottles in the absence of growth, should be at least 21 days. However, the cultivation succeeds with blood culture systems from more than 95% of the positive bottles within the first seven days (Yagupsky 1999). Especially on primary isolation, many strains of the classical species require supplementary CO_2 for growth and growth of the classical species is improved by addition of serum or blood to the culture media.

Antigen tests and biochemical or mass spectrometry methods (MALDI-TOF MS) in combination with appropriate databases can be used for preliminary identification (Lista et al. 2011; Ferreira et al. 2010) and on a RUO basis also down to species level (Mesureur et al. 2018). The identification of *Brucella* spp. by MALDI-TOF has proven to be very useful as it is a rapid and accurate identification method (Karger et al. 2013) preventing laboratory infections (Becker et al. 2018). Using biochemical identification, only few reactions are characteristic for *Brucella*, making identification difficult and reliable species determination almost impossible. Specific reactions for differentiation include urease tests, production of hydrogen sulfide (H_2S), catalase, oxidase, growth in the presence of thionin, and basic fuchsin dyes. For the biochemical identification with commercial systems, misidentifications, e.g., as *Moraxella phenylpyruvica* and *Ochrobactrum anthropi*, are described which have even led to laboratory infections (Vila et al. 2016; Batchelor et al. 1992). Therefore, confirmation and reliable species identification should always be carried out by means of molecular biological methods. In contrast, the differentiation of biovars from *B. melitensis* (3 biovars) and *B. abortus* (8 biovars) and *B. suis* (5 biovars) is carried out traditionally by means of phenotypical tests like growth characteristics, biochemical tests in combination with serotyping and determination for resistance or sensitivity to different *Brucella* phages. In recent years, biotyping has increasingly being replaced by the use of frontline molecular tools like PCRs based on genomic deletions or SNPs (Whatmore et al. 2016).

13.5.2 Serology

For the detection of specific antibodies against *Brucella* spp., a variety of in-house and commercial serological tests are available. Currently, all commercial methods are based on the detection of antibodies against the smooth LPS present in *B. melitensis*, *B. abortus*, and *B. suis*. Since *B. canis* lacks the immunodominant O-polysaccharide of the smooth *Brucella* species, the standard serological tests cannot detect anti-*B. canis* antibodies (Sayan et al. 2011). Therefore, in patients with suspicion of infection with a *Brucella* species with rough LPS-type, *B. canis* strains should be used for ELISA antigen preparation (Cosford 2018; Lucero et al. 2005). In particular,

the M-strain of *B. canis* with its less mucoid phenotype is recommended for antigen preparations from whole cells (Carmichael et al. 1984), and PdhB and Tuf proteins are candidates for recombinant antigens in indirect ELISA assays (Sánchez-Jiménez et al. 2020). For atypical strains, like *B. inopinata*-like strains, no serological assay is evaluated yet.

Due to its rapid and inexpensive performance, the serum agglutination test (SAT) or its microtiter plate variant is most widely used, especially in endemic areas, and is traditionally considered the gold standard in the serodiagnosis of brucellosis. The rose bengal (RBT) test can be used to screen patients and contacts and is also commonly used in endemic regions due to its ease of performance (Díaz et al. 2011). However, the result should always be confirmed by one of the followings methods (Corbel 2006). The complement fixation test (CFT) is used as a confirmatory test because of its high specificity, especially in chronic infections as it provides evidence of active brucellosis. Positive CFT titer often persists for years. Incomplete antibodies can be detected by Coombs test or immunocapture agglutination test (BrucellaCapt®) (Bosilkovski et al. 2010; Casanova et al. 2009). Enzyme-linked immunosorbent assays (ELISA) enable the separate determination of individual antibody classes (IgG and IgM antibodies) and a better evaluation of the results with respect to the course of the disease. During the first week after infection with *Brucella* spp., IgM antibodies directed against the LPS of the bacteria predominate. From the second week on, the IgG antibodies also increase. IgM and IgG antibody concentrations reach their highest level about one month after infection. With the start of adequate antibiotic therapy, IgM antibodies slowly fall. Despite successful therapy, IgM antibodies can be detected for over a year (Ariza et al. 1992; Corbel 2006). In case of therapy failure or relapse, IgG antibodies rise again. However, elevated IgG antibodies alone are not evidence of chronic infection, as they can persist for years after acute brucellosis (Ariza et al. 1992). The immunocapture agglutination test (modified Coombs test) provides additional information to distinguish between a past and a chronic infection or a recurrence (Bosilkovski et al. 2010; Casanova et al. 2009). The interpretation of serological test results can sometimes be challenging especially in endemic areas, where people suffer from reinfections due to continuous exposure to the agent. In particular, low antibody titers are typical in chronic courses or in the early phase of infection, and it can be difficult to distinguish them from past infections. An acute infection is confirmed by a fourfold rise of the specific antibodies after repeated testing at intervals of two to three weeks. However, *Brucella* spp. infections have also been described in which a direct pathogen detection was successful, i.e., the culture and/or PCR were positive, but no seroconversion occurred, i.e., the antibody detection was negative. In particular, this has been observed in local infections, even without known immunosuppression (Raptis et al. 2007; Janmohammadi and Roushan 2009; Çelik et al. 2012; Yaghoobi et al. 2013).

In patients with positive serological findings but without detection of the pathogen by culture or PCR and no brucellosis typical or only nonspecific clinical findings, infections caused by other pathogens should be considered which can

lead to false positive results due to cross-reactivities with *Brucella* spp. LPS. Cross-reactivity has been described for *Yersinia enterocolitica* O9, *Escherichia coli* O:157, *Franciella tularensis*, *Salmonella urbana* O:30 and *Vibrio cholera* (Schoerner et al. 1990; Nielsen et al. 2007; Nielsen et al. 2004; Corbel 2006). As all serological methods available on the market are based on the detection of antibodies against the smooth LPS of *Brucella* spp., a differentiation from cross-reacting antigens in such cases is only possible by excluding the cross-reactive agents, as far as specific tests are available for this purpose. The most common disease in which cross-reactive antibodies occur is yersiniosis. Therefore, in non-endemic regions, if antibodies against *Brucella* spp. are detected without the case definition of brucellosis being fulfilled, an infection with *Yersinia enterocolitica* should always be serologically excluded.

13.5.3 Nucleic Acid Amplification Assays

Conventional polymerase chain reaction (PCR) and real-time PCR (RT-PCR) assays have been attempted for the direct detection of *Brucella* from clinical specimens, to monitor treatment response, and for the identification, speciation, and differentiation of recovered *Brucella* species. PCR-based methods to detect *Brucella* DNA use a variety of targets for genus-specific PCRs: *omp2*, *omp2b*, *bcsp*31, IS*711* (IS*6501*), 16S-23S rRNA spacer region, and 16S rRNA (Wang et al. 2014). Among the listed targets the following two are the most frequently used: Amplification of the insertion sequence IS711, which is present with a variable number of copies in all *Brucella* species (Al-Nakkas et al. 2002). The *bcsp31* gene encodes the synthesis of an immunogenic membrane protein of 31 kDa that is specific to the *Brucella* genus (Al Dahouk et al. 2007a). Due to the high sequence homology, a misidentification of *Brucella* sp. as *Ochrobactrum* sp. or vice versa must be excluded when sequencing of the 16S rRNA gene alone was applied (Scholz et al. 2008d).

Species differentiation as well as determination of the biovar is more complicated. One of the first PCR assays to differentiate among *Brucella* species from pure cultures was the so-called Abortus-Melitensis-Ovis-Suis (AMOS) PCR (Bricker and Halling 1994). This PCR uses a single reverse primer, targeting the *Brucella*-specific insertion element IS711, and four different forward primers, each specific for a given species. Species are differentiated on the basis of different PCR fragment sizes. The disadvantage of this PCR was that not all species could be identified (i.e. *B. canis* and *B. neotomae*) and that some biovars within a given species gave negative results. In 2006, a new conventional multiplex PCR (Bruce-ladder), using eight primer pairs in a single reaction, was developed (Garcia-Yoldi et al. 2006). Later, this PCR was enhanced, to cover novel species such as *B. microti* and *B. inopinata* (Mayer-Scholl et al. 2010). However, some *B. canis* strains and *B. microti* can be misidentified as *B. suis* with this PCR due to a very similar banding pattern. To avoid this and for further differentiation down to biovar level of *B. suis* by PCR, a multiplex PCR assay (Suis-ladder) is recommended (Lopez-Goni et al. 2011).

13.5.4 Molecular Typing

MLST: The conventional multi-locus-sequence typing (MLST) approach uses sequence divergence in housekeeping genes. About seven to nine housekeeping genes are commonly analyzed in order to obtain a reasonable balance between the acceptable identification power, time, and cost for the strain typing. From each housekeeping gene, approximately 450 to 500 base pairs (bp) are amplified by PCR, followed by DNA sequencing and subsequent comparative sequence analysis. Each unique sequence is assigned a specific allele number and alleles are combined into an allelic profile and further assigned to a specific sequence type (ST). New alleles result in a new combination and therefore in a novel ST. Because accumulated changes occur slowly and are regarded as selectively neutral, the MLST approach is a reliable tool for the overall characterization of microbial populations and the investigation of phylogenetic relationships. However, the slow molecular clock rate and the limited number of genes do not allow in-depth phylogenetic reconstructions and analysis of local epidemiological studies. Thus, unlike MLVA, MLST is of little value for outbreak investigations. The classical MLST assay for *Brucella* consists of nine gene targets (Whatmore et al. 2007) and was later expanded to a set of 21 loci in order to achieve better resolution (Whatmore et al. 2016). The MLST database can be accessed via PubMLST (https://pubmlst.org/organisms/brucella-spp).

MLVA: Multiple-locus variable-number tandem-repeat analysis (MLVA) has become a major molecular typing method to characterize several pathogenic bacterial species at the strain level. The *Brucella* MLVA-16 scheme as initially described by Le Flèche et al. (2006) and Al Dahouk et al. (2007b) has been proven to be a valuable tool in epidemiological outbreak investigations with high discriminatory power in several studies (Aftab et al. 2011; Jiang et al. 2011; Gyuranecz et al. 2016; Garofolo et al. 2016). Therefore, MLVA can currently be considered to be the gold standard of high-resolution *Brucella* typing (Scholz and Vergnaud 2013) and is actually the most widely used approach for outbreak investigations (De Massis et al. 2015; Dorneles et al. 2014). Furthermore, for strain comparisons a huge publicly accessible database consisting of MLVA profiles from more than 7000 strains is available (http://mlva.i2bc.paris-saclay.fr/brucella/). On the other hand, MLVA requires sophisticated laboratory skills and high standardization in order to get reliable and reproducible results. In recent years, genome-based methods like SNP analysis and core-genome-based MLST (cgMLST) have started to supplant MLVA due to higher robustness and lower cost at equivalent or even higher genetic resolution.

SNP Typing: Single nucleotide polymorphism (SNP) analysis from whole genomes potentially has the highest discriminatory power among the typing methods, as polymorphisms can be discovered in both coding and noncoding regions of the genome. However, the choice of a reference genome and the specific algorithm applied for SNP identification can significantly influence the number of identified SNPs and the accuracy of the reconstructed phylogenetic relationships. Consequently, depending on a given SNP assay, the genetic resolution can vary significantly. Hundreds of *Brucella* isolates have already been sequenced and analyzed at draft level for whole genome SNP discovery that efficiently complement MLVA typing and clustering

analysis when necessary (Foster et al. 2009; O'Callaghan and Whatmore 2011; Georgi et al. 2017). In all cases, spatial clustering obtained by SNP-Typing was comparable to MLVA and in some cases SNP-Typing outperformed MLVA in terms of genetic resolution (Janowicz et al. 2018; Holzer et al. 2021).

cgMLST: Core-genome based multilocus sequence typing (cgMLST) has become a benchmark tool for bacterial outbreak investigations and was successfully applied to several pathogens. It represents a very robust high-resolution typing method and provides highest reproducibility. Like classical MLST, it uses differences in allelic sequence profiles for strain discrimination, in this case of genes belonging to the core genome. In contrast to classical MLST, hundreds to thousands gene targets of the core-genome are analyzed simultaneously resulting in a genetic resolution comparable to SNP and VNTR typing. Compared to the different SNP assays, cgMLST has the advantage of being readily and consistently applied in different laboratories as it uses a consistent set of well-defined conserved loci. For cgMLST of *B. melitensis*, a typing scheme consisting of 2704 gene targets was developed and validated (Janowicz et al. 2018). It can be downloaded from the Ridom cgMLST.org Nomenclature Server (https://www.cgmlst.org/ncs/schema/6398355/). This scheme is also applicable for high-resolution typing of other *Brucella* species, including atypical isolates. In a direct comparison to MLVA, higher phylogenetic distance resolution was achieved with cgMLST particularly for strains belonging to the same lineage. Another cgMLST assay for *Brucella* spp. using a smaller set of 164 loci of the core genome was published by Sankarasubramanian et al. (Sankarasubramanian et al. 2019). Generally, Illumina paired end sequencing with a coverage of 70x is recommended in order to achieve accurate typing results.

13.6 Disease Symptoms in Humans and Treatment

The usual route of transmission to humans is the ingestion of contaminated food, e.g., unpasteurized dairy products or undercooked meat from infected animals. The disease may also be acquired by handling infected animals or inhalation of infectious aerosols. Occupational exposure is described for hunters, farmers, slaughterhouse, and laboratory workers, as well as accidental exposure of veterinarians, preparing or administering the attenuated live vaccine strains (Pereira et al. 2021).

Regardless of the portal of entry of *Brucella* organisms, bacteria penetrate mucosal barriers and enter the bloodstream, which permits their dissemination throughout the body. The bacterium quickly translocates across the epithelial layer and is endocytosed by mucosal macrophages and dendritic cells (Franco et al. 2007). Internalized *Brucellae* initially localize in the regional lymph nodes and then spread through the bloodstream, entering macrophages-rich tissues such as the liver, spleen, lymph nodes, or bone marrow. There they adopt a facultative and stealthy intracellular lifestyle, evading the innate and adaptive immune responses and the action of many antibiotics (Pappas et al. 2005). Disease-specific symptoms occur within an incubation period of 10 to 21 days, in some cases up to several months. The clinical picture of human brucellosis is not specific, often accompanied with flu-like

symptoms such as undulant fever, sweating, asthenia, myalgia, arthralgia, and headache. The agent can be translocated and adapt to almost any tissue or in vivo site, and in case of improper antibiotic treatment, the disease has a high risk of chronification and/or relapses. To avoid the latter, successful brucellosis-treatment requires long-term antibiotic therapy (Franco et al. 2007; Dean et al. 2012). Due to the intracellular growth and replication of the bacteria and the slow-growing nature of *B. melitensis*, a combination therapy including at least one substance with good cellular penetration is required. Monotherapy is reported to have a high relapse rate. The regimen accompanied with lowest rate of treatment failures and, therefore, recommended by most authors comprise of doxycycline and rifampin and in complicated cases added with gentamycin during the first weeks. Alternative treatment regimens include trimethoprim/sulfamethoxazole and fluoroquinolones (mainly ciprofloxacin) (Ariza et al. 2007; Bossi et al. 2004; Solera 2010). In patients suffering from neurobrucellosis, addition of ceftriaxone is suggested (Erdem et al. 2012; Pappas et al. 2007). Up to now, resistance towards therapy-relevant substances is rare, and treatment failures are associated with noncompliance of patients during the long-term oral treatment or poor absorption of the antibiotics at the site of infection, although mutations are described, e.g., in the *rpoB* leading to resistance towards rifampicin (De rautlin de la Roy et al. 1986; Sayan et al. 2008). The *B. melitensis* Rev-1 vaccine strain is resistant to streptomycin, and *B. abortus* (strain RB51) is resistant to rifampicin. As *B. melitensis* is considered as category B agents of bioterrorism, also engineered antimicrobial resistance is a concern.

13.7 Prevention and Control

The prevention in animals in the EU according to the Veterinary control programs (SANCO/6095/2009) include slaughter or stamping out in infected herds, frequent and regular testing of herds, and the use of tests in association with a compensation scheme. The currently available vaccines, which are officially authorized at European level for the prophylaxis of brucellosis, are *B. abortus* S19 and *B. abortus* RB51 strains for cattle and *B. melitensis* strain Rev.1 for sheep and goats (OIE Terrestrial Manual Brucellosis 2018). They are prepared from adequately derived seed cultures and can potentially provoke two types of adverse effects in the vaccinated animals: the induction of abortion in pregnant females and in the case of the smooth strains (S19 and Rev.1), the persistence of residual antibodies to the classical serological tests (RBT and CFT). The latter may cause diagnostic difficulties in certain situations but can be avoided by the use of conjunctival route for vaccine administration and restrict the age of application to three to four months, maximum six months. No suitable vaccines exist for the control of *Brucella* infection in swine and of canine brucellosis. There are strategies employed for experimental vaccines against *B. canis* including the attenuated mutant vaccine strains such as a *B. canis* mutant in SST4 and a mutant version of *B. abortus* RB51 vaccine strain. Newer studies demonstrated that a *B. ovis* mutant protects against experimental challenge with *B. canis* in mice and is safe for dogs (Eckstein et al. 2020).

In general, vaccinations are recommended depending on the prevalence in the respective region and the circumstances. In Germany, however for reasons of animal disease control, vaccinations against brucellosis of cattle, pigs, sheep, and goats and curative experiments are prohibited. Animals with the disease and animals suspected of having the disease must be separated from the rest of the herd and killed.

Human brucellosis is acquired by direct contact with secretions and excretions from infected animals or by ingestion of contaminated food or dairy products like raw milk or undercooked meat. Pasteurization of milk helps to prevent brucellosis. Cheese made from unpasteurized milk may be contaminated if less than three months old. The World Health Organization recommends storing soft cheeses more than six months if they were made from unpasteurized milk. Meat, blood, and internal organs from animals should be handled carefully and cooked thoroughly. People who handle potentially infected animals or carcasses should wear adequate protective clothing including eyewear and rubber gloves and protect skin lesions from exposure. Wounds should be covered. The risk of infection is greatest when dealing with aborting animals. In several countries, control programs to detect infection in animals, eliminate infected animals, and vaccinate seronegative young cattle and swine are mandatory. There is no human vaccine and the use of the animal vaccine (a live vaccine) in humans is not recommended as it can cause infection. Immunity after infection in humans is short-lived, lasting approximately two years. Antibiotic prophylaxis postexposure is recommended for high-risk exposure (e.g., after unprotected contact with infected animals or *Brucella* cultures in the laboratory or who were exposed to the animal vaccine) and/or people with underlying diseases like *Diabetes mellitus*. Recommended for postexposure prophylaxis are doxycycline plus rifampin for three weeks; rifampin is not used for exposure to inoculation with *B. abortus* (strain RB51) that is resistant to rifampicin.

13.8 Discussion

The overall incidence of human brucellosis in Europe has been dramatically decreased during the previous 40 years. This success can be attributed to several combined public health measures including testing and slaughtering of cattle, livestock vaccination, border control, and surveillance programs that largely eradicated the causative agent from the animal reservoir and minimized the risk of transmission to humans. These efforts resulted in a significant decline of the disease. Consequently, a brucellosis-free status (brucellosis of cattle, sheep, sheep, and goat) was granted by the European Union to most countries of Northern and Western Europe. Eradication of brucellosis in both cattle and sheep and goats is achievable, as it has been demonstrated in most countries and regions within the European Union. However, sporadic introduction into brucellosis free countries cannot be fully avoided, as demonstrated by the recent local outbreak of bovine brucellosis caused by *B. melitensis* bv 3 that occurred in Austria in 2018 and in France 2012 (Mailles et al. 2012; Schaeffer et al. 2021). In some countries where national control strategies

are weakening, the number of cases in animals is moreover rising again like in Eastern Europe, Central Asia, and Eurasia (Beauvais et al. 2017; Kracalik et al. 2016) and the disease is re-emerging.

The *Brucella* ecology, or what we know of it, has evolved rapidly in recent years. WGS has contributed to identify new species and to identify misidentifications by conventional methods and to a better differentiation of atypical *Brucella* spp. from *Ochrobactrum* spp. or *Brucella*-like organisms. Several further atypical species have been isolated from different animal hosts with unknown zoonotic potential. Two novel species, *B. ceti* and *B. pinnipedialis*, with the potential for causing human disease have been isolated from marine mammals. Another novel species, *B. microti*, has been isolated from wildlife animals, while single *B. inopinata*-like species have been detected in human cases. The detection of *Brucella* spp. in a chameleon 2020 confirmed that all three cold-blooded vertebrate classes (fish, amphibians, and reptiles) are susceptible to *Brucella* infection. A first human case caused by an amphibian-type *Brucella* has also been described. An active spillover of *Brucella* between domestic animals and wildlife has been recognized, with elk transmitting *B. abortus* to cattle, wild boars transmitting *B. suis* bv 2 to domestic pigs, alpine ibex transmitting *B. melitensis* to cattle and vice versa freshwater fish becoming infected with *B. melitensis* from waste meat. Some species might be underdiagnosed like *B. canis* and atypical *Brucella* species with rough LPS type that can easily be overlooked by conventional tests.

Therefore, the correct identification in particular of atypical *Brucella* spp., the development of biochemical and serological assays for the detection of all rough LPS-type *Brucella* species, and the estimation of their zoonotic potential remain challenging.

Abstract

About 85 years ago, Q fever research began due to human outbreaks of unknown origin, associated with domestic animals. Since then, some but not all characteristics of this "query" disease, caused by the intracellular bacterium *Coxiella burnetii*, were revealed. In this chapter, the bacteriology of the bacterium, clinical presentation, epidemiology, and transmission of the disease in humans and animals are presented. Domestic small ruminants are the main source of human Q fever. Although Q fever is considered to be an occupational disease, outbreaks affect also people without livestock contact and as such have a major public health impact attracting most attention. The Dutch Q fever outbreak, involving 4000 reported human cases over the years 2007–2010 and at least 40,000 cases presumably unrecognized, is an example of how Q fever can reemerge from an endemic state into an outbreak of unforeseen dimension. In this outbreak, the epidemiological link between dairy goats and human cases was confirmed by genotyping for the first time. This was possible due to the previous development of genotyping assays that are applicable on clinical material. Although Q fever seems to be a blue print for outbreaks, it is not known yet what factors are essential to cause outbreaks and how they interact. To prevent outbreaks, a better understanding of these factors and their interaction is necessary and research should therefore focus on this. Only with a One Health approach involving human medicine, veterinary medicine, and environmental factors, coordinated research under this aspect and up-to-date knowledge and information processing, presentation, and dissemination will be able to reduce the significance of this zoonosis in the future.

14.1 Introduction → Characteristics of *Coxiella burnetii*

The first awareness of Q fever was raised by severe outbreaks among abattoir workers in Brisbane, Australia. These outbreaks had been occurring periodically since 1933, but remained undiagnosed until Edward Derrick was assigned to investigate the cause of these febrile illnesses (Derrick 1983). In order to reveal the cause of the disease, several experiments were done, but Derrick failed to detect bacteria. This led him to the (wrong) conclusion that the etiologic agent was a virus. Further studies on the virus of this query, "Q," fever were published by Macfarlane Burnet and Mavis Freeman, indicating the rickettsia-like properties of the virus (Burnet and Freeman 1983). At the same time, the causative agent of Q fever was also discovered

independently in Montana, USA, due to research on Rocky Mountain spotted fever (Cox 1938). Later on, a laboratory infection revealed the linkage of the two discoveries (Dyer 1938; McDade 1990). So, from the early identification of Q fever and the discovery of the etiologic agent it was obvious that the Q fever agent was zoonotic and able to cause severe outbreaks.

The rickettsia-like properties of the agent resulted in the initial designation of the Q fever agent as *Rickettsia diaporica* (diaporica is derived from the Greek word for having the property or ability to pass through [a filter]) by the American group and as *Rickettsia burnetii* (after Burnet) by the Australian group (McDade 1990). In 1948, Philip (Philip 1948) proposed a reclassification into *Coxiella burnetii*. In this name both Harold Cox and Frank Burnet are honored for their contribution to the identification of the Q fever agent. At a later time, *C. burnetii* has been phylogenetically reclassified from the order of Rickettsiales to Legionellales, based on the sequence of its 16S rRNA (Weisburg et al. 1989).

C. burnetii is an obligate intracellular gram-negative bacterium. The pleomorphic rods have a diameter of approximately 0.2–0.4 μm and are 0.4–1.0 μm in length (Drancourt and Raoult 2005). In the developmental cycle of *C. burnetii* two distinct variants have been identified: a large cell variant (LCV) and a small cell variant (SCV) (McCaul and Williams 1981). The LCV is the metabolically active and intracellular replicative entity of the bacterium. The LCV transforms into the SCV, which is the more resistant form of *C. burnetii*. In this form the bacterium is highly resistant to environmental stress, such as high temperatures, UV radiation, and osmotic pressure. The resistance allows *C. burnetii* to survive in the environment while keeping its infectivity (McCaul and Williams 1981). The SCV can infect host cells, closing the developmental cycle.

Lipopolysaccharide (LPS) is demonstrated in both *C. burnetii* LCV and SCV, although presence of LPS is mainly associated with the SCV (Coleman et al. 2007). Like several other gram-negative species, *C. burnetii* can display two different LPS phenotypes. The phase 1 phenotype expresses full length LPS which corresponds to the smooth LPS of other gram-negative bacteria (e.g., *Brucella* spp. and *Enterobacteriaceae*), while the phase 2 phenotype carries LPS that resembles the rough LPS. Phase 2 LPS lacks the O-antigenic region (Toman et al. 2009). Phase 1 bacteria are highly virulent and able to replicate in immunocompetent hosts. This is contrary to phase 2 bacteria, which are avirulent and unable to replicate in immunocompetent animals (Moos and Hackstadt 1987; Andoh et al. 2007). During serial passage in cell culture, phase 1 *C. burnetii* can convert into phase 2 (Hotta et al. 2002). Both LPS phenotypes are inducing phase-specific antibodies in infected hosts. Phase 1 antibodies are directed against the full length LPS of phase 1, whereas phase 2 antibodies are assumed to direct against common surface proteins (Marrie and Raoult 1997). The hypothesis is that these surface proteins are also present on the surface of phase 1 *C. burnetii*, but may be shielded by the long phase 1 LPS. This may prevent binding of phase 2 antibodies to surface proteins of intact phase 1 bacteria (Hackstadt 1988).

The first complete genome sequence of *C. burnetii* was published in 2003 (Seshadri et al. 2003). Analysis of the original strain isolated from ticks by Davies

and Cox in 1938 (called Nine Mile/RSA493) revealed a circular genome of 1,995,275 base pairs. Today roundabout 100 genomes form *C. burnetii* that are sequenced and available on NCBI (https://www.ncbi.nlm.nih.gov/genome/?term=coxiella+burnetii). The genetic heterogeneity of different *C. burnetii* strains can be assessed with a number of molecular techniques. Different genotyping techniques have been described, mainly based on the identification of differences between selected loci on the genome (Table 1, Massung et al. 2012; Frangoulidis et al. 2022). Accurate identification of the agent is important to differentiate between strains and to identify epidemiological relevant markers. These markers are at the basis of molecular epidemiology, which enables the identification of sources of Q fever outbreaks (Arricau-Bouvery et al. 2006).

In the recent years, a further potential benefit of genomic markers was studied to get an enhanced characterization of *C. burnetii*: the correlation between pheno- and

genotype. This issue was seen since the beginning of using molecular techniques in *Coxiella* research. Already in 1985 Samuel et al. identified the plasmid QpRS that should be associated with chronic disease. This was not confirmed in later studies (Stein and Raoult 1993; Thiele and Willems 1994). Later in 2005 a new genomic marker for acute Q fever was discussed (Zhang et al. 2005), the acute disease antigen A (ada A), but again an in-depth analysis could not confirm the hypothesis although characterization of the ada A region offers some new and interesting typing options for discrimination (Frangoulidis et al. 2013). A SNP at position 431 was predominant in isolates from acute Q fever pneumonia and also carried by most of the sheep strain, consistent with the observation that most of human Q fever cases are sheep related. In 2014, a MLVA (Multiple Locus Variable number tandem repeats Analysis)-based analysis of veterinarian *Coxiella* samples of Germany identified a special cluster, associated to cattle and a mixed cluster with most of the studied isolates from goats and sheep (Frangoulidis et al. 2014). This clustering from MLVA genotypes to animal species was confirmed by a French MLVA study in 2017 (Joulié et al. 2017) and recently in Poland, too (Jodełko et al. 2021).

Beside MLVA the MST (multispacers typing) typing method is also widely used, introduced in 2005 (Glazunova et al. 2005). Lacking the discriminatory power of MLVA in *Coxiella* typing, it shows also some species specific groupings, like the MST genotype 61, strongly associated with cattle.

A more established and much more better evaluated and important use of molecular typing systems in Q fever is the discriminatory power, i.e., the ability to distinguish between unrelated strains. This is determined by the number of different types defined by the test method and the relative frequencies of the types. A single numerical index of discrimination is suggested by Hunter and Gaston (Hunter and Gaston 1988). This Hunter-Gaston Diversity Index (HGDI) is based on the probability that two unrelated strains, sampled from a test population, will be placed into different typing groups. By comparing the HGDI of a typing system the discriminatory power of a method can be identified. It is important to note that the calculated HGDI depends on the panel of strains (i.e., relatedness of the strains), so for an unbiased comparison of typing methods preferably the same panel should be used. Despite its importance for the quality of typing systems the discriminatory power is not assessed for most of the typing systems available for *C. burnetii*. For the ones that were assessed, a HGDI of 0.86 was calculated for RFLP typing (Jager et al. 1998). For the MLVA typing panels 1 and 2 a HGDI of 0.92 is calculated, respectively; for the combination of both a HGDI of 0.99 is calculated (Arricau-Bouvery et al. 2006; Roest et al. 2011b; Frangoulidis et al. 2014). It is suggested that a HGDI of >0.90 is desirable to interpret typing results with confidence (Hunter and Gaston 1988), indicating the MLVA typing system as a useful typing tool for *C. burnetii*. However, still the heterogeneity of the studied population influences the quality. In comparison with the published MST and SNP methods MLVA is probably a more discriminatory typing method for *C. burnetii* (Svraka et al. 2006; Chmielewski et al. 2009; Massung et al. 2012; Frangoulidis et al. 2022).

Recently a study analyzed MLVA, MST, and SNP-associated genomic grouping in *C. burnetii* and postulated a rapid screening marker in one MST-Gen loci (Cox51)

(Hemsley et al. 2021). Future studies will show the benefit of this issue for *Coxiella* typing in humans and animals.

Due to virulence of *C. burnetii* genes, no clear associations could be drawn. So, to date, it is not possible to classify the virulence of strains solely based on the available genotyping methods.

Summing up, genomic typing of *C. burnetii* is an important technique in Q fever outbreak management, especially in back-tracing infections in humans and animals, to identify the source of this zoonotic disease in outbreaks.

Nevertheless, although several efforts have been done, till today an accepted standard laboratory method for *C. burnetii* typing is not established. Despite this, genomic typing data was collected in databases like https://ifr48.timone.univ-mrs.fr/mst/coxiella_burnetii/ for MST and http://mlva.i2bc.paris-saclay.fr/MLVAnet/spip.php?rubrique50 for MLVA and recently in a new database CoxBase (https://coxbase.q-gaps.de/) putting all existing genomic typing data of *C. burnetii* of five different methods and whole genome sequencing information of strains in one place, sharing information and providing analytical tools for comparison (Fasemore et al. 2021). This might support in the future the identification of virulence-associated gene regions of this zoonotic pathogen.

14.2 Disease Symptoms in Animals and Humans

14.2.1 Clinical Presentation in Animals

The most important clinical presentations of Q fever in animals that are relevant for the zoonotic properties of Q fever are abortion and stillbirth. Field observations clearly demonstrate *C. burnetii* as a cause of abortion and stillbirth in goats, sheep, cattle, and cats (van Moll et al. 1993; Guatteo et al. 2011; Berri et al. 2001, 2002; Hatchette et al. 2003; Rousset et al. 2009; Lang 1990; Marrie et al. 1988b). Abortion occurs most frequently at the end of gestation, without preceding clinical symptoms (Arricau-Bouvery and Rodolakis 2005). In nonpregnant animals, *C. burnetii* infection is virtually asymptomatic.

In pregnant goats, abortion, still birth, and also the birth of strong and lively kids can occur after Q fever infection of pregnant animals (Arricau-Bouvery et al. 2005; Roest et al. 2012). When lively kids are born the duration of gestation can be up to 14 days shorter than the normal average gestation duration of 154 days. In dairy goat herds where Q fever abortions occurred, metritis can be observed. Weak kids were reported with low body weight and high mortality. Rearing of apparently healthy kids can be complicated by respiratory and digestive tract disorders (Wouda and Dercksen 2007). Experimental infections with *C. burnetii* in pregnant sheep did not result in any abortions (Martinov et al. 1989; Welsh et al. 1958), while in cattle one experimental infection of a pregnant cow resulted in abortion (Lang 1990). The cause of these differences in pregnancy outcome after infection is unknown. In cattle, *C. burnetii* infection is associated with metritis and reproduction problems (Lang 1990; To et al. 1998).

14.2.2 Clinical Presentation in Humans

In humans infection with *C. burnetii* can manifest in three main clinical presentations: acute Q fever, chronic Q fever, and the Q fever fatigue syndrome (QFS). Following exposure to *C. burnetii* almost 60% of the Q fever cases are asymptomatic. Among the 40% symptomatic acute Q fever patients, the majority will present a nonspecific, self-limiting illness. More severe clinical symptoms include fever, headache, chills, atypical pneumonia, and hepatitis (Derrick 1983; Maurin and Raoult 1999; Raoult et al. 2005). In the Netherlands, the large acute Q fever outbreak between 2007 and 2011 showed a mortality rate of 1.2% within approximately 1 month after hospitalization of patients. All lethal cases suffered severe underlying medical conditions (Kampschreur et al. 2010). Acute Q fever is diagnosed in the laboratory following (i) a positive *C. burnetii* specific PCR; (ii) the presence of IgM phase 2 antibodies in serum accompanied by clinical symptoms; or (iii) a fourfold increase of the IgG phase 2 antibody titer. These laboratory findings are also the notification criteria in the Netherlands (Wegdam-Blans et al. 2010). Acute Q fever can be treated with doxycycline 200 mg per day for 2 weeks. Alternative options are quinolones or trimethoprim-sulphametoxazole.

Chronic Q fever can develop after either a symptomatic or an asymptomatic primary infection in 1–5% of the patients. Chronic Q fever can become manifest years after initial infection. The most common presentations are endocarditis and vascular (prothesis) infection. Clinical symptoms include nonspecific fatigue, fever, weight loss, night sweats, and hepato-splenomegaly (Wegdam-Blans et al. 2012; Raoult et al. 2005). Risk factors for developing chronic Q fever include heart valve surgery, abdominal or iliac aneurysm, vascular prosthesis, and older age (Kampschreur et al. 2012). Diagnosis of chronic Q fever is difficult because of the nonspecific symptoms, but also because C-reactive protein can be normal and echocardiography often does not show typical signs of endocarditis. Proven chronic Q fever is defined as phase 1 IgG $\geq$1024 with a definite endocarditis according to the revised Duke criteria or a proven mycotic aneurysm or infected vascular graft and/or positive PCR for *C. burnetii* on blood or infected tissue (Kampschreur et al. 2012). Probable chronic Q fever is defined as phase 1 IgG $\geq$1024 with a risk factor for developing chronic Q fever, symptoms of a chronic infection, or an atypical focus of infection. In possible chronic Q fever only phase 1 IgG $\geq$1024 is present. ^{18}F-FDG-PET/CT has proven its value in diagnosing prosthetic valve endocarditis and vascular infection in Q fever and is recommended at diagnosis or when complications are suspected during treatment (Kouijzer et al. 2018). After the outbreak in the Netherlands, vascular chronic Q fever was more common than endocarditis (Buijs et al. 2021), but in France endocarditis has always been more common. A combination of both is also possible. Complications such as heart failure, aortoenteric fistulas with gastrointestinal bleeding and/or gram-negative sepsis, abcesses, and/or vertebral osteomyelitis occur in 64% of patients with proven chronic Q fever, while Q fever–related mortality is still 27% despite adequate treatment (Buijs et al. 2021). First-choice treatment is doxycycline with hydroxychloroquine, but doxycycline with a quinolone is a reasonable alternative in case of intolerance (Van Roeden

et al. 2018). Treatment duration is at least 18 months in case of native valve endocarditis and at least 24 months when prosthetic material is present and often longer. Treatment can be stopped after this minimum treatment duration when serum PCR has repeatedly been negative and imaging shows no signs of active infection anymore.

Q fever fatigue syndrome (QFS) is another long-term presentation of symptomatic acute Q fever. Contrary to chronic Q fever, *C. burnetii* cannot be detected in QFS patients. Furthermore, antibody levels against the bacteria are low or negligible. Symptoms of QFS include prolonged fatigue, arthralgia, myalgia, headache, concentration problems, and increase in symptoms after physical activity (Keijmel et al. 2015). The cause of the development of chronic Q fever or QFS in certain individuals is still unknown. Even years after the acute infection, quality of life and social functioning of patients with QFS was significantly lower and anxiety significantly higher compared to patients with diabetes and the general population (Reukers et al. 2019). A randomized controlled trial comparing long-term treatment with doxycycline, placebo, or cognitive behavioral therapy (CBT) showed that CBT is effective in reducing fatigue severity in QFS patients. Long-term treatment with doxycycline does not reduce fatigue severity in QFS patients compared to placebo (Keijmel et al. 2017). Unfortunately, the beneficial effect of CBT on fatigue severity was not maintained 1 year thereafter (Raijmakers et al. 2019).

As in animals, it is suggested that also in pregnant women, *C. burnetii* infection may lead to adverse pregnancy outcome, especially when the acute Q fever remains untreated (Langley et al. 2003; Carcopino et al. 2007). Pregnancy outcomes include spontaneous abortion, intrauterine fetal death and premature delivery, or low birth weight. In pregnant women, the risk to develop chronic Q fever is assumed to be high (Maurin and Raoult 1999; Carcopino et al. 2009). Besides clinical Q fever also asymptomatic infections may lead to the same risk for adverse pregnancy outcomes (Parker et al. 2006). As above was known during the Dutch Q fever outbreak, surveys were set up to investigate the relation between *Coxiella* infection and pregnancy outcome. In a population-based study, including 1,174 women, no relation could be detected between presence of antibodies against *C. burnetii* during early pregnancy and adverse pregnancy outcome (van der Hoek et al. 2011b). An additional study was not supportive to imply a preventive program for seropositive pregnant women as such a program, including serological screening and treatment in case of acute or chronic Q fever, seemed not to be associated with a relevant reduction in obstetric complications in seropositive women.

14.3 Epidemiology and Burden of Disease in Animals

14.3.1 Host Range

C. burnetii can infect a wide range of animal species. The original isolation in the USA was from the tick *Dermacentor andersoni* (Davis and Cox 1938). Since then *C. burnetii* has been detected in over 40 tick species. Several bird species can also

become infected with *C. burnetii*, as experimentally shown (Schmatz et al. 1977a, b; Sethi et al. 1978; Babudieri and Moscovici 1952). Natural infections have been reported in domestic birds and in wild birds (To et al. 1998; Astobiza et al. 2011). In terrestrial as well as in marine wildlife the presence of *C. burnetii* has been confirmed in roe deer, wild boars, rodents, European hare, pacific harbor seal, a Steller sea lion, Northern fur seals, and harbor porpoises (Thompson et al. 2012; Astobiza et al. 2011; Lapointe et al. 1999; Kersh et al. 2010, 2012; Duncan et al. 2012). These data indicate a sylvatic cycle for *C. burnetii*, in which ticks probably play a role as vector.

In domestic animals, *C. burnetii* has been detected in cats, dogs, and horses as well as in domestic ruminants. In cats seroprevalences between 19% and 42% are reported. In dogs seroprevalences up to 22% are detected (Higgins and Marrie 1990; Komiya et al. 2003a; Marrie et al. 1988a; Boni et al. 1998). In domestic ruminants *C. burnetii* infections are widespread. Seroprevalence levels are estimated up to 82% in cattle. In sheep and goats average seroprevalences are slightly lower compared to cattle, with values of up to 73% (Guatteo et al. 2011). Prevalence of *C. burnetii* on cattle herd level as measured from bulk tank milk samples ranges between 32% and 94% (Angen et al. 2011; Kim et al. 2005; Astobiza et al. 2012). These data indicate that animals that live in close contact to humans can become infected with *C. burnetii*.

14.3.2 Excretion Routes

Knowledge of the excretion of *C. burnetii* from infected animals is crucial in understanding the transmission routes and risks for human infection. Abortions in *C. burnetii* infected domestic ruminants are accompanied by massive excretion of the bacteria and spread into the environment. This is the most important excretion route of *C. burnetii*, as up to 10^9 organisms per gram placenta tissue are excreted (Arricau Bouvery et al. 2003). However, experiments in goats indicate that comparable numbers of *Coxiella* are also excreted during the birth of lively kids (Roest et al. 2012). Also sheep can excrete numerous Q fever bacteria during normal parturition. This implies that *C. burnetii* can be excreted without clinical signs of Q fever in the herd. This should be taken into account when tracing sources of human Q fever.

C. burnetii has also been detected in feces, vaginal mucus, and milk of infected domestic ruminants (Berri et al. 2001; Arricau Bouvery et al. 2003; Rousset et al. 2009; Guatteo et al. 2006). In goat herds, both in aborting and nonaborting goats, *C. burnetii* DNA has been detected in feces, vaginal mucus, and/or milk (Rousset et al. 2009). In cattle, also variable excretion via feces, vaginal mucus, and milk has been reported, sometimes independent of an abortion history. However, it is suggested that the presence of *C. burnetii* DNA in feces and vaginal mucus is due to contamination of *C. burnetii* DNA from the environment (Welsh et al. 1958; Roest et al. 2012). Thus, while excretion of high numbers of *C. burnetii* with birth products during parturition is evident, the importance of and the correlation between the excretion routes of *C. burnetii* via feces, vaginal mucus, and milk is much less well established.

How a *C. burnetii* infection persists in a ruminant herd is not clear up to now. During parturition of infected animals high numbers of *C. burnetii* are excreted and can persist in the animal's living environment for years (Rustscheff et al. 2000; McCaul and Williams 1981). Pregnant ruminants can be (re)infected by these persisting bacteria. It can also be considered that once animals are infected, they can be persistently infected with *C. burnetii*. The bacterium can persist in the genital tract (Alsaleh et al. 2011) or mammary tissue (van der Brom et al. 2013) and be excreted into the living environment or internally reinfect placental tissue once available after mating. A recent study suggests that nonpregnant ruminants might also play a role in the persistence of *C. burnetii* in a herd (Roest et al. 2020). In an experimental setting, nonpregnant goats were infected with *C. burnetii* before mating. Although the bacterium could not be detected in placentas and kids, one of the ten infected animals excreted *C. burnetii* in the milk and the bacterium was detected in the mammary gland and associated lymph nodes. So, the persistence of *C. burnetii* in pregnant and nonpregnant animals might play a role in the persistence of the infection in a herd.

14.3.3 Burden of Disease in Animals

It is difficult to assess the burden of disease in farm animals. As an alternative, economic losses can be calculated in farm animal holdings. In the Dutch Q fever outbreak the economic losses have been calculated for goat farms (van Asseldonk et al. 2013). In this paper, it is assumed that about 5% of the animals on Q fever positive farm show clinical signs resulting in production and reproduction losses and that on average 40% of the pregnant goats on the farms resulted in abortion. However, goats abort in late pregnancy and aborting animals recover rapidly, so milk production is hardly affected. Furthermore, the economic value of lambs is low. All this results in a relatively limited loss, mainly due to (re)production losses. Costs on farm level increase when mandatory intervention is implemented. In the Dutch Q fever outbreak the intervention costs are estimated at upon 85 Million Euro (van Asseldonk et al. 2013). These costs consisted of costs for organization (57.96%), culling (21.61%), breeding prohibition (14.19%), and vaccination (6.20%). These costs of intervention were much lower than the total losses in the human domain, which were estimated at 222 Million Euro (van Asseldonk et al. 2013).

14.4 Epidemiology and Burden of Disease in Humans

Humans usually acquire Q fever by inhalation of *C. burnetii*. Alveolar macrophages and other mononuclear phagocytes are thought to be the primary target cells of the pathogen (Shannon and Heinzen 2009). In these cells, *C. burnetii* survives intracellular killing and is able to replicate. A bacteremia will lead to systemic infection with involvement of the liver, spleen, lungs, and bone marrow (Maurin and Raoult 1999). It is assumed that higher doses of *C. burnetii* result in an increasing likelihood of infection and shorter incubation periods (Marrie 1990; Van der Hoek 2012). Human Q fever after oral

ingestion has been suggested, but experimental infection of volunteers via contaminated milk did not result in disease although antibody responses were observed (Benson et al. 1963; Fishbein and Raoult 1992). Rare cases of person-to-person transmission, e.g., sexual transmission and blood transfusion, have been reported, but these routes do not seem to play an important role in the epidemiology of Q fever (Marrie 1990; Milazzo et al. 2001). Thus, in humans Q fever is essentially an airborne infection resulting from the inhalation of contaminated aerosols.

14.4.1 Burden of Disease in Humans

Only a few studies have been published on the burden of Q fever in humans. In general, following exposure, almost 60% will remain asymptomatic. About 40% will become symptomatic, although the majority will only present mild symptoms of a self-limiting disease. This is reflected in the number of infected persons compared to the number of registered Q fever cases in several outbreaks. In the outbreak that occurred in the Val de Bagnes, Switzerland, in 1983, it is suggested that for each patient diagnosed 50 persons remain undiagnosed (Dupuis et al. 1987). In the Dutch Q fever outbreaks during the years 2007–2010 it is assumed that for each Q fever patient, 10 additional people were infected (Kampschreur et al. 2013). The hospitalization rate varies and may depend on the clinical experience of the physicians with Q fever. At the start of the Dutch Q fever outbreak hospitalization rates were up to 50%, whereas in the next year the hospitalization rate went down to 21% (Schimmer et al. 2008; van der Hoek et al. 2010).

Long-term effects of infection with *C. burnetii* have been studied as follow-up of the Dutch Q fever outbreak. Twelve to sixteen months after the onset of illness severe subjective symptoms, functional impairment, and impaired quality of life have been measured (Morroy et al. 2011).

The human disease burden can be quantified via disability-adjusted life years (DALY). For the Dutch Q fever outbreak between 2007 and 2011 the total disease burden is calculated as 2462 DALY, comprising of 22 DALY for acute Q fever, 1481 DALY for QFS, 806 DALY of chronic Q fever, and 153 DALY for the 24 people who died (partly) because of Q fever (van Asseldonk et al. 2013). All this indicates that the impact of Q fever can be significant when outbreaks occur.

14.5 Transmission

In humans, Q fever is essentially an airborne infection resulting from the inhalation of contaminated aerosols (Benenson and Tigertt 1956; Tigertt et al. 1961). Aerosols can become contaminated with *C. burnetii* during abortion and parturition of infected pregnant ruminants (Welsh et al. 1958; Benson et al. 1963). Environmental contamination resulting in contaminated aerosols may also follow excretion of *C. burnetii* via feces, vaginal mucus, or possibly milk of animals. This contributes to the occupational hazard of Q fever. However, contaminated aerosols are able to

travel large distances even up to 18 km and infect humans. Highest risk of infections in urban outbreaks occurs in areas 2–4 km from source farms, while in rural areas this risk was identified within 5 km of infected farms (Clark and Soares Magalhães 2018). Wind (speed and direction) and warm and dry weather conditions can facilitate this transport (Van Steenbergen et al. 2007; Tissot-Dupont et al. 2004; Schimmer et al. 2010; Clark and Soares Magalhães 2018). Also other factors, such as vegetation and soil moisture, seem to be relevant in the dispersion of the bacteria (van der Hoek et al. 2011a; Clark and Soares Magalhães 2018). So, direct contact with animals is not a prerequisite for acquiring Q fever, as outbreaks demonstrate (Salmon et al. 1982; Tissot-Dupont et al. 1999, 2004; Gilsdorf et al. 2008; Roest et al. 2011b). Local residents, having indirect *Coxiella* infected livestock contact, are exposed to risks of acquiring Q fever and as such Q fever has a major public health impact attracting most attention. It is assumed that most animals also become infected via inhalation (Berri et al. 2005), although oral uptake in a heavily infected environment cannot be excluded as this oral infection route is experimentally confirmed (Roest et al. 2012).

Domestic ruminants appear to be the main source of infection for human Q fever. As indicated earlier, parturition in infected pregnant goats, sheep, and cattle results in the massive excretion of *C. burnetii* into the environment. Q fever in cattle seems to result in fewer abortions, probably resulting in a lower risk. Companion animals should also be considered as a source for human Q fever, since several human outbreaks were related to parturient cats and dogs (Marrie et al. 1988b; Pinsky et al. 1991; Komiya et al. 2003b; Buhariwalla et al. 1996). The role of horses and wildlife as a source of Q fever for humans is not clear. In overview, the epidemiology of Q fever can be summarized in a transmission model as presented in Fig. 1 (Roest et al. 2009, 2013a).

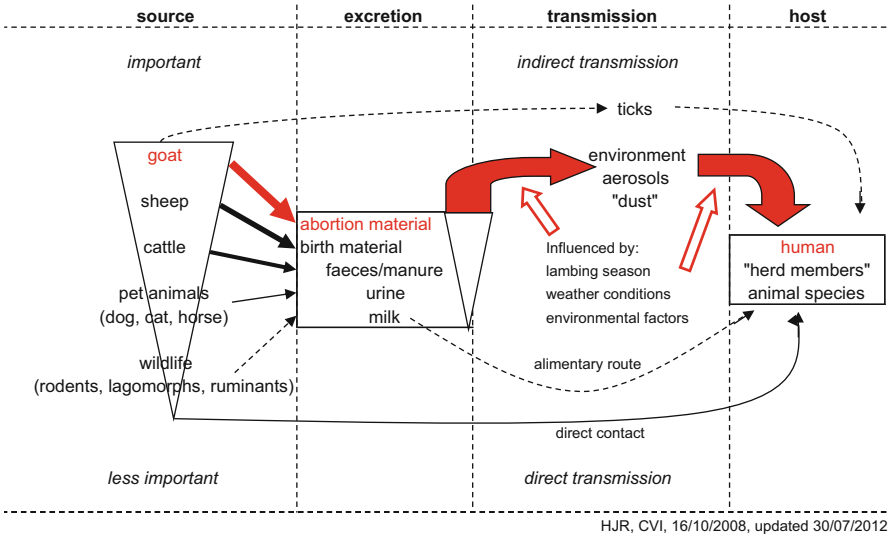

Fig. 1 Transmission model for Q fever

Overview of the possible transmission routes of *C. burnetii* from the animal reservoir to the human (and animal) hosts. The boldness of the arrows indicates the importance of the route, dotted lines indicate possible contributions. The most probable transmission route of *C. burnetii* in the Dutch Q fever outbreak is indicated in red (Roest et al. 2009, 2013a).

14.5.1 Q Fever Outbreaks

Q fever has a major public health impact when outbreaks occur. Outbreaks are reported frequently and worldwide, involving up to 415 laboratory-confirmed human cases per outbreak. Even higher numbers of human cases are reported, but the attribution to Q fever is unclear as cases are not always laboratory confirmed (Van der Hoek 2012; Arricau-Bouvery and Rodolakis 2005; EFSA 2010). Outbreaks are usually geographically localized and restricted to one episode. Sheep are identified as the source in the majority of the outbreaks, with goats as "second best." Only a few outbreaks of Q fever have been related to infected cattle and cats (Van der Hoek 2012; Arricau-Bouvery and Rodolakis 2005; EFSA 2010). Source identification, however, is mainly based on epidemiological examinations. In most outbreaks, confirmation of the identity of the *Coxiella* strain involved in both host and source, for example, by genotyping, is lacking. This is a major drawback in the identification of sources, as sources of Q fever are multiple and *C. burnetii* can be transmitted over larger distances. Thus, identification of the source and confirmation of the relation with human disease is preferably done by genotyping of the involved *C. burnetii* strains.

It should also be remembered that good cooperation and mutual information and communication between the human and veterinary surveillance authorities is essential, otherwise the complete detection and elucidation of a Q fever outbreak is almost impossible!

14.5.2 The Dutch Q Fever Outbreak

Since the 1950s Q fever has been present in the Netherlands. However, only a few human cases were reported until the 1970s. In 1975 Q fever became notifiable for humans (van Vliet 2009) and since that time about 20 cases on average were reported each year. The first human outbreak of Q fever in the Netherlands was reported in 2007: 168 cases were registered in the south of the Netherlands. In 2008 and 2009 the annual number of human cases increased to 1000 and 2355, respectively. Over the years 2007–2010, 4000 human cases were reported making the Dutch Q fever outbreak the largest laboratory-confirmed Q fever outbreak ever seen (Roest et al. 2011b).

Until 2005 Q fever was also known to be present in the animal population by serological investigations, although no clinical symptoms were described. This changed in 2005. Slightly ahead of the human outbreak, Q fever problems started in the dairy goat and dairy sheep population with abortion rates up to 80% per herd (Wouda and Dercksen 2007). Between 2005 and 2009 significant abortions were

registered on 28 dairy goat farms and 2 dairy sheep farms. With goat numbers of 600 up to 7000 per herd huge amounts of *Coxiella burnetii* were spread in the environment during abortion and early birth. These bacteria were transported to the neighboring human population by the prevailing northeast winds in pretty dry spring periods. All this took place in the southeast part of the Netherlands which is highly populated and has a dense dairy goat industry (Roest et al. 2011b). Eventually, the connection between dairy goats and humans was primarily based on epidemiological findings. This connection was confirmed by preliminary genotyping data showing one predominant MLVA type in aborted goats which was also found in infected humans (Roest et al. 2011a; Klaassen et al. 2009). Additional analyses showed also one predominant genotype in humans which was the same as in goats (Tilburg et al. 2012).

As goats were the suspects of the human Q fever outbreaks, increasingly strong measures were imposed to prevent the spreading of *C. burnetii* in the lambing season. The first measures were implemented in 2008, consisting of the notification of abortions in small ruminant holdings, hygiene measure, especially on manure handling and a voluntary vaccination. In 2009 the measures were extended with more tight notification criteria, including positivity of the bulk tank milk for *C. burnetii* DNA, a transport and breeding ban, and a mandatory vaccination. All these measures however did not prevent the increase of human cases in 2009. To ultimately prevent the increase of human cases in 2010 the drastic decision was taken to eliminate all potential high-risk animals. This resulted in the culling of all pregnant goats on Q fever–positive farms. All these measures finally resulted in a decline in human cases in 2010 (Roest et al. 2011b). A number wise summary of the Dutch Q fever outbreak is given in Table 2, based on (van Asseldonk et al. 2013; Roest et al. 2011b; Roest 2013).

The question can be raised at to what the causes of the Dutch Q fever outbreak were. It is clear that dairy goats and sheep were the cause of the human outbreak. Several factors are hypothesized to play a role in the increase in Q fever problems in goats. Firstly, the strong increase in the number of dairy goat herds and goat numbers before 2007. In addition, the partly closed status of some herds to prevent infectious diseases could have made a herd more susceptible for *C. burnetii* or new strains of this bacterium. Finally, the new introduction of a more virulent strain or a genetic shift to a more virulent strain could have contributed to the cause of the outbreak (Roest et al. 2011b).

Although extensive analyses in recent years have shown genomic differences in the Dutch outbreak strains compared to isolates from other countries, these have not provided clear explanations for the unique outbreak in the Netherlands (Kuley et al. 2017).

14.6 Unresolved Issues and Conclusions

An important remaining question is “what are the triggers of an outbreak.” Several factors are known such as *C. burnetii*-infected pregnant small ruminants, abortions in goat herds, probably population density, proximity of small ruminant herds to susceptible humans, and also the virulence of the strain (Georgiev et al. 2013).

Table 2 Overview of the Dutch Q fever outbreak year by year (van Asseldonk et al. 2013; Roest et al. 2011b; Roest 2013, https://www.rivm.nl/q-koorts, vaccination data from 2012 on: personal communication from the Netherlands Food and Consumer Product Safety Authority [NVWA])

However, which combination of factors triggers an outbreak is unknown. Knowledge on the interaction of these factors and the relative importance of these factors would be very beneficial to come to a (epidemiological) model that can predict the risk for Q fever outbreaks.

However, in addition to the aspects of prevention, monitoring of reservoirs, and prediction of outbreaks, a lot of research is still needed on the immunological processes that trigger this infection in humans and animals. Only in this way will it be possible in the future to identify risk factors for chronification and to improve the therapy of chronic courses such as endocarditis and QFS.

The zoonosis Q fever is a perfect example of the need for a joint approach between human and veterinary medicine, taking into account environmental factors, to contain, control, and prevent the disease. This so-called One Health approach of the WHO has been increasingly in the focus of nations worldwide for years and repeatedly shows its importance in Q fever (e.g., Bond et al. 2016). Despite all efforts, *C. burnetii* has retained many secrets that still require clarification. The challenge here is to bring together the respective institutions from biology, human, and veterinary medicine for joint research. An example of such cooperation is the so-called Q-GAPS (Q fever GermAn Interdisciplinary Program for reSearch) network in Germany, which researched and worked on open questions on the topic of Q fever from 2017–2022 (https://q-gaps.de/en/). An important result of this collaboration will be a guideline with instructions for action, which is intended to serve in the sense of the One Health approach to Q fever control (the guideline will be released and published on the cited homepage in 2023). The global challenge of the future is not only to conduct further research on the characteristics of the pathogen and the consequences of the disease, but also to process new findings and information and make them available in such a way that they can be used by all stakeholders and, if necessary, serve as a basis for new methods and procedures in diagnosis, therapy, and prophylaxis of Q fever – "One-Health at its best"!

Abstract

Taenia solium cysticercosis affects both humans and pigs. It has been considered an eradicable disease, and yet its prevalence remains stable in most endemic countries, due to the persistence of risk factors usually associated with the marginalization of an important sector of the population. In this chapter we will review key aspects of its epidemiology, clinical features, diagnosis, treatment, and prevention.

Keywords

Taenia solium · Cysticercosis · Neglected disease

15.1 Introduction

The taeniosis-cysticercosis complex is, in essence, a disease of the poor. Therefore, it is still found in low-income countries where hygiene is lacking, and where people live in close contact with pigs. The adult tapeworm *Taenia solium* lives in the human intestine, its only known definitive host, where it produces thousands of eggs. After ingestion of eggs by humans or pigs, they turn into oncospheres, penetrate the intestinal wall, and become metacestodes (cysticerci) which then can lodge in different tissues including the central nervous system (Sciutto et al. 2000; Larralde and Aluja 2006). Infection of pigs, natural coprophages, occurs if they have access to latrines or if they roam freely in villages and fields to find their food. Humans can also ingest eggs during consumption of contaminated food, through close contact with a carrier or through self-infection if they are themselves carriers of *T. solium*. The cycle is complete when humans ingest undercooked pork containing the parasite larva which develops into a tapeworm in their intestine. In this chapter, we will review several aspects of this potentially very serious zoonosis, including its epidemiology, clinical manifestations, diagnosis, treatment and available preventive measures.

15.1.1 Epidemiology in Humans

15.1.1.1 Epidemiology on a Domestic Level

As the parasite life cycle may suggest, infection with the adult parasite will mainly occur in rural areas where pigs are slaughtered by their owners mostly for local consumption, without previous sanitary inspection. Indeed, in a study conducted in Honduras, where 328 urban and rural inhabitants were examined for intestinal parasites, only one, coming from a rural area, was identified as a *T. solium* carrier (Sánchez et al. 1998). In another study, including 606 rural and urban individuals in northern Vietnam, the only detected *T. solium* carrier was also a rural inhabitant (Somers et al. 2006). The fact that infected pigs are mainly consumed in rural areas has been shown in different studies. Particularly, in a work conducted in rural villages and urban markets of Congo, pigs diagnosed as infected by tongue inspection were found in rural villages only (Praet et al. 2010). Also, it was reported that rural pigs in Mexico are mostly consumed within the locality where they were reared (Morales et al. 2006).

Data on taeniosis epidemiology is scarce, and different factors could explain this fact. One of them is that the infection is frequently asymptomatic. Symptoms and signs such as pain, weight loss, and fatigue have been described, but they are nonspecific, and patients frequently will not attend medical services. Also, laboratory diagnosis is not easy, requiring proglottid or egg identification in stool. The Kato method (Thienpont et al. 1986) is the most used in endemic countries but is not able to distinguish between *Taenia* species. Coproantigen ELISA and copro-PCR exist (Allan et al. 1992, Ng-Nguyen et al. 2017), but the standardization of their exact performances needs additional studies (Praet et al., 2013).

The epidemiology of the infection by *T. solium* larvae (cysticercosis) has different characteristics. The continuous and increasing exchanges between rural and urban areas concerning foods and people explain why cysticercosis infection is not confined to rural areas but can indeed affect all levels of society. A well-known example of this situation was the infection of a New York Jewish family due to the contact with their domestic employee who carried the adult helminth (Schantz et al. 1992). Also, infected urban inhabitants represent a substantial part of patients in several case series (Fleury et al. 2004, Marcin Sierra et al. 2017, Agapejev 2011).

15.1.1.2 Epidemiology on the International Level

As the parasite life cycle shows, endemic regions are those where pigs can be in contact with human feces and where sanitary control is not enforced in all areas.

This explains why almost all non-Muslim underdeveloped countries of Asia, Africa, and Latin America are endemic. The disease distribution map is explicit on this point (Fig. 1; Wertheim et al. 2012).

Interestingly, key differences in the clinical presentation of cysticercosis between continents have been reported. Extra-neurological presentation seems to be very rare in Latin America (e.g., Mexico) compared with Asia and Africa. Likewise, in cases

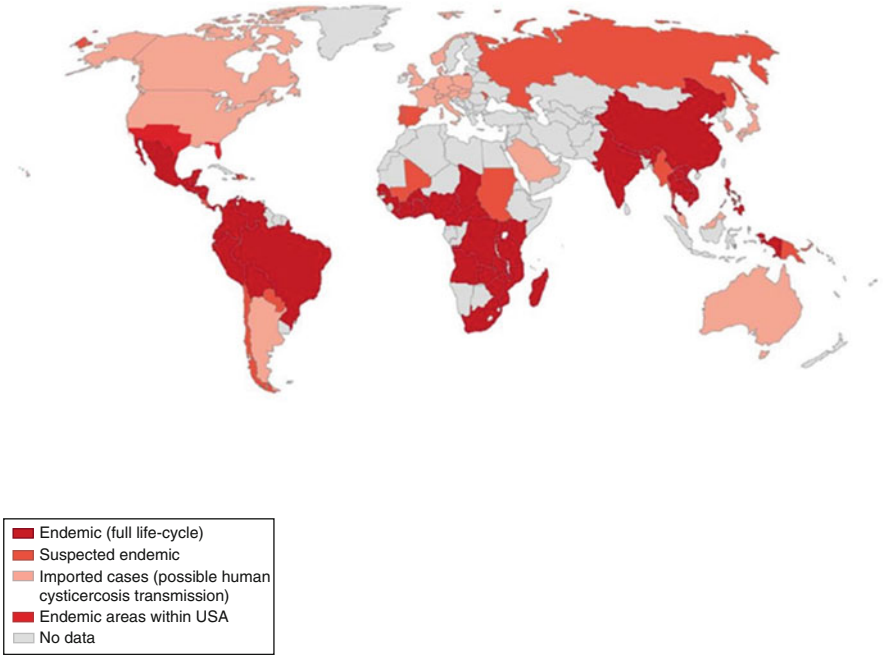

Fig. 1 Global spatial distribution of cysticercosis (updated: January 2010). (From: Wertheim et al. 2012)

of central nervous system (CNS) infection, parasite location in the subarachnoid space and ventricular system seems to be more frequent in Latin America than in India and Africa, where parenchymal location is more frequent (Singh 1997). The reasons for these differences are probably multiple, involving both biological and environmental factors (Fleury et al. 2010). Particularly, although not yet demonstrated, genetic factors, both of the human host and the parasite, might contribute to them. Also, it was recently shown that the intensity of infectious pressure can influence the differences between parenchymal/extra-parenchymal frequencies (Hamamoto Filho et al. 2020). Indeed, time between infection and diagnosis differ between these two groups of patients. The latency seems to be around 5 years in case of parenchymal localization, while it can be around 15–20 years in cases of extra-parenchymal location. So, in case of decrease of infectious pressure and decrease of new cases, we will first observe a reduction of parenchymal NC cases followed by a reduction of extraparenchymal ones (Hamamoto Filho et al. 2020). In this context, the higher ratio of "extraparenchymal NCC cases/parenchymal NCC cases" in Latin America compared, as an example, to India, could be a sign of a current lower incidence of NCC in the former compared to the latter scenario (Hamamoto Filho et al. 2020).

Since around three decades, a concern was raised on the increase of diagnosed cases in non-endemic countries (countries where the life cycle of the parasite did not

take place, i.e., swine cysticercosis is not present), where cases of cysticercosis or taeniasis have been detected (Del Brutto and García 2012). Such cases have been mainly reported in the United States (O'Neal and Flecker 2015; Serpa and White 2012; Croker et al. 2012; O'Neal et al. 2011) and in Spain (Del Brutto 2012; Ruiz et al. 2011; Esquivel et al. 2005), due to the increase of human migration from endemic countries. As migration of *Taenia solium* carriers keeps occurring, autochthonous cysticercosis infections have been reported in these countries due to contact with *T. solium* eggs.

15.1.2 Epidemiology in Pigs

Similar to human cysticercosis, swine cysticercosis is present in most rural areas of Africa, Asia, and Latin America. The results of recent studies evaluating the prevalence of swine cysticercosis are presented in Table 1. Comparison between them is difficult as different diagnostic tests with different sensitivities were used (cf. above). It is clear, however, that swine infection is still present in some rural areas of the three continents. It is also interesting to note that recent studies (>2012) come mostly from Africa and Asia, probably due to the persistence of a higher activity of *Taenia solium*'s life cycle in these continents.

15.1.3 Burden of Disease

The burden of cysticercosis in humans and pigs and of taeniosis in humans is still difficult to assess, as the disease is frequently asymptomatic both in pigs and humans, and since its diagnosis in humans depends on the use of modern radiological tools frequently unavailable for the affected population in endemic countries. However, several estimates have been made (Bhattarai et al. 2013). Current data on DALYs (disability-adjusted life years), mortality, and economic burden are summarized in Tables 2, 3, and 4.

15.2 Clinical Features

15.2.1 Disease in Humans

Clinical manifestations of neurocysticercosis (NC) vary widely and strongly depend on the cyst number and location as well as on the host's immune response to the parasite (Carabin et al. 2006, 2011; Carpio 2002). There is a marked clinical heterogeneity across geographical areas. Most cases from the Indian subcontinent present single lesions, whereas those from Latin America exhibit few viable cysts (Singh 1997; Singh et al. 2010; Vega et al. 2003). These differences are probably due to complex interactions among host, parasite, and environmental factors (Fleury et al. 2010). As previously said, differences in infection pressure could be involved

in the still high prevalence of parenchymal neurocysticercosis and ocular cysticercosis in countries which have a stable infection pressure and in the high proportion of extraparenchymal neurocysticercosis in other countries, which have had a progressive decrease in infection pressure (Hamamoto Filho et al. 2020).

One of the most intriguing aspects of NC is that presumably a high percentage of individuals with NC remain asymptomatic (Fleury et al. 2010). Some patients develop NC clinical manifestations several years after the parasite lodges in the CNS (Carpio 2002), either by inflammation surrounding the parasite or by a mass effect. Studies carried out in the United States, a non-endemic country, including Latin American migrant patients, and in Great Britain, including British soldiers who worked in India for a period of 5 years, have allowed to specify that this period is around 5 years for parenchymal NC and about 20 years for extraparenchymal NC (Dixon and Hargreaves 1944; Nash et al. 2020). In addition, a recent study shows the ability of parasites to survive for a long time in the extraparenchymal location and explains the chronicity of the disease in some patients (Murrieta et al. 2021).

Current information based on evidence has confirmed that NC is not a singular disease. Location of parasites in the parenchymal or in the extraparenchymal compartments determine two distinct diseases from a clinical, immunological, and pathophysiological perspective (Marcin Sierra et al. 2017, Carpio et al. 2016). Particularly, the clinical signs of parenchymal cysts are usually benign; on the contrary, the clinical presentation of extraparenchymal cyst location is life-threatening and may lead to permanent sequelae (Estañol et al. 1986). The prominent role of the inflammatory reaction associated with the presence of parasites in the two locations is now well defined (Hamamoto Filho et al. 2021). Most symptomatic parenchymal NC patients show seizures as the only clinical manifestation and their neurological status is usually normal (Carabin et al. 2011; Carpio et al. 1998).

Furthermore, most of the patients with seizures do not evolve to epilepsy (Carpio et al. 2019). Focal neurological deficits, when present, are usually transient over a few days, weeks, or months, with periods of remission and relapse, probably due to different evolutionary stages of the parasite (Carpio 2002). Headache and increased intracranial pressure are frequent in extraparenchymal cyst location patients (Cárdenas et al. 2010; Fleury et al. 2011; Marcin Sierra et al. 2017). This location is found in about one-third of patients. Acute hydrocephalus secondary to intraventricular cysts and chronic hydrocephalus due to subarachnoid cysts, arachnoiditis, or ependymitis are the most frequent causes of this syndrome (Agapejev et al. 2007). Increased intracranial pressure also occurs in patients with cysticercal encephalitis due to the associated high inflammatory reaction (Carpio 2002; Cárdenas et al. 2010; Fleury et al. 2011).

Spinal cord cysticercosis is rare (Alsina et al. 2002). Patients experience nonspecific clinical manifestations, such as nerve root pain or spinal cord compression syndromes, in accordance with the level of the lesion. Massive cysticercal infection of striated muscles occasionally produces a clinical picture of generalized weakness associated with muscle pseudohypertrophy.

Classically, NC predominantly affects adults in the third and fourth decade of life, being relatively uncommon in children (Kelvin et al. 2009; Sáenz et al. 2006). Most pediatric cases show a single transitional cyst that resolves spontaneously over a few months and do not require any treatment apart from symptomatic and anti-seizure drugs (ASD) (Kelvin et al. 2011; Singh et al. 2010). However, severe forms of NC may exceptionally occur in younger patients, including cysticercal encephalitis, which results in permanent neurologic sequels, such as amaurosis. Hydrocephalus and intraventricular NC are extremely rare in children (Agapejev et al. 2007; Carpio 2002).

15.2.2 Disease in Pigs

In our experience, pigs rarely show definite signs of the parasitosis. Signs are inconspicuous even in animals harboring several larvae in the brain, although they may show somnolence and remain inactive during longer periods.

Convulsions occur mostly at night, during sleep. In a study evaluating presence of seizures in infected pigs (Trevisan et al. 2016), 2 of 16 (12.5%) presented severe seizures. The two symptomatic animals were significantly older than the asymptomatic ones. The total number of parasites and their distribution and localization in the brain were not different between symptomatic and asymptomatic animals.

No significant hematological change was detected in a sample group of 17 pigs (Royo Martínez 1996). In one study (Prasad et al. 2006), the following symptoms were found to be very specific for cysticercosis: excessive salivation (dribbling of saliva), excessive blinking (5–10 blinks/min), and tearing (trickling tears from the eye), as well as single subconjunctival nodules. Unfortunately, these symptoms have not been confirmed by other authors, and thus, diagnosis of pig cysticercosis is impossible on clinical ground alone.

15.3 Diagnosis of Cysticercosis

15.3.1 Diagnosis in Humans

NC diagnosis cannot rely on clinical grounds alone, since no typical clinical picture of NC exists. As previously stated, the most common clinical sign of parenchymal NC is epileptic seizure, which occurs in 60–90% of cases, followed by headache, focal deficits, and psychiatric and cognitive symptoms (Carpio 2002; Rodrigues et al. 2012; Marcin Sierra et al. 2017). Diagnosis of extraparenchymal NC is even more difficult, considering that unspecific symptoms and signs of intracranial hypertension and meningitis may occur, either with or without signs of cerebrospinal fluid inflammation (Cárdenas et al. 2010; Fleury et al. 2011; Marcin Sierra et al. 2017).

NC diagnosis is mainly done by neuroimaging. New imaging techniques, including computed tomography (CT) and magnetic resonance imaging (MRI), have improved the detection of scolex, which can be considered pathognomonic of neurocysticercosis (Fig. 2) (Lucato et al. 2007; Mont'Alverne Filho et al. 2011). Imaging procedures allow visualizing the vesicular, colloidal, granularnodular, and calcified phases of the parasite in CNS (Carpio et al. 2013; Escobar 1983) (Fig. 2). MRI is more sensitive than CT in diagnosing viable and degenerating cysticerci, as well as cysts located in the ventricles or the subarachnoid space. In cases of

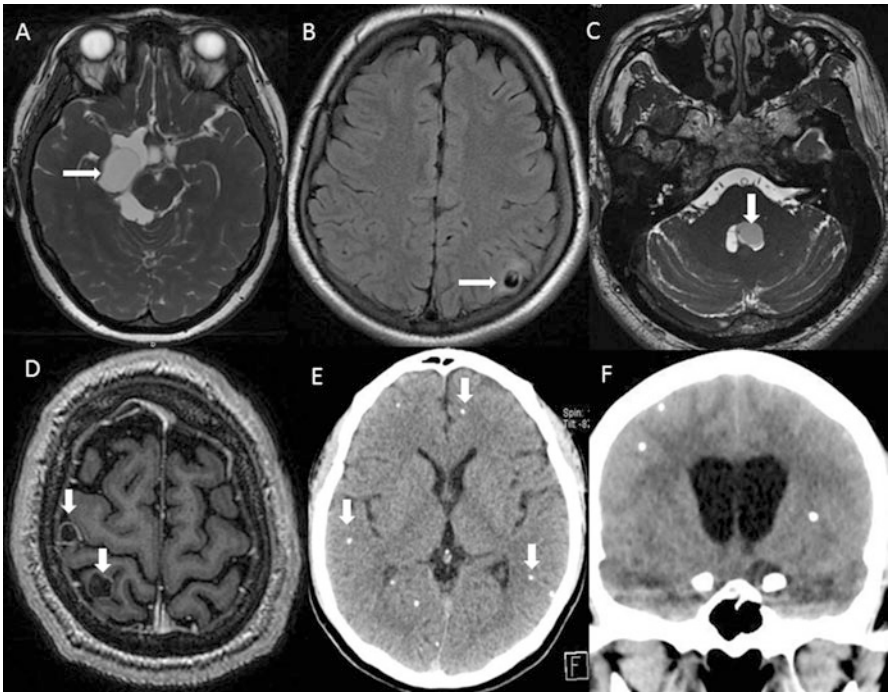

Fig. 2 Neurocysticercosis images

extraparenchymal parasites, 3D MRI sequences increase significantly the sensitivity of the study to diagnose vesicular parasites (Carrillo Mezo et al. 2015). However, CT is more sensitive to detect calcifications (Carpio et al. 2013).

There is no ideal immunological test for diagnosing NC yet. The difficulties of developing a sensitive and specific immunological test for NC diagnosis stem from the characteristics of the disease itself. Different immunological tests have been developed. The most commonly employed methods aiming to detect specific antibodies are enzyme-linked immunosorbent assay (ELISA) and enzyme-linked immunoelectrotransfer blot (EITB) assays (Proaño-Narvaez et al. 2002; Tsang et al. 1989). They are useful to identify individuals who have had systemic contact with the parasite at some time. Seropositivity, however, does not necessarily mean an active systemic infection or central nervous system involvement at any time (Carpio 2002). Recently, a study was performed to compare the validity of seven immunodiagnostic tests. The results allow the conclusion that the simple and low-cost ELISA *Taenia solium* antibody instead of EITB is recommended to support NCC diagnosis (Hernández et al. 2019).

Antigen detection by monoclonal or polyclonal antibodies using the ELISA technique has also been developed (Brandt et al. 1992; Fleury et al. 2007, 2013). Detection of specific antigens in serum or CSF by ELISA in patients with parasites located in the subarachnoid space or the ventricular system is a specific sign of parasite viability and may be used to evaluate treatment response (Fleury et al. 2007, 2013).

In spite of the current immunological and imaging advances, NC diagnosis is still challenging in many patients. Diagnostic criteria for NC have been proposed (Del Brutto et al. 2001). These diagnostic criteria may be useful to identify patients with parenchymal NC, but not so for patients with extraparenchymal NC (Machado 2010). Recently, a new set of diagnostic criteria for NC, which allow the detection of NC with a sensitivity of 93.2% and specificity of 81.4%, was proposed (Carpio et al. 2016). Moreover, the new criteria allow to differentiate between the parenchymal and extraparenchymal disease. For parenchymal NC, sensitivity reaches 89.8% and specificity 80.7%, while for extraparenchymal NC, sensitivity is 65.9% and specificity 94.9%.

15.3.2 Diagnosis in Pigs

Different tools are available to diagnose pig cysticercosis, but the results they yield are frequently divergent.

First, and perhaps the most traditional diagnostic method, is the visual inspection of the inferior surface of the tongue (Leuckart 1879). This is the most frequently used procedure, even though it is a risky operation for the person who performs it and a source of stress for the animal, leading to significant changes in cortisol levels (Pérez-Torres et al. 2012). The method is specific, but it fails to detect all infected animals, as only heavily infected pigs will present parasites in the tongue muscles. Studies comparing the results of tongue inspection with MRI or necropsy found that tongue-test sensitivity was between 70% and 84% and its specificity was at 100% (Gonzalez et al. 1990; Phiri et al. 2006; Singh et al. 2013). However, the results are

highly variable between studies; one recent study found that tongue inspection only detects 10% of infected animals (Chembensofu et al. 2017), while other found that it was able to detect 91% of the infected animals (Flecker et al. 2017).

Another method used is the neck muscle examination: a small, 4–5-cm-long skin incision is cut on the lateral side of the neck, and a trained volunteer inserts two fingers to palpate any nodule (Singh et al. 2013). This diagnostic method is very invasive and may lead to infectious complications but has shown a sensitivity of 100% and a specificity of 75% (Singh et al. 2013), as neck muscle seems to be one of the most common sites for cysticercus infection.

Eyelid examination is also used to some extent: the presence of cyst nodules is tested by direct visualization (Singh et al. 2013). This method is very specific (100%), but its sensitivity is very low (25%) (Singh et al. 2013).

A number of serological tests have also been evaluated: detection of specific antibodies using different antigens (whole crude lysate, cyst fluid, scolex, cyst wall) by ELISA and EITB or specific antigen detection. As shown in Table 5, these tests have shown varying performance among studies, probably due in part, to different infection intensity.

Table 5 Swine cysticercosis diagnosis: sensitivity and specificity of different immunodiagnostic tests

Country (Ref)	Type of swine infection	Method	Antigen	Sensitivity (%)	Specificity (%)
India (Singh et al. 2013)					
	Natural infection	ELISA	Crude lysate	85	98
		ELISA	Cyst fluid	70	98
		ELISA	Scolex	65	96
		ELISA	Cyst wall	45	98
Peru (Gonzalez et al. 1990)					
	Natural infection	ELISA	Crude lysate	79.2	76.2
		EITB		100	100
Mexico (Sciutto et al. 1998)					
	Experimental infection	Ag-ELISA		83.7	95.9
		ELISA	Cyst fluid	86	95.7
	Natural infection	Ag-ELISA		44.4	45.8
		ELISA	Cyst fluid	55.5	75
		EITB		64.7	59.1
Brasil (Nunes et al. 2000)					
	Experimental + natural infection	ELISA	Crude lysate	85.7	96.4
			Cyst fluid	67.8	98.2
Tanzania (Kabululu et al. 2020)					
	Natural infection	Ag-ELISA		82.7	86.3
Zambia (Chembensofu et al. 2017)					
	Natural infection	Ag-ELISA		68	67

Mexican researchers developed a diagnostic method using portable ultrasonography equipment to examine pig muscles, with very satisfactory results (Herrera et al. 2007). A more recent study found that ultrasonography was 100% sensitive and 90% specific for swine cysticercosis diagnosis (Flecker et al. 2017). So, in spite of the high cost of the equipment, this could be a recommended diagnostic method in some circumstances.

15.4 Treatment

15.4.1 Treatment of Humans

NC treatment should be individualized, based on the pathogenesis and natural history of the disease in each patient (Fig. 3). Therapy is limited in most cases to symptomatic treatment for patients with seizures. Oral mannitol or glycerol is used in patients with high intracranial pressure, and analgesics should be given for headache. Corticosteroids are strongly recommended, on the premise that they reduce inflammation and edema around dying parenchymal cysts, to treat arachnoiditis and, associated to cysticidal drugs, to prevent inflammatory complications, mostly in cases of extraparenchymal localizations (Carpio et al. 2013; Fleury et al. 2011). However, the dosage, the treatment duration and form, and most significantly the administration timing are not clearly defined (Carpio et al. 2008). Recently, the possibility that corticosteroids might favor parasite survival was stated and research aiming to find the best anti-inflammatory treatment must be pursued (Toledo et al. 2018; Palomares-Alonso et al. 2020).

Surgery is now almost restricted to ventricular shunt placement for hydrocephalus and to cases of intraventricular cysts, which are mainly removed by endoscopic

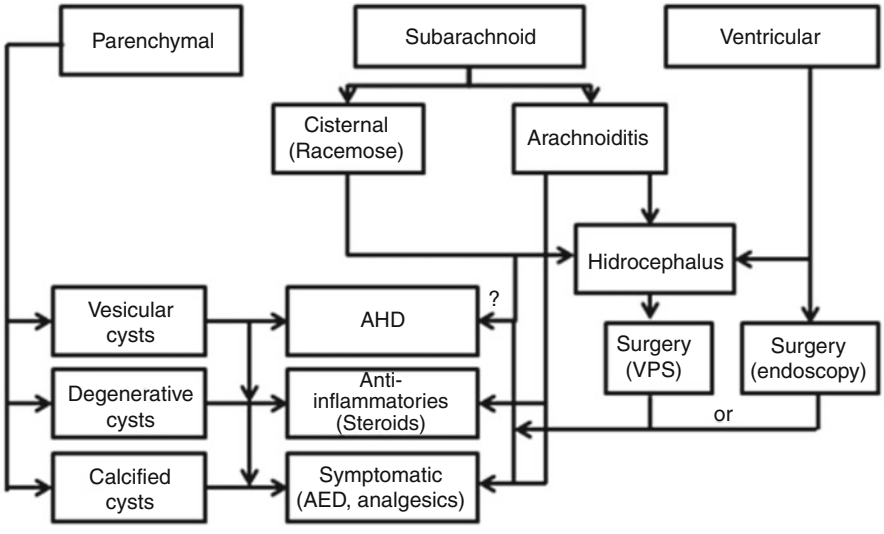

Fig. 3 Neurocysticercosis treatment. (From Carpio et al. 2013)

approach (Torres-Corzo et al. 2010). Transitional or degenerating cysts should not be biopsied or removed if differential diagnosis has been discarded and if mass effect is moderated, since the parasite is dead and will disappear or be calcified spontaneously (Singh et al. 2010).

NC treatment with anti-helminthic drugs (AHD), praziquantel (PZQ) (Robles and Chavarria 1979), and albendazole (ALB) (Xiao et al. 1986) has been available for more than 30 years. PZQ is an acylated isoquinoline-pyrazine with broad anthelminthic activity. Its mechanism of action is not fully understood; however, it is assumed that PZQ changes calcium metabolism and intracellular permeability, with the main effect of inhibiting muscular movements (Garcia-Dominguez et al. 1991). ALB is a benzimidazole with a broad anti-helminthic spectrum, which exerts an anticysticercal effect by inhibiting the glucose uptake through parasitic membranes, thus causing energy depletion (Lacey 1990). There is evidence for the efficacy of AHD treatment for viable parenchymal cysts; however, no controlled clinical trials have so far established definitive doses and treatment duration (Carpio et al. 2013). According to placebo-controlled clinical trials (Carpio et al. 2008; Garcia et al. 2004), AHD are effective in about 30–40% of patients, according to the disappearance of viable parenchymal cysts in imaging studies. The most frequent treatment scheme for PZQ is 50 mg/kg/day for 15 days, and for ALB it is 15 mg/kg/day for 8 days (Carpio et al. 2013). Recently, the combination of the two drugs has been shown to be more effective than ALB alone in the case of multiple parenchymal parasites (Garcia et al. 2016). The more recent Cochrane review (Monk et al. 2021) concluded that ALB probably reduces the recurrence of seizures in people with a single NC cyst (moderate-certainty evidence), while there is no certainty whether ALB reduces seizure recurrence for people with more than one NC cyst (very low-certainty evidence). Also, ALB probably increases the clearance and evolution of cysts in people with NC (moderate-certainty evidence) (Monk et al. 2021).

For extraparenchymal cysts the management is even less clear. While AHD have demonstrated efficacy in some cases, it is clear that not all cases respond to the current treatment (Carpio et al. 2008; Fleury et al. 2011; Osorio et al. 2019). This stresses the urge for looking for new treatment alternatives (Diazgranados-Sánchez et al. 2008).

15.4.2 Treatment of Pigs

Several cysticidal drugs have proven to be effective in destroying the parasite (Gonzalez et al. 2012). Indeed, the treatment of infected pigs has been proposed and successfully tested locally, being oxfendazole the drug most frequently evaluated (Gonzalez et al. 1997; Mkupasi et al. 2013). In spite of their effectiveness, cysticidal drugs have not been extensively used to treat swine cysticercosis, due to practical reasons: treatment is hardly manageable, and the necessity of waiting several months for cysticerci destruction is costly for rural pig breeders. Possible detrimental effects on the environment through the promotion of drug resistance should be considered as well (Domke et al. 2012).

15.5 Preventive Measures

Although this parasitosis has a high impact on human health and on economy, its eradication remains a major challenge.

Different interventions have been proposed and proved effective for control, albeit with varying practical possibilities. The combination of simultaneous actions targeting pigs and humans is probably the approach that achieves the best results.

15.5.1 Focus on Pig-Targeted Actions

Focusing preventive measures on porcine cysticercosis is particularly relevant, since it is the essential step for parasite transmission (Aluja 2008).

In rural communities, pigs become infected because of poverty-related factors, i.e., low hygiene standards and inadequate human feces disposal, which contribute to environment contamination by *T. solium* eggs. In these rural areas, pigs (being natural coprophages) are allowed to freely roam in search of food, favoring them to ingest human feces contaminated with parasite eggs (Copado et al. 2004). This rustic rearing promotes the parasite life cycle, since after ingestion the eggs will evolve to cysticerci and subsequently be delivered to humans via undercooked infected pork meat (Sciutto et al. 2000).

Compulsory meat inspection aiming to avoid infected pork meat consumption seems a reasonable effort. Unfortunately, while this measure is fully operative in official slaughterhouses, it cannot be enforced in rural, hardly accessible small communities where pigs are clandestinely killed and consumed at the occasion of private feasts (Willingham et al. 2010). Educational programs to train the inhabitants of rural communities in good pig sacrificing practices would be a useful intervention to prevent the consumption of undercooked infected meat. Here, too, the challenge will be covering all persons involved in this practice.

Making pig confinement obligatory to avoid contact with human feces would clearly help to interrupt transmission. While this could be a feasible possibility, the poor economic conditions in these rural communities promote the free-roam foraging of pigs to supplement the meager food their owners provide them with (Thys et al. 2016).

Porcine cysticercosis is a vaccine-preventable disease. Thus, pig vaccination may provide an additional tool for taeniosis-cysticercosis control and prevention.

The first report on successful porcine cysticercosis vaccination was established using total extracts from *T. solium* cysticerci, recovered from naturally infected pigs, as a source of vaccine antigens (Molinari et al. 1997). Since then, various native and subunitary vaccine candidates have been identified, but only a few have been found effective under the complex natural field conditions (Huerta et al. 2001; Morales et al. 2008a; Jayashi et al. 2012). Among them figures the vaccine named S3Pvac and the HP6/Tsol18 vaccine. S3Pvac vaccine is composed by three small peptides (KETc1, KETc12, and GK1 [KETc7]), originally isolated from *Taenia crassiceps* and shared by other cestodes including *T. solium.* Both synthetic S3Pvac (Huerta et al. 2001) and S3Pvac recombinantly expressed in filamentous phages (Morales et al. 2008a, 2011) were successfully tested in the field. HP6 antigen, originally isolated from *Taenia*

saginata (Benitez et al. 1996) and reported to induce high protection levels against bovine cysticercosis (Lightowlers et al. 1996), has been found present in *T. solium* (HP6/*Tsol*18) cysticerci and showed a protective effect against porcine cysticercosis (Assana et al. 2010; Poudel et al. 2019; Nsadha et al. 2021).

Finally, infected pigs could be exchanged by vaccinated pigs, better suited to endure the hardship of their lives.

15.5.2 Focus on Human-Targeted Actions

Here, too, different measures have been taken and showed some efficacy. An aggressive hygiene-promotion campaign in rural areas is an obvious start point, since it can eradicate not only *T. solium*, but many other infectious diseases transmitted by human feces (Yap et al. 2012). This type of measures did allow the control of *T. solium*-related diseases in most European countries in the early twentieth century.

However, achieving the same in currently endemic countries would require an economic and social development that does not seem achievable in the near future.

Massively administered human cestocidal treatment to reduce the number of tapeworm carriers is another measure which has been applied in different circumstances (Haby et al. 2020). Human deworming can be achieved using a single oral dose of niclosamide (2 g in adults, 1 g in children), praziquantel (10 mg/kg), or albendazole (400 mg/day) for three consecutive days (Pearson and Guerrant 1983; Pearson and Hewlett 1985; Haby et al. 2020). A priori, niclosamide should be preferred as it is not absorbed by the intestinal mucosa, thus avoiding possible symptoms derived from an occult NC. This strategy has been used in several studies in endemic countries, either administered alone (Cruz et al. 1989; Allan et al. 1997; Sarti et al. 2000; Wu et al. 2012; Ramiandrasoa et al. 2020) or associated with other preventive measures (Garcia et al. 2006, 2010).

Health education programs aiming to promote a better understanding of the parasite transmission mechanisms and to improve the hygienic behavior, pig management, and sanitary conditions which foster transmission is another measure that has been carried out (Keilbach et al. 1989; Sarti et al. 1997; Ngowi et al. 2008; Wohlgemut et al. 2010; Wu et al. 2012).

These interventions, all of which have been implemented on a small to medium scale, have produced generally relevant immediate results, although long-term evaluations are most often lacking.

Finally, it should be noted that the role of national health authorities in these programs is essential and must be promoted. Researchers alone are not able to implement nationwide programs, the only realistic way to eradicate this parasitic disease.

15.6 Conclusions and Unsolved Issues

Cysticercosis is considered a neglected "tools-ready disease" according to WHO (2007), and as a potentially eradicable disease since 1993 (Recommendations of the International Task Force for Disease Eradication). Eradication is feasible, because—as

we have stated earlier—(1) humans and pigs are the only affected species; (2) humans (the definitive host) are the only source of pig *T. solium* infection; and (3) there exist efficient intervention strategies which can interrupt the parasite life cycle.

In spite of this, cysticercosis is still endemic in most countries of Latin America, Asia, and Africa, although its burden is difficult to estimate, and some recent data seem to show a decreasing tendency in some of these countries.

The reasons for this situation are multiple, a major cause being that it is a "forgotten disease of forgotten people" (Hotez 2008), which does not motivate governments to take the necessary measures. As said before, instituting nationwide government control programs is one of the main unresolved issues.

With regard to neurocysticercosis, several items remain unsolved at this point.

Focusing on diagnosis, for instance, neuroradiological studies (currently representing the gold standard), is a strategy not available to all affected population due to its cost; therefore, improving the immunodiagnostic techniques is mandatory, as all existent tools show low sensitivity, particularly in cases of single-cyst infection. At a therapeutic level, further research is required to understand why some patients do not respond to specific cysticidal treatment and to develop alternative treatment approaches for these cases. Additionally, the adequate management of the inflammatory reaction is a pending problem. Corticosteroids are of great utility to avoid inflammatory complications, but they show severe collateral effects, and their possible role in the lack of response to specific treatment forbids their indiscriminate use (Toledo et al. 2018). Further research is much needed with that respect, too.

Finally, it should be stressed that taeniosis/cysticercosis is an eradicable disease and that firm government commitment in affected countries is key to reach this goal.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_14

Abstract

Infections by the protozoan parasite *Toxoplasma gondii* are widely prevalent in humans and animals worldwide. Since the discovery of the life cycle of the parasite (1969), several studies identified sources of contamination for humans through ingestion of viable tissue cysts in raw or undercooked meat or ingestion of food and water contaminated with sporulated oocysts after shedding in the feces of infected felids. Prevalence of toxoplasmosis varies between different countries and regions in the same country depending on age, social culture, eating habits, and environmental factors. In immunocompetent patients, toxoplasmosis is generally asymptomatic or benign, but severe infections are described in tropical areas due to atypical strains. In immunocompromised patients, *T. gondii* is an opportunistic parasite that may induce life-threatening disease; severe disease could occur in HIV-infected patients or in transplant patients. Finally, in case of congenital toxoplasmosis, infection can lead to abortion, cerebral damage, or ocular lesions. New genotyping tools were recently applied to field studies in different continents and revealed a complex population structure for *T. gondii* with a greater genetic diversity than expected, and a relation between genotype of *Toxoplasma* strain and severity of infection is described. According to different routes of transmission, hygienic measures can be recommended to avoid *Toxoplasma* contamination. These measures can be completed by a serological screening of patient at risk for toxoplasmosis as it is recommended in France. Although the cost of screening is expensive, the important preventive role of healthcare policies in the decrease of the burden of toxoplasmosis cannot be denied.

Keywords

Toxoplasma gondii · Oocysts · Cysts · Zoonosis · One health disease

16.1 Introduction

The protozoan parasite *Toxoplasma gondii* has a worldwide distribution and is one of the most frequent parasitic infections. This obligate intracellular parasite was first described in the common gundi *(Ctenodactylus gundi)*, a rodent from North Africa, by Nicolle and Manceaux in 1908, and was subsequently recognized as the agent of a widespread zoonosis involving humans as well as virtually all warm-blooded animals and birds. However, it took several decades until its entire life cycle was definitively understood in the late 1960s (Hutchison et al. 1969; Frenkel et al. 1970), with the

demonstration of the cat as definitive host responsible for oocysts shedding through feces and contamination of intermediate hosts. It is now well established that not only the cat, but all felids, can reproduce the sexual life cycle of the parasite and participate in the spread of the disease, which explains the wide distribution of toxoplasmosis.

Regarding human infection, the most remarkable events were the first reports on cases of congenital toxoplasmosis in 1939 (Schwartzman et al. 1948), the development of the first serologic test by Sabin and Feldman in 1948, and the recognition, in the middle 1970s, that past infection could reactivate in immunocompromised patients (Weiss and Dubey 2009). The high burden of congenital toxoplasmosis led to the progressive implementation of prevention policies in some European countries. During the last decade, the development of new genotyping tools and the multiplication of field studies have increased comprehension of the phylogenetic evolution of *T. gondii* in the world (Mercier et al. 2011), and advances have been achieved in the knowledge on the particular virulence associated with some genotypes (ElHajj et al. 2007; Behnke et al. 2015).

16.2 A Life Cycle Involving All Warm-Blooded Animals

16.2.1 Definitive Hosts and Contamination of the Environment: Not Only the Cat!

While only Felidae can act as definitive hosts and thus shed oocysts in their feces, almost all warm-blooded animals can serve as intermediate hosts. Many host species (birds, rodents, carnivorous, or herbivorous animals) from polar to tropical areas have been identified by serology or bioassay. *Toxoplasma gondii* undergoes sexual reproduction in the felid intestine, resulting in the production of millions of environmentally unsporulated oocysts. Oocysts take 1–5 days to sporulate in the environment and become infective and resistant in environment. Oocysts may survive for months in soil and water, thereby enhancing the probability of transmission to intermediate hosts such as birds, rodents, and humans. Cats become infected after consuming intermediate hosts harboring tissue cysts or directly by ingestion of sporulated oocysts. Animals bred for human consumption and wild game may also become infected with tissue cysts after ingestion of sporulated oocysts in the environment. Humans may acquire *T. gondii* infection via oral uptake of sporulated oocysts from the environment, consumption of raw or undercooked meat containing tissue cysts, or transplacental transmission of the parasite from the non-immune mother to the fetus (Fig. 1).

Oocysts are essential in the life cycle of *T. gondii*, and cats were everywhere, except the frozen artic. In general, the seropositivity increases with the age of the cat, indicating postnatal transmission of *T. gondii*. It is possible that in some young cats, the low antibody titers represented maternally transferred antibodies which generally disappear in the cat by 12 weeks of age (Dubey et al. 2020). At any given time, approximately 1% of cats are expected to shed oocysts (even if most cats only shed oocysts for about 1 week in their life), and this is supported by fecal survey. The

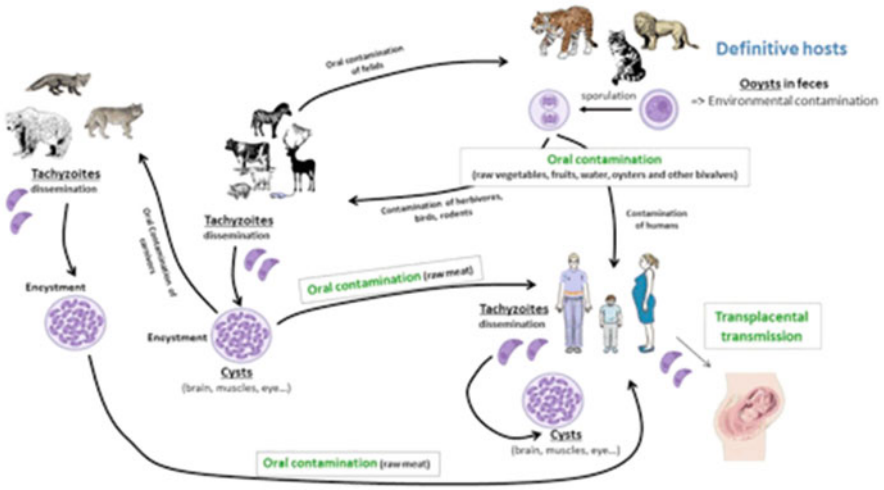

Fig. 1 Life cycle of *Toxoplasma gondii* (partially made using BioRender tools)

number of oocysts shed by naturally infected domestic cats is largely unknown, but probably several millions are disseminated into the environment according to experimental infection. Whether naturally infected cats shed oocysts more than once in their life is unknown. The number of oocysts shed during the secondary infection is usually lower than in primary infection; cats that had excreted oocysts did not re-excrete after challenge within 2–3 months after primary infection (Dubey and Frenkel 1974). Dubey recently reported that concurrent infections with certain feline pathogens can affect *T. gondii* infections in cats, but there is no evidence that they affect the seropositivity of *T. gondii* in cats (Dubey et al. 2020). In addition to domestic cats, wild felids can also shed oocysts. The role of wild felids in parasite transmission to humans may be important especially in areas where the domestic cat, *Felis catus*, is absent (e.g., tropical forest). Cats are essential for the maintenance of *T. gondii* in the environment, since infections are virtually absent from areas lacking cats. A single oocyst is able to infect pigs or mice, but pathogenicity depends on the strain, inoculum, and infection route (Dubey and Beatty 1988); oocysts are less infectious and pathogenic for cats than for intermediate hosts (Dubey and Frenkel 1974).

Based on serologic surveys, up to 74% of the adult cat population may be infected by *T. gondii (Tenter et al.* 2000*)*; but seroprevalence to *T. gondii* varied among countries, within different areas of a country, and within the same city (Dubey et al. 2020). In nature, cats are infected by eating small preys harboring tissue cysts or by ingesting oocysts from soil. Fatal toxoplasmosis is rare and occurs more often in immunocompromised cats and in kittens. Vertical transmission is uncommon and is probably not important for parasite propagation. Cats excrete millions of unsporulated oocysts in their feces after ingesting any of the three infectious stages; the prepatent period is 3–10 days after ingesting bradyzoites and more than or equal to 18 days after ingesting oocysts or tachyzoites. The patent period is only

1–3 weeks, but a re-excretion is possible, at least experimentally, after a second challenge with *T. gondii*, after corticoid treatment or superinfection by *Isospora felis*. Even within a shared habitat, exposure of wild and domestic felids to *T. gondii* may increase or decrease based upon access to prey and dietary preferences (VanWormer et al. 2013). Pet and feral domestic cats showed different prey consumption patterns, with higher predation levels observed in feral cat populations (Fitzgerald 2000). In regions where humans, livestock, and wildlife live in close contact, wild felid prey frequently include domestic livestock such as sheep, goats, and cattle as well as wildlife (Treves and Karanth 2003). In addition, inter-farm and seasonal variations in the risks of exposure to *T. gondii* oocysts for humans and livestock living on farms have been described (Simon et al. 2018).

16.2.2 Life Cycle of *T. gondii* in Domestic Animals and Wildlife

T. gondii is not an obligatory heteroxenous parasite and can propagate clonally (presumably indefinitely) by cycling among intermediate hosts. This can occur vertically through transplacental transmission from mother to offspring (Dubey et al. 1997). Tissue cysts are also orally infectious to carnivorous intermediate hosts, permitting *T. gondii* to bypass the sexual stage in the definitive host (Khan et al. 2007).

Oocysts are responsible for most of the *T. gondii* infections in noncarnivorous mammals and birds whereas other species are mainly infected by eating animals harboring tissue cysts. *T. gondii* infection in wildlife does not occur with the same probability in any species or place. Wild-living species first have variable levels of susceptibility and exposure. Exposure is largely determined by life history traits, especially feeding behavior. Herbivore intermediate hosts acquire infection by food or water contaminated with sporulated oocysts. Carnivores and omnivores may additionally become infected mainly by ingesting meat containing cysts. Hejlíček et al. (1997) suggested that carnivores have a higher prevalence of antibodies to *T. gondii* due to the cumulative ingestion of infected animals and that seroprevalences would be lower, by decreasing order, in omnivorous, herbivorous, and insectivorous animals.

16.2.3 A Wide Range of Opportunity for Human Infection

Human infection can occur from different transmission routes due to several stages of the parasite (cysts, oocysts, and tachyzoites). Even though the sources of *T. gondii* infection for humans are well known, their relative contribution is still unclear. The major routes of transmission vary between different human populations and depend on social culture, eating habits, and environmental factors (Tenter et al. 2000).

The most frequent transmission route appears due to cysts present in meat as a risk-factor analysis indicates that 30–63% of human infections can be attributed to the consumption of undercooked meat (Cook et al. 2000). All warm-blooded animal

species can be infected, but prevalence of infection in meat producing animals is variable among species and countries (Tenter et al. 2000; Dubey 2022). Sheep and pigs seem to be more infected while infection seems rarer in cattle. In Norway and France, consumption of undercooked lamb appears to be a stronger risk factor than consumption of pork (Kapperud et al. 1996; Baril et al. 1999), while in Poland consumption of undercooked pork was identified as the principal risk factor (Paul 1998). Moreover, there are few reported outbreaks due to ingestion of well-identified meat (Dubey 2021; Dubey et al. 2021), and absence of evidence of source of contamination is frequent due to lack of detection of cysts in meat.

Infection through cysts can be also occurring after organ transplantation when an organ from a *Toxoplasma*-seropositive donor is grafted to a *Toxoplasma*-seronegative recipient. Generally, heart, liver, and kidney transplantation is most frequent for this route of transmission (Speirs et al. 1988).

Infection through oocysts is another transmission route for humans. Sporulated oocysts are very resistant (especially to most of disinfectants) in environment, and they may survive during several years and disperse through water or soil movements and contaminate vegetables (Shapiro et al. 2019). They may be an important source of infection for humans, and several waterborne outbreaks of toxoplasmosis linked to oocyst contamination of drinking water are reported (Dubey 2022; Shapiro et al. 2019).

A recent meta-analysis of sporadic toxoplasma infections revealed the significance of transmission by environmental factors such as contact with soil and contact with animals, in particular cats, also the consumption of raw or undercooked meat and unwashed vegetables significantly increased the odds of acquiring an infection (Thebault et al. 2021). Moreover, a recent review (Dubey 2021) reports that there are no apparent differences in type or severity of symptoms in meat-versus oocyst-acquired infections.

The last transmission route of infection is through tachyzoites. Tachyzoites are delicate; they are destroyed by gastric secretions and unable to survive outside their host. So contamination by this route is very rare except in the case of congenital infection due to transplacental transmission from a mother to her fetus after maternal infection acquired during pregnancy. Tachyzoites can be rarely transmitted by transfusion (blood/bone marrow donor) or in case of laboratory accidents. Finally, toxoplasmosis in humans was occasionally reported after transmission by goat milk (Sacks et al. 1982; Skinner et al. 1990). However, few studies have attempted to detect *T. gondii* in milk of naturally infected animal species and dairy samples (Abadi et al. 2020).

16.3 Prevalence and Disease Burden in Humans

16.3.1 Pathophysiology of the Disease

The pathophysiology of toxoplasmosis results from the dissemination of tachyzoites. After transepithelial passage across the intestinal barrier, tachyzoites invade rapidly monocytes and gain access to the blood flow and from there virtually to all organs

(Robert-Gangneux and Darde 2012). In fact, tachyzoites can invade actively all nucleated cell types, which can explain the variety of clinical manifestations possibly observed, in particular in immunocompromised patients. After the onset of an efficient immune response, tachyzoites are not eradicated but convert into bradyzoites within cells and persist as cysts lifelong, mostly in the muscles, retina, and brain.

16.3.2 Toxoplasmosis in Immunocompetent Subjects: Seroprevalence in the World

It is widely admitted that toxoplasmosis is frequently asymptomatic in immunocompetent humans and is mostly responsible for mild nonspecific symptoms including fever, asthenia, and lymphadenopathy in about 20% of patients. Therefore, the diagnosis is often retrospective and is based on serology. Estimates indicate that approximately 25–30% of the world human population is infected by *Toxoplasma* (Montoya and Liesenfeld 2004); recent meta-analysis mention a global IgG seroprevalence 32.9% (95%CI: 29.4–36.4) in pregnant women with large variations among the countries (Bigna et al. 2020).

Seroprevalence varies among countries but also among regions within a same country. Low seroprevalence (10–30%) is observed in North America, in South East Asia, in Northern Europe, and in Sahelian countries of Africa. Moderate prevalence (30–50%) is found in countries from Central and Southern Europe and high prevalence in South America and in tropical African countries. Several factors can be put forward to explain this heterogeneity, e.g., (1) climatic factors affecting survival of oocysts in the environment (Dubey 1998), (2) the prevalence in meat-producing animals, (3) cooking or cultural habits, and (4) socioeconomic level and quality of water. Seroprevalence has declined over the last decades in most industrialized countries, probably as a result of combined factors (increased socioeconomic level and improvement of hygienic conditions, change of farming systems, consumption of frozen meat, and feeding of cats with sterilized food). For example, in France, the seroprevalence in pregnant women was about 80% in the early 1960s and declined to 54% and 44% in two national perinatal surveys in 1995 and 2003, respectively, while at the same time, the average age of first pregnancy increased (Villena et al. 2010). The seroprevalence observed in general population is increasing with age, and seroprevalence in men and women does not differ for the population aged 45 years and under (Bellali et al. 2013).

16.3.3 Congenital Toxoplasmosis: Determinants of Severity and Various Incidences in the World

Vertical transmission can occur when primary infection is acquired during pregnancy, by transplacental transfer of tachyzoites either during blood flow dissemination or at a later stage. The colonization of the placental tissue by the parasite is probably an

important factor in the process, since 50–72% of placentas from infected fetuses still harbor parasites at birth, which makes this biological sample a good tool for diagnosis (Robert-Gangneux et al. 2011). In France, the mean seroconversion rate during pregnancy was estimated to 6–7 per 1000 seronegative pregnant women (Berger et al. 2009). The frequency of vertical transmission and the severity of fetal damage depend on the stage of pregnancy when maternal infection occurs. Fetal infection occurs in less than 10% of cases during the first trimester but increases to 30% of cases in the second trimester and 60–70% in the third trimester and even more close to delivery (Dunn et al. 1999). The severity of fetal infection is inversely correlated, since neonates are usually asymptomatic in more than 80% of cases when infected during the third trimester of gestation (Desmonts and Couvreur 1974). Conversely, when transplacental transmission occurs during the first trimester of pregnancy, the consequences on fetal development are heavy, often leading to severe abnormalities involving the brain and eye tissues or to abortion. Major sequelae include mental retardation, seizures, microcephalus, hydrocephalus, microphthalmia, cataract, increased intraocular pressure, strabismus, uveitis, retinochoroiditis, and possibly blindness. During the second trimester, fetal infection may have variable consequences, including hepatosplenomegaly, intracranial calcifications, epilepsy, anemia, thrombocytopenia-induced petechiae, pneumonitis, or retinochoroiditis. Among the 272 cases collected in 2007 through the French surveillance for congenital toxoplasmosis network (Villena et al. 2010), 11 cases resulted in termination of pregnancy owing to cerebral lesions or fetal death, and 87% of live-born infants were asymptomatic. The remaining 13% of cases had intracranial calcifications (14 cases), hydrocephalus (3 cases), and/or retinochoroiditis of variable severity (12 cases). The tendencies are the same each year, among these 12 last years (data 2019, National Reference Center on Toxoplasmosis, France).

The incidence at birth was about 3 per 10,000 live births in 2007 in France (Villena et al. 2010), which is in the same range as incidence rates reported in other European countries, such as Denmark (2.1/10,000 live births) and Switzerland (4.3/10,000 live births), but is higher than that reported in Sweden (0.73/10,000) or in a pilot study in Massachusetts (1/10,000) (Guerina et al. 1994) and lower than that reported in Brazil (6/10,000) (Takahashi et al. 2019). The disease burden of congenital toxoplasmosis, as represented by disability-adjusted life years (DALY), is the highest among all food-borne pathogens (Havelaar et al. 2007). One study estimated 1.2 million disability-adjusted life years and an estimated 190,100 cases globally (Torgerson and Mastroiacovo 2013).

16.3.4 Toxoplasmosis in Immunocompromised Patients

Whereas toxoplasmosis is usually a mild or asymptomatic infection in immunocompetent subjects, it is a life-threatening infection in immunocompromised patients. Various factors severely impairing the cellular immune response, among which are HIV infection and immunosuppressive therapies, can lead to severe toxoplasmosis, due to either primary acquired infection or to reactivation of latent infection. Indeed, profound immunosuppression can favor cysts' rupture and tachyzoite multiplication and dissemination. Cyst reactivation is mostly localized to the brain and the retina

but can occur in other tissues, as *Toxoplasma* can invade all organs that can be subsequent potential sites for cyst reactivation (Patrat-Delon et al. 2010). This peculiarity puts transplant patients at risk for both reactivation and organ-transmitted infection. The risk for disseminated infection is closely related to the duration and degree of immunosuppression, with hematopoietic stem cell transplant (HSCT) patients being most at risk (Derouin and Pelloux 2008), whereas focal disease, such as cerebral toxoplasmosis or retinochoroiditis, is more commonly observed in HIV-infected patients. In HIV-positive patients, the incidence of toxoplasmosis is closely related to $CD4^+$ T cell counts, with an increasing risk when it falls below 100 cells/ μL. The incidence of TE has decreased and is now stabilized since the use of highly active antiretroviral therapy; it represents about 200 cases/year in France (Abgrall et al. 2001). In the absence of implementation of a recording system, there are no data available regarding the incidence of toxoplasmosis in transplant recipients.

16.3.5 New Insights into the Comprehension of Parasite Virulence: The Role of Genotype Strains

Although one single parasite species is responsible for toxoplasmosis in humans and animals, it has been shown from the 1990s that clinical isolates from Europe and USA could be divided into three major genotypes, types I, II, and III, equivalent to clonal lineages (Darde et al. 1992; Howe and Sibley 1995; Ajzenberg et al. 2002a).

However, more recently new genotyping tools such as multilocus sequence typing were applied to field studies in other continents and revealed a much more complex population structure with a greater genetic diversity, likely reflecting frequent exchanges of strains between hosts, as well as recombination of isolates during sexual life cycle within the definitive hosts (Ajzenberg et al. 2004). This led to the generation of recombinant isolates (I/II, I/III, or II/III) but also to new clonal haplogroups and, in some areas, particularly in South America, to atypical genotypes with many unique polymorphisms. Type II strains markedly predominate both in humans in Europe (Ajzenberg et al. 2002b; Aubert et al. 2010) and are isolated in more than 90% of congenital infections in France. Other clonal lineages are occasionally (type III) or exceptionally (type I) described in Europe. The exceptional isolation of atypical strains in France can be related to travels in South America or consumption of imported meat (Pomares et al. 2011). In North America, type II strains also predominate (Howe and Sibley 1995), but a higher prevalence of atypical strains is observed, and a clonal haplogroup (haplogroup 12) has been recently identified (Khan et al. 2011). By contrast, atypical genotypes largely predominate in South America, whereas type II isolates are rare (Pena et al. 2008). In Africa, clonal lineages known as *Africa 1-3* haplogroups coexist with type II and III lineages (Mercier et al. 2010) potentially leading to severe infection (Leroy et al. 2020). But, taken together with recent studies of *T. gondii* isolates from Africa, it is clear that the three clonal lineages (types I, II, and III) predominate not only in North America and Europe but also in Africa (Velmurugan et al. 2008). Until now, few data in humans are available from Asia, but some studies reveal a more limited genetic diversity than in South America, the presence of type III strains, and the widespread detection of a

clonal lineage in pigs in China (Zhou et al. 2010). Recently, clustering methods were used to organize the marked genetic diversity of 138 unique genotypes into 15 haplogroups that collectively define six major clades (Su et al. 2012).

It has long been known that clonal genotypes have variable virulence. Genotypes I and II have, respectively, a high and low virulence, whereas genotype III has an intermediate virulence. What emerges from recent epidemiologic studies using new genotyping data is that atypical strains are highly virulent and challenge the concepts of pathophysiology of the disease, at least in some parts of the world. First of all, the fact that infection is usually asymptomatic when it occurs in an immunocompetent subject is not questioned in Europe and North America, but recent experience from French Guiana shows that severe and even lethal toxoplasmosis can be observed in immunocompetent patients infected with atypical strains (Carme et al. 2002). Regarding congenital toxoplasmosis, a comparative prospective cohort study of infected children in Brazil and Europe showed that, independently of treatment, Brazilian children had a five times higher risk than European children for developing eye lesions and their lesions were larger, more multiple, more recurrent, and more likely to impair vision (Gilbert et al. 2008; Lago et al. 2021). More recently, phylogeography of *T. gondii* points to a South American origin which may explain geographic heterogeneities in disease burden (Bertranpetit et al. 2017).

Besides, recent observations have shown that (i) reinfection with an atypical strain of a previously immunized woman could lead to congenital transmission (Elbez-Rubinstein et al. 2009) and (ii) the rate of severe congenital infections was higher when women were infected with an atypical or recombinant strain than with a type II strain, whatever the stage of pregnancy at maternal infection was. Cumulative data (2006–2019) of the French surveillance for congenital toxoplasmosis network show that about 84% of congenital infections with type II strains are asymptomatic infections, whereas 83% of infections with atypical or recombinant genotypes are symptomatic. The large predominance of type II strains of low virulence in France (92% of cases), and more generally in Europe, explains the relatively low burden of the disease in those countries.

16.4 Prevalence and Disease Burden in Animals

Contact and interaction between wild fauna, domestic animals, and human beings may lead to an increased risk of transmission of zoonotic pathogens (Artois 1993). Wild mammals and birds are exposed to *T. gondii* through the ingestion of food or water contaminated with sporulated oocysts derived from felid feces (Dubey and Jones 2008). Additionally, wild carnivores and omnivores may also be infected by feeding birds and mammals with *T. gondii* cysts.

16.4.1 Wild Life

Serologic studies have assessed *T. gondii* infection in several species of wild animals from Europe (Jakubek et al. 2001; Sobrino et al. 2007; Richomme et al. 2009; Beral

et al. 2012) and other continents (Dubey et al. 1999). Mammals like cervids, wild boars, canids, viverrids and mustelids, as well as different kinds of birds, are among those wild animals found with antibodies to *T. gondii*, either at a group or on an individual level (Dubey et al. 2004). The modified agglutination test (MAT) has proved to be a very sensitive and specific assay for the serological diagnosis of *T. gondii* infection in many species of wild mammals and birds (Sobrino et al. 2007; Literák et al. 1992; Gauss et al. 2006; Gennari et al. 2016).

Exposure to *T. gondii* is highest in carnivorous species (Cabezon et al. 2011). High *T. gondii* seroprevalence is also reported in large predator species as lynx and the European wildcat (Sobrino et al. 2007) which is of epidemiological significance because infected felids shed oocysts in the wild environment.

In most species, *T. gondii* infection is generally unapparent, provoking only mild symptoms. However, a limited number of highly susceptible species have been discovered, in which *T. gondii* infection leads to frequent clinical disease and mortality. Marsupials and New World monkeys, which have evolved largely separately from cats, are among the most vulnerable species (Tenter et al. 2000). Fatal toxoplasmosis is also well-documented in hares (Jokelainen et al. 2011). *T. gondii* infection can be present at a high level in many wild birds without any clinical impact, but toxoplasmosis can be clinically severe in pigeons and canaries (Dubey 2002). The ingestion of infected birds is considered an important source of infection for cats (Khan et al. 2007; Dubey 2022).

16.4.2 Meat-Producing Animals

Tissue cysts of *T. gondii* contained in meat, meat-derived products may be important sources of infection for humans. However, for public health purposes, it is important to note that the tropism of *T. gondii* and the number of tissue cysts produced in a certain organ vary with the intermediate host species. In livestock, *T. gondii* tissue cysts are most frequently observed in various tissues of infected pigs, sheep, and goats and less frequently in infected poultry, rabbits, dogs, and horses. By contrast, tissue cysts are found only rarely in skeletal muscles of cattle or buffaloes (Tenter et al. 2000). Recently, a good correlation between seropositivity and the presence of tissues cysts in wild boar and roe deer was showed (Stollberg et al. 2021). Finally, prevalence in meat-producing animals varied among species and countries and is largely dependent on the methods of measure.

Prevalence of toxoplasmosis is highest in sheep and toxoplasmosis is implicated in 10–20% of sheep flocks with an abortion problem. The prevalence increases with age, reaching more than 90% in some studies (Tenter et al. 2000; Halos et al. 2010); the prevalence in ewes is more than twice than that in lamb. Viable *T. gondii* has been recovered from as many as 67% of sheep samples. Among the infected meat, lamb meat is supposed to be a major source of toxoplasmosis worldwide (Tenter et al. 2000). *T. gondii* has been recognized as one of the main causes of infective ovine abortion in New Zealand, Australia, the UK, Norway, and the USA (Dubey and Beatty 1988). Goats appear to be more susceptible to clinical toxoplasmosis, and even adult goats have died of acute toxoplasmosis.

Seroprevalence levels were lower in cattle, and very variable infection rates are found in pigs (1–60%) and poultry (0–30%), depending on their lifestyle (indoor or outdoor). In pigs, clinical cases of the infection are rare (leading to rare cases of myocarditis and encephalitis (Dubey and Jones 2008)), but the real problem of toxoplasmosis in pigs lies in the fact that tissues of infected animals may contain *T. gondii* tissue cysts. Infections with this parasite are common in pigs worldwide. The prevalence of *T. gondii* infection has decreased significantly with changes in pig production. It was suggested that infected pork products cause 50–75% of all cases of human toxoplasmosis in the USA, but the large study of Dubey et al. (2005) showed a seroprevalence of 0.57% and parasite isolation in only eight cases (0.38%). It is estimated that one pig is consumed by 200–400 individuals, and meat products are often made by combining the meat from different animals, thereby enhancing the risk of transfer of infection (Kijlstra and Jongert 2009). Moreover, an upsurge in consumer demand for "organically raised," "free-range" pork products has resulted in increasing numbers of hogs being raised in non-confinement systems. So, the prevalence of *T. gondii* in 33 market pigs raised under certified organic management conditions on two farms from Michigan, USA, was 90% (30/33) leading to the isolation of 17 strains (Dubey et al. 2012). This study indicated that organic pork meat may pose an increased risk of transmitting *T. gondii* to humans. Bayarri et al. (2012) have analyzed 50 samples of fresh pork meat and commercial cured ham collected in the city of Zaragoza (Spain), and *T. gondii* was detected in two samples of rib, reflecting a frequency of 8% positive fresh pork meat.

T. gondii has rarely been isolated from bovine tissue. It is unclear whether this is associated with fast elimination of cysts from cattle tissues or with inconsistent cyst formation following infection. In a study analyzing more than 2000 samples of beef, *T. gondii* was not isolated by bioassay in cat (Dubey et al. 2005). Moreover, a large French study reports a low prevalence in beef, but isolation of two strains (genotype II) was possible (Blaga et al. 2019). The prevalence of viable *T. gondii* in chickens produced in intensive farming is usually very low but may be high in free-range chickens. It is not known how many tissue cysts result in the infection of humans, but ingestion of one cyst is sufficient for a cat to become infected.

During the production of various meat products, meat of many animals is mixed, which also amplifies the risk in cases where only few animals would be infected (Aspinall et al. 2002).

Cases of acute toxoplasmosis and two recent outbreaks among hunters in Wisconsin and Illinois, USA, have already been linked to the consumption of insufficiently heated or raw game (Schumacher et al. 2021; Gaulin et al. 2020) underlining the risk of this kind of meat, as described a few years ago (Carme et al. 2002).

16.4.3 Genotype Distribution

In Europe, the majority of isolates from wildlife contain type II strains, with a few type III strains. From 26 *T. gondii* DNA extracts from red fox in Belgium submitted to a genotyping analysis with 15 microsatellite markers (Ajzenberg et al. 2010),

25 were type II, and only 1 type III (De Craeye et al. 2011). Similarly, using 6 loci microsatellite analysis, only type II strains were observed in 46 French isolates including 21 from wild boar (Richomme et al. 2009); 12 from roe deer; 9 from foxes; 1 from mouflon, red deer, and mallard (Aubert et al. 2010); and 1 from tawny owl (Aubert et al. 2008). Using the same molecular technique, Jokelainen et al. (2011) also identified the clonal type II in 15 DNA extracts from hare in Finland. In a recent study in Central and in Eastern Germany, Hermann et al. (2010) determined the complete genotype for 12 samples tissues from red foxes, using nine PCR-RFLP markers. Interestingly, this study showed evidence of a mixed infection, as well as infection with a *T. gondii* genotype that may represent a recombination of *T. gondii* types II and III. Su et al. (2006) developed a standardized restriction fragment length polymorphism (RFLP) typing scheme based on nine mostly unlinked nuclear genomic loci and one apicoplast marker. These markers enable one to distinguish the archetypal from atypical types. In addition, these markers can easily detect mixed strains in samples. Mixed infection of *T. gondii* strains in intermediary hosts has been previously reported (Ajzenberg et al. 2002a; Aspinall et al. 2002). In Svalbard, a Norwegian arctic archipelago, 55 artic foxes were found infected with *T. gondii*: 27 harbored clonal type II (17/27 were apico I and 10/27 apico II) and 4 had clonal type III (Prestrud et al. 2008). Strains from 22 foxes (40%) could not be fully genotyped, but 2 (3.6%) shared more than one allele at a given locus. Again, the most prevalent genotype in this study was clonal type II with a few types III genotypes. It is noteworthy that type II is also the dominant type in domestic mammals in Europe. For instance, Halos et al. (2010) analyzed 433 hearts of sheep by using PCR-restriction fragment length polymorphism and microsatellite markers on parasites isolated after bioassay in mice. All 46 genotypes belonged to type II, except for 1 strain from the Pyrenees mountains area, which belonged to genotype III, which is the first non-type II genotype found in sheep in Europe (Owen and Trees 1999) and Denmark (Jungersen et al. 2002). This similarity between strains found in wildlife and domestic species in Europe suggests that no clear separation exists between the two cycles.

In North America, strains of *T. gondii* are more diverse. A recent study analyzed 169 *T. gondii* isolates from various wildlife species and revealed the large dominance of the recently clonal type 12, followed by the type II and III lineages; these three major lineages accounted for 85% of strains from wildlife in North America (Dubey et al. 2011). The strains isolated from wildlife in North America are thus more diverse but may also be more different from strains found in the domestic environment than in Europe. Although type 12 has been identified from pigs and sheep in the USA, it may be more specifically found in wildlife (Su et al. 2012). The relative high diversity in *T. gondii* genotypes isolated from wildlife samples compared to those from domestic animals raised the question whether distinct gene pools exist for domestic and sylvatic hosts (Wendte et al. 2011).

This high genetic diversity in tropical wildlife in connection with a sylvatic life cycle has been firstly evoked in French Guiana where severe cases of human toxoplasmosis were detected after eating Amazonian undercooked game or drinking untreated river water (Darde et al. 1998; Carme et al. 2009). These cases were due to

highly atypical strains, all with a unique genotype, as determined by microsatellite analysis (Ajzenberg et al. 2004).

Finally, using multilocus genes sequencing (MLST) (in which the nucleotide sequences of several loci coding for housekeeping genes are analyzed) or whole genome sequencing, this diversity was shown to cluster into 16 haplogroups belonging to 6 ancestral groups (clades) and distributed throughout the world (Su et al. 2012; Lorenzi et al. 2016).

16.4.4 Most Frequent Sources for Human Infection: Case-Control Studies, Outbreaks

Different approaches have been used to estimate the relative importance of sources of contamination, using risk-factor analyses or estimation of the fraction of attributable risk, either in the general population (chronic infection) or in cases of seroconversion in pregnant women. These studies clearly identified the ingestion of undercooked meat as a risk factor (Cook et al. 2000; Kapperud et al. 1996; Baril et al. 1999; Berger et al. 2009). However, this result is probably partly due to this risk being easier to characterize than the risk due to oocysts. Several reports concerning toxoplasmosis outbreaks have been published in recent decades, mainly regarding outbreaks associated with the consumption of undercooked meat (Dubey 2022; AFSSA 2005). Moreover, it is difficult to link outbreaks due to *Toxoplasma* contamination, because most of infections are asymptomatic. In France, only few familial outbreaks were reported due to consumption of raw lamb (Ginsbourger et al. 2010).

However, outbreaks can be reported when infections are symptomatic due to virulent strains (from atypical genotype). In this way, previous studies demonstrated that game from the Amazonian forest was strongly associated with the risk of developing 10–20 days later severe toxoplasmosis (Carme et al. 2002). In French Guiana, atypical strains of *T. gondii* originating from a complex rainforest cycle involving wild felids have been linked to severe infections in humans, but these cases of Amazonian toxoplasmosis are sporadic, and outbreaks are rarely described. An outbreak of toxoplasmosis from December 2003 through mid-January 2004 involving 11 cases among the 38 inhabitants of a village in Suriname near the French Guiana border was described (Demar et al. 2007), and more recently another outbreak was reported linked to consumption of untreated water or meat or contact with soil (Blaizot et al. 2020). Severe toxoplasmosis after consumption of semi-raw game (Brazilian Tapir, locally known as Maipouri) was reported (Groh et al. 2012).

Recently, an emerging risk was observed in France with severe human infection transmitted by imported horse meat; the source of infection seems to be linked with consumption of raw horse meat from South America where atypical strains are circulating; these strains are virulent and responsible for severe congenital toxoplasmosis or death in immunocompetent humans (Pomares et al. 2011). This risk must be evaluated by survey of imported meat in large scale, and French authorities and EFSA are informed.

Moreover, severe toxoplasmosis was also observed after waterborne outbreaks due to contamination by oocysts. The first large outbreak was reported in British

Columbia, Canada, where drinking water taken from a reservoir was suspected to be contaminated by oocysts from cougar (Bowie et al. 1997). Unfortunately, oocysts were not detected after the outbreak in the reservoir. In contrast, *T. gondii* oocysts were isolated once in Brazil from samples taken from small reservoirs on roof tops. To assess this detection, the water was filtered through membranes, and the filters were fed to pigs and chickens, which developed toxoplasmic infection (de Moura et al. 2006). Although detection of oocysts in environmental samples is difficult (Dumetre and Darde 2007; Jones and Dubey 2010), methodological development is being made (Shapiro et al. 2019). Several methods to detect the presence of oocysts in filtered water is described using PCR to detect DNA (but not viable oocysts) from *T. gondii* after concentration (Kourenti and Karanis 2004; Villena et al. 2004). Oocysts can also contaminate vegetables and lead to human infection, but associated cases with identified vegetables are very rare. One case-control study of an outbreak of acute toxoplasmosis in Brazil was described with implication of escarole and green vegetables (Ekman et al. 2012).

While differentiating routes of *T. gondii* acquisition has been historically difficult, a recently recognized oocyst-specific antigen (Munoz-Zanzi et al. 2010) applied in a study of 76 mothers of congenitally infected infants in the USA demonstrated that 78% of these women had oocyst-acquired infections (Boyer et al. 2011).

Recently, a meta-analysis of the main identified and known risk factors for toxoplasmosis was published (Thebault et al. 2021). In this meta-analysis, the quality assessment stage was passed by 213 primary studies investigating risk factors for sporadic infection. The meta-analysis of toxoplasma sporadic infections revealed the significance of transmission by environmental factors such as drinking water, contact with soil, and contact with animals – in particular cats. The consumption of raw or undercooked meat and unwashed vegetables significantly increased the odds of acquiring the disease. Shellfish and raw milk were also identified as significant sources of toxoplasmosis. Almost all meat categories were identified as risk factors: pork, poultry, beef, processed meat, lamb, and game meat.

16.5 Impact on Public Health and Healthcare Decision-Makers

16.5.1 Implementation of Prevention Measures: Depending on Seroprevalence

16.5.1.1 Hygienic Measures

Hygienic measures can be recommended to seronegative patients (pregnant women or immunocompromised patients) to avoid *Toxoplasma* contamination. The prevention messages currently associate hygienic measures relative to the cat, to the consumption of well-cooked meat and thoroughly washed vegetables eaten raw, as well as to hands cleaning (Table 1). Drinking water has recently emerged as a new risk factor in some countries, depending on the source of the water supply network (surface or ground water) and on the sanitary level or the use of well water. Indeed, several outbreaks have been reported in Brazil, India, and Canada (Bahia-Oliveira et al. 2003; Bowie et al. 1997). Besides, ingestion of contaminated water from lakes or rivers during

Table 1 Hygienic measures according to prevention of *Toxoplasma* infection in seronegative population

Action or situation	Prevention measures
Cat contact	Wash hands carefully after stroking a cat Wear gloves when changing the cat litter Change the litter frequently and wash the tray with hot water (>60 °C) Avoid the litter in the kitchen
Meals	Cook the meat well-done or stew Avoid microwave cooking for meat Avoid raw vegetables at restaurants Avoid raw shellfish Avoid raw goat milk
Preparation of meals	Wash thoroughly vegetables, fruits, and herbs eaten raw, especially if they grow close to the ground Wash hands, knives, any containers, and table thoroughly after meat manipulation or cutting
Water	Prefer mineral water to tap water
Gardening or outdoor activities	Wash hands thoroughly and brush nails after any outdoor activities in contact with soil Wear gloves for gardening Avoid ingestion of water during recreation activities in lakes or rivers

recreational activities has been recently stressed out as a potential source for *Toxoplasma* infection (Jones and Dubey 2010), which could explain the large proportion of unexplained toxoplasmosis in pregnant women as shown in a study in Northern USA (Jones et al. 2009). The environmental contamination by wild felids is more difficult to master, but basic hygienic measures during or after external activities can help to overcome the risk. Finally, the trends of biologic food consumption should not lead to hazardous behavior, and it is worth being reminded that, even marginal, unpasteurized goat milk or raw shellfish can also be food at risk (Jones et al. 2009).

Recent knowledge on strain virulence should be taken into consideration, and these recommendations should now be applied to travelers who are visiting countries where virulent strains predominate, such as South America or Africa, even if they were previously immunized.

16.5.1.2 Serologic Screening

Serologic screening of pregnant women has been proposed to reduce the burden of congenital toxoplasmosis and has been implemented in France in 1987, with repeated monthly testing of seronegative women from 1992. The rationale of this approach relies on the possibility to perform a prenatal diagnosis and to treat the mother in case of seroconversion. Intuitively, this approach is pertinent when the seroprevalence is relatively high; thus the probability of infection during pregnancy is also high. Conversely, a low prevalence of the disease overweighs the cost of such public health policy. Therefore, the cost-benefit ratio should be carefully evaluated before the implementation of such screening measures. Other countries have a screening policy (Austria, Belgium, Italy, Lithuania, Slovenia) (Benard et al. 2008), but the frequency of serologic testing may vary from one- to three-monthly

testing. Some countries do not recommend this screening (the UK, Norway, Finland, and more recently Switzerland), arguing either for a too high cost or maternal stress in case of diagnosing a seroconversion or even fetal risk associated with amniocentesis. In France, a trend towards a regular decrease in seroprevalence has been observed since the 1970s and has been measured through three national perinatal surveys in 1995 (55%), 2003 (44%), and 2010 (37%), thus questioning the cost of maintaining a full screening of seronegative women (Robinson et al. 2021).

Postnatal screening of neonates at risk is another option, which has been implemented in some countries where prenatal screening was not considered to be a health priority, as is the case in Sweden, Denmark, Poland, or the USA (Massachusetts, New England). It allows the treatment of infected neonates in the aim to reduce the development of eye or neurologic sequelae. The cost of such screening has been also debated in Denmark, where it was estimated that the low burden of disease (1.6 per 10,000 live-born infants) did not justify continuing neonatal screening (Roser et al. 2010). In contrast, two cost-benefit analyses (CBA) found prenatal retesting for toxoplasmosis to be cost saving, one with the hypothesis of applying the French screening protocol in the USA (Stillwaggon et al. 2011) and the other examining the Austrian screening protocol (Prusa et al. 2017).

As for congenital toxoplasmosis, there is no consensus about serologic screening in immunodeficient patients, yet an annual serologic testing is usually recommended in HIV-infected patients previously seronegative for *Toxoplasma*. Prevention messages on how avoiding contamination should also be the rule, as for pregnant women. A chemoprophylaxis is recommended when CD4+ T cells is under 200/μL.

In transplant patients, the decision of *Toxoplasma* antibody screening varies highly among countries and is again mostly explained by the differences in the incidence rate of toxoplasmosis. A case-control study (Fernandez-Sabe et al. 2011) showed that primary infection observed in about solid organ transplant patients was due to a mismatch D+/R- in about half of patients, emphasizing the interest of primary prevention through both donor/recipient screening and hygienic measures. In France, serologic screening of the organ donor is mandatory and is strongly recommended (in practice, always done) in the recipient, whereas in the USA serologic screening of donors and recipients greatly depends on the transplant center. Serology of the donor is also routinely performed in 11 European countries (Derouin and Pelloux 2008). The knowledge of both recipient and donor serologic status allows starting primary chemoprophylaxis at the time of transplantation in case of a mismatch, particularly for heart transplant patients. More detailed information on the risk and prevention can be found in a recent review (Robert-Gangneux and Darde 2012).

16.5.2 Impact of Prevention and Screening on the Burden of Disease: Congenital Toxoplasmosis

A French retrospective study by Wallon et al. (2013) estimated the incidence of congenital transmission and the proportion of severely impaired infected neonates before and after onset of screening policy associated with prevention measures and maternal treatment, i.e., before and after 1992, respectively. They clearly found a

significant impact of monthly mandatory re-testing of seronegative women on the transmission rate of congenital infection, as well as an impact of treatment strategy adapted to prenatal diagnosis. The continuous treatment of women with positive prenatal diagnosis with pyrimethamine-sulfadiazine significantly reduced the severity of clinical signs in infected children.

In the USA, several longitudinal clinical studies showed that newborn postnatal screening and treatment were associated with better neurologic and developmental outcomes (Roizen et al. 1995; McLeod et al. 2006; Darde et al. 1992). By contrast, in ancient series, untreated infants, although asymptomatic at birth, developed high rates of ocular lesions or neurologic sequelae or suffered from recurrent episodes of retinochoroiditis (72%), despite spot treatment at time of diagnosis and at each recurrent lesion (Phan et al. 2008). More recently, Stillwaggon et al. (2011) evaluated the societal cost of congenital toxoplasmosis and concluded that implementation of a similar prevention program as that currently applied in France (maternal serologic screening, prenatal diagnosis and treatment) would be cost-saving at the scale of the USA, even if the seroprevalence is low, with an infection rate of 1 per 10,000 live births. However, the pattern of infection in North America could be more harmful than previously suspected, probably related to the genotypes of circulating strains. This study estimated the cost of mild vision loss and of severe toxoplasmosis at a rate of 500,000 US$ and 2.7 million $, respectively.

The role of the epidemiology of parasite strains in North America has recently been discussed because of the discovery of the circulation of type non-II strains, which could be more virulent than those responsible for toxoplasmosis in Europe (McLeod et al. 2012). It has been hypothesized that the disease burden in the USA could be due not only to the absence of prenatal management or postnatal treatment. However, the important preventive role of healthcare policies in the decrease of the burden of toxoplasmosis in France cannot be denied, and a recent cost effectiveness study modeling the monthly retesting programs vs. neonatal screening has demonstrated the benefit of the French prenatal screening program (Binquet et al. 2019).

Trichinella and Trichinellosis: From Wildlife to the Human Beings

17

Edoardo Pozio and María Ángeles Gomez Morales

Contents

Abstract

Trichinellosis is a cosmopolitan infection transmitted to humans through the consumption of raw or undercooked meat of domestic and wild pigs, horses, and carnivorous animals infected by nematode larvae of the genus *Trichinella*. These parasites are maintained in nature by a sylvatic cycle. Spillover from wild animals to domesticated animals can occur when there is improper management in segregating livestock and wildlife. The symptoms associated with trichinellosis vary with the number of infecting larvae ingested, the time after infection, and the *Trichinella* species. Progression of the disease follows the biological development of these

nematodes. Most of the clinical features of trichinellosis are immunopathological in origin and are related to the capacity of these parasites to induce allergic responses.

Keywords

Trichinellosis · Trichinella · Meatborne disease · Swine · Game meat

17.1 Introduction

Trichinellosis is a foodborne disease caused by infection with nematode worms of the genus *Trichinella*. Infection results from the ingestion of meat of mammals, birds, and reptiles harboring the infective larvae of the parasite (Gottstein et al. 2009). The disease has long been known as trichinosis because the parasite genus was formerly called *Trichina* (Pozio 2021a). Today, the term trichinellosis has gained wide acceptance internationally. The parasite that causes trichinellosis was discovered in the United Kingdom in 1835. It was first observed in human muscles during a routine autopsy and was regarded as a mere zoological curiosity for a long time (Gaeta and Bruschi 2021). The worm was originally named as *Trichina spiralis* Owen, 1835. In 1895, the genus name was changed to *Trichinella* (Pozio 2021a). In 1860, *T. spiralis* was found in the muscle tissues of a patient who had died of a serious painful muscle disease, and this important case revealed both the pathogenicity of this zoonotic parasite and the link between the disease and the ingestion of undercooked pork. During the latter part of the nineteenth century, the essentials of the life cycle were worked out, and the pathogenicity of this roundworm was shown dramatically by several severe outbreaks in Germany (Gaeta and Bruschi 2021).

This group of zoonotic parasites shows a cosmopolitan distribution in all the continents except Antartica (Pozio and Zarlenga 2013). Today, 13 taxa separated into two clades are recognized in the genus (Zarlenga et al. 2020), one clade that encompasses species that encapsulate in host muscle tissues following muscle cell reprogramming and a second clade that does not encapsulate. The species and genotypes of the first clade parasitize only mammals. Among the three species that comprise the second clade, one infects mammals and birds (*Trichinella pseudospiralis*) and two parasitize mammals and reptiles (*Trichinella papuae* and *Trichinella zimbabwensis*) (Zarlenga et al. 2020).

These parasites are unusual among other nematodes in that the worm undergoes a complete developmental cycle, from larva to adult and then to larva, in the body of a single host, which strongly influences the epidemiology of these parasites and the human disease. When the cycle is complete, striated muscles of infected animals and humans contain a reservoir of larvae, capable of long-term survival. Animals and humans acquire the infection by ingesting muscle tissues infected by viable larvae.

17.2 Taxonomy

For more than 100 years, the genus *Trichinella* was considered monospecific, and *Trichinella spiralis* was considered the only species with a cosmopolitan distribution, infecting a very large number of mammals including humans. The domestic

cycle involving grazing domestic pigs and farm rats was considered the predominant mode of circulation for *T. spiralis*; surrounding wildlife were considered as an ancillary part of on-farm transmission. The expansion of helminthological investigations on wild animals starting from the 1950s highlighted the presence of nematodes of the genus *Trichinella* with biological characters different from those of *T. spiralis*, but without discernable morphological characters at any of the developmental stages that could be used to differentiate species (Pozio and Zarlenga 2021). The switch from a classical taxonomy to new taxonomic studies first based on crossbreeding experiments in laboratory animals, and then on biochemical (allozymes) and molecular characters, has allowed the identification of ten sibling species and three genotypes divided into two clades based on the presence or absence of a collagen capsule around the muscle larva. The clade in which the muscle larvae do not induce capsule formation infects mammals and birds (*T. pseudospiralis*) or mammals and reptiles (*T. papuae* and *T. zimbabwensis*). The clade characterized by the presence of a collagen capsule around the nurse-cell-larva complex infects only mammals. This clade is comprised of seven species (*T. spiralis*, *T. nativa*, *T. britovi*, *T. murrelli*, *T. nelsoni*, *T. patagoniensis*, and *T. chanchalensis*) and three genotypes (*Trichinella* T6, T8, and T9). Each taxon is characterized by a well-defined distribution area; however, there are two species which, for different reasons, have a cosmopolitan distribution: *T. spiralis* spread by the passive introduction of infected swine in most continents and *T. pseudospiralis* spread by birds worldwide. Carnivores are the main hosts of *Trichinella* species and genotypes, with the exception of *T. spiralis* which is also very well adapted to swine and consequently represents the main causative agent of human trichinellosis. This taxonomic scheme is supported by the analysis of more than ten thousand *Trichinella* isolates from different host species and continents. However, there remain some geographical areas from which no *Trichinella* parasites have been collected and identified at the species/genotype level such as Central America and most of South America and India. The phylogeny of the genus showed that the encapsulated and non-encapsulated clades diverged from their most recent common ancestor in Asia about 21 million years ago (mya) with taxon diversifications commencing about 10–7 mya. The currently described thirteen *Trichinella* taxa cannot be identified by their morphology at the species or genotype level. Each taxon can be reliably identified only by molecular methods (Pozio and La Rosa 2010; Sharma et al. 2020; Zarlenga et al. 2020).

17.3 Natural Cycle and Parasite Biology

Nematodes of the *Trichinella* genus develop two generations of worms in the same host. Gravid female worms (1.26–3.35 mm × 29–39 μm) embedded in the intestinal mucosa produce newborn larvae (NBL, 110 × 7 μm) which migrate into the lymphatic vessels and then enter the blood vessels to reach and penetrate striated muscle cells. In the muscle cell, NBL develop to the infective L1 (the muscle larva measure 0.65–1.1 mm × 25–40 μm) in about 15 days without making any molt unlike other nematodes (Despommier 1998). In muscle cells, larvae are coiled and

enclosed by a collagen capsule (encapsulated species) or appear to be free among the muscle fibers (nonencapsulated species). The size of the collagen capsule is about 350–450 × 180–300 μm. In this ecological niche, larvae can survive for many years (over 20 years in polar bears and up to 40 years in humans) waiting to be ingested by a new host. When a new host ingests infected muscle tissues, the larvae are released from the muscle cells in the stomach by digestion. In the duodenum, they penetrate the villi and within 2 days undergo four molts and rapidly develop to the adult stage. Males and females copulate, and within 6–7 days postinfection (p.i.), the females begin to produce NBL for at least 1–2 weeks or longer as influenced by the host's immune response at the gut level, which usually develops and results in the adult worm expulsion.

17.4 Epidemiology

17.4.1 In Animals

Trichinella spp. are prevalent in wildlife. The transmission cycles of the different *Trichinella* species and genotypes are closely related to their host species' biology and environmental characteristics. Predation probably accounts for the transmission of these pathogens in some instances, but the eating of carrion is of great epidemiological significance. Carnivores are the main reservoir hosts in the wild. Human behavior can strongly influence the sylvatic cycles both favoring and reducing the transmission of *Trichinella* spp. Carcasses of *Trichinella* sp.-infected animals left by hunters in the field after skinning, removing, and discarding the entrails, or road accidents represent a great biomass of these parasites readily available to the wild cycle. Epidemiological surveys carried out in Africa, Europe, and North America have shown that *Trichinella* spp. are more prevalent in wild animals living in natural or undisturbed areas such as parks and forests, protected areas, and mountainous regions, where human activity has not strongly modified the habitat (Pozio and Murrell 2006). Spillover from wild animals to domestic animals can occur when there is improper management in segregating livestock and wildlife (Pozio and Murrell 2006). There is no documented evidence of infection in pigs reared in herds kept under controlled management conditions (Pozio 2014). *Trichinella spiralis* is the species more adapted to swine, and, consequently, it is the species more frequently detected in domesticated pigs. The domestic and the sylvatic cycles can function either independently from each other or interactively. The term "domestic cycle" refers to the transmission pattern where the focus is on a swine herd being fed, e.g., uncooked pork scraps, carrion, uncooked garbage (i.e., garbage-fed pigs), or the pigs can feed on carcasses that are not promptly removed from the farm; transmission can also become domestic via synanthropic animals (e.g., rats and mustelids) living near swine herds (Pozio 2014). Horses fattened with pork scraps or with carcasses of carnivorous animals became infected with *Trichinella* spp. The use of *Trichinella*-infected meat of slaughtered crocodiles or farmed fur mammals (e.g., foxes) to feed other farmed crocodiles or foxes, respectively, has been reported

(Pozio and Murrell 2006; Pozio 2021b). Since nematodes of the genus *Trichinella* are mainly circulating among wildlife and backyard or free ranging pigs, these pathogens do not represent a great concern for the international meat trade. From the 1950s to today, according to the international literature, there are only 43 reports describing the importation of *Trichinella* sp.-infected animals or meat by the international trade to Europe. Most (60%) of these reports refer to live horses or their meat, 18.6% to pigs, 4.7% to wild boar, and 14.3% to bears. In contrast, the scientific literature is rich of reports on meat from pigs, wild boar, and bears, illegally introduced in personal baggage causing trichinellosis outbreaks in several European countries (Pozio 2015).

17.4.2 In Humans

The most common source of infection for humans is pork and pork-derived products from backyard and free-ranging pigs, wild boar, wild pigs, warthog, and bushpig; other sources responsible for outbreaks and single infections include meat and meat-derived products of horse, dog, bear, walrus, cougar, fox, badger, and jackal (Pozio 2014, 2021b; Rostami et al. 2017). Suspected meat sources were from soft-shelled turtle, monitor lizard, and squirrel. Among domestic animals, the meat of sheep and beef has been considered as the source of trichinellosis in China; however, *Trichinella* sp. larvae have never been detected in naturally infected sheep and cattle, suggesting that herbivorous animal meat may be mixed with infected meat from other sources and sold in restaurants and stores. With the exception of *T. zimbabwensis*, *Trichinella* T8, *T. patagoniensis*, and *T. chanchalensis*, all other species and genotypes of *Trichinella* have been reported from humans. In 2007, an average yearly incidence of ten thousand trichinellosis infections with a mortality rate of 0.2% was estimated, cumulating the highest number of infections detected worldwide in a year (Pozio 2007). Reliable estimates of the incidence of trichinellosis among humans and its effect on health were investigated between 1986 and 2009 in a systematic review of the international and grey literature (Murrell and Pozio 2011). During this period, 65,818 cases and 42 (0.06%) deaths were reported from 41 countries. The WHO European Region accounted for 87% of cases; 50% of those occurred in Romania, mainly during 1990–1999. The incidence in this country ranged from 1.1 to 8.5 cases per 100,000 inhabitants. Trichinellosis affected primarily adults (median age 33.1 years) and almost equally men (51%) and women. Out of 196 officially recognized countries in the world, *Trichinella* spp. infections in humans, acquired through the consumption of local animals, have been documented in 47 (23.9%) countries in the last 20 years (Pozio 2021b). *Trichinella* sp. infections in humans are more related to cultural food practices which include dishes based on raw or undercooked meat of different animal origins than to the presence of the parasite in the domestic and wild animals of the country. Muslim countries are not exempted from trichinellosis. The largest outbreak (about 500 infected people) occurred in Izmir (Turkey) for the consumption of meatballs fraudulently made with beef and pork from domestic pigs infected by *T. britovi* (Akkoc et al. 2009).

In France and in Italy, most of the trichinellosis cases are due to the consumption of raw horse meat, because this food habit is strongly related to the French culture imported also in Italy (Boireau et al. 2000; Pozio 2015). In Finland, where there is a high prevalence of infection in animals, no infection leading to disease has been documented in humans, due to the practice of eating only well cooked meat (Pozio 2007). In Romania, the highest prevalence of trichinellosis in humans occurs in the Transylvanian region, which was colonized by German people who have kept their food habits which are known to be risk factors for trichinellosis (Blaga et al. 2007). In the European Union (EU), the number of human cases and the notification rate (per 100,000 population) have been kept low from 2015 to 2019. The highest rate (0.03%) was reported in 2015 and 2017 and the lowest rate in 2018 (0.01%), which was the lowest rate ever reported since the beginning of *Trichinella* surveillance at the EU level in 2007. One death due to trichinellosis was reported in Portugal in 2019, resulting in an EU case fatality of 4.2% (EFSA 2021). In Israel, Lebanon, and Syria, human outbreaks of trichinellosis have been documented following consumption of pork from wild boars only among the Christian populations or immigrants from Thailand (Pozio 2007). In Algeria and Senegal, where the majority of the human population is Muslim, trichinellosis has only been documented in expatriates from France and very seldom in the local population. The migration of persons from eastern to western countries of Europe has resulted in several human outbreaks of trichinellosis in Denmark, Germany, Italy, Spain, and the United Kingdom (Pozio and Marucci 2003; Gallardo et al. 2007; Stensvold et al. 2007). The increasing number of international travelers has resulted in many reports of tourists who acquired *Trichinella* sp. infections for the consumption of warthog meat in Africa; of bear meat in Canada and Greenland; of pork in China, Egypt, Indonesia (Bali Island), Laos, and Malaysia; and wild boar meat in Turkey and Algeria (Pozio and Murrell 2006). In developed countries of North America and Europe in the last 20 years, there was a switch of the source of trichinellosis from pork and derived products to wild game meat (Rostami et al. 2017; Pozio et al. 2019).

17.5 Clinical Aspects

17.5.1 In Humans

The incubation period exhibits a variable length related to the number of larvae ingested, frequency of consumption of infected meat, type of meat consumed (raw, semi-raw), and the involved *Trichinella* species. The length of the incubation period ranges from 2 to 45 days (Table 1). It is generally thought that the shorter incubation period is correlated with a worse prognosis.

The clinical picture reflects the parasite cycle in the human body. In the early phase of the infection, i.e., during the intestinal phase, the most common sign and symptom are diarrhea and abdominal pain, which may be absent in individuals with a mild infection. The stools that can be loose up to 10–15 times a day are greenish brown in color and frequently with an admixture of mucus but containing no blood. Persistent diarrhea usually causes deterioration in the patient's general conditions,

Table 1 Clinical symptomatology, laboratory features, and convalescence in the course of trichinellosis

Clinical symptomatology	**Severity of the infection**	**Weeks p.i.**[a]
Enteral phase (diarrhea, nausea, vomiting)	Severe	0.5/5
	Moderate	1/3
	Mild	
Parenteral phase		
Myalgia	Severe	1.5/8
	Moderate	2/6
	Mild	2/5
Fever	Severe	1/6.5
	Moderate	2/5.5
	Mild	2/3.5
Periorbital edema, conjunctivitis	Severe	1/6
	Moderate	1.5/5.5
	Mild	1.5/4.5
Laboratory features		
Eosinophilia	Severe	1.5/10
	Moderate	2/8.5
	Mild	3/7
CPK	Severe	1.5/8
	Moderate	2.5/6
	Mild	3/5.5
Anti-*Trichinella* IgG	Severe	3–4/years
	Moderate	3–4/years
	Mild	4–6/15–20
Convalescence	Severe	6/16
	Moderate	5/12
	Mild	5/9

[a]Week of onset/disappearance

leading possibly to dyselectrolytemia and marked hypoproteinemia. Nausea and vomiting usually appear during the first days of the infection. This symptomatology usually precedes fever and myalgia by 3–4 days and then disappears in less than 1 week. The frequency of gastrointestinal disturbance is estimated at 6–60% of cases in various foci of trichinellosis. General weakness, chills, and headache are accompanied by fever (occasionally up to 40 °C), which may be continuous and persist up to 3 weeks during the acute phase in severe clinical forms. In mild cases, subfebrile body temperatures are frequently noted, which disappear after a few days of effective treatment. The frequency of fever varies from 41% to 100% of cases in various foci of the disease. Profuse sweating is frequently reported in trichinellosis (Kociecka 2000; Dupouy-Camet et al. 2002).

The parenteral or muscular phase (also known as systemic phase) corresponds to the acute phase of the infection, and it is associated with inflammatory and allergic responses caused by the larvae during migration and invasion of the skeletal muscle cells. Symmetrical eyelid and periocular edema frequently develop in 17–100% of

the patients, and the edema can involve the entire face. In severe cases, edema may even extend to the upper and lower extremities and usually vanishes in 5–6 days, particularly after glucocorticoid treatment. Eyelid edema is usually accompanied by conjunctival hyperemia, itching, lacrimation, and, occasionally, light intolerance. Eye pains upon ocular movements have been observed in around 77% of patients. Also, disturbed sight acuity and sometimes bilateral exophthalmia deserve attention. Nystagmus, reflecting involvement of ciliary muscles of patients, may occur. Approximately 25% of patients exhibit petechiae and subungual hemorrhages. Early symptoms develop at varying intervals and intensity. They also do not disappear in a defined constant sequence (Pozio et al. 2003).

Muscle pain involves various groups of muscles, and the intensity reflects the severity of the disease course. Pain develops in nuchal and trunk muscles, in the muscles of the upper and lower extremities, and less frequently in masseter muscles. It affects patients during execution of movements (particularly in lower extremities), while spontaneous pain is less frequently observed. Moreover, most persons with severe trichinellosis or phlebitis associated with trichinellosis also experience myalgia at rest. In some patients with severe course, adynamia dominates, which may persist for a long time, reflecting pronounced intensity of angiomyositis-type pathology or neuromuscular disturbances. Severe myalgia generally lasts 2–3 weeks (Pozio et al. 2003).

Itching and numbness or tingling sensation in various muscle groups frequently manifest together with muscle pain. Restricted motility due to muscle pain associated with movements may lead to contractions, particularly in knee and elbow joints, nuchal pseudorigidity, and difficulties in opening the mouth. The signs gradually subside during convalescence, to arrive to complete regression, especially with the aid of physiotherapy.

Fever, eyelid and periorbital edema, and muscle pains form the principal set of clinical signs/symptoms of trichinellosis. They are usually accompanied by hypereosinophilia and by high white blood cell counts. A correlation between the eosinophil levels and serum muscle enzymes such as lactate dehydrogenase (LDH) and creatine phosphokinase (CPK) has been observed in these patients. According to a retrospective survey on trichinellosis outbreaks involving 5377 cases, carried out worldwide during 1986–2009, the typical clinical signs of trichinellosis were myalgia, diarrhea, fever, facial edema, and headaches that, after treatment, disappeared within 2–8 weeks. Their rapid recovery reflects improvements in diagnostic methods and drug treatment (Murrell and Pozio 2011).

17.5.1.1 Complications

Complications usually develop within the first 2 weeks in severe cases but also in moderate cases, for individuals improperly treated, or those for whom the treatment was started too late. A positive correlation has been observed between age and the frequency and severity of complications (Dupouy-Camet et al. 2002).

Cardiovascular disturbances can occur in moderate or severe cases, usually between the third and fourth week p.i. (Compton et al. 1993; Lazarević et al. 1999; Puljiz et al. 2005; Neghina et al. 2010; Messiaen et al. 2016). Myocarditis develops in 5–20% of symptomatic persons. The symptoms include pain in the heart region, tachycardia, and electrocardiogram abnormalities. (i.e., flattened T waves,

decreased ST, lowered QRS complex, acute Q waves, and disturbances in atrioventricular or interventricular conduction). Intensity of the signs/symptoms depends upon the time at which therapy was started and the health condition before the larval invasion began. Pain in the heart region (6.2%) and tachycardia (22.1%) occur, with a possible evolution to a fatal ventricle fibrillation (Pozio et al. 2003). Thromboembolic disease can also occur, specifically deep thrombophlebitis, intraventricular thrombi, and/or pulmonary embolism, which can all be fatal. Sudden death may result from embolism of the pulmonary artery (Kociecka 2000).

Neurological complications (neurotrichinellosis; Bruschi et al. 2013) include a variety of signs and symptoms (Ellrodt et al. 1987; Fourestie et al. 1993; Bruschi et al. 2013) and have been reported in 3–46% of patients, depending on the outbreaks. Persons with severe disease can show consciousness disorders or excessive excitement and frequently somnolence and apathy; some of the persons with these symptoms show signs of meningitis or encephalopathy. Dizziness, nausea, and tinnitus are transient. Anisocoria, facial nerve paresis, and Babinski reflex have also been observed in severe cases. Brain damage, which is usually observed within a few days after the onset of fever, can result in diffuse encephalopathy or focal signs such as disorientation, memory disturbances, frontal syndrome, behavioral disturbances, transient hemiparesis or hemiplegia, oculomotor dysfunction, aphasia, and cerebellar syndrome. Small hypodensities are seen with the computer tomography (CT) scan or magnetic resonance imaging (MRI) (Fourestie et al. 1993; Feydy et al. 1996). In most persons with neurological complications, there is an improvement of focal lesions within 2–4 weeks p.i. Most CT scan or MRI brain abnormalities disappear in 4–8 weeks p.i. Neurological complications could be less frequent if the infected person is treated early. Neurological complications and myocarditis, which are both life-threatening, are often simultaneously present (Fourestie et al. 1993).

Complications of the ocular lesions include edema and altered microcirculation at the level of the uvea, the retina, and, in some cases, in the optic nerve. Rarely, lesions of the retina may be induced by migrating *Trichinella* larvae, which penetrate ciliary arterioles and the central artery of the retina, leading to irreversible damage to eyesight. An intense invasion of the muscles of the ocular bulb provokes pain when moving the eyeballs, muscle paralysis, diplopia, or a disturbed accommodation (Pozio et al. 2003).

Dyspnea is relatively common and is caused primarily by parasite invasion and subsequent inflammation of respiratory muscles such as the diaphragm. Respiratory complications are uncommon. They can occur during both the early and late stages of trichinellosis. They consist of pneumonia, obstructive bronchitis, or Löffler-type infiltrates.

Digestive complications occur during the acute stage of infection, and they consist of massive proteinic exudation leading to hypoalbuminemia and localized edemas, acute intestinal necrosis, or prolonged diarrhea (Dupouy-Camet et al. 1998).

Death is rare. Of the more than 6500 infections reported in the EU from 1980 to 2005, only five fatalities were documented, all due to thromboembolic disease, in individuals over 65 years of age; deaths have been reported in two large outbreaks which involved more than 1000 cases (Ancelle et al. 1988). In a study period of 24 years (1986–2009), 42 deaths occurred worldwide (Murrell and Pozio 2011).

Most of the deaths were caused by *T. spiralis* due to its high pathogenicity to humans; less than 20 deaths were caused by other taxa (*T. nativa*, *T. murrelli*, *T. nelsoni*, and *T. papuae*) reported to have caused infections in humans.

The chronic stage begins when the adult females cease to release migrating larvae, and those already established have completed their development into the muscle cells. The transition to this stage is characterized by the progressive disappearance of the signs and symptoms of the disease and by the return of laboratory parameters to normal values. This stage usually begins between the sixth and the 8 week p.i., but infected persons might still have a severe asthenia for several weeks and chronic muscular pain for up to 6 months. Most persons will then become asymptomatic, although live larvae will persist in their muscles for years if they are not properly treated.

17.5.2 In Animals

Trichinellosis in animals has only been observed in the course of experimental infections, for both the acute and the chronic stages of the disease. In naturally infected pigs and horses, no clinical signs of trichinellosis can be observed. This makes control and prevention difficult, since farmers may mistakenly think that infected animals are healthy, as their appearance and growth remain within normal parameters. Significant differences in weight gain (10–15%) were observed in domesticated pigs experimentally infected with *T. spiralis* larvae from 40 to 100 days p.i. in comparison with uninfected animals (Ribicich et al. 2007). The impact of *T. spiralis* infection on weight gain was observed in pigs (Ribicich et al. 2007) but not in wild boar (Lacour et al. 2013). In experimentally infected horses, transient muscular disorders were observed, but none of the horses had fever (Soule et al. 1989).

17.6 Diagnosis

17.6.1 In Humans

The diagnosis of trichinellosis should be based on anamnesis (e.g., raw meat consumption), clinical signs and symptoms, and laboratory tests (immunodiagnosis or muscle biopsy). According to the European Centre for Disease Prevention and Control case definition, any person meeting the clinical criteria (i.e., at least three of the following six criteria: fever, muscle pain, diarrhea, facial edema, eosinophilia, and subconjunctival, subungual, and/or retinal hemorrhages) with an epidemiological link is considered as a probable case. Any person meeting the clinical criteria and the laboratory criteria (antibody response specific to the *Trichinella* spp. detected using indirect immunofluorescent assay (IFA), enzyme-linked immunosorbent assay (ELISA), or Western blot (WB) is considered as a confirmed case (European Commission 2018). The International Commission on Trichinellosis (ICT) recommends ELISA for screening followed by WB to confirm ELISA-positive sera. Both tests should use excretory/secretory products as antigens, which are obtained from in vitro maintenance of *T. spiralis* muscle larvae. These antigens recognize anti-*Trichinella*

antibodies produced against the larvae of all species (Bruschi et al. 2019; Gómez-Morales et al. 2012). Seroconversion occurs between 12 and 60 days p.i. To recover the larvae for species identification or confirmation of infection, muscle biopsy (0.2–0.5 g of muscle tissue) should be collected preferentially from the deltoid muscle. *Trichinella* larvae can be detected in the biopsy by compressorium, HCl-pepsin digestion, or histological analysis. The collection of the muscle biopsy is seldom because it is an expensive, invasive, and a very painful method.

17.6.2 In Animals

According to the European Commission (2015) or the ISO 1870/2015, the artificial digestion of a muscle sample collected from preferential muscles or an equivalent method should be used to test the presence of *Trichinella* larvae in meat from all *Trichinella*-susceptible animals intended for human consumption, unless carcasses have undergone a freezing treatment. For species or genotype identification, a single multiplex PCR is recommended by the ICT (Pozio and Zarlenga 2021). Serological tests are recommended only for epidemiological studies, since animal hosts can harbor infective larvae before antibodies are detectable. On the other hand, for some species (*T. britovi* and *T. pseudospiralis*), the persistence of muscle larvae in the muscle is shorter than that of specific antibodies (Pozio et al. 2020). For these reasons, serological methods should not be used for the detection of *Trichinella* infection in individual food animal carcasses to assure food safety (Gajadhar et al. 2009; Gamble et al. 2004).

17.7 Therapy

The two drugs of choice are mebendazole (25 mg/kg 2–3 times day for 15 days) and albendazole (20 mg/kg 2–3 times a day for 15 days). Corticosteroids should be used for symptomatic treatment (e.g., prednisolone 30–60 mg/day) and always in combination with anthelmintic, but caution should be exercised due to the possibility of anaphylactic shock (Dupouy-Camet et al. 2002). Treatment with benzimidazoles is very effective during the intestinal phase, and as the development of the larvae progresses, the treatment becomes less and less effective (Pozio et al. 2001).

17.8 Prevention

Since parasites of the genus *Trichinella* circulate mainly among wildlife, the main preventative measures for farmed animals are to avoid the following: (1) access to wild animal carcasses, their scraps, and offal to domesticated animals; (2) the use of wild animal carcasses, their scraps, and offal for feeding domesticated animals; (3) access to pig carcasses, their scraps, and offal to domesticated animals; and (4) free range of domesticated pigs in the wild (Office International des Epizoties 2013; Pozio 2014). The best result to prevent *Trichinella* sp. transmission in the farm

and, at the same time, to prevent many other zoonotic and non-zoonotic infectious diseases at the farm level has been obtained from breeding pigs in high containment level farms, which must be periodically monitored by an independent body. An excellent example is represented by the European Commission (2015).

To reduce the spread of *Trichinella* sp. among wild animals, public health services must educate hunters not to leave the carcasses or parts thereof of hunted animals on the ground or in unfenced waste dumps. Carcasses of animals killed by cars should be quickly removed, and wild animals should be prevented from accessing food waste dumps.

17.8.1 Prevention at the Consumer Level

Consumer education about the cause and mode of *Trichinella* worm transmission gives the ability to avoid infection by eschewing meat that has not been frozen or cooked thoroughly. Ethnic or cultural practices that entail special risk may call for special educational measures. Cooking meat at an internal temperature of 70 °C kills the larvae in 1 minute, that is, when the meat color switches from pink to brown. Grilled meat or meat-derived products (e.g., sausages) can be at high risk, because larvae can survive in uncooked muscle portions in the core of the product or close to bones. Microwaves cannot be considered secure to kill *Trichinella* sp. larvae. Freezing meat is also an alternative way to kill the larvae, but the freezing time and freezing temperature should be monitored in the core of the meat products with a recording system. The use of a home freezer can represent a risk, because the temperature is not controlled, and frequent thermal shocks due to its frequent daily use may occur. Furthermore, muscle larvae of some *Trichinella* species can survive freezing for a long period of time; in fact, human infections caused by the consumption of previously frozen wild boar or bear meat have been documented (Gari-Toussaint et al. 2005; Houzé et al. 2009).

The survival time of *Trichinella* larvae in cured meat products is strictly related to the curing time and curing conditions. In industrialized products, fermentation or drying kills larvae in two weeks, that is, once the water activity value is reduced to 0.90, one could assume that *Trichinella* larvae are no longer infective (Porto-Fett et al. 2010). At high risk, there are homemade meat products from game and from free-ranging and backyard pigs, since the curing conditions and the curing times are not controlled and the prevalence of infection can be quite high in these animals. *Trichinella* larvae survive in meat for a long period of time under vacuum, lard, oil, or other substances that prevent dehydration.

17.9 Investigations in the Course of Trichinellosis Outbreaks

As previously reported, the clinical picture of trichinellosis is very complex and difficult for physicians to interpret, if they have no previous experience. Generally, *Trichinella* infection affects a group of individuals who have consumed the same

food based on raw or undercooked meats or their derivate products (e.g., sausages, salami). Single cases of trichinellosis are very rare and often appear as such only because a single individual has consumed a large amount of meat infected by a low number of larvae. Consequently, individuals who have consumed less of the same meat are asymptomatic or pauci-symptomatic. The intestinal phase hardly comes to the attention of physicians. It is the invasive phase which, due to the severity of the symptoms, induces patients to go to a hospital. When the physician suspects that it may be trichinellosis, he/she should immediately question the patient(s) about what kind of meat was consumed in the last 2–3 weeks, where this food was consumed, and with whom it was consumed. As soon as this initial information has been acquired, the physician must notify the public health service and the veterinary service to try to trace the infected meat that may have not yet been consumed and to identify the animal species and, if it is pig meat, the farm of origin. In most cases, investigations reveal that the source of the infection is to be traced back to a pig illegally bred or to an animal subject to hunting, often poached, and not subjected to veterinary controls. If the meat suspected to be the source of the infection can be traced in refrigerators, it must be immediately confiscated and tested by artificial digestion for the isolation of the larvae and their subsequent typing at the species level and the count of larvae per gram of muscle tissue. This information is very useful for physicians to evaluate the severity of the infection, the clinical course, and the antibody response and for veterinarians to know the risk of transmission of the pathogen to other animals at the farm or to wild animals.

17.10 Conclusions

Although the parasites of the genus *Trichinella* are among those most studied and controlled by the veterinary services, they continue to represent a public health problem that varies from country to country according to the conditions of pig farming and the consumption of game meat and, above all, based on food and cultural habits. Therefore, it is necessary that the public health services in conjunction with the veterinary services play a control and preventive role. Furthermore, this infection occurs sporadically in "leopard spots" in different countries for which most of the physicians do not know the disease and have diagnostic difficulties due to the lack of reliable tests.

Christa Ewers

ESBLs in livestock – How big is the piece in the complex puzzle on antimicrobial resistance?

Contents

Abstract

In the past decades, we faced a rapid increase in human infections caused by third-generation cephalosporin-resistant bacteria, e.g., *Escherichia* (*E.*) *coli*, *Klebsiella* (*K.*) *pneumoniae,* and *Salmonella*, mainly due to the plasmid-encoded production of extended-spectrum β-lactamases (ESBLs) and AmpC β-lactamases. The primary reservoirs of ESBL/AmpC-producing bacteria are still contentious. However, it is believed that livestock animal- and food-related sources play a possible but yet not quantifiable role in the spread of such bacteria. The use of large quantities of antibiotics in this sector, but also in the medical field, undoubtedly contributes to

the global rise of antimicrobial resistant (AMR) bacteria. Entry of multidrug-resistant microorganisms early in the livestock production cycle, as well as their frequent occurrence in healthy animals and food products, together with the finding of common molecular characteristics suggests that a livestock animal-to-human transmission could occur. However, links between ESBL/AmpC-producing bacteria from these two sources have been drawn mainly from observational epidemiological data while studies providing unquestionable proofs for transfer directionality and quantifying the risk for human health are limited. In any case, food animal production should be regarded a major player in the expansion of the global resistome. Therefore, efforts need to be further directed toward reducing reliance on antimicrobials in this sector wherever possible. More than ever, good veterinary and farming practices, including responsible use of antibiotics and implementation of biosecurity, hygiene, and disease prevention, e.g., by vaccination or by improving the animals' gut health, are regarded essential in the containment of AMR. Many fields, including medicine, veterinary medicine, animal husbandry, environment, and trade, are involved in this complex issue. Thus, isolated, sectorial efforts in the food animal production field will not be that efficient unless concerted efforts from all those involved are applied on a global scale, following a One Health approach.

18.1 Resistance Mechanisms in Broad-Spectrum Cephalosporin-Resistant Gram-Negative Bacteria

Beta-lactams are the most widely used antibiotics in clinical practice over the world and strong selective pressures upon them have resulted in a continuous increase of AMR bacteria (Bush and Bradford 2016; WHO 2018a,b). The β-lactams interfere with the metabolism of the bacterial cell wall by mimicking and thereby inactivating one of the building blocks, i.e., penicillin-binding proteins, used by enzymes to construct peptidoglycan (Bush and Bradford 2016). Resistance to β-lactams can be due to mutations in the penicillin-binding proteins, a reduced permeability of the cell wall, and the production of β-lactamase enzymes able to hydrolyze and inactivate the β-lactam-ring, which is by far the most common mechanism in *Enterobacterales*. Penicillin was one of the first β-lactams developed for clinical use in humans, and as early as 1940, β-lactamase activity was described as a penicillin-inactivating mechanism that threatened the use of this critical class of β-lactam antibiotics (Bush and Fisher 2011). With the introduction of new β-lactams (e.g., the penicillin derivatives methicillin and oxacillin, first to fourth generation) and most recently fifth-generation cephalosporins, monobactams, and carbapenems with improved activity on specific bacteria and increasing stability to hydrolysis, new β-lactamases emerged

and are continuously evolving with the ability to hydrolyze the β-lactam bond in almost all β-lactam-containing molecules (Bush and Fisher 2011; Bush and Bradford 2020). To date almost 3000 unique, naturally occurring small-, broad-, and extended-spectrum β-lactamases grouped into four Ambler classes A–D based upon amino acid sequence homology have been described. Class A and C β-lactamases are the most commonly found in *Enterobacterales* and are mainly represented by extended-spectrum β-lactamases (ESBLs) and AmpC β-lactamases (in this chapter referred to as "AmpCs"), respectively (Smet et al. 2010; Bush and Fisher 2011; Bush and Bradford 2020).

Enterobacteriaceae producing ESBLs are resistant to third- and fourth- generation cephalosporins and to aztreonam, while they are usually inhibited by β-lactamase-inhibitors, such as clavulanate, sulbactam, tazobactam, and avibactam. They are also not hydrolyzed by cephamycins and carbapenems. While early ESBLs mainly evolved from natural narrow-spectrum TEM-1/TEM-2 (named after a Greek patient "Temoneira") and SHV-1 ("sulfhydryl reagent variable") β-lactamases, CTX-M (cefotaximase Munich)-type enzymes, all of which reveal an ESBL phenotype, succeeded over the last decades and currently represent the most common ESBLs (Livermore et al. 2007; Liakopoulos et al. 2016; Bevan et al. 2017; Bush and Bradford 2020). Other ESBL groups, such as OXA, GES, PER, and VEB β-lactamases, have been described more recently and are found only sporadically and often in nonfermenting gram-negative bacteria, including *Pseudomonas* and *Acinetobacter* spp. (Potron et al. 2015). The genes that encode CTX-M-type ESBLs have once been mobilized from the chromosomes of environmental *Klyuvera* spp. and nowadays are predominantly encoded on transferable plasmids in both clinical relevant and commensal bacteria (Livermore et al. 2007). Currently, members of the *Enterobacterales* order are the most often encountered bacteria possessing ESBL/AmpC enzymes. After their initial observation in humans in the 1980s, ESBL/AmpC-producing *Enterobacteriales* emerged in companion animals more than a decade later and shortly after that in food-producing animals as well as in wildlife and various environmental sources (Guenther et al. 2011; Ewers et al. 2012; Lee et al. 2020; Palmeira et al. 2021). The rapid and extensive dissemination of CTX-M-type ESBLs in medical and veterinary settings, among commensal bacteria of humans and animals and in the environment, is regarded as one of the most successful histories of AMR observed in the antibiotic era. It is probably driven by one or a combination of the following factors: (i) efficient capture and spread of $bla_{\text{CTX-M}}$ genes by mobile genetic elements; (ii) association of these mobile elements with highly successful bacterial genotypes; and (iii) extensive use of extended-spectrum cephalosporins and other antimicrobials which can co-select ESBL-producing strains resulting in high selective pressure (D'Andrea et al. 2013).

AmpC- β-lactamases historically were chromosomal cephalosporinases *in Pseudomonas aeruginosa* and many *Enterobacterales* (Jacoby 2009; Bush and Bradford 2020). Since the 1980s, a growing number of genes for AmpC enzymes have escaped from the chromosome of different gram-negative bacteria onto transmissible plasmids. These "acquired" or "plasmidic" AmpCs consequently can now appear in bacteria

usually lacking or poorly expressing chromosomal bla_{ampC} genes, such as *E. coli* or *K. pneumoniae*. AmpC-β-lactamase mechanisms can be divided into the following categories: (a) inducible resistance by chromosomally encoded *ampC* genes (e.g., *Enterobacter cloacae*, *Citrobacter freundii*, and *P. aeruginosa*); (b) resistance due to mutations in promoter and/or attenuator sequences (e.g., *E. coli* and *Acinetobacter baumannii*); or (c) plasmid-mediated resistance (e.g., *K. pneumoniae*, *E. coli*, *Salmonella*, etc.) (Tamma et al. 2019). Although many gram-negative bacteria produce a chromosomal β-lactamase (cAmpC), it is the transferable plasmidic AmpC that is responsible for most of the multidrug resistance observed in gram-negative isolates (Bush and Fisher 2011; Tamma et al. 2019). AmpC-β-lactamases mediate resistance to most penicillins, first- to third-generation cephalosporins, cephamycins, and inhibitor β-lactam combinations (e.g., amoxicillin/clavulanate), but usually not to fourth-generation cephalosporins and carbapenems (Jacoby 2009). According to their original chromosomal producers they once developed from, AmpCs can be divided into at least five phylogenetic groups: the *Citrobacter freundii* group (CMY-2-like, LAT, and CFE), the *Enterobacter* group (MIR and ACT), the *Morganella morganii* group (DHA), the *Hafnia alvei* group (ACC), and the *Aeromonas* group (CMY-1-like, MOX, and FOX) with the most prevalent and widely disseminated being CMY-2-like enzymes (Meini et al. 2019). Although to date resistance due to pAmpCs is less common than ESBL production in most parts of the world, it may be (i) more difficult to detect in the clinical laboratory, probably underestimating its occurrence, and (ii) broader in substrate spectrum, probably resulting in significant therapeutic failure (Jacoby 2009; Meini et al. 2019).

Broad-spectrum cephalosporins have long been the treatment of choice for serious infections with enterobacterial and other gram-negative pathogens. Since ESBL/AmpC-producing bacteria rapidly increased over the past two decades, other critically important antimicrobials had to be used alternatively (Bush and Bradford 2016). However, mobile genetic elements, such as plasmids and transposons, frequently encode not only ESBL/AmpC genes but in addition genes coding for resistance, e.g., to aminoglycosides, quinolones, sulfonamides, and tetracyclines. Thus, the way was paved for the spread of bacteria with broad-spectrum cephalosporin resistance in both hospital settings and the community. As a result, clinicians were increasingly forced to use carbapenems for the treatment of severe infections caused by multidrug-resistant bacteria. This in turn has led to the selection of acquired carbapenemases among *Enterobacterales*, e.g., KPC (*K. pneumoniae* carbapenemase), OXA (oxacillinase)-48-like, NDM (New Delhi metallo-β-lactamase), VIM (Verona integron metallo β-lactamase), and other gram-negative bacteria, such as *A. baumannii* (e.g., OXA-23-like and OXA-58-like). Resistance to carbapenems is currently one of the most pressing public health threats relating to antibiotic resistance (Nordmann 2013; Dropa and Daoud 2022). Again, it was first described in humans and later, and still relatively rare, in companion and livestock animals (Fischer et al. 2012; Poirel et al. 2012; Nordmann 2013; Stolle et al. 2013; Ewers et al. 2016; Koeck et al. 2018).

18.2 Livestock Animals and Food as a Possible Source of ESBL/AmpC-Producing Bacteria

The primary reservoirs of ESBL/AmpC-producing *Enterobacteriaceae* are still controversial. Early reports described the occurrence of these bacteria in healthy humans (Valverde et al. 2004; Pitout et al. 2009; Overdevest et al. 2011), companion animals (Ewers et al. 2010, 2011; Dierikx et al. 2012; Pomba et al. 2014), wild animals (Literak et al. 2010; Fischer et al. 2014), and the environment (Mesa et al. 2006; da Costa et al. 2013). Since the late 1990s, ESBLs/AmpCs have been detected in poultry (Hasman et al. 2005; Kojima et al. 2005; Girlich et al. 2007; Fischer et al. 2017; Saliu et al. 2017), pigs (Riano et al. 2006; Djeffal et al. 2017; Vidovic and Vidovic 2020; De Koster et al. 2021), cattle (Frye et al. 2008; Wieler et al. 2011; Madec et al. 2012; Reist et al. 2013; Hering et al. 2014; Duse et al. 2015; Bergspica et al. 2020; De Koster et al. 2021), and retail meat (Jensen et al. 2006; Jouini et al. 2007; Bergenholtz et al. 2009; Doi et al. 2010; Cohen Stuart et al. 2012; Geser et al. 2012a,b; Kola et al. 2012; Vidovic and Vidovic 2020) almost globally. Hence, several studies raised questions in particular about the possible role of livestock animal- and food-related reservoirs in the spread of ESBL/AmpC-producing bacteria (Canton et al. 2008; Carattoli 2008; Hunter et al. 2010; Smet et al. 2010; Ewers et al. 2012; Seiffert et al. 2013; Vidovic and Vidovic 2020). Notably, healthy animals might not only carry multidrug-resistant commensal, i.e., nonpathogenic microorganisms, but may particularly be a source for primary or secondary pathogens leading to various diseases (e.g., gastroenteritis, urinary tract infection, wound infection, bacteremia, and septicemia) in immunocompromised patients or even in healthy individuals (Canton et al. 2008; Smet et al. 2010). One of the earliest descriptions of poultry as carriers of ESBLs and AmpCs was by Brinas et al. (2003), who recovered CTX-M-14, SHV-12, and CMY-2 β-lactamases in *E. coli* from the feces of healthy chickens in Spain in 2000 (Brinas et al. 2003). After that, studies from numerous countries followed and reported about the frequent presence of different types of ESBLs and AmpCs in *E. coli* and less frequently in *Salmonella* isolates from poultry (Girlich et al. 2007; Smet et al. 2008, 2010; Randall et al. 2011; Ewers et al. 2012; Saliu et al. 2017; Lee et al. 2020). First indications for the presence of ESBLs/AmpCs in healthy pigs came from Spain, where an SHV-12-producing *Salmonella* isolate was identified in 1999 (Riano et al. 2006), and from the USA, where researchers detected CMY-2-producing *E. coli* isolates during the years 1998 and 1999 (Winokur et al. 2000). Nearly within the same time frame, initial reports were published from the first findings of AmpC-producing *Salmonella* and ESBL-producing *E. coli* isolates in healthy cattle in the USA (Gupta et al. 2003) and Japan (Duse et al. 2015), respectively. Likewise, ESBL/AmpC-producing bacteria were recovered more than a decade ago from sick animals, animal manure, and the farm environment, indicating additional sources (Mesa et al. 2006; Carattoli 2008; Smet et al. 2010; Ewers et al. 2012; Friese et al. 2013).

18.3 Occurrence of ESBL/AmpC-Producing Bacteria in Livestock Animals

Total prevalences of ESBL/AmpC-producing bacteria in healthy animals of the major livestock species, i.e., poultry, pigs, and cattle, vary largely with study type. Nevertheless, poultry production was considered as the major contributor to the selection and spread of third-generation cephalosporin-resistant bacteria. Here, percentages of ESBLs (mainly targeted in the cited studies) and/or AmpCs range from 0.1–26.6% for *Salmonella* spp. (Smet et al. 2008, 2010; Randall et al. 2011; Ewers et al. 2012; Bai et al. 2015; Djeffal et al. 2017; Sabry et al. 2020) and from 1.7–96.4% in *E. coli* isolates (Kojima et al. 2005; Riano et al. 2006; Girlich et al. 2007; Smet et al. 2008, 2010; Ewers et al. 2012, 2021; Geser et al. 2012a,b; Dierikx et al. 2013; Laube et al. 2013; Hering et al. 2014; Huijbers et al. 2015; Nguyen et al. 2019; Gazal et al. 2020; Kuhnke et al. 2020; Kakooza et al. 2021) mainly originating from broilers, but also from turkeys in different European, Asian, and African countries and in North and South America. Also *Klebsiella pneumoniae*, which are of critical importance in human medicine, have been identified as ESBL producers in broiler carcasses (Wu et al. 2016; Projahn et al. 2019; Chenouf et al. 2021).

Rates of *Salmonella* and *E. coli* isolates producing ESBLs/AmpCs described for pigs are between 0.2% and 8% and between 1% and 84% (Riano et al. 2006; Wu et al. 2008; Smet et al. 2010; Ewers et al. 2012, 2021; Hammerum et al. 2014; Hansen et al. 2014; Randall et al. 2014; Stefani et al. 2014; von Salviati et al. 2014; Dohmen et al. 2017; Kraemer et al. 2017; Kaesbohrer et al. 2019; Bergspica et al. 2020; Kuhnke et al. 2020; Lay et al. 2021), and those for cattle these range from 0.6–2.4% and from 0.7–91.0%, respectively, in the cited studies (Gupta et al. 2003; Frye et al. 2008; Hunter et al. 2010; Smet et al. 2010; Wieler et al. 2011; Ewers et al. 2012, 2021; Hordijk et al. 2013; Reist et al. 2013; Duse et al. 2015; Hille et al. 2017; Palmeira and Ferreira 2020; Weber et al. 2021; Gelalcha and Kerro Dego 2022). The overall heterogeneity of these global data may not simply refer to differences between animal species or national/local variations in pathogen prevalence and susceptibility patterns or to global differences in antimicrobial use. It could be also due to different study designs, i.e., with respect to inclusion criteria (e.g., animal age, production system, and previous antimicrobial treatment) and microbiological procedures (e.g., usage of selective or nonselective cultivation media; sample enrichment). However, it was commonly agreed that livestock should be regarded as major player in the maintenance and/or expansion of the global bacterial resistome with a noticeable trend toward a more frequent colonization with ESBL/AmpC-producing bacteria of poultry compared to pigs and cattle (in rank).

With the increased pressure of AMR in the veterinary field, several European countries, including Germany (GERMAP), Finland (FINRES), Sweden (SVARM), Denmark (DANMAP), the Netherlands (MARAN), and Norway (NORM-VET), established active surveillance and monitoring programs to provide an estimation of whether the level of resistance has increased or decreased over time and to measure the impact of specific interventions or programs implemented at the national level (Mader et al. 2022). Such programs have also been initiated by non-European

countries, such as Canada (CIPARS 2002–2021), the USA (NARMS 2003–2018), and Japan (JVARM 2000–2017). Since 2004, Member States of the European Union are required to monitor and report AMR data on *Salmonella* and *Campylobacter* on mandatory basis and on indicator bacteria, i.e., commensal *E. coli* and enterococci on voluntary basis from food-producing animals (at farm or slaughterhouse level) and food thereof. In accordance with Commission Implementing Decision 2013/652/EU, the monitoring in indicator *E. coli* isolates has also become mandatory. Under the framework of Directive 2003/99/EC, the European Food Safety Authority (EFSA) publishes these data in a yearly joint summary report with the European Center for Disease Prevention and Control (ECDC) (EFSA/ECDC 2022). In addition, non-governmental initiatives, such as the AMR monitoring undertaken by the Centre Européen d'Etudes pour la Santé Animale (CEESA), initiated pan-European programs to create insight into the AMR development to provide an alert for the pharmaceutical companies to increase resources in research and development of novel antibiotics (Schrijver et al. 2018). Among the four different programs conducted by CEESA, the European Antimicrobial Susceptibility Surveillance in Animals (EASSA) examines the AMR of zoonotic and commensal bacteria in healthy food animals, and VetPath surveys AMR of bacterial pathogens from diseased animals. CEESA programs are financed by the veterinary pharmaceutical industry, but the results are presented to peer-reviewed journals to ensure independent reporting (de Jong et al. 2013; Schrijver et al. 2018; Ewers et al. 2021). It should be noted that EFSA and EASSA make use of different readouts. EFSA categorizes all isolates with a MIC value above the epidemiological cutoff (ECOFF) as "resistant," while EASSA categorizes strains into "decreased susceptible" and "clinically resistant" as they apply both ECOFFs and clinical breakpoints (Moyaert et al. 2014).

In the years 2019–2020, presumptive ESBL producers (i.e., isolates with minimal inhibitory concentartions [MICs] >1 mg/L for cefotaxime and/or ceftazidime and a synergy test positive for any of these antimicrobials together with susceptibility to meropenem) and presumptive AmpC producers (i.e., isolates with MICs >1 mg/L for cefotaxime and/or ceftazidime and cefoxitin MIC >8 mg/L together with susceptibility to meropenem) determined by routine monitoring (i.e., by using non-selective culture medium) in *Salmonella* isolates from broilers, fattening turkeys, and laying hens in EU Member States were observed at very low levels, varying between 0% and 1.9% (EFSA/ECDC 2022). For indicator *E. coli* isolates from broilers, fattening turkeys, fattening pigs, and bovines >1 year, the levels ranged from 0.1–1.5%. To ensure comparability of official monitoring data across the European Union, the EFSA provided technical specifications on the harmonized monitoring (e.g., usage of selective primary isolation media) and reporting (e.g., usage of epidemiological cutoffs instead of clinical breakpoints) of AMR (EFSA 2012). Data from the specific monitoring of ESBL and AmpC producers (using selective culture medium containing cefotaxime at 1 mg/L, as recommended by EUCAST) differ considerably from routine monitoring data. Percentages for presumptive ESBL producers ranged between 29.7% (broilers) and 34.1% (pigs), and those for AmpC producers between 3.6% (bovines, <1 year) and 11.3% (broilers). Marked variations in the prevalence of presumptive *E. coli* ESBL/AmpC producers

were reported between the EU Member States. It ranged from 2.1% (Cyprus) to 99.2% (Italy) in fattening pigs, from 1.1% (Italy) to 70.8% (Germany) in bovine animals >1 year of age, from 0.3% (Finland) to 98.6% (Slovakia) in broilers, and from 0% (Sweden) to 70.4% (Spain) in fattening turkeys (EFSA/ECDC 2022). The median occurrence of presumptive ESBL/AmpC producers was quite similar to the figures obtained in 2018. It appears that *E. coli* is the major source of third-generation cephalosporin resistance, which is less frequently found in Salmonella isolates. Of note, a statistically significant decrease in the prevalence of ESBL/AmpC producing *E. coli* has been observed in both broilers and turkeys over the period 2016–2020. A previous study from the Netherlands demonstraed a decreasing prevalence of contamination with ESBL *E. coli* in retail chicken already in the period from 2013–2015 (Huizinga et al. 2019). Another study from France reported that the nationwide drastic reduction of ceftiofur use and all other antibiotics in chicken production late 2011 had no impact yet on the ESBL/AmpC prevalence in retail chicken meat in that country (Casella et al. 2017).

The percentages of livestock animals colonized with third-generation cephalosporin resistant and/or ESBL/AmpC-producing *E. coli* mostly exceed what has been determined for human healthy carriers so far. While initially human fecal carriage of predominantly ESBL-producing isolates has been mainly reported along with nosocomial outbreaks, these isolates passed into the community almost in the mid-2000s (Canton et al. 2008). Proportions of humans colonized with ESBL-producing bacteria strongly vary by the study population and only exceptionally amount up to 80%, if, for example, travel-related fecal colonization, i.e., colonization after people had traveled to ESBL/AmpC "high-risk countries," is also considered (Ewers et al. 2012; Geser et al. 2012a,b; Nicolas-Chanoine et al. 2013; Seiffert et al. 2013; Kuenzli et al. 2014; Lubbert et al. 2015; Arcilla et al. 2017). This emphasizes the importance of the community reservoir in the evolution and dynamics of ESBL/AmpC-producing pathogens.

The contribution of food sources to the burden of antimicrobial resistance in humans is another controversial issue. Contamination of meat products with AMR bacteria may not only contribute to a theoretical spread of these organisms within the human population but also to a rapid transfer of AMR genes from foodborne commensals to human pathogens (da Costa et al. 2013). People could ingest ESBL/AmpC-producing bacteria by consuming the contaminated food directly or through cross-contamination on noncooked foods. Indeed, the presence of ESBL/AmpC-producing bacteria on retail meat has been documented repeatedly since many years (Hasman et al. 2005; Bergenholtz et al. 2009; Doi et al. 2010; Egea et al. 2012; Geser et al. 2012a,b; Casella et al. 2017; Kaesbohrer et al. 2019). Mainly following selective enrichment procedures, rates of ESBLs/AmpCs and/or presumptive ESBLs/AmpCs detected in beef and pork meat ranged from 0–21.7% (Jensen et al. 2006; Jouini et al. 2007; Lavilla et al. 2008; Ewers et al. 2012; Geser et al. 2012a,b; Kaesbohrer et al. 2019; Vidovic and Vidovic 2020). Much higher proportions, almost ranging between 30% and 100% have been reported in several studies performed on poultry meat in the recent couple of years worldwide (Hasman et al. 2005; Jouini et al. 2007; Bergenholtz et al. 2009; Doi et al. 2010;

Leverstein-van Hall et al. 2011; Overdevest et al. 2011; Randall et al. 2011; Cohen Stuart et al. 2012; Egea et al. 2012; Ewers et al. 2012; Kola et al. 2012; Kluytmans et al. 2013; Casella et al. 2017).

According to the latest report from EFSA/ECDC, in 2019–2020, presumptive ESBL/AmpC producers were observed in *Salmonella* isolates from broiler, pig, and bovine meat at very low levels during routine monitoring, varying between 0% and 0.2% (EFSA/ECDC 2022). Specific monitoring revealed presumptive *E. coli* ESBL/AmpC producers in pig, bovine, and broiler meat varying between 0.7% and 9.3% (AmpC) and between 4.3% and 23.4% (ESBL). These data again varied considerably between countries. The prevalence of presumptive *E. coli* ESBL/AmpC producers ranged from 0.3% (Finland) to 100% (Malta) in broiler meat, while it was less variable in meat from pigs, ranging from 0% (Finland and the Netherlands) to 24.4% (Portugal) and from bovine animals, where it ranged from 0.3% (UK) to 24.0% (Bulgaria).

Notably, reports about differences in ESBL/AmpC contamination of conventional versus organic (restricted antimicrobial use in animal rearing) chicken or retail chicken products are controversial. According to studies from Germany (43.9% vs. 36%) (Kola et al. 2012) and from the Netherlands (100% vs. 84%) (Cohen Stuart et al. 2012), there was a difference but it was not significant. It was suggested that ESBL-colonized 1-day-old chickens were introduced into organic farms or that cross-contamination between conventional and organic flocks during rearing or slaughtering or through an ESBL-contaminated environment accounted for the colonization of animals. Colonization of 1-day-old chickens and farm environmental contamination with ESBL-producing bacteria has also been shown in other studies (Bortolaia et al. 2010; Laube 2013). Also in a study from the USA, substantial variations in bacteria resistant to critically important antimicrobials were not found among organic and conventional retail chicken products (Mollenkopf et al. 2014). In contrast, significant differences were observed in studies from Italy (27.9% vs. 12.9% cloacal isolates; 31.3% vs. 1.4% skin isolates) (Musa et al. 2020) and Turkey (46% vs. 22%) (Uyanik et al. 2021). Regarding pigs, a recent study demonstrated that the percentage of ESBL-positive pens was significantly higher on conventional (55.2%) than on organic farms (44.8%) (Meissner et al. 2022). However, the authors determined similar proportions of ESBL-positive pens on conventional farms (54.3–61.9%) and a wide variation (7.7–84.2%) on organic farms. They found that the original farms, from which weaner pigs were purchased, had a major influence on the ESBL status.

Another important criterion in the complex issue of AMR is age-related and production cycle–dependent colonization of animals. The industrial production of broiler meat is the final or bottom level of a four-step pyramid, below the parent, grandparent, and primary breeder steps, and few reports suggest that ESBL/AmpC-producing bacteria are not uncommon in the top of some production pyramids. For instance, in Sweden, transmission of such bacteria from imported breeding chickens was documented by findings of *E. coli* carrying respective resistance genes in environmental samples from hatcheries rearing production animals or breeding stock (parent animals) (SVARM 2003–2021). Obviously, ESBL/AmpC-producing

E. coli have also been introduced in the Dutch poultry production chain through imported day-old grandparent chickens and the occurrence of these bacteria in the different levels of layers are likely attributed to vertical transmission (MARAN 2003–2022). In a longitudinal study from Denmark, a significant decrease in the carriage of identical ESBL-producing *E. coli* was detected from piglets to weaners and finishers (AbuOun et al. 2021). A reverse relationship between the prevalence of AMR bacteria in the intestinal microbiota and animal age has been demonstrated at dairy farms as well, which has been attributed either to a higher fitness of the resistant strains in young calves or selection pressure due to the feeding of waste milk that may contain antimicrobial residues (Geser et al. 2012a,b; Hordijk et al. 2013; Weber et al. 2021). A scoping review published by Gaire et al. (2020) also revealed an age-dependent AMR phenomenom in cattle and swine that was irrespective of geographic location and specific production practices (Gaire et al. 2020). Such findings emphasize that knowledge about the epidemiology of ESBLs/AmpC at the farm level should be improved as it may be of great value for the proper design of surveillance and intervention studies.

18.4 ESBL/AmpC Types

Irrespective of the origin, i.e., associated with fecal carriage or food contamination, CTX-M-1 has long been by far the most frequent ESBL type identified in all major groups of livestock animals in Europe and in other parts of the world, followed by CTX-M-14, TEM-52, and SHV-12. Other ESBL types frequently isolated include variants belonging to the CTX-M (e.g., CTX-M-2, -3, -8, -9, -15, 20, -27, -32, and -55), SHV (e.g., SHV-2 and -5), TEM (e.g., TEM-20, -24, -71, -106, and -126), and OXA (e.g., OXA-10) families (Ewers et al. 2012; Seiffert et al. 2013; Saliu et al. 2017; Palmeira and Ferreira 2020; Widodo et al. 2020). The type of AmpC β-lactamase detected was almost always the CMY-2 variant, followed by DHA-1, while other types are detected less often. CMY-2 is also one of the major enzyme isolated from poultry in Europe, while it is less common in bacteria from pigs and cattle (Smet et al. 2008; Doi et al. 2010; Kola et al. 2012; Fischer et al. 2017; Saliu et al. 2017; MARAN 2022).

The most frequent ESBL types in humans worldwide are CTX-M-15 and CTX-M-14, while CTX-M-1, which was initially rarely present in humans, slightly increased in recent years (Bevan et al. 2017). The $bla_{\text{CTX-M-15}}$ gene has spread in a pandemic fashion, mainly driven by plasmids of incompatibility group IncF and by a certain *E. coli* clonal lineage, namely multilocus sequence-type ST131 (Livermore et al. 2007; Pitout and DeVinney 2017). CTX-M-14 is also prevalent in poultry and cattle in Asia and to a moderate extent in livestock animals in non-Asian countries, suggesting possible transmission scenarios in the respective area. It is rather interesting to note that the most common ESBL type in humans, namely CTX-M-15, has invaded animal production compartments only in the past years, after a long period of low impact in livestock animals compared with a common occurrence in companion animals (Ewers et al. 2012). This enzyme type is no longer rare in bacteria

from livestock sources and its presence was increasingly detected in bacteria from cattle, poultry, and pig sources (Smet et al. 2010; Randall et al. 2011; Wieler et al. 2011; Hammerum et al. 2012; Madec et al. 2012; Fischer et al. 2014; Diab et al. 2017; Djeffal et al. 2017; Saliu et al. 2017; Fournier et al. 2020; Palmeira and Ferreira 2020; Ramos et al. 2020). Also, the shiga toxin producing *E. coli* O104:H4 strain, that was responsible for a severe outbreak of enterohaemorrhagic *E. coli* (EHEC) infection via contaminated food in Germany in 2011, carried ESBL-type CTX-M-15 (Ewers et al. 2011). For a detailed spatial and temporal distribution of ESBL/AmpC type in livestock animals, the author would like to refer to scientific reviews (Ewers et al. 2012; Saliu et al. 2017; Palmeira and Ferreira 2020; Ramos et al. 2020) and the annual EFSA/ECDC and national EU Member State reports.

The frequent carriage of ESBL/AmpC-producing bacteria by healthy cattle, pigs, or poultry and high prevalence of these organisms in food products indicates that food-producing animals may be the origin of at least part of the human infections. The following chapter will show that knowledge on the genetic makeup and epidemiology of plasmid and bacterial host is the minimum necessary for further assessing the foodborne risk and may also be valuable for source attribution. It is generally accepted that thorough cooking destroys bacteria in food, while cross-contamination to uncooked food may occur in case of inadequate hygiene measures, and these are important lessons from foodborne outbreaks due to *Salmonella*, *Campylobacter*, and enterohemorrhagic *E. coli* (EHEC) bacteria. As we currently cannot determine the magnitude of the mode of transmission of ESBL/AmpC-producing bacteria via the food chain, this theoretical hazard to human health requires further assessment.

18.5 Antimicrobial Drug Usage and Its Supposed Impact on the Emergence of ESBL/AmpC-Producing Bacteria in Livestock Animals

Antimicrobials are essential for both human and animal health. Many antimicrobial drugs administered to food animals are the same classes as those utilized in human medicine. Any antimicrobial usage (AMU), whether in the human or animal sector, can select for AMR and promotes the dissemination of AMR bacteria, regardless they are commensals, pathogens, or environmental strains. This greatly influences the population structure of microbial communities resulting in unpredictable consequences for public health (EFSA/ECDC 2013). Even though this is widely accepted, the evidence linking antibiotic use in food-producing animals with AMR bacteria emerging in humans is a long and controversially discussed issue. With the increasing emergence of ESBLs/AmpCs and more recently of carbapenemases in bacteria implicated in human infections, this debate reached a novel peak. Antimicrobial resistance genes and AMR bacteria have mainly evolved as a result of selective pressure, which is amplified by misuse (e.g., unnecessary use, subinhibitory dosage, or inappropriate duration of treatment) and overuse, particularly of broad-spectrum antimicrobials (Chantziaras et al. 2014; Guardabassi et al. 2018). In addition, we

must be aware that AMR may also be of ancient origin, implying that we all basically live in a surrounding filled with AMR genes and their precursors, the so-called resistome (D'Costa et al. 2011). The resistome refers to the collection of all AMR genes associated with microbiota in a given environment and is greatly influenced by the AMU in the different medical sectors. Based on metagenomic sequencing, it has been shown that there are abundant AMR genes in the fecal microbiota of food-producing animals which were not always always directly related to AMU, but were undoubtedly influenced by the use of injectable antimicrobials or their administration through feed or water (Ma et al. 2021). Understanding the complex events in the microevolution and dissemination of AMR in different compartments is therefore essential to estimate the impact of food animal production on this global health crisis.

Antimicrobial usage can differ in humans and food-producing animals in terms of methods of administration and quantities administered. There are also important variations between and within food-producing animal species, as well as between countries (Guardabassi and Kruse 2008; EFSA/ECDC 2013). In humans, antibiotics are administered individually to patients for therapeutic purposes, i.e., to treat infections, whereas prophylactic use of drugs to prevent the emergence of infections is the exception. This is quite comparable to what we encounter in small-animal and equine veterinary medicine. Antimicrobial prophylaxis refers to the administration of an antimicrobial substance to a healthy animal in the presence of a specific risk factor or stressors, such as weaning for piglets, intra- or interfarm transportation of calves, or drying off for dairy cows (Guardabassi et al. 2018; EMA 2019; Jerab et al. 2022). According to the WHO (2018a,b) and the European Medicines Agency (2019), unnecessary prophylactic AMU should be avoided, particulary if it is used to compensate poor health management and biosecurity. It should be restricted to individual animals or a group of animals at high risk of developing infections that have a significant impact on animal health and herd productivity (Guardabassi et al. 2018, WHO 2018a,b, EMA 2019).

In industrial farming, antimicrobials are commonly given to a whole group of animals (herd or group medication) to treat both diseased and clinically healthy in-contact animals that are presumably infected. Metaphylaxis shall prevent healthy animals from developing clinical signs and to prevent further spread of the disease (Guardabassi et al. 2018). The European Surveillance of Veterinary Antimicrobial Consumption (ESVAC) report from 2021 revealed that 86.9% of the antimicrobial products sold for veterinary care in Europe were products suitable for group medication (i.e., oral powders, oral solutions, and premixes) (EMA 2021; Jerab et al. 2022). Metaphylaxis in commercially reared cattle and pig holdings was most often implemented after weaning, transportation, and regrouping as these stressors often result in disease (Kasabova et al. 2021; Jerab et al. 2022). The new VMP Regulation (EU) 2019/6, which came into force in January 2022, states: "Antimicrobial medicinal products shall be used for metaphylaxis only when the risk of spread of an infection or of an infectious disease in the group of animals is high and when no other appropriate alternatives are available" (EC 2019; Jerab et al. 2022). It also provided for a wide range of additional, concrete measures to fight AMR and to promote a prudent and responsible AMU in animals. These include the obligation for

Member States to collect data on the sales and use of antimicrobials in animals per species; the possibility to reserve certain antimicrobials for human use only; a ban on the preventive use of antibiotics in groups of animals; and a reinforced ban on the use of antimicrobials for promoting growth and increasing yield (EC 2019). Notably, several member states have already implemented programs to collect antimicrobial sales data for animals, but often not per animal species. In Germany, for example, obligatory monitoring was adopted by the 16th Amendment of the German Pharmaceuticals Act ("Arzneimittelgesetz," AMG) in 2014, which regulates the official monitoring of the use of antibiotic drugs for weaners and fattening pigs, beef cattle, and poultry (Schaekel et al. 2017). Indeed, veterinary professional associations strongly advocate the principles of antimicrobial stewardship and responsible use. However, there is some concern that a ban of metaphylactic group treatment could likely result in high morbidity and mortality, for example, due to infections with *E. coli* in all major livestock species and with *Streptococcus suis* in pigs (Jerab et al. 2022). A recent study performed over a period of 11 months demonstrated a significant decline of multidrug-resistant *E. coli* and a significant increase in the proportion of isolates that were fully susceptible to the tested antimicrobials after withdrawal of group treatment of pigs on a farm (De Lucia et al. 2021). The authors suggested that their findings might support policymakers in the implementation of measures to control AMR and reduce antimicrobial use.

Another practice still common in livestock production in some countries is the use of antimicrobials to spur animal growth and to improve feed efficiency (Gilbert 2012). Antimicrobial use for growth promotion refers to the exposure of healthy animals to subtherapeutic concentrations in feed to improve growth rate, efficiency of feed utilization, and reproductive performance (Guardabassi et al. 2018). Since 1997, the WHO, together with the Food and Agriculture Organization (FAO) and the World Animal Health Organization (OIE), has consistently recommended restrictions on nontherapeutic uses of antimicrobials in food animals, which resulted in several countries adapting their legislation over time (Anonymous 2007). The European Union banned most antimicrobial growth promoters (AGPs) (e.g., avoparcin, tylosin phophate, bacitracin zinc, virginiamycin, and spiramycin) at the end of the 1990s because their in-feed application has been associated with the selection of resistance to clinically important antimicrobials in human medicine (Aarestrup et al. 2001). For example, in the Netherlands, 14% of people living near turkey farms where the growth promoter avoparcin was used were found to carry vancomycin-resistant enterococci (VRE), which are frequent causes of nosocomial infections (Bergspica et al. 2020). Soon after the remaining growth promoters have been phased out in Europe from January 2006, some types of antimicrobial resistances were indeed substantially reduced and the supposed benefits of growth promoters could obviously be achieved by other measures aiming at disease control, such as good health management conditions, biosecurity, and vaccination (Guardabassi and Kruse 2008). In recent years, many countries worlwide prohibited or restricted the addition of AGPs to feed. For example, the USA prohibited the use of medically important antimicrobials for growth promotion in 2017, while they still allow the use of nonmedically important antimicrobials, such as the ionophores

(Food and Drug Administration Center for Veterinary Medicine 2017). Recently, the Chinese government launched a regulation to withdraw medicated feed additives in accordance with the National Action Plan to Combat AMR from Animal Resources (2017–2020). Vietnam announced the ban of AGPs in 2020, and Bangladesh, Bhutan, Indonesia, Myanmar, Nepal, Sri Lanka, and Thailand have announced some AGP restrictions (Ma et al. 2021).

Nowadays a wide range of antimicrobial agents are authorized for use in the food animal production and these are frequently the same, or belong to the same classes, as those used in the human medicine (EFSA/ECDC 2013). Due to public health concerns, a much greater scrutiny is focused on therapeutic use of antimicrobials in food-producing animals, particularly for substances that have analogues in human medicine (Meini et al. 2019), in particular if these are ranked as "critically important." To be classified in this category, an antimicrobial agent must serve the following criteria: the antimicrobial class is (i) the sole, or one of limited available therapies, to treat serious bacterial infections in people alternatives to treat human diseases, and (ii) used to treat diseases caused by (1) bacteria that may be transmitted from nonhuman sources, or (2) bacteria that may acquire resistance genes from nonhuman sources (WHO 2018a,b). Some antibiotic classes, including third- and fourth-generation cephalosporins, quinolones, and aminoglycosides, are defined as "critically important" for both human and animal health, by WHO and OIE, respectively (Pomba et al. 2018). This raises a particular concern in the prioritized use of these antimicrobials in the veterinary area to assure an appropriate balance between animal health needs and public health considerations (Anonymous 2007). Regarding the emergence of ESBL/AmpC-producing bacteria, the possible selective pressure by β-lactam antibiotics is of special interest. Systematic reviews and guidelines about β-lactams currently licensed for use in food-producing animals have been published previously (Burch et al. 2008; Constable et al. 2008; Smet et al. 2010; Liebana et al. 2013). Due to a very broad spectrum, short or zero withdrawal times for milk and the availability of "long acting" formulations for certain indications cefquinom and ceftiofur are commonly used in veterinary medicines where they are authorized for the treatment of various diseases caused by defined pathogens in cattle and pigs (Burch et al. 2008; Constable et al. 2008; Liebana et al. 2013). The former authorization of ceftiofur for injection of day-old chicken for prevention of septicemia in some Member States of the EU has been phased out and currently no cephalosporin-containing products are licensed for poultry species in the EU and in many other countries.

According to a joint report by the ECDC, EFSA, and EMA, an analysis of AMU and ESBL/AmpC prevalence data from food-producing animals based on the time periods 2015–2016, 2016–2017, and 2017–2018 showed a statistically significant association between the prevelance of ESBL/AmpC-producing *E. coli* and consumption of third- and forth-generation cephalosporins in livestock production (ECDC (European Centre for Disease Prevention and Control) 2021). In addition, several experimental and on-farm studies have been published supporting the hypothesis that the veterinary use of β-lactams, and also undetermined factors not related to antimicrobial use, may select for ESBL/AmpC-producing *Enterobacteriaceae* in

animals. There is, for example, evidence that parental therapy with ceftiofur significantly increases the likelihood of dairy cows to be colonized with third-generation cephalosporin-resistant *E. coli* (Tragesser et al. 2006; Volkova et al. 2012; MARAN 2022). In Denmark, an increased frequency of ESBL-producing *E. coli* was identified on farms with high versus no consumption of third- and fourth-generation cephalosporins (70% ESBL versus 20% ESBL) (Hammerum et al. 2014). In pigs inoculated intragastrically with an *E. coli* expressing CTX-M-1 an increase in the number of CTX-M-1-producing *E. coli* was highest after administration of cephalosporins and interestingly this was mainly due to the proliferation of indigenous isolates that probably acquired the ESBL plasmids via conjugation (Cavaco et al. 2008). The authors pointed out that pigs treated with cephalosporins and sent to slaughterhouses shortly after the end of the withdrawal time may still shed high numbers of ESBLs (up to 10^6 CFU/g feces), favoring contamination of food products and the environment. In Canada, a strong correlation between a reduction in ceftiofur-resistant *Salmonella* Heidelberg and *E. coli* (both producing AmpC) from human infections and retail poultry and withdrawal of ceftiofur use for disease prophylaxis in hatcheries has been reported (Dutil et al. 2010). Usage of ceftiofur and cefquinom and probably also environmental contamination due to the excretion of their metabolites mainly with the urine may have influenced the emergence of acquired AmpCs and ESBLs in both gram-negative pathogens and commensals in livestock animals (Aarestrup 2005; Tragesser et al. 2006; Subbiah et al. 2012). A study from Japan revealed a decreased resistance to broad-spectrum cephalosporins in *E. coli* from healthy broilers after voluntary withdrawal of ceftiofur (Hiki et al. 2015). Finally, an association between the prophylactic ("off-label") use of ceftiofur in 1-day-old piglets for disease prevention and the occurrence of CTX-M-1-producing *E. coli*, which could not be detected on control farms without a recent history of ceftiofur usage, was recently demonstrated (Apostolakos et al. 2020). Conversely, the transfer of a CMY-2 plasmid to *Salmonella* spp. and commensal *E. coli* in cattle was not attributed to ceftiofur treatment (Poirel et al. 2018). Similarly, CTX-M-producing *E. coli* persisted on a dairy farm in the absence of the use of any β-lactam for longer than 6 months (Liebana et al. 2006).

Most ESBL/AmpC-producing bacteria carry further resistances to commonly used veterinary drugs, e.g., amoxicillin, sulfonamides, trimethoprim, fluoroquinolones, and aminoglycosides, such that dropping the use of cephalosporins may be only one out of several necessary steps in reducing AMR resistance (EFSA/ECDC 2013). Co-selection of third-generation cephalosporin resistance, as evidenced by the isolation of ceftiofur-resistant CMY-2-producing *E. coli* upon administration of florfenicol, has, for example, been reported recently for French cattle (Meunier et al. 2010). In a study from Belgium, the administration of amoxicillin in poultry was significantly associated with the emergence of third-generation cephalosporin-resistant *E. coli* (Persoons et al. 2011). Likewise, an experimental chicken model clearly illustrated how, in *E. coli*, "old" antimicrobials, e.g., amoxicillin, may co-select antimicrobial resistance to third-generation cephalosporins by favoring resistance plasmid exchange (Dheilly et al. 2012). However, beyond antimicrobials the authors identified poor hygienic condition, lack of acidification of drinking water, repeated

feed changes during the production cycle, and hatchery of origin as additional risk factors possibly promoting the spread of resistant bacteria in poultry.

Since clear evidence has been provided for a linkage between AMU and selection of third-generation cephalosporin-resistant organisms in livestock animals, a significant reduction and rationale therapeutic use of antimicrobial agents is warranted. With respect to this, various national and international veterinary organizations have developed general ethical guidelines to encourage a prudent use of antibiotics in line with a "good veterinary practice" (Guardabassi and Kruse 2008). This would for instance include: (i) the use of antimicrobials by veterinary prescription and oversight only (which is a standard prerequisite for the use of veterinary medical products containing antimicrobials for food-producing animals in the European Union already); (ii) decision on therapeutic options guided by susceptibility testing of the identified pathogen; and (iii) prioritization of antimicrobial use according to the critical importance of the respective substance for humans, and several other issues aiming to reduce AMR in livestock animals while ensuring animal welfare at the same time. The decision on exceptional off-label use of antimicrobials (i.e., use in a different species, for a different disease, or at a dosage different to that on the label) to avoid causing unacceptable suffering should strictly follow a specific cascade (Directive 2011/82/EC). This is also to ensure a restrictive use of substances of critical importance for human health. In several countries, off-label use of cephalosporins in food-producing animals is no longer allowed, after it has long been used in the USA and Europe to prevent early mortality due to septicemia in poultry hatcheries or to treat diarrhea or prevent systemic infection in piglets (EFSA/ECDC 2013; Seiffert et al. 2013). Several national guidelines from EU Member States, including the German guideline for prudent use of antimicrobials in veterinary medicine, recommend a restrictive use of antimicrobials ranked as critically important for human health in sick individual animals and only in case microbiological identification and susceptibility testing of the target pathogen have been performed (BTK-AGTAM 2015). The US Food and Drug Administration has proposed a ban on the use of ceftiofur in livestock which was heavily criticized by representatives from the veterinary field as an intrusion on veterinary practice, whereas people from food safety agencies considered it at best a minor step (Kluytmans et al. 2013). As mentioned before, pig and poultry producers in some countries have introduced voluntary bans on the use of broad-spectrum cephalosporins; in other countries, e.g., in Germany, third- and fourth-generation cephalosporins are not authorized for poultry (DANMAP 2003–2021; MARAN 2003–2022).

In Denmark, the occurrence of ESBL *E. coli* in pigs at slaughter fell from 11.8% in 2010 to 3.6% in 2011, that of pigs tested on farms from 11% in 2010 to 0% in 2011 after the voluntary ban was introduced in July 2010 (Agerso and Aarestrup 2013). Also in the Netherlands, some benefits regarding a drop in AMR are seen after the reduction in the use of antimicrobials (>50%) by the veterinarians over the last couple of years. Compared with 2009, a steady decrease in resistance in several animal species, including pigs, to antimicrobials of critical importance for human health has been reported (MARAN 2003–2022). Finally, two systematic reviews, that analyzed a large body of literature, showed that interventions designed to reduce

use of antibiotics in food-producing animals have a positive effect on reducing the prevalence of AMR in both animals and humans, particulary those humans that are in direct contact with food-producing animals (Tang et al. 2017; Scott et al. 2018). Although these data are very encouraging, long-term implications for animal health cannot entirely be foreseen yet.

The overall quantity of antibiotics used in the food-producing animal industry is difficult to assess due to a number of confounding factors in the provided data (e.g., use of different technical units, lack of precise information on specific purpose for antibiotic use, and clear separation of antibiotic use for food-producing animal species and companion animals) (Seiffert et al. 2013). The majority of high-income countries have national monitoring programs that capture antibiotic prescriptions in animals. In some countries, the date are stratified by animal species, age, and disease indication (Sanders et al. 2020). In contrast, due to a lack of capacitiy or resources, only 6% of low-income countries monitor AMU in animals, most probably due to lack of capacities (WHO 2021).

In 2009, the European Surveillance of Veterinary Antimicrobial Consumption (ESVAC) was launched by the European Medicine Agency (EMA) to develop a harmonized approach for the collection and reporting of data on veterinary antimicrobials based on national sales figures, and combined with estimations of consumption in at least the major groups of species, including poultry, pigs, and veal valves (EMA 2021). The ESVAC strategy for 2016–2020 aimed to enable the analysis of European-level trends in AMU per animal species using data that are standardized between countries. Werner et al. (2018) provided an excellent, comprehensive summary about relevant methods and applications in national, EU-wide, and global programs to monitor the usage of antimicrobial drugs in animals. They further discuss key figures and variables that are essential to describe AMU in animals and give an overview of monitoring systems in the European Union and in non-European countries.

18.6 Transmission of ESBL/AmpC-Producing Bacteria or Resistance Genes Between Livestock Animals and Humans and Zoonotic Aspects

A number of ESBL/AmpC-producing bacteria, such as *E. coli*, *K. pneumoniae*, *Salmonella*, and other gram-negative bacteria, are not only of clinical and economic impact in human medicine, but can also cause infections in animals and are potent colonizers of the gut of healthy animals at the same time (Canton et al. 2008; Smet et al. 2010; Ramos et al. 2020). This makes a transmission of these microorganisms, whether they are AMR or not, between animals and humans a possible scenario. Transmission of ESBL/AmpC-producing bacteria can occur through direct contact or indirectly via the food chain and the environment (Carattoli 2008). The transfer and spread of ESBLs/AmpCs among different habitats (i.e., animals, humans, and the environment) is mainly driven by mobile genetic elements, such as plasmids, insertion sequences, integrons, and transposons. Due to an often occurring physical

linkage of multiple genetic determinants on the same plasmid, self-conjugative properties, and the capability to acquire additional mobile genetic elements (e.g., insertion sequences and transposons), plasmids have been signified as major vehicles of ESBLs/AmpCs in gram-negative bacteria over the past decades (Bush and Fisher 2011; Carattoli 2013). Different ESBL/AmpC types are linked with distinct plasmid incompatibility (Inc) groups (based on replicon types) and these plasmid scaffolds are important factors in understanding the spread of AMR bacteria across the different habitats. For instance, the $bla_{\text{CTX-M-1}}$ gene is frequently carried by IncN, IncFII, IncFIB, and IncI1 plasmids and those plasmids have been observed in human samples as well (Carattoli 2013; EFSA/ECDC 2013). Several *bla* genes are frequently, although not exclusively, associated with plasmids of distinct Inc. groups, such as $bla_{\text{CTX-M-1}}$ with IncN, IncI1 and IncF, $bla_{\text{CTX-M-14}}$ with IncK and IncF, $bla_{\text{CTX-M-15}}$ with IncF and IncI1, $bla_{\text{CMY-2}}$ with IncI1 and IncA/C, and SHV-12 with IncF, IncI1, and IncX3 (Carattoli 2009, 2013; Seiffert et al. 2013; Hammerum et al. 2014; Liakopoulos et al. 2016). Apart from plasmid dissemination by horizontal gene transfer, clonal expansion of distinct bacterial genotypes largely contributed to the public health burden of AMR. This is probably best exemplified by the pandemic dissemination extraintestinal pathogenic *E. coli* O25b:H4-ST131 subclades C1/H30R (associated with fluoroquinolone resistance) and C2/H30-Rx (associated with extended-spectrum cephalosporin resistance conferred by the ESBL CTX-M-15) that cause millions of AMR infections annually (Pitout and DeVinney 2017; Duprilot et al. 2020).

Accordingly, investigating outbreaks due to ESBL/AmpC-producing bacteria, tracing the spread of AMR determinants in epidemiologically linked strains, and comparison of strains from different sources on a global scale substantially relies on a combinational methodological approach, considering both bacterial host and resistance genes carrying plasmid. An integral part of plasmid epidemiological surveillance is plasmid replicon typing to determine incompatibility groups. Plasmid multilocus sequence typing (pMLST), by which plasmids are assigned to sequence types (STs) (http://pubmlst.org/plasmid/), allow for an even finer resolution, e.g., of same plasmid families revealing identical replicon types. The latter is in analogy to the MLST for bacterial genomes (e.g., for *E. coli* [http://mlst.ucc.ie/mlst/dbs/Ecoli/]) which also aims at identifying groups of clonally related strains (Carattoli 2011; Seiffert et al. 2013). With the increasing affordability of whole genome and plasmid sequencing, higher-resolution methods became available that will have a great impact on the assessment of possible transmission events of ESBL/AmpC-producing bacteria and their plasmids between different ecological compartments.

Although the majority of cases of colonization with ESBL/AmpC-producing bacteria among humans cannot be clearly linked to livestock and food-producing animals (on a sound scientific basis), several studies suggested that direct contact with livestock animals can be a risk factor for human colonization. In an experimental model mimicking the human gut microbiota, an *E. coli* strain of poultry origin established itself very well and easily transferred its plasmid (IncI) and *bla* gene (TEM-52) to commensal human *E. coli* even in the absence of antimicrobial selective pressure (Smet et al. 2011). This may not simply demonstrate a theoretical

scenario as supported by previous findings that the prevalence of ESBL-producing *E. coli* among people working in meat-processing companies or among farmers was higher than usually recorded for the general population at the given time and region (Lavilla et al. 2008; Geser et al. 2012a,b; Dierikx et al. 2013). Moreover, in some studies, patients suffering from gastrointestinal disease due to infections with ESBL-producing *Salmonella* had more contact with food-producing animals than subjects with susceptible isolates (Gupta et al. 2003; Fey et al. 2000). In a study from the Netherlands, human and pig isolates within the same farm harbored similar ESBL gene types and had identical sequence and plasmid types on two farms, suggesting clonal transmission. The ESBL carriage in humans (6%) was associated with the average number of hours working on the farm per weak and with the presence of ESBLs in pigs (Dohmen et al. 2015). Genetically related IncI1 plasmids (i.e., with the same plasmid sequence type) carrying the $bla_{\text{CTX-M-1}}$ gene were determined in *E. coli* and *Salmonella* isolates from colonized and diseased humans, food-producing animals, and from meat samples in various European countries (Carattoli 2011; Leverstein-van Hall et al. 2011). Similar reports refer to $bla_{\text{CTX-M-1}}$ gene carrying IncN plasmids that are extensively distributed among different livestock animal species, but were also identified in *Enterobacteriaceae* from humans and retail meat (Cavaco et al. 2008; Moodley and Guardabassi 2009; Bortolaia et al. 2010; Carattoli 2011; Randall et al. 2011; Ewers et al. 2021). In a study from Germany, an ESBL *E. coli* isolate from a farm worker and a cattle fecal sample from the same farm shared an identical sequence type (ST3891) and CTX-M allele, indicating a zoonotic transfer. Two other pairs of human-pig and human-cattle *E. coli* isolates encoded the same ESBL genes but did not share the same ST, which may indicate resistance plasmid transfer (Dahms et al. 2015). In 6 of 18 farmers (33%), Dierikx et al. (2013) identified isolates producing ESBL/AmpC types (CTX-M-1, SHV-12, and CMY-2), which were also present in the samples from their animals. Five farmers even showed identical plasmid families (IncI1, IncK, and IncN) and in isolates from two farmers the genes were carried on identical plasmid subtypes (IncI1-ST12 and IncN-ST1) indicating plasmid transfer between animals and farmers in the Netherlands (Dierikx et al. 2013). A Danish study demonstrated the presence of *E. coli* with identical CTX-M enzymes, macrorestriction profile, and MLST type in both pigs and farmers at 4 of 20 investigated pig farms (Hammerum et al. 2014). According to their findings, the authors considered it likely that the CTX-M-1-, CTX-M-14-, and CTX-M-27-producing *E. coli* frequently detected in patients in Denmark could be of animal origin. However, they suggested that further studies would be neccessary to quantify a possible zoonotic link between ESBL-producing *E. coli* and human infections. Using whole genome sequence analysis, van Hoek et al. (2020) could only confirm six of eight previously suggested (based on *E. coli* STs, plasmid families, and ESBL/AmpC genes) transmission events between broilers, farmers, and their family members on the same farm (van Hoek et al. 2020), underlining the added value of high-resolution methods. Likewise, de Been et al. (2014) could demonstrate that the majority of ESBL/AmpC-producing *E. coli* isolates from broilers, meat, and human infections, that were supposed to be identical based on lower-resolution methods, were indeed rather dissimilar based on

WGS analysis (de Been et al. 2014). Plasmid reconstructions revealed three distinct plasmid lineages of the IncI1 and IncK type that carried ESBL/AmpC genes. As the plasmid backbones within each lineage were virtually identical and were shared by genetically unrelated human and animal isolates, the authors suggested that ESBL/AmpC genes are mainly disseminated in animals and humans via distinct plasmids rather than by clonal transmission of strains.

There are also studies that found no transmission link between zoonotic and/or AMR pathogens of animal and human origins. Ludden et al. (2019) compared more than 430 *E. coli* isolates, including 155 ESBL-producing isolates from livestock and retail meat with the genomes of 1517 *E. coli* isolates associated with blood stream infections from the UK. They found that these two groups of *E. coli* were genetically distinct populations that in addition revealed only a limited overlap in AMR-gene-carrying mobile elements (Ludden et al. 2019). Investigating genomic and plasmid backbone, Kluytmans et al. (2013) found just one perfect match between geographically and temporally matched *E. coli* from humans and chicken meat (Kluytmans et al. 2013), implicating chicken meat as a source of human colonization with ESBL-producing *E. coli* isolates. Also other authors found that ESBL-producing *E. coli* from humans were generally different to that from animals, i.e., chickens, cattle, turkey, and pigs in the same region (only 1.2% [3/258] related strains), as judged from antimicrobial and virulence gene profiles in combination with clonal complexes, suggesting a widespread human-to-human transmission as a strong possibility (Wu et al. 2013). Likewise, in a recent Swedish study there was no indication of the spread of *E. coli* carrying $bla_{\text{CMY-2}}$ from broilers to human clinical settings (Borjesson et al. 2013).

We need to be clear that the majority of studies performed around the topic of AMR transfer so far did not particularly focus on confirming precise transmission paths, but aimed to explore whether bacteria similar at the genetic level occurred in different animal species and humans, indicating possible epidemiological links (Wu et al. 2013). If such links, mainly created on the basis of observational findings, are indeed consistent with transmission through the food chain, remains inconclusive, unless infections with ESBL/AmpC-producing bacteria cannot be clearly traced back to a foodborne source. This in turn would implicitly assume that (i) *bla*-gene carrying plasmid and bacteria are transmitted jointly through a single event, and (ii) the strain transmitted is capable of causing disease in humans in a given period of time, which for instance has been the case in one of the first foodborne nosocomial outbreaks due to an ESBL-producing (SHV-1, CTX-M-15) *K. pneumoniae* isolate in Spain (Calbo et al. 2011). A very good example showing that even with an apparently sufficient molecular dataset the direct contribution of livestock animals to the transmission of AMR microorganisms might be overstated has been published previously. By using comparative whole genome analyses, Mather et al. (2013) could demonstrate that, contrary to current belief, the epidemic multidrug-resistant *Salmonella Typhimurium* DT104, responsible for human gastrointestinal infections worldwide, was largely maintained within animal and human populations separately (Jerab et al. 2022). Based on WGS, they could show that the isolates and their resistance genes were mainly kept within their host orgns with

limited transmission, pointing toward alternative sources for these MDR strains. This study emphasizes the critical importance of integrated genotypic datasets, including whole genome analysis, in understanding the ecology of bacterial zoonosis and AMR.

Interestingly, and this is best known for *E. coli*, bacterial isolates supposed to be nonpathogenic for otherwise healthy individuals seem to be more prone to acquire ESBL/AmpC β-lactamase genes than their pathogenic counterparts are. For example, extraintestinal pathogenic *E. coli* (ExPEC), i.e., highly virulent *E. coli* strains that are basically decipherable by their virulence gene profile and assignment to phylogenetic group and/or multilocus sequence type, are not among the majority of ESBL/AmplC-producing strains identified from infected and colonized humans and animals (Ewers et al. 2012). The sudden worldwide increase of *E. coli* clone O25:H4-ST131-CTX-M-15 in hospital- and particularly in community-onset infections is the most compelling exception from that (i.e., with respect to the extent of its spread) (Nicolas-Chanoine et al. 2014; Pitout and DeVinney 2017; Duprilot et al. 2020). ST131 is part of the highly virulent phylogenetic group B2 and since its first recognition in 2008 it developed to the most dominant ExPEC genotype worldwide (Pitout and DeVinney 2017). *E. coli* strains of this clonal group are commonly associated with bacteremia, urinary tract infections, and urosepsis, and due to their multidrug resistance, discordant antimicrobial therapy and increased morbidity and mortality are increasingly observed (Nicolas-Chanoine et al. 2014). The number of reported livestock animal and food-associated ST131 isolates, whether they harbor ESBLs or not, is negligible compared to its incredible frequency in humans. Nevertheless, there are findings of ESBL-producing ST131 isolates in livestock animals, for example, in healthy poultry from Spain (CTX-M-9) (Cortes et al. 2010; Mora et al. 2010), in diarrheic poultry from Tunisia (CTX-M-15) (Jouini et al. 2021), in broiler liver in Algeria (Chenouf et al. 2021), or in diarrheal pig in China (CTX-M-9 & CTX-M-14) (Liu et al. 2018). Several other researchers failed to detect this genotype among ESBL producers, e.g., from poultry and retail poultry meat (Overdevest et al. 2011; Egea et al. 2012) and from cattle (Madec et al. 2012; Diab et al. 2017). In contrast, a much wider distribution of CTX-M-type-producing ST131 *E. coli* strains has been observed in companion animals, only a few years after its first emergence in humans (Ewers et al. 2010; Dierikx et al. 2012; Pomba et al. 2014). Thus, this clonal group basically circulates among humans, but crossed the species barrier to dogs and cats in particular, suggesting a spillover from humans and a subsequent dissemination among companion animals. In any case, it is clear that livestock animals are currently not a threatening source of this highly virulent and multidrug resistant clonal group, while the reasons for low carriage rates with such strains are yet unsolved (Ewers et al. 2012).

Nevertheless, there is evidence for the existence of shared clones of ESBL/AmpC-producing *E. coli* in food-producing animals and humans, indicating that some common genotypes, plasmid, and β-lactamase types could indeed be circulating between them (Lavilla et al. 2008). Though less prevalent among highly virulent B2 ExPEC strains, ESBL/AmpC-producing *E. coli* are generally dispersed over the entire population of this bacterial species (Ewers et al. 2012). There is an apparent accumulation of AMR isolates in certain non-B2 genotypes and strains of various

clonal groups, including ST10, ST23, ST38, ST117, ST167, ST405, ST410, ST617, and ST648. These lineages are circulating widely across species and sources, i.e., humans, animals, and food products (Oteo et al. 2009; Cortes et al. 2010; Bortolaia et al. 2011; Leverstein-van Hall et al. 2011; Overdevest et al. 2011; Ewers et al. 2012, 2014; Liu et al. 2018), which does not automatically indicate clonal transmission between these compartments.

In summary, robust studies providing unquestionable proofs for the livestock animal-to-human transmission and quantifying the true burden for public health are still rare. Overlaps in bacterial strain and plasmid characteristics among humans and food animals almost often refer to one of these criteria only. Accordingly, several studies consistently emphasized the key role of plasmid versus clonal dissemination in the spread of ESBL/AmpC genes between animals and humans and vice versa. The notion that people who have direct contact with infected animals or contaminated meat, such as farm workers, slaughterers, or people working in the food-producing industry, face a particular risk to acquire AMR bacteria requires further consideration. With the increasing availability of molecular epidemiological data, particularly of combined WGS and plasmid sequence data, knowledge about initial microevolutionary events leading to the introduction and further enrichment of ESBL/AmpC-producing bacteria in food-producing animals will hopefully increase in the near future.

18.7 Conclusions

The frequent occurrence of ESBL/AmpC-producing bacteria in the food production chain, i.e., in healthy livestock animals and food thereof, and its unpredictable impact on food safety and environmental pollution is a major concern in the global debate on AMR. Problems related to AMR are inherently associated with the use of antibiotics in any environment, i.e., related to veterinary and human medicine. Accordingly, its use in the livestock production cycle may be one among other important factors in promoting the development of MDR bacteria and genetic resistance determinants of zoonotic relevance.

Even if the impact of food-producing animals to AMR in humans cannot be quantified yet, antimicrobial consumption in these animals undisputedly contributes its part in the maintenance or even expansion of the global bacterial resistome. Therefore, AMU in this sector needs to be kept at levels as low as possible without losing sight of any aspects of animal welfare. Generally, the judicious and rational use of antimicrobials, particularly those that are “critically important” for human health, should be regarded as a naturally ethical issue in the veterinary profession. However, this would be only one step toward preserving the benefits of antimicrobials for people. Beyond antimicrobial consumption, animal husbandry, extensive trade, farm hygiene, and biosecurity as well as intensive farming are considered the most compelling risk factors contributing to the global emergence of ESBL/AmpC-producing *Enterobacteriaceae* in livestock. In all major food animal production systems, massive movement of animals from reproduction to fattening farms

occurs and also food is traded globally, facilitating a virtually boundless transfer of MDR microorganisms between farms and countries, which might weaken regional or national mitigation measures considerably. This makes joining transnational forces to contain the risks of spreading AMR one essential part in an overall holistic approach. In this context, risk assessment, i.e., identification of stages within the food production chain (e.g., slaughter of animals, distribution, handling, and consumption of foods) that may pose an increased risk of human infection with AMR bacteria, should be generally included as a mature part of this global effort.

Resistance will probably never return to pre-antibiotic use levels; weak market encouragements and increasing difficulty and cost to develop new effective antimicrobial substances have greatly discouraged investment in this area. Not only for these reasons are alternatives to antimicrobials urgently required in veterinary medicine. Implementation and optimization of biosecurity on farms and overall good hygiene practices at all stages of the food chain, i.e., pre- and postharvest, have already shown excellent results in reducing the impact of multidrug-resistant bacteria in livestock animals. Several other options that have been proposed to lower the burden of AMR, such as pre- and probiotics, antimicrobial peptides, phytocompounds, competitive exclusion products, and vaccines, bacteriophages have shown variable effects so far, but represent promising approaches that need to be intensified, as there is no more time to lose. Finally, more recent concepts, such as modified CRISPR-Cas approaches, that target AMR genes in bacteria and reverse the selective pressure of resistance, or nanoparticles, that could help in blockage of enzyme pathways and alteration of cell wall might be essential pieces in the global effort to combat antimicrobial resistance.

Zoonotic Transmission of Antimicrobial-Resistant Enterococci: A Threat to Public Health or an Overemphasized Risk?

19

Valeria Bortolaia and Luca Guardabassi

Contents

Abstract

Enterococci are intrinsically resistant to various antimicrobial classes and able to acquire resistance to clinically relevant drugs via chromosomal mutations and horizontal gene transfer. Consequently, therapeutic options for treatment of enterococcal infections are limited. Zoonotic transfer of antimicrobial resistance in enterococci has been studied for many years. The first studies hypothesizing possible animal-to-human transmission of resistant strains and mobile genetic

elements are dated 1993. Since then, a considerable amount of papers has been published on this subject, providing the groundwork for important decisions limiting antimicrobial use in animal husbandry. In this chapter, the relative contribution by animal enterococci to antimicrobial resistance in infections in humans was reviewed taking into consideration the potential impact associated with different enterococcal species, animal hosts, epidemiological routes, and mechanisms of transfer. The authors conclude that potential zoonotic risks mainly concern horizontal transfer of resistance genes and clonal transmission of multidrug-resistant *Enterococcus faecalis* lineages such as ST16 from a variety of animal species. The risk of clonal transmission appears to be negligible for *Enterococcus faecium*, which is markedly more host-specific than *E. faecalis*, and mainly limited to companion animals, which are a potential reservoir of ampicillin-resistant, hospital-associated lineages such as ST78 and ST192. Of note, such conclusions are largely based on studies from developed countries that never used or banned the use of antimicrobial growth promoters in livestock for nearly two decades (at the time of writing this review), which has significantly reduced the occurrence of resistance to clinically relevant antimicrobials in enterococci in animals. As for horizontal transfer of mobile genetic elements, although it has been demonstrated experimentally that antimicrobial-resistant enterococci of animal origin can transiently colonize the human digestive tract and transfer their resistance genes to the indigenous microbiota, the magnitude and clinical implications of this phenomenon, which currently appear to be limited, have not been fully elucidated. Further research is warranted to explore the ecology and epidemiology of enterococcal mobile genetic elements carrying resistance genes of clinical relevance, especially aminoglycoside and linezolid resistance in *E. faecalis*.

19.1 Introduction

Enterococci are commensal bacteria in the intestinal microbiota of humans and animals, but are also opportunistic pathogens that can cause a variety of infections (Gilmore et al. 2013). In humans, *E. faecalis* and *E. faecium* are well-known causes of hospital-acquired infections, including endocarditis, bacteremia, meningitis, wound and urinary tract infections, and peritonitis (Arias and Murray 2012). Together, these two species are ranked as the second and fourth most frequently reported cause of nosocomial infections in the USA and Europe, respectively (Weiner-Lastinger et al. 2020; Suetens et al. 2018), with *E. faecalis* being the species most frequently isolated, followed by *E. faecium* (Weiner-Lastinger et al. 2020).

Therapeutic options to treat *E. faecalis* and *E. faecium* infection are limited because enterococci are intrinsically resistant to important antimicrobial classes in clinical practice as they tolerate low concentrations of β-lactams, quinolones, aminoglycosides, and lincosamides and are able to metabolize preformed folic acid, thereby bypassing inhibition of folate synthesis by trimethoprim and sulfonamides (Murray 1990; Hollenbeck and Rice 2012). Treatment of severe enterococcal infections usually consists of a penicillin (ampicillin or penicillin) either as monotherapy or in combination with a cephalosporin (ceftriaxone) or an aminoglycoside (gentamicin or streptomycin) (Rosselli del Turco et al. 2021). Glycopeptides such as vancomycin are the best alternative if the causative strain is resistant to one or more first-line drugs or if the patient has β-lactam allergy or renal impairment (Rosselli del Turco et al. 2021). Daptomycin and linezolid are also good options if the patient has renal impairment and if the local prevalence of vancomycin resistance is high. Other antimicrobials which may be used for treatment of enterococcal infections include quinupristin-dalfopristin (for *E. faecium* only), tigecycline, and fifth-generation cephalosporins. Older antibiotics such as chloramphenicol, doxycycline, minocycline, and nitrofurantoin may be used for specific indications (Arias and Murray 2008). Unfortunately, enterococci have a particular ability to acquire exogenous resistance genes via conjugative transposons and plasmids, which has resulted in the emergence of resistance to virtually all available therapeutic options (Werner et al. 2013). Globally, *E. faecalis* and *E. faecium* were responsible for some 112,000 and 200,000 deaths associated with antimicrobial resistance, including 30,000 and 51,000 deaths attributable to antimicrobial resistance, respectively, in 2019 (Antimicrobial Resistance Collaborators 2022).

Several authors have hypothesized zoonotic transmission of antimicrobial-resistant enterococci since the early 1990s. At that time, vancomycin-resistant enterococci (VRE) were emerging as nosocomial pathogens worldwide (Leclercq et al. 1988; Uttley et al. 1988; Sundsfjord et al. 2001). Although initially it was believed that nosocomial use of vancomycin was the only factor selecting for VRE, this assumption was partly revisited after a considerable reservoir of VRE was reported in the community and in production animals in Europe (Bates et al. 1993; Klare et al. 1993; Torres et al. 1994; Goossens 1998; Martone 1998). In 1995, two independent studies established a correlation between usage of the vancomycin-analogue avoparcin as a growth promoter in livestock and occurrence of VRE in chickens and pigs (Klare et al. 1995; Aarestrup 1995). Subsequent studies confirmed that (i) there is cross-resistance between avoparcin and vancomycin (van den Bogaard et al. 1997a, b), (ii) avoparcin use was associated with occurrence of VRE in animal feces and meat products (Bager et al. 1997; Aarestrup et al. 2000a), and (iii) occurrence of VRE in food animals and meat products was correlated to occurrence of VRE in fecal samples of community-dwelling humans (Pantosti et al. 1999; Klare et al. 1999; van den Bogaard et al. 2000). The risk that animal VRE could be transmitted through the food chain was regarded as high since enterococci are particularly resistant to heat, disinfectants, and other decontamination procedures used at slaughterhouses (Giraffa 2002). All these evidences provided the basis for establishing and maintaining the ban on avoparcin use enforced in the

EU since 1997 in accordance with the precautionary principle (Anonymous 1997). Additional links between antimicrobial-resistant enterococci in production animals and antimicrobial-resistant enterococci in healthy humans were hypothesized on the basis of similarities in the patterns of resistance to quinupristin/dalfopristin, erythromycin, tetracyclines, gentamicin, and chloramphenicol, as well as in the distribution of genes conferring resistance to these antimicrobials (Welton et al. 1998; Werner et al. 1998; Aarestrup et al. 2000a, b; Del Campo et al. 2003; Klare et al. 2003; Kieke et al. 2006). These findings contributed to support the ban on use of all antimicrobials as growth promoters in the EU, which was ratified through different EU Regulations enforced in 1999 and in 2006 (Anonymous 1998a, b, 2003). Although the public health benefits of the ban on the use of antimicrobials for growth promotion have been debated (Wallinga and Burch 2013), and such use is still practiced in about 26% of countries in the world (World Organization for Animal Health 2021), there is compelling evidence showing that the diminished use of avoparcin achieved with the ban has been effective in reducing the presence of VRE in animal populations (Nobrega et al. 2021). On the basis of a systematic review and meta-analysis on this subject, it was concluded that the ban on avoparcin use was also significantly associated with a diminished presence of VRE in human samples (Nobrega et al. 2021). However, these findings most probably referred to samples from healthy individuals in the community since, in hospital settings, the population-weighted mean percentage of vancomycin resistance in *E. faecium* increased significantly in the EU/EEA countries in the period 2016–2020, according to data retrieved from the Surveillance Atlas of the European Centre for Disease Prevention and Control (ECDC) (https://www.ecdc.europa.eu/en).

This chapter is a narrative review of the literature regarding the possible contribution by enterococci of animal origin to antimicrobial resistance problems in human medicine. The topic is reviewed taking into consideration the roles played by different enterococcal species (*E. faecium* vs. *E. faecalis*), animal hosts (food vs. companion animals), epidemiological routes (foodborne transmission vs. transmission by contact with animals), and mechanisms of transfer (clonal transmission vs. horizontal gene transfer). Aquatic animals and derived seafood were not included in the review, as enterococci isolated from these sources often derive from anthropogenic contamination. The chapter is organized into four sections addressing occurrence of antimicrobial resistance in human, animal, and food isolates (section "Occurrence of Antimicrobial Resistance"), evidence of transmission between animals and humans (section "Transmission of Antimicrobial Resistance Between Animals and Humans"), genetic links between clinical and animal strains (section "Genetic Links Between Clinical and Animal Strains"), and conclusions by the authors (section "Conclusions").

19.2 Occurrence of Antimicrobial Resistance

Occurrence of antimicrobial resistance varies significantly depending on host species and geographical regions. Local data on occurrence of antimicrobial resistance often reflect the specific patterns of antimicrobial usage within each host species, and

marked differences between hosts may provide useful epidemiological indications on potential reservoirs of antimicrobial resistance within defined geographical areas. The Danish Integrated Antimicrobial Resistance Monitoring and Research Programme (DANMAP) founded in 1995 was the first initiative for systematic collection of country-wide data on occurrence of antimicrobial resistance in *E. faecium* and *E. faecalis* in human patients, healthy production animals, and retail meat, with the purpose of identifying possible zoonotic links (www.danmap.org). Since then, several national and international antimicrobial resistance surveillance programs have been established with similar purposes worldwide. The two following paragraphs summarize the most recent publicly available information on the occurrence of antimicrobial resistance in *E. faecium* and *E. faecalis* from human patients, production animals, and meat obtained from national surveillance programs monitoring these bacteria within the last 10 years at the time of writing this review, and reflect the content of Tables 1 and 2, respectively. Typically, isolates included in these surveillance programs derived from invasive infections in humans, from cecal content or feces of healthy production animals, and from meat at retail. Occurrence of antimicrobial resistance, defined as the percentage of resistant isolates as a proportion of the isolates tested, is defined rare (<0.1%), very low (0.1–1.0%), low (>1–10.0%), moderate (>10.0–20.0%), high (>20.0–50.0%), very high (>50.0–70.0%), and extremely high (>70.0%), following the categorization used by the European Food Safety Authority (EFSA) (EFSA and ECDC 2021).

19.2.1 Patterns of Antimicrobial Resistance in Animal and Human *E. faecium*

Clinically relevant antimicrobial resistance phenotypes in *E. faecium* include resistance to ampicillin, daptomycin, gentamicin, linezolid, quinupristin-dalfopristin, teicoplanin, tigecycline, and vancomycin. Clear host-specific patterns in occurrence of resistance to ampicillin and gentamicin were observed in the reports examined (Table 1). Ampicillin resistance occurred at extremely high level in human clinical isolates, whereas it ranged from rare to moderate in isolates from animals and meat irrespective of the geographical origin (Table 1). Similarly, occurrence of gentamicin resistance ranged between moderate to high in human clinical isolates and from rare to low in isolates from animals and meat in any country (Table 1). Based on these observations, and on the fact that occurrence of ampicillin and gentamicin resistance has been stable or decreased in several animal and meat sources from most countries based on 5- and 10-year trends (Table 1), it seems unlikely that animal sources constitute an important reservoir of ampicillin- and gentamicin-resistant *E. faecium* causing severe infections in humans. A possible exception could be represented by ampicillin-resistant *E. faecium* (AREFm) in companion animals (see section "Transmission via Direct Contact with Companion Animals"), which are not covered by national surveillance programs.

Geographical patterns of vancomycin resistance are useful to discern potential epidemiological links between animals and humans. Occurrence of vancomycin resistance ranged from rare to low in human clinical isolates in different European

Table 1 Prevalence of antimicrobial resistance in *Enterococcus faecium* isolated from humans (invasive isolates) and animals (indicator isolates) obtained from publicly available national surveillance program reports

countries and in Japan and was nearly absent in isolates from animal sources from the same countries (Table 1). In the USA, vancomycin resistance was also virtually absent in animal and meat *E. faecium* isolates, whereas it occurred at very high level (68%) in human clinical isolates (Table 1). This strongly indicates that occurrence of vancomycin resistance among human clinical isolates is primarily driven by hospital use of glycopeptides.

Different considerations can be made with regard to the occurrence of quinupristin/dalfopristin resistance, which ranged almost invariably from moderate to extremely high among isolates from animals and meat in Europe and in the USA. The frequent recovery and increasing occurrence of quinupristin/dalfopristin-resistant strains in animals according to 5- and 10-year trends is surprising since the quinupristin/dalfopristin analogue virginiamycin, which is likely selecting for quinupristin/dalfopristin resistance, has not been used since 1999, at least in European countries. Genetic linkage of quinupristin/dalfopristin resistance genes with genes conferring resistance to other antimicrobials used in animal production (e.g., macrolides) may explain the persistence of these genes in food animals in Europe (Hammerum et al. 2001). Data on occurrence of quinupristin/dalfopristin resistance in human isolates were not readily available. Occurrence of this resistance phenotype was lower in human isolates compared to animal isolates, suggesting the existence of a potential animal reservoir for quinupristin/dalfopristin resistance (Donabedian et al. 2006; Kieke et al. 2006; Hammerum et al. 2009) which, however, does not seem to pose a major resistance problem in human infections at present. A recent study investigating risks for selection for quinupristin/dalfopristin-resistant *E. faecium* in humans derived from virginiamycin use in food animals in China concluded that such risks are close to zero (Cox et al. 2020). However, the study investigated risks for selection for quinupristin/dalfopristin resistance in vancomycin-resistant *E. faecium* (VREFm) only and was based on the unproven assumption that resistance cannot be transferred from animal-origin strains to strains causing infections in humans.

Occurrence of daptomycin resistance was rare or low in isolates from animal and meat sources from all countries, except Belgium (Table 1). In this country, occurrence of daptomycin resistance ranged from moderate in *E. faecium* from calves and pigs to high in *E. faecium* from broilers (Table 1). No national surveillance data on occurrence of daptomycin resistance in *E. faecium* from humans were readily available for comparison. A study investigating patients with daptomycin-resistant

Data sources: Belgium, Garcia-Graells et al. 2019 and ECDC Surveillance Atlas: Antimicrobial Resistance 2019; Denmark, DANMAP 2019, 2020; Japan, NAOR 2019; the Netherlands, Nethmap-MARAN 2016, 2017; Norway, NORM/NORM-VET 2019, 2020; Sweden, Swedres-Svarm 2016 and ECDC Surveillance Atlas: Antimicrobial Resistance 2016; Switzerland, Swiss Antibiotic Resistance Report 2018; USA, NARMS Now and ResistanceMap: Antibiotic resistance 2022. Blank cells indicate that no information was available

[a]Animal sources represent healthy meat-producing animals, meat sources represent meat sold at retail, and human sources represent diseased patients with invasive infections. From the USA, bovine isolates are from steers and heifers (and not from calves). No., number of isolates tested

[b]Resistance (R) defined according to EUCAST ECOFFs for animal and meat isolates and EUCAST clinical breakpoints for human isolates (www.eucast.org). Of note, quinupristin-dalfopristin resistance in animal isolates is defined using EFSA cutoff values as no EUCAST ECOFF is available (EFSA et al. 2021)

[c]Trends indicate increased, decreased, or stable percentage of resistance in the time period indicated (y, years)

[d]Resistance (R) defined according to CLSI breakpoints. Limited to Japan, tetracycline refers to minocycline in humans and oxytetracycline in animals

[e]6y trend for animal isolates

[f]2y trend for vancomycin resistance in isolates of animal origin

[g]Data on trends of antimicrobial resistance for *E. faecium* isolates of animal origin are available only for all animal categories merged

[h]*HLR* high-level resistance

E. faecium infections found a possible association between acquisition of daptomycin resistance and residential proximity to animal or crop operations (Kelesidis and Chow 2013). However, the number of patients was too limited for drawing definitive conclusions (Kelesidis and Chow 2013).

Occurrence of resistance to linezolid, teicoplanin, and tigecycline was rare in human, animal, and meat isolates, with few exceptions, which however are not indicative of any large animal or human reservoir (Table 1).

It is important to note that occurrence of resistance to macrolides (e.g., erythromycin) and tetracyclines was frequently observed among animal and meat isolates, likely as a consequence of veterinary use of these drugs (Table 1). Genetic linkage between macrolide and tetracycline resistance genes and genes conferring resistance to clinically relevant antimicrobials may explain the occurrence of linezolid, quinupristin/dalfopristin, and glycopeptide resistance in animals, as a result of co-selection by veterinary use of macrolides and tetracyclines (Hammerum et al. 2001; Novais et al. 2005; Tyson et al. 2018; Rushton-Green et al. 2019). Unfortunately, data on resistance to macrolides and tetracyclines, which represent useful epidemiological markers indicating flow of antimicrobial resistance genes from livestock to humans, are generally not generated for human clinical isolates in surveillance programs from most countries, with the exception of Japan and Switzerland (Table 1). In these countries, erythromycin and tetracycline resistance occurred at similarly high and even very high level in *E. faecium* from most animal and human sources (Table 1), which indicates a possible animal reservoir, mainly linked to broilers and pigs, of enterococci resistant to these antimicrobials.

19.2.2 Patterns of Antimicrobial Resistance in Animal and Human *E. faecalis*

From a contemporary clinical perspective, the only antimicrobial resistance phenotype in *E. faecalis* that could be possibly linked to animal reservoirs is gentamicin resistance. Resistance to ampicillin, daptomycin, linezolid, teicoplanin, tigecycline, and vancomycin was rare or even not detected in animal isolates, with stable 5- and 10-year trends, based on national antimicrobial surveillance programs from several countries worldwide (Table 2).

Occurrence of gentamicin resistance was similar in *E. faecalis* from most animal and human sources (Table 2). These data indicate possible existence of an animal reservoir of gentamicin-resistant *E. faecalis*, though linked to different animal sources in different geographical areas. For example, in European countries and in Japan, the proportion of *E. faecalis* displaying gentamicin resistance ranged from moderate to high in cattle and pigs, and from rare to low in poultry, with the exception of turkeys in Belgium (Table 2). In the USA, occurrence of gentamicin resistance was rare in isolates from cattle, whereas it ranged from low to high in isolates from pigs and poultry (Table 2).

Remarkably, the occurrence of gentamicin resistance was higher in animals than meat thereof, with the biggest differences observed between cattle and beef and between pigs and pork (Table 2). Although comparison of occurrence of gentamicin

Table 2 Prevalence of antimicrobial resistance in *Enterococcus faecalis* isolated from humans (invasive isolates) and animals (indicator isolates) obtained from publicly available national surveillance program reports

resistance in *E. faecalis* obtained from animals and meat should be done with caution due to the overall low number of animal isolates included and to the fact that meat may also be of imported origin, these data indicate low risk of carcass contamination in cattle and pig slaughtering and consequent low human exposure to gentamicin-resistant *E. faecalis* through consumption of beef and pork. As observed for *E. faecium*, resistance to macrolides and tetracycline is widespread among *E. faecalis* isolates from animals and meat, possibly as a consequence of the widespread use of these antibiotics in livestock production (Table 2). Macrolide and tetracycline resistance data for human *E. faecalis* isolates were generated in the national surveillance programs of Japan and Switzerland only (Table 2). In these countries, erythromycin and tetracycline resistance occurred at similarly high and even very high level in *E. faecalis* from most animal and human sources (Table 2), which indicates a possible animal reservoir of enterococci resistant to erythromycin and tetracycline. This potential animal reservoir may represent a risk to human health in case of genetic linkage between erythromycin and tetracycline resistance genes and genes conferring resistance to clinically relevant antimicrobials, but unfortunately this type of genetic information is not routinely generated in national surveillance programs.

19.3 Transmission of Antimicrobial Resistance Between Animals and Humans

Transmission of antimicrobial resistance between animal and human enterococci may happen through different epidemiological routes and mechanisms. Humans can acquire animal enterococci by direct exposure to animals and animal-contaminated environments or indirectly, through consumption of contaminated food of animal origin and vegetables from crops treated with animal manure.

19.3.1 Foodborne Transmission

Foodborne transmission may result from consumption of contaminated animal food products and cross-contamination in the kitchen (Wegener et al. 1997). *E. faecium* and *E. faecalis* generally contaminate raw meat and cheese at concentrations of

[h]*HLR* high-level resistance

10^2–10^4 and 10^5–10^7 colony forming units (CFU) per gram, respectively (Giraffa 2002). Experiments conducted on healthy human volunteers have shown that animal enterococcal strains occurring in ingested food are shed with feces for a limited time period of about 1–3 weeks. In an experiment performed on himself, Berchieri established that a minimum concentration of 10^7 CFU of VREFm of poultry and pig origin was necessary to be able to isolate the same strain from feces for a period of 20 days (Berchieri 1999). Sørensen et al. demonstrated that VREFm from poultry meat and quinupristin/dalfopristin-resistant *E. faecium* from pork ingested at 10^7 CFU could be detected in the feces of 8 out of 12 volunteers 6 days after ingestions, at different concentrations (Sørensen et al. 2001). One out of 12 volunteers excreted the strain also 14 days after ingestion (Sørensen et al. 2001). In a similar experiment, Lester et al. demonstrated that animal VREFm transiently colonizing the human gut could transfer the *vanA* vancomycin resistance operon to resident commensal *E. faecium* strains in three out of six volunteers, indicating that occurrence of VREFm in food may result in the transfer of vancomycin resistance to the microbiota of consumers (Lester et al. 2006). Furthermore, Al-Ahmad et al. showed that foodborne *E. faecalis* could integrate into dental oral biofilm in five out of six volunteers for at least 5 days, indicating a potential risk for endodontic infections that may evolve into bacteremia (Al-Ahmad et al. 2010).

According to a study in Switzerland (Collineau et al. 2018), poultry meat poses the highest risk of transmission of antimicrobial-resistant enterococci for the consumers, especially transfer of tetracycline and macrolide resistance. The authors attributed the highest risk mainly to cross-contamination during the slaughter process in poultry production and to a lesser extent to high consumption of poultry meat. An American study assessing exposure to antimicrobial-resistant bacteria in ground beef consumers estimated that the probabilities of exposure to tetracycline-resistant enterococci are on average 6.2% per serving, which are double than the probabilities of being exposed to tetracycline-resistant *E. coli* (3.1% per serving) (Zhang et al. 2021). To our knowledge, no data are available on foodborne exposure to enterococci that are resistant to clinically important antimicrobials but this is likely to be low due to infrequent occurrence of resistant isolates in meat products (Tables 1 and 2).

The hypothesis that antimicrobial-resistant enterococci of animal origin could be transferred to the intestine of healthy humans via food is indirectly supported also by studies describing clonally related strains in meat products and in the feces of healthy meat consumers. Donabedian et al. described closely related gentamicin-resistant *E. faecalis* strains in multiple pork samples and one human sample, and indistinguishable strains in a chicken meat sample and a human sample in the USA (Donabedian et al. 2003). Agerso et al. demonstrated clonal relatedness between five vancomycin-resistant *E. faecalis* (VREFs) from turkey meat and from the intestine of healthy humans in Denmark (Agerso et al. 2008). Similarly, in an additional study from Denmark, Hammerum et al. reported the occurrence of highly related VREFm isolates in Danish pig samples and in the intestine of a healthy human who reported no contact with pigs but had eaten pork (Hammerum et al. 2004).

In conclusion, based on the current knowledge, ingested antimicrobial-resistant enterococci of animal origin can be shed with feces for a variable time, likely depending on the numbers of enterococci ingested as well as on host factors, but it

remains unknown whether animal strains are able to permanently colonize the human intestine and to what extent their transit through the intestinal lumen allows for a significant transfer of antimicrobial resistance genes to the indigenous microbiota.

19.3.2 Transmission via Direct Contact with Food Animals

Farm and slaughterhouse workers and veterinarians are the main categories at risk for this transmission route since they are daily exposed to high numbers of animals. High density of animals and animal excreta implies a high load of fecal bacteria in farm environments. Various studies showed that genetically related antimicrobial-resistant enterococci can be isolated from animal feces, insects, dust, and air inside and in proximity of farms, which indicates the existence of multiple sources of human exposure to animal enterococci, as extensively reviewed by the European Food Safety Authority (EFSA BIOHAZ Panel 2021). Different studies reported occurrence of genetically related enterococci strains displaying specific resistance phenotypes in the feces of animals and healthy farm workers. VREFm clones shared by turkey, turkey farmers, and turkey slaughterers and by broiler and broiler farmers were detected in the Netherlands and in Norway (van den Bogaard et al. 1997a, b; Simonsen et al. 1998; Stobberingh et al. 1999; Jensen et al. 2003). Clonally related quinupristin-/dalfopristin-resistant *E. faecium* were isolated from a poultry farmer and his animals in the Netherlands (Jensen et al. 1998). Closely related plasmids and indistinguishable Tn*1546* variants harboring *vanA* have been reported in genetically unrelated VREFm isolated from poultry and workers within farms (Stobberingh et al. 1999; van den Bogaard et al. 2002; Sletvold et al. 2007), suggesting that *vanA* of animal origin may be horizontally transferred to the intestinal microbiota of farm workers. Evidence of human infections caused by antimicrobial-resistant enterococci transmitted by direct contact with production animals is limited to a single study. Das et al. reported a VREF-infected wound in a worker who was injured while working at a factory packaging chickens (Das et al. 1997). The strain isolated from the wound had the same resistance profile of isolates from the factory and the patient had no risk factors for a VREF infection, strongly supporting animal origin of the infection (Das et al. 1997).

19.3.3 Transmission via Direct Contact with Companion Animals

The role of companion animals as reservoirs of antimicrobial-resistant enterococci was first hypothesized in 1996, when van Belkum et al. discovered that (i) 17% of dogs and cats examined harbored VREFm while the incidence among people living in the same area was 2–3% and (ii) VREFm isolates from a dog, a cat, and a human carrier were indistinguishable by pulsed-field gel electrophoresis (PFGE) (van Belkum et al. 1996). The authors concluded their article by raising the question, “which dog poses a greater risk to the postman: the one that barks or the one that wags its tail?” (van Belkum et al. 1996). Companion animals represent potential

sources of antimicrobial-resistant bacteria since they live in close contact with their owners and are often administered antimicrobials belonging to the same classes used for treatment in humans (Guardabassi et al. 2004; Jackson et al. 2009). Antimicrobial-resistant enterococci can be isolated from different animal body sites and from feces, which may represent a source of contamination of domestic and urban environment (Jackson et al. 2009; Ghosh et al. 2011). AREFm were detected in a considerable proportion of dogs and cats in different European countries, being reported in 23% (of 183), 30% (of 79), and 76% (of 25) of dogs in the UK, the Netherlands, and Denmark, respectively, and in 13% (of 85) of cats in the Netherlands (Damborg et al. 2009; de Regt et al. 2012). This is in contrast with food-producing animals, where AREFm are rare or not detected by national surveillance programs (Table 1), and may reflect the frequent usage of aminopenicillins and other β-lactam antibiotics in small animal veterinary medicine. In addition, VREFm were detected in 1.4% (out of 71) and 13% (out of 87) of dog feces samples examined in Portugal and Spain, respectively (Herrero et al. 2004; Poeta et al. 2005). Occurrence of VRE in dogs was reported also outside Europe. The first VREFm reported in a dog in the USA was shown to harbor a mutated form of Tn*1546* described in human patients (Simjee et al. 2002). A VREF from a dog with mastitis displayed a PFGE profile prevalent among human isolates in New Zealand (Manson et al. 2003). A recent meta-analysis and systematic review indicated a significant heterogeneity of the data on the prevalence of VRE in companion animals with a pooled prevalence in dogs and cats of 18.2% and 12.3%, respectively (Wada et al. 2021). These studies suggest that VREFm and *vanA* may be exchanged between humans and dogs but the importance and prevalent direction of this transmission route is impossible to assess.

19.4 Genetic Links Between Clinical and Animal Strains

Even if it appears plausible that antimicrobial-resistant enterococci of animal origin transiently colonize the digestive tract of humans and/or transfer resistance genes to human-adapted strains, the magnitude and the clinical consequences of this biological phenomenon are controversial. This section reviews the knowledge of the genetic similarities between human clinical and animal strain populations of *E. faecium* and *E. faecalis*. This information, complemented with epidemiological data, is of paramount importance to assess the risk of zoonotic transmission of antimicrobial resistance by clonal propagation and horizontal gene transfer.

19.4.1 Genetic Links Between Clinical and Animal *E. faecium*

E. faecium can be divided into two genomically distinct groups, A and B, which include hospital-associated and community-associated isolates, respectively (Lebreton et al. 2013). Within group A, an additional separation into clade A1, including the vast majority of hospital-associated isolates, and clade A2, mainly associated with animals but also including clinical isolates, has been proposed and validated with different strain collections (Lebreton et al. 2013; Raven et al. 2016a;

Manson et al. 2019; van Hal et al. 2022). Clade A1 comprises the epidemic lineages associated with nosocomial infections worldwide, which are clonal complexes 17 (including, among others, sequence types ST16 and ST17), 18 (ST18), and 78 (ST78 and ST192), as identified using multilocus sequence typing (MLST) (Willems et al. 2012). These hospital-associated lineages are generally characterized by ampicillin resistance and are particularly enriched in genes encoding colonization and adhesion factors, which likely play a role in virulence (Somarajan and Murray 2013). Animal strains rarely overlap with the hospital-associated lineages, with the notable exception of canine *E. faecium* strains. Indeed, AREFm belonging to the hospital-associated ST78 and ST192 have been frequently detected in dogs but they generally lack genes encoding putative virulence factors (Damborg et al. 2009). Thus, it appears that animal and clinical *E. faecium* strains constitute two distinct subpopulations in relation to ampicillin resistance and occurrence of putative virulence factors. Similar conclusions have been drawn for VREFm. The population structures of VREFm isolated from human patients and animals are generally diverse and overlap only sporadically (Woodford et al. 1998; Jung et al. 2006; Biavasco et al. 2007; Donabedian et al. 2010; Freitas et al. 2011; Hammerum 2012; Tzavaras et al. 2012; Willems et al. 2012; Getachew et al. 2013). Among lineages of clinical relevance, there are single reports of *vanA*-positive VREFm ST132 (related to ST18) in swine in Portugal, *vanA*-positive VREFm ST78 in rabbit meat, and *vanB*-positive VREFm ST17 in chicken meat and veal in Spain (Lopez et al. 2009). VREFm lineages grouped in clonal complex CC5, which are common among porcine strains of diverse geographical origin, have been sporadically reported as a cause of urinary tract infections in hospitalized patients (Freitas et al. 2011). Altogether, these findings suggest that animal VREFm strains have a limited zoonotic potential.

A series of evolutionary studies based on comparative genome analyses of large collections of *E. faecium* with different antimicrobial resistance profiles and isolated from various geographical regions has conclusively substantiated the limited genetic links between animal and clinical *E. faecium*. These studies have shown that animal and clinical strains, although evolutionary linked, constitute different subpopulations or clades that diversified mainly through recombination and acquisition or loss of mobile genetic elements (MGEs) and eventually adapted to different ecological niches (van Schaik et al. 2010; de Regt et al. 2012; Galloway-Pena et al. 2012; Willems et al. 2012; de Been et al. 2013; Lebreton et al. 2013; Gouliouris et al. 2018; O'Dea et al. 2019; Arredondo-Alonso et al. 2020; Lee et al. 2021). Recent taxonomy studies support that the strains of *E. faecium* clade B should be classified as *Enterococcus lactis* (Belloso Daza et al. 2021).

19.4.2 Genetic Links Between Clinical and Animal *E. faecalis*

Also in *E. faecalis*, few genetic lineages such as CC2, CC9, CC87, and ST16 are particularly enriched among nosocomial isolates and associated with multidrug resistance, as shown by molecular epidemiological studies using MLST and further confirmed by studies based on whole genome sequence (WGS) data analyses

(McBride et al. 2007; Freitas et al. 2009; Willems et al. 2011; Palmer et al. 2012; Tedim et al. 2015; Raven et al. 2016b). However, differently from *E. faecium*, the *E. faecalis* hospital-associated clones are phylogenetically closely related to human commensal and animal strains, indicating the absence of a clear boundary between clinical and non-clinical strains (Palmer et al. 2012; Kim and Marco 2014; Guzman-Prieto et al. 2016; Pöntinen et al. 2021). For some of the lineages enriched among hospitalized patients, like CC2 and CC87, the genetic link between clinical and animal strains seems to be weak as descriptions in animal sources have been only sporadic and included, for example, findings in a black rat in Spain; in dogs, pigs, and natural gilthead seabream in Portugal; and in crows in the USA (McBride et al. 2007; Freitas et al. 2009; Freitas et al. 2011; Barros et al. 2012; Kuch et al. 2012; Oravcova et al. 2014; Lozano et al. 2015; Marques et al. 2018). On the contrary, ST16 is well represented among isolates in hospitalized patients as well as healthy humans and animals (Ruiz-Garbajosa et al. 2006; Willems et al. 2011; Kuch et al. 2012; Tedim et al. 2015; León-Sampedro et al. 2019). In a study examining 386 contemporary human *E. faecalis* from hospital and community sources in 6 European countries, ST16 represented 11% and 15% of the total hospital- and community-associated strains, respectively (Kuch et al. 2012). Half of the ST16 strains from each source displayed gentamicin resistance, suggesting that up to 6% of nosocomial infections by gentamicin-resistant strains may be acquired in the community (Kuch et al. 2012). Notably, ST16 was found highly predominant among gentamicin-resistant *E. faecalis* isolated from pigs and pork in Denmark in 2001–2002 and represented 9% of 22 *E. faecalis* isolates from endocarditis patients in the same country in 1996–2002 (Larsen et al. 2010). These porcine and human strains were shown to be closely related genetically using pulsed-field gel electrophoresis (PFGE), which suggested a link between gentamicin-resistant *E. faecalis* ST16 in pigs and human patients in Denmark (Larsen et al. 2010). When sequencing 32 *E. faecalis* from retail chicken meat in the USA and comparing them with available sequences of 149 clinical, commensal, and animal isolates, Manson et al. identified a cluster of gentamicin-resistant ST16 *E. faecalis* including 2 chicken meat strains, 9 porcine strains, and 1 clinical strain. The strains in this cluster differed for 56–92 single nucleotide polymorphisms (SNPs) based on single-copy core genome phylogeny, strongly indicating high genetic similarity between clinical and animal strains (Manson et al. 2019). Gentamicin-resistant ST16 strains have also been associated with nosocomial infections in Cuba, Japan, and Saudi Arabia, with urinary tract infection patients and their chickens in Vietnam, with urinary tract infections in cats, and with swine and poultry sources in Portugal (Freitas et al. 2009; Quinones et al. 2009; Watanabe et al. 2009; Poulsen et al. 2012; Novais et al. 2013; Marques et al. 2018; Farman et al. 2019). Multidrug-resistant ST16 strains displaying additional resistance to linezolid have been reported in patients in Belgium, China, Colombia, Cuba, Denmark, Germany, Greece, Japan, Korea, Malaysia, Thailand and the UK (Quinones et al. 2009; Spiliopoulou et al. 2011; Diaz et al. 2012; Weng et al. 2013; Kudo et al. 2014; Vorobieva et al. 2017; Bender et al. 2018; Angeles Argudín et al. 2019; Tsilipounidaki et al. 2019; Saavedra et al. 2020; Park et al. 2020; Ma et al. 2021; McHugh et al. 2022); in healthy humans in Portugal and the USA (Freitas et al. 2009; Freitas et al. 2020); in pigs in Colombia, Italy, Korea,

and Portugal (Novais et al. 2013; Tamang et al. 2017; Fioriti et al. 2020; Freitas et al. 2020); and in goats in China (Yang et al. 2022). Vancomycin-resistant ST16 strains have been isolated from poultry meat in Portugal (Freitas et al. 2009), American crows in the USA (Oravcova et al. 2014), and migrating birds in Tunisia (Ben Yahia et al. 2018). The widespread distribution of *E. faecalis* ST16 resistant to clinically important antimicrobials across several host species and countries provides ample opportunities for spillover from a reservoir to another, which may ultimately result in disease in humans. Also other *E. faecalis* lineages are shared between human patients and animals. For example, ST108 is predominant among VREFs isolated from humans and poultry in New Zealand and also shows bacitracin resistance, which is consistent with a possible transfer to humans after resistance to this veterinary antibiotic is acquired in poultry production (Rushton-Green et al. 2019). Linezolid-resistant ST480 of bovine, porcine, and human clinical origin in Belgium has been shown to differ only by 10–25 SNPs out of 1945 loci used to build the phylogeny, and such close phylogenetic relationship along with the common geographical origin suggests an epidemiological link between these strains (Timmermans et al. 2021).

In summary, a zoonotic transmission of antimicrobial-resistant *E. faecalis* clones appears to be possible based on the available epidemiological studies, but there have not been enough studies to date to prove the robustness of this information.

19.4.3 Genetic Links Between Mobile Genetic Elements in Clinical and Animal Enterococci

The transfer of MGEs carrying antimicrobial resistance genes from animal enterococci to human pathogenic strains may be considered a zoonosis. Transferability of MGEs from animal to human enterococci strains has been demonstrated in vitro and/or in animal models, including transferability of gentamicin resistance in *E. faecalis* and of ampicillin, gentamicin, and vancomycin resistance in *E. faecium* (Lester and Hammerum 2010; Ghosh et al. 2011; Sparo et al. 2012; Novais et al. 2013). However, these studies were not designed to determine if the strains with the newly acquired, animal-origin antimicrobial resistance caused infections in humans. Early studies based on traditional typing methods indicated the occurrence of host-specific mutations in transposons and resistance genes and inferred possible animal-to-human transmission based on the occurrence of animal-specific mutations in strains of human origin. For example, a point mutation (G to T) in *vanX* in Tn*1546* has been consistently associated with *E. faecium* isolated from poultry (G) and pigs (T), while both types occur among human clinical isolates (Jensen 1998; Hammerum 2012). Similarly, different *erm*(B) alleles occurred at different frequencies among macrolide-resistant *E. faecium* isolates from pigs and poultry, and all variants were present among isolates from healthy and diseased humans (De Leener et al. 2005). These studies, as well as evidence of indistinguishable MGEs in healthy animal and clinical human strains (Hegstad et al. 2010; Werner et al. 2013), suggested exchange of MGEs carrying antimicrobial resistance genes between animal and clinical enterococci. However, studies using WGS have

minimized this risk. A study investigated a large ($n = 1644$) collection of *E. faecium* isolates from hospitals, healthy individuals, and animals using short- and long-read sequencing in combination with a machine learning classifier. The study revealed that evolution of plasmids in *E. faecium* is driven by host and ecological factors that hinder transmission between different reservoirs (Arredondo-Alonso et al. 2020). Another large-scale study conducted on *E. faecium* isolates from livestock, retail meat, wastewater, and bloodstream infections in the UK provided further evidence for niche adaptation and limited exchange of antimicrobial resistance genes between these reservoirs on a national scale (Gouiliouris et al. 2018). The picture seems to be rather different for *E. faecalis*. WGS analysis of a unique collection of 2207 *E. faecalis* strains isolated from different sources over a period of 82 years (1936–2018) showed that the accessory genome of this species is shared between various host types, including animals and human patients (Pöntinen et al. 2021). The authors concluded that *E. faecalis* is an ecological generalist microbe that carries genes or adaptive variants that enable its survival in different ecological niches, as opposed to *E. faecium*, which appears to be highly host-specific and comprises lineages that are clearly adapted to specific hosts.

19.5 Conclusions

Enterococci are among the leading causes of life-threatening infections in humans, such as bacteremia and endocarditis. These infections are generally treated empirically and the consequences of treatment failure may be fatal to the patient if infection is caused by a strain resistant to first-line agents. By this chapter, the authors made an attempt to evaluate to what extent resistance problems in enterococcal infections in humans are attributable to strains and MGEs of animal origin. Aquatic animals and derived seafood were not included in the review, as enterococci isolated from these sources often derive from anthropogenic contamination. The authors' conclusion is that, in general, clinical *E. faecium* strains are not genetically linked to animal sources, whereas the boundary between animal and clinical *E. faecalis* strains is not well defined. Although there is a potential risk of clonal transmission of AREFm from companion animals, which are frequent carriers of hospital-associated lineages such as ST78 and ST192, the magnitude of such risk appears to be limited since strains isolated from these animals usually lack the putative virulence factors present in hospital strains. On the contrary, clear overlap is evident for multidrug-resistant *E. faecalis* ST16, which has been associated with both human patients and various animal species. Detailed population genetic analysis of *E. faecalis* indicates that this species is an ecological generalist able to adapt to different hosts, thereby providing opportunities for transfer of antimicrobial resistance between farms and hospitals, as opposed to *E. faecium* that appears to be an ecological specialist.

Even though resistance genes of clinical relevance have been reported in enterococci isolated from animals, comparison of data on occurrence of antimicrobial resistance in animal, meat, and human clinical isolates indicates that antimicrobial-resistant enterococci of animal origin pose an overall limited zoonotic risk, with differences linked to geographical region, specific types of resistance, and animal

sources. The major risk seems to be associated to horizontal transfer of gentamicin resistance genes through consumption of poultry meat, especially in the USA, where resistance to this first-line agent is relatively frequent in isolates from broiler and turkey meat. Farm-to-fork transmission of gentamicin resistance genes is plausible since aminoglycosides are used in livestock production but hardly ever used for systemic antimicrobial therapy in the primary health-care sector because of parenteral administration and high toxicity. However, lack of prevalence and genomic data on carriage of gentamicin resistance strains in the community hampers quantification of this zoonotic risk. Similarly, zoonotic implications of linezolid-resistant strains from bovines and pigs have been described in Belgium but based on circumstantial evidence only. VRE strains causing human infections are not obviously linked to animals as indicated by the fact that they are prevalent in countries where avoparcin has never been used in livestock. Indigenous anaerobes in the patient's digestive tract seem to be a more important source of *vanB* operons than farm animals. As for *vanA* operons, the risk of zoonotic transfer was significantly reduced by the ban on avoparcin and by the consequent decrease of VRE in livestock.

The risk of foodborne transmission of antimicrobial-resistant enterococci is significantly higher for poultry meat than for other food products of animal origin, mainly due to higher risk of carcass contamination in poultry slaughtering and higher consumption of poultry meat. Although horizontal transfer of resistance genes from animal to human enterococci has been demonstrated to occur in the human digestive tract under in vivo conditions, the clinical significance of this phenomenon appears to be negligible, or at least limited, for *E. faecium* but not for *E. faecalis*. Thus, future research should focus on the ecology and epidemiology of MGEs carrying resistance genes of clinical relevance to assess the animal contribution to antimicrobial resistance in *E. faecalis* infections in humans.

It should be emphasized that these conclusions are largely based on studies from developed countries that either never used or banned the use of antimicrobial growth promoters in livestock for nearly two decades (at the time of writing this review), which has significantly reduced the occurrence of clinically relevant antimicrobial-resistant enterococci in the animal reservoir. Further research is needed to assess the risk of antimicrobial resistance transmission in countries where growth promoters continue to be used, which include developing and least developed countries that lack policies governing antimicrobial use and apply less efficient biosecurity measures to prevent zoonotic transmission.

Methicillin-Resistant *Staphylococcus aureus* in Food Animals

20

Host-Adaptive Evolution, Epidemiology, and Public Health Threat

Anders Rhod Larsen, J. Ross Fitzgerald, and Jesper Larsen

Contents

Abstract

Methicillin-resistant *Staphylococcus aureus* (MRSA) is an opportunistic human pathogen primarily associated with skin and soft tissue infections (SSTIs), but it is also an important cause of invasive and life-threatening infections. The emergence of livestock-associated MRSA (LA-MRSA) clones over the last two decades is worrisome, as they pose an additional threat to human health. LA-MRSA is most prevalent in industrial pig production systems in Europe and Asia but has also been increasingly recognized in other food animals and geographical regions. *S. aureus* has a remarkable ability to adapt to different host species, which is mediated by fixation of beneficial mutations and acquisition of mobile genetic elements encoding antimicrobial resistance determinants as well as colonization and virulence factors. LA-MRSA is a major cause of SSTIs among livestock workers, who are thought to serve as a source of transmission

to their household members and into the local rural community, from where the bacterium can spread into healthcare settings. Importantly, these populations include a higher proportion of elderly and immunocompromised people with an elevated risk of developing invasive staphylococcal illnesses. In contrast, the risk of foodborne transmission appears to be low, even though LA-MRSA is a frequent contaminant of retail foods. Thus, there is an urgent need to identify and implement effective control measures to prevent spillover of LA-MRSA from livestock workers into the general population.

20.1 Introduction

Staphylococcus aureus is an opportunistic pathogen that colonizes the nares, pharynx, perineum, and other mucosal surfaces of about 50% of the human population worldwide, of whom about 20% are persistent carriers (Lowy 1998; Wertheim et al. 2005; van Belkum et al. 2009). *S. aureus* usually spreads through direct exposure (e.g., via hands) to colonized persons, and people colonized with *S. aureus* are at increased risk for developing infections, especially when the skin or mucosal barriers are breached or if the immune system is suppressed (Lowy 1998; von Eiff et al. 2001; Wertheim et al. 2005). *S. aureus* is primarily associated with skin and soft tissue infections (SSTIs) but is also a prominent cause of invasive, life-threatening infections, including bacteremia, endocarditis, osteomyelitis, and arthritis (Lowy 1998; Wertheim et al. 2005).

Methicillin-resistant *S.* aureus (MRSA) continues to be one of the most common antibiotic-resistant bacteria causing invasive disease in humans. It is estimated that in Europe alone MRSA causes approximately 171,000 invasive infections each year (ECDC and EMA 2009). MRSA is resistant to nearly all β-lactam antibiotics, which has serious implications for the treatment of severe infections. For example, it has been estimated that MRSA was responsible for more than 100,000 deaths and 3.5 million disability-adjusted life-years (DALYs) attributable to methicillin resistance based on an alternative scenario in which all MRSA infections were replaced by methicillin-susceptible *S. aureus* (MSSA) infections (Antimicrobial Resistance Collaborators 2022). As a consequence, the World Health Organization now considers MRSA to be one of the greatest threats to human health (WHO 2017). MRSA was first described in patients in 1961 shortly after the introduction of the β-lactam antibiotic, methicillin, as a treatment option against emerging penicillin-resistant *S. aureus* (Jevons 1961). For a long while, hospitals and other healthcare institutions

were the only reservoir for MRSA, but this changed dramatically in the 1990s with the emergence of numerous MRSA clones in the community (Chambers and DeLeo 2009). These geographically and evolutionary distinct community-associated MRSA (CA-MRSA) clones, such as USA300 in North America, continue to pose a major threat to public health due to their rapid spread in the general population and their ability to cause infections in young and otherwise healthy people.

Methicillin resistance in *S. aureus* is mediated by the *mecA* or *mecC* gene encoding enzymes called penicillin-binding protein 2a (PBP2a) and penicillin-binding protein 2c (PBP2c), respectively, which confer resistance to virtually all β-lactam antibiotics, including penicillinase-labile penicillins (e.g., penicillin G), penicillinase-stabile penicillins (e.g., methicillin), and cephalosporins (e.g., cefoxitin). The *mecA* and *mecC* genes are located on chromosomally integrated mobile genetic elements (MGEs) known as staphylococcus cassette chromosome *mec* (SCC*mec*), which can be classified into types defined by the combination of the type of *ccr* gene complex, which encodes unique site-specific cassette chromosome recombinases, and the class of the *mec* gene complex, which is composed of *mecA* or *mecC* and their regulatory genes (IWG-SCC 2009). MRSA clones are commonly defined by their multilocus sequence type (e.g., ST8) or clonal complex (e.g., CC8; a CC is a group of STs sharing at least five of seven identical alleles with at least one other ST in the group) and the SCC*mec* type (e.g., SCC*mec* IV).

The first reports of MRSA in pigs and pig farmers originated from France and the Netherlands and were published in 2005 (Armand-Lefevre et al. 2005; Voss et al. 2005), which marked the beginning of a new wave of methicillin resistance. Livestock-associated MRSA (LA-MRSA) is most prevalent in industrial pig production systems but has also been reported from other food animals worldwide, although the specific clones that have emerged vary with geographical location. For example, CC398 is the predominant LA-MRSA clone in Europe, whereas most LA-MRSA isolates from Asia belong to CC9. There is a wealth of literature concerning the presence, characterization, and geographic distribution of LA-MRSA clones in food animals, including the latest edition of this book and recent literature dedicated entirely to this subject (Fitzgerald 2012; Guardabassi et al. 2013; Chuang and Huang 2015; Butaye et al. 2016; Fitzgerald and Holden 2016; Aires-de-Sousa 2017; Haag et al. 2019). Our goal here is to discuss the origin, evolution, and host adaptation of *S. aureus* in animals and the epidemiology and disease burden of LA-MRSA in the human population, with special emphasis on CC398.

20.2 Origin and Evolution of MRSA in Animals

S. aureus is a model multihost pathogen responsible for an array of important infections in both humans and food animals. The evolutionary origin of *S. aureus* in different animal hosts has been an area of significant research interest over the last 10 years. In particular, the remarkable ability of *S. aureus* to adapt to different host species has underpinned its expansion into new host niches and its corresponding

economic and veterinary health impact. An understanding of the mechanisms facilitating *S. aureus* host adaptation can reveal novel targets for the development of therapeutics for controlling infections, some of which might be relevant to multiple host species, including humans.

The availability of large numbers of whole genome sequences for *S. aureus* isolates from different clinical, geographic, temporal, and host sources has led to significant improvements in our ability to investigate the evolution of *S. aureus* (Fitzgerald and Holden 2016). Although studies of animal *S. aureus* clones have traditionally lagged behind research of human *S. aureus* clones, large numbers of whole genome sequences have recently become available for animal isolates, thus enabling us to trace the events that have promoted the evolution of animal-specific clones (Richardson et al. 2018; Hoekstra et al. 2020; O'Dea et al. 2020; Ekesi et al. 2021; Shittu et al. 2021). These population genomic studies also provide a framework to investigate the mechanisms of pathogenesis that underpin adaptation to different host species.

Several studies have employed a population genomic approach to explore the evolutionary history of animal *S. aureus* isolates and their relatedness to human *S. aureus* isolates. Richardson et al. provided the most comprehensive analysis to date, involving over 800 *S. aureus* isolates from 43 different host species across 50 countries (Richardson et al. 2018). The analysis demonstrated that much of the diversity within *S. aureus* is represented by human isolates, while animal isolates often represent animal-specific subtypes that are interspersed among human clones in the *S. aureus* species phylogeny. Evolutionary analysis revealed that animal clones have evolved through host switch events with humans being a major hub, although cows also represent a reservoir for new pathogenic clones emerging in human populations. The earliest of these host switch events occurred several thousand years ago and have continued up to recent decades, correlating with the Neolithic era and the subsequent expansion, industrialization, and globalization of agriculture.

After a host switch event, *S. aureus* has been shown to be able to overcome narrow bottlenecks and high levels of genetic drift that reduce fixation of beneficial mutations in order to adapt to the new host species. In an experimental model of host switching, adaptive mutations were rapidly selected for and swept through the infecting population (Bacigalupe et al. 2019). In fact, single mutations can have a powerful impact on the capacity for bacterial host adaptation. For example, Viana et al. demonstrated that clinical *S. aureus* isolates recovered from natural infections of rabbits contain mutations in the *dltB* gene that are essential and sufficient for pathogenicity (Viana et al. 2015). In addition to mutations, acquisition of genes that are beneficial in the new host niche is critical for survival in the early stages after a host switch. MGEs such as prophages, staphylococcal pathogenicity islands (SaPIs), and plasmids have been identified that encode effectors facilitating innate immune evasion in different host species. For example, human *S. aureus* clones harbor the so-called immune evasion cluster 1 (IEC1) on a ΦSa3int prophage integrated into the *hlb* gene on the bacterial chromosome (Bae et al. 2006; Richardson et al. 2018). The IEC1 element encodes one or more determinants, including staphylococcal complement inhibitor (SCIN), chemotaxis inhibitory protein of staphylococci

(CHIPS), staphylokinase (SAK), staphylococcal enterotoxin A (SEA), and staphylococcal enterotoxin P (SEP), each of which interacts specifically with components of the human innate immune system (Thammavongsa et al. 2015). In addition, a family of phages encodes leukocidin toxins, which have a host-dependent tropism for neutrophils (Spaan et al. 2017). SaPIs commonly encode superantigens that contribute to immune evasion by stimulating the activation of host-specific subsets of T cells, leading to dysregulation of the T cell immune response (Deringer et al. 1997; Wilson et al. 2018). SaPIs can also encode von Willebrand factor binding proteins (vWbps) that stimulate coagulation of plasma promoting abscess formation (McAdow et al. 2012). While all *S. aureus* isolates contain a chromosomal copy of the *vwb* gene, the encoded vWbp does not coagulate plasma from ruminants but the SaPI-encoded variant does, thereby conferring the capacity for abscess formation in cows, sheep, and horses (Viana et al. 2010). In parallel to gene acquisition, gene loss is a common feature of host adaptation as demonstrated particularly for ruminant *S. aureus* (Guinane et al. 2010; Richardson et al. 2018). A particularly striking example is the evolution of a subtype of *S. aureus* subsp. *anaerobius,* a species that is a highly host-specialized pathogen associated with a specific pathology of superficial lymph nodes in goats and sheep known as Morel's disease. During host restriction, large chromosomal rearrangements have occurred along with the accumulation of over 200 pseudogenes, resulting in a highly fastidious metabolism (Yebra et al. 2021). Moreover, the number of insertion sequences (IS) has expanded, particularly in intergenic regions where they provide distinct mechanisms for the control of expression of flanking genes (Yebra et al. 2021). In addition to gene acquisition and loss, over a longer period of time in the new host, mutation and recombination contribute to further refinement to differences in nutrient availability that exist in the new host. For example, bovine *S. aureus* exhibits enhanced utilization of lactose, the major source of carbohydrate in milk, which might be the result of mutations affecting expression of sugar transport systems (Richardson et al. 2018).

The evolutionary history of important *S. aureus* clones in food animals has been explored previously. For example, the first report of a host switch event leading to the emergence of a poultry-adapted *S. aureus* CC5 clone provided evidence for its origin in humans followed by acquisition of avian-specific MGEs that promote protection against killing by avian heterophils (Lowder et al. 2009; Ekesi et al. 2021). The *S. aureus* CC5 clone was subsequently disseminated around the world via the globalized broiler poultry industry.

Subsequently, Price et al. used a comparative genomic approach to dissect the evolutionary history of *S. aureus* CC398, which comprises the predominant LA-MRSA clone in Europe (Price et al. 2012). The analysis showed that LA-MRSA CC398 evolved from a human variant of *S. aureus* CC398, and that the host switch was accompanied by simultaneous loss of the IEC1-harboring ΦSa3int prophage and acquisition of a transposon containing the tetracycline resistance gene *tet*(M). This was later followed by acquisition of different SCC*mec* elements and other determinants conferring resistance to some of the most frequently used veterinary antimicrobials (Price et al. 2012; Sieber et al. 2018). LA-MRSA CC398 has become particularly widespread in large-scale confined pig holdings (EFSA 2009, 2010) but

is also found in other animals such as veal calves, horses, mink, and poultry, with some of the isolates showing signs of further host adaptation through gene acquisition (Abdelbary et al. 2014; Larsen et al. 2016; Hansen et al. 2020; EFSA and ECDC 2021). The rapid spread of LA-MRSA CC398 is primarily facilitated by animal movements, although spread via human carriers and contaminated fomites has also been documented (Grøntvedt et al. 2016; Sieber et al. 2018; Smith et al. 2018).

The other major LA-MRSA clone, CC9, is common in pigs in some parts of the world particularly in Asia (Ji et al. 2021; Jiang et al. 2021; Yu et al. 2021). Yu et al. showed that LA-MRSA CC9 evolved from a human variant of *S. aureus* CC9 through a stepwise trajectory resembling that of LA-MRSA CC398, including initial loss of the IEC1-harboring ΦSa3int prophage and subsequent acquisition of different SCC*mec* elements and other determinants, such as the tetracycline resistance gene *tet*(L) and the SaPI-encoded vWbp protein associated with abscess formation in cows, sheep, and horses (Yu et al. 2021).

20.3 Epidemiology and Disease Burden of LA-MRSA CC398 in Humans

Much of our knowledge about the epidemiology and disease burden of LA-MRSA in humans comes from studies on the CC398 clone in Europe.

20.3.1 Epidemiology

The mechanisms leading to *S. aureus* colonization, transmission, and infection are multifactorial and include both host and bacterial determinants (Wertheim et al. 2005). For example, *S. aureus* has to overcome several obstacles in order to colonize the nares. First, *S. aureus* needs to come in contact with the nose. Second, *S. aureus* must adhere to receptors in the nose. Third, *S. aureus* must be able to resist the host defenses. Finally, *S. aureus* needs to be able to propagate in the nose. Hands are considered to be the most important vector for *S. aureus* transmission to the nasal niche. Most *S. aureus* infections are caused by the patient's own *S. aureus* inhabiting the skin or mucosal membranes prior to disease onset, and persistent carriers therefore have a higher risk for developing an *S. aureus* infection (von Eiff et al. 2001). On the other hand, the mortality rate from *S. aureus* bacteremia is higher in non-carriers than in carriers, suggesting that partial immunity might play an important role (Wertheim et al. 2004).

LA-MRSA CC398 is frequently transmitted to persons who have direct exposure to food animals, leading to carriage rates of up to 87% (Cuny et al. 2009; Garcia-Graells et al. 2013). The frequency and duration of carriage seems to depend on the intensity of livestock exposure. Livestock workers might carry LA-MRSA CC398 outside the farm environment for long periods up to several weeks. For example, Köck et al. showed that the prevalence among pig farm workers decreased from 77% to 46% during summer vacation (Köck et al. 2012), while Graveland et al. found that

the prevalence among veal calf farmers was 26% to 11% in periods with and without animal exposure, respectively (Graveland et al. 2011). In contrast, persons with short-term exposure to positive animals are less likely to establish and maintain LA-MRSA CC398 carriage for more than a few days (van Cleef et al. 2011a; Angen et al. 2017). LA-MRSA CC398 is also commonly found in household contacts of colonized or infected livestock workers and veterinarians, albeit usually at relatively low frequencies of up to around 5% (Cuny et al. 2009; Garcia-Graells et al. 2013; van Cleef et al. 2014; Verkade et al. 2014). LA-MRSA CC398 is primarily associated with SSTIs among young and otherwise healthy livestock workers but is also capable of causing serious illness and even death in the general population, which includes a higher proportion of elderly and immunocompromised people with an elevated risk of developing invasive staphylococcal illnesses (Lekkerkerk et al. 2012, 2015; van Rijen et al. 2014; Deiters et al. 2015; Larsen et al. 2015, 2017; Kinross et al. 2017; Sieber et al. 2020). This is illustrated by surveillance data from Denmark, which showed that approximately 30% of all LA-MRSA CC398 SSTIs and 60% of all LA-MRSA CC398 bloodstream infections (BSIs) occur in people without livestock exposure (Larsen et al. 2017).

There is a clear spatiotemporal relationship between LA-MRSA CC398 infections in people with and without livestock exposure, suggesting that persons with direct livestock exposure might serve as a source of transmission to their household members (indirect exposure) and into the local rural community, from where the bacterium can spread into healthcare settings (Larsen et al. 2015). It should be noted, however, that the transmissibility of LA-MRSA CC398 in community and healthcare settings is significantly lower than that of other MRSA clones (Bootsma et al. 2011; Wassenberg et al. 2011; Hetem et al. 2013; Verkade et al. 2014), which might explain why LA-MRSA CC398 only causes sporadic illness in persons living in urban areas and minor outbreaks in healthcare institutions. LA-MRSA CC398 has undergone several genetic changes that in theory could have reduced the bacterium's ability to survive and cause disease in the human population. For example, LA-MRSA CC398 lacks many of the colonization and virulence factors found in human *S. aureus* clones, including extracellular matrix-binding protein-binding protein (Empbp), elastin-binding protein (EbpS), Panton-Valentine leukocidin (PVL), toxic shock syndrome toxin 1 (TSST1), staphylococcal enterotoxin B (SEB), staphylococcal enterotoxin C (SEC), staphylococcal enterotoxin K (SEK), staphylococcal enterotoxin L (SEL), staphylococcal enterotoxin Q (SEQ), and exfoliatin A (Hallin et al. 2011). LA-MRSA CC398 also lacks the IEC1 element and the associated ability to evade our innate immune system due to loss of the ΦSa3int prophage during the human-to-animal host switch event (Price et al. 2012). Finally, LA-MRSA CC398 has acquired several MGEs encoding resistance to a wide range of the most frequently used antimicrobial drugs in pigs, which are likely to exert a considerable fitness cost outside the livestock reservoir (Andersson and Hughes 2010; Sieber et al. 2018).

LA-MRSA CC398 is a frequent contaminant of retail foods in Europe, including pork, beef, veal, chicken, turkey, lamb, and mutton, and it therefore seems reasonable to assume that people are exposed to this bacterium with some frequency

through consumption or handling of contaminated food products (Kluytmans 2010). Indeed, it has been shown that contaminated poultry meat can be a source of LA-MRSA CC398 infection (Larsen et al. 2016). However, the majority of LA-MRSA CC398 infections occurs in persons living in rural areas where food animals are raised, as mentioned above, suggesting that the spread of LA-MRSA CC398 into the general population is mainly due to local transmission from nearby animal farms. LA-MRSA CC398 has also been detected in low concentrations in air and soil samples collected around pig farms, but it is currently unknown whether, and to what extent, these environments play a role in LA-MRSA CC398 transmission to humans (Schulz et al. 2012; Angen et al. 2021).

20.3.2 Disease Burden

MRSA continues to pose a significant public health threat worldwide. For example, MRSA accounted for approximately 22% of infections caused by antibiotic-resistant bacteria of public health concern within the European Union and European Economic Area (EU/EEA) during 2015, 21% of attributable deaths, and 19% of DALYs (Cassini et al. 2019). In a more recent study, MRSA was found to be the leading pathogen-drug combination worldwide during 2019, when it caused more than 100,000 deaths and 3.5 million DALYs (Antimicrobial Resistance Collaborators 2022). In contrast, the relative disease burden of LA-MRSA CC398 is geographically heterogeneous. Kinross et al. estimated the burden of human infections caused by MRSA CC398 in seven EU/EEA countries during 2013, measured as the proportion of LA-MRSA CC398 cases among the total number of MRSA cases (Kinross et al. 2017). Overall, LA-MRSA CC398 accounted for 9.0% of the total number of MRSA cases. Denmark, the Netherlands, and Spain had a substantially higher estimated disease burden of LA-MRSA CC398 than France, Germany, Norway, and Poland (16.7%, 21.5%, and 9.7% vs. 1.7%, 2.6%, 1.5%, and 1.8%, respectively). In comparison, the burden of LA-MRSA CC398 in Denmark and the Netherlands was much lower in a similar study conducted by van Cleef et al. in 2007 (1.6% and 11.9%, respectively) (van Cleef et al. 2011b). This temporal trend was paralleled by a shift in the proportion of MRSA bloodstream infections (BSIs) caused by LA-MRSA CC398, which increased from 0.6% in 2007 to 4.6% in 2013 (van Cleef et al. 2011b; Kinross et al. 2017). Surveillance data from Denmark and the Netherlands suggest that LA-MRSA CC398 still accounts for a substantial proportion of the total number of MRSA cases (DANMAP 2021; NethMap 2021).

There are two main reasons that explain the high relative burden of LA-MRSA CC398 in Denmark and the Netherlands. First, both countries are relatively small with a population of 5.8 and 17.3 million, respectively (https://data.worldbank.org/), but have large industrial pig production systems (https://www.fao.org/faostat/) with a high prevalence of LA-MRSA CC398 (EFSA and ECDC 2021). Second, Denmark and the Netherlands have very low levels of other MRSA clones compared to other European countries. This is illustrated by the fact that MRSA accounted for only 2.2% and 1.6% of all episodes of *S. aureus* BSI in Denmark and the Netherlands in

2019, respectively, when the population-weighted EU/EEA mean was 15.5% (ECDC 2020).

Surveillance data from Denmark illustrate the connectivity between the prevalence of LA-MRSA CC398 in pigs and the disease burden. Larsen et al. showed that the prevalence of LA-MRSA CC398 in Danish pig farms increased from 16% in 2010 to more than 60% in 2014, which was paralleled by an increasing number of LA-MRSA CC398 SSTIs and BSIs (Larsen et al. 2017). In 2014, LA-MRSA CC398 accounted for 16% and 21% of all MRSA BSIs and SSTIs, corresponding to 1.2 and 37.4 cases of BSI and SSTI per 1,000,000 person-years, respectively. Approximately 30% of all patients with LA-MRSA CC398 SSTI and 60% of all patients with LA-MRSA CC398 BSI reported neither direct nor indirect livestock exposure, reflecting the fact that the general population comprises a higher proportion of people at elevated risk of developing invasive infections, compared to people with livestock exposure. The 30-day case-fatality rates among patients with LA-MRSA CC398 BSI and other types of MRSA BSI were not significantly different from each other (35% vs. 21%), which suggests that LA-MRSA CC398 is as capable as other MRSA clones of causing death once it has entered the bloodstream.

20.3.3 Emerging Public Health Threats?

The last 10 years of population genomics have improved our understanding of the evolution of LA-MRSA. However, it is evident that new clones are emerging and existing clones continue to evolve. For example, two recent studies from Australia identified a hitherto unrecognized LA-MRSA clone, CC93 (Sahibzada et al. 2017, 2020). Analyses of the isolates showed that they are closely related to isolates belonging to the predominant CA-MRSA clone in Australia, CC93, suggesting that they might have evolved through a recent human-to-animal host switch event. In contrast to LA-MRSA CC398, a substantial proportion of the LA-MRSA CC93 isolates carry the same IEC1 element and PVL-encoding *lukS-PV* and *lukF-PV* genes as their presumed CA-MRSA CC93 progenitor. The presence of PVL in LA-MRSA CC93 has raised public health concerns because of the association between PVL and development of severe staphylococcal diseases, including sepsis, in young and otherwise healthy people (Tong et al. 2010).

Other studies have shown that LA-MRSA CC398 might be capable of adapting to the human host through acquisition the phage-encoded immune modulators. For example, a Danish study showed that 6% of human LA-MRSA CC398 isolates collected during 2004–2011 harbored the IEC1 element, while a German study found a low, albeit slightly increasing, prevalence of IEC1 among LA-MRSA CC398 isolates from hospital patients during 2000–2015, ranging from 1.1% during 2000–2006 to 3.9% during 2007–2015 (Larsen et al. 2015; van Alen et al. 2018). In another study, Gerlach et al. showed that 40% of LA-MRSA CC398 isolates from pigs in Denmark produce another phage-encoded immune modulator enzyme known as TarP, which enables *S. aureus* to evade antibody-mediated immune recognition by altering the dominant cell surface epitope known as wall teichoic acids (Gerlach

et al. 2018). In a later study, Sieber et al. were able to demonstrate that reacquisition of the IEC1-harboring ΦSa3int prophage by LA-MRSA CC398 facilitates household transmission and further spread into the community and healthcare settings (Sieber et al. 2020). The additional disease burden attributable to IEC1-positive LA-MRSA CC398 isolates was nevertheless relatively low, and the authors found no evidence to suggest that they have become self-sustainable in the general population. In contrast to IEC1, TarP did not influence household transmission of LA-MRSA CC398.

Antimicrobials are widely used for treatment of animals with clinical infectious disease, disease prevention, and growth promotion in food animals. In EU/EEA, antimicrobial use in food animals is estimated to account for approximately 50% of the annual antimicrobial consumption, some of which are important for human medicine, including the treatment of *S. aureus* infections (EMA 2019; ECDC et al. 2021). The widespread use of antimicrobials in food animals is thought to be a major driver of antimicrobial resistance and, in the worst case, might lead to the emergence of multidrug-resistant bacteria that are difficult to treat in humans. In accord with this view, most LA-MRSA isolates are resistant to multiple classes of veterinary antimicrobials such as β-lactams (mediated by the *mecA* or *mecC* gene), aminoglycosides, lincosamides, macrolides, pleuromutilins, quinolones, streptogramins, and tetracyclines. However, there are still several alternatives available for the treatment of LA-MRSA infections, including rifampin, fosfomycin, vancomycin, daptomycin, linezolid, fusidic acid, and tigecycline, although it should be noted that resistance to rifampin and linezolid has been described previously in LA-MRSA CC398 and LA-MRSA CC9 (Kehrenberg et al. 2009; Li et al. 2016).

20.4 Research Needs

The dynamic nature of *S. aureus* genome evolution and its striking host adaptability underscores the need for continued surveillance at the human-animal interface to detect genetic as well as epidemiologic changes that affect public health. Most LA-MRSA clones and isolates lack the IEC1 element, and many studies have used PCR-based detection of the *scn* gene encoding SCIN (a marker of IEC1) to differentiate between LA and human variants. However, many variables can influence the performance of this test in different settings, including the genetic background of the local *S. aureus* populations (e.g., a relatively high proportion of LA-MRSA CC93 harbors the IEC1 element) and local evolutionary events (e.g., reacquisition of the IEC1-harboring ΦSa3int prophage by LA-MRSA CC398). Whole genome sequencing (WGS) is increasingly used for *S. aureus* outbreak investigation and surveillance and, as summarized in the current chapter, has been used to investigate the epidemiology and population structure of LA-MRSA clones (Price et al. 2012; Yu et al. 2021). These reference population structures enable rapid and accurate typing of isolates based on their phylogenetic relationships with the reference isolates as well as identification of genetic changes that might affect the epidemiology. Furthermore,

machine learning approaches could be applied to identify high-risk clones with potential to spread and cause disease in human populations.

The impact of LA-MRSA on human morbidity and mortality will likely increase in the near future if LA-MRSA CC398 and other LA-MRSA clones are allowed to spread into the general population, and it is therefore important to identify and implement effective control measures to reduce the rate or level of LA-MRSA carriage among livestock workers when they leave the farm (e.g., handwashing and disinfection and change of clothes and footwear) in order to minimize the risk of transmission outside the farm environment. There is also a need for studies that evaluate the role of foodborne transmission and environmental contamination in the expansion of LA-MRSA into the general population.

Food animals also carry MSSA isolates (Hasman et al. 2010). Yet, their impact on public health has not been well studied. Preliminary surveillance data from Denmark show that two-thirds of all LA *S. aureus* CC398 BSI isolates are methicillin-susceptible, of which one-fourth harbor the IEC1 element (A. Larsen & J. Larsen, unpublished data). Future studies should aim to determine the relative disease burden of LA-MRSA and LA-MSSA in other parts of the world.

20.5 Conclusions

In summary, *S. aureus* has a remarkable capacity to adapt to different host species and acquire resistance to antimicrobials. These traits demand close and continued scrutiny via surveillance employing high-throughput WGS and phylodynamic and machine learning approaches in order to identify high-risk clones and implement measures to limit spread into and within human populations.

Abstract

At present, various zoonotic and multidrug resistant (MDR) bacteria, including but not limited to *Staphylococcus aureus* and *Escherichia coli*, are well-equipped to survive and conquer new habitats, environments, and host species. These bacteria carry the ability to cross host species barriers through host-range broadening virulence factors and antimicrobial resistances, combined with mechanisms allowing them to spread and prosper, not only in clinical environments but also beyond their natural surroundings. This phenomenon can colloquially be summarized as an "enlarging the cake" strategy, meaning that from a long-term evolutionary perspective, generalist variants of bacterial species diverge into distinct habitats on their way to a specialized existence within a niche. While knowledge on the pathomechanisms behind bacterial diseases and infection sources are readily available, trans-sectoral research on the transmission of MDR bacteria across humans, animals, and the environment, although considered to be a prime example of the One Heath concept, lies still in its infancy, especially with respect to the role of companion animals. In addition, challenges such as the mobilization of novel antimicrobial resistance genes from the global resistome as well as incalculable external influences on this matter arising from both climate and landscape changes are predicted to arise in the near future. However, new opportunities to combat MDR bacteria in human and veterinary medicine lie within research conducted across the One Health framework: Novel technologies powered by bioinformatics that permit bacterial identification, typing, and source attribution on a nearly unlimited scale, allowing to unravel the natural forces driving bacterial evolution and enabling the development of suitable intervention strategies.

21.1 Rising Awareness of Antimicrobial-Resistant and Zoonotic Bacteria in Human and Animal Medicine

Surviving under the selective pressure of an anti-infective agent to which the bacteria originally had been susceptible is referred to as antimicrobial resistance (AMR) (WHO 2017a). Acquired antimicrobial resistance is a result of either mutations within the bacterial genome or an uptake of foreign genetic material (Schwarz et al. 2017). Only recently AMR among common zoonotic bacteria has been recognized as an emerging threat for public health (Rozman et al. 2019). Infections associated with AMR pathogens often require extensive clinical care as well as *enhanced and/or sophisticated antibiotic treatment*, which in turn can lead to an increase of severe side *effects for both, human and animal patients. Prolonged patient* suffering or even death, enhanced medical expenses, as well as considerable economic costs are direct results of bacterial infections caused by resistant pathogens (Wozniak et al. 2019). A recent study investigated 471 million individual records and isolates world-wide with respect to AMR in human medicine. As a result, the authors estimated a global burden of 1.2 million deaths from infectious diseases being associated with AMR bacteria in 2019 alone (Murray et al. 2022). The leading causes behind fatal outcomes were, among others, infections with *Escherichia coli*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, and *Pseudomonas aeruginosa*. As stated in the report (Murray et al. 2022), all of these bacteria had previously been categorized as priority pathogens by the World Health Organization (WHO 2017b). Since the early 2000s, reports on the occurrence and spread of bacteria exhibiting AMR or even multidrug resistance (MDR), many of which can spread between humans and animals such as methicillin resistant *Staphylococccus aureus* (MRSA) and extended-spectrum β-lactam (ESBL)-producing bacteria of livestock and companion animal origin, have increased the awareness of this particular topic and have highlighted its relevancy for public health (reviewed in Walther et al. 2017; Walther 2021).

A PubMed search run illustrates the continuing annual increase of publications tackling both leading topics during the last 20 years (Fig. 1).

While AMR entering the food-chain through animal products is monitored within the European Union and many other industrialized countries, few countries monitor AMR in bacteria of companion animal origin on a regular basis (Weese 2008). However, reports on bacteria exhibiting AMR are only expected to increase even further (Ogeer-Gyles et al. 2006).

A recent review suggests that the number of pathogens reported as causes behind hospital-acquired infections (HAIs) in human medicine is limited to only 12–17 microorganisms, which account for up to 87% of the reported cases (Haque et al. 2018). This group comprises Gram-positive bacteria like *S. aureus*, coagulase-negative staphylococci *Enterococcus* spp., Gram-negative enterobacteria, such as *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., as well as nonfermenters *P. aeruginosa* and *A. baumannii*. The authors estimated that 16–20% of all HAIs

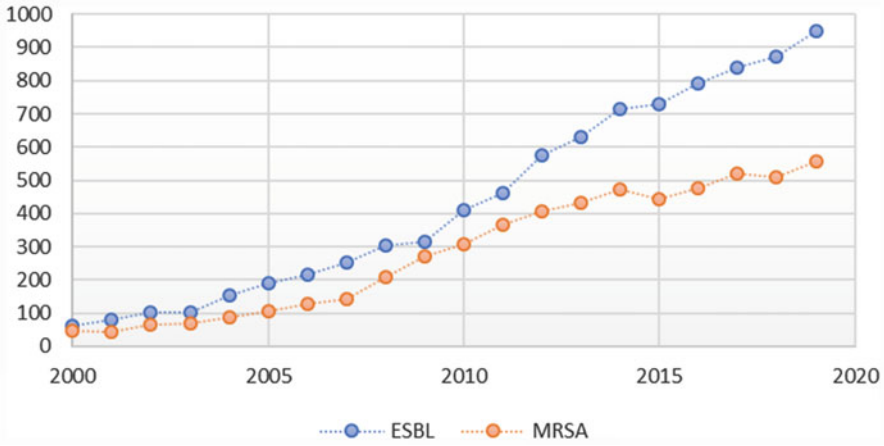

Fig. 1 Increase of publications on MDR bacteria associated with animals 2000–2019. PubMed search result (5 May 2021) of publications (total numbers (y)- and years on x-axis) on MRSA and ESBL-producing bacteria associated with animals using search query: [((animal) AND (extended-spectrum)) AND (lactamase) OR (ESBL)] and [(animal) AND ((aureus) AND (methicillin)) OR (MRSA) AND (animal) per year]

were caused by MDR bacteria including MRSA, vancomycin-resistant *E. faecium*, extended-spectrum β-lactam (ESBL)-producing *Enterobacteriaceae*, carbapenem-resistant enterobacteria, and Gram-negative nonfermenters (Haque et al. 2018).

Of note, bacteria exhibiting AMR often reside within human-, but also veterinary hospitals (Walther et al. 2017). Numerous reports on HAIs or even outbreaks associated with transmissible MDR bacteria are currently available not only from small animal clinics but also horse clinics (reviewed in Walther 2021). The most frequently reported HAIs associated with the companion animal health care sector are surgical site infections (SSI), blood stream infections, diarrhea, and urinary tract infections (Walther et al. 2014; Stull and Weese 2015). Due to the lack of systemic surveillance systems for recording infectious diseases across companion animals, including zoonotic pathogens and HAIs, reliable data on the occurrence and frequencies of various pathogens associated with outbreak scenarios in these hospitals are mostly absent (Walther 2021). However, ESBL-producing *Enterobacterales* and MRSA were among the most frequently reported causes of HAI in veterinary clinics (Wieler et al. 2015).

β-lactams, such as penicillin and cephalosporins, are known for their excellent pharmacokinetic properties which are commonly accompanied by a low toxicity for both humans and animals. Therefore, this group of well-tolerable anti-infective substances is among the first-line options for empirical antibiotic treatment of severe infectious diseases assumed to be caused by β-lactam susceptible bacterial species, including life-threatening scenarios such as septicemia (Walther 2021). Since β-lactam resistance is common among bacteria such as *Escherichia coli* and *Staphylococcus aureus* isolates from human as well as animal clinical origin, antibiotic options for severely ill patients are highly limited. Resistances toward other classes of antibiotics are frequently associated with β-lactam resistance

exhibiting bacteria such as ESBL-producing *E. coli* and MRSA (Geffers and Gastmeier 2011; Ruiz-Ripa et al. 2021) and can lead to a further reduction of therapeutic treatment options. Unsurprisingly, the development of specifically-tailored strategies to reduce the global burden of bacterial AMR is currently regarded as an urgent priority (Murray et al. 2022).

Understanding the evolutionary mechanisms and driving forces leading to the accumulation of AMR in bacteria, especially those considered to be transferable between humans and animals, is necessary in order to develop targeted and effective interventions for lowering the burden associated with both, the occurrence and spread of zoonotic AMR bacteria.

21.2 Mechanisms and Driving Forces Leading to the Emergence and Spread of Zoonotic and Antimicrobial Resistant Bacteria

21.2.1 The Accumulation of Mobile Antimicrobial Resistance in Bacteria Is Influenced by Selective Pressure

Several environmental bacteria and other microorganisms produce, beyond other metabolites, antibiotics to compete with co-habitants of their living space (Allen et al. 2010) (Fig. 2). As defensive measures, these microorganisms have developed

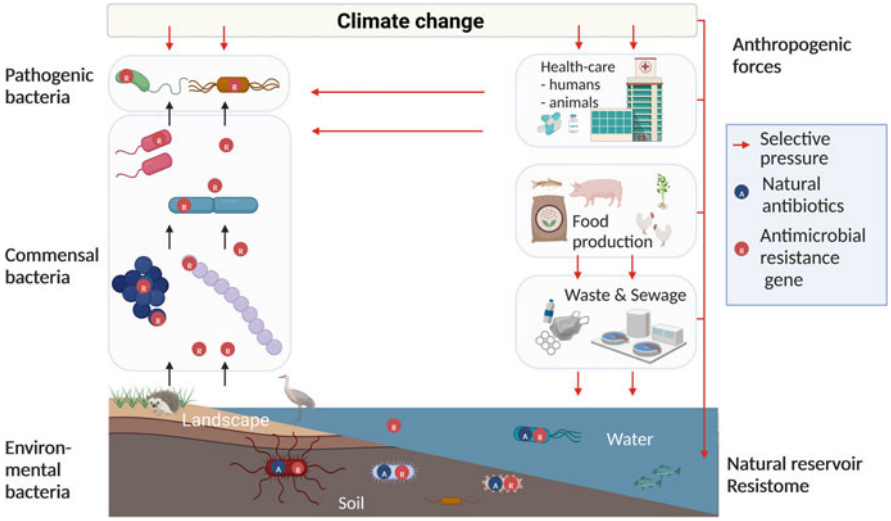

Fig. 2 Illustration of the mobile resistome: Evolutionary and ecological relationship of antimicrobial resistance genes (ARGs). (Adapted from an idea published in Walther (2021) illustration (created with BioRender.com, license BW (01.02.2021)). Natural and anthropogenic forces contribute to the selective pressure that ultimately mobilizes ARGs (Allen et al. 2010). Transmission of ARGs occurs through various pathways, summarized as horizontal DNA transfer (HDT) (reviewed in von Wintersdorff et al. 2016)

different mechanisms to exhibit AMR toward their own toxic agents (Davies and Davies 2010).

Some of these AMR encoding genes have gained mobility throughout prolonged periods of evolution, which in turn levelled the path for competing bacteria to also adapt resistances (D'Costa et al. 2011). Specific lineages of MRSA, for instance, emerged in European hedgehogs long before β-lactams were introduced for clinical usage (Larsen et al. 2022). Moreover, it has been demonstrated that the hedgehog dermatophyte *Trichophyton erinacei* produces two β-lactam antibiotics which provide a natural selective environment for MRSA in this particular host (Larsen et al. 2022).

All mobile genetic elements of pathogenic, commensal, as well as environmental bacterial origin constitute the global reservoir of antimicrobial resistance genes (ARGs) (referred to as the "mobile resistome," Fig. 2) from which susceptible bacteria can acquire resistance via horizontal gene transfer (HGT) (Schwarz et al. 2017). The prevalence of AMR in wild animals is in fact positively correlated with the level of human impact on the respective environment (Lagerstrom and Hadly 2021). While AMR among bacterial species residing in complex ecosystems is a natural and ancient phenomenon (D'Costa et al. 2011), accumulation of mobilized ARGs in bacteria is undisputable strongly anthropogenically influenced through artificial substances inducing a selective pressure on microorganisms in distinct life sectors (Wright 2007; Sultan et al. 2018) (Fig. 2). Thus, the use and misuse of antibiotics, heavy metals, and many other selective agents result in an increased spread of ARGs through mobile genetic elements (MGEs) from the environmental resistome to the commensal and finally to pathogenic bacteria (Fig. 2) (McEwen and Collignon 2018). The impact behind local and global changes in climate, especially temperature, and their association with increased antibiotic resistance and spread (Fig. 2) has recently shifted into focus of scientific interest (Rodriguez-Verdugo et al. 2020): many infectious diseases, including several vector- and water-borne diseases, are strongly influenced by climate variability resulting from large-scale environmental phenomena (Cavicchioli et al. 2019), and, to further complicate this issue, a recent prediction outlined that climate change will also increase rates of AMR in *Escherichia coli*, *Klebsiella pneumoniae,* and *Staphylococcus aureus* (MacFadden et al. 2018).

The emergence of AMR bacteria in companion animals is a complex field of research which is of increasing impact to both animal patient and public health issues (Weese 2008). In light of the emerging importance of ESBL-producing *E. coli* within farm and companion animals (Fig. 1), transmission of AMR pathogens (or resistance conferring genes) between distinct habitats including the environment, other animals, and humans, through manure (Schaufler et al. 2015; Kauter et al. 2021; Koeck et al. 2021) or close physical contact (Ewers et al. 2011; Wieler et al. 2011), for example, has gained scientific attention. ARG transfer between bacteria commonly residing within the intestines of humans and animal species, for instance, seems of high importance in respect to ARG accumulation of pathogens (Hu et al. 2016): Impressive networks for ARG transfer were identified for distinct genera such as Proteobacteria, Firmicutes, Bacteroidetes, and Actinobacteria – bacteria that are prone to HDT-mediated uptake of AMR (Hu et al. 2016). Among these, the species

Escherichia coli, *Bacteroides fragilis,* and *Staphylococcus aureus* were found to share the highest level of ARG interconnectivity, with each of them having the ability to exchange resistance conferring genes with more than 260 bacterial species (Hu et al. 2016).

21.2.2 The Emergence of Bacteria in Novel Habitats and Host Species Followed by Subsequent On-Site Adaptation Depends on Evolutionary Rules

Throughout recent years, new insights into the driving forces and mechanisms behind the transmission of zoonotic infectious diseases were gained. Novel sequencing technologies, for instance, allow comparative genomics of microorganisms residing in completely different locations (habitats), including bacteria associated with specific hosts, such as plants, fungi, and animals, but also bacteria associated with non-living environmental habitats (Sriswasdi et al. 2017). As a result, most bacterial species on earth fulfil the criteria for specialists, i.e., bacteria that are well-adapted to a specific living space and its particular environmental conditions, while generalists are characterized by their ability to prosper in different habitats (Sriswasdi et al. 2017). A habitat is defined as a specific space in which an organism commonly occurs. It seems that the emergence of generalist species (Fig. 3) possessing the ability to cross habitat (and species) barriers is, compared to the across-the-board range of the more prevalent specialized species, likely a transition phase (Sriswasdi et al. 2017). This period has been proposed to begin with the sudden intrusion of a generalist species into a (naïve) habitat, accompanied by a significant local proliferation and tendency to spread into further habitats (Fig. 3).

Once a generalist species has gained access to a novel habitat, the process of adaptation begins immediately (Sriswasdi et al. 2017), since only rapid adaptation allows the intruding bacteria to survive the novel environmental challenges (Fig. 3) and putative co-habitants with respect to long-term survival on-site (Sriswasdi et al. 2017). To illustrate the mechanisms and evolutionary drivers behind the interspecies transmission of AMR resistant bacteria, a closer inspection of habitat generalist prime examples, such as *Escherichia coli* and *Staphylococcus aureus*, seems reasonable, although only few lineages of the respective generalist population may actually be more prone to cross multiple species barriers (Sheppard et al. 2018). Consequently, these extended host spectrum genotype (EHSG) lineages (Walther et al. 2009) are of highest concern with respect to zoonotic transfer and accumulation of MDR, including high-risk clonal lineages (Wieler et al. 2015).

Of course, many vital events and circumstances promote or hinder the emergence of a novel species within an unaffected living space (habitat), especially its accessibility (Peterson 2011). At present, the accessibility of naïve habitats for bacteria and other pathogens is largely influenced through direct and indirect anthropogenic forces (Allen et al. 2010). Moreover, zoonotic host diversity increases in human-dominated ecosystems (Gibb et al. 2020). First and foremost, the undamped encroachment of humankind into our pristine nature has at least two significant,

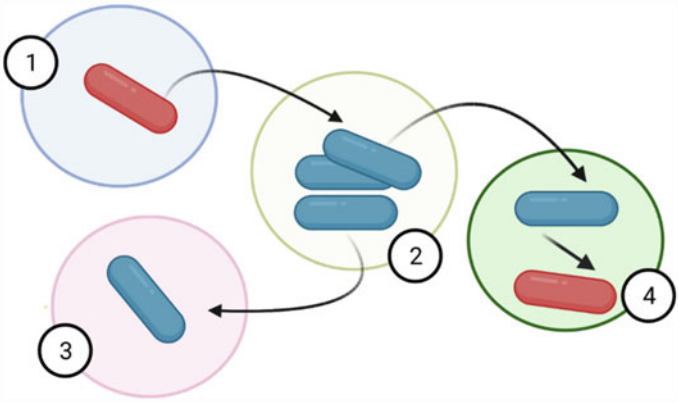

Fig. 3 Illustration of the generalist-specialist cycle of bacteria (Sriswasdi et al. 2017). A specialist (red) (**1**) develops into a generalist (blue), invades a novel habitat and proliferates (**2**). The generalist species (**2**) spreads into additional habitats (indicated by differently coloured circles) (**3** and **4**); if the generalist is not immediately become extinct within the novel living space (**4**), adaptive processes (ultimately) lead to a novel specialist fully equipped for long-term survival within the particular environment. The overall existence range of a habitat generalist seems, compared to the dominance of specialists, much shorter (Sriswasdi et al. 2017)

direct effects in regards to habitat accessibility of zoonotic bacteria: novel bacteria (and ARGs) are carried to locations they have never entered before and, on the other side, bacteria from these so far unexplored places are given access to the (general) population.

Prominent examples of such indirect forces include climate change, availability of essential supplies, selective pressure on bacterial habitats and, not at least, behavioural changes of humans and animals alike. Frequent, close physical contact, for instance, has become common between dogs and their owners (Wieler et al. 2015). A survey of a dog show event revealed that 68.5% of dog owners allowed their dog(s) to rest on the sofa, 39.8% allowed their dog(s) to lay on their bed, 93.5% let them lick their hands, and 52.8% let them lick their face (Walther et al. 2012). An additional study revealed that dog ownership not only significantly increases the shared skin microbiota in cohabiting adults, but dog-owning adults also share more "skin" microbiota with their own dogs than with other dogs (Song et al. 2013). Thus, close contact promotes the exchange of bacteria between humans and their companion animals, including horses, dogs, and cats (Bhat 2021). Access to novel habitats, as illustrated above, challenges bacteria with novel environmental conditions, resulting in either adaptation and survival or extinction. Examples of habitat generalists include prominent MDR bacterial species such as MRSA and *E. coli*; species which are of rising concern with respect to animal-human and human-animal transmission. Taken together, both, the invasive capabilities of bacteria as well as the consecutive process of on-site adaption challenged by novel habitats represents a force of nature (Sriswasdi et al. 2017) and therefore requires consideration in future research on the emergence of resistant and zoonotic bacteria in general.

21.3 A Closer Inspection of Prime Examples for Zoonotic and MDR Bacteria Reveals an Ongoing Adaptation Processes Toward Novel Environments and Host Species

21.3.1 Picturing Adaptation Strategies of MDR Bacteria Associated with Skin and Mucosal Surfaces: MRSA

21.3.1.1 *Staphylococcus aureus* Resides on Skin and Membranous Surfaces

Staphylococci are part of the commensal microorganisms residing on the skin and mucous surfaces of mammals and many other animals (Foster 2002). Classifying between coagulase-negative (CNS) and coagulase-positive (CPS) staphylococci is of high clinical relevancy: *S. aureus*, *S. pseudintermedius*, *S. coagulans*, *S. hyicus*, as well as some species of minor importance for healthcare (Foster 2002) are characterized by their ability to induce blood plasma coagulation via conversion of fibrinogen to fibrin (Pickering et al. 2021). The resulting clot acts as a mechanical shield, as it protects the bacteria from phagocytosis, enhances local adhesion opportunities and, not at least, provides a space for local population development (Foster 2002).

21.3.1.2 Clinical Importance of *S. aureus* in Human and Veterinary Medicine: A Brief Classification

While up to 40% of the general population occasionally carries *S. aureus*, 12–30% appear to be colonized permanently (Becker et al. 2017). Whenever outer barriers of the body, i.e., the skin or mucosal surfaces are vulnerable or damaged through either internal or external factors, *S. aureus* can gain access to the underlying tissues or the bloodstream and cause infection (Lee et al. 2018). The spectrum of illnesses caused by *S. aureus* ranges from toxin-associated diseases, i.e., food-poisoning, exfoliative/ulcerative skin diseases, and the toxic-shock syndrome, to severe invasive infections such as wound infections (especially surgical site infections), septicemia, pneumonia, and cellulitis. The reported incidence rates of *S. aureus* bacteremia range from 20 to 50 cases/100,000 population per year in different countries, and fatal outcomes were recorded for at least 10% of these cases (van Hal et al. 2012). An immediate suitable antibiotic intervention is essential in order to successfully combat *S. aureus* bloodstream infections, a fact that has been severely hampered due to the emergence of MRSA since the late 1970s. In recent years (2016–2020), the percentage of MRSA among *S. aureus* reported to the EARS/net in Europe has decreased, in some countries even below 5% (e.g., Spain, France, Germany). Other countries, however, still reported a rate above 25% (e.g., Greece, Italy, and Bulgaria) (www.atlas.ecdc.europa.eu/public) in 2020, highlighting the fact that MRSA remains an important pathogen, especially when combined with resistance toward further antimicrobial groups (EARS-Net 2021).

A German-wide representative study of 5229 samples from wound infections submitted by 1170 veterinary clinics illustrated the relevancy of *S. aureus* and MRSA for companion animal medicine. Swabs obtained from wound infections of dogs and cats revealed a *S. aureus* rate of 5.8% and 12.2%, respectively, and 22.8% for

samples of horse origin. The proportion of MRSA among these *S. aureus* was 62.7% (dogs), 46.4% (cats), and 41.3% (horses) (Vincze et al. 2014). Numerous studies performed comparative genomics on MRSA of companion animal origin. As a result, the majority of the isolates were identified to be part of phylogenetic lineages either dominating in human clinical cases ("epidemic lineages"), in livestock ("la") animals, or, to a much lesser extent, in free living animals and the environment (Cuny et al. 2010; Haenni et al. 2017; Larsen et al. 2022). MRSA currently dominating in European livestock animals and horses are of sequence type (ST) 398 or its variants and have successfully established a human/animal interface – this EHSG lineage (or generalist) is assumed to likely become a threat to public health through continued acquisition of virulence- and antibiotic resistance genes (Diene et al. 2017).

21.3.1.3 Adaptative Capabilities of *S. aureus*: Mechanisms Harnessed by a Habitat Generalist

Considering the general adaptation capabilities of *S. aureus*, recent research revealed that the species is a "master" with respect to its broad arsenal of immune evasion strategies (de Jong et al. 2019). Specific adaptations to evade host immune responses through the acquisition of MGEs harboring genes encoding immune evasion proteins were reported at least since 2013 (McCarthy and Lindsay 2013). Comparative analysis of the presence of genes mediating plasma-coagulation and the actual coagulation abilities of different CPS toward plasma of various host species (i.e., humans, birds, ruminants, horses, and pigs) has recently revealed that the *coa* gene encoding staphylocoagulase mediates plasma coagulation in *S. aureus*, while other CPS such as *S. pseudintermedius* depend on the presence of homologues of genes encoding the von Willebrand factor binding protein (*vwb*) (Pickering et al. 2021). It has been demonstrated that the ability to induce plasma coagulation was acquired on multiple occasions throughout the evolution of staphylococci (Pickering et al. 2021). Therefore, *S. aureus* harboring not only *coa* but also Staphylococcal Pathogenicity island (SaPI) encoded variants of the von Willebrand factor-binding protein (vWbp) are likely well-equipped to clot plasma of various host species (Viana et al. 2010) which indeed seems beneficial for "host jumping" bacteria.

Since activation of the complement system is essential for an effective immune response of mammals against invading pathogens, *S. aureus*-derived convertase inhibitors play a crucial role for the bacterial survival (Jongerius et al. 2007). The human-specific immune evasion complex (IEC) is commonly associated with temperate phages (van Wamel et al. 2006; Walther et al. 2018). The backbone of the IEC includes genes for a complement-protein cleaving Staphylokinase (SAK) and the Staphylococcal complement inhibitor (SCIN) known to interfere with the activation of complement factor C3 (McCarthy and Lindsay 2013). Of note, interfering with phagocytosis through inactivation of the C3 convertase complex in the alternative pathway of complement factor activation is among the most important immune evasion strategies of *S. aureus* (Ricklin et al. 2009). MRSA ST398 of horse origin harboring distinct allelic variants (*scn*, *scn*bov, *scn*eq) for encoding SCIN were reported across horses in different countries (Haenni et al. 2017; Walther et al. 2018). Functional analysis of the equine SCIN variant (SCINeq) revealed its general activity in plasma of multiple hosts, including horses, humans, and pigs (de Jong

et al. 2018). Since equine MRSA belonging to ST398 often harbour different combinations of *scn* variants (Walther et al. 2018), this lineage seems fully equipped to survive and prosper at least among humans, ruminants, pigs, and horses – a prime example of a host generalist (Walther 2021).

Of course, factors promoting host or habitat adaptation are not limited to immune evasion or plasma coagulation. Additional genes, often located on MGEs, encode adhesins, toxins, and further immunomodulatory factors known for their specific abilities to enhance survival in distinct hosts (Everitt et al. 2014; Diene et al. 2017; Walther 2021). Therefore, the broad host range associated with MDR MRSA, such as MRSA-ST398, have clear implications for biosafety and infection control (Walther 2021).

21.3.2 Adaptation Strategies of MDR Enterobacteria: *Escherichia coli*, the Classical "Jack of All Trades"

21.3.2.1 *Escherichia coli* Belongs to the Gut-Associated Microbiota in Humans and Animals

While staphylococci represent bacteria residing foremost on outer parts of the body such as skin and mucosal surfaces, *E. coli* are typical members of the gut microbiota, at least in mammals and birds (Guenther 2015). The commensal and thus usually apathogenic *E. coli* representatives are differentiated from intestinal (InPEC) and extra-intestinal pathogenic *E. coli* (ExPEC) (Pitout 2012). Pathogenic representatives can cause infectious diseases including sepsis, urinary tract and wound infections (UTI and WI), as well as diarrhea in humans and animals (Ewers et al. 2012). *E. coli* can be transmitted through the fecal-oral route either by direct or indirect contact via contaminated fluids, including surface water, food, and other carriers (de Graaf et al. 2017), regardless of their pathogenicity or AMR profile. *E. coli* are currently regarded as a significant indicator species for antimicrobial resistance in both veterinary and human medicine (Koeck et al. 2021). Overall, the gastrointestinal tract is regarded as an important reservoir for AMR Gram-negative bacteria in all mammals (Gibson et al. 2011), particularly the species *E. coli* which is among the key organisms with respect to acquired AMR in human and veterinary medicine, but also across extra-clinical environments (Guenther 2015).

21.3.2.2 Clinical Importance of *E. coli* in Human and Veterinary Medicine: A Brief Classification

E. coli is among the most frequently isolated organisms from clinical specimens in humans and animals. Besides its relevance as an etiological agent of diarrhea, *E. coli* is one of the leading causes of different extra-intestinal diseases in humans, with millions of cases resulting in billions of dollars of associated health care costs annually in the USA alone (Vila et al. 2016). On the other hand, considerable suffering of animals and substantial economic losses are caused by pathogenic *E. coli* across the various livestock sectors (Rhouma et al. 2017; Kathayat et al. 2021).

Beyond the clinical relevance of β-lactam resistance exhibited by ESBL-producing *E. coli,* these bacteria are often resistant against additional antibiotics such as

fluoroquinolones, tetracyclines, and aminoglycosides, and recently, against last-resort antibiotics like colistin and carbapenems, which exacerbates the overall tense clinical situation in case of infection (Koeck et al. 2021). The most common ESBL-genes in both humans and animals encode cefotaximases (CTX-M), such as $bla_{\text{CTX-M-1, 15, 14, 9}}$, followed by different TEM (from the Greek patient "Temoniera") and SHV (from "sulfhydryl variable") types (Ewers et al. 2012).

Considering the overall phylogenetic diversity of the *E. coli* species, comprising of more than 10,000 distinct STs, only a limited number of so-called international, high-risk clonal lineages dominate the global *E. coli* pool (Woodford et al. 2011). These clonal lineages (e.g., belonging to ST131, ST410, and ST648) are characterized by their broad dissemination across various host species, MDR and occurrence in human and veterinary medicine (Mathers et al. 2015; Schaufler et al., 2016b, 2019; Guenther et al. 2017).

A study from the United Kingdom summarized results on antimicrobial susceptibility testing (AST) for 29,330 canine and 8279 feline Enterobacterales isolates between April 2016 and July 2018 obtained from 2237 companion animal clinics: *E. coli* was the most commonly isolated Enterobacteriaceae in dogs (69.4%) and cats (90.5%). MDR was reported in 14.1% of canine and 12.0% of feline *E. coli* isolates (Singleton et al. 2021). Considering ESBL-types, $bla_{\text{CTX-M-15}}$ was most prevalent; and concerningly, the *E. coli* international high-risk clonal lineage ST131 predominated, further demonstrating the link between humans and companion animals in the context of AMR and successful, pathogenic clonal lineages (Singleton et al. 2021).

AMR *E. coli* are ubiquitous, not only in the context of clinical settings, animal husbandry, and companion animals, but also across wildlife of more remote areas (Guenther et al. 2011; Homeier-Bachmann et al. 2022). As illustrated above, anthropogenic forces largely impact both AMR mobilization from their environmental reservoirs as well as their consecutive spread (Allen et al. 2010), but also dissemination through migrating wildlife such as birds, wild boars, and other animals contribute to this (Guenther et al. 2011; Homeier-Bachmann et al. 2022). In more urban scenarios, rodents have been shown to further disseminate ESBL-producing *E. coli* (Guenther et al. 2010; Schaufler et al. 2018). However, a recent review revealed a striking paucity of information on *E. coli* in wild animals, despite clear evidence that these harbor pathogenic and antimicrobial-resistant *E. coli* among their gut microbiota they may even serve as melting pots for novel genetic combinations potentially harmful to human (and animal) health (Lagerstrom and Hadly 2021).

21.3.2.3 Occurrence and Distribution of an Important Multifaceted Generalist Species: *E. coli*

Previous studies illustrated the overall adaptive capabilities of the generalist *E. coli* to living "habitats" including the intra-macrophage environment, gastric passage and the intestine but also to host independent habitats such as, for instance, survival in sand, aquatic environments, and soil (Azevedo et al. 2016; Gekenidis et al. 2020; Rumball et al. 2020; Homeier-Bachmann et al. 2021). However, as mentioned above, only a limited number of clonal lineages are widely distributed across different habitats and hosts: To survive the adverse conditions of a competitive and demanding environment, such as the medical sector, tailored virulence, and the development of AMR are key

features of international high-risk clonal lineages (Beceiro et al. 2013), including Enterobacterales. These features are exemplified by the formation of biofilms as part of the host colonization capacities of *E. coli* ST648 or an enhanced iron acquisition and adaptation to conditions present in the urinary tract (e.g., the *pap* operon) of ST131. Rapid adaptation represents a key feature of Enterobacterales – as already outlined with regards to its genetic transfer network described above. Considering gut-associated bacteria, *E. coli* and *K. pneumoniae* seem to share the largest number of mobile ARGs (Hu et al. 2016), indicating the importance of HDT between these particular species. In some cases, a single event, such as a new plasmid acquisition, can result in an "ideal combination" of MDR and enhanced virulence for the survival and spread of the bacteria (Schaufler et al., 2016a).

At present, approximately 10% of horses admitted to clinical care in specialized veterinary clinics are already colonized with ESBL-producing *E. coli* upon hospital admission (Kauter et al. 2021). While raw meet diets for dogs were frequently contaminated with AMR bacteria, including ExPEC lineages which are of particular concern for human medicine (i.e., ST69 and clonal complex (CC) 648) (Nuesch-Inderbinen et al. 2019), herbivores such as horses are likely colonized through other sources. Contaminated water seems one plausible source, since ESBL-producing bacteria have been identified within bodies of water, such as wastewater and sewage, rivers, and lakes (Zarfel et al. 2013; Homeier-Bachmann et al. 2021). However, recent research also indicates that ESBL-producing Enterobacterales harbor genes promoting (i) their endophytic lifestyle and (ii) survival of acidic conditions. This includes (but is not limited to) international high-risk clonal lineages carrying ESBL CTX-M-15 enzymes (*E. coli* CC38 and CC648 and *K. pneumoniae* CC307) (Lopes et al. 2021). The authors further speculated that fresh vegetables may act as a figurative "Trojan horse" for the hidden spread of critical priority pathogens, since survival and growth in fresh vegetables and subsequent tolerance to gastric acidity may increase the chances of becoming colonized with these ESBL-producing Enterobacterales (Lopes et al. 2021).

Consequently, understanding the adaptation and persistence kinetics of AMR bacteria across different environmental habitats such as soil, water, and plants, including, but not limited to, ESBL-producing *E. coli*, aids in determining essential actions and strategies in order to mitigate their spread to people (Gekenidis et al. 2020) and, not at least, also to animals.

21.3.3 Challenges and Chances Associated with Zoonotic and Epidemic Bacteria Exhibiting AMR

21.3.3.1 Challenges Arising from the "Enlarging the Cake" Strategy of Zoonotic and MDR Bacteria Call for a Broader Research Perspective on the Subject

While the term "spillover" is widely used to describe the transmission of AMR bacteria from animals to humans and vice-versa, it might trivialise the dynamics associated with access and opportunities for these and other bacteria, including their ability to conquer novel habitats (i.e., hosts and environments). In fact, a zoonotic

spillover is defined as "processes that enable a pathogen from a vertebrate animal to establish infection in a human" (Plowright et al. 2017). These complex processes link the ecological dynamics within the reservoir host, pathogen development, survival and dissemination with the epidemiological and behavioural determinants of exposure and susceptibility of the recipient host (Plowright et al. 2017). A recent perspective on "Impacts of biodiversity and biodiversity loss on zoonotic diseases" highlights this aspect. The authors declare that "the current paradigm for research on spillover of zoonotic pathogens to humans emphasizes a single animal host species and an original spill over event, although, in reality, most zoonotic pathogens have multiple host species whose specific roles in transmission to and from humans are not known" (Keesing and Ostfeld 2021).

While the "generalist state" of bacteria is characterized by their – in comparison with the overwhelming majority of specialized bacterial species – short existence cycle (Sriswasdi et al. 2017), it allows for distinct pathogens (or even subtypes) to emerge and proliferate in completely different habitats, and, is therefore, often a characteristic feature of bacteria transmissible between humans and animals. Consequently, unidirectional views ("transmission from A to B") on the subject tend to ignore the "enlarging the cake" strategy of generalists: The existence of MDR bacteria fully equipped to conquer multiple habitats (hosts and environments), might appear transient from a long-term evolutionary perspective (Sriswasdi et al. 2017) but their emergence, on the other hand, is of highest importance in regards to research on reservoirs and pathways of inter-species transmission. Since only a limited number of lineages or subgroups within a specific transmissible bacterial population seem prone to cross habitat and/or species barriers (Sheppard et al. 2018), their particular adaptive capacity and AMR (including MDR) represent worthwhile research opportunities (Schaufler et al. 2016b; Huber et al. 2020). However, with respect to accumulation and spread of MDR bacteria, several hot spots have already been identified, including facilities providing health care for humans (Geffers and Gastmeier 2011; van Alen et al. 2017) as well as companion animals (Walther 2021). Consequently, staff of both human and veterinary medical facilities are frequently confronted with MDR bacteria. While hospital hygiene is an established clinical and research topic in human medicine, questions concerning biosecurity of veterinary personnel have emerged due to companion animals either being colonized or infected with MDR bacteria (Wieler et al. 2015; Walther et al. 2017). To ensure appropriate workplace safety and biosecurity with respect to transmissible MDR bacteria for people working in the field of veterinary medicine and, not at least, animal owners, initial hygiene recommendations acknowledging specific animal-depending work-place factors have been developed (Weese 2004; Gehlen et al. 2020).

21.3.3.2 Chances to Counteract AMR Bacteria Emerge from a Holistic Perspective on the Subject and Enhanced Interdisciplinary Efforts

To assess the risk of spillover, case studies should be developed that enable quantifying determinants of the complex process network involved in the transmission certain pathogens (Plowright et al. 2017).

While the importance of systematic and continuous data collection of the occurrence and spread of AMR bacteria (including their pathogenic traits) has been widely accepted, the European One Health action plan (2017) stated that initiatives need to be broadened, such as extending the One Health approach to include the environment and tackling AMR more comprehensively on the basis of improved data collection, monitoring, and surveillance (Union 2017). A tangible concept representing an interconnected and integrated One Health surveillance framework focusing on antimicrobial resistance as well as antimicrobial consumption has already been published (Queenan et al. 2016), but its implementation, especially the interconnectivity of various sectors, has not been achieved yet.

Moreover, the development of strategies involving new antimicrobials or non-antimicrobial compounds and novel point of care diagnostic methods that focus on high-risk clones and/or virulence markers may help to resolve the increasing problem of the association between virulence and resistance.

21.3.3.3 Tracking AMR in Commensal and Pathogenic Bacteria of Animal, Human, and Environmental Origin

Given the increasing knowledge of environmental reservoirs for resistances, it should now be possible to establish early warning systems of potential resistance mechanisms to new or old antibiotics and thus prepare for future problems in the clinic through a proactive manner (Martinez 2009). Monitoring of AMR in animal and human pathogens as well as in commensal bacteria enables to detect not only new resistance properties, but also potential transmission events and important reservoirs. The (still) ongoing development of DNA sequencing techniques allow fast and accurate genomics even on a population-wide scale. While novel DNA sequencing techniques have been made widely accessible and more user friendly, the data analysis and interpretation that follows still requires specialized bioinformatics expertise and appropriate computational and IT resources, as recently reviewed in (Maljkovic Berry et al. 2020). With respect to the early detection and surveillance of pathogens or even commensals harboring worrisome genes conferring AMR or enhanced pathogenicity (or a combination of both), automation with respect to pathogen detection, genome construction, and advanced analysis is required (Maljkovic Berry et al. 2020). However, gene calling and subsequent automated detection of virulence and resistance in an exploratory manner to gain insights into pathogenic potential, treatment options, and transmission patterns usually depend on the up-to-date state of different databases (Maljkovic Berry et al. 2020). Consequently, to detect important and/or novel factors enhancing pathogenicity or conferring AMR in bacteria, intelligent approaches are needed to connect clinical, phenotypical, and genomic data. Genome wide association studies (GWAS), for instance, provide opportunities to determine genes calling for a specific phenotype (Epping et al. 2021) without the drawbacks that are commonly associated with the use of reference databases. Moreover, host-specific traits of *E. coli* have recently been identified by using a GWAS-based approach and revealed, beyond others, genes that are strongly associated with sublineages dominating the human gut (Tiwari et al. 2022), indicating once more that

adaptation to a specific habitat is in fact a force of nature that drives the evolution of specific sublineages toward specialization, even though they may be part of a generalist species. Thus, GWAS generated data can be used with respect to risk analysis as well as diagnostic and monitoring purposes (Tiwari et al. 2022). Furthermore, culture-independent methods, such as metagenomics, represent unique opportunities for the surveillance of environmental resistance reservoirs (Danko et al. 2021).

Moreover, artificial intelligence (AI) represents a new paradigm to combat AMR (Lv et al. 2021), including AI-based AST prediction. However, as reviewed in (Lv et al. 2021), the lack of unified standardization and infrequent data updates in AMR databases currently hinders an efficient training of AI-based AMR predictive models.

21.4 Conclusion

The COVID-19 pandemic has certainly made the risks of zoonotic diseases a vivid and harrowing reality for every person on earth (Keesing and Ostfeld 2021).

In addition, due to the increased use and misuse of antibacterial agents and cleaners during the pandemic, a rise of bacterial resistance toward anti-infective agents is expected to emerge within the post-pandemic era (Mahoney et al. 2021), at least in some parts of the world. Although distinct sectors of the One Health framework (human, animal, and environmental health) are facing their own intrinsic issues associated with AMR, such as HAIs, lack of prudent use of antibiotics, environmental contamination by antibiotics and drug resistant bacteria, the rise of MDR bacteria in one sector always affects the other areas as well (Fig. 2). While the necessity and importance of inter-sectoral research (e.g., experts representing human, veterinary and environmental health, social and behavior science) is clear, a current lack of systematic research on the transmission of ARGs and/or AMR commensals/pathogens between different habitats restricts the early detection of presumptively clinically relevant strains, including, but not limited to, novel types and combinations of AMR and virulence factors. Moreover, it hinders the implementation of infection prevention strategies to halt further spread of zoonotic pathogens. In addition, after next-generation sequencing, we need to focus on "next-generation hazard perception" including up-to-date bioinformatic routines and tools for both primary diagnostics and research purposes. However, curating suitable databases for rapid and reliable species identification, virulence factor, and ARG detection is a challenging task that requires experienced microbiologists. Even approaches that integrate artificial intelligence to identify, for instance, novel resistance mechanisms or host-specific virulence factors will most likely depend on sufficient and reliable input data. Finally, yet importantly, epidemiology expertise and predictive mathematical models are fundamental to understand the course of transmission events and to plan and assess effective intervention and mitigation strategies.

Influenza from a One Health Perspective: Infection by a Highly Versatile Virus

22

Leslie A. Reperant and Albert D. M. E. Osterhaus

Contents

Abstract

Influenza A viruses (IAVs) are among the most versatile viruses, in terms of host range, pathogenesis, route of transmission, transmissibility efficiency, and evolutionary dynamics. Several IAVs are recognized pathogens of a wide range of avian and mammalian species. On the one hand, AIVs that evolved in wild water birds, their natural reservoirs, cause mild or asymptomatic infections of their intestinal tract, resulting in annual epidemic cycles fueled by IAV fecal-oral transmission in watershed habitats. On the other hand, they may cause disease manifestations in avian and mammalian species, including humans, upon sporadic cross-species transmission—including spill-back transmission into wild birds—and during self-limiting outbreaks

or large-scale airborne epidemics. In these spillover host species, clinical signs and symptoms range from inapparent to severe and often fatal respiratory and extra-respiratory conditions. A feature of IAVs in animal spillover hosts including humans is their ability to adapt to these new species to eventually be maintained independently of new introductions from their natural host reservoirs. In humans, IAVs of animal origin can be the precursors of pandemic influenza viruses. These pandemic viruses eventually evolve into seasonal influenza viruses that cause recurring epidemics of seasonal influenza. The unprecedented diversification and spread of highly pathogenic avian influenza viruses of the H5N1 and other H5Nx subtypes in wild birds in and across Asia, North America, Europe, and Africa, with spillover into wild mammals in Europe, over the past few years mark a worrying paradigm change in influenza epidemiology. Through their versatile nature, IAVs are a striking example of the flexible and ever-evolving nature of zoonotic threats and of the richness of avenues zoonotic pathogens can take to burden animal and public health.

22.1 Introduction

IAVs are orthomyxoviruses closely related to influenza B, C, and D viruses (Palese and Shaw 2007; Henritzi et al. 2019). IAVs are enveloped single-stranded negative-sense RNA viruses with eight gene segments. These include two genes coding for the hemagglutinin (HA) and neuraminidase (NA) surface glycoproteins and six genes coding for several other internal proteins, including the polymerase complex, matrix and nonstructural proteins. The surface glycoproteins HA and NA interact with cellular receptors and are important antigenic targets of the host's specific immunity mediated by neutralizing and other biologically active antibodies. Most internal proteins are involved in IAV structure or replication. Influenza B viruses (circulating in humans, pigs, and seals) have a similar genomic arrangement, while influenza C viruses (circulating in humans, pigs, cattle, dogs, and camels) and influenza D viruses (found in cattle, small ruminants, pigs, horses, camels, and wild boars) lack a neuraminidase and express a hemagglutinin esterase fusion surface protein (Henritzi et al. 2019; Liu et al. 2020).

The replication of IAV RNA genome lacks effective exonuclease proofreading capability and is known to introduce base mutations at relatively high rates. In addition, the segmented genome allows for reassortment during coinfection with different IAVs, resulting in new viruses containing gene segments of mixed parental origin. The high mutation rate and extensive reassortment have led to an unmatched diversity of IAV lineages (Chen and Holmes 2006; Joseph et al. 2017).

Based on the HA gene, IAVs may have emerged at least 4000 years ago, from a common ancestor with influenza B viruses, while the split between influenza A/B and influenza C viruses is estimated to have occurred over 8000 years ago

(Suzuki and Nei 2002). Influenza D virus, more closely related to the influenza C virus, appears to have a more recent evolutionary history, diverging from the other three influenza genera less than 1200 years ago (Yu et al. 2021). However, recent metagenomics studies of the diversity of RNA viruses in "lower" vertebrates demonstrated the presence of influenza-like viruses in amphibians, fish, and even jawless vertebrates. These viruses, forming basal sister groups with the four influenza types, share a common ancestor with a diverse group of invertebrate viruses, highlighting the largely hidden complexity and long evolutionary history of the influenza orthomyxoviruses (Wille and Holmes 2020; Harvey and Holmes 2022).

IAV HA and NA genes are grouped into 18 and 11 different subtypes, respectively. Although most IAV HA and NA subtypes likely split 2000 to 3000 years ago, IAV diversity within each subtype is fairly recent, dating from the past hundred to several hundred years (Suzuki and Nei 2002; Chen and Holmes 2006).

Several IAVs are recognized pathogens of a wide range of avian and mammalian species, and their natural history in their wide host range clearly illustrates the one health principle, whereby human health, animal health, and ecosystem health are closely interrelated. Wild water birds are considered the natural reservoirs of IAVs (Webster et al. 1992), yet IAV lineages, acquired upon cross-species transmission, have established themselves in domestic animal species. In turn, domestic animals, especially poultry and swine, are the main sources of zoonotic IAV infections. Zoonotic IAVs may spark influenza pandemics in humans, should they acquire efficient human-to-human transmissibility, which they typically lack upon cross-species transmission. Pandemic influenza viruses eventually evolve into human seasonal influenza viruses, causing annual epidemics that spread globally. While IAV cross-species transmission has occurred probably since IAV emergence several thousands of years ago, their versatile epidemiology and evolutionary dynamics in an expanding host range have been influenced by the expanding human species, especially during the past few hundred years. The relentless growth of domestic swine and poultry populations in the last decades has contributed to increased genetic diversity of IAVs circulating in wild and domestic animals and occasionally infecting humans, expanding the pool of IAVs with pandemic potential (for review see (Reperant and Osterhaus 2012)).

In this chapter, we will review IAVs population-level epidemiology, evolutionary dynamics, and associated host-level pathogenesis of infection in their wide host range. In addition, we will describe the adaptive changes associated with IAVs host switch and their sustained establishment in novel host species.

22.2 Population-Level Epidemiology and Evolutionary Dynamics

22.2.1 Natural Reservoirs

The majority of the currently known diversity of IAVs is maintained in avian hosts of the order Anseriformes, Charadriiformes, and Gruiformes, which encompass water birds such as geese, ducks, gulls, waders, and coots (for review, see (Olsen et al.

2006; Reperant et al. 2013; van Dijk et al. 2018)). Wild freshwater birds thus are traditionally considered IAVs natural reservoirs. IAVs harboring most of the 144 combinations of the first 16 and 9 subtypes of HA and NA genes, respectively, have been isolated from wild water birds (Munster et al. 2007). However, a sampling bias towards these orders is suspected as a wide diversity of IAV RNA has been detected in other avian orders across much of the world's ecosystems—and sufficiently sampled to allow the detection of a 1% AIV genetic prevalence (Caron et al. 2017). These diverse orders include the Psittaciformes (parrots), Apodiformes (swifts), Cuculiformes (cuckoos), Phoenicopteriformes (flamingos), Podicipediformes (grebes), Coraciiformes (kingfishers and bee-eaters), Passeriformes (passerines), Gaviiformes (loons), Columbiformes (doves and pigeons), Pelecaniformes (pelicans), Pteroclidiformes (sandgrouse), and Piciformes (woodpeckers and barbets) with a detected prevalence based on RT-PCR detection between 1% and 7%, and the Galliformes (quails and grouses), Accipitiformes (raptors), Strigiformes (owls), Ciconiiformes (egrets and storks), Sphenisciformes (penguins), Suliformes (gannets), Falconiformes (falcons), and Procellariiformes (shearwaters and petrels) with a detected prevalence below 1%. Overall, IAV RNA was more often detected in birds of the Indo-Maley and Afrotropic regions, followed by birds of the Palearctic, Neotropic, Antarctic, Nearctic, and Australasian regions. Avian IAV natural wide host range, counting over 110 wild bird species from 23 different orders, likely contributes to IAVs remarkable diversity in these species.
