Introduction

This, the fourth edition of "Knobil and Neill's Physiology of Reproduction," is a major departure from its first three editions by having Editors in Chief not previously involved in managing the production of this work. Before his death in the year 2000, Ernst Knobil and I had made plans for the transition to an Editor in Chief who had been trained at the postdoctoral level in one of our laboratories. Dr Tony M. Plant was chosen from among several excellent candidates who had the requisite characteristics needed to continue production of a work that would have the same high standards we hoped to have maintained in the earlier editions. I first met Tony in the early 1970s while I was a young faculty member at Emory University in Atlanta, Georgia, and he was employed at the Georgia Mental Health Institute also located in Atlanta. I received a letter from Ernst Knobil inquiring about my impression of Tony, who had applied for a postdoctoral fellowship in Ernst's laboratory where I had trained as a fellow but had recently relocated to Emory. My reply was a strong endorsement of Tony, which was borne out in subsequent years. Tony Plant chose Dr Tony Zeleznik as a Co-Editor in Chief to share with him the demanding tasks of editorship requiring a broad base of information in the field and a high level of academic rigor. My perusal of the list of authors and their chapter titles suggests that the information presented in this edition will rival in quality that presented in the first three editions, i.e., the work is a modern synthesis of reproductive physiology of mammals at the molecular, cellular, and organismic levels. This is not surprising given the excellent past records of the two Editors in Chief.

Ernst Knobil and I believed strongly that any work claiming to be comprehensive and hewing to the highest principles of scholarship must include a summary of the founding and the founders of the field. Because Dr Roy O. Greep was one of the leading founders of the field, we requested that he provide that information together with an overview of the future of the field in his Foreword for the first edition in 1988. Thus, the original Foreword had the great strength of being written by one of the last surviving founders in the field, and thus avoided the greatest weakness of all historical analysis, namely that history is defined as what professional historians define it to be.

A new Foreword has been prepared by Dr M. Susan Smith to address, in part, Greep's predictions of progress that might occur in the field in the succeeding years after his Foreword first appeared. Susan is a prominent leader in reproductive physiology due, for example, to her Presidency of the Endocrine Society, Directorship of the Oregon National Primate Research Center, and maintaining an National Institutes of Health (NIH)-funded laboratory running for several decades. I am pleased that her fellowship training occurred in my laboratory at Emory University during which we published the most highly cited paper of my career, of which she was the senior author.

Jimmy D. Neill

Vet-ebooks.com

Preface

Having had the fortune of being mentored by Ernst Knobil in the early stages of our careers and serving as assistant professors in his faculty in the Department of Physiology at the University of Pittsburgh School of Medicine, we were greatly honored by the invitation to serve as Editors in Chief for the 4th edition of this book that has come to be recognized by many as the "Bible of Reproduction." At the same time, we undertook the task with considerable trepidation, being fully aware of how difficult it would be to fill the shoes of Professors Knobil and Neill, who, with their utmost attention to scientific rigor, had, together or individually, guided the previous three editions.

Given the foregoing challenge, we began by evaluating whether the structure and content of the previous edition needed to be refocused. It quickly became obvious that this was indeed the case because of the rapidly growing use of "omics" approaches in most, if not all, areas of reproductive biology. In this regard, it is noteworthy that the first edition of this text was published in 1988, a year before the first use of the "gene knockout" approach in mice was described. Over the course of the 25-year history of this text, the ability to delete or modify individual genes has increasingly and significantly added to the classical armamentarium of organ ablation/hormone replacement paradigms previously available to investigators studying reproduction. In addition, the application of genetics/genomics to elucidate the etiology of human disease has increased in parallel to the use of transgenesis in experimental animals. Collectively, these powerful approaches have provided new, and often serendipitous, information on the regulation of reproduction. For example, our view of the neuroendocrine control of the hypothalamic–pituitary–gonadal axis is now completely dominated by kisspeptin. This hypothalamic peptide, which, in the context of reproduction, was unheard of before 2003, surfaced because mutations of its receptor, then known as GPR54, were identified in individuals with delayed puberty.

Accordingly, our authors were confronted with the need to integrate information gleaned from "classical" whole animal studies with results generated by contemporary "omics" approaches in order to provide a holistic overview of reproductive processes. In keeping with this approach, we encouraged authors to discuss the historical underpinnings of their respective fields and to identify the burning questions that remain to be addressed.

In this 4th edition, Volume 1 focuses on basic processes of male and female reproduction while the thrust of Volume 2 is on the physiological control systems that govern reproductive processes, including those regulating sexual behavior. A chapter on meiosis has been included for the first time, and discussions of epigenetic mechanisms that are emerging as important regulators of reproduction, as well as fetal origins of adult diseases, have been expanded. New chapters on spermatogonial stem cells and hormone signaling in the testis that provide contemporary views of the control of testicular function replace the more classical approach to the control of spermatogenesis that was presented in prior editions of the text. We have also expanded the discussion of the regulation of reproductive behavior, which, having moved far away from its origins in ethology, is now dominated by genomic, epigenetic, cellular, and molecular approaches to the understanding of sexual motivation, partner preference, and parental behavior. For those chapters that have been updated, we are confident that these new versions present the most current discussion of the subject material.

Such restructuring of this book would not have been possible without the enthusiasm and commitment of our section editors, to whom we are greatly indebted. A feature of the 3rd edition that has been maintained is the inclusion of the Foreword by Professor Roy O. Greep that was written for the 1st edition, published in 1988. As recognized by Professor Neill, the Editor in Chief of the previous edition, Greep's account of the future of research on the physiology of reproduction continues to remain remarkably relevant, now 26 years after it was written. We are pleased to include a second Foreword that was written by Dr M. Susan Smith, who worked with Jimmy Neill as a postdoctoral scholar and was also a member of Ernst Knobil's Department of Physiology at the University of Pittsburgh School of Medicine. Dr Smith's broad understanding of both whole animal and molecular approaches used in the study of reproductive processes makes her uniquely qualified to comment on how the study of reproduction has progressed since Greep's original Foreword in 1988, as well as to identify the challenges to be met in future years.

Vet-ebooks.com

This 4th edition of *Knobil and Neill's Physiology of Reproduction* will be the last available in a print version. While our purpose here is not to debate the loss of hard copy, electronic publishing will enable, on the one hand, the addition of new chapters covering important emerging fields and, on the other, the replacement or revision of outdated chapters, both with relative ease. In this way, we anticipate that the *Physiology of Reproduction* will continue to be highly contemporary and comprehensive and therefore remain, for the future, the authoritative text of the field.

It is our expectation that this 4th edition of *Knobil and Neill's Physiology of Reproduction* will continue to kindle the importance of physiology in the understanding of reproductive processes and, in the words of Neill and Knobil in their preface to the first edition, be "useful to all serious students of reproductive physiology be they scientists, teachers or physicians."

Tony M. Plant
Anthony J. Zeleznik

Foreword* by Roy O. Greep

I am pleased and honored to have been asked to prepare the Foreword to this volume of work depicting the progress in research on the physiology of reproduction as well as the resulting gains in understanding made over the past few years. The expertise that is represented by the numerous contributors to this work is so impressive that I am humbled even to contemplate adding anything of note. It is only by virtue of having personally witnessed a very large segment of twentieth century research on reproduction that I am emboldened to reflect on the byways and the trailblazings that have brought this field to its present proud state of enlightenment with regard to the long sought-after means of controlling the procreative process in humankind. Clearly, there are many important and knotty problems yet to be resolved, but the pace of progress over the past several years has quickened to the extent that one is left in expectant wonderment as to where and when the next revolutionizing development will occur.

The experimental method of studying reproduction was initiated in 1849 with Berthold's discovery of a blood-borne activity that came from the testis and stimulated growth of distant organs such as the comb and wattles. In so doing he utilized one of the most fundamental means of demonstrating the function of an endocrine organ, namely, surgical removal to determine what deficiencies follow, coupled with implantation or transplantation to ascertain whether the deficiencies were repaired. At that time it was not possible to take the next step, namely, preparation of an active extract of the testes, because nothing was known about the nature of the bioactivity. Forty years later, Brown-Séquard claimed to have prepared an active extract of dog testes; however, as is well known, his enthusiastic claims for restoration of his own sexual activity at an advanced age were not substantiated. Actually, these simple means of studying reproductive physiology persisted well into the twentieth century, including the studies of such pioneering stalwarts as Marshall, Heape, Prenant, Bouin, Ancel, Loeb, Cushing, and Aschner. Observations otherwise were limited to cyclic and seasonal changes in sexual behavior among common laboratory and small domestic animals. This type of eyeball research remained in vogue through the early 1920s and overlapped the extension of visualization to the microscopic level. The latter revealed, for the first time, the precise timing of events in the ovarian cycle through microscopically observable cellular changes in the vaginal fluid. My point in mentioning these early studies is to emphasize that although the tools and techniques were inordinately primitive by present standards, the results established a firm base of knowledge on which to build.

The study of cyclic changes in the vaginal smear in rats and the findings of estrogenic activity in follicular fluid during the early 1920s led to an explosion of interest in the study of reproduction. The field was fortunate in attracting to its ranks a small band of exceedingly able biologists and biochemists who, in 1932, were to become authors of the classic first edition compendium, Sex and Internal Secretions, a volume overwhelmingly devoted to reproductive endocrinology. It was this landmark of progress that finally gave propriety to the study of reproduction and put it on a par with the study of other major bodily systems. Incredible as it may seem, it was only a decade earlier that a distinguished panel of the National Research Council had declared that sex research was not a fitting topic for scientific study.

Lest our pride in today's spectacular pace of progress unduly bedazzle the mind, it should not be overlooked that the developments recorded in the 10-year span from 1926 to 1936 may never be equaled. Among those monumental achievements, all of the native sex steroid hormones were brought to light, their structures were determined, their functions were defined, and they were made available in pure form for research and therapy. Similarly, all of the pituitary, placental, and urinary tropic hormones were identified, and their functions were defined. Like today's competition for priority rights, publicity, and potential financial gain, these earlier periods also were times for intense rivalries, but rarely with prospects for financial rewards. It would be difficult to overstate the boost that was given to basic and clinical research in reproduction as a result of the availability of estradiol-17β, testosterone, and progesterone in pure form and of known potency. The replacement of

*This Foreword by Roy O. Greep is reprinted from the 1988 (first) 1994 (second) and 2006 (third) editions of this work (E. Knobil and J. D. Neill, The Physiology of Reproduction. Raven Press, New York. Copyright Elsevier). This now-deceased author wrote a remarkably prescient account of the future of research in the field that remains as relevant today as it did in the first three editions.

Vet-ebooks.com

homemade extracts and such elastic entities as rat units, mouse units, capon units, and so forth, with micrograms of pure hormone was revolutionizing and allowed the study of reproduction on a quantitative basis.

Prior to World War II the thrust of research on reproduction dealt predominantly with the steroid hormones. This was the heyday of steroid biochemistry. After World War II the emphasis shifted to the protein and peptide hormones, where it still remains strong. This prolonged and difficult effort yielded many biochemical triumphs. Most notable among these were the isolation of the pituitary, placental, and urinary gonadotropins, as well as the determination of their primary structure as glycoproteins comprised of two dissimilar and covalently bonded subunits, the isolation and synthesis of the gonadotropin-releasing hormone (GnRH) of hypothalamic origin, and the isolation and structural characterization of relaxin.

The availability of pure protein and polypeptide hormones made possible the production of hormone-specific antibodies as well as the application of immunological techniques to the study of reproduction. An outcome of great consequence was the development of radioimmunoassay as the new means of measuring all of the hormones relating to reproduction. The sensitivity of this new technique was so great that it made possible, for the first time, the measurement of all these hormones in the body fluids. It had the further distinct advantage of requiring such a small amount of fluid that the monitoring of blood levels of the hormones of reproduction could be done throughout an estrous or menstrual cycle by close serial sampling. This revealed still another and most unexpected finding, the pulsatile pattern of secretion.

Identifying the homeostatic mechanism(s) responsible for maintaining a steady state in various physiologic systems of the body has been fraught with many challenging problems, but these pale in comparison with the difficulties encountered in trying to elucidate the mechanisms maintaining a constantly changing system, a characteristic of the reproductive system of female mammals. The earliest piece of evidence suggested the existence of a "push–pull" mechanism that later came to be known as negative feedback. It was based on the demonstration that an estrogenic extract administered to immature rats would maintain the ovaries in an infantile state. This was quickly followed by conclusive evidence that estrogen acted to inhibit pituitary follicle-stimulating hormone (FSH) stimulation of follicular growth and maturation; however, the effect on luteinizing hormone (LH), ovulation, and luteinization remained unsettled. Gaps continued to exist in all proposed explanations of reproductive cycles. None of these explanations took into account the influence of photoperiodicity on seasonal breeders, nor did they account for the role of the stimulus of mating in nonspontaneous ovulators. Following the discovery of the hypothalamic control of pituitary function, estrogen was shown to exert its action on both the pituitary and the hypothalamus; however, the problem of accounting for cyclicity remained. Adding to the complexity, radioimmunoassay revealed an unexpectedly high level of blood estrogen just prior to ovulation, an event not in keeping with the negative feedback concept.

Finally, after many years of searching for a way out of this frustrating situation, a glimmer of light appeared at the end of this long dark tunnel—light that soon turned to brilliance. In 1969, Goding and associates found that the administration of large doses of estrogen to ewes at the time of estrus did not block, but instead entrained, ovulation. Shortly thereafter, in more elaborate examination of the relationship of blood estrogen levels and ovulation in rhesus monkeys in Knobil's laboratory, it was revealed that elevated estrogen levels preceded and appeared to trigger ovulation. On further examination, Knobil and colleagues found that when blood estrogen reached a critical level, the feedback mechanism switched from a negative to a positive, or stimulative, action. This utterly new finding greatly advanced our understanding of the endocrine mechanism governing reproductive cycles. There still remain, however, some uncertainties: Why does the switch in feedback action occur; to what extent and at what stage of the cycle does estrogen act at the level of the pituitary or the hypothalamus, or both; and lastly, what role, if any, do the ovarian peptides, especially inhibin, play in controlling reproductive cycles?

The progress of research on reproduction has been chronicled in numerous review articles by individual authors. Many have appeared in Recent Progress in Hormone Research, Volumes 1–42. Other major sources include the multiple editions of such titles as: Marshall's Physiology of Reproduction, Fourth Edition (1990); Sex and Internal Secretions, whose third and last edition was issued in 1961; two volumes on the Female Reproductive System (1973), and one on the Male Reproductive System (1975) in Section 7 of the Handbook of Physiology, published by the American Physiological Society; and four serial volumes on reproductive physiology in the International Review of Physiology, the last one being issued in 1983. The present volume will provide comprehensive coverage and meet the current needs of the field of reproductive physiology, a field that is rapidly gathering momentum from the application of new and highly sophisticated tools and techniques.

In viewing the vast literature dealing with research on the male and female reproductive systems and considering the rate at which it is accumulating, one might ask whether this staggering proliferation of books and articles is essential to progress; the answer is an emphatic "Yes!" The yardstick by which progress is measured

Vet-ebooks.com

in this or any other field is not in the number of articles published or the amount of financial support but in improved understanding. Such gains are generally marked by sharp peaks at indeterminate intervals, separated by avalanches of incremental gains, as recorded in an ever-growing list of journals. The point to remember is that without this persistent chipping away at a major problem there would be no solutions and no quantum leaps forward. In research very little comes from out of the blue. Part of the driving force in research is its adventuresome nature and ever-present possibility that one's efforts will pay off in an important manner. It may not be entirely fair, but in research (as in most human activities), the spoils go to the victor in the form of kudos, prizes, awards, public attention, and, increasingly in the present technological age, monetary gains—sometimes of great magnitude. What effect this latter may have, if any, on the long-cherished sanctity of science has not been determined, but it has become a matter of concern.

This volume bears the title The Physiology of Reproduction. Physiology, by traditional consensus, is that branch of science, which studies the functions of a living organism or any of its parts and includes the basic underlying processes. It will be understood that most of the studies reviewed here will be based more on holistic research than on research at the submicroscopic or molecular level. It is unfortunate that the excitement generated by recent fantastic advances in molecular biology and development has tended to downgrade the value of whole-animal research, and physiology in particular is sometimes looked upon as passé. Actually, the two categories of research are complementary, and both are essential for maximum advancement of knowledge. Whole-animal research cannot become outdated because it is the quintessence of biological relevance and the means by which molecular findings must ultimately be evaluated.

In the same vein, no one immersed in reproductive endocrinology can be unaware of the current tendency to regard research at the molecular level as representative of exceptional scientific talent. This is a common consequence of the opening of a new arena of investigation. I recall an incident that happened at a scientific meeting back in the 1930s. The first three papers in a session chaired by an eminent embryologist were on endocrine topics—mine was the third. That being ended, the chairman took pains to assure the audience that the meeting could now turn to considerations of more fundamental nature. One of the other three papers was given by Herbert M. Evans, who bristled noticeably but held his fire. There was also an earlier period when one either worked on steroid biochemistry or something of lesser appeal like biology. Anyone who remembers the 1950s will recall a flash in the pan ignited by cybernetics, a study of automatic control systems both neural and physical. The gurus of cybernetics captured the attention of the press and of audiences throughout the land, but eventually this obsession suffered the fate of other passing preoccupations. My own observation is that the closer one approaches the molecular level of research, the more one becomes dependent on highly sophisticated instrumentation to make the observations and to read out results that are often quite free of extraneous variables. Toward the obverse situation, one's dependence on an extensive background of experience and physiological increases as does the unavoidable complex of in vivo variables that must be taken into account. In either case we have today the availability of far more diverse approaches to a given problem in any field of biomedical research than has ever existed before. In Berthold's day there was only one experimental method available; today's number is untold but is probably in the hundreds, perhaps thousands. This is an exceedingly promising situation and one to which investigators of all persuasions must adjust. Open minds will experience exhilaration over substantive achievements at any point on this observational spectrum.

One of the major factors influencing research on reproduction has been the availability of funds or lack thereof. Prior to the institution of federal funding (i.e., prior to the middle of the twentieth century), reproductive research was sparsely supported by university departmental funds, industry, small grants from the Committee for Research in Problems of Sex within the National Research Council, and some aid from the Rockefeller Foundation. The National Institutes of Health were slow in providing significant support of research on reproduction because of restrictions on the support of work related in any way to birth control. This occurred despite the simultaneous postwar baby boom. What kept research afloat during this critical period was major support by the Ford Foundation plus lesser contributions by other major foundations. It was not until the establishment in 1968 of the Center for Population Research in the NICHD that major governmental funding in this area became available, but the boost was short-lived. As a result of the imposition of fiscal restraints in the early 1970s, federal support dwindled and has remained at a minimal level ever since. Support from all sources is woefully incommensurate with the distressing expansion of the human population and the need for safe, effective, economical, and readily available means of limiting human fertility.

The physiology of reproduction is predominantly under hormonal control. The first essential step in studying reproduction was identification of the hormones involved and the functions they serve. This having been accomplished, efforts turned to a detailed analysis as to how hormones act within the body. During the 1980s there has been a rising tide of interest

Vet-ebooks.com

in the binding of steroid, protein, or peptide hormones to receptors on specific target cells. Much effort is currently being directed toward the isolation and chemical characterization of these receptors. They are known to be composed of a protein or proteins, and some information has already been gained as to their partial or provisional structure. This, however, is only a preliminary step in the complex process whereby hormone action results in an end response such as growth, secretion of a target cell hormone, or altered behavior. The curtain has already been raised on the climatic and final chapter of the story on how hormones act. This involves linkage of the hormone–receptor complex with the nuclear genetic apparatus leading through a now well-defined series of processes to the manifestation of a physiological response in the living organism. Genes that bring about the expression of certain hormonal signals are being isolated, modified, transferred between species, and also inserted into bacteria where they direct the biosynthesis of specific hormones in large quantity. Thus genes are being manipulated in ways that raise the potential of altering the reproductive process. It is largely as a result of developments in endocrinology at the molecular level that bewildering possibilities loom on the horizons of reproductive research—they are within reach; they are science, not fiction; and they stagger the imagination.

It being granted that nothing succeeds like success, then the new edition of this highly successful two-volume compendium on The Physiology of Reproduction is destined for an illustrious fate. This second edition will maintain the same high standards of the first and again fulfill an existing need in a field that is experiencing rapid growth and exhilarating progress. Like the first edition, this one will provide a critical assessment of the state of the art in every aspect of research on the physiology of reproduction by eminent authorities.

In the years intervening between this edition and the last, notable changes have taken place in the study of reproduction. These stem largely from major advances in technology. Remarkable new instruments, techniques, and methods have enabled investigators to probe ever deeper into the interaction between hormones and genes, thereby eliciting in vivo responses. New parameters are being added to the target tissues of the classical reproductive hormones as revealed by the presence of receptor sites in tissues, the physiologic significance of which often remains tantalizingly obscure. Similarly, newly identified substances of endocrine or paracrine nature are being added to this domain of research with persisting frequency. Some of these substances—the endothelins, interleukins, activins, inhibins, and prorenin, to name a few—also exhibit a puzzling array of effects on extraneous tissues. Their study is being aided by the fact that their structure is known and, though rare, they are available.

Great strides are also being made in many other aspects of research on reproduction. Much work is being done on the structure of receptors and the loci of binding sites on segments of the folded gonadotropic molecules. A full-scale effort is underway seeking an elucidation of the neural mechanism underlying pulsatile secretion. Neuroendocrinologists are closing in on an elusive pulse generator located in the central nervous system. This looms as another landmark discovery in reproductive biology.

Research on reproduction is flourishing and the future appears bright. The taboos are gone. All aspects of the reproductive process are an open book. One area that has taken a quantum leap forward is the clinical application of an important body of relevant new knowledge gained in both basic and clinical spheres. Expanded opportunities have been opened by greatly improved diagnostic procedures, more effective treatment of disorders, and new methods of controlling fertility. Contributing greatly to this explosive development is the dissemination of information on reproductive matters to the lay public by the mass media. Concerned individuals have been made aware of the existing new means of manipulating the male and female reproductive systems for enhancement or inhibition of fertility. The joys and comforts that accrue respectively to these opposing modes of fertility control have enriched the lives of a grateful public. To that end I may note that it was by virtue of these frontier reproductive measures that my own progeny includes a new grandson and namesake.

Roy O. Greep

Vet-ebooks.com

Foreword by M. Susan Smith

I am truly honored to write the Foreword for the 4th edition of this book; it is a humbling task to follow in the footsteps of Professor Roy O. Greep, whose Foreword is herein reprinted from the 1st, 2nd, and 3rd editions of this work. His remarkable account of the field of the physiology of reproduction was written 26 years ago, yet as you read it, you will develop an overwhelming appreciation for how fortunate we were to have Professor Greep as one of the foremost leaders in our field. It is especially gratifying for me to be associated with this great work, since my scientific lineage is part of the Greep/Knobil/Neill 'family', having trained with Professor Neill and served as a faculty member in Professor Knobil's Department of Physiology at the University of Pittsburgh.

Since the publication of the 3rd edition of this book in 2006, there continues to be remarkable progress in the physiology of reproduction, reflecting the use of advanced technologies, such as those spurred by contemporary genetic and genomic approaches. However, the challenge today is to understand how this genetic and molecular information is integrated into the manifestation of a physiological response. Greep's thoughts on this are still prescient today, "Actually, the two categories of research are complimentary…." "Whole animal research cannot become outdated because it is the quintessence of biological relevance and the means by which molecular findings must ultimately be evaluated."

Professor Greep issued a challenge in his Foreword: "Developments recorded in the ten-year span from 1926 to 1936 may never be equaled." I posit that the 10-year span from 2004 to 2014 was, at the very least, equally important, as we have made a paradigm shift in how we conduct our science. In the more traditional way of science, experiments focused on understanding control systems; this then led to the discovery of new molecules. Today, in contrast, the use of massively parallel sequencing (exome sequencing, ChiP-seq, and RNA-seq) allows us to identify all the players, even though we may have no idea of their function. We then "reverse engineer" results from these studies to discover where a particular molecule is produced, how its production is regulated, and what its function is. These sequencing techniques were used in the groundbreaking studies that signaled the important role of kisspeptin and neurokinin B in regulating the pituitary–gonadal axis; subsequent studies located their sites of production in the hypothalamus and identified their critical function in controlling GnRH neuronal activity. All of these sequencing techniques generate massive amounts of data and necessitate application of the extensive bioinformatics infrastructure that goes with managing large databases. Greep was right when he stated, "the closer one approaches the molecular level of research, the more one becomes dependent on highly sophisticated instrumentation to make observations and to read out results that are often quite free of extraneous variables." As an example of the power of these databases that are available to the scientific community, there is one that identifies all the transcribed genes in the ovary of the nonhuman primate and maps changes in their individual activities throughout the duration of a menstrual cycle and into early pregnancy. Not too long ago it would have been impossible to imagine being able to follow the activity of one gene through such a time course. Importantly, these databases can be used for comparative analyses among species and should provide enlightenment about the evolution of different approaches to reproduction.

The material in the chapters of this 4th edition reflects advances that have been made at all levels of the hypothalamic–pituitary–gonadal axis and the reproductive tract; many of these advances have been made possible by the new tools available to scientists. The most notable is the discovery of kisspeptin in the hypothalamus that fundamentally changed our concept of the control of GnRH neurons and has expanded our knowledge of the neural networks that govern reproductive function. Significant advances have also been made in our understanding of how G-protein coupled receptors function; such as the insight gained by the discovery of GnRH receptor misfolding that results in a loss of trafficking of the receptor to the plasma membrane and, thus, functionality, a deficit that can be overcome by artificial chaperones. New areas of research have come forth, such as oncofertility, a term coined to signify the restoration or maintenance of fertility in cancer patients whose gonadal function is diminished or lost due to the side effects of their radiation treatment or chemotherapy. Studies using new techniques, such as 3-dimensional culture of follicles in an extracellular matrix and differentiation of gamete stem cells, have provided new insights into the processes controlling folliculogenesis and gametogenesis, with translational

Vet-ebooks.com

opportunities for promoting or controlling fertility. In addition, there is an explosion of interest in stem cell biology, a field that was rooted in reproductive research and the practice of in vitro fertilization. There is also a new appreciation for the role of the environment in fetal development and this has led to the birth of a new area of medicine known as DOHAD (Developmental Origins of Health and Disease). Maternal under- and overnutrition both lead to epigenetic changes in the fetus that can have long-lasting consequences in the adult. Similarly, exciting new research shows environmental influences on epigenetic modifications of DNA in sperm that may result in paternal transmission of disease risk.

When considering all of this new research, some caveats need to be kept in mind. There appear to be significant species differences in a number of reproductive processes, including puberty, ovarian cyclity, and parturition, yet current research focuses primarily on the transgenic mouse model because of the ability to manipulate the expression of specific genes. Therefore, many of our current ideas about the control systems regulating reproductive processes are "mouse-centric" and may not be directly applicable to other species. This may create problems as we look to translate this information into new therapeutics for use in human and veterinary medicine.

What new advances can we look forward to in the near future? New technologies, such as optogenetic/pharmacogenetic tools, designer receptors, and advanced imaging, will likely contribute to the making of another "best decade" from 2014 to 2024. But it will be important to develop better methods, with increased specificity and sensitivity, for measuring hormones and other substances in the blood. There are also growing concerns over the use of sex steroids in clinical therapies. As a result, there is considerable interest in developing "nonhormonal", i.e., nonsteroidal, selective therapies that act at the local or intracellular levels.

Future studies must also focus on the still many critical unanswered questions in the physiology of reproduction. Just in the area of neural regulation of reproduction alone, there are numerous examples. Many external signals modulate reproductive function, such as stress, endocrine disrupters, diet, photoperiod, and pheromones. Yet we still do not know how these external signals are transmitted to directly alter kisspeptin or GnRH neuronal activity and thus, reproductive function. Perhaps, Greep's assertion that "The physiology of reproduction is predominantly under hormonal control," needs to be expanded to include nonhormonal factors that are important modulators. Another mystery is what heralds the onset of puberty. Detailed information is known about the regulation of kisspeptin gene expression and its upregulation at the time of puberty, but the specific signals that bring about these epigenetic changes are still completely unknown. Similarly, although neuroendocrinologists are closing in on the GnRH pulse generator located in the central nervous system, the actual mechanisms involved in pulse generation remain elusive. Greep recognized that "This looms as another landmark discovery in reproductive biology." The processes involved in the positive feedback effects of estrogen on gonadotropin secretion also remain a mystery. With the current recognition that there are likely species differences in these processes, negative and positive feedback of estrogen might be achieved through two different populations of kisspeptin neurons (rodent model) or two different populations of GnRH neurons (nonhuman primate model).

While the future for research in reproduction appears bright, with more landmark discoveries in the making, there is also cause for concern. Funding for basic research in reproduction at the federal level is declining, as the emphasis shifts to translational research relevant to human health and disease. In the bench-to-bedside continuum of research, it is critical to keep "bench" in the equation. There are still many areas in reproduction where we do not understand the basic underlying controlling mechanisms, making it difficult to devise therapeutics. Studies of various species will also be harder to support. This is regrettable, since comparative studies have revealed differences in how reproduction is regulated, and this collective information may be critical to solving long sought after questions, such as, what constitutes the GnRH pulse generator, how is puberty initiated, how is parturition initiated, and what is the impact of environmental factors on germ cells. A good example of the value of studying various species is the seasonal regulation of reproduction that led to a focus on photoperiod and how time-of-day signals are transmitted to GnRH neurons. These studies were instrumental in advancing the field of chronobiology to the recognition today that all cells appear to have clock genes that regulate their function. It is also regrettable that there are still constraints on contraception research even though the link between the ability to control fertility and the economic development of a country is well established. Finally, in this age of "big data," it is well to remember that analysis of large databases can detect correlations, but it cannot determine whether the correlations are meaningful or provide information about causality or mechanisms. This is the province of basic research: to discover the critical information about control systems that then provides the underpinnings for translational research and the development of new human therapeutics.

CHAPTER

1

Mammalian Meiosis

Paula E. Cohen, J. Kim Holloway

Department of Biomedical Sciences, Cornell University, Ithaca, NY, USA

INTRODUCTION

Basic Overview of Meiosis and Comparison with Mitosis

Mitosis and meiosis are the two types of cellular division that are common amongst eukaryotic organisms. While mitosis involves the faithful replication of cellular contents, including DNA, to produce two daughter cells of identical genetic and cellular composition, meiosis is confined only to those cells that participate in sexual reproduction: the germ cells (or gametes) in mammals. The goal of meiosis, in contrast to mitosis, is to produce gametes that have half the content of DNA within them so that, upon fertilization, the new zygote will contain the full complement of genetic information. This is achieved by virtue of the fact that each cell in a diploid organism contains two copies of every chromosome, each chromosome being referred to as "n" and a diploid organism therefore being referred to as a "2n"-containing organism. The two copies (or homologs), one of every chromosome, are provided by two parents: one maternal copy of every chromosome (chromosome 1, chromosome 2, chromosome 3, etc., up to chromosome 22, plus one X chromosome in humans) and one paternal copy of every chromosome (chromosomes 1 to 22, plus either an X chromosome or a Y chromosome in humans). Figure 1.1 provides a cartoon graphic depicting an imaginary meiotic species containing just four chromosomes: two paternal and two maternal. In this example, the long chromosomes (black and gray) are chromosome 1 homologs and the shorter chromosomes (white and off-white) are chromosome 2 homologs. Meiosis in germ cells begins with one round of premeiotic DNA replication to achieve "4c" DNA content, with each chromosome (each maternal "n" and each paternal "n" chromosome) now consisting of a pair of sister chromatids (each termed "c") that are tethered together through the process of cohesion. In Figure 1.1, therefore, the premeiotic replication results in the same four chromosomes, but now each chromosome consists of two chromatids, making a total of four chromatids for chromosome 1 and four chromatids for chromosome 2 (hence, two black chromosome 1 chromatids, two gray chromosome 1 chromatids, etc.).

Following DNA replication, cells enter meiosis, which consists of two consecutive rounds of division producing haploid gametes; these two rounds encompass meiosis I and meiosis II, respectively. In meiosis I, homologous chromosomes pair during prophase I (Figure 1.1: black and gray chromosomes pair, and white and off-white chromosomes pair) and then separate at metaphase I, resulting in the formation of two daughter cells each containing just one of the homologs for each chromosome (Figure 1.1: black or gray, and white or off-white). The meiosis I division is referred to as "reductional" because it results in daughter cells that contain only half the number of chromosomes that existed in the originating parent cell (although the daughter cells' chromosomes each now consist of paired chromatids). As will be discussed in detail in this chapter, some portions of these homologous chromosomes are exchanged in a process known as homologous recombination, and this is largely responsible for keeping the homologs together until metaphase I. Once the meiosis I daughter cells are formed, these can then undergo meiosis II, in which the paired sister chromatids now separate. This division is called "equational" because it results in the same overall number of chromosomes in the daughter cells as in the parental cell at the end of meiosis I. As can be seen in Figure 1.1, there are distinct differences in the number of products that arise following meiosis I and meiosis II in male and female germ cells, and these differences will be discussed in detail here.

The unique and defining features of meiosis occur during meiosis I, which consists of prophase I, metaphase I,

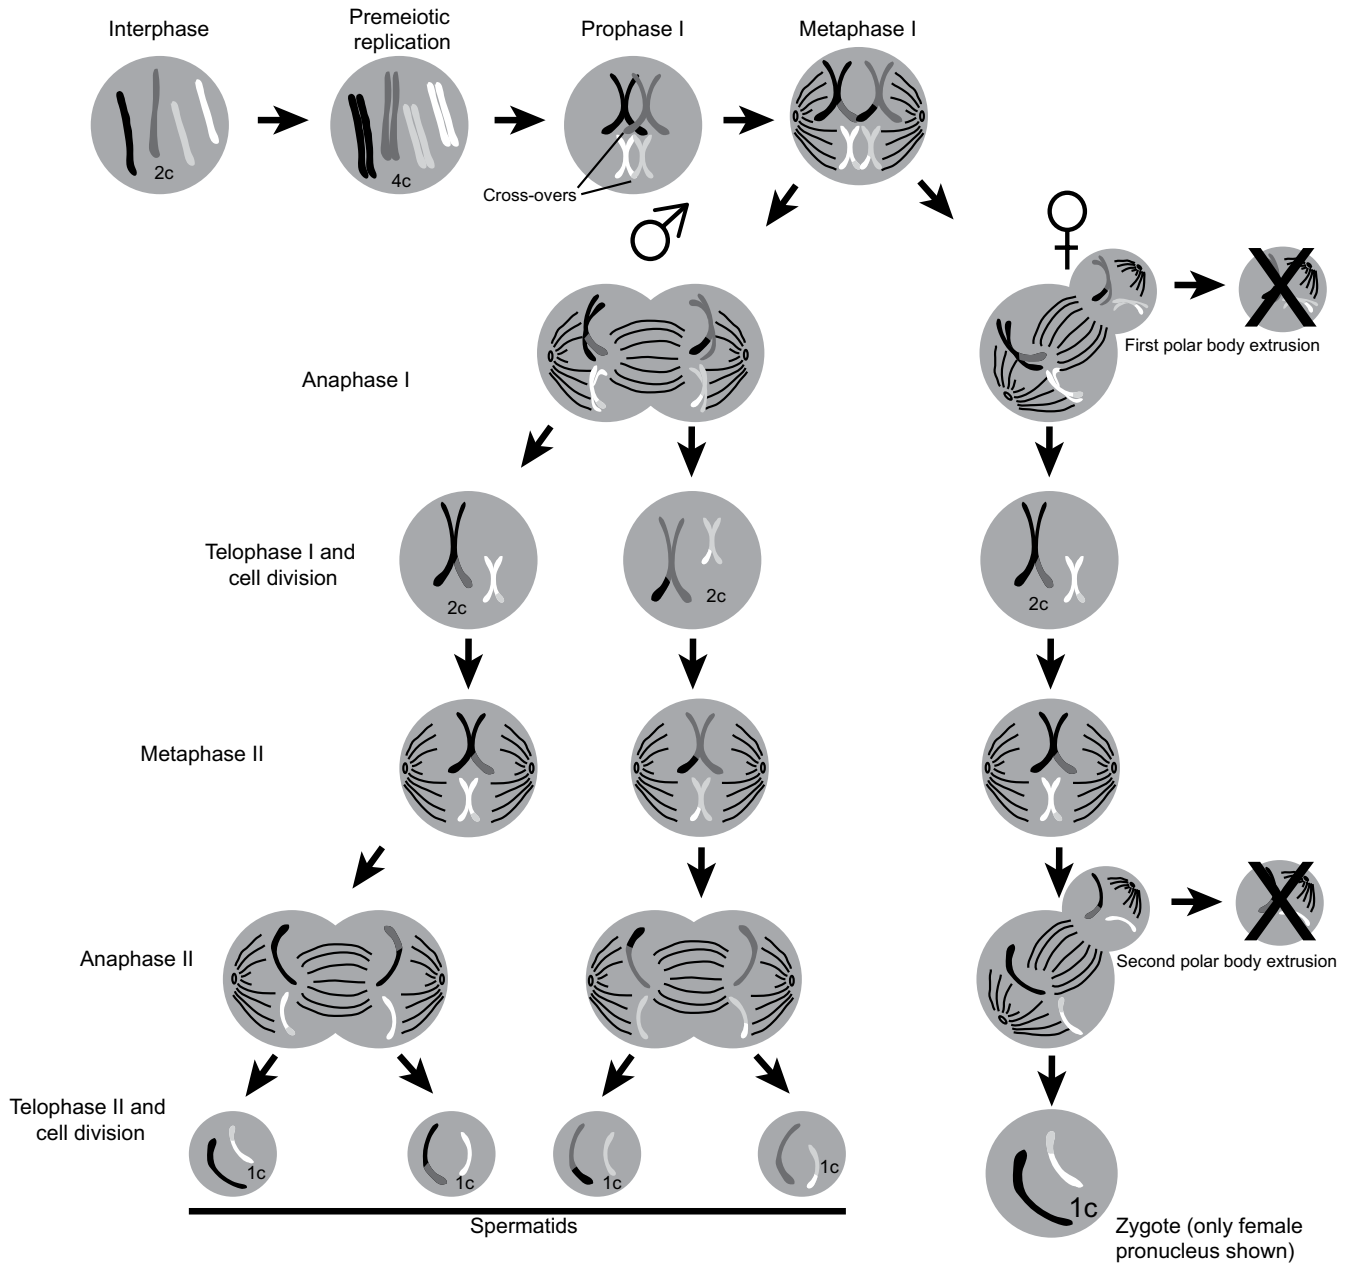

FIGURE 1.1 **Stages of meiosis.** Prior to the start of meiosis, the chromosomes are copied in a stage of premeiotic replication, taking the DNA compliment from 2c to 4c. In other words, there are still two copies of each chromosome (2n), but each of them has two sister chromatids (2c each, for a total of 4c). Upon entry into meiotic prophase I, the homologous chromosome pairs undergo two important events, synapsis and recombination. They then enter metaphase I, where the homologs line up on the metaphase plate and are attached to the meiotic spindle. Homologous chromosomes are separated during anaphase I, and the separation of the nuclei is completed during telophase I. Cell division (cytokinesis) then follows to produce two daughter cells with a chromosome compliment of 1n each, but with each chromosome still containing two sister chromatids (2c). In males, this process divides the cellular components equally between both daughter cells, while in females, half of the genetic complement is retained in the oocyte, and half becomes encapsulated into a smaller structure known as the first polar body. In this case, the asymmetrical division results in the majority of the cytoplasm and cell organelles dividing into the oocyte, with very little getting passed to the polar body. The second meiotic division is much more like a mitotic division, where the two sister chromatids are separated during metaphase II, anaphase II, and telophase II, resulting in haploid (1n and 1c) daughter gametes. Again, in the females, one of the products of this division is the second polar body, and it contains the second half of the genetic complement of the second division.

anaphase I, and telophase I (Figure 1.1), during which maternal and paternal homologous chromosomes come together and pair in a process known as synapsis, and then exchange genetic information through crossing over via the process of recombination. As will be described in this chapter, synapsis and recombination serve a single purpose: to keep homologous chromosomes tightly associated with each other so that they may then be

Vet-ebooks.com

segregated equally to daughter cells. These daughter cells, each containing just one of the originating homologous chromosomes, then enter meiosis II. Meiosis II, consisting of prophase II, metaphase II, anaphase II, and telophase II, resembles more of a mitotic (reductional) division. Mitosis is the process by which cells replicate their DNA from 2c to 4c (but still 2n), and then divide the nucleus in half, separating their sister chromatids (and, thus, their DNA) equally into two daughter (diploid but still 2n) nuclei. Thus, mitosis is "cyclical" in nature, and can truly be called a cell cycle, because the resulting 2n daughter cells can be used as starting material for future cycles of DNA replication and cellular division, while meiosis is less of a cell cycle and more unidirectional considering that, once produced, gametes need to undergo fertilization in order to achieve their full diploid status and become capable of cellular proliferation through repeated mitotic cycles.

History and Discovery of Meiosis

As with so many developmental processes, meiosis was first observed and described cytologically in sea urchin eggs by the German biologist Oscar Hertwig (1849–1922) and further characterized at the chromosome level by the Belgian zoologist Edouard Van Beneden (1846–1910) in eggs from the parasitic roundworm *Ascaris*. This new nematode model, with its larger sperm size (some 10-fold larger than that of sea urchins) and abundance of synchronously developing oocytes, facilitated more precise cytological observations of chromosome movements,[1] allowing Van Beneden to observe the halving of chromosome content even before the significance of chromosomes for heredity was fully realized. It was not until the studies of August Weismann (1834–1914), however, that the significance of the two earlier studies became clear. Weismann's *germ plasm* theory held that inheritance in a multicellular organism is the product of the germ cell, or *gamete*, while the normal proliferative activity leading to the growth and development of the individual is undertaken in the somatic cell lineages. Germ cells can give rise to soma or to germ cells themselves, whereas soma can only give rise to somatic cells, a concept referred to as the *Weismann barrier* and now arguably dispelled in the era of stem cells and reprogramming. Weismann went on to demonstrate that sea urchin eggs undergo both a reductional division and an equational one, and that both were essential to provide haploid gametes that could then collectively derive a diploid daughter cell following fertilization. His work preceded the rediscovery of Mendel's work by Hugo de Vries and others in the 1900s, and these events culminated in 1911 with the discovery by Thomas Hunt Morgan of crossing over, which is the exchange of genetic information between homologous chromosomes as a result of recombination, and the raison d'être of meiosis. Hunt Morgan's landmark studies in *Drosophila melanogaster* females earned him the Nobel Prize in 1933. The term *meiosis* was coined by Farmer and Moore in 1905 to explain the process of division of germ cells, but it was the accumulation of all of the studies described above that led to full realization of the crucial role of meiosis for gamete formation.

Conservation of Meiosis across Eukaryotes

Comparative evidence seems to indicate that meiosis appeared early in eukaryotic cell history, most likely arising only once, given its high degree of conservation among many species. Even in prokaryotes, similar machineries exist for repairing recombination intermediates to those found in highly evolved species. For example, the prokaryotic single-stranded binding protein RecA, which is essential for DNA repair, has evolved to form several RecA homologs in all eukaryotes, some of which appear to be specific to meiosis, while others are shared between different forms of recombination repair. Many other meiotic proteins, such as Spo11, MutS homologs 4 and 5 (Msh4 and Msh5, respectively), and MutL homologs 1 and 3 (Mlh1 and Mlh3, respectively), all of which are described in detail in this chapter, are also functionally conserved from yeast to human.

Meiotic processes involving the establishment and maintenance of cohesion between sister chromatids, and the physical attachment of homologous chromosomes through synapsis, recombination, and crossing over, are highly conserved, if not always achieved in the same manner in all species. For example, the hallmark structural component of prophase I, the synaptonemal complex, exists in the majority of eukaryotes but may consist of different proteins (examples of synaptonemal complexes from different organisms are provided in Figure 1.2). Meiotic recombination occurs in the majority of species studied, but does not occur in male *D. melanogaster*, only in the female flies. Msh4–Msh5 proteins are major components of the meiotic crossover (CO) pathway in eukaryotes (described in detail in this chapter) but do not exist in *Saccharomyces pombe*. Similarly, MLH1 and MLH3 proteins are the major determinants of COs in many eukaryotes, but *Caenorhabditis elegans* lacks these proteins. Interestingly, however, *C. elegans* does possess MSH4 and MSH5, the binding partners for MLH1–MLH3, raising the question of whether other functionally similar proteins are present in worms to substitute for MLH1–MLH3. Therefore, in these model organisms, meiosis itself is highly conserved, but the major players may be interchangeable or the processes slightly adapted to suit each organism.

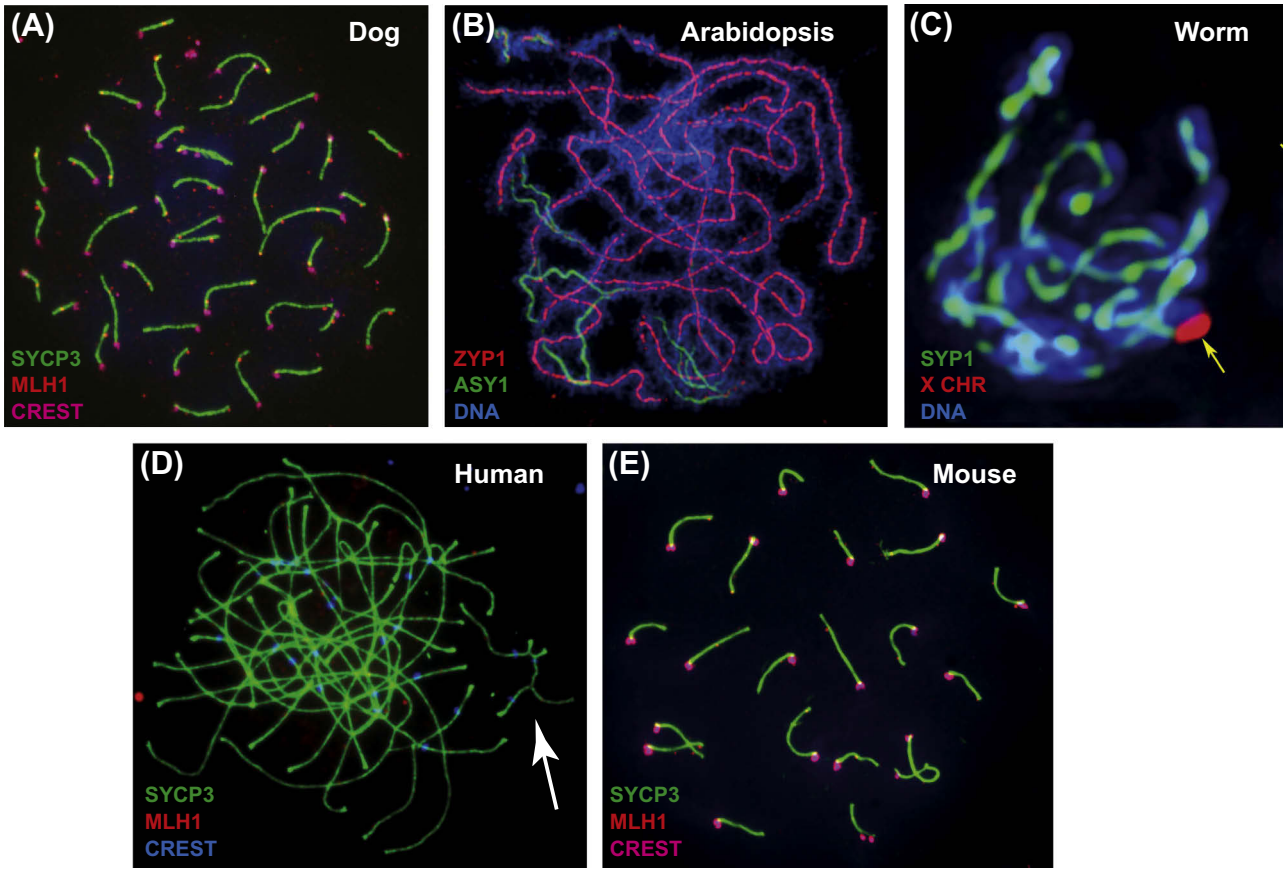

FIGURE 1.2 **Comparative meiosis across eukaryotic species.** This figure is reproduced in color in the color plate section. (A) Pachytene cell from an adult dog testis stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, pink). (B) Immunolocalization of the *Arabidopsis* synaptonemal complex transverses filament protein ZYP1 (red), polymerizing between the homologous chromosome axes marked by ASY1 (green) and the DNA loops (blue) in a late-zygotene nucleus. The ASY1 signal (green) is reduced in synapsed regions (red), and an interlock is being resolved. (C) A *C. elegans* pachytene nucleus immunostained to show that the synaptonemal complex (green) is normal and that the pairing center ends of the X chromosome are fully paired (red); *(Source: Adapted from Saito et al., PLoS Genet, 2009.)* (D) A trisomic human embryonic oocyte at the pachytene stage stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, blue). The three copies of chromosome 21 can be seen attempting to pair (arrow). (E) Mouse pachytene cell stained immunostained with SYCP3 (green), MLH1 (red), and cREST (centromere, pink).

Sexual Dimorphism and Timing of Meiosis

In mammals, one of the defining features of meiosis, and of gametogenesis in general, is that there are distinct differences in the mechanism, timing, and success of meiotic events between the sexes (reviewed by Ref. 2). The most fundamental difference lies in the number of products of meiosis, with four haploid spermatozoa being produced during meiosis in males, and only one oocyte in females, with the remaining chromosomal contents being extruded into two polar bodies, following a distinctly asymmetric division (Figure 1.1). In females, meiosis is not completed before fertilization occurs, and it is the process of sperm penetration of the oocyte cytoplasm that elicits the cascade of events that culminate in completion of the second meiotic division and extrusion of the second polar body (Figure 1.1, and see Chapter 4 for further details).

Meiosis in females begins in midgestational fetal life, with all oogonial precursors entering meiosis in a semisynchronous fashion. Oocytes undergo two periods of arrest; the first lasts weeks in mice and years in humans, and involves the entire oocyte pool. Following birth, each estrous or menstrual cycle is marked by the growth and development of a cohort of follicles, only a subset of which go on to be ovulated (one or two in humans), while the others undergo atresia. Only those oocytes that are ovulated will resume meiosis. In primates at least, the resulting diminution of the oocyte pool leads to reproductive senescence. In males, on the other hand, meiosis is initiated at or around puberty (or just after birth in rodents), and spermatogonial precursors enter meiosis in waves along the seminiferous epithelium of the testis, which reoccurs throughout the life of the individual.

Vet-ebooks.com

For humans, perhaps the most fundamentally important difference between males and females lies in the distinct difference in meiotic error rates observed in females compared to males. This is possibly most startling in humans, in whom meiotic error rates approach 40–60% in women but remain under 3% in men (Source: U.S. Centers for Disease Control). Studies of mouse mutants have pointed to the fact that female meiosis appears to be less stringent in its regulation, providing at least one possible explanation for the differences in error rates. In this chapter, many points of divergence between male and female mammals will be discussed, some or all of which may contribute to the differences in success rates for male versus female meiosis.

Scope of the Chapter

This chapter aims to describe the main features of the meiotic process, from the earliest stages of induction during embryogenesis in females, to the last stages of meiotic cell division. Complex mechanisms are described that control meiotic induction, cohesin assembly and disassembly, prophase I events such as synapsis, silencing and meiotic recombination, and meiotic segregation. For each of these, we provide an introductory overview at the beginning of each section before delving further into the often complex molecular mechanisms involved. Environmental and aging effects on meiotic mechanisms are discussed in detail, and diseases arising from meiotic errors also feature. Overall, the chapter focuses on mammalian meiosis, with an emphasis on those stages and events that differ from mitosis, but it draws evidence from non-mammalian meiotic species for the purposes of comparison and further illustration of key regulatory processes.

INITIATION OF MEIOSIS IN MAMMALS

One of the key features that distinguishes gametogenesis in male and female mammals is the time during development in which the oogonia or spermatogonia cease their proliferative activity and enter meiosis. Early in embryonic development, the primordial germ cells (PGCs) arrive in the bipotential or indifferent gonad and begin a rapid and rampant phase of proliferation, during which time they increase in number exponentially over several days to weeks. In the mouse, for example, approximately 3000 PGCs take up residence in the bipotential gonad at around 10.5 days postcoitum (dpc) at a time when the gonadal structure has barely arisen from the intermediate mesoderm. The PGCs continue to proliferate, reaching a number of some 30,000 by 13.5 dpc,[3,4] at which point the first sign of sexual dimorphism becomes evident. The PGCs of the female stop proliferating and enter prophase of the first meiotic division, while PGCs of the male arrest in G0/G1 of the mitotic cycle and then only resume proliferation and enter meiosis after birth[5] and, most usually (although not always), at puberty.

Retinoic Acid (RA) is the Key Trigger for Meiosis in Males and Females

It has been well established that male germ cells fail to enter meiosis during fetal life as a result of inhibitory factors secreted by the developing testis, while they can be induced to undergo meiosis when co-cultured with embryonic ovaries[6] or when cultured with conditioned medium from adult testes.[7–10] Such observations gave rise to the suggestion that meiotic entry is a cell-nonautonomous event, being regulated locally, either within the gonad or by tissues in the vicinity of the developing gonad, but not by the germ cells themselves. The mesonephros, which is closely apposed to the developing gonad, was suggested as the site of "meiosis induction" when it was demonstrated that co-culture of mesonephros with fetal bipotential gonads could induce feminization, or meiotic entry.[11–13] These studies were confounded, however, by early observations showing that ectopically located germ cells (that migrate aberrantly to other regions of the embryo) spontaneously initiate meiosis without close proximity to the mesonephros,[14,15] raising the possibility that gonad-intrinsic factors may also induce meiotic entry.

Evidence for the role of vitamin A–retinol metabolite, retinoic acid (RA), as the trigger for meiotic initiation in both sexes arose out of studies demonstrating that the entry into meiosis was dependent on expression stimulated by retinoic acid gene 8 (*Stra8*) in both sexes.[16–20] As its name suggests, *Stra8* expression is dependent on RA,[21] and both *Stra8* expression and meiotic entry by female germ cells during embryogenesis can be blocked by RA antagonists.[16–18] These observations were preceded by studies demonstrating the existence of RA receptors (RA receptor (RAR) and retinoid X receptor (RXR)) in embryonic gonads[22,23] and the finding that exogenous RA could induce premature meiosis in fetal ovary cultures.[22,24] The source of RA in vivo has been somewhat contentious, but it is thought to be produced in the neighboring mesonephros via a two-step process that converts retinol into retinaldehyde and then into RA (see Box 1.1). Accordingly, the mesonephros maintains high expression of the genes encoding RA synthetic enzymes, including retinol dehydrogenase 10 (*Rdh10*) and retinaldehyde dehydrogenase 2 (*Raldh2*, also called *Aldh1a2*),[25] along with *Raldh3*/*Aldh1a3*, the latter at lower levels.[26–28] Importantly, however, while the mesonephroi of both male and female embryos can synthesize large quantities of RA,[25] local levels of RA are maintained at 80% lower levels in the developing testis than in the ovaries as a result of high expression of cytochrome

BOX 1.1

RETINOIC ACID SYNTHESIS AND ACTION

Retinoic acid (RA) is a lipid-soluble derivative of vitamin A (retinol) and is essential for many aspects of embryonic development (reviewed by Refs 32,33). RA regulates the expression of genes involved in body patterning and morphogenesis, while disruptions in RA signaling result in a wide range of congenital abnormalities, including skeletal and central nervous defects, cardiac malformation, and craniofacial abnormalities.

Retinol is bound to retinol-binding protein (RPB) for transport through the circulation. Upon reaching its target tissue, defined by the presence of STRA6 receptors on the cell surface, retinol is released from RPB and binds instead to cellular retinol-binding protein (CRBP). Both retinol and CRBP serve as the principal substrate for RA synthesis, through oxidation to retinaldehyde by retinol dehydrogenase 10 (RDH10), but free retinol can also undergo oxidation by more nonspecific alcohol dehydrogenases. This first step of RA synthesis is considered to be rate limiting and is reversible.[34] In light of the higher substrate affinity of RDH10, CRBP provides a substrate specificity mechanism by which specific RDH activity is promoted by the retinol–CRBP complex at the expense of free retinol oxidation through alcohol dehydrogenase.

The second step of RA synthesis is also enhanced through retinaldehyde binding to CRBP, and involves the irreversible oxidation of retinaldehyde to RA by the retinaldehyde dehydrodgenases (RALDHs), of which at least three have been described (RALDH1, RALDH2, and RALDH3; also known as ALDH1A1–3, respectively), encoded in the mouse by the genes *Aldh1a1*, *Aldh1a2*, and *Aldh1a3*, respectively. Each of these is expressed in unique patterns across developing mouse embryos, and each results in the production and secretion of RA from the cell to act in a paracrine fashion on neighboring cells and/or tissues.[27,35–38]

Uptake of RA into responding cells is achieved through binding to the cellular retinoic acid–binding protein (CRABP), which prevents the nonspecific degradation of RA in the target cell. Alternatively, RA may bind, and be degraded by, the P450 hydroxylase CYP26 enzymes, which include CYP26A1, B1, C1, and D1, and which may act in a partially redundant fashion to hydroxylate RA into less bioactive 4-oxo-RA. CYP26A1 is itself regulated by RA in a feedback regulatory loop.[32,33]

RA is transported into the nucleus, where it binds to one of a class of three retinoic acid receptors (RARα, RARβ, and RARγ), which are transcription factors of the retinoid receptor family. The retinoid X receptors (RXRα, RXRβ, and RXRγ) also belong to this group and, upon ligand binding, they dimerize with RAR. The RXR–RAR heterodimeric transcription factor, in association with co-activators and histone acetyl-transferase, then associates with RA response elements (RAREs) upstream of transcriptional targets across the genome, thereby initiating gene transcription.

P450 26B1(*Cyp26b1*), a gene that encodes a P450 enzyme that is responsible for degradation of RA[18,29–31] (see Box 1.1), specifically within the supporting somatic cells (Sertoli cells) of the male gonad. Thus, in females, meiosis is brought about by the expression of *Stra8* in PGCs, which is in turn stimulated by the production of RA, presumably in the mesonephros (Figure 1.3(A) and discussed further here). In males, on the other hand, fetal RA production by the mesonephros is counteracted by the expression of *Cyp26b1* by the developing testis, which acts to degrade RA and lower local RA concentrations (Figure 1.3(A)). Expression of *Cyp26b1* begins at 11.5 dpc in males, concurrent with the onset of *Raldh2* expression in the mesonephros of both sexes.[25] (See Refs 27,32–38.)

In male mice, RA production resumes postnatally, at around 3 days postpartum, as the PGC population (now known as *gonocytes*) differentiates into A1 spermatogonia. In both prepubertal and adult testis, *Raldh2/Aldh1a2* expression predominates in the Sertoli cell, although *Raldh1/Aldh1a1* is also expressed to appreciable levels.[39,40] Importantly, *Raldh2/Aldh1a2* is also expressed in premeiotic germ cells of the mouse testis, as well as in pachytene spermatocytes,[40] indicating perhaps some potential for RA synthesis by germ cells themselves. Moreover, studies exploring the relative contributions of different retinoid receptors have indicated that RA may act directly on the Sertoli cells through RARα/RXRβ receptors, as well as through RARγ receptors on spermatogonia[39,41] (Figure 1.3(B)). Thus, it is likely that RA may act in both autocrine and paracrine fashion to facilitate meiotic entry in males. This possibility is supported by recent studies involving cell-specific ablation of all three *Raldh/Aldh1a* genes.[40] Loss of all three *Raldh* genes specifically from Sertoli cells results in a failure of spermatogonial differentiation from A-type to A_1-type, which represents an irreversible first step toward meiotic initiation.[40] This effect is mediated specifically via the RARα receptor on Sertoli cells, indicating an important autocrine effect of RA in this context. Conversely, RA produced by preleptotene spermatocytes (those that are just about to enter prophase I of meiosis) may act in a cell-autonomous fashion to induce meiotic entry

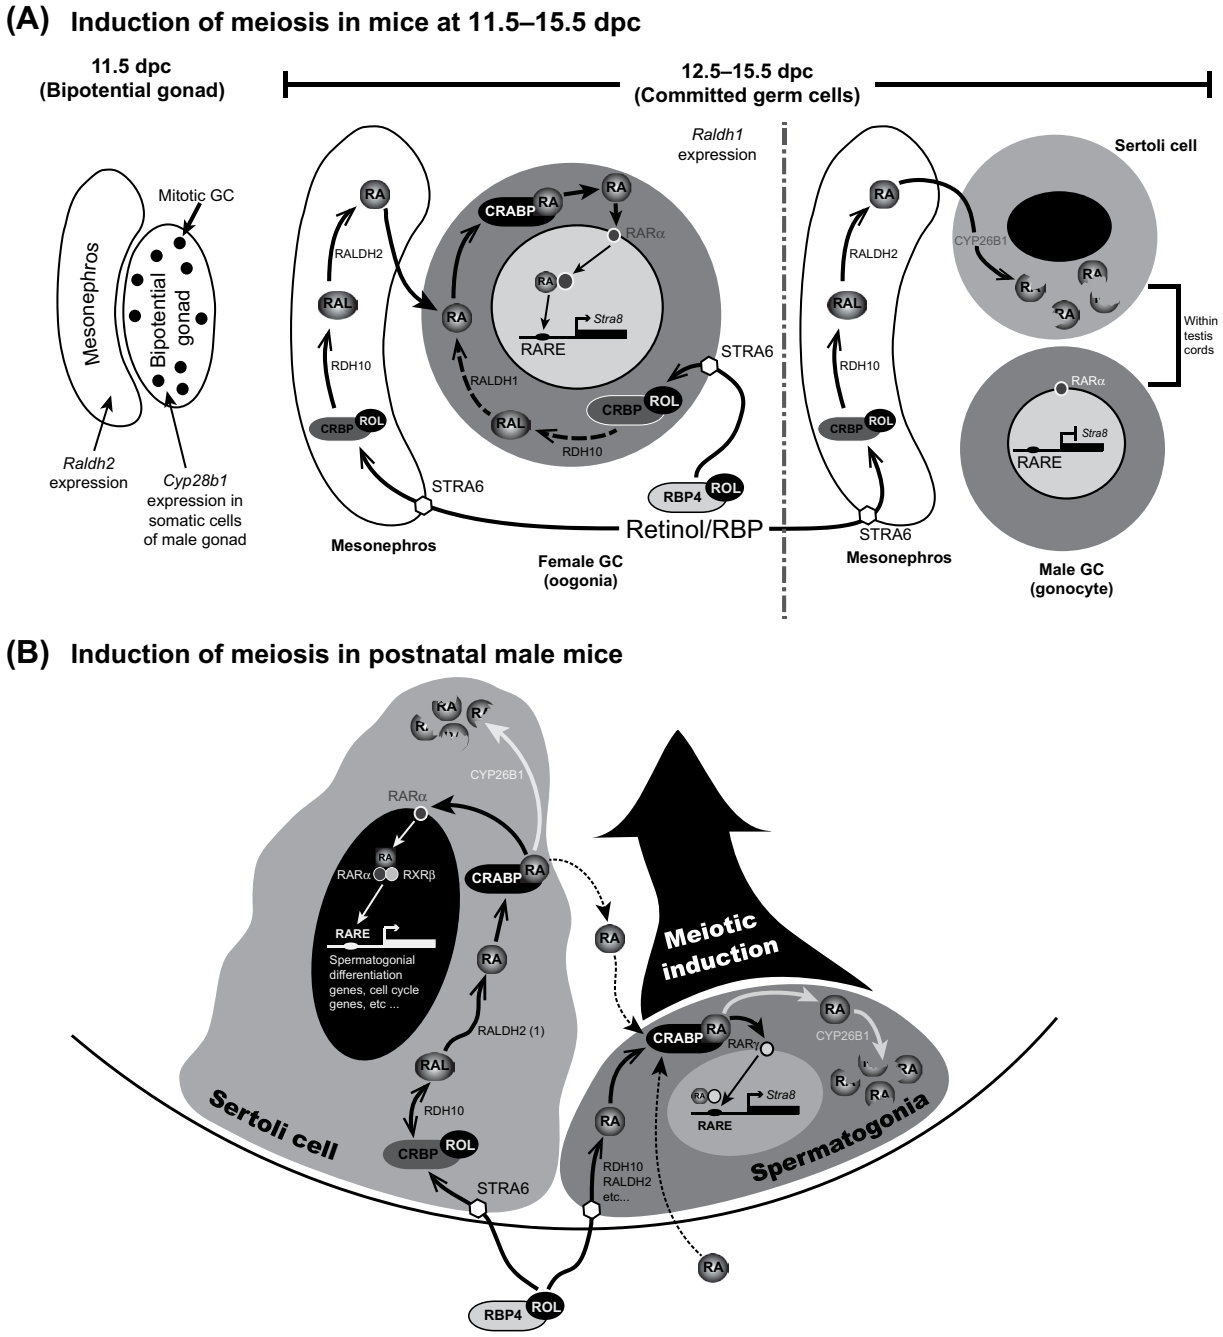

FIGURE 1.3 **Induction of meiosis in (A) female and (B) male mice.** (A) Females initiate meiosis during embryonic development, starting at around 12.5 dpc. Retinol and retinol-binding protein (RBP) are transported to the mesonephros and taken up via STRA6 receptors. Retinoic acid (RA) is produced through sequential steps, through retinaldehyde, and the RA is then released into the adjoining gonad. Alternatively, RA may be produced directly in germ cells, although this is somewhat contentious at the current time. Once in the oocyte, RA is taken up into the nucleus by binding to RARα, and the complex binds to retinoic acid response elements (RAREs) upstream of RA-responsive genes. In the cell, retinol and its metabolites are bound to appropriate binding proteins (e.g., CRBP and CRABP). In males, RA is degraded in the Sertoli cells of the developing testis cords by CYP26B1, preventing its activity on adjoining male germ cells. (B) In postnatal male mice, retinol is transported to Sertoli cells in which resides all of the appropriate machinery for RA synthesis. CYP26B1 is downregulated in the Sertoli cell, resulting in elevated RA levels. This RA is directed toward adjoining spermatogonia, and can induce expression of RA response genes through RA–RARγ uptake into the nucleus. Once again, CYP26B1-mediated degradation of RA is prevented by downregulating its expression in male germ cells. See the accompanying text for further details.

Vet-ebooks.com

via RARγ-mediated induction of *Stra8* expression[17,40,41] (Figure 1.3(B)). Importantly, however, the requirement for autocrine signaling of RA within the Sertoli cell to induce initial spermatogonial differentiation appears necessary only for the first wave of spermatogenic initiation, and is dependent on RARα, while RARγ is not required,[41] presumably because it resides within the germ cells. Conversely, Sertoli cell RA signaling through RARα does not appear to be required for subsequent waves, the induction of RA being now relegated presumably to the germ cells.[30] All of this information notwithstanding, it seems that the question of where RA is synthesized in the postnatal testis is not yet fully resolved, and more studies are required to confirm the spermatogonia and spermatocyte populations as sources of autocrine RA.

This potential role of germ cells in inducing meiotic initiation helps to clarify an important controversy regarding the role of RA in meiotic entry. Kumar et al.[42] utilized female mice bearing mutations in the *Raldh2/Aldh1a2* gene, or in both the *Raldh2/Aldh1a2* and *Raldh3/Aldh1a3* genes specifically in the mesonephros during embryogenesis, and showed that *Stra8* expression was still observed in fetal oocytes.[42] They also demonstrated that inhibition of CYP26B1 activity with ketokonazole allows for RA-independent induction of *Stra8* expression in the wild type or in the mutant embryos, but only if the mesonephros remains intact, while RA activity is not detected in wild-type fetal testes following ketoconazole treatment.[42] Taken together, these findings would suggest (1) that RA does not act directly on the gonad to induce meiotic entry during fetal life, and (2) that CYP26B1 acts to inhibit entry into meiosis but not at the level of gonadal RA activity. The authors concluded from these observations that RA was not acting to promote meiotic entry since they could find no evidence of another (gonadal) source of RA that could be responsible for meiotic initiation in females. Furthermore, they concluded that the target of CYP26B1 was a non-RA molecule within the mesonephros.[42] However, these data are in line with those described for the male here, and lead to a model in which RA produced by the developing ovary, and more specifically by the oogonia, is responsible for inducing meiotic progression either in a cell-autonomous manner to promote *Stra8* expression and/or indirectly by acting in a paracrine fashion to induce RA-responsive genes in the mesonephros (Figure 1.3(A)). Thus, ketoconazole inhibition of CYP26B1 could result in the loss of RA signaling specifically in the mesonephros, but with the RA originating from the fetal gonad. In support of this, a recent report suggests that RA can be produced from retinol by PGCs in the fetal ovary, with the RALDH1/ALDH1A1 protein being localized specifically in germ cells from 12.5 to 15.5 dpc[43] (Figure 1.3(A)). Such an observation is supported by those early studies of ectopic germ cell entry into meiosis, which is well clear of any influence of the mesonephros.[14] Taken together, these recent studies lend support to the idea that the germ cells themselves, rather than supporting cells and tissues, are the source of the RA that triggers meiotic progression, but that the effect of RA may require these supporting cells for paracrine interactions that lead to the onset of meiotic events.

Stra8 and the Induction of Meiosis

The major target of RA activity in mouse germ cells is to induce the expression of *Stra8*,[18,25] a gene initially described and characterized in P19 embryonal carcinoma cells.[21,44] In the mouse embryo, *Stra8* expression is observed from 12.5 dpc in females, approximately one day prior to the onset of meiosis. Prior to this time, male and female germ cells are indistinguishable, expressing similar genes such as Deleted in azoospermia-like (*Dazl*; Figure 1.4(A) and (B)). Interestingly, the entry into meiosis is not synchronous, but instead occurs in an anterior-to-posterior wave through the ovary.[45,46] Thus, germ cells in the anterior region of the ovary are exposed to RA, express *Stra8*, and enter meiosis from 12.5 dpc, while those of the posterior end enter somewhat later, with RA activity being evident from 13.5 dpc and *Stra8* expression extending to 16.5 dpc.[8,45] This *Stra8* expression occurs under a backdrop of high RA levels, coincident with downregulation of *Cyp26b1* expression (Figure 1.4(A), (C)–(F)), and leads within hours to the downregulation of pluripotency markers, such as POU-domain class 5 transcription factor 1 (*Pou5f1*; also known as octamer-binding transcription factor 4 (*Oct4*)), and the increased expression of meiotic markers such as Synaptonemal complex protein 3 (*Sycp3*), *Spo11*, and the meiosis-specific RecA homolog, Disrupted meiotic cDNA 1 (*Dmc1*).[9,25,47] *Stra8* expression is not required for proliferative activity of the female germ cells, but appears instead to be essential for the premeiotic S phase and meiotic entry.[16] The evidence that similar mechanisms exist in humans is provided by the observation that RA can induce *STRA8* expression in human fetal gonad explant cultures.[48,49]

In males, as in females, RA leads to induction of *Stra8*, but this occurs postnatally and usually around the time of puberty in most mammals. In mice, however, *Stra8* induction occurs co-incident with downregulation of *Cyp26b1* during early postnatal life, from around day 8 postpartum (pp), immediately prior to the onset of meiotic prophase I (Figure 1.4(A), (D), and (E)).[50] Loss of *Stra8* in males appears to result in a failure to transition from preleptotene stages into prophase I, but this appears to be a background-specific phenomenon, since the failure to enter meiosis

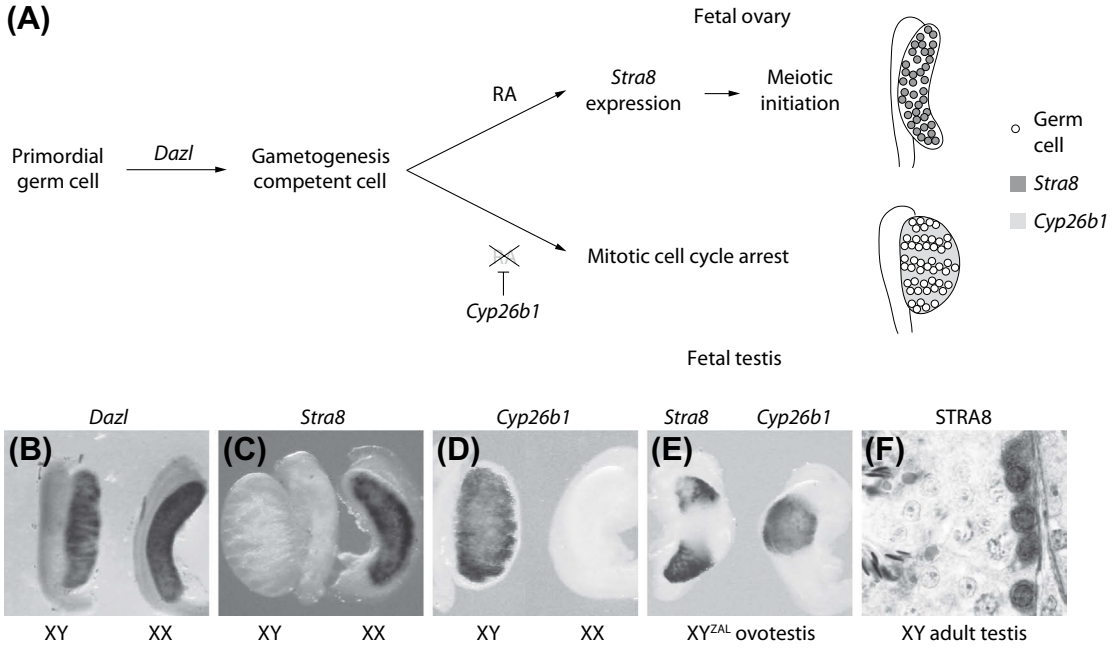

FIGURE 1.4 Regulation of meiotic initiation in mice. (A) Ovarian germ cells initiate meiosis during embryogenesis, whereas testicular germ cells undergo G0/G1 mitotic cell cycle arrest and do not initiate meiosis until after birth. Primordial germ cells in the fetal gonad express *Dazl*, thus acquiring competence for gametogenesis and gaining the ability to interpret RA as a meiosis-inducing signal. In the fetal ovary, signaling by retinoic acid (RA) induces *Stra8* expression and thereby meiotic initiation in germ cells. In the fetal testis, cytochrome p450 (*Cyp26b1*), an RA-metabolizing enzyme, is expressed in somatic cells surrounding the germ cells and prevents premature *Stra8* expression. (B–D) Whole-mount in situ hybridization on fetal testes and ovaries (B) at embryonic day 13.5 (E13.5) for *Dazl*; and at E14.5 for (C) *Stra8* and (D) *Cyp26b1*. (E) In E14.5 XY^{ZAL} ovotestes, *Stra8* is expressed in the polar regions exhibiting ovarian histology, and *Cyp26b1* is expressed in the central region exhibiting testicular histology. XY^{ZAL} embryos carrying a Zalende-derived Y chromosome on a C57BL/6 genetic background are often partially sex-reversed and have ovotestes. (F) Immunohistochemistry for STRA8 in adult testis. STRA8 is expressed in preleptotene germ cells in stage VII/VIII tubules. *Source: Figure kindly provided by Dr David Page and Shirleen Soh, Whitehead Institute, MIT, with additional images provided by Yanfeng Lin (panel B) and Tsutomu Endo (panel F). is strain specific.[16,17,51] In one *Stra8* mutant mouse line, meiotic entry was not impeded by the loss of *Stra8*, but instead meiotic progression was disrupted as a result of premature chromosome condensation.[51] As a result, Hogarth et al. concluded that genes other than *Stra8* must also be required to promote meiotic entry, and they went on to identify three potential candidates, at least one of which was RA responsive. Indeed, the RA-responsive gene, Establishment of cohesion 1 homolog 2 (*Esco2*), is expressed in embryonic ovaries at around 14.5 dpc, and in postnatal testis at day 10 pp, the protein appears to reside within the nucleus and is an essential component of the sister chromatid cohesion complex.[50,52] The roles of *Esco2* as well as of other genes whose profiles correlate with *Stra8* expression, such as *Setdb2* and *Uba6*,[50] remain unclear at the current time.

Recent studies have identified the mammalian Doublesex-related transcription factor 1 (DMRT1) as a transcriptional repressor of *Stra8* in both male and female germ cells.[53,54,55] However, it appears that the effect of DMRT1 on meiotic initiation is cell context specific and perhaps relies on differential posttranslational modification of the protein, resulting in sexually dimorphic regulation of meiotic entry. In adult males, expression of *Dmrt1* prevents the transition from spermatogonial to spermatocyte stages by limiting RA-induced transcription of *Stra8*, and at the same time promotes spermatogonial development by induction of genes required for differentiation from A- to B-type spermatogonia, including the Spermatogenesis and oogenesis-specific helix–loop–helix 1 transcription factor (*Sohlh1*).[54] DMRT1 was shown to bind to the *Stra8* promoter close to the RA response elements, presumably preventing binding of RA and thus limiting meiotic entry.[54] Interestingly, DMRT1 also alters expression of *Cyp26b1* and some of RA's synthetic enzymes, suggesting a direct action of DMRT1 on RA production and stability.[54] Alternatively, given recent evidence that pachytene spermatocytes can synthesize RA,[40] the reduced expression of these RA enzymes in the absence of DMRT1 may result from a loss of cells that are themselves a major source of RA. In either case, it appears that DMRT1 may modulate RA responsiveness

Vet-ebooks.com

by spermatogonia, thereby providing a modulating influence for meiotic entry in the premeiotic cell population. Taken together, these new observations present a mechanism by which meiotic entry is controlled by the exquisite interplay between opposing pathways to both limit and regulate how and when cells can initiate prophase I.

Unlike the situation in postnatal males, DMRT1 does not appear to play a role in preventing meiotic entry in fetal mouse testes.[55] *Dmrt1* expression arises prior to sex determination in the bipotential gonad at 11.5 dpc,[53,56] but its expression in the ovary is transient, disappearing from somatic cells by 13.5 dpc and then from germ cells by 15.5 dpc.[53,56] Despite this transient expression, loss of *Dmrt1* in *Dmrt*$^{-/-}$ female embryos results in significantly reduced expression of *Stra8* and a consequent failure to form the full complement of primordial follicles.[53] The level of expression of *Stra8* is sufficient to allow some cells to enter meiosis, albeit aberrantly, but these cells subsequently fail to proceed normally through prophase I. This is exactly the opposite situation to that seen in postnatal male germ cells, in which DMRT1 is required to suppress meiotic entry through downregulation of *Stra8* expression.[54]

Sry Induction of the Male Germ Cell Program during Fetal Development

While the destruction of RA by CYP26B1 is a major mechanism by which male germ cells avoid meiotic entry, a recent study has suggested that secretions from cells other than the germ cells may also function to restrict meiotic entry by male germ cells in utero. This was demonstrated by the observation that XY germ cells in cultured mouse fetal testes can occasionally enter meiosis when secretory activity is prevented by the compound Brefeldin A.[57] One such secretory protein appears to be fibroblast growth factor 9 (FGF9), which is essential for male germ cell survival during fetal life, and deletion of which is known to result in male-to-female sex reversal.[58,59] *Fgf9* expression arises in the somatic cells of the bipotential gonad prior to gonadal sex determination, but by 11.5 dpc becomes restricted to the developing testis,[60,61] having been suppressed in females by the female factor gene, wingless-related MMTV integration site-4 (*Wnt4*) (reviewed by Ref. 62). FGF9 treatment of cultured mouse gonads restricts meiotic entry, resulting in reduced *Stra8*, *Dmc1*, and *Sycp3* expression,[61,63] but at the same time it promotes the expression of pluripotency factors such as *Oct4* and Sex determining region Y (Sry)-box 2 (*Sox2*), along with markers of male fate, including Nanos homolog 2 (*Nanos2*) and DNA methyltransferase 3-like (*Dnmt3L*).[61,63] The action of FGF9 occurs directly on germ cells, most likely via the FGF receptor FGFR2, which is present on the surface of germ cells at 12.5 dpc. It has been postulated that the action of FGF9 on germ cells results in upregulation of the RNA-binding protein NANOS2 in primordial germ cells of both sexes and in premeiotic spermatogonia, leading to suppression of meiotic entry.[63] Studies using in vitro culture of fetal tissues indicate that FGF9 most likely acts by reducing the responsiveness of germ cells to RA, possibly via *Nanos2* regulation, reducing the ability of RA to induce *Stra8* expression,[64] while at the same time suppressing expression of *Wnt4*.[65] Thus, loss of *Fgf9* induces upregulation of *Wnt4*, which induces germ cells to become feminized, while loss of *Wnt4*, in turn, induces a male fate via upregulation of *Sox9* (reviewed by Ref. 66). *Sox9* is a direct target of the sex determination gene *Sry*, whose expression in males initiates a feedforward loop between *Sox9* and *Fgf9* (Figure 1.5), leading to upregulation of the latter.[65] Taken together, these observations suggest that suppression of meiotic entry in male gonads during embryogenesis is brought about by SRY-induced *Sox9* expression that, in turn, results in the expression of *Fgf9* (Figure 1.5(A)). The action of FGF9 is to suppress *Wnt4* expression and to impair the ability of male germ cells to respond to RA, through mechanisms that remain largely undefined. In addition, expression of *Cyp26b1* is enhanced both by SOX9 and by the transcription factor steroidogenic factor 1 (SF1) to promote RA degradation (Figure 1.5(A)).[67]

In the absence of SRY in females, germ cell sex determination is marked by increased expression of *Wnt4*, whose expression is regulated by R-spondin1 (RSPO1), leading to suppression of *Sox9* and *Fgf9* expression.[62]

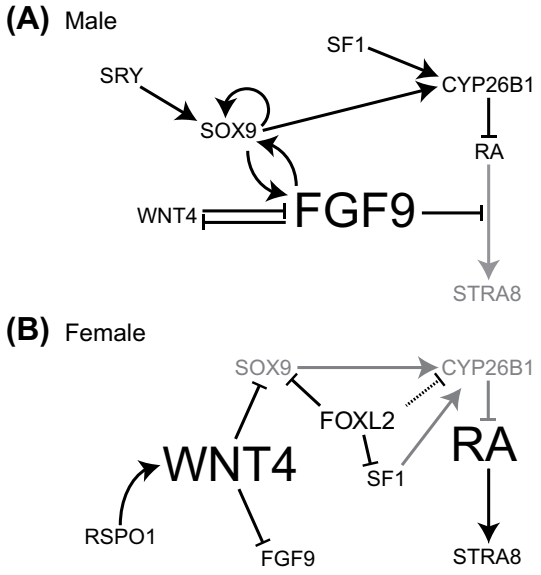

FIGURE 1.5 Summary of key sex determination signals that inhibit retinoic acid (RA) induction in male germ cells (A), and those that induce RA in female germ cells during embryonic development (B). See the main text for further details.

Vet-ebooks.com

At the same time, elevated expression of forkhead transcription factor 2 (*Foxl2*) acts to suppress production of CYP26B1 through several mechanisms: by further suppressing *Sox9* expression, by repressing *Sf1* expression,[67] and possibly also by other mechanisms. Thus, in females, the drivers of sex determination consist of WNT4 and FOXL2, which help to promote meiotic entry via suppression of *Cyp26b1*, thereby stabilizing RA levels in the gonad (Figure 1.5(B)). Whether WNT4 and FOXL2, or indeed any other factors, have a direct effect on RA metabolism and action is uncertain at the current time.

Early Indications for a Role for Small RNAs in Meiotic Entry

Recent studies have indicated a role for small RNA species in meiotic initiation. Members of the microRNA family *Mirlet7*, for example, are expressed in premeiotic and meiotic germ cells in response to RA signaling.[68] The induction of *Mirlet7* expression by RA signaling has been shown to occur via repression of the RNA-binding protein LIN28.[68] Furthermore, in mice lacking the Argonaute 4 (*Ago4*) gene, which encodes a member of the AGO family of proteins that are defining components of the small RNA–processing machinery, early postnatal spermatogonia enter meiosis approximately 4–6 days early.[69] This precocious entry into meiosis is associated with early upregulation of genes such as *Stra8*, *Esco2*, and *Sycp3*, and also altered expression of genes encoding the RA synthetic enzymes and *Cyp26b1*, suggesting that small RNAs that associate with, and function alongside, AGO4 may modulate meiotic entry through feedback mechanisms that regulate RA metabolism. These studies are at a very early stage, but they raise the possibility that meiotic induction and RA metabolism in germ cells are intricately linked to small RNA biogenesis and action.

PROPHASE I

Overview of Prophase I

Events during the first meiotic stage (meiosis I) are designed expressly to ensure that homologous chromosomes (one maternal and one paternal in origin) segregate equally at the first meiotic division (Figure 1.1). By contrast, during the second meiotic division, as in mitosis, it is the sister chromatids that must segregate equally. For meiosis II and mitosis, this is relatively easy, since the sister chromatids are already tethered together via the process of cohesion (discussed further in this chapter). It stands to reason, therefore, that the homologous chromosomes of meiosis I must first find a similar pairing mechanism that will enable them to segregate in a similarly efficient manner. Thus, the necessity of homologous chromosome pairing adds a level of complexity to meiosis I that is unique and defining for this stage. These events all take place during prophase I, and pairing is ensured by two distinct mechanisms, synapsis and recombination, the former through protein–protein interactions and the latter through DNA–DNA interactions. Both events require that homologous chromosomes must first locate each other, recognize their homologs, and then interact physically, and both are specifically designed to allow the tethering of homologs until the first meiotic division, much as sister chromatids are physically connected through cohesion.

As a result of the added complexity, meiotic prophase I is extended compared with its mitotic counterpart, and can take several days to complete in mammalian species. Separated into five distinct substages (Figures 1.6 and 1.7(A)–(E)) based on the cytological appearance of the chromosomes, prophase I is the most complex and long-lived stage of meiosis. Figure 1.6 summarizes the events of prophase I in temporal order from left to right, including the synapsis events (described in the upper portion of the figure) and recombination events (described in the lower portion of the figure). The status of the sister chromatids and homologous chromosomes is depicted in cartoon form in the middle of Figure 1.6.

The first substage of prophase I is known as leptonema (from the Greek *leptos*, meaning "thin"). It is the stage immediately following premeiotic DNA replication where the chromosomes are still fairly long, decondensed, and threadlike. The main event during leptonema involves the initial assembly of a proteinaceous structure, termed the synaptonemal complex, which begins to form a scaffold along each homologous chromosome between the sister chromatids. These scaffolds are termed axial elements, and they first assemble as short stretches along each homologous chromosome, the stretches coalescing to become longer filaments until they extend down the entire length of the chromosome in late leptonema and into the zygotene stage. Concurrent with synaptonemal complex assembly, meiotic cohesins are also assembled onto the homologous chromosomes, and subsequently disassembled, a process that is discussed in detail in this chapter.

During the second substage of prophase I, termed zygonema (from the Greek *zygon*, meaning "adjoining"), homologous partner chromosomes begin to pair, and then to synapse, the latter resulting in the physical tethering between homologs. Simultaneously, the DNA begins to condense, making the chromosomes more visible cytologically. This process of synapsis requires that the axial elements along each

Vet-ebooks.com

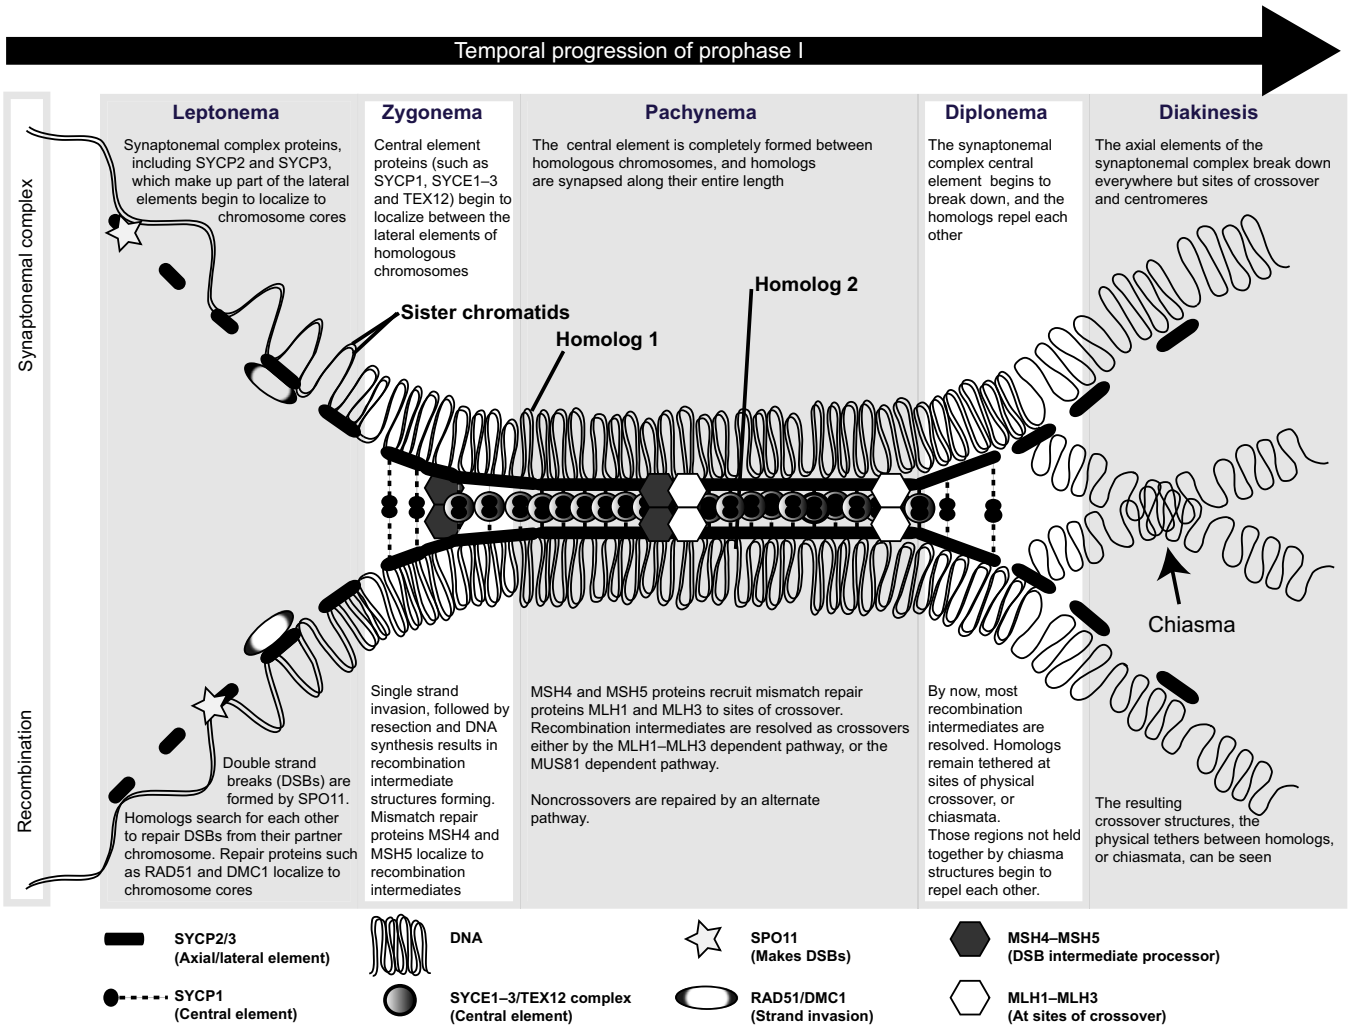

FIGURE 1.6 Dynamics of recombination and synapsis in prophase I. Events occurring during the five substages of prophase I (leptonema, zygonema, pachynema, diplonema, and diakinesis) are depicted schematically, according to their involvement in either synapsis events (along the top) or recombination events (along the bottom).

homolog are stabilized and joined together in a zippering process that involves multiple protein complexes, collectively termed the central element. Once the homologs have been joined together by the central element, they are said to have synapsed, and, once this occurs, the axial elements are reclassified as lateral elements. Upon complete synapsis along the entire length of the homologous axes, the cell enters the third substage of prophase I, known as pachynema (after the Greek *pachy*, meaning "thick", given that the chromosomes are now fully condensed and have a short, fat cytological appearance). Pachynema is the longest of the substages and can last up to 10 days in some rodent species, and even longer in humans. Once pachynema is complete, the central element of the synaptonemal complex begins to break down, and the chromosomes begin to repel each other. This fourth substage is known as diplonema (from the Greek *diplo*, meaning "double", given that two homologs become clearly visible again). Despite the central element breaking down and the synaptonemal complex disassembling, the homologs remain joined at the physical sites of meiotic COs, called chiasmata. These COs are generated by the process of repairing meiotic double-strand breaks (DSBs), discussed further in this chapter, in a process that is initiated in preleptonema and leptonema and that progresses concurrently with synaptonemal complex assembly. The fifth and final substage of prophase I, diakinesis, is named for the Greek *dia* (meaning "through") and *kinesis* (meaning "movement"), so in essence it means "moving through", indicating the final stage before proceeding to the next phase of meiosis, metaphase I. At this point, the homologs are connected only by the remnants of the synaptonemal complex found at the centromeres and at the CO sites.

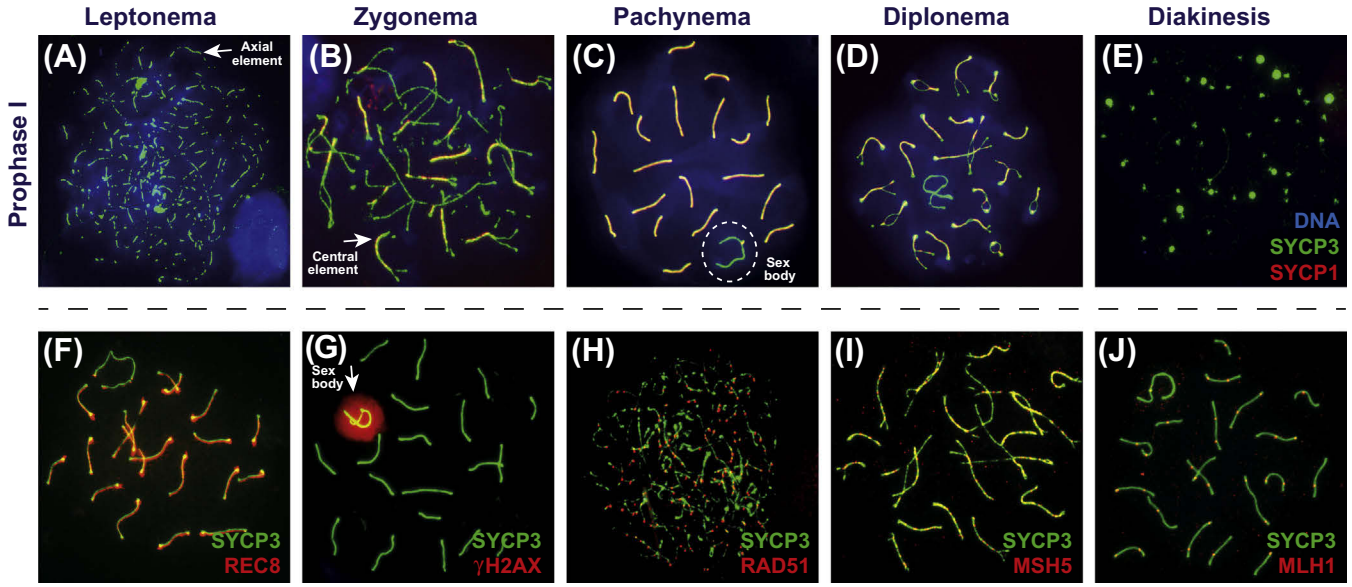

FIGURE 1.7 Immunofluorescent analysis of meiotic prophase I events in mouse spermatocytes. This figure is reproduced in color in the color plate section. (A–E) Synaptic events in the five substages of prophase I, visualized by staining with antibodies against axial–lateral element protein SYCP3 (green) and central element protein SYCP1 (red), where the overlay between the two appears in yellow. (F–J) Immunolocalization of SYCP3 (green) with key meiotic markers during prophase I; (F) REC8, (G) λH2AX, (H) RAD51, (I) MSH5, and (J) MLH1 all in red, and SYCP3 in green.

Chromosome Dynamics and Pairing in Early Prophase I

Chromosome Movements, Telomere Clustering, and Telomere Bouquet Formation

One of the fascinating aspects of meiotic prophase I is the delicate, yet dramatic, orchestrated "dance" that occurs between homologous chromosomes. The reorganization of the nuclear contents, and their situation with respect to the nuclear envelope, are, quite understandably, critical to the success of homolog alignment and, as a consequence, are essential for prophase I progression. It is notable that although there exists a large body of data concerning the molecular events that occur following synapsis of chromosomes, far less is known about how homologs recognize and pair with one another. Almost certainly, numerous mechanisms exist to promote homolog recognition and pairing, and these may be utilized to differing degrees in different organisms. For example, in many organisms, while pairing may occur at numerous sites along chromosomes, there are often defined locations where initial pairing interactions take place. The so-called pairing centers of *C. elegans* are a strong example of this.[70] The congregation of pairing centers coincides with the generation of highly conserved rapid chromosome movements, which have been demonstrated for many species, including mammals and both budding and fission yeast.[71,72] Driven by the Sad1p, UNC-84 (SUN)–Klarsicht, ANC1, syne homology (KASH) family of nuclear membrane–bound proteins, rapid chromosome movements are propagated by telomere connections to cytoplasmic motors that drive oscillatory movements.

Another important feature of chromosome interactions during early prophase I is the "telomere bouquet". The bouquet describes the clustering of telomeres at one location across the nuclear envelope, and is noted in many meiotic species.[73,74] However, the relative importance of rapid chromosome movements and bouquet formation appears to be species specific, since, for example, in *Sordaria macrospora*, the bouquet stage follows homolog pairing[75] and also follows early synapsis in female mice,[76] while in *Saccharomyces cerevisiae*, rapid chromosome movements appear to be more critical than bouquet formation for pairing.[77]

The oscillatory rapid chromosome movements of the fission yeast, *S. pombe*, are particularly noteworthy due to their long-lived activity and their dramatic motion through the nuclear space. During this so-called horsetail motion,[78] the telomeres gather in a tight bouquet adjacent to the spindle pole body (the microtubule organizing center that is itself outside the nuclear membrane on the cytoplasmic side) early in prophase I. The spindle pole body then proceeds to drag the entire nucleus backward and forward, powered by a meiosis-specific dynein motor while meiotic recombination is taking place.[79] Mutants in which telomeres coalesce normally but that are incapable of spindle pole body–driven nuclear movements show more severely impaired

Vet-ebooks.com

meiotic recombination than mutants with impaired bouquet formation, indicating that the horsetail movements of the nucleus are more critical for recombination events in *S. pombe*.[73] In contrast, mutants that exhibit altered bouquet formation have more defective asci (spore-bearing cells), suggesting that the bouquet may play additional roles in later or additional meiotic events.

Telomere clustering also plays a prominent role in meiotic prophase I in budding yeast (*C. elegans*) and in mammals (reviewed in Refs 80,81,82). However, the relative importance of rapid chromosome movements and bouquet conformations for homolog pairing and synapsis in mammals is relatively less well understood. In early prophase I in mouse meiocytes, rapid chromosome movements are readily observed and can be visualized in real time.[83] In addition, telomeres attach to the nuclear envelope via a conical thickening of the axial element.[81,82] These telomeres coalesce, as they do in other organisms, to form a defined bouquet structure. Moreover, in male mice, the bouquet is short-lived and often hard to find, but occurs concomitantly with homolog alignment and pairing, calling into question whether pairing is dependent on these telomere events in mammals. Loss of synaptonemal complex protein 3 (SYCP3) does not affect bouquet formation, despite the loss of axial elements,[84] whereas loss of the cohesion component (structural maintenance of chromosomes 1 beta (SMC1β)) results in failed nuclear envelope attachment.[85] Telomeric repeats also appear important for the clustering of telomeres in mouse, yeast, and worm (reviewed in Ref. 82).

Involvement of SUN–KASH Proteins in Telomere Tethering to the Nuclear Envelope

At the molecular level, the pathways that regulate telomere movements and bouquet formation are only just being elucidated, most of the prominent players having been identified in fission yeast. In *S. pombe*, Bqt1 and Bqt2 proteins connect telomeres to the spindle pole body via their interactions with Rap1, and, together, these three proteins form a bridge from the telomere to Sad1, a spindle pole body protein associated with the inner nuclear membrane.[86,87] Rap1, in turn, requires Taz1 for its association with the telomere in *S. pombe*.[88] Sad1 is the founding member of the SUN domain proteins, whose orthologs are present across the spectrum of meiotic species.[89] For example, in budding yeast, the telomere-associated protein Ndj1 is critical for telomere movements and bouquet formation,[82,90,91] and its function is dependent on interactions with the SUN domain protein, Mps3, present on the inner nuclear membrane.[91,92]

SUN proteins function together with KASH domain proteins, located on the outer nuclear membrane, forming a bridge that links telomeric DNA ends with specific elements of the cytoskeleton.[93] KASH domain proteins include Kms1 in *S. pombe* and ZYG12 in *C. elegans*, and they have also been reported for mammals (reviewed by Refs 89,94,95). In budding yeast, in contrast, Csm4 is required for telomere clustering and for homologous recombination[91,96,97] and, while not strictly a KASH domain-containing protein, appears to interact with Mps3 and Ndj1.[89]

In mammals, at least six SUN proteins have been described, only some of which have been associated with a specific KASH protein (reviewed by Refs 94,95). The two major SUN proteins involved in mammalian meiosis are SUN1 and SUN2, both of which utilize a common meiosis-specific KASH protein, KASH5, for tethering to cytoplasmic microtubules.[95,98,99] Localization of both SUN1 and KASH5 is restricted to meiotic prophase I, and more specifically to the telomeric regions of chromosomes during leptotene of prophase I onward.[98,100] Loss of *Sun1* in mice results in loss of telomere attachment to the nuclear envelope and synapsis failure during prophase I, resulting in male and female sterility.[100] Similarly, mutation of the *C. elegans* ortholog of *Sun1*, Matefin, disrupts its interaction with the KASH protein, ZYG12, and prevents synapsis and homologous recombination.[101]

What is clear from all these comparative studies of chromosome dynamics is that chromosomal connection to the cytoskeletal machinery, via the nuclear envelope, is a conserved feature of early prophase I progression and is essential for initial chromosome interactions and/or recombination. Conserved protein families mediate these interactions, including proteins of the SUN and KASH family (Figure 1.8). Most commonly, the attachments at the telomere may involve meiosis-specific proteins, such as Ndj1 in budding yeast and Bqt1 and Bqt2 in fission yeast, although no such linker protein has yet been identified in mammals. Rap1, which is essential for such interactions in fission yeast, appears to play no role in telomere attachment during meiosis in mice.[102] The SUN and KASH components involved in telomere clustering and homolog pairing in the plant kingdom remain to be elucidated, but are almost certainly conserved like their animal kingdom counterparts.

Pairing Centers and Noncanonical Mechanisms to Induce Homolog Pairing

It is interesting to note that in organisms that do not display a defined bouquet, nuclear envelope interactions remain critical for prophase I progression. *Caenorhabditis elegans* is an example of this in which pairing is mediated by pairing centers,[70] which themselves associate with the nuclear envelope during early stages of prophase I.[103] Pairing centers on each chromosome are bound by a single member of a family of zinc finger proteins, HIM8, and the ZIM proteins, ZIM1, ZIM2, and ZIM3.[103] These proteins mediate

Vet-ebooks.com

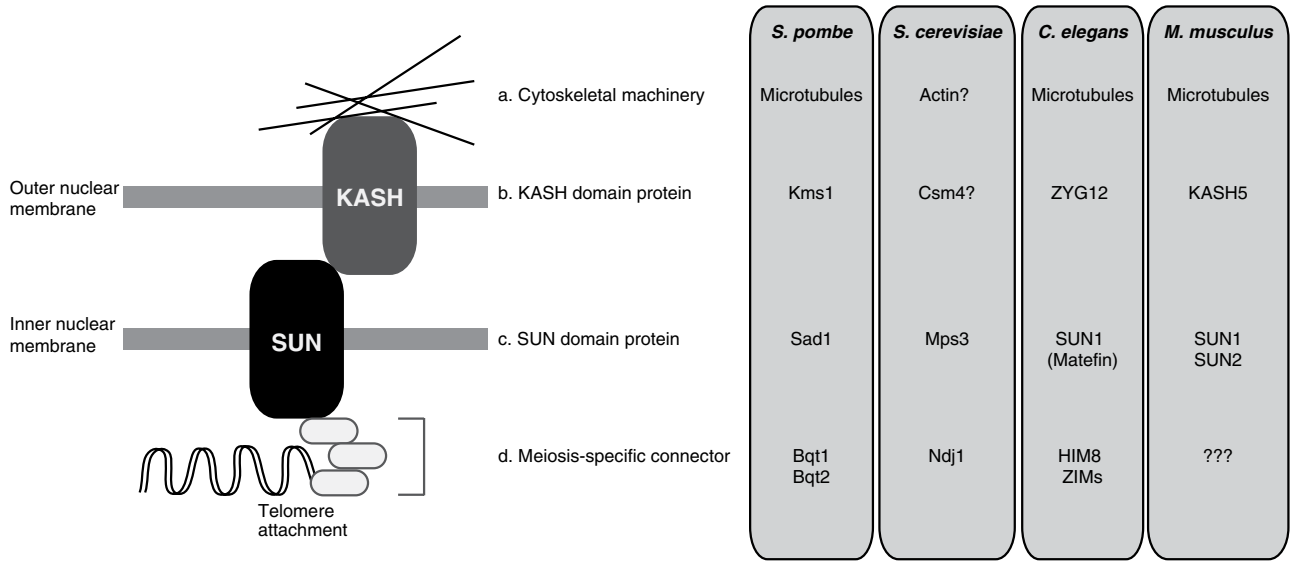

FIGURE 1.8 Chromosome movement and association with the nuclear envelope are coordinated through the highly conserved SUN–KASH family of nuclear membrane proteins. The left panel represents a simplified cartoon of SUN–KASH interactions with meiotic chromosomes and with the cytoskeletal machinery. On the right, known mediators of these events are shown for fission yeast, budding yeast, worms, and mice.

binding of the pairing center to the nuclear envelope in a bouquet-like fashion. Thus, while no specific bouquet is formed, the nucleus of early prophase I meiocytes in *C. elegans* displays a distinctly polarized appearance, and the chromosomes are clearly asymmetrically distributed.[104] This nuclear association of chromosomes is dependent on the SUN protein Matefin (SUN1) and the KASH protein ZYG12.[101,105] Thus, nuclear attachment is mediated at pairing centers rather than at telomeres, but is also mediated through SUN–KASH interactions with the ZIM proteins.

A recent report from studies in *S. pombe* indicates that a novel RNA-induced homolog-pairing process may exist in this organism.[106] Ding et al. demonstrate that the *SME2* locus is among the first to pair during the horsetail stage. This locus encodes a meiosis-specific noncoding RNA that appears to mediate homolog recognition. In *S. pombe*, meiotic initiation is regulated by Mei2, an RNA-binding protein. Mei2 forms a distinct focus at the *SME2* locus, and it sequesters Mmi1, another RNA-binding protein that is required for elimination of meiosis-specific mRNA transcripts in mitotic cells. Thus, the Mei2-induced removal of Mmi1 allows meiotic progression. At the same time, the binding of Mei2 and Mmi1 to *SME2* transcripts is sufficient to induce pairing at this locus, as well as between ectopic loci on nonhomologous chromosomes. It appears, however, that while *Sme2* transcripts can act as *cis*-acting pairing factors, there may be other, similar noncoding RNA loci that play similar roles in pairing and meiotic initiation across the *S. pombe* genome.

The Synaptonemal Complex and Synapsis

The synaptonemal complex was first visualized by Moses and Fawcett in 1956.[107,108] As a complete tripartite protein structure, it consists of two lateral elements that align each homolog and the central element. In addition, transverse filaments have one end anchored in the lateral element and the other in the central element, and function to "zipper" the two homologs together during early prophase I, in the process known collectively as synapsis (Figure 1.6). In the mouse, a significant amount of chromosome pairing occurs premeiotically, prior to the initiation of the DSBs at leptonema, and is dependent on the SPO11 and SUN1 proteins.[109]

Upon entry into meiosis, in the leptotene stage, the synaptonemal complex begins to form short stretches of axial element along the sister chromatids of each homologous chromosome, with the chromatin extending perpendicularly out from the development axial element to form loops (Figure 1.7(A)). The two major components of the axial elements are SYCP2 and SYCP3, first identified in the rat but later identified in many other mammalian species.[110,111,112,113] SYCP3 consists of two proteins in mice and rats (30 and 33 kDa in size) that are transcribed from the same gene, with the shorter isoform very highly conserved among vertebrate species,[114] whereas SYCP2 is a much larger protein at 173 kDa.[113] SYCP2 and SYCP3 form heterodimers that are dependent upon the conserved coiled-coil domain in SYCP2. Both proteins begin to localize to chromosomes to form axial elements during leptonema.[115,116] Mutations in either *Sycp2* or *Sycp3* in the mouse result in a

Vet-ebooks.com

similar phenotype, namely, the absence of functional axial elements and proper synapsis, along with impaired specificity of chromatin loop attachment, resulting in male sterility and female subfertility.[84,115,117,118] Intriguingly, mutant SYCP2 protein still localizes to the axial element in certain *Sycp2* mutants, but it cannot recruit SYCP3, demonstrating that functional SYCP2 is required for SYCP3 localization.[115] In addition, SYCP2, but not SYCP3, is known to be a physical link between the transverse filament and the axial element.[119,120]

During zygonema, homologous chromosomes are joined together in a "zipper"-like fashion by the transverse filament and central element (Figure 1.7(B)). This tripartite structure is highly evolutionarily conserved among species, from yeast to worm, mouse, and human. The C-terminal of SYCP1 is known to embed within the lateral element of the synaptonemal complex, while the N-terminal region is known to associate with the central element (Figure 1.6, pachynema). Additionally, the N-terminal of SYCP1 interacts strongly with itself, suggesting that SYCP1 subunits lie head-to-head within the space between the lateral elements of homologous chromosomes, and physically associate with the central element, effectively joining the two elements together.[119] More recent evidence shows that upon its localization, SYCP1 recruits other proteins to the central element, such as SYCE1, SYCE2, SYCE3, and TEX12.[121,122,123] SYCE1 and SYCE2 bind to one another and to SYCP1, while TEX12 forms a complex with SYCE2, thus only forming an indirect interaction with SYCP1.[122,124] Localization patterns of SYCP1, SYCE1, and SYCE3 are similar, forming a continuous staining pattern along the synaptonemal complexes of synapsed chromosomes,[121,123] whereas SYCE2 and TEX12 display a more punctate staining pattern and do not necessarily co-localize with SYCP1.[122,123] The complex formed by SYCE2 and TEX12 is thought to have an architectural purpose within the central element of the synaptonemal complex, as it consists of a hetero-octamer made up of one SYCE2 tetramer and two TEX12 dimers bound together.[124] It is postulated that this complex, within the confines of a "zipper" analogy for the synaptonemal complex, would be the slider that pulls the SYCP1–SYCE1–SYCE3 "teeth" together to zip up the synaptonemal complex. Other protein components are thought to be members of the central element scaffold, such as FKBP6, although very little is known about their role in synaptonemal complex assembly.[125] Recent studies suggest that FKBP6 may be a player within the RNA interference (RNAi) pathway during meiotic prophase I, with a role specifically in the biogenesis of P-element-induced wimpy testis (PIWI)-interacting RNAs (piRNAs) in premeiotic mouse testes, and in suppressing LINE1 retrotransposon integration into, and thus disruption of, the genome.[126] Given the long history of associations between LINE elements and the synaptonemal complex, and their possible role in facilitating and directing synaptonemal complex assembly, this is an exciting area of research that needs to be more fully explored.[127]

Mutations in synaptonemal complex protein genes have severe implications for meiotic progression in murine systems. Mutations in SYCP2 and SYCP3 show a very similar phenotype, with a failure to form axial element structures and defective synapsis in spermatocytes, resulting in a block of prophase I around zygonema and male infertility.[84,115,117] Female *Sycp2* and *Sycp3* mutants, however, are both subfertile, having severely reduced litter sizes and a reduced reproductive life span.[115,117] SYCP3 protein is required for correct CO formation, and its absence increases nondisjunction in these mutant female oocytes.[117] *Sycp3* mutant females show increased aneuploidy, in which the abnormal karyotype is inherited by the offspring, often resulting in fetal demise, a situation that increases with advancing maternal age. *Sycp1* null males also exhibit a fertility defect as a consequence of large-scale asynapsis in prophase I.[128] In *Sycp1* null females, there is a complete absence of follicles in adolescent female ovaries; however, this can be partially alleviated by crossing to an *Sycp3* null background. This, along with other evidence, suggests that SYCP3 may play a role in meiotic checkpoint mechanisms in mice.[129,130] However, *Sycp1–Sycp3* double-null mice remain male and female infertile due to a lack of synapsis and a block of the DSB repair pathway (discussed further in this chapter) prior to CO resolution. Interestingly, these mice are still able to load cohesins onto the chromosome cores (also discussed further), even in the complete absence of a functional synaptonemal complex.[129]

In central element–defective mice, such as those with homozygous mutations in *Syce1*, *Syce2*, and *Syce3*, severe defects in synapsis and DSB repair (discussed further here) are evident, despite an apparently "normal" loading of SYCP1, resulting in complete infertility in both sexes. This suggests that although SYCP1 can load onto the axial element, assembly of the central element is impaired and thus synapsis cannot be achieved.[123,131,132] Interestingly, SYCE2 interacts with the recombination repair protein RAD51 (also discussed further here), indicating that sites of RAD51 localization might be candidates for synapsis initiation sites in the mouse.[132]

In addition to appropriate synaptonemal complex formation, there is an additional requirement to monitor the regulation of homolog interactions in the mouse. HORMA (Hop1p, Rev7p, and MAD2) domain-containing proteins, HORMAD1 and HORMAD2, localize selectively along unsynapsed chromosomes in wild-type mice, and dissociate upon accumulation of central element proteins. This reciprocal distribution of HORMAD and central element proteins is not dependent upon DSB repair components, but is absolutely dependent upon the presence of a functional synaptonemal complex, in addition to the AAA

Vet-ebooks.com

(adenosinetriphosphatases (ATPases) associated with diverse cellular activities)–ATPase, thyroid hormone receptor interactor 13 (TRIP13).[133,134] HORMAD2 is also required for the accumulation of checkpoint kinase ATR (ataxia telangiectasia and Rad3-related protein) along unsynapsed cores in prophase I, as *Hormad2*$^{-/-}$ mice show defective ATR accumulation along the synaptonemal complex, suggesting that the HORMAD proteins play a major role in the meiotic prophase I asynapsis surveillance mechanism in mice (discussed further here).[135]

Very little is known about the synaptonemal complex disassembly process in mammals, but the beginning of the transition from prophase I to metaphase I involves both synaptonemal complex disassembly and chromatin compaction. During diplonema, the central element begins to disassemble, SYCP1 is lost from the chromosome cores, and the homologs repel each other[136] (Figure 1.7(D)). HORMADs relocalize to the cores upon desynapsis, while SYCP3, although remaining associated with the cores, begins to redistribute to the centromeres. Thus, the chromosomes are still held together by the synaptonemal complex at the centromeres and CO sites, and by the physical COs themselves, continuing into diakinesis[133,137,138] (Figure 1.7(E)). It is thought that central element disassembly begins with phosphorylation of SYCP1 and TEX12 by polo-like kinase 1 (PLK1), which facilitates their removal from the synaptonemal complex.[139] Subsequently, SYCP3 removal and lateral element reconfiguration processes are regulated by both the cyclin-dependent kinases (CDKs) and the aurora kinases (AURKs).[140,141] Further evidence to support the role of phosphatases and kinases in the transition process is that the phosphatase inhibitor okadaic acid can speed the G2–M transition in meiotic prophase cells.[142] SYCP1 remains localized to the centromeres until such time as meiotic kinetochores localize to the centromeres, consistent with a role for SYCP1 in assembly of these complexes in meiosis.[138] SYCP3 remains bound to the centromeres into diakinesis, where it promotes bi-orientation of homologous centromeres to help ensure proper segregation.[138]

Proper synaptonemal complex assembly and disassembly are critical steps in achieving appropriate DSB repair and subsequent correct meiotic segregation of chromosomes. This is true of humans as well as laboratory mouse models, and cases of mutation in synaptonemal complex component genes, such as *SYCE1* and *SYCP3*, have been implicated in women with premature ovarian failure and recurrent pregnancy loss.[143,144,145] Ectopic expression of synaptonemal complex genes has also been implicated in some rare incidences of cancer, demonstrating that meiosis-specific expression of these genes is crucial.[146]

Cohesins: Establishment and Assembly

As in mitosis, to ensure proper meiotic progression and correct chromosome segregation, sister chromatid cohesion needs to be established early in meiosis, and must be maintained until such time as the homologs and the sister chromatids need to separate at anaphase I and II, respectively. Thus, while cohesion is not meiosis specific per se, there are features of cohesion during meiosis that are very different from those of mitotic cells. The cohesion complex is similar in both cell cycles, consisting of two SMC proteins that enclose the DNA in a hinge, and two non-SMC proteins, the kleisin and stromalin subunits[147] (Figure 1.9(A)). In mitosis in higher organisms, cohesin loads onto chromosomes during replication and remains tightly bound until prophase, when the bulk of this cohesin dissociates from the chromosomes. By anaphase, all the cohesin has been removed, and the sister chromatids separate.[148,149] The timely removal of this cohesin is crucial for the proper segregation of sister chromatids. Cohesin binds along the entire length of the chromosome arms, but is intensely bound at the centromere, the region that is responsible for tightly binding sister chromatids.[150,151] During meiosis, however, the pattern of cohesin binding is very different; cohesion is established by cohesins binding to the chromosome arms, resulting in cohesion of paired homologous chromosomes, whereas once the first meiotic division has taken place, the sister chromatids remain joined by centromeric cohesion only.[152,153] Once the cohesin at the centromeres is disassembled in meiosis II, the sister chromatids may separate, similar to mitotic division.

Cohesion during cell division is maintained by specific cohesin complexes, the somatic cohesins SMC1 and SMC2, joined by kleisin RAD21 bound to stromalin SA1–SA2 (Figure 1.9(B)). In addition, most organisms contain meiosis-specific cohesins (Figure 1.9(C)), including SMC1β, REC8, RAD21L, and STAG3, which can combine with the canonical cohesins SMC1α, SMC3, and RAD21 to form varying complexes specific to meiosis. These proteins can be immunoprecipitated together as distinct complexes,[154] suggesting the presence of these varied subunit complexes in meiosis.

The timing of assembly and disassembly of meiotic cohesins through prophase I is complicated, and little is known about it in mammals; however, evidence from other eukaryotes suggests that cohesin assembly is a multistep process.[155] Cohesin assembly in mouse meiocytes begins with the localization of meiotic kleisin REC8 to chromosomes slightly before the premeiotic S-phase, followed by loading of the SMC proteins, SMC1β and SMC3, and synaptonemal complex axial element proteins, SYCP2 and SYCP3.[156] REC8 then remains localized to the chromosome arms longer than either SMC1β or SMC3, or the axial element proteins SYCP2 and SYCP3

Vet-ebooks.com

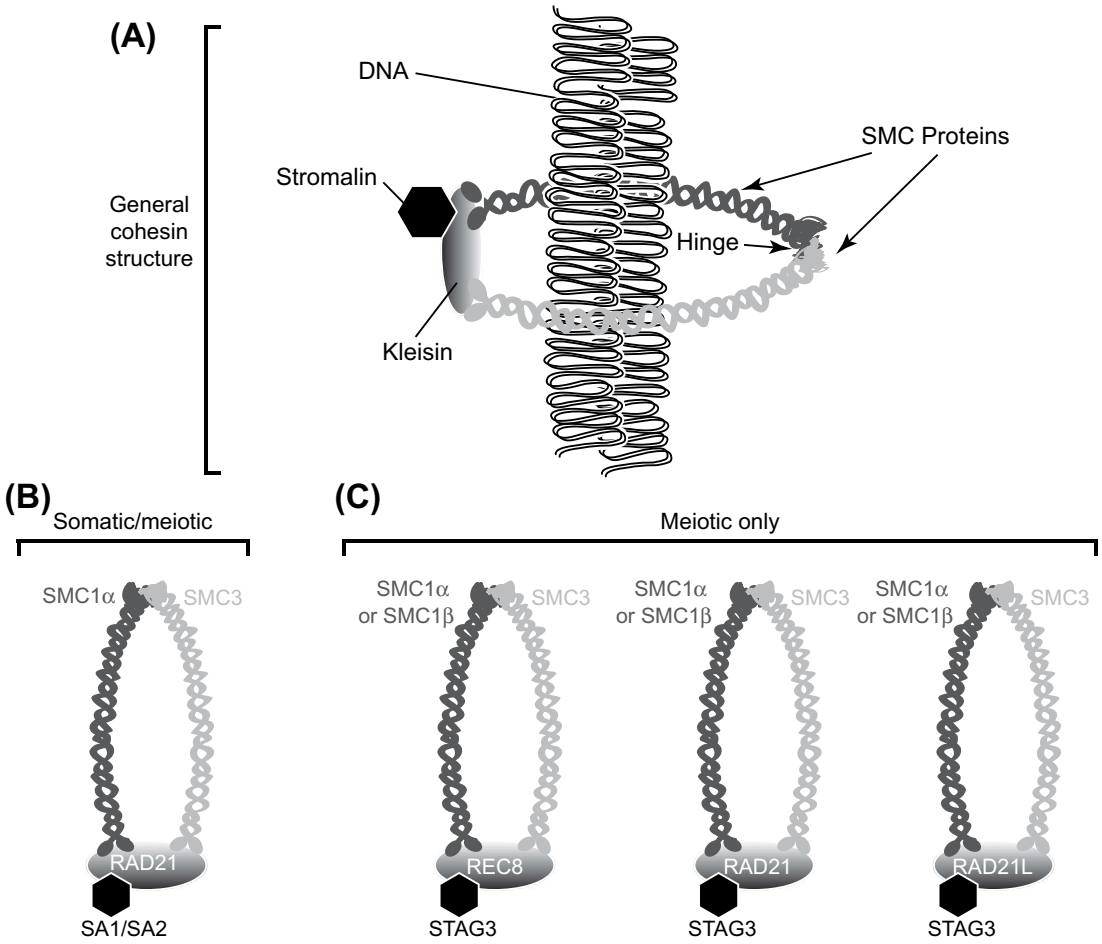

FIGURE 1.9 Cohesin structure in meiosis. (A) General cohesion structure consists of two SMC proteins (gray), which form a hinge around the DNA and are joined by a kleisin and stromalin subunit. (B) Somatic and meiotic cohesin. (C) Meiosis-specific cohesins.

(all of which dissociate from the arms by metaphase I, but remain localized at the centromeres) (Figure 1.7(F)). By anaphase I, REC8 is disassembled from the arms by separase cleavage, but is retained strongly at the centromeres. During meiosis II, all these proteins are disassembled from the centromeres simultaneously at anaphase II.[152,156,157] *Rec8* null mice are male and female infertile, with a complete arrest of spermatogenesis at meiotic prophase I, resulting from a failure to properly synapse. *Rec8* mutants do establish sister chromatid cohesion and accumulate synaptonemal complex proteins such as SYCP3 and SYCP1; however, the "synapsis" that they undergo is usually between sister chromatids, and thus they tend to suffer from precocious separation of sister chromatids, resulting in arrest at pachynema.[158,159]

A second kleisin subunit, RAD21L, also loads onto meiotic chromosomes early in leptonema, co-localizing with axial element proteins,[154,160,161,162] and it remains localized to the synaptonemal complex until pachynema or mid-diplonema, with strong staining on the axes of the X and Y chromosomes in males. Co-staining with REC8 in meiotic cells reveals mutually exclusive staining of these two kleisin complexes, suggesting that REC8 and RAD21L might form distinct cohesin-enriched domains along the axial elements, which consequently would form a unique pattern along the axial elements of chromosomes, resulting in a "barcode" that has been hypothesized to aid in homolog recognition.[154]

The third meiotic kleisin, RAD21, does not follow a localization pattern that is similar to those of REC8 and RAD21L. Instead, it tends to disappear during leptonema and zygonema, before reappearing in pachynema as RAD21L is dissociating from the cores, suggesting that it may be replacing RAD21L (and to some extent REC8, although the timing of REC8 removal from chromosome cores is not certain from data collected in several studies[154,156,157]). By metaphase I, RAD21 has also disassembled from the arms and remains only at the centromeres, similar to other cohesin localization patterns at this stage.[162,163,164] Given this differing localization pattern, it is thought that RAD21 may have a role in stabilizing sister chromatid cohesion at the time of DSB repair (during pachynema[165,166,167]), whereas REC8 and RAD21L may

Vet-ebooks.com

have a more canonical role in sister chromatid cohesion during early prophase I. It appears that REC8 may be the basis for the loading of cohesin complexes at this time, given that REC8 loads onto chromosomes before any other cohesin or synaptonemal complex proteins,[156] and that REC8 remains bound to chromosome arms longer than the other cohesins, therefore being the only means by which cohesion is maintained until anaphase I. *Rad21l* mutant mice exhibit total male sterility, resulting from a lack of synapsis in prophase I and subsequent meiotic arrest at zygonema, reminiscent of the situation in *Rec8* mutants, whereas females exhibit age-related problems with fertility, most likely due to premature depletion of the oocyte pool, as is common with other female meiotic cohesin mutants.[162,168,169]

In mammals, the meiosis-specific stromalin subunit of cohesin, stromalin antigen 3 (STAG3), and the meiotic SMC proteins, SMC1β and SMC3, all localize in early leptonema of prophase I to the axial element in mammalian oocytes,[164,170] until late in prophase I, when they disassemble from the chromosome arms. The disassembly of these cohesins from chromosome arms appears to be dependent on kinases, such as NEK1.[171] STAG3 is removed from the chromosome arms at or around metaphase I,[172] as are SMC3 and SMC1β.[173,174] SMC1β remains localized to centromeres until metaphase II, presumably to retain sister chromatid cohesion until separation of the sister chromatids at meiosis II.[173] *Stag3* mutant rats exhibit sterility, presumably as a result of the pachytene arrest due to loss of STAG3 protein; however, this mutation has not been fully characterized, nor has *Stag3* been knocked out in a mouse model to date.[175] *Smc1β* mutant males exhibit pachytene arrest of spermatocytes due to incomplete synapsis, whereas in the mutant females, oocytes progress to metaphase II. Axial elements in the mutants are shorter, and the chromatin extends further from the core, suggesting that SMC1β is involved in chromatin loop formation and organization.[85,176,177] In addition, in these mutants, CO structures and meiosis-specific telomere adjustments are absent. This, along with other evidence, indicates that SMC1β plays an important role, both in maintenance of telomeres during meiosis and as a chiasma-binding factor that stabilizes CO structures until anaphase I.[85,178] This is important evidence toward providing a link between axial element length and chromatin loop size with cohesin components. STAG2 (similar to mitotic stromalin (stromalin 2, or SA2)) has also been implicated in meiosis, although it is unclear in which complex it functions; it might be functionally associated with RAD21, as the localization patterns remain the same, and may cooperate with STAG3 complexes, although very little is known about its function in meiosis.[179]

Phylogenetic analyses have identified two further proteins belonging to the SMC family,[180] known as SMC5 and SMC6. In mammals, these proteins are highly expressed in the testes, and are associated with the XY chromosomes during prophase I of meiosis.[181] Very little is known about the role of these SMCs in mammalian meiosis; however, they have been implicated in repair processes in human somatic cells[182] and joint molecule resolution in yeast, not all of which are formed as a result of SPO11-dependent DNA breaks (discussed further in this chapter).[183,184] They do not appear to function in the cohesion-like processes for which other family members are best known. Other cohesin proteins have been implicated in meiotic repair pathways in many eukaryotic organisms, such as mouse, *C. elegans*, *D. melanogaster*, and *Arabidopsis thaliana* (mouse,[178] *C. elegans*,[185] *Drosophila*,[186] and *Arabidopsis*[187]), and in somatic repair.[165,188,189]

Meiotic Recombination

Overview of Meiotic Recombination

As described in this chapter, one of the ways in which homologous chromosomes can remain physically paired until the first meiotic division is via DNA:DNA interactions between maternal and paternal genomes. To do this, homologous chromosomes must break and interhomolog DNA connections must form. This process is known as crossing over, or reciprocal recombination, since there is a reciprocal exchange of DNA between maternal and paternal chromosomes (because exactly the same length of DNA must be swapped). Therefore, crossing over is the second fundamental process of prophase I and involves the exchange (or recombination) of genetic information between homologous (maternal and paternal) chromosomes.

In almost all species examined to date, crossing over is initiated by the formation of a DSB in one sister chromatid of one homologous chromosome during leptonema. Thus, while most cells of an organism must actively avoid DNA breaks, meiotic cells undergo genetically programmed breaks that must then be repaired in a specific way that is extremely tightly controlled both temporally and spatially. The formation of a DSB in leptonema and its subsequent repair through prophase I are called homologous recombination, which serves three crucial functions during prophase I. First, the exchange of genetic material between homologs generates diversity within gametes by shuffling the DNA and introducing variation; second, the physical events of recombination allow for homology searching between chromosomes (explained further here); and, third, and arguably most importantly, it creates the physical manifestations of crossing over, the chiasmata, that hold homologous chromosomes together at the metaphase plate during meiosis I, thus reducing the risk of

Vet-ebooks.com

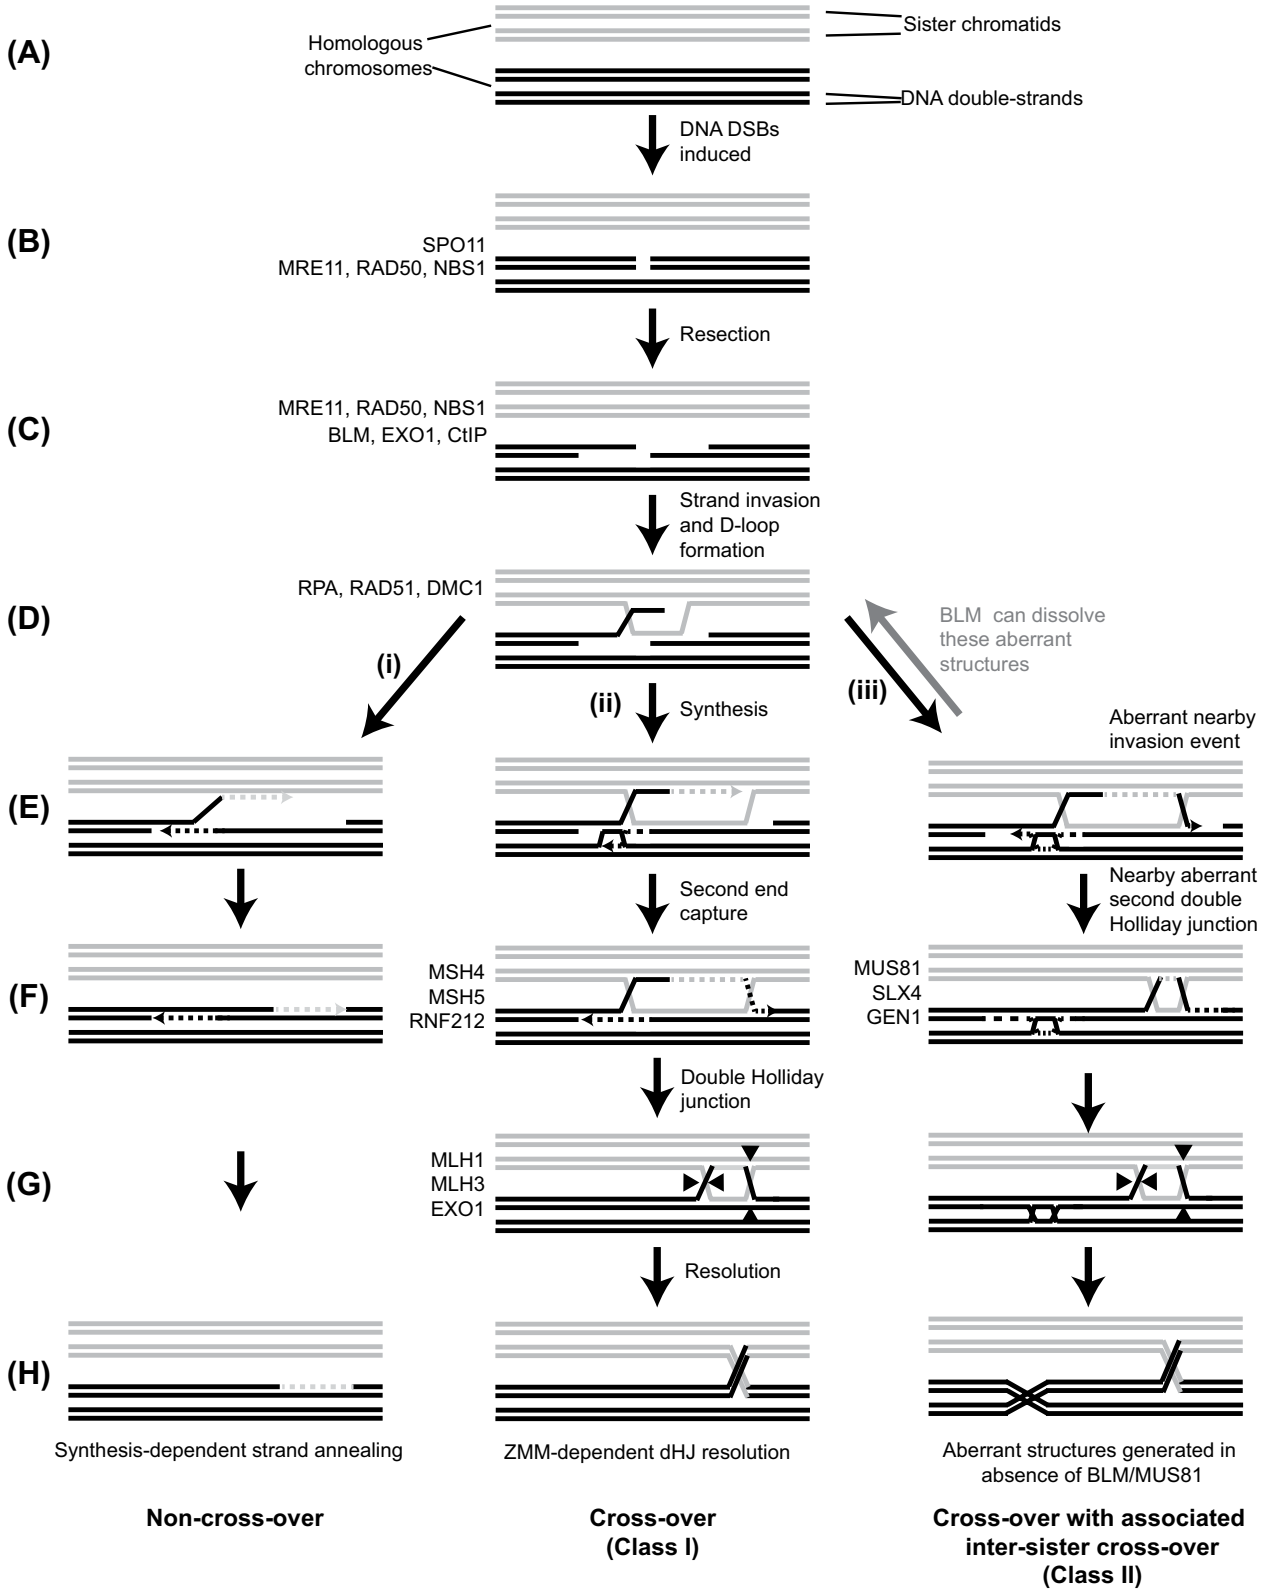

FIGURE 1.10 **Double-strand break repair model in eukaryotes.** A schematic representation of double-strand break repair (DSBR) in eukaryotic meiosis. (A) Homologous chromosomes (gray and black) undergo DSBR during meiotic prophase I. (B) SPO11 and its accessory factors form a DSB in the DNA of one homolog (in this case, the black one), which can then be repaired by one of several pathways: either as a non-crossover (left panel), as a class I crossover (middle panel), or as a class II crossover (right panel). (C) The cut DNA ends are resected back by exonucleases to form free 3′ overhanging strands. (D) These 3′ overhangs (black) may "invade" the opposing homologous partner (gray) to form a D-loop structure. (E) Depending on the method of repair, the D-loop can form several intermediate structures, and the DSB can be repaired in a number of ways. (F–H) Non-crossovers are thought to be repaired by a process known as synthesis-dependent strand annealing (SDSA, left panel, pathway i), during which no classic double

Vet-ebooks.com

aneuploidy in future gametes. This third requirement also demands that CO are placed at defined points throughout the genome, with at least one CO exchange event occurring on each chromosome, and with the placement of one CO limiting the placement of nearby CO events. Thus, as described here, the repair of DSBs is extremely tightly regulated at all stages of recombination.

DSB repair is extremely complex, and it is described in detail in this chapter. Briefly, however, the chromatid that is broken must be processed to allow one end of the break to become invasive. This invading end can then insert into other DNA strands to "test" them for homology (by simple base pairing) and to initiate homolog interactions. Once the appropriate homolog is located, these DSBs must then be repaired, either by forming hybrid DNA molecules with the opposing homologous sequence or by reannealing to the other end of DSB. Multiple DNA repair mechanisms exist for these purposes, many of which are similar between meiotic and mitotic cells, but which have been selectively "repurposed" to allow for the formation of distinct CO structures between homologous chromosomes. It is important to note, therefore, that DSB repair is not confined to meiosis, but also occurs in response to spontaneous (unprogrammed) DSBs that can arise in somatic cells. The molecular events of DSB repair in gametes are reminiscent of those in somatic cells, with a few major differences, as detailed in this chapter. Due to the problematic nature of studying these processes in detail in mammals, most of what is known about the mechanisms of meiotic DSB repair comes from research in yeast; however, due to the highly conserved nature of most meiotic processes, much of this data has been extrapolated to mammals. In fact, many of the fundamental steps of DSB repair involve proteins that are highly conserved across species, from yeast to humans.

Physical Events in Meiotic Recombination

The term "recombination" encompasses a number of DNA modification events that occur during prophase I, all of which are initiated by the induction of a DSB into the DNA, creating a blunt end nick in one sister chromatid of a recently replicated sister chromatid pair. The DSB is processed initially by resection of the two 5′ ends (Figure 1.10(C)), which results in 3′ single-stranded overhangs that are then capable of invading an opposing homolog and, in doing so, displace a stretch of DNA from the opposing homolog, known as the D-loop (Figure 1.10(D)). The D-loop may be repaired by several mechanisms, depending on the nature of the initial strand invasion event, the placement along the chromosome, and other factors. In the case of most CO events, the D-loop becomes further processed to form a structure known as a double Holliday junction (dHJ): (1) DNA synthesis from the end of the invading overhang (having lost a portion of DNA sequence due to the original resection event), using the opposing homolog as a template, stabilizes a "single end invasion" intermediate[190]; (2) subsequent religation of the invading strand with its original 3′ end results in what is termed "second end capture"; and (3) this occurs in tandem with DNA synthesis from the noninvading 3′ overhang, using the displaced D-loop as a template, followed by religation, all resulting in the formation of two stretches of heteroduplex DNA within what now is known as a dHJ (Figure 1.10(E), pathway (ii)).[191] Repair of this structure can give rise to COs, in which a flanking DNA is reciprocally exchanged, or non-crossovers (NCOs). However, for reasons that are not entirely apparent, dHJ repair in meiosis is heavily biased toward the formation of COs (discussed further here).

COs may also form from structures other than dHJs in yeast, but these have yet to be observed in mammals. In addition, it is possible for nearby DSB repair events and/or events that involve multiple-strand invasions from a single DSB to result in recombination intermediate structures involving all four chromatids (Figure 1.10(E)–(H), pathways (iii)). These structures, termed "multichromatid joint molecules" in *S. cerevisiae*, can be repaired in a number of ways, but appear to be rare events that are processed through specialized machinery.

As will be discussed here, the majority of DSBs do not become COs and instead are processed through NCO pathways, giving rise to repair events that do not involve exchange of parental genetic information. Given the bias of dHJ repair in meiosis toward COs, it appears that NCOs are achieved by temporally distinct mechanisms that arise during strand invasion and/or D-loop formation. For example, in *S. cerevisiae*, NCOs are obtained from DSB repair through a process called the synthesis-dependent strand annealing (SDSA) pathway, in which the invading strand is ejected from the D-loop and religates to its own 5′ end with the assistance of DNA synthesis using either the sister chromatid or the opposing homolog as the template, the latter resulting in a gene conversion event (Figure 1.10(E)–(H), pathways (i)).

◀ Holliday junction (dHJ) is formed (F, left panel). Conversely, class I crossovers (middle panel, pathway ii) are thought to be formed by the formation and repair of a dHJ (F, middle panel). Class II crossovers are seemingly more complex (right panel, pathway iii), perhaps being constructed as a result of repairing aberrant joint molecule structures (F,G, right panel) that arise too close to class I crossovers, or as a result of multiple invasion events during DSB repair, resulting in closely spaced crossover products (right panel, H). (F–H) Non-crossovers are thought to be repaired by a process known as synthesis-dependent strand annealing (SDSA; see left panel, pathway (i)), during which no classic double Holliday junction (dHJ) is formed (F, left panel). Conversely, class I crossovers (middle panel, pathway (ii)) are thought to be formed by the formation and repair of a dHJ (F, middle panel). Class II crossovers are seemingly more complex (right panel, pathway (iii)), perhaps being constructed as a result of repairing aberrant joint molecule structures (F, G, right panel) that arise too close to class I crossovers, or as a result of multiple invasion events during DSBR repair, resulting in closely spaced crossover products (right panel, H).

Vet-ebooks.com

An intriguing aspect of meiotic recombination is the fact that many more DSBs are formed than are actually processed into COs. This has prompted the conclusion that recombination serves multiple purposes beyond those that involve reciprocal recombination. In other words, physical tethering of homologous chromosomes through crossing over represents just one function of recombination. Indeed, in mammals, approximately 10-fold more DSBs are created than are processed into COs, with the remaining DSBs being repaired either through intersister chromatid interactions or through NCOs,[192] neither of which contribute to homolog segregation because they do not involve the formation of heteroduplex DNA between the homologous chromosomes. They may, however, contribute to the processes of homology searching and recognition since their repair progression includes initial strand invasion.

Initiation of DSBs

DSBs are introduced in high numbers in leptonema by the topoisomerase SPO11, an enzyme that introduces an asymmetric break in the DNA strand (Figure 1.10(B)). *Spo11* is expressed predominantly in the testes and ovaries of mice, although real-time polymerase chain reaction studies have found expression in certain somatic tissues in humans.[193,194,195,196] SPO11 protein is found in early prophase I, during leptonema, and mice lacking a functional *Spo11* gene show severe defects in prophase I progression. These defects include a complete absence of synapsis and a lack of DSBs, resulting in complete infertility of both male and female mice.[193,194,197,198,199] DSB induction and at least partial prophase I progression can be restored by cisplatin treatment, which induces DNA lesions that are similar to those created by SPO11.[199] Loss of *Spo11* in these mice also affects the downstream expression of several other genes involved in DSB initiation and processing, such as *Hop2*, *Brca2*, *Mnd1*, and *FancG*.[200] Importantly, the synapsis defects in *Spo11* mutant mice, and indeed in many mutants that disrupt DSB repair, demonstrate the requirement for recombination events to ensure homolog recognition and the ensuing pairing events.

In wild-type mice, SPO11 protein is expressed as two separate isoforms as a result of alternate splicing of exon 2, producing an exon 2-skipped isoform, SPO11α, and an exon 2-containing isoform, SPO11β. *Spo11β* is expressed from the onset of prophase I in juvenile male mice, whereas *Spo11α* is expressed from pachynema and is responsible for the unique, temporally distinct COs that form on the XY chromosomes (discussed further in this chapter). Both isoforms are present in female meiosis, although female mice expressing the *Spo11β*-only isoform are fertile, while their male counterparts are sterile, indicating this α isoform does not play a major role in female prophase I progression, which is expected given that its role in male meiosis is restricted to the X and Y chromosomes.[195,196,201,202]

Spo11 does not act alone; in yeast, it is known to require at least nine accessory proteins, both to localize Spo11 appropriately and to facilitate DSB formation (Figure 1.10(B); reviewed in Ref. 203). The catalytic activity of Spo11 comprises a nucleolytic attack of the DNA, resulting in a 5′ phosphotyrosyl bond and a 3′ hydroxyl, and Spo11 protein remains bound to the DNA ends until it is actively removed. It is these Spo11-bound DNA ends, or oligos, that are the basis for recent deep sequencing approaches that have identified Spo11-binding sites in the yeast genome.[204] This cleavage activity requires the MRX complex (MRX: Mre11, Rad50, and Xrs2), which is also known as the MRN complex in mammals (MRE11, RAD50, and NBS1).[205,206,207] The MRX complex works in conjunction with its partner Sae2–Ctp1 (reviewed in Refs 208,209), as well as several other factors such as Mei4, Rec102, Rec104, Rec114, Mer2, and Ski8, a subset of which have been identified in mammals as MEI4 and REC114[210] (and are reviewed in Ref. 203). MEI4 and REC114 have been shown to functionally interact in the mouse, and localize to meiotic chromosomes in early prophase I.[210] *Mei4*$^{-/-}$ mice show defective DSB formation, leading to infertility, indicating a role for these proteins similar to that of their yeast homologs, and of mammalian SPO11, in facilitating DSB formation.[210] A separate gene, *Mei1*, which is not conserved in yeast, has been identified by forward genetic screen to be crucial for DSB formation in mice.[211]

Previously, it was assumed that SPO11-induced DSBs were generated randomly throughout the genome and, while the presence of CO homeostatic mechanisms such as interference (discussed further in this chapter) dispelled this myth, only recently has it been possible to demonstrate the lack of randomness at the nucleotide level through next-generation sequencing methodologies. Recent advances in the mapping of DSB sites, along with techniques such as SPO11-associated oligo mapping (described here) in yeast and mouse, have allowed for a new understanding of how DSBs are targeted to specific genomic locations. Indeed, DSBs appear to be preferentially induced at very specific locations, termed DSB initiation hotspots, where recombination occurs at rates that are many thousandfold higher than the genome average.[196,212,213,214] Both the genomic map gleaned from the positions of single-stranded ends processed after DSB processing, and the more specific map extracted from sequencing Spo11 oligos, align very well (reviewed in Ref. 215). In agreement with many previous studies showing the preference for hotspot locations, the vast majority of Spo11 oligos map to nonrepetitive elements, mainly gene promoters, and GC-rich regions of the genome, both features associated

Vet-ebooks.com

with a more accessible chromatin structure, and where Spo11 can presumably more easily act on the DNA. SPO11-associated oligos have been extracted from mice also, although mapping of these has not yet been performed in detail.[196]

Initial DSB Processing

Following DSB formation, DNA resection takes place to leave single-stranded DNA overhangs. In budding yeast, resection initiation depends upon Sae2 protein and is severely hindered in the absence of Mre11 and Exo1.[216,217,218] Recent studies in yeast have determined that this resection is also bidirectional, with Mre11 first nicking the DNA several hundred bases away from the 5′ terminus of the DSB, and then resection occurring by Mre11 in a 3′ to 5′ direction toward the DSB, while Exo1 mediates 5′ to 3′ resection away from the DSB (Figure 1.10(C)).[217] In mammals, orthologs of these genes, *Mre11*, *CtIP* (the *Sae2* ortholog), and *Exo1*, are all required for meiotic prophase I progression. *Mre11* hypomorphic mice showed high levels of asynapsis of homologous chromosomes, with a different effect on male (increased) and female (decreased) frequency of MLH1 foci (indicative of nascent COs), whereas *Exo1* null mice progress apparently normally until diakinesis, where they lack sufficient chiasmata to progress further. This later phenotype of *Exo1* null mice might be due to a distinct role for EXO1 in promoting CO formation, entirely independent of its putative early prophase I role as an exonuclease, similar to that seen in yeast and other organisms[219,220,221,222] (discussed further here). Other factors, such as yeast Dna2, are required for mitotic DNA resection at sites of repair, but as yet, very little is known about their function in mammalian meiosis.[223]

Following resection, the single-stranded DNA (ssDNA) becomes coated in replication protein A (RPA), which prevents the ssDNA from looping back on itself and forming aberrant secondary structures (reviewed in Ref. 224). In mice, RPA localizes to meiotic chromosome cores, coincident with DSB sites.[225,226] ATM colocalizes with RPA along meiotic chromosomes, indicating a possible functional interaction between the two proteins.[225] The ssDNA then loads the RecA homologs, RAD51 and the meiosis-specific DMC1, both of which physically interact with RPA in human cells and may be loaded onto chromosome cores by the TEX15 protein.[226,227,228,229,230] Together, RAD51 and DMC1 facilitate invasion of an opposing homolog by the ssDNA end, which displaces one strand of the recipient homolog to form the D-loop, while in mitotic cells, RAD51 performs a similar role without the aid of DMC1. Both RAD51 and DMC1 localize at meiotic DSB sites in mammals, at a frequency of around 250 per nucleus in the mouse, beginning by associating with single cores but later lying between homologous cores as synapsis proceeds, a process that may be facilitated by the RAD51 associated protein 1 (RAD51AP1; Figure 1.7(H)). RAD51AP1 enhances the ability of DMC1 to capture the duplex DNA homologous partner and may mediate interactions between DMC1 and RAD51 in meiosis.[227,231,232] *Dmc1* mouse mutant spermatocytes fail to proceed past pachynema and both males and females are completely sterile (Figure 1.11(G)), indicating that DMC1 protein is absolutely required for proper meiotic DSB repair.[233]

Recent data suggest that D-loops coated with human RAD51 in vitro are more easily dissociated by factors such as RAD54 than those coated with DMC1 protein, and thus are more susceptible to repair as NCOs by SDSA (Figure 1.10, pathway (i)), suggesting that DMC1 might localize to D-loops destined to be repaired as COs, while sites designated as NCOs accumulate RAD51.[234] This is supported by recent evidence showing that the joint molecule (JM) function of Rad51 is completely dispensable for CO formation in yeast, while CO formation is entirely dependent on the JM function of Dmc1.[235] It is also known from yeast studies that Dmc1 and Rad51 are loaded using separate protein complexes and pathways, although these may differ from organism to organism, but are loaded in a side-by-side pattern on meiotic chromosomes.[236,237,238] Further evidence from *A. thaliana* suggests that DMC1 and RAD51 have functionally and spatially distinct roles, and each localizes to the opposite side of a DSB.[239] Additionally, Rad51 filaments are thought to be dissociated from D-loops in yeast by Srs2 protein, and indeed, *SRS2* mutants display an increase in COs, suggesting that due to RAD51 nonremoval from the D-loops, more COs are formed in the absence of Srs2.[240,241] In the mouse, RAD51 and DMC1 localize to the nucleus during leptonema, usually in large numbers of 250–300 foci per cell (Figure 1.7(H)),[242] but little is known regarding the preferential binding of these proteins for NCO and CO events, and it has been assumed until recently that the two proteins function in concert.

The serine–threonine kinases, ATM and ATR, master regulators of the ubiquitous DNA damage response, have been shown to play a major role in meiotic prophase in mammals: by localization studies showing they are present on meiotic cores, by mutational analysis showing that ATM is directly required for meiotic progression in mice, and by recent data showing that ATM is responsible for regulating the number of SPO11-induced DSBs in meiosis via a negative-feedback loop, in which DSB formation induces ATM expression and/or activation and ATM, in turn, downregulates SPO11 activity.[243,244,245] Thus, spermatocytes lacking ATM show a 10-fold increase in SPO11-linked oligonucleotides, indicating that ATM regulates the frequency of DSBs. Conversely, mice bearing one mutant allele of *Spo11* (*Spo11*$^{+/-}$) and two mutant alleles of

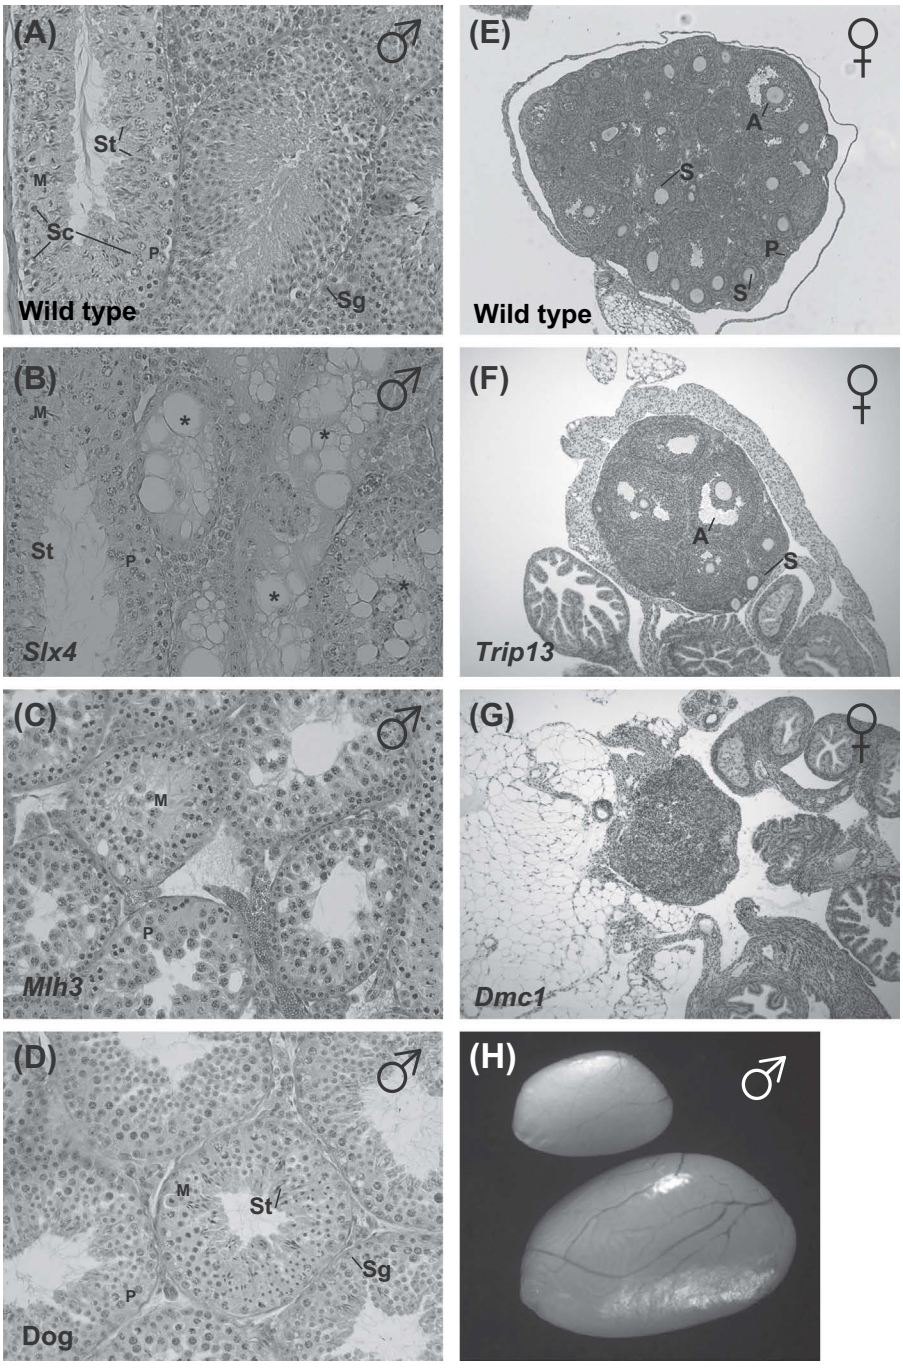

FIGURE 1.11 Phenotypic variation in meiotic mutants. (A–C) Testis sections from (A) wild type, (B) *Slx4* mutants, and (C) *Mlh3* mutants. Wild-type sections show a range of cell types from spermatogonia (Sg), to spermatocytes (Sc) in pachytene (P) and metaphase I (M) stages, to spermatids (St). *Slx4* mutants show these cell types in some tubules, but have other tubules completely devoid of meiotic cells (asterisk), indicative of a premeiotic stage error. *Mlh3* mutants show germ cells in every tubule, but no cells at a later stage than spermatocyte, indicating an arrest at the end of prophase I, due to meiotic errors. (D) Dog testis section shows a very similar morphology to that of the wild-type mice. (E–G) Ovaries from female mice that are (E) wild type, (F) *Trip13* mutant, and (G) *Dmc1* mutant. Wild-type ovaries show a mix of follicle stages, including primary (P), secondary (S), and antral (A). *Trip13* mutants show different stages of follicles, but vastly fewer in number in the whole ovary than wild type, and no primary follicles, indicating a premature loss of the oocyte pool. *Dmc1* mutants show no follicles at all, indicating they never made it past the very initial stages of meiosis before dying. (H) Size difference between testis of a wild-type male mouse and a meiotic mutant littermate (*Nek1* mutant).

Atm (*Atm1*$^{-/-}$) exhibit a less severe meiotic defect than do *Atm*$^{-/-}$ mice, suggesting a complex interdependent feedback loop between the two proteins. It is possible that ATM serves either to directly phosphorylate SPO11, or one of its accessory proteins, at DSB sites to prevent subsequent DSBs from forming in the same vicinity, or to restrict excessive DSB formation across the genome. ATM is functionally active at the sites of DSBs, given that one of its major targets, the histone H2AX, is phosphorylated at DSB sites in many organisms.[197,245,246] ATM–ATR homologs are also responsible for other important phosphorylation events during DNA repair, including phosphorylation of Sae2 in yeast meiotic DSB resection and phosphorylation of Rpa in mitotic yeast cells, and although these interactions might be true also in mammalian systems, little is known about their roles in meiosis.[247,248]

The Bloom's syndrome mutated (BLM) helicase also plays an important role in DSB repair in both meiotic and mitotic cells, and it has a critical role in meiotic progression in mice (as does its yeast homolog, Sgs1). BLM/Sgs1 is thought to act at sites of DSBs, where it localizes to chromosome cores in early prophase I, and also in the latter

Vet-ebooks.com

stages, during which it is thought to play a similar role to that in yeast, that of: untangling aberrant recombination structures, along with MUS81–EME1 (discussed further in this chapter).[249,250,251,252,253,254] Mice with a conditional knockout of BLM helicase in their spermatocytes display errors in meiotic synapsis, as well as in the proper repair of DSB intermediates, resulting in higher levels of unrepaired DSB intermediates at diakinesis and an increase in chiasmata-like structures at metaphase I.[254] BLM has been implicated as a major component of the Class II CO pathway in mice (also discussed further here).

CO versus NCO Fates: The Role of the ZMM Proteins

The decision to become a CO or an NCO following the initial common intermediate steps of DSB repair is regulated by several processes, not least of which is the fact that each and every chromosome must receive at least one CO, and that these COs must be appropriately spaced to prevent aberrant recombination events and/or to reduce the risk of genome instability. Following D-loop formation, DSB repair intermediates may be processed through one of several pathways, resulting in the formation of NCOs or COs (Figure 1.10). Studies in *S. cerevisiae* have revealed that NCO events are resolved much earlier in prophase I than COs, pointing to different resolution pathways for the two recombinant products. Instead, a temporally distinct NCO pathway has been proposed for yeast: the SDSA pathway (Figure 1.10, pathway (i)). In this scenario, failure to capture the second end of the DSB (discussed further here) leads to displacement of the invading strand in the D-loop, and instead the two strands can anneal, resulting in an NCO with minimal gene conversion (Figure 1.10, pathway (i)).[255,256]

Originally, it was thought that processing of DSBs through the dHJ intermediate and the subsequent cutting and resolution of that dHJ via one of two possible orientations could result equally in either COs or NCOs.[257] However, through mechanisms that are not clearly understood, dHJ resolution is extremely biased toward the formation of COs.[258] Members of the so-called ZMM family of proteins are thought to mediate this bias, including in yeast the synaptonemal complex protein Zip3 (along with Zip1, Zip2, and Zip4), the DNA mismatch repair proteins MutS homolog 4 (MSH4) and MSH5, and the adenosine triphosphate (ATP)-dependent helicase Mer3. Mammals and other organisms possess orthologs of the ZMM proteins, including worm ZHP3 and mouse and human RNF212 (orthologs of Zip3); MSH4/5 in mouse, human, and worm; and mouse HFM1 (ortholog of Mer3).[259] The cyclin B interacting protein, HEI10 (or CCNB1IP1), present in mouse and *Arabidopsis*, has recently been added to the list of ZMM proteins.[260,261] These proteins function collectively to ensure that dHJ processing results only in COs, as demonstrated by the fact that COs are significantly reduced or entirely absent in mutants for each of the ZMM genes across eukaryotes (reviewed by Ref. 192).

The DNA Mismatch Repair Pathway Regulates the Major Pathway for Crossing Over

Second end capture results in the formation of a dHJ, which is stabilized by the meiosis-specific MutS homolog heterodimer of MSH4 and MSH5, known as MutSγ. Hydrolysis of ATP through the MutSγ ATPase domains allows the MSH4–MSH5 heterodimers to form a sliding clamp that may displace the complex from the immediate vicinity of the dHJ, facilitating further clamp loading.[262,263,264] In mice, MSH4 and MSH5 proteins localize in distinct foci along chromosome axes during zygonema of prophase I, usually in much higher numbers than the eventual number of COs in the nucleus, at around 150 per nucleus (Figure 1.7(I)). MSH4–MSH5 numbers gradually decline into pachynema, until by the mid-pachytene stage they number approximately 30 per nucleus.[226,265,266] Recent data have suggested that certain MSH4–MSH5 foci are designated from the entire pool of foci as future CO sites, and these sites are stabilized in the mouse spermatocyte by the Zip3 homolog RNF212.[267] In addition, data from *C. elegans* suggest that preselected CO sites are processed by the cyclin-related protein COSA1, which is recruited only to sites of CO. Both MSH4 and MSH5 are critical for proper meiotic progression in the mouse, and the loss of either protein results in the absence of COs and complete sterility in males and females.[265,266] In addition, they load with similar temporal and spatial frequency on synaptonemal complexes from human oocytes, indicating similar functions.[268]

The MutSγ heterodimer recruits a second MMR heterodimer, this time composed of the MutL homologs, MLH1 and MLH3 (MutLγ).[269,270,271,272] Surprisingly, the complex is recruited sequentially in pachynema, MLH3 appearing on prophase I chromosome cores slightly prior to MLH1 in mouse, and localizing to cores even in *Mlh1*$^{-/-}$ mutants, indicating that MLH3 can bind to DNA without MLH1 present.[273] MLH1 then proceeds to co-localize with MLH3 at all but a small subset of foci in mouse spermatocytes, thus marking the position of the Class I COs (Figure 1.7(J)).[273] This Class I pathway is well characterized in lower eukaryotes, such as *S. cerevisiae* and *A. thaliana*, but very little is known about the control mechanisms in mammals.[274,275] Studies of a well-characterized recombination hotspot in the mouse, *Psmb9*, as well as cytogenetic studies in mutants for *Mlh1* and *Mlh3* have indicated that 90–95% of COs depend upon the Class I, MLH1–MLH3-dependent, pathway, while the remaining COs are processed through a Class II pathway that is regulated by the MUS81–EME1 endonuclease (discussed further in this chapter).[273,276,277,278] Additional proteins localize to sites of Class I COs in the

Vet-ebooks.com

mouse, and are crucial for proper progression of meiosis in the mouse. These include the cyclin-dependent kinase CDK2, which co-localizes with MLH1 in spermatocytes, and in which a mutation can cause infertility in the mouse; RAD51C, which localizes to sites of CO in late prophase I, is critical for meiotic progression in mice, and is required for HJ processing in somatic cells; and EXO1, which has been shown to have a crucial late role in CO processing following MLH1–MLH3 accumulation in the mouse, with *Exo1*$^{-/-}$ mice accumulating MLH1–MLH3 normally, but then having very few COs, leading to sterility.[221,279,280,281,282] Class I-processed dHJs are resolved into COs late in prophase I, by as yet unidentified resolvases. Many proteins have been implicated in this role in both mammals and lower eukaryotes, including MUS81, MLH3, EXO1, YEN1, and SLX4; however, no definitive single resolvase has yet been discovered.[283,284]

A Second Class of COs that are Independent of MutLγ

A second class of CO is thought to generate about 10% of COs in mammalian gametogenesis, given that *Mlh1* or *Mlh3* mutant mice have two to three residual chiasmata per cell and retain about 10% of total COs at hotspots.[270,272,276,277] These COs are not regulated by the ZMM proteins, and are instead thought to be dependent on the structure specific endonuclease, MUS81, because in *Mus81* mutant mouse spermatocytes the number of MLH1 foci increases in pachynema; however, the total number of chiasmata at diakinesis remains the same, indicating that the MLH1–MLH3 Class I CO pathway somehow compensates for the loss of MUS81.[278] In yeast, it is thought that Mus81 acts in concert with Sgs1 (the BLM helicase yeast homolog) to disassemble aberrant joint molecule structures that occur as a result of improper stand invasion events during DSB repair.[250,251,252,253] This may be true in mammals also, as mice displaying a testis-specific conditional knockout of *Blm* show an increase in chiasmata-like structures at diakinesis.[254] It might be the case that perhaps many resolvases are present to generate both classes of CO in meiosis, and that they have overlapping and compensatory roles in processing intermediates, which certainly appears to be the case in yeast, where several of these components can be removed and COs still processed.[222,285]

Multistage Regulation of CO Placement and Frequency through Prophase I

It is clear that the frequency and location of DSB induction in mice are tightly controlled. One example of their regulation was presented here, namely, the feedback control on Spo11 activity in both yeast and mouse by the ATM kinase.[245] Recent evidence has shown that DSB position is also tightly controlled, being preferentially initiated at regions that correspond to testis-specific trimethylation of lysine 4 on histone H3.[286] This methylation mark is a result of binding and methyltransferase activity by the zinc finger protein, PRDM9.[287,288,289] PRDM9 is thought to trimethylate histones upon binding to specific recognition sequences of the genome, which in turn attracts SPO11 to these hotspot sites.[286,290] DSBs occurring in *Prdm9* mutant mouse spermatocytes are not preferentially biased toward hotspots, but instead arise at alternative regions of the genome that have H3K4 trimethylation marks, such as gene promoters.[291] The formation of these DSBs is also kinetically slower than that in wild-type mice. PRDM9 is highly specific in its recognition of DNA sequence, and slight changes in the highly variable zinc finger motif render it incapable of binding certain alleles and more likely to bind elsewhere. Indeed, in humans, individuals with differing PRDM9 alleles can use entirely different sets of CO hotspots, raising a key issue known as the hotspot paradox.[292,293] This paradox is borne out of the fact that any PRDM9 allele that is active receives a DSB preferentially, while a nonactive allele does not. Due to the nature of dHJ formation, which by necessity includes repair of heteroduplex DNA, the intact homolog, which is inactive for hotspot activity, is used as a template for repair, effectively inactivating the recombination hotspot at this location through the process of gene conversion. This process, it is hypothesized, could eventually lead to the extinction of this initiating allele from a population, unless mechanisms (yet to be determined) exist to preserve the hotspot activity.[294,295]

Studies in a wide range of mammals have confirmed that PRDM9 is a global regulator of meiotic recombination in mammalian species. Intriguingly, though, PRDM9 is completely absent from dogs and their related species, with all canids showing a significantly different recombination landscape across the genome from that seen in humans and mice. These data indicate that there is an alternative pathway available for generating the recombination landscape across the mammalian genome.[291,296,297]

In yeast and mice, an interesting phenomenon occurs, by which CO frequency is maintained, even in the presence of fewer initiating DSB events, and is termed CO homeostasis.[298] This process ensures that, even in the case of fewer Spo11-induced DSBs, the final tally of COs is maintained, ensuring one CO per chromosome, or obligate CO. CO homeostasis is demonstrated in mice by the fact that number of DSBs induced during early prophase I far exceeds the number of eventual COs that result from repair of these breaks and that, although DSB numbers can change, final CO is exceptionally tightly controlled.[299] For example, an early marker for DSB repair is RAD51. The number of RAD51 foci in early zygonema is 100–500 per nucleus, with an average of around 219 foci per zygotene nucleus. A somewhat later (zygotene–pachytene) marker, MSH4, shows lower

Vet-ebooks.com

focus numbers per nucleus in the mouse, around 100–200, with the difference being accounted for by NCO mechanisms. Finally, the late pachytene marker MLH1 shows many fewer foci, in the region of 20–25,[270,300] again the balance being made up of DSB repair events that are destined toward NCO pathways. Not only does the number of foci for each of these recombination markers decline as prophase I progresses, but the regulation of marker frequency becomes increasingly stringent also, with lower variability in focus frequency, and steadily decreasing coefficients of variation in focus numbers as we proceed from zygonema to pachynema. The final tally of MLH1 foci in late pachynema is extremely conserved, with very, very low variability between nuclei. Even if DSB frequency is varied by changing the dosage of SPO11 protein in mice, the eventual number of MLH1 foci remains surprisingly unchanged, with the variable frequency being that of NCOs, in favor of COs.[300]

Given that this CO assurance ensures a minimum effective DSB rate, what mechanism prevents excessive DSBs from forming? Once DSBs are formed in early prophase I, a third level of regulation is implemented, which is entirely dependent upon ATM kinase. SPO11–oligo complex levels are highly increased in *Atm* mutant mice, and *Atm* mutant cells are very sensitive to variations in SPO11 level, indicating that ATM acts upon DSB initiation to prevent further DSBs from forming, in a negative-feedback loop.[197,245,301]

CO products marked specifically by MLH1–MLH3 are also tightly regulated, in both their frequency and their distribution along chromosomes, in a process known as CO interference.[302] The phenomenon ensures that, once a CO occurs at one point along a chromosome pair, no other COs will take place nearby. If two or more COs occur along homologous chromosomes, they will be spaced far apart, to ensure that the stability of the bivalents is maintained during segregation. The precursors to Class I COs, MSH4–MSH5 foci, are also controlled by interference, indicating this is a step-wise process in mammals.[303] COs that are designated as Class II COs, mediated by MUS81–EME1, are not subject to interference, such that in species that only have the Class II system (e.g., *S. pombe*), interference does not play a role in CO placement.[304] In mice, the loss of *Mus81* results in a compensatory increase in the number of MLH1–MLH3 foci at pachynema, resulting in normal CO rates by diakinesis. Interestingly, these additional MLH1–MLH3 foci reduce the overall level of interference between foci, indicating that the additional foci may not follow interference rules.[278]

COs occurring on the pseudo-autosomal region of the XY chromosomes appear to have a different level of regulation from that of autosomal COs. DSBs occurring on the PAR are formed later than those on the autosomes, specifically by the alpha isoform of SPO11, and the chromatin of the pseudo-autosomal region appears to be packaged differently from the autosomal chromatin, indicating that the initiating DSBs may be under separate control.[201] Further evidence for this comes from the *Prdm9* mutant mouse, in which the DSBs are redistributed from recombination hotspots to promoter regions on the autosomes, but are formed normally on the PAR, indicating a PRDM9-independent mechanism for DSB formation in this region.[291]

Role of Small RNA Pathways in Mammalian Meiosis

A conserved feature of small RNAs is that they must be bound to an Argonaute protein for stability and/or function, with different classes of small RNA binding to distinct classes of Argonautes. The Argonaute protein family is divided into two clades. Those that exhibit greater homology to *Arabidopsis thaliana* AGO1 are the AGO-like proteins and include AGO1–4 in mouse and human (also known as EIF2C1–4), AGO1 and AGO2 in *D. melanogaster*, and Ago1 in *S. pombe*.[305] AGO-like proteins bind both small interfering RNA (siRNA) and micro-RNA (miRNA) species. The second clade of Argonaute proteins constitutes the PIWI-like clade, including proteins related to *D. melanogaster* PIWI, including *D. melanogaster* Aubergine (Aub) and AGO3, and mouse and human MILI, MIWI, and MIWI2.[305] *S. pombe* has no known proteins in the PIWI-like clade. PIWI-like proteins bind another class of small RNAs, known as piRNAs in mammalian systems.

AGO-like Proteins, siRNAs, and miRNAs in Gametogenesis

The AGO-like proteins rose to prominence due to their involvement in RNAi, an evolutionarily conserved mechanism of gene silencing whereby small RNAs are able to target mRNAs for degradation or translational inhibition. RNAi relies on the small RNA-binding capabilities and nuclease activity of an AGO-like protein within the RNA-induced silencing complex (RISC) to "slice" target mRNA. Slicing is achieved via the PIWI domain; however, only a subset of AGO-like proteins has this catalytic activity, despite the presence of the PIWI domain in all AGO-like proteins. The single *S. pombe* AGO1 protein has slicing activity,[306] along with two of the 10 *A. thaliana* AGO-like proteins, AGO1 and AGO4.[307,308,309] Of the four mouse–human AGO-like proteins, only AGO2 has slicing activity, despite the fact that all four mouse AGOs are able to bind small RNAs.[310,311] Recent studies have implicated mammalian AGO3 and AGO4 in regulating meiotic entry and in transcriptional silencing of the sex chromosomes during meiotic prophase I in males (discussed further in this chapter), while *Ago1* has nearly undetectable expression in germ cells.[69]

Vet-ebooks.com

The biogenesis of miRNAs has been extensively reviewed[312,313] and involves transcription by RNA polymerase II to yield primary miRNAs, which are then cropped by the DROSHA–DGCR8 complex to yield shorter precursor miRNAs (pre-miRNAs). Pre-miRNAs consist of 60–70 nucleotide hairpin structures that are exported from the nucleus by exportin 5. Once in the cytoplasm, pre-miRNAs are processed by the RNase III nuclease DICER to remove the hairpin and to leave approximately 22-nucleotide miRNA–miRNA* duplexes. It is thought that the miRNA becomes loaded onto, and thus stabilized by, one of the four AGO proteins, while the miRNA* (or passenger) strand becomes degraded. Endogenous siRNAs (or endo-siRNAs) are produced in a similar fashion, except that they arise in situations where transcripts are able to form double-stranded RNA (dsRNA) or long stem–loop structures. These dsRNA transcripts are exported to the cytoplasm, where they, too, become the target for DICER and are then loaded onto AGO2.[313] Thus, a key distinction between miRNA and siRNA biosynthesis is the dependence (in the former) on DROSHA–DGCR8.

The relative roles of the siRNA and miRNA classes of small RNAs in germ cells have been discerned mostly through loss-of-function and conditional ablation of genes required for the generation and/or stability of these small RNA classes. For example, loss of *Dicer* by conditional deletion in the germline using Cre recombinase-mediated *LoxP* recombination has resulted in different phenotypes, depending on the *Cre* deletion mouse used and the lab from which the data were reported.[314] Since DICER is upstream of both the miRNA and siRNA pathways, it is not surprising that the most severe phenotype reported is that of complete testicular degeneration within days of birth in males, as a result of defects as early as the spermatogonial (premeiotic) stages when DICER is deleted from Sertoli cells.[315,316] *Dicer* deletion specifically in germ cells of male mice, in contrast, results in a variety of phenotypes, depending on the timing of CRE-mediated gene ablation. For example, loss of *Dicer* using a Neurogenin 3–*Cre* (*Ngn3–Cre*) mouse, which deletes around day 5 postpartum, results in slightly increased spermatocyte apoptosis but apparently normal meiotic progression for the majority of spermatocytes.[317,318] By contrast, deletion of *Dicer* during embryogenesis, using a *Ddx4–Cre* mouse, results in a more severe loss of spermatogenic cells and in infertility, resulting from delayed transition into, and through, early prophase I.[318] Two other groups utilized a *Stra8–Cre* strategy to delete *Dicer* prior to meiotic entry, and showed variable effects on meiotic progression, suggesting at least some role for DICER-driven events during prophase I in males.[319,320] Similarly, loss of *Dicer* in female germ cells results in meiosis I arrest and infertility.[321]

Loss of *Dgcr8* or *Drosha*, whose protein products play roles specifically in the miRNA pathway, also results in spermatogenesis defects from the spermatocyte stages onward,[322] while females remain fertile.[323] Loss of *Ago2*, which ablates siRNA function but not miRNA function, has no effect on germ cell proliferation or meiotic progression.[324] Taken together, these studies, while somewhat conflicting, point to a role for at least miRNA populations in meiotic progression. As will be discussed in this chapter, these functions may include regulating meiotic onset and/or transcriptional silencing.

Role of PIWI-Interacting RNAs in Mammalian Meiosis

The piRNAs were named for their exclusive association with Argonaute proteins of the PIWI clade, as opposed to the AGO clade that associates specifically with miRNA and siRNA species. PIWI clade proteins have been identified in a number of species, including *D. melanogaster*, for whose Piwi protein the clade was named. In mammals, three PIWI proteins exist—MILI, MIWI, and MIWI2—and the expression of these genes is restricted to germ cell lineages. Of the three major classes of small RNA found in mammals, piRNAs were discovered most recently and are highly enriched in germ cells. Importantly, while they were originally thought to be specific to germ cells, it now appears that they are found in other cells, including embryonic stem cells.[325] At 26–29 nucleotides in length, the piRNAs are larger in size than other small RNAs, and their biogenesis appears to be very different from that of other classes of noncoding RNA. Their synthesis is not dependent on DICER, and they arise from large genomic piRNA clusters that can exceed 100 kb in length and that encode many piRNAs of overlapping sequence.[326,327] Instead, their biogenesis appears to initiate by the formation of long single-stranded precursors transcribed from the piRNA loci, which are then processed by unknown mechanisms to form pre-piRNAs. These pre-piRNAs then load onto PIWI protein complexes for further processing and, in the case of pre-pachytene piRNAs, may be amplified through a *ping-pong* amplification mechanism, described in detail in Refs 313,327,328,329,330.

In mammals, piRNAs are most abundant during prophase I, but are also observed at high levels in prospermatogonia and, to a lesser extent, in oocytes.[328,331] Indeed, in male germ cells, two distinct populations have been identified: the pre-pachytene piRNA pool, which interacts with MIWI2 and MILI, and which is enriched in repeat-derived sequences,[328] and the pachytene piRNAs, which derive mostly from intergenic sequences and which interact with MILI and MIWI in pachytene spermatocytes and round spermatids.[332,333] Mouse knockouts for *Mili* and *Miwi2* result in spermatogonial stem cell loss, consistent with their interaction

Vet-ebooks.com

with pre-pachytene piRNA populations. Conversely, deletion of *Miwi* in the mouse results in meiotic disruption, but spermatogenic failure does not occur until the round spermatid stage.[332,334,335,336,337,338]

The major function of pre-pachytene piRNAs, and their associated PIWI proteins, is to silence retrotransposons, through both transcriptional (epigenetic) and posttranscriptional (mRNA) activities.[335,339] This activity is distinct from the DNA methylation mechanism in which de novo methylation of retrotransposons occurs via the action of DNMT3L during fetal life.[340] Prior to meiotic entry, MILI and MIWI2 act to facilitate this de novo methylation such that the phenotype of *Mili* and *Miwi2* mutants mimics that of *Dnmt3l* loss, and MIWI2 appears to play a direct role in facilitating this methylation event.[327,337] Prior to prophase I, MILI may also act to cleave transposon mRNAs through its slicer activity.[327] MIWI, in contrast, appears to function exclusively during prophase I, associating with regulatory proteins that include the RNA-binding protein, mouse vasa homolog (MVH–DDX4), the ortholog of *Drosophila* Maelstrom (MAEL), and various Tudor domain-containing proteins, TDRD1, TDRD6, and TDRD7.[341,342,343,344] All of these proteins reside in the perinuclear diffuse structure known as the *Nuage* (meanining "cloud"), which is rich in RNAs and associated proteins. The mechanisms by which MIWI acts during pachynema remain unclear, but it appears to affect both mRNA stability and translational activity.[327] Part of the difficulty in understanding the role of MIWI during prophase I has been due to the fact that loss of *Miwi* (or any of the nuage proteins) does not deplete all the pachytene piRNAs in mouse spermatocytes, since MILI-associated piRNAs persist. Instead, conditional deletion of *Mov10l1*, a putative RNA helicase, during prophase I appears to selectively remove all pachytene piRNAs, and these mice exhibit massive DNA damage in postmeiotic round spermatids. These data indicate that pachytene piRNAs are required for maintaining genomic integrity postmeiotically, but that this function is not associated with any effects on retrotransposon repression.[345]

Meiotic Silencing

Meiotic silencing is the process by which unsynapsed chromatin is transcriptionally repressed during prophase I, and has been described in many organisms, including mouse, nematodes, fungi, and birds.[346,347,348] In the animal kingdom, meiotic silencing most commonly occurs in the heterogametic sex as a means of silencing the largely asynapsed sex chromosomes. This process has been termed meiotic sex chromosome inactivation (MSCI), and it is absolutely crucial for normal prophase I, since mouse mutants that fail to silence their sex chromosomes display meiotic arrest.[348,349,350,351] MSCI is just one example of a larger silencing mechanism called *meiotic silencing of unpaired chromatin* (MSUC), which can be directed at any region of the genome that fails to undergo synapsis (asynapsed). Thus, MSUC itself can be considered a pathological response to aberrant asynapsis, and usually results in apoptotic cell death, whereas MSCI is a normal feature of meiotic prophase I in male mammals and meiosis cannot proceed without it.

The purpose of meiotic silencing is not entirely proven, but it is thought to represent an ancient mechanism for suppressing heterologous chromatin as a means to protect the host genome from exogenous DNA, such as retrotransposons.[352,353] Alternatively, or in addition, meiotic silencing may serve to limit transcription from regions of damaged DNA,[354] or may prevent the expression of sex-linked genes that would otherwise be lethal to the process of prophase I (discussed further here). The existence of non-sex-chromosome-associated silencing mechanisms would argue against this latter option, however.

Meiotic Sex Chromosome Inactivation

During pachynema in mammalian spermatocytes, the X and Y chromosomes become sequestered into a defined heterochromatin-rich subdomain of the nucleus called the *sex body*. This domain is enriched in specialized histones,[246,355] proteins that mediate DNA damage responses through phosphorylation cascades,[348,356] and RNA.[69,357] Together, these mediate both sex body formation and silencing itself through mechanisms that are only slowly becoming elucidated. Histone marks associated with MSCI include H3K9me2,[358] ubiquitylated H2A,[352] and the phosphorylated histone variant of H2AX, γH2AX.[359] The importance of this latter modification is highlighted by the fact that mice lacking the critical phosphorylation site on H2AX fail to establish a sex body and cannot undergo prophase I, leading to infertility.[246,360] Interestingly, XO female mice, who possess only a single univalent X chromosome, also show sex body formation in a proportion of oocytes as a result of the failure to pair their single X.[351,352] As a result, these cells die because of silencing of essential X-linked genes without the presence of autosomal "backups". A proportion of cells exhibit self-synapsis of the X chromosome, which loops back on itself in a hairpin configuration, thereby protecting itself from the MSCI machinery and allowing the cells to proceed through meiosis.[348,351]

BRCA1 is an early marker of the sex body,[361] and this protein recruits ataxia telangiectasia and Rad-3 related (ATR) protein and its activator, TOPBP1.[197,356,362,363] These proteins assemble on the unsynapsed sex chromosomes in early pachynema, and they spread throughout the sex chromatin as pachynema progresses. This process of spreading is co-incident with ATR-mediated phosphorylation of H2AX, to become γH2AX, and

Vet-ebooks.com

this mark becomes a defining feature of the sex body at pachynema.[246] Furthermore, the spreading of the BRCA1, ATR, and TOPBP1 signal throughout the chromatin may be mediated by MDC1, a binding partner of γH2AX, although their initial loading is not dependent on MDC1.[364] Importantly, the genesis of γH2AX at the sex body is temporally and functionally distinct from that of γH2AX found at sites of DSBs from leptonema to pachynema. Instead, it is likely that other kinases, perhaps ATM or DNA–PK,[365] are responsible for phosphorylation of H2AX and sites of SPO11-induced breaks.

The outcome of γH2AX appearance in the sex body is the condensation of the sex chromatin, and the exclusion of RNA polymerase II from the sex body, leading to transcriptional repression. The loss of expression from the X and Y is compensated for, in certain essential cases, by the expression of autosomal paralogs that are specifically active during male meiosis.[346] However, several sex-linked genes are known to be "toxic" during prophase I, and thus their expression must be repressed. These include the *Zfy1* and *Zfy2* paralogs, whose ectopic expression on the nonsilenced autosomes is sufficient to induce mid-pachytene apoptosis in transgenic animals.[366,367]

Analyses of meiotic mutants for genes involved in synapsis and/or DSB repair have indicated that the loss of these pathways also affects sex body formation and MSCI. Thus, spermatocytes with defective synaptonemal complexes or those that fail to properly repair their DSBs exhibit aberrant sex body formation, including those from homozygous mutant males for *Msh5*, *H2ax*, and *Sycp1*.[128,368] The loss of spermatocytes in these mutant animals occurs at mid-pachynema, when sex body silencing should be fully engaged, and is associated with increased expression of genes from the X and Y chromosomes.[368] However, it was unclear until recently whether loss of cells from these mutants was the consequence of checkpoint activation, due to persistent unrepaired breaks, or due to impaired MSCI. Royo et al. showed that in XYY males, in which single YY bivalents prevent transcriptional repression of Y-linked genes without any effects on DSB repair, the mid-pachytene loss was similar to that seen in DSB repair and synapsis mutants. Thus, it is likely that the loss of spermatocytes from many DSB repair mutant mice reflects improper Y-linked gene expression, and may account for the increased severity of the male meiotic phenotype compared to that of the female mutants for these genes.[350,368]

Meiotic Silencing of Unpaired Chromatin

As stated in this chapter, autosomes can also display meiotic silencing under certain conditions, and this is most clearly displayed in some of the mouse mutants for DSB repair and synapsis (some of which are listed here). This has led researchers to think more carefully about the links between synapsis, recombination, and the various silencing mechanisms. As described here, some of these meiotic mutants display synapsis defects that lead to normal MSUC, an example of this being *Spo11* homozygous mutant animals.[368] However, these mice exhibit disrupted MSCI.[198] Other mouse mutants, however, show aberrant MSUC as well as disrupted MSCI, and these include mice lacking *Msh5*, *Dmc1*, and *Sycp1*.[368] The interesting observation came with *Dmnt3l* homozygous mutant males, however, in which spermatocytes display increasing levels of asynapsis, and this is associated with a progressive decline in the efficacy of MSUC.[368] Importantly, the levels of MSUC-inducing BRCA1 associated with autosomal regions of asynapsis appear to be restricted such that it did not increase with the increasing severity of asynapsis in the *Dmnt3l* mutant spermatocytes, thus providing an explanation for failed MSUC. In addition, this BRCA1 relocation to the autosomes also results in reduced sex body-associated BRCA1, resulting in failed MSCI. Since BRCA1 initially localizes to DSB sites, this restricted pool of BRCA1 might also be sequestered at persistent DSBs in the face of impaired DSB repair pathways, perhaps providing an explanation for the impaired MSUC in DSB repair mutants (*Msh5*, *Dmc1*, etc.) but not in DSB-devoid mutants (*Spo11*).

Taken together, these different mouse mutants displaying extensive asynapsis with or without persistent unrepaired DSBs show differing MSUC responses, but all fail to silence their sex chromosomes.[368] This would suggest that the presence of asynapsed autosomes reduces the overall load of BRCA1 in the vicinity of the sex body, in turn reducing the recruitment of ATR. The amount of BRCA1 in females also appears to be somewhat limiting, since mouse oocytes bearing more than two or three asynapsed chromosomes fail to recruit enough BRCA1 to activate MSUC, whereas those with three or fewer asynapsed chromosomes possess enough BRCA1 to initiate silencing at each chromosome.[369]

One caveat to this model is the fact that some spermatocytes from *Brca1* mutant mice can evade meiotic arrest and might suggest an alternative mechanism for recruiting ATR. The obvious candidate for this alternative pathway is the 9-1-1 complex of RAD9, HUS1, and RAD1, which has been shown to accumulate in the sex body at pachynema,[354,370,491] and which is upstream of ATR in the somatic cell DNA damage repair pathway. Whether ATR is recruited to DSBs and the sex body by the same mediators is also the subject of debate at the current time.

Small RNA Participation in Meiotic Silencing

The involvement of small RNAs in meiotic silencing was first alluded to in *Neurospora crassa*, where the associated process of MSUD was first shown to involve Sad1, an RNA-directed RNA polymerase.[371] In

Vet-ebooks.com

mammals, recent studies have demonstrated that the small RNA–associated Argonaute protein AGO4 is localized to the sex body during pachynema and to regions of induced asynapsis (e.g., in translocation mutant mice) during prophase I.[69,372] This is an exciting finding because mammalian Argonautes commonly perform their small RNA functions exclusively in the cytoplasm and are not known to reside in the nucleus of somatic cells, unlike the situation in worms and other organisms where nuclear Argonaute complexes have been functionally characterized.[312,373] In mouse spermatocytes, however, AGO4 and, to a lesser extent, AGO3 both reside in the sex body, and are associated with many miRNAs that originate from both the sex chromosomes and the autosomes.[69] Loss of *Ago4* results in altered sex body morphology and failure to silence many genes on the X and Y chromosomes, including *Zfy1* and *Zfy2*, whose expression is toxic to the cells. However, AGO3 can partially compensate for loss of AGO4 such that *Ago4* mutant mice are only subfertile. Importantly, loss of *Ago4* results in dramatic downregulation of miRNAs from pachytene spermatocytes, over half of which originate from the sex chromosomes.[69] This is counterintuitive to the finding that RNA polymerase II access to the sex body is upregulated in these animals, but fits well with other studies demonstrating that specific sex-linked small RNAs evade the normal silencing mechanism that is characteristic of the sex chromatin during pachynema.[374] Moreover, these data fit with those from *Dicer* conditional knockout mice showing that deletion of *Dicer* (which is required for miRNA and siRNA pathways upstream of AGOs) results in failed MSCI.[320] Taken together, these observations suggest that small RNAs, and their associated AGO proteins, play essential roles in mediating the silencing of unpaired chromatin during meiotic prophase I in mammals in a mechanism that may resemble the process of RNA-induced transcriptional silencing found in *S. pombe*.[375,376] How these RNA-driven processes interface with the known molecular pathway that induces meiotic silencing is unclear at the present time, and is the subject of intense investigation.

Checkpoint Control of Synapsis and Recombination

There are many processes active during meiosis that ensure that the correct number of gametes arises and that defective gametes are eliminated from the population. Without these safeguards in place, defective gametes may well be utilized for reproduction, resulting in the inheritance of mutations in the subsequent generation. In prophase I, there are two important surveillance mechanisms, or checkpoints, that monitor the developing gamete for any abnormalities, namely, the synapsis checkpoint and the recombination checkpoint. These two checkpoints monitor nuclear events, ensuring that complete synapsis between homologs and effective repair of DSB intermediates, respectively, have been completed before the cell can progress beyond prophase I. So, for example, spermatocytes lacking *Spo11*, which fail to undergo complete synapsis of their chromosomes but which have no DSBs and no recombination defects, succumb to the synapsis checkpoint,[198,199] while mutation of mouse *Trip13*, the ortholog of yeast pachytene checkpoint 2 (PCH2), results in loss of prophase I cells at pachynema without affecting synapsis but instead resulting in recombination failure at a subset of DSB events.[377] The apoptosis of cells at the pachytene checkpoint in *Trip13* mutants is thus intact, despite normal synapsis (the opposite situation to that seen for *Spo11* mutant mice), providing evidence that failed recombination alone can trigger this checkpoint.

Other mutants that affect DSB repair (e.g., *Msh4*, *Msh5*, and *Dmc1* mutants) also succumb to the recombination checkpoint.[349,378] However, given that defects in DSB repair often result in synapsis failure too, it is often difficult to separate the two checkpoints from each other, and thus, they are collectively termed the pachytene checkpoint. Importantly, most of these mutants also exhibit failures in MSCI, while failure to induce MSCI itself results in activation of the pachytene checkpoint, leading to the proposal that failed MSCI may comprise a major mechanism for checkpoint induction in mammalian meiosis.[349]

In males, this checkpoint is extremely stringent and serves to eliminate defective cells at pachynema via the process of apoptosis. Indeed, even in wild-type male mice, there is an abundance of apoptotic cells present in the testes, indicating that the checkpoint is highly efficient in wild-type male mice.[379] In females, the checkpoint appears to be much less rigid, such that gametes bearing synapsis and recombination defects may progress beyond pachynema. Oocytes with more minor abnormalities can also progress to the end of meiosis, perhaps maintaining these errors from prophase I in the form of aneuploidies in the resulting gamete.[380] This sexual dimorphism is largely poorly understood in mammals; however, the general thinking is that because males make millions of sperm throughout their lifetime, whereas females only make oocytes once prior to birth, the amount of effort invested by the female organism in generating the gamete is such that they simply "make do" and repair their defects as best they can, whereas males eliminate these defective cells entirely.

It is important to note that defects later in prophase I, after synapsis and recombination are largely completed, may also result in apoptosis, but that this checkpoint may not occur until metaphase I in males, and even later in females. One example of this is *Mlh1*-deficient mice. *Mlh1* mutant males exhibit almost complete loss of chiasmata in diakinesis, with cells undergoing apoptosis

Vet-ebooks.com

around the time of metaphase.[270] *Mlh1* mutant oocytes progress somewhat further, however, with a proportion of them extruding a first polar body, albeit at low rates and with highly likelihood of nondisjunction.[381,382] Similar results are observed in *Mlh3* mutants,[272] and in both cases are associated with poor bipolar attachment on the first meiotic spindle and subsequent defects in spindle morphology. These data suggest that later prophase I defects evade the pachytene checkpoint, but instead are identified by a second checkpoint upon attachment to the meiotic spindle.

CHROMOSOME SEGREGATION AT METAPHASE I (MI) AND MEIOTIC PROGRESSION

A fundamental and defining feature of the mitotic and meiotic divisions is the ability to sequentially and equally segregate genetic material to opposite poles and thus to produce daughter cells that contain the same amount of genetic material through two rounds of division, one equational and one reductional (Figure 1.1). During mitosis or during the second meiotic division, this segregation involves sister chromatids that are, by necessity, held together by cohesion (discussed further here) until they become captured by microtubules emanating from each mitotic spindle pole (Figure 1.12). Sister chromatid cohesion is an essential prerequisite for their attachment to microtubules emanating from opposite poles, a configuration known as amphitelic attachment (or bi-orientation; Figure 1.13), which, in turn, ensures the equal segregation of sister chromatids at anaphase. By contrast, during the first meiotic division, segregation separates the homologous chromosomes, each of which consists of paired sister chromatids (Figure 1.1). The role of prophase I events is to maintain homologous chromosome interactions up until the time of segregation. Thus, by the end of prophase I and into metaphase I, chiasmata-intact chromosomes align along the midplate of the cell and initiate the first meiotic division. This process is tightly regulated to ensure that homologous chromosome pairs align appropriately along the midplate in the correct bi-orientation to facilitate segregation of homologs to opposite poles of the cell, while sister chromatids remain mono-oriented (unlike during mitosis), or in syntelic attachment, to ensure that they move toward the same pole (Figure 1.13). Thus, a fundamental distinction between the two meiotic divisions is the syntelic versus amphitelic attachment behavior of the sister chromatids.

In order for these events to occur normally, chromosomes must engage a functional bipolar spindle and must also stabilize the spindle to ensure appropriate tension with which to facilitate equal segregation. Destabilization of the spindle can result in loss of tension, which will increase the potential for one or more chromosomes to fail in their attempts to move to the appropriate pole. One of the key processes that prevents catastrophe at this critical time is the spindle assembly checkpoint (SAC), a system that detects imbalances in the meiotic spindle (caused by loss of tension and/or unstable chromosome connections) and induces metaphase arrest until the problem is resolved. Many of the components of the SAC are preserved between mitosis and meiosis; however, by necessity, their functions extend in meiosis to ensure that homologous chromosomes, rather than sister chromosomes, become stably bi-oriented and attach to the spindle.

Our ability to study meiotic spindle assembly and checkpoint control has been limited largely to studies in oocytes, since disruption of spindle structures in male gametes using microtubule-destabilizing drugs results in early prophase I defects and arrest, precluding analysis of metaphase I and beyond.[383,384] Thus, much of what will be discussed in this section will focus on studies performed in lower eukaryotes and in females, with extrapolation where possible to analogous events in males. The relative difficulties in monitoring spindle assembly and progression in males are just the tip of the iceberg when it comes to differences in meiotic progression between the sexes. Indeed, female meiosis imposes several complexities on the process of spindle assembly and stability, not least of which is the long length of time during which the chromosome chiasmata must persist from their establishment in utero during prophase I to their critical role on the meiosis I spindle following meiotic resumption in the adult. Indeed, the entire spindle stability rests on the integrity and robustness of the chiasmata, the *raison d'être* for prophase I events in the first place. The importance of proper chromosome segregation during meiosis cannot be overstated, since chromosome mis-segregation during the first meiotic division can result in the generation of gametes containing the wrong number of chromosomes, a condition known as aneuploidy. Aneuploidy most commonly arises due to mis-segregation of homologous chromosomes, referred to as nondisjunction, but also can arise during the second meiotic division. As will be discussed in this section, nondisjunction is particularly prevalent in humans and, more specifically, in females.

The Spindle Assembly Checkpoint

The SAC is conserved between mitosis and meiosis, and is essential for monitoring the accurate segregation of genetic material, thereby signaling to the cell cycle machinery to continue the cell cycle or to arrest the cell in metaphase. This system acts at the level of the spindle to ensure that all chromosomes are attached to microtubules emanating from the appropriate pole, and to

Vet-ebooks.com

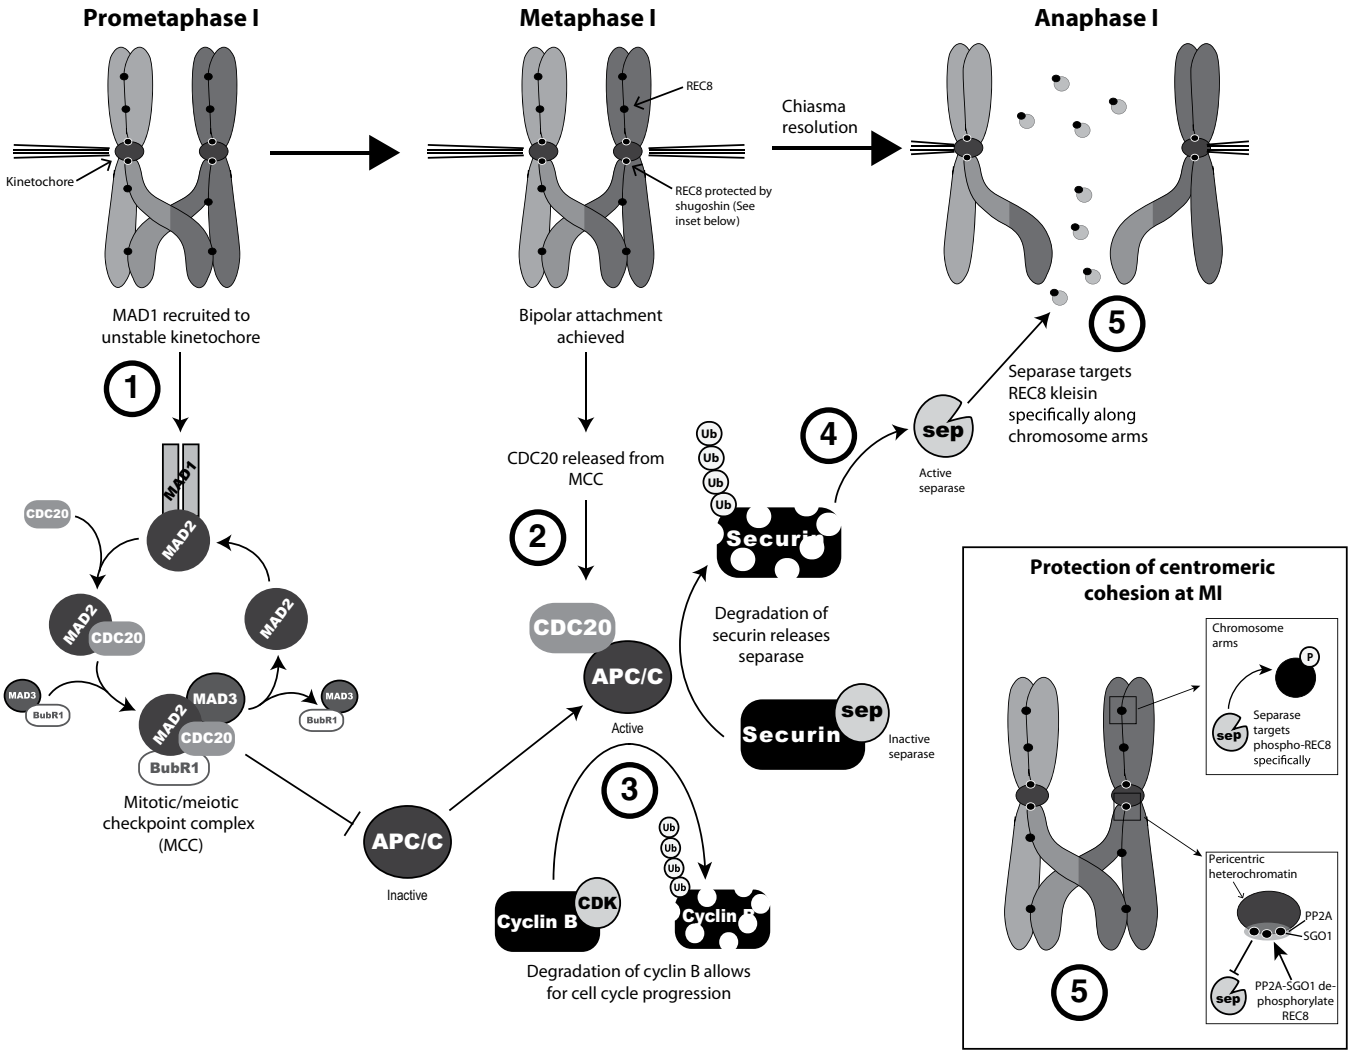

FIGURE 1.12 **Summary of events at the metaphase-to-anaphase transition in mammalian meiosis.** Step 1: Spindle assembly checkpoint (SAC) components are recruited to unstable kinetochores through the initial association of MAD1 and the subsequent recruitment of the mitotic–meiotic checkpoint complex (MCC). This inhibits APC/C activation. Step 2: If and when bipolar attachment is achieved, the MCC is destabilized, releasing CDC20, which can then bind to, and activate, APC/C. Step 3: APC/C can then ubiquitylate cyclin B–CDK complexes, resulting in their destruction, which facilitates cell cycle progression. Step 4: At the same time, APC/C ubiquitylates securin, releasing separase, which can then mediate phospho-REC8 destruction along chromosome arms, a process that is essential for disjunction of homologous chromosomes. Step 5 (inset panel): Importantly, SGO1 together with PP2A dephosphorylate REC8 at the centromere, which prevents separase-mediated destruction of REC8 at this location and thus preserves sister chromatid cohesion.

monitor tension within the spindle. Once all of these processes are in place, the SAC is silenced, and the anaphase-promoting complex/centrosome (APC/C) is activated, resulting in chromosome or chromatid movement to opposite poles and anaphase entry.

The SAC was discovered through a series of genetic screens in budding yeast that led to the identification of the key components of the checkpoint: the mitotic arrest deficient proteins, including Mad1, Mad2, and Mad3 (BUBR1 in vertebrates); and the budding uninhibited by benzimidazole proteins, Bub1 and Bub3, along with Mps1.[385,386,387,388,389,390,391] Classic laser ablation studies demonstrated that unattached kinetochores generate an inhibitory signal that delays anaphase onset, while destruction of the centromere (including both associated sister kinetochores) results in release of the checkpoint and anaphase progression. These studies indicated that activities in the vicinity of the kinetochore are responsible for monitoring mono-orientation and kinetochore attachment and for facilitating metaphase-to-anaphase progression.[392,393] Accordingly, most SAC components were later localized to the kinetochore,[387] and were found to be highly conserved in vertebrates.[394,395,396,397,398,399]

BUB1 is a protein kinase that localizes to kinetochores, senses microtubule attachment and stability, and may be involved in regulation of cyclin B (Figure 1.12, step 1). Similarly, MAD1 is recruited specifically to unattached, mono-oriented

Vet-ebooks.com

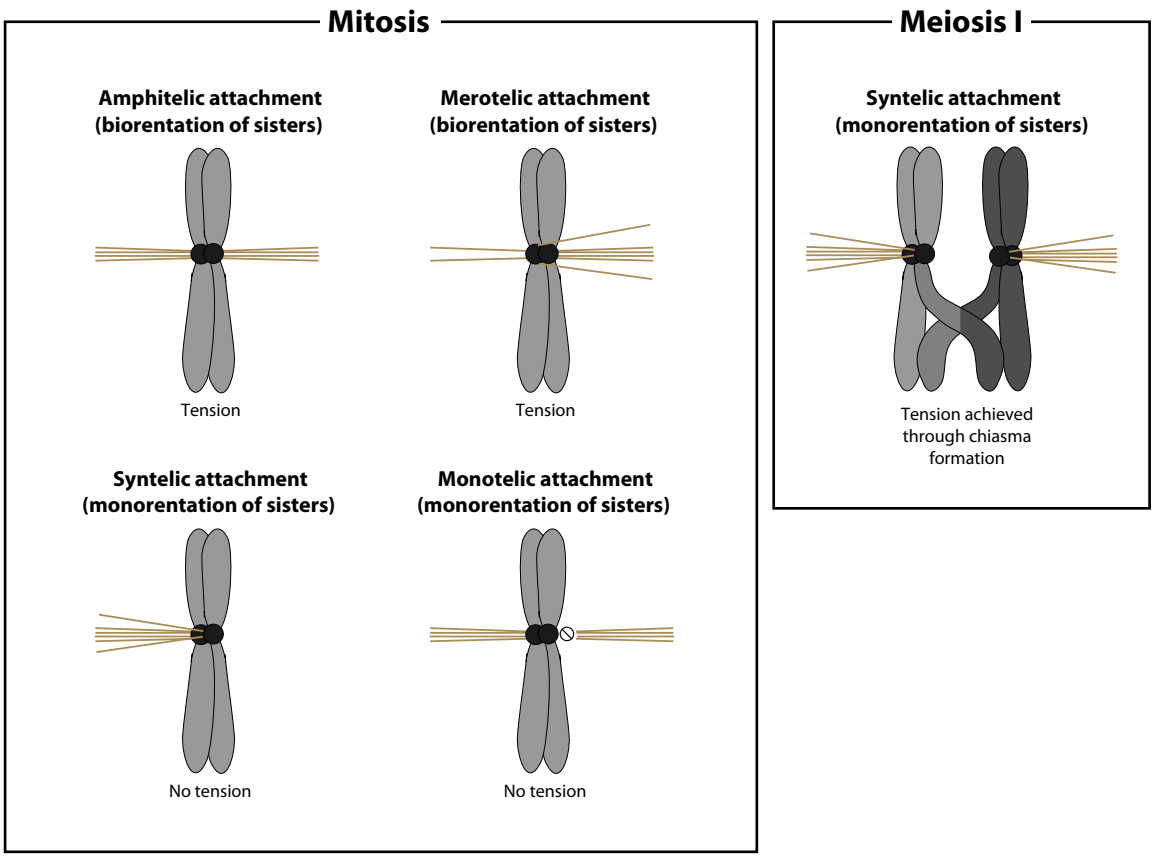

FIGURE 1.13 Sister chromatid interactions with spindle microtubules during mitosis and meiosis. During mitosis, sister chromatid kinetochores must attach to microtubules in bi-orientation to ensure tension across the spindle and, thus, equal segregation at metaphase. This attachment is referred to as amphitelic. However, bi-orientation can be achieved through merotelic attachment, although these interactions can be somewhat less stable. Mono-oriented attachment (such as those shown in the left-hand box) result in loss of spindle tension. During meiosis I (right-hand box), sister kinetochores must be mono-oriented toward the same pole, resulting in syntelic attachment. Tension across the metaphase I spindle is achieved through stable chiasmata formation.

kinetochores, and recruits with it MAD2. The localization of MAD1–MAD2 complexes at centromeres is at least indirectly dependent on MPS1.[400,401,402,403] MAD2 is capable of heterodimerizing and thereby recruits free MAD2 from the cytosol.[387] Upon spindle damage in mitotic cells or in the presence of unattached kinetochores, BUB1 phosphorylates MAD1, leading to the dissociation of MAD1–MAD2 complexes from the kinetochore. This dissociation allows MAD2 to sequester CDC20, an activator of APC/C. The formation of complexes of MAD2 and CDC20, together with BUBR1 and BUB3 (collectively known as the mitotic–meiotic checkpoint complex, or MCC; Figure 1.12, step 1),[387] prevents activation of APC/C and thus prevents the ability of the latter to invoke anaphase progression. Loss of this SAC mechanism in mammalian cells causes premature sister chromatid disjunction, leading to mis-segregation of chromosomes and cell death.[393,404,405]

During meiosis, the SAC acts at both metaphase I and II, and the functional components of the SAC appear to be conserved through both divisions.[403] During meiosis I, however, bi-orientation of sister kinetochores is prevented and instead the tension necessary to ensure stable microtubule attachment is provided by the chiasmata, which maintain homolog interactions (Figure 1.13). Moreover, during meiosis in the mouse, the preferred activator of the APC/C is CDH1, rather than CDC20, which is utilized during mitosis (Figure 1.12, step 2).[406] Studies of XO mice have demonstrated that, despite the absence of a pairing partner for the single X chromosome, failure to pair a single chromosome in oocytes does not result in meiotic failure, although the females exhibit somewhat reduced fertility. This has led to suggestions that the SAC is absent in vertebrate oocytes.[407,408] This does not appear to be the case, however, since overexpression of dominant negative forms of *Bub1* in mouse oocytes results in accelerated completion of MI and polar body extrusion (PBE).[409] Moreover, conditional mutant mice that do not express *Bub1* specifically in their oocytes display massive chromosome mis-segregation at meiosis I, precocious loss of cohesion between sister chromatids, and premature resolution of chiasmata and PBE.[410] These accelerated events

Vet-ebooks.com

are the result of early activation of APC/C.[410] BUB1 appears to have additional roles within the context of the meiosis I metaphase-to-anaphase transition, namely, it is required for congression of bivalents onto the metaphase I spindle, and to prevent premature destruction of sister–centromere cohesion (discussed further here). Interestingly, loss of one allele of *Bub1* in oocytes causes similar meiotic defects to homozygous deletion at this locus, whereas loss of a single copy of *Bub1* in spermatocytes has no such effect,[411] perhaps due to the existence of alternative testis-specific *Bub1* transcripts.[412]

In line with the differences in sister chromatid orientation during the first meiotic division, MAD2 localization during meiosis I in mouse spermatocytes differs from that seen during mitosis. MAD2 is present at most, if not all, kinetochores from prometaphase of the first meiotic division, and remains associated with the kinetochore throughout MI. It does not dissociate during metaphase and anaphase, as is the case for mitosis. Thus, progression to anaphase at the first meiotic division is not dependent on loss of the SAC complexes from kinetochores, at least in male mammals. In contrast, MAD2 localization during MII mimics that seen in mitotic cells, initially localizing to most kinetochores at the start of the second meiotic division, and then being lost as chromosomes arrive at the spindle equator.[413] Thus, loss of MAD2 from MII kinetochores during male meiosis occurs once stable spindle connections have been established and, presumably, facilitates the release of MAD2-mediated APC/C inhibition.

The aforementioned SAC proteins all function at the kinetochore, with the exception of MAD1 in mouse oocytes, which assembles at the spindle pole and from there is recruited to the kinetochore when unstable microtubular connections are formed.[414] By contrast, MAD1 in *Xenopus* oocytes remains kinetochore associated and is responsible for recruitment of MAD2 and other proteins to unattached kinetochores.[398] Regardless of its position on the spindle, MAD1 is thought to act as a sensor of spindle tension, whereby loss of tension induces and reinforces MAD1 localization at the kinetochore, which, in turn, inhibits APC/C activity.[403] This localization is dependent on preloading of MPS1, whose activity also appears to be required for meiosis in a number of organisms, including yeast, flies, mice, and zebrafish,[415,416,417] and this involvement extends to both meiotic divisions.[402] MPS1 activity may also be required for cytostatic factor (CSF) arrest at metaphase II (as discussed further in this chapter; and see Ref. 418).

The First Meiotic Division: Kinetochore Orientation and Cohesion Function

Given their similar progression and molecular regulators, the processes of mitosis and meiosis are often compared, particularly with respect to spindle assembly and chromosome segregation. The most obvious differences, however, are observed at the first meiotic division when, by the end of meiotic prophase I, when the synaptonemal complex breaks down, bivalent homologous chromosomes are seen to be connected by their chiasmata. The homologs each consist of paired sister chromatids, held together through cohesion, while cohesion also serves to maintain homolog interactions distal to the chiasmata sites. This arm cohesion must be lost during the first meiotic division, while maintaining cohesion at the centromeres to ensure that sister chromatid pairing remains intact through meiosis II (Figure 1.12, step 5). Meiosis-specific centromeric cohesion is also important as it serves to facilitate differences in the way that the centromeres attach to microtubules during the first meiotic division (Figure 1.12, step 5). In stark contrast to the events in mitosis, and in order to ensure spindle tension, the homologous sister chromatid pairs (i.e., two chromatids) must attach to microtubules emanating from the same pole such that their microtubule attachment points at the centromere (large protein complexes known as kinetochores) are mono-oriented toward one pole, while the opposing homologous sister chromatid pair is mono-oriented in the opposite direction (Figure 1.13). Indeed, in yeast, amphitelic attachment of sister chromatids is actively prevented by the monopolin proteins.[419] To this end, sister kinetochores are fused or closely aligned so as to ensure their syntelic attachment to microtubules from a single spindle pole, while the fused kinetochores from the opposing homolog (or bivalent) are captured in syntelic fashion by microtubules from the opposing spindle pole, to achieve bipolar tension and stability of the overall spindle.

Metaphase-to-Anaphase Transition during the First Meiotic Division

The downstream target of the SAC is the anaphase-promoting complex, or cyclosome (APC/C), a multimeric ubiquitin E3 ligase whose activity targets several proteins for degradation.[420] APC/C is activated by CDC20 or by CDH1, and the association of these activators with APC/C is downregulated by sequestration of CDC20–CDH1 by MAD2 when the SAC is activated.[406] Thus, when chromosomes align correctly and spindle stability is ensured, the release of CDC20 or CDH1 from the MAD2 complex allows for activation of APC/C (Figure 1.12, step 2). APC/C then targets a number of key proteins for degradation via ubiquitylation, and these include securin and cyclin B (Figure 1.12, steps 3 and 4). Securin is an inhibitory chaperone of the protease separase. During mitosis, separase cleaves the α-kleisin RAD21, resulting in the uniform loss of cohesion across the paired sister chromatids, and leading to chromatid movement to opposite spindle poles.[406]

Vet-ebooks.com

Studies in yeast, flies, and vertebrates have indicated that the APC/C–CDC20–CHD1 system is also responsible for metaphase–anaphase progression during meiosis and that securin is the major target of APC/C.[421,422] Events during meiotic prophase I are somewhat different with respect to cohesion, with the meiosis-specific α-kleisin, REC8, being used in place of RAD21. At the end of prophase I, with the synaptonemal complex degraded, cohesins distal to the chiasmata maintain cohesion along the chromosome arms and provide the tension and pulling force necessary for correct bivalent alignment on the metaphase I spindle. Once stable chromosome alignment is achieved, APC/C is activated, resulting in the degradation of securin and cyclin B, and this leads to cleavage of REC8 by active separase, thus inducing anaphase I onset in a manner analogous to that seen in mitosis. Importantly, this cleavage event occurs in concert with resolution of the chiasmata and only across the chromosome arms, allowing homologs to move to opposite poles, while retaining sister chromatid attachments' pericentromeric region (Figure 1.12, step 5).[423] The mechanism by which this differential protection of cohesion is achieved was uncovered in three distinct yeast screens for mutants affecting Rec8-mediated cohesion.[424,425,426] In the first, Kitajima et al. demonstrated that replacement of Rad21 by Rec8 during mitosis in fission yeast was not sufficient to replicate the stepwise loss of cohesion at anaphase, indicating that it was not Rec8 itself that promoted this centromeric protection phenomenon.[424] Furthermore, ectopic expression of a cleavage-resistant *Rec8* prevented sister chromatid separation, suggesting that, unlike in meiosis, mitotic separase is capable of cleaving Rec8 in a timely fashion. Thus, the existence of a meiotic-specific "centromeric protector of Rec8" was postulated, and a suitable candidate emerged in one screen for mutants that are toxic when expressed mitotically in the presence of Rec8, as well as in other screens for mutants that exhibit abnormal chromosome segregation during meiosis.[424,425,426] One gene was identified and named *Shugoshin*, a Japanese word meaning "guardian spirit", the budding yeast homolog for which was named *Sgo1*. Further homology searches revealed a second paralog in fission yeast, *Sgo2*, as well as orthologs in many species, including *Drosophila MeiS322*, which had been previously described as a gene essential for centromeric cohesion.[423,427,428]

As expected, both Sgo1 and its paralog, Sgo2, are meiosis specific, and both localize to centromeres in a Bub1-dependent fashion.[423,424,429] Importantly, their distribution alters radically in meiosis II, with SGO2 redistribution throughout the centromere facilitating separase-induced cohesin cleavage at this site.[430] During meiosis I, however, Shugoshin proteins prevent removal of cohesins from the centromere, at least in part by recruiting protein phosphatase PP2A to the pericentromeric region. PP2A is a serine–threonine phosphatase that, together with Shugoshin, can dephosphorylate the usually heavily phosphorylated Rec8 (Figure 1.12, step 5, inset).[431,432] In mice and in yeast, localization of PP2A to the centromere is dependent on Shugoshin,[433] while loss of PP2A in yeast results in premature loss of centromeric cohesion.[431,434]

While loss of Rec8 phosphorylation is now established as an important feature of maintenance of centromeric cohesion, the kinases involved in initial hyperphosphorylation remain the subject of debate. Clearly, Rec8 is heavily phosphorylated under normal conditions, and this phosphorylation is essential for cleavage by separase. In yeast, three kinases have been implicated in Rec8 phosphorylation, namely, polo-like kinase (Cdc5), casein kinase 1δ/ε (CK1), and Dbf4-dependent Cdc7 kinase (DDK)[423,435] and a number of reports present conflicting data with regard to the relative importance of each of these kinases. On the one hand, loss of Cdc5 in budding yeast during meiosis results in hypophosphorylated Rec8 and a failure to cleave cohesin,[436] while during mitosis in yeast, cohesion cleavage is promoted through phosphorylation of the cohesin subunit, Scc1, by Cdc5.[437] On the other hand, mutation of the Cdc5 target sites on Rec8 has surprisingly little effect on cohesin cleavage in meiosis I,[438] while, under certain mutant conditions, Rec8 is cleaved even when *Cdc5* is not expressed.[439,440] Thus, it is more likely that Cdc5 may act further upstream of Rec8 to modulate cleavage, although not directly on Rec8 itself. Instead, it appears that CK1 and DDK may instead be the kinases directly responsible for Rec8 phosphorylation since combined deletion of these kinases results in a block in Rec8 cleavage.[435] It is also possible that other kinases may participate in these events, since deletion of CK1, for example, does not cause as severe a block to Rec8 cleavage as does mutation on the CK1 phosphorylation sites on Rec8.[441]

Resumption of Meiosis in Females following Dictyate Arrest: The Roles of MOS, MPF, and CSF

A key feature of meiotic progression in female vertebrates is the punctuated progression of meiotic events. In mammals, prophase I progresses through fetal life up until the point that chromosomes are fully synapsed and COs are evident. This is the stage of diplonema, and the synaptonemal complex has, by this time, broken down. The process of prophase I arrests at this point, in a stage known as dictyotene or dictyate arrest. In many animals, this occurs at around the time of birth, and may be semisynchronous across all the oocytes in an individual.

At this stage, the oocytes are in a structure known as a cyst in which many common cytoplasmic components

Vet-ebooks.com

are shared. The role of the cyst is unknown, but one common belief is that the cyst structure allows for one or a few oocytes to gain nutritional and energy advantage, while the others die off, perhaps explaining the huge wave of oocyte death, or atresia, at birth. During dictyate arrest, the oocyte grows in size somewhat, and the pre-granulosa cells form primordial follicles, thus dissolving the cyst structure. The follicles wait in this state until the correct endocrine cues to resume division, or activation.

Meiosis does not resume in mammals until after puberty, at which time circulating gonadotrophins induce ovulation and meiotic resumption and completion of the first meiotic division. The major factor that induces meiotic resumption is the maturation promoting factor (MPF), so named in 1971 by Masui and Markert.[442,443] While its effects in oocytes had been known for several decades, it was not until the late 1980s that the constituents of MPF became known: cyclin B and CDK1.[444,445]

MPF activation is dependent on at least three activities of luteinizing hormone (LH; Figure 1.14(A)). Prior to the surge in LH at estrus, and in order to maintain dictyate arrest, MPF activation is prevented by high levels of cyclic adenosine monophosphate (cAMP) in the oocyte. cAMP levels are kept high by both intrinsic and extrinsic factors. In the case of the latter, cAMP is provided by the surrounding granulosa cells via gap junctions that pervade the zona pellucida, the glycoprotein coat surrounding the oocyte. These gap junctions also supply cyclic guanosine monophosphate (cGMP), which suppresses oocyte phosphodiesterase 3A (PDE3A), which would otherwise degrade cAMP (reviewed by Ref. 446). Elevated cAMP results in increased protein kinase A (PKA) levels that phosphorylate key kinases, WEE1 and MYT1. These kinases, in turn, phosphorylate MPF. Phosphorylated MPF is inactive and cannot induce meiotic resumption. PKA also phosphorylates (and inactivates) CDC25B, the major phosphatase required to activate MPF.

Upon LH stimulation, cAMP levels decline due to an effect of LH on the granulosa: First, LH induces a mitogen-activated protein kinase (MAPK) cascade that results in reduced cGMP levels, which facilitates increased PDE3A hydrolyzing activity to degrade cAMP in the oocyte. Next LH reduces cAMP in the oocyte by directly upregulating PDE3A hydrolysis of cAMP. Third, LH induces mitochondrial sequestration of PKA by A-kinase anchoring proteins (AKAP) and facilitates the dephosphorylation of CDC25B, which can then remove the phosphate group from CDK1 and thus activate MPF.

A key step in the activation of MPF, at least in females, involves MOS, the product of the Maloney murine sarcoma virus *c-Mos* proto-oncogene. MOS is a protein kinase that functions upstream of the MAPK cascade that ultimately results in the phosphorylation and activation of $p90^{RSK}$. MOS and $p90^{RSK}$ downregulate MYT1–WEE1, thus promoting further the activation of MPF and progression through to anaphase I.[447]

Induction of metaphase I results in completion of the first meiotic division, which involves condensation of the chromosomes, assembly onto the meiotic spindle, and nuclear envelope breakdown, also called germinal vesicle breakdown (GVBD). Instead of cleaving into two daughter cells, however, the excess half complement of chromosomes are shunted into a rudimentary structure called the first polar body (PB1 in Figure 1.14) in a clearly asymmetric division.

There is no intervening S-phase before entry into meiosis II, and oocytes progress to metaphase II rapidly, only to arrest again under the influence of cytostatic factor (CSF; Figure 1.14(B)). High CSF activity induces stabilization and reaccumulation of MPF again by inhibiting the action of the anaphase-promoting complex, APC/C, which would otherwise target MPF for proteosomal degregradation via polyubiquitination of cyclin B[406] (Figure 1.14(C)). MOS is also important for maintenance of high levels of MPF,[448] possibly upstream of CSF, in turn resulting in the second meiotic arrest at metaphase II (MII). It is only upon fertilization that this block is removed, via the influx of calcium ions that is triggered by sperm penetration, allowing MII progression once the sperm enters the egg.[449] Thus, if eggs remain unfertilized, the MII arrest persists. In contrast, *c-Mos* knockout female mice exhibit parthenogenetic activation of unfertilized oocytes, indicating that loss of *c-Mos* allows oocytes to proceed to the second meiotic division without the need for fertilization.[450,451] Importantly, MOS does not appear to be required for meiotic progression in male mice.

Despite its initial characterization in the 1970s, along with MPF, the molecular nature of CSF has never been completely resolved. It is plausible, given the relationship between MPF and APC/C activity, that CSF is an inhibitor of the latter and/or may constitute one or more components of the MCC (Figure 1.13). However, loss of one or more components of the MCC in oocytes does not affect APC/C function, nor does it affect calcium-induced loss of CSF activity,[452] suggesting that SAC proteins do not constitute the elusive CSF. Instead, it has been suggested that MOS–MAPK constitutes the true CSF activity, since introduction of *Mos* into a blastomere of a two-cell embryo results in CSF-like arrest, while both MOS protein and mRNA are rapidly degraded upon fertilization.[452] However, the mechanism by which the downstream target of MOS, $p90^{RSK}$, acts to suppress APC/C activity remained elusive for many years. Recent studies have pointed to EMI2 as a mediator of

Vet-ebooks.com

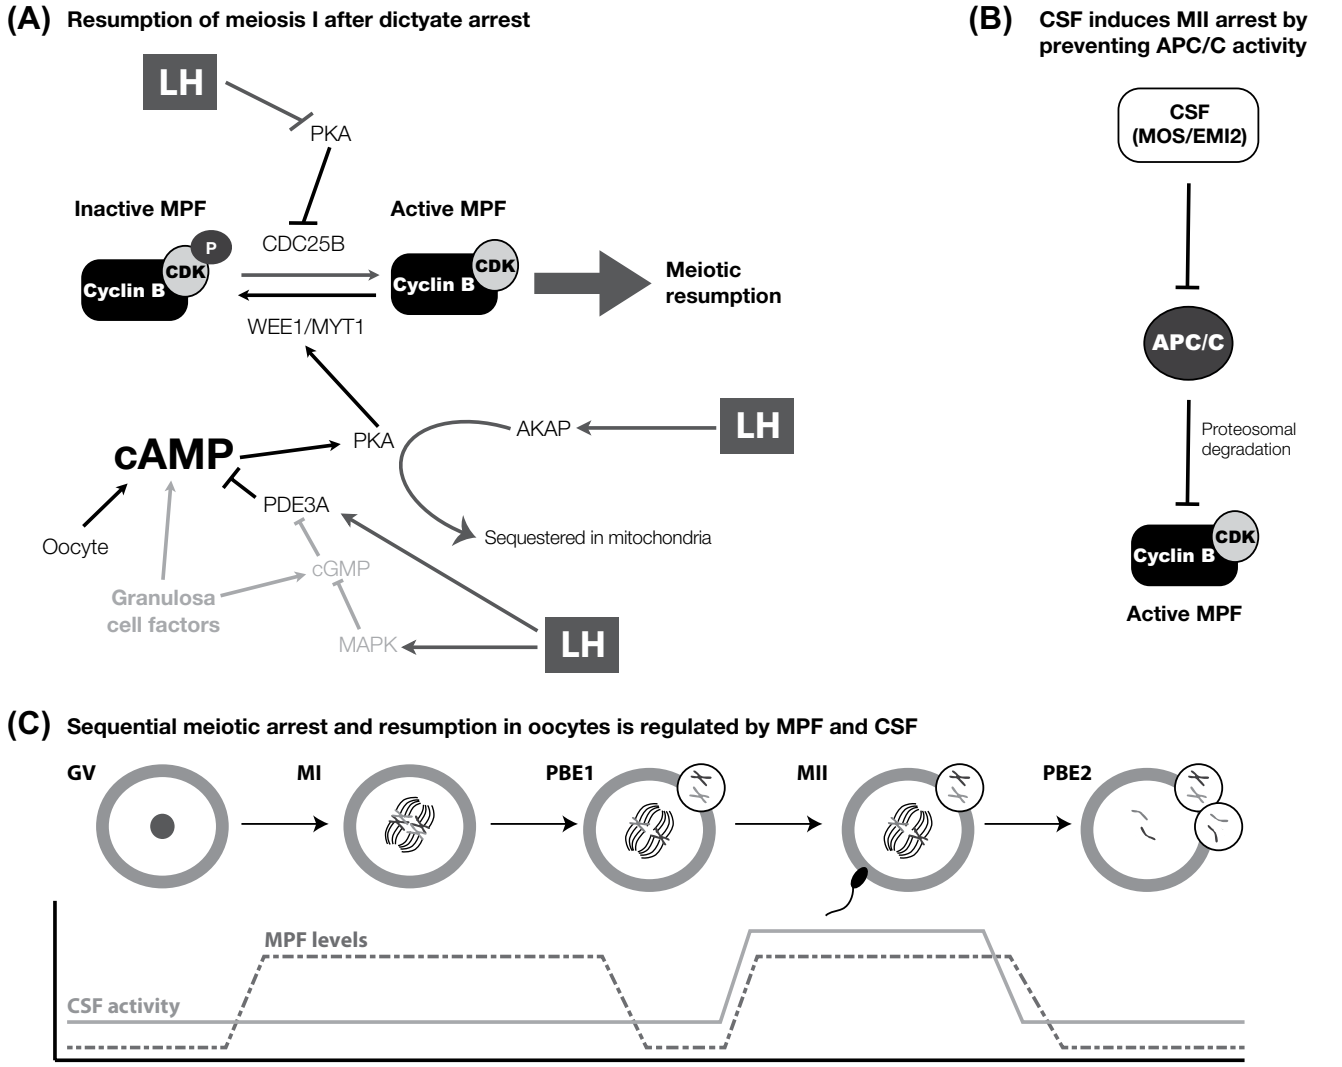

FIGURE 1.14 Resumption of meiosis I after dictyate arrest in females is mediated by MPF and CSF activity. (A) Dictyate arrest is achieved through the inactivation of MPF (cyclin B–CDK) via phosphorylation of CDK. This phosphorylation is brought about by maintaining high levels of cAMP within the oocyte. cAMP activates protein kinase A (PKA) that phosphorylates WEE1–MYT1 to maintain the phosphorylation status of CDK. PKA also inhibits CDC25B, the phosphatase that would ordinarily dephosphorylate cyclin B–CDK. Upon stimulation by luteinizing hormone (LH), PKA is inhibited through several routes, first by increasing PDE3A-mediated hydrolysis of cAMP through several routes. LH induces the MAPK cascade within the supporting granulosa cells that possess LH receptors, and this, in turn, suppresses cGMP release. In the dictyate-arrested oocyte, cGMP usually passes through gap junctions into the oocyte, where it suppresses hydrolysis of cAMP by PDE3A, and thus suppression of cGMP in the granulosa cells overcomes this suppression. In addition, LH induces closure of the gap junctions, further restricting movement of cGMP into the oocytes. Finally, LH stimulation results in upregulation of AKAP, which sequesters PKA within the mitochondria, preventing its access to the WEE1–MYT1 substrate. LH-mediated alleviation of MPF inactivity results in dephosphorylation and completion of the first meiotic division. (B) Following progression through the second meiotic division, oocytes arrest again in the presence of high CSF activity. CSF is thought to be composed of c-MOS and EMI2 and, together, they ensure suppression of APC/C activity, thus preventing inactivation of the steadily accumulating MPF. Fertilization of the oocyte by sperm results in an influx of calcium ions that, in turn, alleviates this inhibition, resulting in activation of APC/C and subsequent degradation of MPF. (C) Meiotic arrest and resumption are exquisitely timed events, all centering on the activation and inactivation of MPF and CSF activities. This graphical representation highlights key events in the bioactivity of these factors.

this APC/C inhibition, since depletion of EMI2 from egg extracts results in CSF release, while CaMKII, which is upregulated at fertilization, promotes EMI2 degradation, thereby relieving APC/C inhibition and promoting MII exit.[453,454] Importantly, EMI2 is a downstream target of $p90^{RSK}$,[455,456] providing the link between MOS activation and CSF activity.

DISORDERS OF MEIOSIS

Chromosome aneuploidy is a major cause of pregnancy loss and abnormal births in humans. Aneuploidy in fetuses tends to result in spontaneous miscarriage, as the vast majority of these render the fetus nonviable. Even those that survive to birth will have congenital

Vet-ebooks.com

abnormalities associated with an incorrect chromosome complement. The incidence of genetic aneuploidy in live births is around 0.3%; however, the true incidence of abnormal chromosome number during pregnancy is more likely to be in the region of 35–50%, taking into account those that are stillborn or spontaneously abort.[268,457] Upward of 70% of these errors are thought to arise due to maternal meiosis, with a vast proportion of these as a consequence of defective crossing over during prophase I in humans.[268] In contrast, mouse aneuploidies occur in <2% of meioses, which is surprising given the conservation of meiotic processes in mammalian systems. One reason for this massive discrepancy is likely to be the control of CO frequency and placement, which differs vastly from mouse to human. In mouse oocytes, MLH1 focus numbers are stringently controlled, numbering around 27.5 (±3.7) foci per nucleus.[268,458,459] In humans, in contrast, the number of MLH1 foci in fetal oocytes during pachynema is much more varied, ranging between 10 and 107 per nucleus, and representing a 10-fold difference in frequency from cell to cell, which is evident on the chromosomal level by chromosome arms missing MLH1 foci entirely or being overloaded with MLH1 foci.[268] This variation also differs between individuals, being more severe in some than others. Clearly, this vastly incompetent loading of MLH1 onto female oocytes in the human fetus would have a profound effect on the chromosomes during segregation. Given that these events occur in utero, they are distinct from any etiological causes in postnatal females or in adult women. As such, it is likely that genetic variation and/or changes in the molecular regulation of prophase I events are causes for such alterations in recombination frequency. In addition, it is possible that environmental factors may play a role in inducing this MLH1 variability, leading to the postulation that grandmaternal effects, such as smoking or drug use, may adversely affect meiotic events in female embryos.

Another fundamental cause of the high rate of maternal aneuploidy is the premature breakdown of cohesins associated with meiotic chromosomes in dictyate-arrested oocytes. Given the timing of human female meiosis, in which cohesins are sequestered on the chromosomes during fetal life and must remain there for several years until puberty, it is unsurprising that errors occur. There is evidence from mouse oocytes that once cohesins are recruited to the chromosomes prior to prophase I, they are not regenerated, and thus must maintain cohesion for a considerable period of time, possibly leading to nondisjunction in meiosis I.[460] This cohesin defect is also thought to be a major determinant of female age-related increases in aneuploidy (see below). Less than 10–20% of meiotic errors occur at meiosis II, and these are generally as a result of a precocious loss of centromeric cohesin.[461] Other meiotic genes also might be responsible for high levels of aneuploidy in mammals; a recent study found that mutations in *SYCP3* in females might increase the risks of pregnancy loss due to aneuploidy,[145] and *RNF212* haplotype variation has been implicated as a controlling factor in determining recombination rate in both males and females.[462] Recent evidence has suggested that different patterns of error origin are dependent upon the chromosome in question; for example, errors in separation of chromosomes 16 and 22 more often occur at meiosis II, whereas those in chromosomes 13, 18, and 21 occur at meiosis I.[463]

Maternal Age Effect

As mentioned above, cohesins in mammalian meiosis are thought to play a major role in age-related female aneuploidy, given the comparatively long time between the initial localization of cohesins on chromosomes during prophase I in the female in utero, and the time at which the oocyte emerges from dictyate arrest at the onset of ovulation. For example, *Smc1β* mutant mouse oocytes decrease in fitness with advancing age, with those from one-month-old females showing almost normal meiosis, while those from two-month-old females have vastly increased nondisjunction and meiotic errors.[178] A conditional knockout of *Smc1β*, which prevents SMC1β protein from being synthesized past dictyate arrest around birth, was, however, entirely fertile and showed no age-related loss in fertility, indicating that SMC1β production during prophase I was sufficient to ensure proper chromosome segregation.[464] However, several lines of evidence suggest that this is not the case with other cohesins. REC8 has been implicated as an important regulator of age-related meiotic errors, as it dissociates from chromosome arms and centromeres upon aging, and is not regenerated, leading to destabilized chiasmata and resulting aneuploidy in aged mice. Centromeric cohesin protector SGO2 is also required for proper segregation; however, its localization declines with age in mice.[460,465,466]

CO frequency and distribution are also thought to affect the rate of age-related aneuploidy. In divergent mouse strain crosses (divergence about 1%), aneuploidies in young mice increased relative to controls by around 10-fold, indicating that the sequence divergence was having a profound effect on recombination. In aged mice from the divergent crosses, aneuploidy rose by a further twofold, indicating that the problem was exacerbated in older mice.[467] Studies from human trisomies present a blurred picture as to the extent of influence that CO location has on aneuploidy in humans. One study showed that trisomies from young mothers contained COs more distal or proximal on chromosome 21 than those arising from older mothers; however, another

Vet-ebooks.com

study claimed that a single pericentromeric exchange correlated with increasing maternal age.[468,469,470] More recent high-resolution mapping of COs in human pedigrees reveals a significant decrease in recombination rate in older women, which is localized around the midsection of the chromosome arms and subtelomeric region.[471] It may be that COs in a certain position render the chromosome susceptible to age-dependent deterioration.

The SAC in human oocytes also may be a cause of age-related increases in aneuploidy. Decreased expression of critical SAC components, such as *Mad21l* and *Bub1*, has been observed in aged oocytes in humans and mice.[472,473,474,475] However, more recent data from mice reveal no apparent role for SAC in preventing aneuploidy in aged mice, given that MI lasts the same length of time in old and young mice, and they both have an equally robust checkpoint response.[465,476]

Human Diseases Caused by Meiotic Error

Many genetic diseases are caused by meiotic errors, the majority of these resulting from incorrect segregation of chromosomes in the oocytes and sperm. This mis-segregation can result in the offspring carrying too many (trisomy) or too few (monosomy) chromosomes. Typically, full chromosome autosomal monosomies are not found in the human population, but partial chromosome or mosaic monosomies do occur. The most prevalent monosomy in humans involves the deletion of one of the X chromosomes, known as Turner syndrome, which is viable in humans only because of the phenomenon of X inactivation, meaning that many of the cells will still possess a full complement of genes expressed. Diseases caused by chromosomal trisomy are more common in the human population, with the most common of these being trisomy 21, or Down syndrome. Down syndrome sufferers display developmental defects, along with severe mental retardation and a decreased life span. Down syndrome is the most common trisomy disorder seen in humans due to the fact that chromosome 21 is a small autosome, and therefore the trisomic cells can endure this extra chromosomal complement more so than a larger chromosome. Other trisomic diseases have been reported, including Edwards syndrome (trisomy 18) and Patau syndrome (trisomy 13), which have varying degrees of disease severity and life expectancy for the sufferer.[477,478] Trisomic disorders involving the sex chromosomes are more common than those involving autosomes, and include XXX, XYY, and XXY (Klinefelter syndrome). In the case of the latter, more than half of documented cases arise from paternal nondisjunction, rather than maternal, which is more common in humans.[479] All patient cohorts of sex chromosome trisomies exhibit some learning and behavioral difficulties as well as fertility problems, and XYY patients often have anger control issues.[480,481]

Environmental Effects on Aneuploidy

There is growing evidence supporting the fact that environmental factors have a large effect on the quality of gametes produced in mammalian species, particularly in oocytes. Diet has long been known to affect oocyte growth and maturation; however, a plethora of recent evidence has indicated the extent to which this is true. High lipid concentrations and maternal obesity have been demonstrated to have a negative correlation with oocyte health, inhibiting germinal vesicle breakdown and preventing the oocyte from proceeding beyond the prophase I stage[482,483]; whereas, conversely, animals maintained on a calorie-restricted diet do not display the usual aneuploidies associated with advancing maternal age.[484]

Smoking is also known to decrease fertility in both men and women, and for women the effect of smoking harms not only their own fertility but also that of their unborn female children.[485,486] Other toxic environmental factors include exposure to the estrogenic chemical bisphenol A (BPA), a component of many plastics and everyday items to which humans are exposed. Experimental evidence from mouse models and rhesus macaques has shown that BPA disrupts meiotic prophase sufficiently to cause synaptic defects, recombinational changes, and nondisjunction in the resulting chromosomes.[487,488] More recently, it has also been shown to have an effect on mouse germline stem cell differentiation, increasing levels of ovarian markers while decreasing levels of testicular markers.[489] So disastrous are these effects that BPA has subsequently been removed from much of the plastic sold in the United States. Temperature changes have also been shown to have an effect on oocyte growth in vitro, whereby the meiotic spindle of human oocytes was disrupted by transient cooling during culture.[490]

CONCLUSION

Our knowledge of the events of mammalian meiosis has evolved rapidly over the past 30 years, driven by impressive advances in our understanding of comparative cytogenetics and genomics, and our ability to extrapolate from similar processes that regulate events such as somatic cell mitosis and DNA repair through gene network analysis. The conservation of events between these processes and across species is remarkable and yet, at the same time, there are features that are unique to mammals, even differing between males and females, which continue to amaze and surprise us.

Vet-ebooks.com

These differences and similarities across species and sexes encourage and urge us to use comparative approaches at all times to elucidate the mechanisms of meiotic regulation. The next frontier in our understanding will come from continued understanding of the molecular pathways involved in recombination and checkpoint control, and how the epigenetic and RNA regulatory events integrate with those pathways. For example, our understanding of how DSB events are regulated at the chromatin level through *Prdm9* action has radically changed the way we think about DSB placement and CO assurance. More surprising has been the evidence from canids showing that, in the absence of a functional *Prdm9* allele, DSBs are directed to GC-rich regions and are evolutionarily more stable than recombination hotspots in other organisms.[296,297] This has led to speculation that recombination in the dog may be controlled by an ancestral mechanism that is found in other mammalian species but is outcompeted for in terms of DSB repair resources by the PRDM9-driven mechanism. What has also become clear in recent years is that CO placement is controlled by three distinct mechanisms: not only by interference, as had been previously thought, but by chromatin structure and CO homeostasis as well. The future in this area of research is particularly exciting. With exciting technologies to study recombination mechanisms, using methods such as ChIP-seq and SPO11-associated oligo mapping, already emerging, it seems the high-throughput approach to studying recombination is the direction that future studies will take. In addition, with the prospect of fast and inexpensive whole genome sequencing on the horizon, recombination events could be mapped over entire genomes in individual organisms or cells in the not-too-distant future.

A unique feature of mammalian, and specifically male, meiosis is the mechanism of meiotic silencing, particularly of the sex chromosomes. What has emerged in recent years is a picture whereby MSCI is inextricably linked to recombination and synapsis through the availability of specific mediators of each process, and these mediators (i.e., BRCA1 and ATR, but there may be others) act through heterochromatin formation and potentially utilize small RNA-driven mechanisms. This paradigm establishes an exciting interrelationship between gene-coding and noncoding mechanisms acting at the level of the DNA to regulate meiotic processes, and the elucidation of these RNA-based interactions over the coming decades is likely to change the meiotic landscape considerably.

Increasingly, studies specifically into meiotic processes in mice have helped advance similar studies in humans, and have led to major changes in the way we view human health. Advances in aneuploidy research and the massive effects that environmental factors can have on both male and, particularly, female meiotic health have led to changes in the way people choose to live their lives. The "grandmaternal effect" of exposing our unborn daughters to factors that may influence their reproductive health in years to come has changed international government policies on using these toxins in our plasticware. Research into female meiosis and the possible existence of oogonial stem cells isolated from both aged mice and humans has challenged the central dogma in reproductive biology stating that only a finite pool of oocytes exists at birth, and that this pool is never added to in later life. This area of reproductive biology remains controversial, but the broader questions of how germline stem cells become competent to undergo meiosis and, more importantly, how they do so with the exceptionally high fidelity needed to ensure the success of sexual reproduction represent an exciting area of continued and future research. Elucidating the molecular basis for meiotic entry and accurate progression has huge implications for our understanding of why human females exhibit such high rates of meiotic errors. Indeed this disparity between species in meiotic success rates remains one of the most poorly understood disease-related phenomena in human fertility despite the strict conservation of meiotic processes across eukaryotes.

Acknowledgments

We are grateful to Andrew Modzelewski, Swapna Mohan, Xianfei Sun, and Ewelina Bolcun-Filas for reading this manuscript, and to Ewelina Bolcun-Filas for providing unpublished images for Figure 1.11. In addition, Judith Yanowitz (University of Pittsburgh School of Medicine) provided extensive editorial input in the writing of this chapter, for which we express our sincere thanks. The authors thank the following individuals for providing images and figures: David Page (The Whitehead Institute), Monica Colaiacovo (Harvard Medical School), and Chris Franklin (University of Birmingham, UK). This work was supported by National Institutes of Health funding to PEC (GM097263 and HD041012) and to JKH (R00 HD065870-3).

CHAPTER

2

The Mammalian Oocyte

David F. Albertini

Department of Molecular and Integrative Physiology, Institute of Reproductive Health and Regenerative Medicine, Kansas University Medical Center, Kansas City, KS, USA

INTRODUCTION

The oocyte is distinct from all other metazoan cells by its ability to become a totipotent zygote. This fundamental property of female germ cells is not only retained in mammals but has required adjustments in design and function to meet the demands of the wide variety of reproductive strategies exhibited in mammals. While diversity between mammalian species exists with respect to the time required for oocyte development, there is remarkable conservation in basic processes governing the differentiation of a cell capable of effecting fertilization and embryogenesis. As stated above, among the most unique properties of the mammalian oocytes is the ability to generate totipotency. While subtle differences exist between mammalian species, the ability of the oocyte to reprogram the reconstituted diploid genome of the zygote, or that of a differentiated somatic cell nucleus, into a complete organism has been the culmination of researches encompassing more than two centuries.

Many historical accounts of the mammalian oocyte have been published, and for reaching into the deep past in this area, the reader is encouraged to examine "The Ovary of Eve".[1] That the ovum of vertebrates constitutes the generative cell was first suggested by William Harvey by the oft-cited statement, "*ex ovo de vivum*". It has taken many years to fully appreciate the ovum's totipotent character, requiring in retrospect the realization that the oocyte is contained within the ovarian follicle and undergoes a process of "maturation" as it is released from the ovary at ovulation, and finally accepting that fusion of egg with sperm launched a transformation of the ovum into the zygote, from which the embryo would develop.[2] These initial milestones are recorded in great detail in E. B. Wilson's treatise "The Cell in Development and Heredity," where the first glimpses of the process of oogenesis were described for the many studies on invertebrate animal models readily accessible in quantity and quality to analysis at the microscopic level.[3,4] Most important, these classical comparative studies on the oocyte formed the foundation upon which the basic principle that oogenesis presupposes embryogenesis was firmly established.

Appreciation that the oocytes of vertebrates more broadly applied to the biology of early development awaited the observational studies of the mid-twentieth century, where both the commonalities and distinctions of the oocytes of mammals were contributed by the likes of Austin, Beams, and Short. Among the principles reinforced from this era of research were: (1) the realization that the initial energy reserves for the embryo were deposited in the oocyte; (2) the appearance of extracellular coats for protection of the embryo and establishing the block to polyspermy; (3) the recognition that meiosis proceeds from diplotene to metaphase two in a highly developmental sequence under hormonal control; and (4) the interrelationship of oogenesis and folliculogenesis. This latter point was debated with vigor as the work of Sir Solly Zuckerman proposed that female mammals were born with a finite supply of oocytes that gradually diminished with advancing maternal age. The next significant phase of discovery took place in the latter half of the twentieth century, as has been summarized by Biggers.[4,5] Insights into the ultrastructure of the mammalian oocyte and the regulation of the meiotic cell cycle were obtained during this period of research.

Electron microscopic investigations defined in great detail the variety of organelles that constitute the "mother lode" of information that will carry the embryo to and through early development.[6,7] As shown in Figure 2.1, these descriptive studies revealed that the continuity of organelles through the female germ line to the embryo embodied mitochondria, the Golgi complex, endoplasmic reticulum, ribosomes, cortical granules,[8] and more specialized structures such as annulate lamellae (not

Upon activation, oocytes enter the growth phase of oogenesis (B). (B) summarizes the major ultrastructural features of a growing oocyte within a preantral follicle noting the assembly of the extracellular coat or zona pellucida, the enlarged nucleus or germinal vesicle with prominent nucleoli (NO), subcortical Golgi complexes with associated cortical granules, abundant perinuclear mitochondria, and the elaboration of microvilli on the oocyte plasma membrane interacting with somatic cell projections known as transzonal processes.

shown), and cytoplasmic inclusions of various kinds that often were unique to certain mammalian species.[9] Moreover, ultrastructural studies reinforced and extended mechanistic thinking as it pertained to interactions of somatic cells with the oocyte and alterations in the structure and function of the oocyte plasma membrane known as the oolemma.

Concurrent with ultrastructural investigations, technologies were being honed that would permit the isolation and culture of oocytes, ova, and embryos, opening up an era of hypothesis-driven research making possible studies coupling structure with function. The foundations for this field were made by Gregory Pincus and colleagues at the Worcester Foundation for Experimental Biology during the 1930 and 1940s.[10] Although rarely acknowledged, Pincus' pioneering work established in vitro oocyte maturation (IVM) technology.[11] Some 20 years later, Bob Edwards established the utility of IVM for many mammalian species that conceptually laid the framework for much of what we know about the meiotic cell cycle today and led to the practice of human in vitro fertilization as we know it today.[12,13] Finally, experimental strategies for the ex vivo manipulation and analysis of virtually all stages of oogenesis in the mouse were established.[5,14] It was at this point that research flourished using the mouse model, as evidenced by the appearance of a number of papers that established the foundation for biochemical and molecular investigations of mammalian oogenesis.[15–18]

Important discoveries soon followed. For example, direct evidence documenting the dependence of the mouse oocyte on cumulus cell metabolism[19] was obtained. Work from Bob Moor's group validated the use of in vitro techniques in sheep oocytes, allowing for a detailed analysis of protein synthesis changes and meiotic cell cycle progression kinetics during IVM.[20–22] Importantly, these studies established the impact of culture on oocyte quality and developmental competence with respect to hormonal factors that remain relevant to

TABLE 2.1 Competencies Acquired by Mammalian Oocytes during Oogenesis

Competency	Stage Acquired	Function
Meiotic	Late G	Resumption and completion of meiosis
Imprinting	Late G	Methylation of imprinted genes
Cortical granule fusion	M	Block to polyspermy
Calcium oscillations	M	Egg activation
Male pronucleus	M	Protamine S–S reduction; histone exchange
Cleavage	PM/M	Ability to sustain blastomere divisions
Compaction	PM/M	Ability to undergo cell polarization and lineage allocation
Embryonic stem cell derivation	G/PM/M	Ability to propagate stem cells from inner cell mass
Term birth	G/PM/M	Ability to sustain term gestation

Derived primarily from studies in the mouse based on phases of oogenesis described in Figure 2.2. Abbreviations: G, growth phase; PM, prematuration; M, maturation phase.

human assisted reproductive technologies (ARTs) to this day. Patterns of RNA synthesis were documented,[22] and the first studies describing an inhibitory role for adenosine 3′,5′-cyclic monophosphate (cAMP) in maintaining meiotic arrest appeared[23] (see Chapter 1). This discovery, the first to probe the mechanisms of cell cycle control during mammalian oogenesis, has become a centerpiece for much of the work exploring the relationship between cumulus cells and the oocyte over the past 40 years. Moreover, experiments of this kind paved the way for asking important clinical questions as to why some oocytes are able to develop after fertilization and why some fail. Whether mammalian oocytes are able to enact the events leading to successful embryonic development has been operationally defined as competence. Throughout this chapter, reference will be made to the oocyte competencies acquired at specific stages of oogenesis, as shown in Table 2.1.

The background literature up to this point sets the stage for much of the content of this chapter. While any attempt to cover the topic mammalian oocytes would fall far short of recognizing the many important contributions made prior to the "molecular genetic" era, there are several central tenets in the biology of the oocyte that have withstood the test of time and form recurrent themes of great importance to reproductive physiology.

The first theme embodies the notion that embryogenesis begins with oogenesis.[24,25] Maternal effect genes, products of oogenesis required for embryonic development, have been identified as have a variety of non-coding RNAs that are likely to play a role following fertilization.[26,27] Many of the proteins, and their posttranslational modifications, exerting control of the cell cycle from mitosis to meiosis and back to embryonic mitoses have been characterized (see Chapter 1). Together, the cytoplasm of the mammalian oocyte has been more critically defined in molecular terms, and to no surprise, the changing requirements at the protein level have taken on an aura of complexity that typifies the changing landscape within the oocyte as it proceeds through oogenesis. Figure 2.2 provides a framework for this chapter.

As Figure 2.2 illustrates, the process of oogenesis begins in the fetal ovary with the assembly of primordial follicles after the transition of primordial germ cells into meiotic prophase (see Chapter 1). With the formation of primordial follicles, oocytes have entered the diplotene stage of prophase one and will remain arrested in the cell cycle until luteinizing hormone (LH) induces ovulation and the resumption of meiosis. For the purposes of this chapter, oogenesis is divided into the growth phase, the pre-maturation phase, and finally, the maturation stage as shown in Figure 2.2. It is important to first appreciate that as the oocyte progresses through oogenesis, it maintains a temporal relationship within the ovarian follicle ensuring that the two processes, oogenesis and folliculogenesis, are integrated (see Chapter 21). When the primordial follicle is activated, oocyte growth proceeds in tandem with follicle growth in a gonadotropin-independent fashion. Once the follicle becomes sensitive to the action of gonadotropins, oocytes make the transition from the growth to pre-maturation phases, signaling the onset of the gonadotropin-dependent phase of folliculogenesis. As will be discussed below, the major factors that regulate development during the pre-antral growth phase involve paracrine and gap–junction mediated signaling mechanisms. In antral follicles, follicle-stimulating hormone (FSH) promotes growth and differentiation of somatic cells, ensuring that they eventually acquire sensitivity to LH, the primary trigger for ovulation and oocyte maturation. Each of these phases has been identified as error-prone in terms of nuclear (genetic, epigenetic) or cytoplasmic quality and have been implicated as determinants of embryonic developmental competence.[24,25,28–30]

Thus, the second major theme implies that oogenesis and folliculogenesis are inseparable from one another and any deviation from their coordination and integration spells failure to the reproductive fitness of a given species (see Chapters 21 and 22). From the vantage point of the oocyte, the growth phase of oogenesis relies heavily on direct forms of paracrine signaling between the oocyte and

Vet-ebooks.com

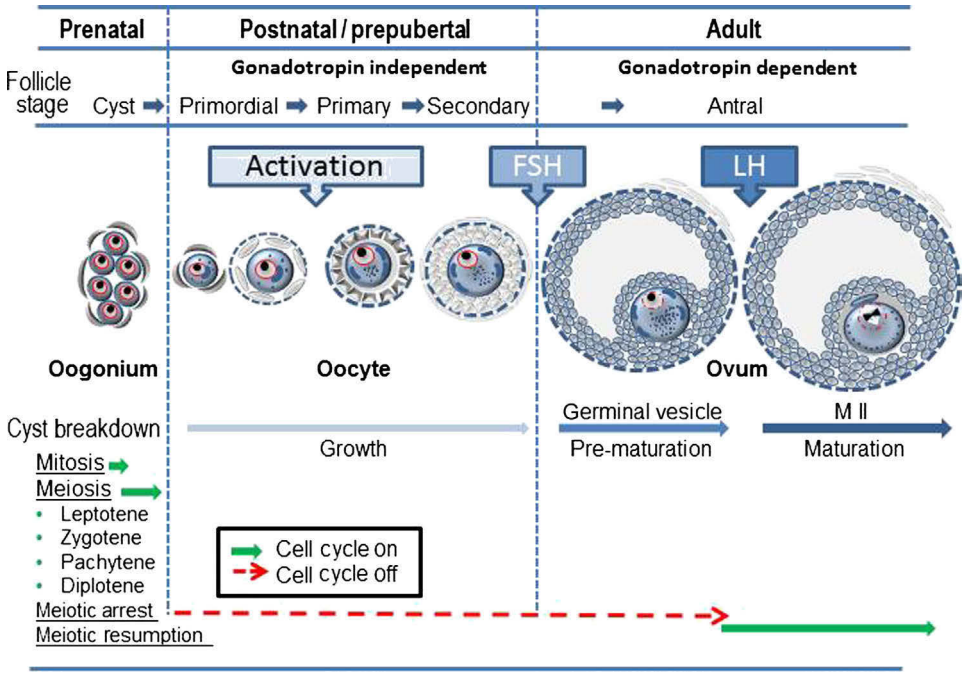

FIGURE 2.2 **Stages of oogenesis defined on the basis of the oocyte cell cycle state as it occurs in the mouse.** This figure is reproduced in color in the color plate section. Mitotic proliferation of oogonia occurs in the prenatal gonad and is accompanied by entry into meiotic prophase as follicle formation and cyst breakdown take place. The cell cycle is then turned off for the duration of the growth phase of oogenesis that occurs during the preantral stages of follicle development. While FSH is required to advance follicle development, the oocytes remain in meiotic arrest with a germinal vesicle in the prematuration stage. In response to the LH surge, meiotic arrest is released and the oocyte proceeds through maturation being ovulated at the metaphase two stage of meiosis, which is maintained until the fertilization signal elicits completion of meiosis two. Note that in general the growth phase of oogenesis occurs independent of gonadotropin stimulation, whereas the prematuration and maturation phases require gonadotropin stimulation.

surrounding somatic cells without direct involvement of gonadotropins (Figure 2.2). For basic and clinical scientists alike, the notion that the oocyte maintains communication with the soma throughout the various stages of follicle development has great significance.[31] The communication pathways at the interface of cumulus cells and the oocyte are now understood to involve many different forms of intercellular signaling that impact the development of both cell types.[32] Moreover, such communication pathways integrate germline and somatic cells to the overall benefit of embryo quality and the establishment of pregnancy.[33] There is good evidence to support the idea that the impact on the embryo is realized by epigenetic regulation. Importantly, epigenetics plays a role in separating genetic regulation of oocyte differentiation from that of the process of meiosis.[34] And during the growth phase of oogenesis, the expression of totipotency factors such as *Oct4* is modulated by gonadotropins through specific histone alterations.[35]

The third and final major theme for this chapter regards the problem of ovarian aging and the associated loss of oocyte quality. Humans are unique among mammals in the propensity with which their oocytes obtain an aneuploid condition, especially with advancing maternal age. Why our species is uniquely susceptible to genetic instability is not understood, but current opinion advocates faulty control of the meiotic and mitotic cell cycle.[36] Moreover, recent evidence suggests that other forms of genetic instability involving translocations, inversions, and DNA damage repair mechanisms are at play and that the oocyte itself may have a limited corrective potential for rectifying defects inherited paternally or maternally. Potential links between lifestyle alterations, environmental contaminants and reproductive failure have been proposed to find causality in these forms of genetic instability, clinically manifest in the high incidence of mosaicism observed in human embryos.[37]

Thus, in providing scope for this chapter, the link between oogenesis and embryogenesis, and the integration of oogenesis and folliculogenesis bear directly on the problem of ovarian aging and the clinical ramifications now being confronted in the context of human health and disease. This raises the interesting question as to the meaning of commonalities and differences in mammalian oocytes when compared between species. As shown in Figures 2.1 and 2.3, many structural properties exhibited by mammalian ova are conserved, such as the large size of the nucleus, prominent nucleoli, the presence of cortical granules, and the zona pellucida. Many of these properties are shared with the oocytes of lower vertebrates and invertebrates.[38] Where possibly of importance, attention

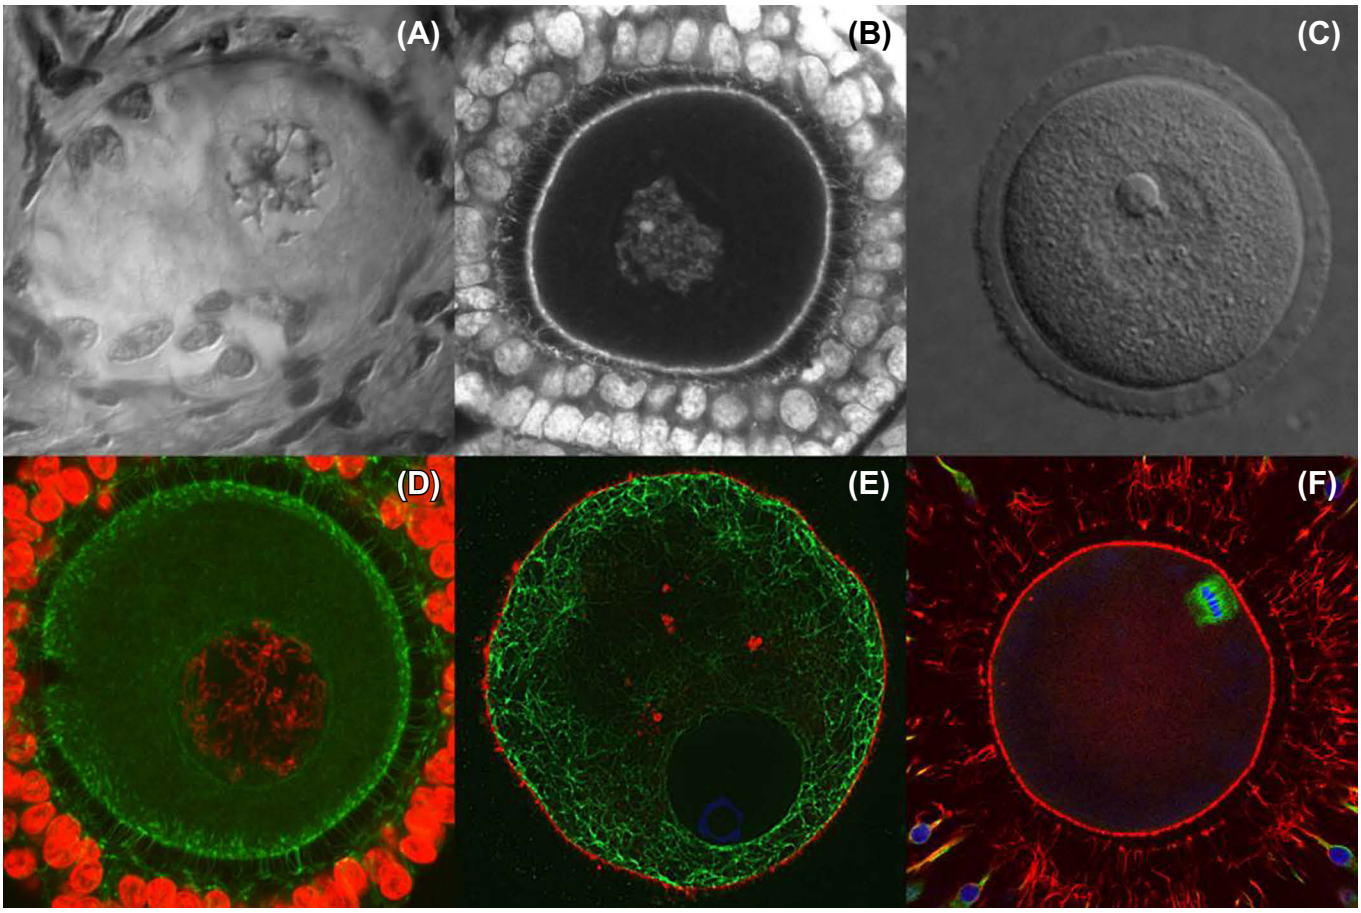

FIGURE 2.3 Prominent morphological features of the mammalian ovum at various stages of oogenesis in various species. This figure is reproduced in color in the color plate section. (A) depicts a resting primordial oocyte within the bovine ovary in which the germinal vesicle chromatin assumes a distinctly fibrillar pattern of organization. (B) represents a primary growing oocyte from the mouse containing a centrally positioned germinal vesicle and illustrating the prominent actin-rich cortex and numerous transzonal projections emanating from surrounding granulosa cells. (C) demonstrates the appearance of a full-grown immature mouse oocyte following isolation from the ovary; note the prominent eccentrically positioned nucleolus within the GV and the cell free zona pellucida. (D) depicts a full-grown immature bovine oocyte isolated from a Graafian follicle; note the clear organization of bivalents in the GV and the presence of numerous foci at the oocyte cell surface, which represent terminal connections with corona TZPs (preparation labels f-actin using rhodamine phalloidin). (E) illustrates an immature GV-stage human oocyte that has been labeled for chromatin and microtubules (fibrillar structures); note that the chromatin is aggregated around the nucleolus of the GV and that a dense network of cytoplasmic microtubules is present in the outer regions of ooplasm. (F) illustrates a mature metaphase two arrested oocyte from a horse following controlled ovarian hyperstimulation; this preparation has been dual-labeled for tubulin (green) that highlights the cortical anchored meiotic spindle and f-actin (red) that labels the prominent corona cell projections or TZPs that appear detached from the oolemma.

will be drawn to variations in mammalian oocytes that aid in understanding their physiology.[39]

CELL BIOLOGY OF THE OOCYTE

By far, one of the most striking features of the mammalian oocyte is its size. The transition from a quiescent non-growing state within the primordial follicle to that of active growth is one of the most dramatic examples of cellular hypertrophy known. Expansion in size occurs as a consequence to robust gene activation, selective protein synthesis, and hyperplasia of organelles. Of the new proteins and RNAs synthesized during the growth phase are those required for housekeeping and sustaining hypertrophy, those involved with regulation of the meiotic cell cycle, and those whose function will not be realized until later stages of development, so-called "maternal effect genes". Thus, the oocyte, arrested in diplotene of prophase in meiosis 1 (Chapter 1), exhibits a burst of transcriptional activity upon primordial follicle activation that persists until the oocyte has completed growth, as was first demonstrated in the mouse.[40] The unique challenge posed in the oocyte is how to selectively translate or store maternal RNAs of various classes, ensuring the readout of transcripts temporally restricted to the growth phase, cell cycle transitions, or after fertilization. Compounding this phase of development are emerging

Vet-ebooks.com

epigenetic requirements, exemplified by the dimethyl transferase variants used for maintenance methylation found in oocytes or embryos.[41] The importance of epigenetic regulation during the growth phase has been recognized in the now classical studies of Kono and colleagues, reinforcing the notion that events at early stages of oogenesis are critical for later development.[42] Thus, the conspicuous hypertrophy common to all mammalian oocytes is the first obvious sign of the investment the germ cell lineage will make toward the developmental potential of the embryo. And while inheritance of organelles like mitochondria has long been recognized, it is becoming increasingly clear that many other subcellular components will also contribute to embryogenesis.[42] Figure 2.1 illustrates the main features of the mammalian oocyte.

Traditional descriptions of growing oocytes relied heavily on the use of electron microscopy to validate and extend histological observations confirming the accumulation of mitochondria, Golgi complexes, and cortical granules, the specialized organelles that participate in the process of fertilization. Studies on the human oocyte identified constituents such as annulate lamellae and the characteristic perinuclear aggregate of organelles known as Balbiani's body[43] (Figure 2.1), a structure that will disperse upon follicle activation. Comparable constituents were described in bovine oocytes,[44] and Sathanathan has documented how these organelles are rearranged in human oocytes as they proceed from the growth stage through to the mature state.[45] In the oocytes of most mammals, it is generally appreciated that organelle amplification and migration to the oocyte cortex are a common feature of growing oocytes. Some exceptions do exist. For example, cortical granules are produced during oocyte growth in rodents[7] but formation is restricted to the maturation phase of oogenesis in sheep.[46] With interest shifting to the mechanisms that control entry into the growth phase of oogenesis,[47] more emphasis has been placed on the identification of specific molecules and organelles using contemporary imaging strategies.

The Germinal Vesicle—A Specialized Nucleus

One of the most prominent features of the mammalian oocyte is the large nucleus or germinal vesicle (GV) (Figures 2.3 and 2.4). The GV is located in a central or eccentric location, contains prominent nucleoli that can vary in number, and displays chromatin as condensed heterochromatin or diffuse euchromatin. Transitions between heterochromatin and euchromatin are generally believed to represent varying levels of transcription during oocyte growth, and there is wide variation between species with respect to whether the diplotene chromosomes remain chromosomal and fibrillar or are diffuse through the nucleoplasm (Figure 2.4). The states of chromatin organization are thought to reflect the level of ongoing transcriptional activity, as is discussed below. The presence of one or more nucleoli active in the generation of ribosomal RNAs is a common feature, with portions of the chromosomes bearing nucleolar organizing genes maintaining a stable pattern of heterochromatin at their surface (Figure 2.4). The nuclear envelope of the GV is rich in nuclear pores that mediate the robust level of RNA trafficking that occurs during the growth phase (Figure 2.4(F)).

Focus in recent years on the GV of mammalian ova has been placed on the nucleolus and interactions with surrounding chromatin (Figures 2.4 and 2.5). First described by Parfenov and colleagues, the compaction of chromatin around the nucleolus of human oocytes was named the karyosphere[48] (Figure 2.4(B,D,E)). It was proposed that this modification in chromatin reflected transcriptional repression near the end of the growth phase of oogenesis. Similar results were obtained in the rat[49] but the exact developmental timing and functional implications of this change in nuclear organization remained unclear. Studies in the mouse then showed that the gradual encapsulation of the nucleolus with heterochromatin (compare Figures 2.5(A,B,C)) occurred at the time of antrum formation, consistent with transcriptional repression known to occur at the end of the growth phase.[50] These and related studies then revealed that encapsulation of the nucleolus with heterochromatin coincided with a G2 to M phase cell cycle transition.[51] This implies coordination of chromatin remodeling with transcriptional and cell cycle control, a relationship reinforced in studies in rodents[52,53] and other mammals,[54] including the human.[55]

Specific reference to the transformation of chromatin from a diffuse (non-surrounded nucleolus (ND)) (Figure 2.4(A)) to perinucleolar and heterochromatized state (surrounded nucleolus (SN)) (Figure 2.4(B and C)) was proposed by Zuccotti,[52] Debey,[56] and others,[57–59] and general agreement now exists that this event also signifies a major change in cell cycle status that is associated with the acquisition of meiotic and developmental competence (Table 2.1). The experimental demonstration of meiotic competence refers to the ability of oocytes to reinitiate meiosis and proceed to metaphase of meiosis two when oocytes are removed from follicles and subjected to maturation in vitro.

Support for this broad generalization linking chromatin reorganization with competencies required for the completion of meiosis (meiotic) or embryogenesis (developmental) has been reported for the human,[60,61] bovine,[62] and primate[63] oocyte. Together, these findings demonstrate the importance of coordinating alterations in nuclear organization with key developmental transitions between the growth and pre-maturative phases of oogenesis. However, upon close examination, it has been reported that the basic distinctions for NSN and

Vet-ebooks.com

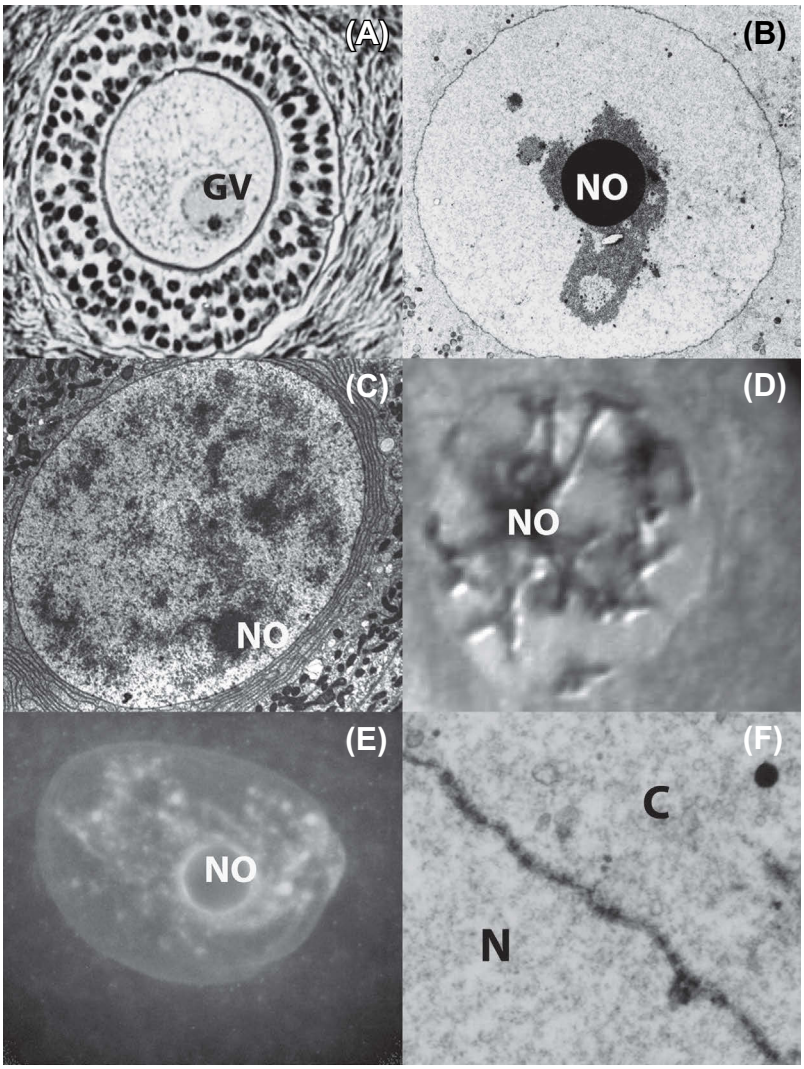

FIGURE 2.4 The immature mammalian oocyte nucleus or germinal vesicle (GV). (A) illustrates the general appearance of the GV using conventional histology; in this section from the rhesus monkey ovary, the GV assumes an eccentric position and exhibits a prominent nucleolus (NO). (B) is an electron micrograph of a human oocyte GV demonstrating the circular boundaries of the nucleus and the presence of heterochromatin surrounding the nucleolus (NO). In many mammals, fibrillar chromatin can be observed as shown here for the macaque (C) and the bovine (D); note that in both cases the bivalents are associated with the nucleolus centrally (NO) and at the inner aspect of the nuclear envelope. (E) illustrates the nuclear lamina in a mouse oocyte GV that has been labeled with antibodies to B-type lamins; the chromatin in this fully grown oocyte is superimposed on the lamin signal. In (F), a high-magnification electron micrograph of a human oocyte shows the high density of nuclear pores in the nuclear envelope that separates the nucleoplasm (N) from the cytoplasm (C).

SN used to describe the mouse oocyte do not hold when oocytes from other mammals are examined. Rather, the equivalent NSN configuration in ungulates and primates is more typical of condensed chromatin bearing the signature bivalent structure with crossover points well-defined (Figure 2.5(D–F)). And in human oocytes, the SN configuration is represented by the complete contraction of GV chromatin (Figure 2.5(G and H)) that is distinct from diakinesis (Figure 2.5(I)). Caution should be exercised in the use of such generalized descriptors given species variance in the organization of GV chromatin. Some of the factors that regulate chromatin reorganization in the GV have been identified through the use of transgenic mice.

For example, the oocyte specific gene for growth and differentiation factor 9 (*Gdf9*) produces a growth factor that is responsible for development of the follicle past the primary stage. In mice lacking *Gdf9*, the oocytes undergo pathological hypertrophy, exhibit impaired organelle proliferation, and show precocious transcriptional repression as evidenced by SN GV configurations.[64] In contrast, in mice bearing deletions in either the *FSH beta*[65] or *Gja37*[66] genes, follicles are arrested at the preantral stage, and contain oocytes exhibiting NSN configurations consistent with transcriptional activity. When animals are treated with FSH, follicle development is restored and oocytes proceed to an SN configuration showing the importance of gonadotropin stimulation in the regulation of GV organization and transcriptional status.[65] Many other factors have been identified that influence chromatin organization in mouse oocytes, including specific genes,[67] cell contact,[68] gonadotropins,[35] and the nuclear chaperone *Npm2*.[69]

It should be pointed out that some controversy remains as to the exact relationship between chromatin remodeling and transcriptional silencing in the mouse oocyte.[69,70] In other species, such as the cat, chromatin remodeling is not associated with the acquisition of meiotic competence.[70] The interested reader is referred to recent reviews on this topic.[57,71]

Vet-ebooks.com

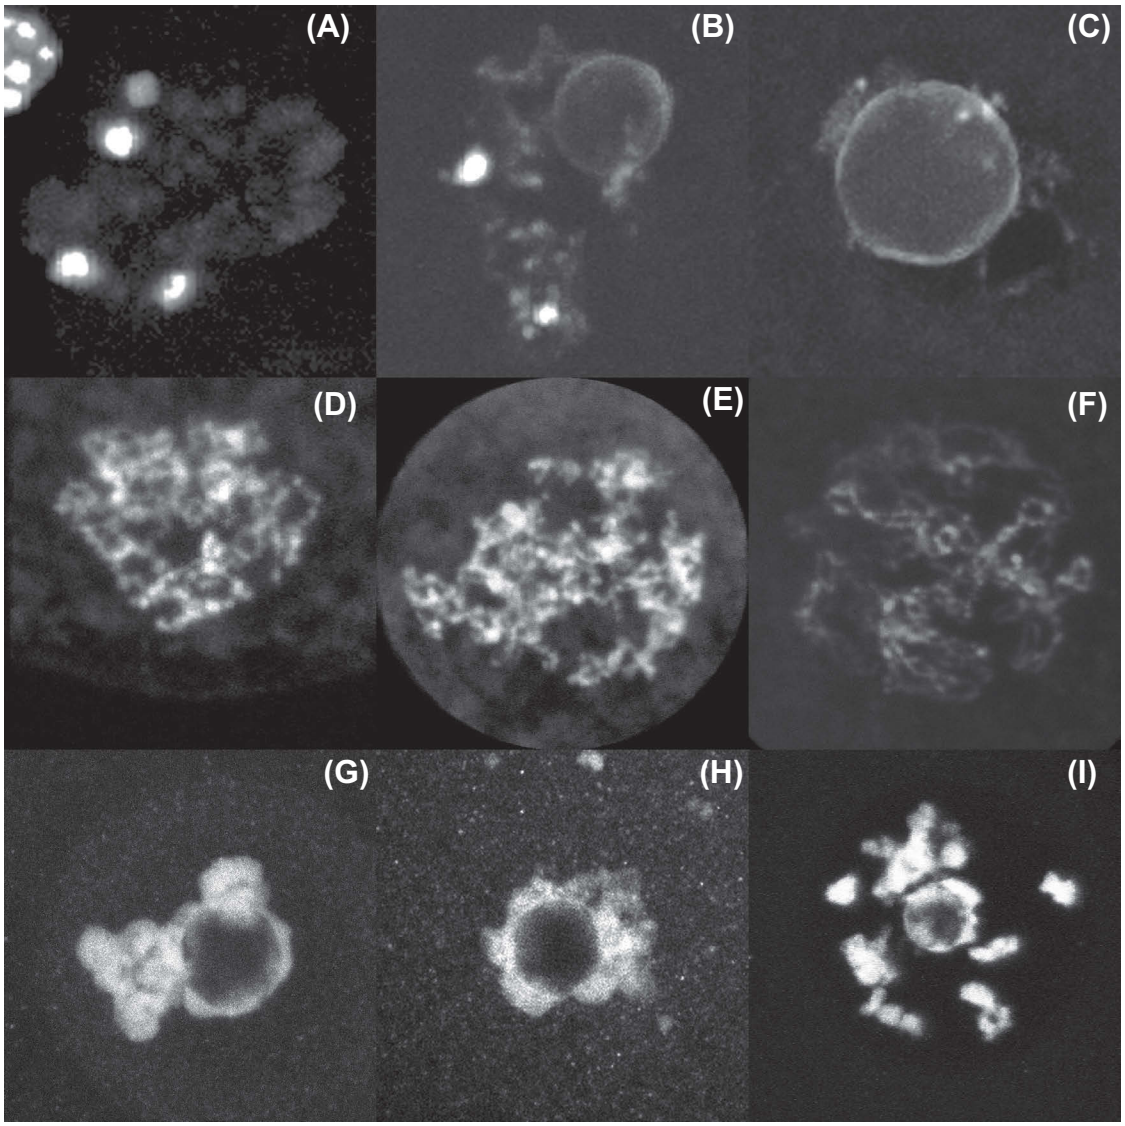

FIGURE 2.5 High-resolution fluorescence microscopy of patterns of chromatin organization in the GVs of immature oocytes from the mouse (A–C), Bovine (D–F), and human (G–I). It should be noted that all images were collected from fixed oocytes and chromatin is labeled with Hoechst dyes that detect only adenosine-thymidine–rich domains of chromatin; where apparent, unstained spherical structures represent the nucleolus. In rodents, growing oocytes exhibit a diffuse pattern of chromatin (A) that progressively heterochromatizes (B) and envelops the surface of the nucleolus (C). The GVs of most domesticated species tend to display fibrillar patterns of chromatin (D and E) that at the end of the growth phase assume a characteristic bivalent form typical of diplotene (F). Human oocytes that have been retrieved from ART cycles, and are presumed to have completed their growth, to exhibit condensed patterns of chromatin that encircle the nucleolus (G and H, karyosphere), or to exhibit properties of having entered diakinesis (I).

Cytoplasmic Composition of Mammalian Oocytes

Most initial characterizations of the composition of oocyte cytoplasm, known as ooplasm, drew upon the resolving power of the electron microscope and the use of histochemistry to gain insight into the enzymatic activities that distinguished oocytes from surrounding granulosa cells[72,73]. Many studies of this kind focused on the changes in distribution and structure of a particular organelle through the program of oogenesis and into early embryogenesis.[6,7] Studies of this kind laid a general foundation by identifying major organelles such as mitochondria, and documenting extensive hyperplasia of this organelle with changing functionality along the course of oogenesis. Besides documentation of the expected accumulation of ribosomes, endoplasmic reticulum, Golgi, and lysosomes, both new organelles such as annulate lamellae[74] and old favorites like Balbiani's body[43] were brought into the realm of oocyte biology (Figure 2.1). In keeping with the notion that oocyte ultrastructure

Vet-ebooks.com

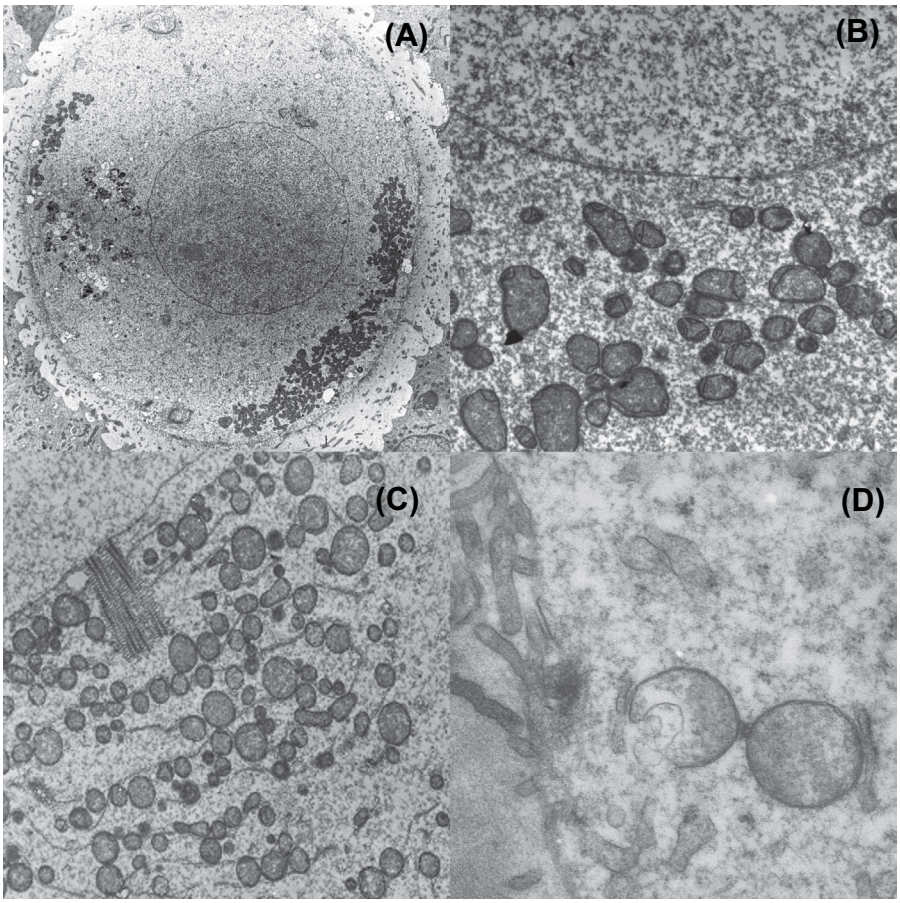

FIGURE 2.6 Ultrastructural appearance of mitochondria in resting primordial (A and C) or growing oocytes (B and D) from the primate (A–C) or mouse (D). In resting oocytes, the mitochondria tend to be collected at one pole and are either associated with the perinuclear Balbiani body or in a subcortical location (A). Independent of their position, there is great variation in the number and structure of mitochondria, but in general oocyte mitochondria are known to have few or no cristae, tend to be found in clusters of varying sizes, and lack electron-dense granules in the matrix (B). Not infrequently, oocyte mitochondria are associated with cisterns of smooth endoplasmic reticulum (C), and as the oocyte nears completion, many assume a cortical position with dumbbell configurations that may represent fission or fusion (D).

continues to play a role in our understanding of oogenesis, an overview of organelles is provided below and is followed by a discussion of the other major part of cytoplasm, that of the oocyte cytoskeleton formerly referred to as ground substance.

Without question, oocyte mitochondria continue to be a well-studied but poorly understood organelle (Figure 2.6). As noted above, what makes the oocyte mitochondria truly unique among organelles in general is their direct contribution to the immediate metabolic demands of the embryo and as providers of the mitochondrial genome to the next generation. From a structural point of view, the starting point for maternal inheritance begins with the formation of the primordial oocyte and the population of founder mitochondria from the primordial germ cells. In primordial oocytes, a mitochondrial cloud, or aggregate is typically situated in a perinuclear location in association with Balbiani's body (Figure 2.1). Oocyte mitochondria in arrested or growing oocytes are unusual in bearing relatively few cristae, usually thought to indicate a low level of metabolic activity. Once oocyte growth commences, expansion of the mitochondrial pool steadily occurs with amplified populations assuming a random (Figure 2.6 (B and D)) or highly polarized (Figure 2.6(A and C)) distribution that varies between species. Independent of their overall disposition, examples of mitochondria undergoing fission, or possibly fusion, are numerous (Figure 2.6(D)). How variations in number and location influence oocyte quality and development will be addressed in greater detail in a later section.

The themes of expansion and relocation noted above for mitochondria are similarly valid for the topic of the Golgi lysosome system (Figure 2.7). Being the control center for the biosynthesis of proteins, endosomes, cortical granules, and lysosomes, the Golgi complex of the oocyte has understandably been the subject of much attention given the proliferation and cortical dispersion observed during oogenesis. The primary functions of the Golgi that commence upon follicle activation are best characterized as secretory. The major secretory products at this stage include the glycoproteins that will comprise the zona pellucida, the membrane proteins designated for insertion into an expanding plasma membrane, and the proteins that must be synthesized, processed, and incorporated into lysosomes. With the availability of antibody reagents to identify these products, it has become apparent that a diverse distribution of Golgi-associated precursor molecules are evident in growing oocytes including components of the zona pellucida

Vet-ebooks.com

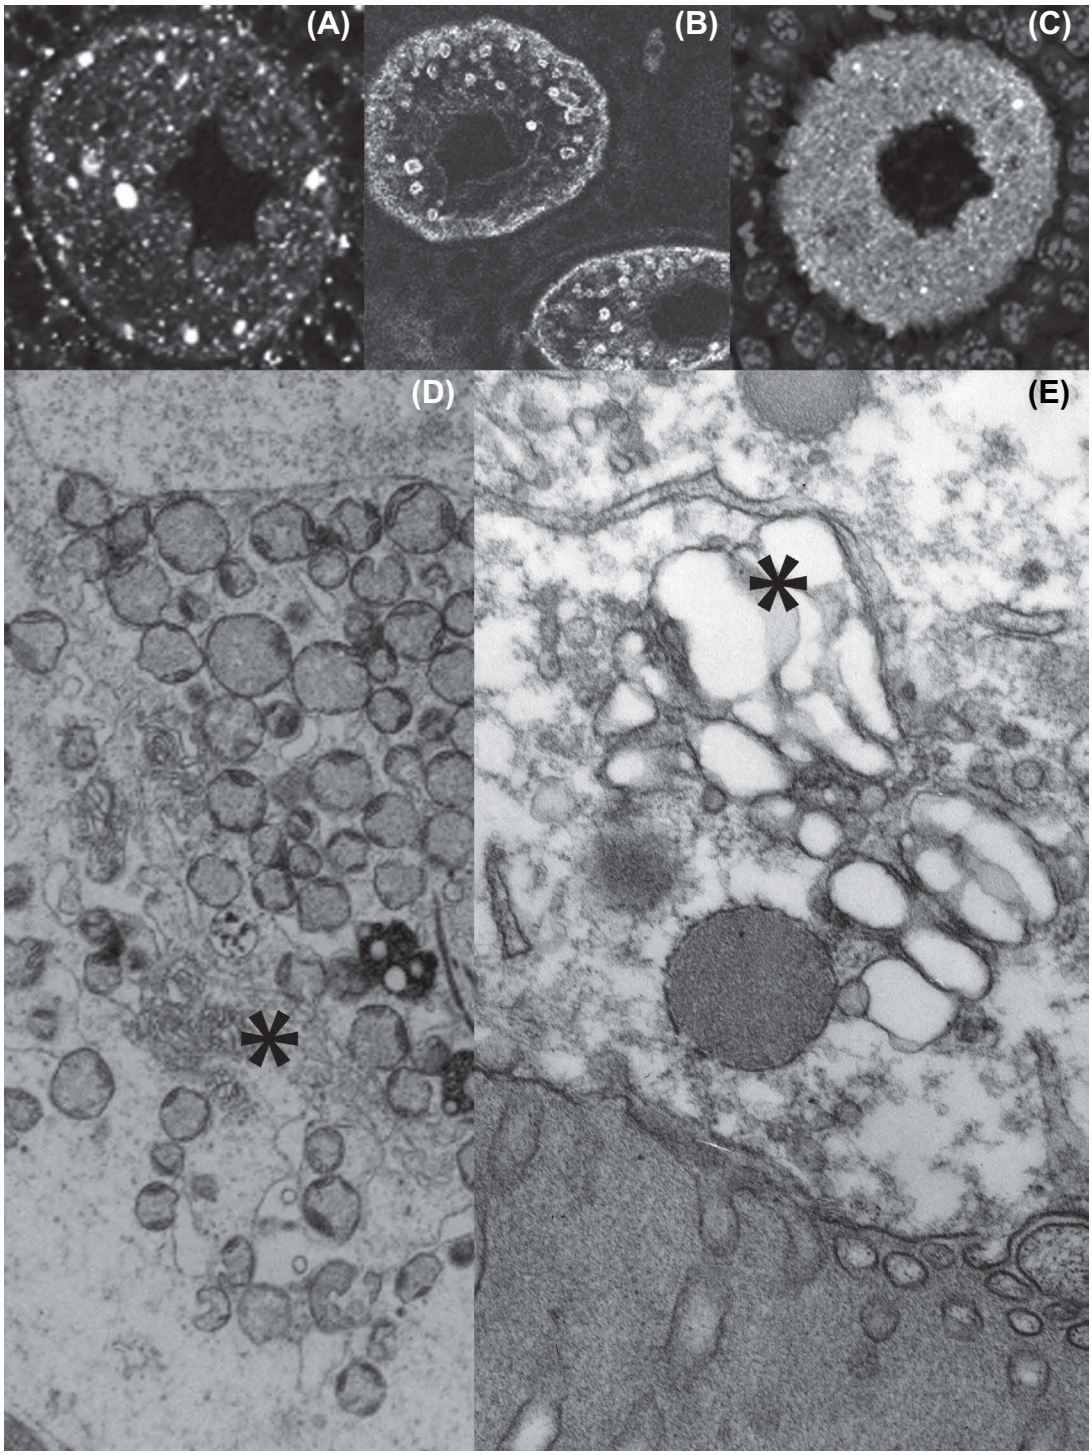

FIGURE 2.7 Disposition and structure of the Golgi lysosome system in mammalian oocytes of the mouse (A–C), human (D), and macaque (E). (A) illustrates the lysosome pattern revealed after staining with the lysosome membrane–specific antibody LAMP-2; small particles represent primary lysosomes, whereas large clumps are indicative of the multiple Golgi complexes found during the growth phase of oogenesis. A clear indication of the multiple Golgi complexes is shown in (B), where immunofluorescence microscopy has been used to label the zona pellucida protein ZP-1; in (C), a similar labeling strategy was used to detect the oocyte-specific factor BMP-15.

(Figure 2.7(A and B)), and lysosomes (Figure 2.7(C)). The spectrum of these patterns of distribution is consistent with earlier findings reporting the cytoplasmic and subcortical Golgi complexes that would be expected to be processing zona proteins.[9] Examples of this repositioning are illustrated in Figure 2.7. The Golgi disperses into multiple complexes that come to lie just beneath the oolemma (Figure 2.7(E)). The subcortical Golgi

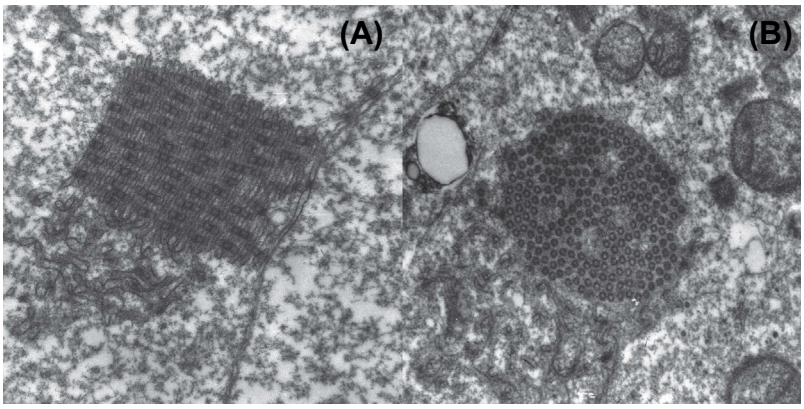

FIGURE 2.8 Ultrastructural appearance of annulate lamellae in a chimpanzee primary oocyte seen in cross section (A) and tangential (B) views. (A) shows the continuity of nuclear pores from the nuclear envelope into a stack of annulate lamellae. In (B), a tangential section through the surface of a stack of annulate lamellae revealing the closely packed organization of nuclear pore complexes.

complexes are actively engaged in the production of cortical granules, as first demonstrated by Nicosia.[8] The mechanisms underlying the dispersion and repositioning of the Golgi complex during oocyte growth remain poorly understood, but this dynamic and widely conserved feature of the mammalian oocyte emphasizes again the importance of positional information while a variety of products are being assembled whose functions will be realized in distinct ooplasmic regions. How such a division of labor is achieved will await further study using live cell imaging techniques.

An additional ultrastructural feature of mammalian oocytes that appears to be common to most mammals excluding rodents is that of annulate lamellae (Figure 2.8.) The distinct appearance of this historically recognized and elaborately designed organelle prompted earlier investigators to suggest that it provided stores of nuclear pore complexes that would be utilized after fertilization for the assembly of blastomere nuclear envelopes.[5] A detailed analysis of primordial oocytes by Hertig in the 1960s provided some support for this idea by documenting the physical contiguity of nuclear pores between the GV nuclear envelope and the adjoining annulate lamellae.[43] Given the subsequent ultrastructural analyses of human oocytes and embryos and the plausible role for annulate lamellae in embryonic development, it is surprising that this oft-neglected and yet prominent component of ooplasm has not received discriminating attention.

Largely ignored in the earlier descriptive ultrastructural work was the topic of cytoplasmic ground substance, classically defined as the highly cross-linked protein matrix within which organelles reside. The main reason for this omission of what has become an intensely studied aspect of oocyte biology was the failure to preserve components of the cytoskeleton using electron microscopy protocols that invariably damage all but the most stable of these structures, such as spindle microtubules, axonemes, and cytoplasmic lattices, a subject that will be dealt with in much greater detail below. Nevertheless, several salient and provocative features of the oocyte cytoskeleton have now come under scrutiny using more contemporary technologies, and are reviewed here.

Of central importance to the theme of maternal inheritance is the topic of the centrosome, a subject engrained in the study of oocyte biology that has fascinated developmental and cell biologists since the early twentieth century.[3,5] Centrosomes are classically recognized at the major microtubule organizing center (MTOC) in all cells displaying the prominent and telltale feature of asters due to a radiating pattern of microtubules. It was in the 1980s that Maro and colleagues first noticed these MTOCs within the cytoplasm of mouse oocytes and proposed that besides their involvement in the formation of the meiotic spindle, perhaps they represented a maternal supply of MTOCs that would be used to support the mitotic cell divisions in the early embryo.[75] As in other cell types, it was subsequently shown that rodent oocyte MTOCs contained the signature protein components gamma tubulin (TUBG1, TUBG2)[76] and pericentrin[77,78] and undergo cell cycle–specific alterations during meiotic progression from diplotene GV stage to metaphase two.[79] The biochemical characterization and essential role played by these structures in mouse oocyte and embryo cell cycle control have been thoroughly reviewed and reinforce the original suggestion that oocyte MTOCs are indeed a major maternal determinant of embryo quality.[80,81] But this more recent history of maternal MTOCs raised several questions in light of the seminal contributions of Szollosi and colleagues published in 1972.[82] This pioneering electron microscopic study documented a major change in MTOC composition that took place as mitotic oogonia transitioned into meiotic prophase in the mouse. Whereas classical centrosomes in somatic cells bear true centrioles within the pericentriolar matrix, Szollosi and coworkers documented that while oogonial centrosomes were indeed centriole-containing, the centrosomes within diplotene-arrested primordial and primary oocytes lack detectable centrioles. These findings, confirmed by others, raised the interesting question of how and when are centriolar centrosomes regenerated in the early embryo? While much debate has ensued

Vet-ebooks.com

over the origin and continuity of centrioles and centrosomes during oogenesis and embryogenesis, Szollosi, in collaboration with Ozil, went on to show that centriolar centrosomes could be generated de novo within rabbit embryos produced by parthenogenetic activation.[83] An excellent review on this topic has been authored by Sathananthan and colleagues[84] that describes the history of this problem[85] and the implications it poses for the treatment of human infertility as originally uncovered by Schatten and colleagues.[86] Together with more recent advances documenting the mechanisms by which mitochondrial inheritance impacts human oocyte quality and embryo development,[87,88] continuing efforts are indicated to explore the inheritance of centrosomes and other oocyte components whose direct contributions to the embryo impact the health and well-being of children produced by human ARTs.

Besides the microtubule cytoskeleton, two other classes of cytoskeleton proteins play important and somewhat distinct roles in the biology of the mammalian oocyte. It is worthwhile at this juncture to keep in mind that the transcriptional, translational, and post-transcriptional control of cytoskeletal proteins during oogenesis,[15,16] if compromised, could impose risks on the embryo where priorities are assigned to supporting key cell cycle and morphogenetic events necessary at later times. These classes of filaments include the contractile protein actin, and its associated motility-producing proteins such as myosin, and the proteins that comprise intermediate filaments which are thought to primarily confer rigidity within and between cells. The subject of actin filaments has been mostly studied in the context of meiotic maturation when dramatic remodeling of the actin cytoskeleton mediates meiotic spindle positioning, polarity, and polar body extrusion, and will be discussed in the section Clinical Parameters of Oocyte Biology.

Intermediate filaments in hamster oocytes have been characterized with respect to their assembly during oogenesis and utilization in the embryo with regard to establishment of junctional complexes required for compaction and blastocyst formation.[89] Subsequent to this work on the hamster, and following the earlier studies in the mouse,[7] the Capco[90–92] and Coonrod[93–96] laboratories have made major contributions to our understanding of the role of intermediate filaments in these rodent species.

This work has buttressed the notion that in order for the growing oocyte to maintain molecular order and physical stability, the deposition and arrangement of protein scaffolds composed of intermediate filaments is a necessary prerequisite that mediates a variety of biochemical processes. Among these are organelle positioning, the ordering of signal transduction systems that participate in the maintenance of meiotic arrest and the resumption of meiosis during maturation, and the provision of a stable matrix upon which meiotic spindle assembly can take place.[93] A slightly different but equally important tack has been taken in studies on the mouse oocyte with respect to the crystalline lattices that populate the cytoplasm of rodent species.

Here the emphasis and implications regarding the lattices have delved into the prospects that these stable components of the cytoskeleton undergo compositional variations that mediate processing of macromolecular complexes and/or positioning and protection of molecules destined for use in the early embryo. For example, PADI6 has been characterized as a lattice component that mediates the allocation of ribosomal constituents and ensures their availability for timely control of translation in the embryo.[94] In elaborating upon the role of PADI6, further studies have implicated the lattices in positioning of MATER, a maternal effect gene, as well as the control of microtubule organization and organelle positioning.[93–96] Taken together, this line of work further establishes the role of cytoskeletal stability in maintaining and regulating spatial organization required for the successful completion of oogenesis and the enactment of embryogenesis.

Membrane Specializations and Extracellular Coats

In achieving some semblance of order in such a large cell that is undergoing volume expansion, it comes as no surprise that physical forces generated from within and without the oocyte would assume pivotal roles in the design and shaping of the mammalian oocyte. As noted above, and as will be further discussed, the cytoskeleton provides an internal scaffold upon which to maintain shape, effect positioning of organelles, and stabilize the inner surface of the oolemma. It would be predicted that without balancing forces generated internally with those outside the oocyte, growth to extremely large proportions would result in the absence of externally imposed constraints. With this fundamental principle in mind, as evidenced by the invariant size and volume properties displayed by mammalian oocytes in each species examined, the hallmarks of the extracellular matrix and attendant modifications in the oolemma are next taken into consideration (Figure 2.9).

The most obvious external manifestation common to the oocytes of mammals is the zona pellucida (Figures 2.1, 2.3, and 2.9). The zona pellucida (ZP) is a specialized extracellular matrix serving a number of functions. Constructed from glycoproteins synthesized, processed and secreted from the oocyte (ZP1, 2, 3), this structure has long been recognized to serve as a protective barrier to the oocyte while within the follicle and following release at ovulation. Embedded within the substance of the ZP are two kinds of cellular projections originating from the granulosa cells externally and from the oolemma internally (Figure 2.9(A)).

Vet-ebooks.com

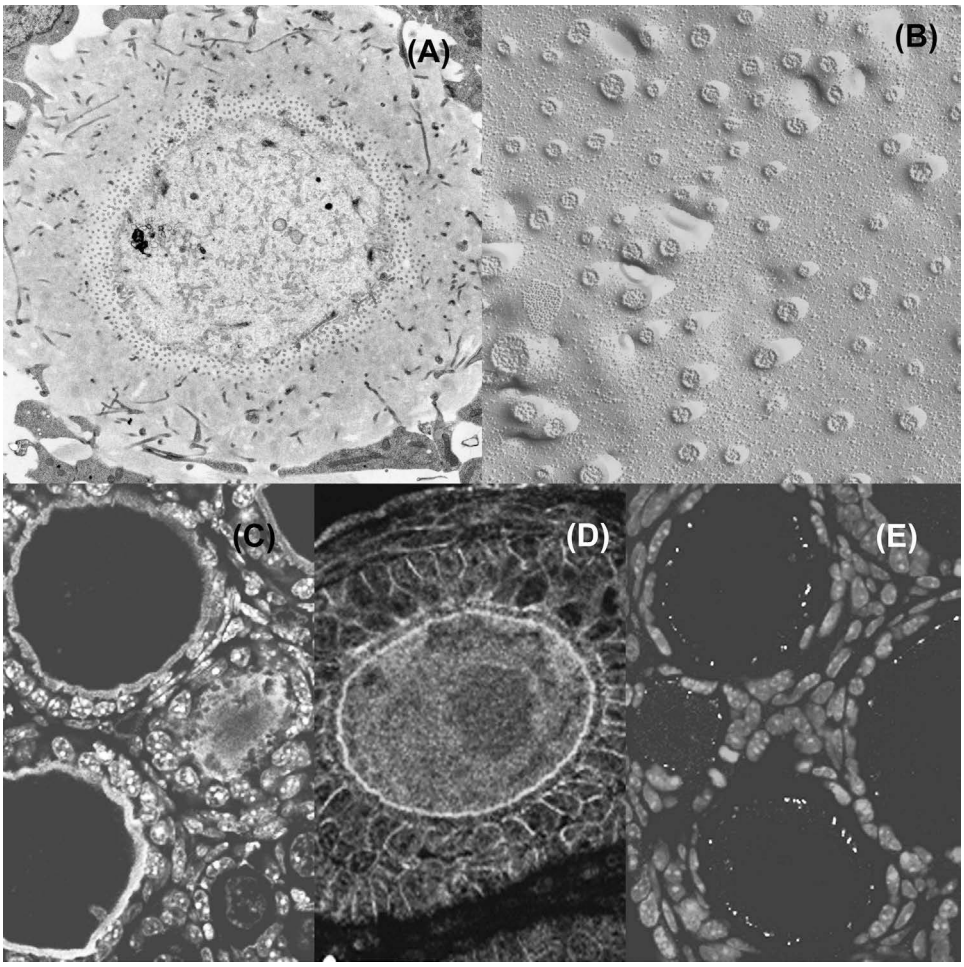

FIGURE 2.9 Membrane and extracellular coats in mammalian ova. (A) is an electron micrograph of a tangential section through the cortex of a mouse oocyte; note the extent of the zona pellucida and the penetration of numerous TZPs. (B) is a freeze-fracture electron micrograph through the oolemma of a rabbit oocyte showing the cleaved bases of microvilli and a solitary gap junction. C, D, and E illustrate disposition of ZP3 (C), beta-catenin (D), and CXN 37 (E) detected immunocytochemically on sections of adult mouse ovary.

The somatic cell projections are known as transzonal processes (TZPs) and will be dealt with in greater detail below. As the oocyte develops, the oolemma acquires a microvillus character that remains homogeneous until the time of oocyte maturation when the entire cortex becomes remodeled. As shown in Figure 2.9(B), a freeze-fracture image through the oolemma, the lawn of microvilli extend into and are anchored to the ZP, affording structural stability to the oocyte cortex. Additional membrane specializations reinforce the oocyte cortex as the process of growth comes to an end. These include the localization of the cell adhesion protein beta-catenin (Figure 2.9(D)) and the appearance of secretory granules containing zona proteins (Figure 2.9(C)) that gradually accumulate in the cortex as the oocyte enlarges. The most well-studied of the secretory vesicles is the cortical granule,[8] which along with the role of the ZP in mediating sperm–egg interactions[97] (see Chapter 4), demonstrate that the maturation of the oocyte cortex is designed, and the specializations contained therein, to ensure formation of the conceptus.

Cortical granules have long been understood to establish the block to polyspermy due to their secretion upon fertilization. But the pathway to assuring exocytosis is regulated in discrete steps, at least as shown in studies on the mouse oocyte. For example, Ducibella and colleagues showed that cortical granules and calcium sequestering vesicles are accumulated in full-grown oocytes and confer fusion competence to cortical granules that is independent of the distance between cortical granules and the oolemma.[98] Physical approximation of cortical granules and fusion competence were attained during the course of meiotic maturation, implying a major restructuring process that demarcates the boundary between the prematurative and maturative stages of oogenesis.[99] But the degree of cortical remodeling is significant for other reasons besides fertilization preparedness. As the meiotic spindle assumes its cortical location, a cortical granule free domain appears over the spindle, evidencing the first obvious signs of cell polarity. In the mouse, the mechanism underlying clearance of cortical granules from this region has been shown to be driven by chromatin.[100]

Several additional membrane specializations have been recognized as central features of the mammalian oocyte that further illustrate the mosaic nature of the oolemma. These include cholesterol-rich lipid rafts that are inherited by the embryo[101] and participate in

the process of fertilization in the mouse.[102] Moreover, a variety of junctional specializations have been identified in the oolemma. It is thought that connexin-based gap junctions and adhesion junctions play a central role in communication and signaling between the oocyte and surrounding granulosa cells.[103] Of these, GJA37 has been shown to be the predominant connexin in mouse oocytes, but there is growing evidence that multiple connexin types exist in various mammals[104] with full classification awaiting the use of oolemmal proteomics.[105]

In conclusion, the compartmentalization and cellular specializations first suggested by ultrastructural

Vet-ebooks.com

studies of mammalian oocytes have been reinforced and extended in recent years to provide a more complete picture owing to the adoption of new technologies. The landscape that emerges is one that emphasizes the role of stage-specific modifications in oocyte gene expression that will serve the full-grown oocyte as it engages in and proceeds through meiotic maturation, fertilization, and the cleavage divisions of embryogenesis (Figure 2.10). These advances pale by comparison to the new knowledge accumulated over the past 20 years regarding the molecular biology of the mammalian oocyte during the growth phase of oogenesis.

THE GROWTH PHASE OF OOGENESIS

Patterns of Gene Expression

If one major theme fairly summarizes what has been nearly two decades of research on gene expression in mammalian oocytes, it is that feedback loops precisely regulate the pattern of gene expression toward the end of integrating the oocyte with the follicle, ensuring competencies that the oocyte must acquire, and depositing a genetic framework in time and space that is essential for the initiation and progress of embryonic development (Figure 2.10). While gleaned mostly from studies on the mouse,[28] these thematic issues find practical application in deepening our understanding of human oocyte biology at a level materially greater than what could have been imagined before the introduction of human ARTs. The pioneering efforts of Wassarman necessarily emphasized expression of abundant genes that were accessible with the technology available at that time.[106] Fast forward to the era of genomics and the exploitation of the mouse genome with transgenic approaches and, as illustrated in Figure 2.10 (and discussed in Chapter 21), we have witnessed the revelation of genetic networks driving the earliest stages of oogenesis as entry into meiosis and the growth phase are identified and characterized at the level of specific genes with demonstrable functions.[107,108]

Probing the upstream control of the birth of mammalian oocytes has uncovered first principles of gene expression in mammalian oocytes. Most significant among these was the discovery of the *Nobox* gene as a central regulator of follicle assembly and prime mover for genes with exclusive expression in the female germ line.[109] *Nobox* emerged as a transcription factor regulating the promoters of *Gdf9* and *Pouf51* based on this work, and set the stage for establishing a launching pad required for both the survival and eventual differentiation of the oocyte. Key players in this definitive transcriptional network include the transcription factors *Sohlh1*,[110,111] *Sohlh2*,[112] and *Lhx8*.[110] Excellent reviews on this subject have appeared[107,108] placing into context the linkage of these genes with subsequent patterns of transcription that had already been associated with advancing stages of oogenesis.

Among the downstream genes generally again bearing an oocyte-specific character of expression are *Bmp15*[113] and *Gdf9*.[114] Whereas *Gdf9* knockout mice exhibit a characteristic early block at the primary follicle stage with signs of aberrant oocyte growth, the phenotype of the *Bmp15* knockout mouse exhibits a temporally distinct later defect in oogenesis with more complex gene dosage requirements. The basic helix–loop–helix transcription factor *Figla* is another oocyte specific gene identified by the Dean laboratory that acts uniquely during the initial stages of oogenesis to promote oocyte gene expression but suppress gene expression in the male germline.[115,116] Thus, transgenic manipulations in the mouse have collectively provided a roadmap of interactions between oocyte-specific genes essential for the birth, survival, and earliest stages of oocyte differentiation (Figure 2.10). The more complete listing of oocyte-specific genes and their expression profiles have also been obtained through the use of transcriptomic approaches.

Using the strategy of single cell RT-PCR, individual mouse oocytes recovered follicles ranging from primordial to antral stages and transcript abundance was assessed semi-quantitatively with respect to the oocyte-specific genes *Nobox, Oct4, Bmp15, Gdf9, Oogenesin1,* and *Oogenesin*.[117] While transcript abundance for all of these genes exhibited a progressive increase during what would be equivalent to the growth phase of oogenesis in untreated mice, some subtle changes in expression were noted if oocytes were collected from animals receiving exogenous stimulation. Not surprisingly, upon completion of the growth phase, transcript numbers decreased progressively up to the metaphase two stage, with values very similar to those obtained for the primordial oocytes in both analyzed conditions. The transition from growth to pre-maturation was accompanied by enhanced expression of *Nobox* and *Oogenesin2* genes, whereas *Oogenesin1* was diminished. It was concluded that coordinate regulation of the *N*obox and *Oct4* genes distinguished oocytes with high developmental potential from those of lesser competence; the validity of these observations was strengthened by the corresponding demonstration of protein expression that is typically absent from transcriptomics studies of this kind. It is relevant to point out that associations between patterns of gene expression and developmental competence often invoke the use of the NSN and SN chromatin configurations as competence biomarkers at the time of transcriptional silencing. But the validity of this association remains questionable, as noted above, even though potential candidates for regulating gene

Vet-ebooks.com

switching, such as the TATA-binding protein have been implicated at specific stages of oogenesis and embryogenesis in the mouse.[118]

Central to any discussion that attempts to link differential patterns of gene expression in the oocyte to the growth, pre-maturation, and maturation stages of oogenesis and the later events of fertilization and embryogenesis is the state of knowledge regarding the specific products of transcription and their impending translational utilization and/or degradation. Some oocyte gene products are assigned functionality during oocyte differentiation whereas others are clearly reserved for use in the embryo. The latter, as mentioned previously, comprise the family of so-called maternal effect genes, of which *Spindlin* is one of the first to be identified.[119] But for the vast majority of transcripts made in the oocyte that define the female germ line in its "pre-totipotent" state, abundance and selectivity in processing and stability remain the *raison d'etre* for their existence.

One of the first in-depth transcriptomic studies took advantage of the ability to not only separate specific stages of mouse oocyte development from one another but also cultured oocytes isolated at one particular stage of development through to a later stage.[120] These and subsequent studies from the Eppig and Schultz laboratories revealed somewhat surprising trends in the overall complexity of gene expression in addition to more predictable features consistent with the eventual transcriptional silencing known to occur once the growth phase of oogenesis had been completed. Among these were the abundance and variety of transcripts evident in the primordial and primary oocyte and timely appearance of competency genes associated with the cell cycle and cytoskeleton alterations effected at later stages of oogenesis. When superimposed with results obtained from the same group of investigators for patterns of transcript degradation,[121] a complex scenario emerges for the regulation of gene expression that begs the overarching question: How is such a delicate balance between transcription, translation, and degradation of mRNAs accomplished with temporal and spatial precision in mammalian oocytes destined for life after fertilization? And a necessary corollary with clinical implications: To what extent are artificial conditions imposed by exogenous gonadotropin stimulation or in vitro manipulations directly or indirectly perturbing gene expression so as to compromise developmental potential prior to or following fertilization?

Evidence cited above for the mouse[117,120] has been confirmed and extended in other mammalian species,[122] with the resounding conclusion reached that indeed manipulations of the ovarian environment in which oogenesis must proceed do have a long and lasting influence on oocyte and embryo quality parameters that likely underscore some of the observed deficiencies apparent in offspring generated by ARTs.[25,41,42] One of the principal targets for explaining the etiology of such conditions has revolved around the discovery and subsequent investigation of genomic imprinting within the germline.

Classically recognized by the allele and gender-specific hypermethylation of promoter elements of certain genes, the critical role subserved by the family of dimethyl transferases expressed during oogenesis on embryonic development first came to light in the studies of Howell and colleagues in 2001.[41] With this formative finding, and the studies that followed, the general patterns of demethylation and remethylation have been well-established in the mouse, as summarized in Figure 2.11.

At the heart of how genomic imprinting effects oogenesis and later embryogenesis is the demonstration that the housekeeping methyltransferases responsible for de novo cytosine methylation in the oocyte genome (*Dnmt3a, Dnmt3b,* and *Dnmt3L*) are expressed in a temporally specific pattern during the growth phase of oogenesis, and the translation product for one of these, known as *Dnmt1o*, is stored in the cortex of the mouse oocyte until the eight-cell stage of development when it is deployed for the remethylation of zygotic genes.[42,123,124] This remarkable case of spatial and temporal control of gene expression during the course of an early stage of oogenesis exemplifies the role of maternal effect genes on development

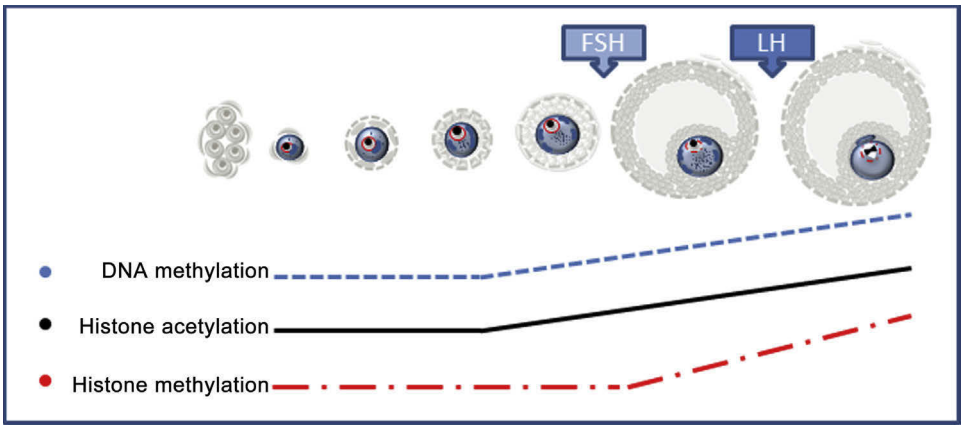

FIGURE 2.11 Epigenetic modifications of chromatin during the course of oogenesis. This figure is reproduced in color in the color plate section. Genes subject to imprinting show progressive signs of DNA methylation beginning during the growth phase of oogenesis and ending at some point in the preovulatory follicle. Histone acetylation in developing oocytes follows a similar time course as DNA methylation, whereas histone methylation is reported to occur following the growth phase. Data are based primarily on studies in the mouse.

Vet-ebooks.com

of the embryo. It places special significance on the link between oogenesis and embryogenesis in demonstrating a separation of function between the expression and utilization of *Dnmt* genes designated either for gametogenesis or development and proffers a plausible mechanism for how the maternal effect genes play out their accorded functions following fertilization. The list of maternal effect genes continues to grow (Table 2.2) and includes gene products likely to play similar roles in genetic or epigenetic processes conferring embryo quality.[27] In this category, *Tubg1*,[125] *Stella*,[126] *BRG1*[128], and *Basonuclin*[129] have been investigated and the recent studies on *Ring 1* and *Rnf2* set the novel precedent for components of the Polycomb-repressive complex 1 (PRC1) regulating chromatin remodeling during both oogenesis and embryogenesis.[127]

TABLE 2.2 Maternal Effects Genes Identified in Mammalian Oocytes

Name	Protein Function	Embryonic Defect	References
Mater (NLRP5)	Transcription enhancer	Two-cell block	26
Tle6	Transcription enhancer	Two-cell block	27
Zar1	Unknown	One-cell block	27
Padi6	Peptidyl arginine deiminase	Two-cell block	93,96
Filia	Unknown	Cell cycle delay	27
Floped (0oep)	Unknown	Cell cycle delay, abnormal cleavage	27
Tubg1	Microtubule nucleation	Blastocyst block	125
Dnmt1o	DNA methyltransferase one	Compaction block	41,124
Stella (Dppa3)	Methylation maintenance	Compaction block	126
Npm2	Nucleoplasmin two chromatin remodeling	Two-cell block	69
Ring 1, Rnf2	Transcriptional repression	Two-cell block	127
Spindlin	Unknown	ZGA	119
BRG1	Unknown	ZGA	128
Basonuclin	Nucleolar organizer	Two-cell block	129
TBP-2	TATA binding protein	Unknown	118

Abbreviations: MATER, maternal antigen that embryos require; DNMT1O, oocyte specific isoform of dimethyl transferase; ZGA, zygotic gene activation.

From a functional perspective, there is some indication that the products of some maternal effect genes may contribute to the loss of genetic stability that is associated with maternal aging in mouse models.[130]

And finally, for the sake of thoroughness, it should be emphasized that the relatively recent discoveries of small interfering (siRNAs), micro (miRNAs), and long-noncoding (lncRNAs) RNAs (see Chapter 52) will add a level of complexity to our understanding of gene expression in the mammalian oocyte that is only beginning to be unraveled.[131]

Regulation of Protein Synthesis

Just as we have seen for the expression and utilization of RNAs, so, too, the products of translation follow a temporal pattern that coincides with the major transitional milestones of oogenesis in mammals. These have been referred to as translational cascades extending well beyond the formal purview of oogenesis, given the inescapable contributions the oocyte makes to the embryo, a trait that is widely conserved among metazoans but adjusted to meet the demands of each species depending on the reproductive strategies displayed.[132] One of the most dramatic modifications, splendidly illustrated in the case of the oocyte, is the divergence in the processing of mRNAs for purposes of translating constitutive proteins, like those comprising the cytoskeleton or macromolecular entities such as organelles, from those proteins whose function is restricted to specific stages of oogenesis.[15–18] What has made it possible to distinguish between protein synthesis of the constitutive variety compared to that of a more regulative kind is the introduction of siRNA technology in conjunction with antibody neutralization and microinjection, and the attendant identification of oocyte proteins with limited lifespans.

The most tractable category of proteins studied in this way is those involved with cell cycle regulation. As mentioned earlier, developing oocytes acquire a series of competencies, the manifestation of which is generally realized by removing the oocyte from its in vivo context and assaying a change in behavior under in vitro conditions (Table 2.1). This experimental paradigm has been used to establish meiotic,[51] cortical granule fusion,[98] and embryonic competencies.[128] The expression of meiotic competence, manifest by the breakdown of the GV and progression to metaphase of meiosis one, is a clear example of a G2 to M cell cycle transition. Among one of the first proteins in mammalian oocytes whose mechanism of translational regulation was well-studied is cyclin B, the regulatory subunit that drives cell cycle progression from G2 into M phase. The timely translation of cyclin B mRNA is now known to require modifications at the 3′ untranslated region that control interaction of the

Vet-ebooks.com

cytoplasmic polyadenylation binding element (CPEB) necessary to initiate readout.[133] Coordinating CPEB phosphorylation, a requirement for translation initiation, is itself modulated by cell cycle status, thus ensuring synthesis of a burst of cyclin B to sustain M-phase progression through all of meiosis one and up to metaphase two arrest, itself a cell cycle arrest condition dictated by the c-mos proto-oncogene. In fact, many of the key cell cycle transitions exhibited in mouse oocytes appear to be mediated by selective translation of cell cycle regulatory proteins whose mRNAs are synthesized and stored at times preceding their actual utilization.[134] This is not likely to be the case in other mammals.

That protein synthesis is required for the G2 to M transition in nonmurine oocytes was first recognized in several species of primates,[12,135] along with the demonstration by Osborn and Moor[136] that de novo gene expression was an absolute requirement for germinal vesicle breakdown (GVBD), the morphological indication that cell cycle re-entry has indeed taken place. Thus, unlike the spontaneous progression from G2 to metaphase of meiosis one observed in the mouse, most other mammals require de novo protein synthesis and active transcription to reinitiate the meiotic cell cycle. That there is much more behind the various means of translational regulation in mammalian oocytes besides interspecies variations is also evidenced by differences in protein phosphorylation that discriminate between nuclear and cytoplasmic maturation[137] and the discovery of a new class of RNA granules seemingly acting as cyclin B mRNA storage sites that must be disassembled as a prerequisite for translation.[138]

As deeper databases of the transcriptome and proteome[139] become available, new levels of complexity for the control of translation in mammalian oocytes will become evident and redirect the current focus of attention. In the meantime, caution continues to be warranted in this area of oocyte biology. Eichenlaub-Ritter and Peschke have called attention to variations in translational efficiency in in vivo– and in vitro–produced oocytes that may underlie the loss of oocyte quality observed under culture conditions as well as implicated translational control in the etiology of oocyte aging and aneuploidy.[140,141]

Protein Posttranslational Modifications

A rapidly moving, but still immature aspect of mammalian oocyte biology is that of protein posttranslational modifications (PTMs). Here, too, there has been a focus on the alterations in protein function that mediate the maturative stages of oogenesis involved with key cell cycle transitions,[137] but the recent work remains descriptive. The kinds of studies performed to date have relied upon the use of PTM-specific antibodies to localize changes in candidate proteins at a microscopic or biochemical level[142] and suffer from a number of limitations. Among these are the lack of reagent specificity, the paucity of material available, and the quantitative limitations imposed by nuclear magnetic resonance mass spectroscopy approaches that have become the approach of choice in studies of other cell types. Because the work on oocyte PTMs has more direct bearing on the subject of meiotic maturation, the key advances in this area will be covered in the section Maturation Phase of Oogenesis: The Final Act.

Epigenetic Modulation of the Genome

The broad definition gaining acceptance for the field of epigenetics is one that engages the genome as a modifiable construct within which changes in gene expression are attributed not to alterations in nucleotide sequence but to modifications in the structure of chromatin that not only regulate patterns of gene expression but effect long-term performance of the genome at times distal to the original modification (see Chapter 52). With this principle in mind, we have already introduced the notion of genomic imprinting, and in so doing emphasized how the expression of enzymes responsible for promoter methylation impact de novo methylation during oocyte growth and methylation of imprinted genes later in development.[42,123,124] Here, we turn our attention to the more specific matter of when these epigenetic modifications occur during the course of oogenesis and why these alterations in the oocyte genome are relevant to the zygote (Figure 2.11). As a prelude to this section, it should be noted that understanding the epigenetics of oogenesis ultimately led to the production of the first completely parthenogenetic offspring in a mammal.

In an elegant series of nuclear transplantation experiments using mouse oocytes, Kono and colleagues first established that the epigenetic marks conferring developmental competence were acquired during the growth phase of oogenesis[143] (Table 2.1). They then went on to demonstrate that the completion of oocyte growth was required for maternal imprinting[144] and direct manipulation of gender specific methylation marks overcame the restricted development previously observed in digynic parthenotes.[145] Following this accomplishment, the birth of the first viable and reproductively competent mice was reported[146] and the insights gained from these experiments on the expression of imprinted genes has since been exploited to improve the overall efficiency for producing bimaternal offspring.[147] Not to be constrained with their work on the mouse, this group is now applying their experimental stratagem to the bovine oocyte with hopes of further dissecting the pattern of genomic imprinting in other mammalian species.[148]

Vet-ebooks.com

In this regard, several outstanding questions remain. Are there similar temporal properties for executing methylation in the oocytes of other mammals? When one considers the relative brevity of oogenesis in the mouse (c. 20 days) compared to that of the human (c. 100 days), is the expression pattern for *DNMT*s and the storage of *DNMT1o* in the oocyte cortex a rodent attribute or one generally shared with the oocytes of other mammals? And in addition to DNA methylation, a number of histone modifications collaborate with *DNMT*s to effect the chromatin remodeling needed for successful imprinting that have yet to be fully studied. One report has appeared implicating histone methylation in the expression of meiotic and developmental in cat oocytes.[149]

Clearly, epigenetics will continue to be an important area of enquiry in the field of oocyte biology and recent work is already expanding the molecular mechanisms at play beyond those of the traditional methyltransferases given the discovery of Tet enzymes in the female germline that hydroxylate 5-methyl cytosine residues, as recently reported by the Zhang laboratory.[150]

Coordination of Oogenesis with Folliculogenesis

Research over the past decade has contributed to a deeper understanding of how the oocyte is tightly integrated with the follicle (Figure 2.2). The emphasis placed on this topic, and the compelling body of evidence supporting it, make clear that the processes of oogenesis and folliculogenesis are not dissociable from one another. The physiological manifestation that arises from the integration of the somatic and germ cells within the follicle is manifold with each cell type contributing to the stepwise differentiation of its companion cell. As shown in Figure 2.12, integration appears to be accomplished through the deployment of distinct signaling pathways that operate at sequential stages of oogenesis that range from direct communication via gap junctions to the feedback control exercised by the array of growth factors implicated at various steps beginning with follicle activation. Thus, timely differentiation of the oocyte or granulosa cell necessitates deployment of diverse signaling pathways, the consequences of which are alterations in gene expression, cell cycle status, survival. and differentiation commencing with the initiation of follicle development,[152] as discussed in Chapter 21.

Momentum for this concept first arrived with the demonstration of the potent array of influences that the oocyte can impose on the surrounding granulosa cells (GC). Thus, oocytes were shown to promote GC proliferation,[153] enhance FSH-induced expansion of the cumulus,[154] suppress the expression of the LH receptor gene (*Lhr*),[155] regulate synthesis and secretion of kit ligand,[156] maintain metabolic cooperativity,[157] and modulate cumulus cell mitogen-activated protein kinase (ERK1/2).[158] While this work was being carried out in the mouse, the broader implications of oocyte influences in the follicle were made apparent with the realization that the oocytes' developmental potential was a byproduct of enforcing this bidirectional interaction[159,160] beginning with the elaboration of the hyaluronate-rich matrix at ovulation which ensures ovum capture[161,162] (see Chapter 22). As noted in Figure 2.1, the GCs of the follicle are of two types. Those immediately in contact with the oocyte are known as

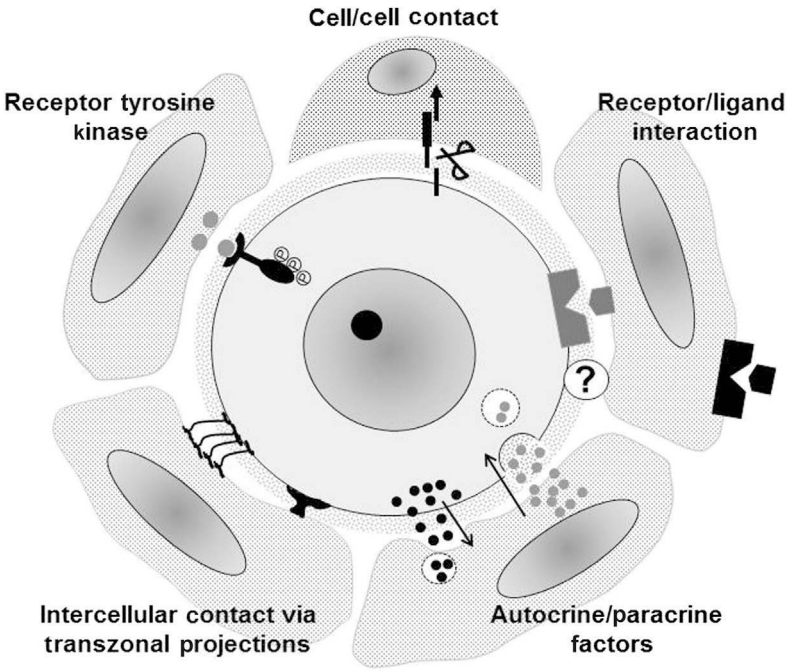

FIGURE 2.12 **Diagram summarizing types of signaling interactions known to exist between oocyte or granulosa cells that impact the survival, growth, and differentiation of the oocyte.** Cell–cell contacts involving proteolytically cleavage-based receptor activation shown at top and counterclockwise examples include receptor tyrosine kinases such as c-kit ligand, direct gap junction–mediated communication via transzonal projections, paracrine modes of communication involving secretion and/or uptake of ligands, and classical receptor–ligand interactions expressed on the granulosa cell surface but not confirmed for the oocyte cell surface (?). *Source: Image is redrawn from McGinnis et al. (2012) where specific examples are cited[151] and content is based primarily on results from targeted gene deletion experiments in the mouse.*

Vet-ebooks.com

cumulus GCs, whereas those lining the wall of the follicle are known as mural GCs. The latter are the precursors of the luteal cells that will produce progesterone after ovulation, while cumulus GCs mediate metabolic support of the oocyte during growth and maturation.

The documentation of metabolic integration between oocytes and GCs is one of the most significant outcomes from this line of investigation[163] (Table 2.3). Specific ion transporters in the oocyte require cumulus GCs for their regulation during maturation,[170] and modulation of calcium impacts oocyte survival via caspase-2.[168] The broad spectrum of events occurring during the various stages of oogenesis which are reliant on somatic cells is but one manifestation of how the oocyte influences follicle development, currently envisioned to be mediated by oocyte-secreted factors like GDF9 and BMP15.[159] But the reverse is also true; the granulosa cells direct specific developmental transitions in the oocyte.

One of the best examples of this pertains to the process of meiotic competence acquisition (Table 2.1). In the mouse, meiotic competence acquisition is strictly correlated with the size of the oocyte. Whether oocytes initiate but fail to complete maturation in vitro distinguishes those oocytes that have acquired only partial rather than complete competence.[51,171,172] As noted previously, the gradient reflected in meiotic competence according to a growing or fully grown state is also linked to the acquisition of genomic imprinting[42] and the accumulation of cell cycle factors whose posttranslational modifications indicate the earliest signs of a G2 to M cell cycle transition.[172,173] Follicle culture experiments have further established that meiotic competence acquisition can occur ex vivo, but also emphasize that excess gonadotropin can delay or inhibit the acquisition of full competence as a result of deficiencies in metabolic cooperation.[174–177] These studies and others implicate failure to maintain oocyte chromatin in an open NSN state as one consequence resulting in competence acquisition impairment in rodents and primates.[174,178] It is interesting to note that among the genes whose continued expression seems necessary for continued growth and competence acquisition in rodents is the transcription factor *Oct4*.[179]

TABLE 2.3 Metabolic Substrate Sharing between Granulosa Cells and Oocytes

Substrate	Contact-Dependent	Documentation	References
Pyruvate	Yes	Tracer-based	19,164
Alanine	Yes	Tracer-based, Transcriptome Monitoring (TM)	165
Cholesterol	Yes	Tracer-based, Transcriptome Monitoring (TM)	157
Glutathione	Yes	Direct measurement of oxidative metabolism (REDOX) potential	163,166,167
Calcium	Yes	Ratiometric measurement	168
Cyclic guanosine monophosphate	Yes	Tracer-based	169
Bicarbonate/chloride exchange	Yes	Tracer-based	170

Contact-dependent refers to the requirement for cell coupling between oocyte and granulosa. Documentation refers to radioactive tracer usage (tracer-based) or transcriptome profiling to validate expression of enzymes in a given metabolic pathway as present in granulosa and absent in oocytes.

In summary, the initiation of oocyte growth within the follicle is critically dependent on the maintenance of an integrated metabolism between oocytes and GCs (Figure 2.12). This dialogue forms the basis for modulating the progressive differentiation of oocyte and GC and appears to be a conserved feature for mammalian oocytes that will eventually ensure full developmental competence[165] as specific genes are identified and their interactive networks documented.[180] This has been achieved in the mouse, where a series of transgenic lines have been used to map out the network of genes responsible for maintaining quiescence or activating primordial oocytes, a topic recently reviewed[181] (see Chapter 21). What has remained more elusive, however, is the definition of pathways for communication that would mediate the sequential episodes of signaling during and after the growth phase.

One of the first modalities for signaling identified was that of the gap junction, a well-established plasma membrane specialization known to mediate metabolic cooperation between cells (Figures 2.1, 2.12, and 2.13). First described by Zamboni,[182] freeze fracture electron microscopy verified the existence of gap junctions between granulosa cells and oocytes in several mammalian species and implicated gap junctions in the exchange of molecules that would maintain meiotic arrest.[23,183,184] Dekel and Beers then provided direct evidence for their role of oocyte-granulosa cell contact in the transport of cAMP.[185,186] Eppig and colleagues have since summarized these and other findings to elaborate a tractable scheme for the role that gap junctions play in conjunction with paracrine modalities of communication to effectively syncitialize the oocyte and its companion GCs[62] throughout the course of oogenesis,[31,187] explaining in part their earlier observations implicating GC support in the acquisition of developmental competence.[188] One of the more elegant examples of how paracrine signaling and heterocellular contact ensure metabolic synergy between oocytes and granulosa cells derives from the demonstration of cholesterol synthesis in the cumulus cell supplying the oocyte with stores of this substrate, since

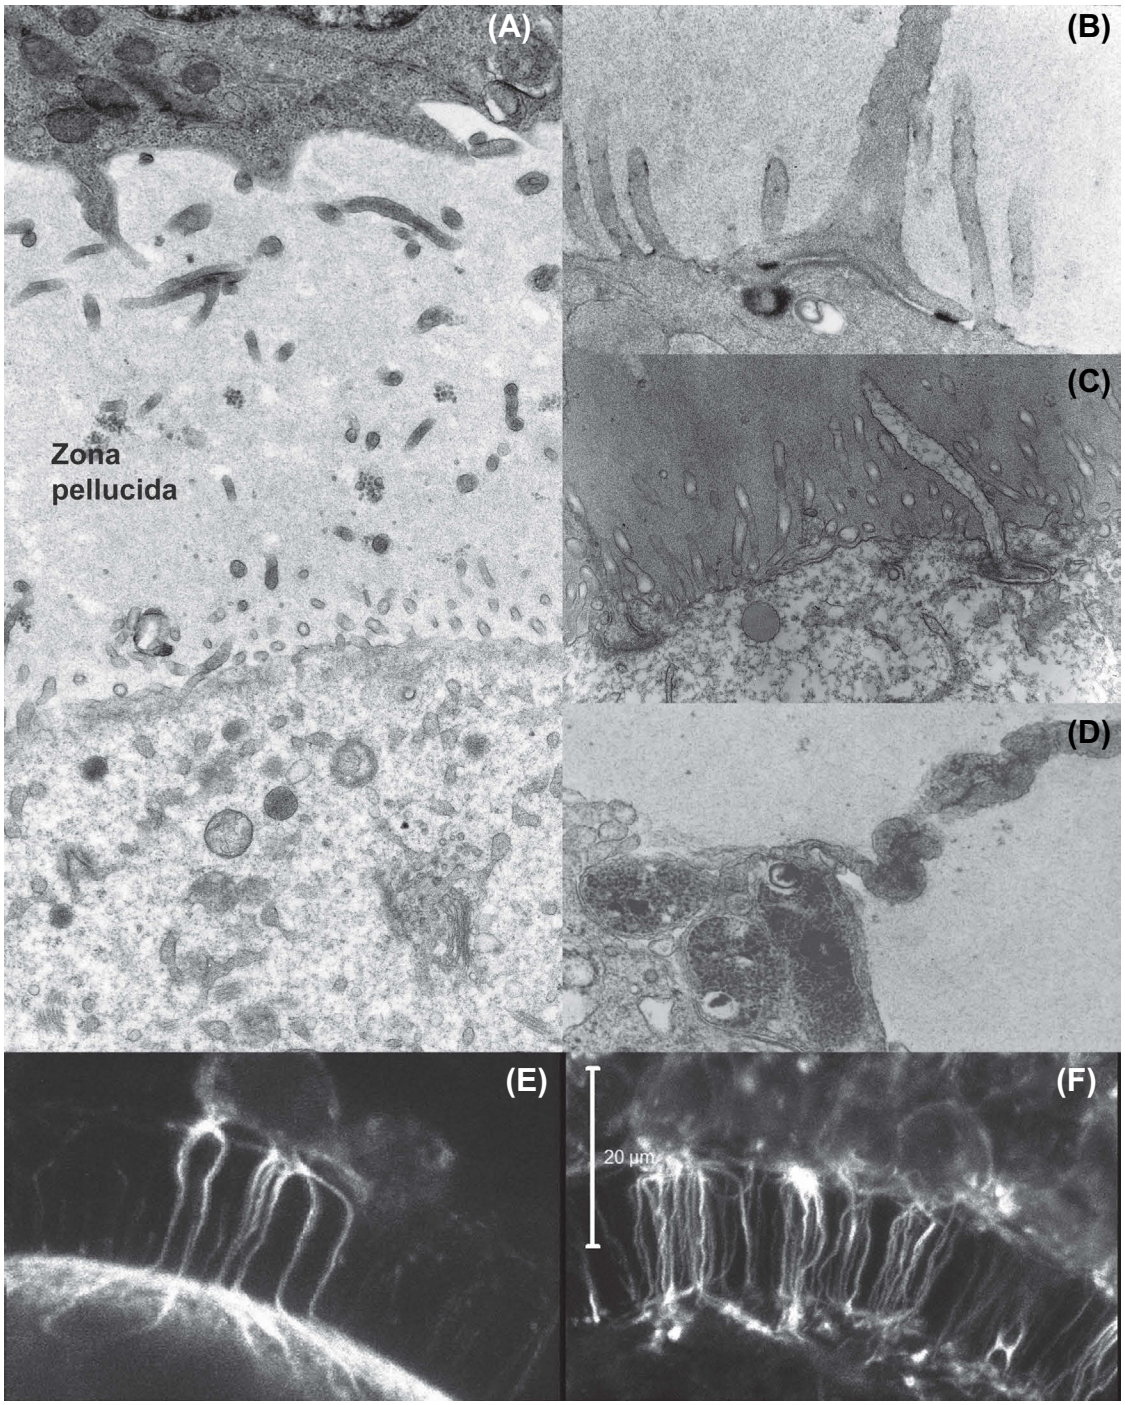

FIGURE 2.13 Appearance and structural organization of transzonal projections (TZPs) between somatic granulosa cells and oocyte during oogenesis and in different mammalian species. The electron micrograph in (A) is from a full-grown mouse oocyte within an antral follicle; portions of a cumulus cell are at the top, and in descending order, TZP roots are apparent at the outer margin of the zona pellucida traversing through the zona and attaching to the microvillus-rich oolemma (bottom). (B) and (C) are electron micrographs of rhesus macaque oocytes in which the planar attachment of the TZP is situated between oocyte microvilli; the dark reaction product in (B) highlights the location of gap junctions at the terminus of the TZP. (D) The TZPs after oocyte maturation are less dense and take on a highly tortuous course terminating as large dilations filled with various organelles (in vitro matured porcine oocyte, courtesy of Virginia Rider). (E) and (F) are three-dimensional projected views from a confocal stack of images which illustrate the arborization of TZPs from immature bovine oocytes retrieved from Graafian follicles; the preparation was labeled with rhodamine phalloidin and highlights the density of actin filaments within the TZPs and at attachment sites with the oolemma.

Vet-ebooks.com

the oocyte lacks and therefore must rely upon somatic cell–derived resources for its survival and development.[164]

In what may be referred to as the final act of oogenesis, the concept of metabolic regulation has been invoked to advance our understanding of the mechanisms involved at ovulation that foster release of meiotic arrest and the resumption of meiosis (Chapters 1 and 22). This field has been advanced using transgenic murine models and molecular physiology to unravel what has lingered as a controversial and yet pivotal event in the course of oogenesis in mammals (Figure 2.14). The cascade of signaling events elicited by the LH surge at ovulation is now believed to be initiated by de novo production of epidermal growth factor (EGF)-like molecules from the granulosa causing selective closure of gap junctions as a result of MAP kinase-dependent phosphorylation of connexin 43 gap junctions.[169,189] Modulating cyclic guanosine monophosphate[190] and EGF signaling pathways conspire to initiate and sustain meiotic progression[191] in a manner reminiscent of the interplay between gonadotropin and growth factor receptors in the regulation of follicular steroidogenesis.[192] Coupled with the genetic dissection of tumor growth factor-beta in other mammalian species,[193] the weight of the evidence supports the presence of a feedback loop of counteracting molecular signaling machines that ultimately serve to coordinate the processes of oogenesis and folliculogenesis to the benefit of yielding developmentally competent ova (Chapter 21).

The structural substrate for achieving integration of function within the follicle resides at the interface of the oocyte and granulosa cells. Transzonal projections (TZPs) were introduced above as specialized extensions from granulosa cells that penetrate the zona pellucida and attach to the oolemma.[182–184] Without TZPs, intercellular junctions could not exist. As noted above, gap junctions form at the TZP–oolemmal interface and in rodents are known to require interaction of connexin 37 subunits of oocyte origin with connexin 43 subunits originating from granulosa cell.[194] The changing architecture of the cumulus–oocyte complex during ovulation first implicated TZPs as regulators of meiotic maturation based on the persistence of gap junctions with the oocyte, but also raised the intriguing prospect for transport and delivery of molecules and organelles toward the oocyte as maturation proceeds.[195] In fact, the generalized notion that gap junction uncoupling engages cell cycle reentry in rodents does not appear to be operative in the oocytes of other mammals.[167] Studies on several lines of mice in which gene ablation has been imposed leading to fertility defects, following deletion of genes for GDF9, connexin 37, and the beta subunit of FSH (Figure 2.10), collectively establish the role of TZPs in the regulation of oocyte growth and meiotic competence acquisition and demonstrate a direct role for FSH in modulating their formation and stability.[64–66] It follows, then, that defects in TZP maintenance, and hence gap junction functionality, could lead to impairments in genomic imprinting that would compromise subsequent embryonic or fetal development, as has been recently demonstrated.[196] The possibility that must then be seriously entertained is that the original studies implicating TZP withdrawal as a signal for meiotic resumption[197] fail to identify the need for prolonging gap junction communication well into the maturative phase of oogenesis (Figure 2.2). In fact, it has been recognized for many years that the bovine oocyte acquires and accumulates reduced glutathione based on the metabolic provisions received by oocytes from the cumulus cells with which they maintain contact.[166] Reduced glutathione, required for remodeling of the male genome after fertilization, may then qualify as one of many metabolic substrates of somatic cell origin that serve to fuel the maturing oocyte as it acquires the final properties that will ensure developmental competence.

MATURATION PHASE OF OOGENESIS: THE FINAL ACT

Background: The Importance of Spatial Patterning

Certain generalizations can be gleaned from the foregoing discussion that set the stage for a comprehensive treatment of oocyte maturation. First, the cell cycle of

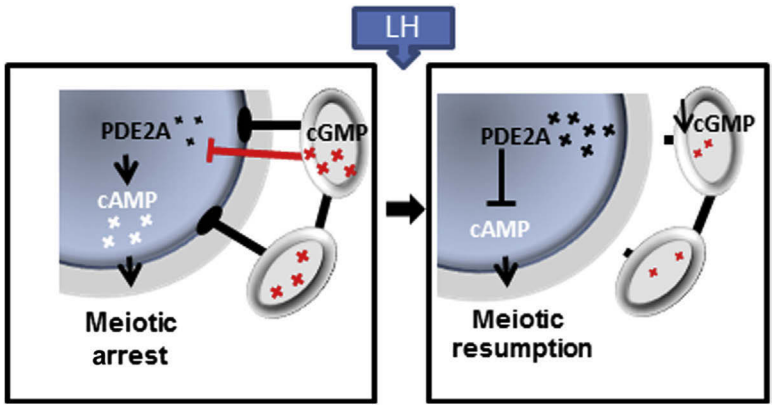

FIGURE 2.14 Modifications in cell communication proposed to explain the resumption of meiosis following the LH surge. Panel on left depicts the role of cyclic guanosine monophosphate as a meiosis arresting agent requiring an intact system of gap junctions. Following the LH surge (right panel), junctional uncoupling results in enhanced activation of oocyte PDE2A permitting the oocyte cell cycle to proceed from G2 to M-phase.

Vet-ebooks.com

the mammalian oocyte must acquire the molecular machinery needed to formally enact a G2 to M transition in order to complete meiosis (Chapter 1). Second, transcriptional competence following a profound period of gene expression becomes repressed, and will remain so until the zygotic genome reactivates after fertilization. Third, the fully grown but immature GV oocyte resting in a cell cycle arrested in diplotene of meiosis one awaits reception of somatic cell signals that will elicit meiotic progression to meiotic metaphase two, the state in which it will be ovulated (Figure 2.2). By inference, then, the maturative phase of oogenesis, encompassing a time course of hours in rodents to days in humans, must reliably support in a temporally and spatially regulated manner the final stage of oogenesis that will predate the onset of embryogenesis. Most of what we have learned about oocyte maturation over the past decade derives from studies in the mouse that address two questions: How is the cell cycle regulated? What role does the cytoskeleton play in preparing the oocyte for fertilization?

Insights into the molecular underpinnings of oocyte maturation have been reviewed in the context of the requirements that must be fulfilled to effect oocyte activation at fertilization and ensure embryonic development up to the point of zygotic gene activation[198,199] (Chapter 6). But the first principles drawn upon to explain switching the cell cycle from an off–on–off–on motif common to all mammalian oocytes have led to the realization that much of the cell cycle controls displayed are best understood through a consideration of spatial organization achieved primarily by the remodeling of the cytoskeleton. A striking example of this was first alluded to by Kubiak and colleagues, who showed that the critical switch governing the transition from meiosis to embryonic mitosis required the intact metaphase two spindle to elicit the prompt and complete destruction of the cyclin B.[200] Cytoskeletal control of oocyte maturation was also suggested by protein localization and gene expression studies confirming the importance of spatial patterning and compartmentalization of cell cycle molecules.[201–204] Bypassing inhibitory control elements[205] added further evidence for a role for microtubule stability in initiating GVBD,[66] as did new evidence identifying the involvement of protein kinase B.[206] Together, the landscape for the execution of meiotic competence takes on a level of complexity invoking control features of temporal and spatial dimensions.

Over a similar time period, characterization of the metabolic determinants for the maturative phase of oogenesis was taking place largely as a result of the continuing efforts of Downs and colleagues.[207] In fact, their original studies brought to surface the notion of EGF and FSH as players in the resumption of the oocyte meiotic cell cycle,[208,209] a subject that has received thorough coverage in a highly recommended recent review.[210] With the adoption of fluorescence imaging techniques affording greater temporal and spatial resolution, oocyte maturation has come under closer scrutiny. In this vein, Carroll and colleagues have now provided compelling evidence in support of the somatic cell influences for ATP provisions that guide and support the energy-consuming demands of the oocyte cell cycle.[26] It is important to emphasize the impact of cell culture on the study of meiotic maturation. The obvious benefits obtained from experiments conducted in vitro include the ability to control environmental conditions, carefully monitor and assay time-dependent processes, establish a paradigm conducive to live cell imaging, and afford the opportunity for subsequent in vitro fertilization and embryo culture permitting the evaluation of developmental competencies (Table 2.1). But adverse consequences from in vitro maturation have been noted in several mammalian species.[199]

The Meiotic Spindle: A Microtubule-Based Scaffold

The meiotic spindle is the major structure involved with the segregation of chromosomes at anaphase of meiosis one and meiosis 2 (Figure 2.15). Invariably, the spindle is anchored to the oocyte cortex and deploys centrosome proteins at the spindle poles. In mice, meiotic spindle organization is strikingly altered when in vivo matured oocytes are compared to oocytes matured in vitro.[211,212] Moreover, differences in culture conditions impact both spindle morphogenesis and the expression of developmental competence despite apparently normal rates of meiotic progression and efficiency.[213] In fact, modifications in culture media composition such as growth factor supplementation can have profound effects on embryonic developmental competence.[214] Importantly, with the move from using oocyte in vitro maturation as a basic science tool to one with clinical indications, there is a mounting practical imperative to explore and define conditions that will most likely recapitulate this phase of oogenesis in a fashion that limits disruptive influences on oocyte quality pertaining especially to defects in spindle organization that have been associated with aneuploidy.

Toward this end, the use of chemical agents that inhibit the spontaneous G2 to M meiotic cell cycle transition elicited when oocytes are removed from the follicle is an experimentally acceptable and widely employed manipulation that permits the synchronization of meiotic cell cycle progression. A number of studies have employed phosphodiesterase type–specific drugs to maintain G2 meiotic arrest in mouse[215] and human[216] oocytes, with generally favorable results with respect to the completion of maturation and demonstration of developmental competence. Comparative

gene expression profiling in human oocytes matured in vivo or in vitro has revealed differences in transcript abundance and type suggesting that in vitro conditions may compromise the stability of certain mRNA species whose significance awaits further research.[217] While exercising caution in the use of IVM for clinical purposes remains an important perspective for the treatment of infertility, the benefits cited above have been of enormous value in contributing to our understanding of the relationships between the cell cycle and cytoskeleton in animal models.

For in-depth coverage of the oocyte cell cycle, the reader is encouraged to see the review of Jones, which provides a complete description of the biochemical components that mediate the various starts and stops typically displayed by mammalian oocytes.[218] This foundational biochemical approach has complemented a series of more recent live cell imaging studies that have focused directly on processes such as spindle dynamics and chromosome segregation. Among the most telling of these are studies coming from the Ellenberg laboratory.[219] By introducing reporter constructs for the cytoskeleton, and tracking individual mouse oocytes over the course of meiotic maturation, novel insights have been obtained that provide a workable hypothesis for how, in the absence of classical centrosomes, MTOCs orchestrate the morphogenesis of the meiotic spindle through self-assembly intervals coinciding with important cell cycle transitions. The principle of "self-organization," especially as it applies to maturation-associated remodeling of the oocyte cytoskeleton, is gaining traction as a driving force that oversees the successful separation of chromosomes during meiosis and embryonic mitoses, a subject reviewed by Dumont and Brunet.[220] The biological relevance of studies of this kind bear directly on the problem of age-related aneuploidy and the mechanistic origins of chromosome imbalance propagated during meiotic maturation (see Chapters 1 and 37)

One likely mechanism contributing to female meiotic aneuploidy concerns the functionality of cell cycle checkpoints that in somatic cells eliminate imbalanced products of cell division. It appears as though the checkpoints engaged in mouse oocytes differ from those deployed in somatic cells in fundamental ways such that surveillance of the spindle is dissociable from the checkpoints that monitor chromosome position[221] (see Chapter 1). The mechanisms behind checkpoint control in mouse oocytes seem based on unique ways to ensure stability of cyclin B and in effecting activation of the anaphase-promoting complex/cyclosome (APC/C).[221–223]

Vet-ebooks.com

Whether comparable mechanisms are at play in human oocytes remains unknown.

The Oocyte Cortex: An Actin-Based Scaffold

One of the most distinguishing and universal features of mammalian oocytes is the asymmetric nature of cytokinesis that ensures the extrusion of polar bodies. Polar body extrusion serves two vital roles for the maturing oocyte. First, the spatial restriction of the contractile forces required to form both polar bodies guarantees that the byproducts of anaphase-1 and anaphase-2 chromosome segregation result in retention of one chromosome set in the ooplasm and one being discarded. Second, by limiting the size of the polar bodies, the oocyte is able to retain most of the molecular and organellar constituents destined for utilization and consumption in the zygote. This was first elucidated by Longo and Chen, who defined the mosaic patterning of the actin cytoskeleton and cortical granules at the ultrastructural level.[224] With the documentation of spatial reorganization for many organelles, and the suggestions of cytoskeletal dependence for inward or outward displacements,[98,225,226] only a fragmentary picture of cytoplasmic dynamics during oocyte maturation could be assembled with the exception of the more obvious events associated with meiotic spindle assembly and function noted above. Progress in this field was again limited due to the lack of experimental reagents and the compounding issue resulting from the effects of culture conditions on organellar redistribution.[227] In the end, tracking organelles in ooplasm fails to identify the operative motility systems in biochemical terms; and with rare exception, few pathways invoked in meiotic cell cycle progression appear linked to cytoplasmic reorganization. One possible link may be through the action of tyrosine protein kinases, based on recent studies in the mouse oocyte.[228]

FYN kinase exhibits activation latency with respect to the consequences of inhibition on later stages of meiosis involving spindle location and cytokinesis.[229] This kinase targets a spatially distinct cortical set of protein substrates when compared to the protein substrates targeted by the CDK1 kinase that drives the cell cycle.[230] In fact, recent studies on protein tyrosine kinase signaling suggest involvement in motility-based processes more in line with known actin cytoskeleton targets in somatic cells and influencing events in the zygote that follow the completion of maturation, a subject that has been recently reviewed.[231] This general theme of spatial organization and the possible role that the actin cytoskeleton plays was first raised by studies showing that the actin linker protein, beta catenin, was deployed in the oocyte cortex and used at later times in embryogenesis, confirming its identity as one of the first maternal gene products recognized in mammalian oocytes.[232] Since then, and as alluded to above, the role of calcium,[233] a potent modulator of the actin cytoskeleton, and the reorganization of calcium sequestering endoplasmic reticulum[234] among other organelles, raise the likelihood that fundamental remodeling events during maturation have both a short- and long-term impact on oocyte quality, possibly as a result of the selective activation of SRC family kinase members.[235] From a regulatory point of view, the historical focus on calcium metabolism, and the recent discovery of the role of zinc ions as a potent mediator of meiotic cell cycle progression,[236,237] imply the existence of a far more complex array of ionic factors that are likely to impact the oocyte cytoskeleton.

As noted above, the mammalian oocyte exhibits a distinct polarity in the mature metaphase two state and the actin cytoskeleton provides a driving force for the generation of polarity. Overlying the meiotic spindle, an actin-rich and microvillus free cap appears that is rich in myosin two and lacks cortical granules.[99,238,239] Chromosomes provide the signal for the localized reorganization within actin caps,[100] which have also been shown to contain markers of cell polarity such as usually encountered at the apical surface of epithelial cells.[240] The mechanism by which chromosomes exert their influence on actin reprogramization has been thoroughly studied and involves MAP kinase,[241] myosin light chain kinase,[242] and RAN GTPase.[243] As summarized in a recent review, the actin cytoskeleton in mammalian oocytes is a dynamic system that directs the establishment of cell polarity by a cytoplasmic streaming activity that positions and anchors the meiotic spindle in the cortex.[244] Significant biophysical alterations have been documented to occur as a result of the combined actions of the myosin two motor molecule and members of the Ezrin/Radixin/Moesin (ERM) family of actin-binding proteins.[245] In summary, remodeling of the cortex in mouse oocytes is a major feature of meiotic maturation that is essential for spindle migration and attachment, and stabilization of the microvillus portions of the plasma membrane. It seems likely that the positioning and localization of maternal effect gene products, as mentioned previously for MATER, which assumes a similar asymmetric disposition, is also dependent on the forces deployed to achieve cell polarity.[94] In the mouse oocyte, one additional cortical specialization deserves mention in the context of polarity as it has practical bearing on the topic of cloning.

Microtubule organizing centers were discussed earlier with reference to their role in assembly of the meiotic spindle. These structures are silenced with respect to their microtubule nucleation capacity at specific cell transitions such as metaphase of meiosis one or meiosis two, but upon anaphase onset they nucleate a cortical network of asters excluded from the actin cap.[78] In enucleated oocytes prepared for somatic cell nuclear transfer or cloning, MTOCs are retained ensuring the inheritance of maternal centrosomes in reconstructed embryos.[246,247] This situation implies that the introduction of a somatic cell into an enucleated oocyte will result in an admixture of

Vet-ebooks.com

centrosomes of somatic and maternal origin.[248] Cell cycle progress and chromosome segregation involve MTOCs due to their AURORA kinase-A activity, a situation that has been proposed to complicate cell cycle regulation in the embryo, especially after somatic cell nuclear transfer (SCNT).[249,250] The general theme that emerges from this discussion is that scaffold functions served by both actin-based and tubulin-based components of the cytoskeleton drive the maturative phase of oogenesis, and interactions between these components appear to be bridged by the family of proteins known as formins.[251,252] As shown in Figure 2.16, the remodeling of the cytoskeleton as finally enacted during the maturation phase of oogenesis also drives the positioning of organelles involved with developmental competence. Thus, CGs assume a subcortical location and maternal effect gene products become localized in anticipation of their recruitment for events such as compaction in the embryo (see Chapter 6).

Because most of our knowledge to date comes from studies on the mouse, it is difficult to predict the importance of cytoskeletal remodeling as manipulations of mammalian oocytes are attempted for clinical purposes. With some assurance, however, it can be stated that the requirements for egg activation imposed by SCNT have been met through a deeper understanding of the role of calcium transients[253] and their application to the production of cloned embryos in other mammalian species.[254] Moreover, when cytoskeletal dynamics as described above are manipulated in the context of the cell cycle state, the retention of egg quality contributes to an improved efficiency for procedures like SCNT[255,256] or embryo splitting.[257]

CLINICAL PARAMETERS OF OOCYTE BIOLOGY

The human oocyte is now well within the purview of contemporary research, given the enormous growth in the field of human ARTs. Because of the large-scale use of human oocytes for the treatment of infertility, and emerging strategies for fertility preservation including oocyte cryopreservation and in vitro follicle development, exploration of human oocyte biology has been realized. Thus, for the first time, modern investigative approaches are providing a knowledge base exceeded in content only by that ascribed to rodent animal models. What makes the human oocyte unique relative to those of other mammals is now gaining clarity and will soon aid in the diagnosis and treatment of reproductive disorders for which there has been little information with which to proceed. This section will introduce topics of clinical relevance in hopes of providing a basis of comparison between the human oocyte and those of other mammals. It is designed to guide and inform future work for purposes of therapeutic advancement.

Regulating Genetic Integrity

Among the distinguishing features of the human oocyte, relative to those of other mammals, is the high degree of chromosome imbalance that arises during oocyte maturation and early cleavage divisions of the embryo. What makes the human ovum so predisposed to genetic instability and what is the underlying basis for the age-related increase in aneuploidy? These questions prompt consideration of this problem on two levels that have been reviewed above. First, and at the level of the organism, advances in our general understanding of genetic stability have been contextualized for human oocytes at the mechanistic level with respect to the management of DNA damage. Second, data are now in hand that allow for a detailed examination of the origins of chromosome imbalance with respect to the relationship between the cell cycle and cytoskeleton.

Metazoans have evolved mechanisms for the detection and repair of DNA lesions that can be incurred by any variety of factors such as oxidative stress, chemotherapy, radiation exposure, or lifestyle conditions.

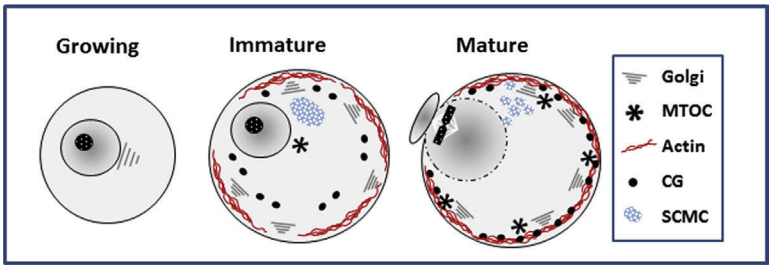

FIGURE 2.16 Illustration depicting the patterning of organelles and the cytoskeleton in mouse oocytes during growth phase (left), as a fully grown oocyte (center), and following meiotic maturation to the metaphase two stage (right). Legend shows summary of principal organelles that undergo remodeling, including the Golgi complex, cortical granules (CG), and the subcortical maternal complex (SCMC). Note dispersion of perinuclear Golgi into multiple subcortical complexes, elaboration of multiple microtubule organizing centers (asterisk, MTOC), and the assembly of a prominent network of f-actin that subtends the oolemma at all sites except where the spindle is located.

Vet-ebooks.com

Better known as the DNA damage and repair response (DDR), lesions in DNA elicit a cascade of enzymatic reactions localized to single- or double-stranded breaks that are repaired through high-fidelity (homologous recombination) or error-prone (non-homologous recombination) mechanisms as occurs during meiotic prophase (see Chapter 1). Transcriptome analyses of human oocytes and embryos have confirmed the expression of proteins for both of these repair pathways, and only recently has evidence been provided that the DDR is alive and well in human oocytes.[258] As the DDR serves as a vital checkpoint for genetic stability in somatic cells, failure to effectively repair DNA damage typically results in the elimination of damaged cells through a p53-mediated programmed cell death pathway. Given the hallmark attrition of oocytes accompanying aging in female mammals, analysis of this pathway in mouse models has been a point of departure for probing mechanisms of genetic stability in the female germ line.

As shown in Figure 2.17, the expression of DDR in the mouse follows a developmental course that utilizes a surveillance system that is distinct from both the male germ line and somatic cells. Rather than drawing upon p53 for execution of damaged cells, as occurs in somatic cells and sperm, the surveillance system in oocytes uses the p63 variant. This has been demonstrated using mice bearing a null mutation for TAp63 in which radiation-induced DNA damage results in oocyte loss due to apoptosis unless p63 is genetically ablated.[259] Earlier work had identified the protective role of TAp63 in eliminating damaged oocytes as they remain arrested in diplotene[260] and prompted the suggestion that the accumulation of DNA damage, as would occur during maternal aging or after inducing double-strand breaks, if carried through the course of oogenesis might explain why oocytes show an aneuploid tendency after ovulation. It remains unclear as to whether the TAp63-mediated checkpoint evident at diplotene is linked to age-related aneuploidy or whether distinct checkpoints operate at sequential stages of oogenesis to ensure genetic stability of fully matured mouse oocytes. This topic has been the subject of recent reviews.[261,262] One of the reasons for the lack of clarity in this field is due to the fact that both DNA damage–dependent and DNA damage–independent pathways have been shown to mediate oocyte loss.[263] In the case of DNA damage–dependent oocyte loss, recent mechanistic studies have identified mediators of oocyte elimination as described below.

A reliable marker for DNA double-strand breaks is an antibody that recognizes the gamma-phosphorylation of histone H2AX. Since the phosphorylation of this histone two variant represents the activation of the DDR, both the resident capacity for eliciting a repair response and the loss of signal signifying completion of repair can be monitored in sections of ovarian tissue. Using gamma irradiation to induce the DDR in neonatal mouse ovaries, Kerr, Hutt, and colleagues demonstrated that TAp63 elicits the expression of Puma gene as an effector of apoptosis.[264] Interestingly, a recent report implies that failure to complete the DDR impacts chromosome segregation. This study reports that the persistence of H2AX double-strand breaks is correlated with a loss of the apoptosis

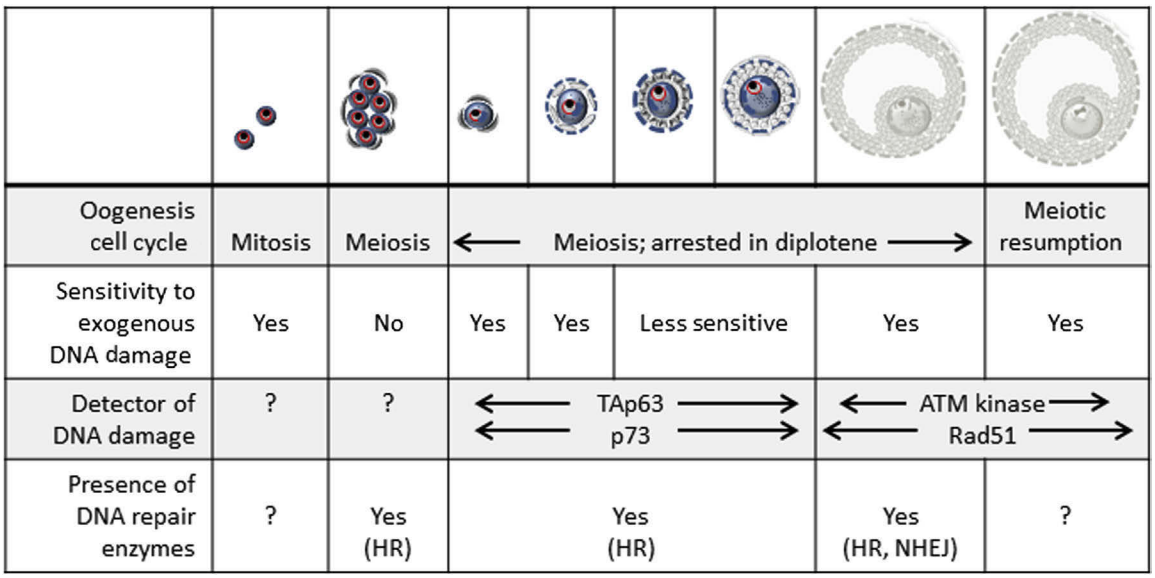

FIGURE 2.17 Schematic demonstrating stages of oogenesis that are most sensitive to DNA damage. Oogonia to full-grown oocytes are shown at the top as a function of the type of cell cycle engaged and current estimates of relative sensitivity to genotoxic agents; sensitivity may also vary depending on the damaging agent as gamma-irradiation or chemotherapeutic compounds. Line four shows checkpoint targets at later stages, and the bottom line summarizes types of DNA damage and repair pathways thought to be operative.

Vet-ebooks.com

effector PARP-1,and oocytes presenting these properties are likely to undergo aberrant chromosome segregation resulting in aneuploidy.[265] They further show that PARP-1 mediates the recruitment of the checkpoint protein BUB3 to centromeric regions of meiotic chromosomes, providing a potential mechanism that would link the DDR of diplotene oocytes with ploidy balance at the end of oogenesis. While these studies are derived from the mouse oocyte, as will be shown below, there is mounting evidence that comparable mechanisms may be at play in the human oocyte that could account for the age-related loss of genetic stability.

Reproductive Aging and the Human Oocyte

Many factors have been implicated in the well-documented loss of oocyte quality that occurs upon advancing maternal age (see Chapters 1 and 37). Keefe and co-workers have long proposed that oocytes resident in the primordial follicle for protracted periods of time would be subjected to repeated episodes of oxidative stress, which if exacerbated by the accumulation of DNA mutations in the mitochondrial genome, would contribute to a burden of lesions in the nuclear and cytoplasmic genomes.[266] One contributory factor widely recognized to be central to the loss of oocyte quality in humans is aneuploidy,[267] and the incidence of this form of genetic instability has been confirmed repeatedly from clinical studies. As noted above, mitochondrial function is suspected as being a causative factor in oocyte aging due to a decline in efficiency of free radical management with advancing maternal age.[268] The theme of declining metabolic or organellar functionality upon loss of oocyte quality resonates through many of the studies attempting to provide a molecular understanding of the aging effect in mammalian oocytes. By far, the best studied, as might be expected, is that of cell cycle checkpoint control, a topic of mounting interest that has been recently reviewed[269] (see Chapter 1).

Because the events involved with the generation of aneuploidy occur at the level of the interaction between the meiotic spindle and chromosomes, concerns about the stability of cyclin B and that of the spindle have remained an important target for investigation in animal models.[221] Similarly, the role of cohesins, molecules that maintain the interaction of homologous chromosomes and sister chromatid pairs, has been implicated in studies on mouse oocytes, and there is some indication that as a result of advancing maternal age, the cohesin-mediated linkages between chromosomes are weakened through an as-yet ill-defined process.[270] It is generally assumed in these and related studies that either mammalian oocytes have robust checkpoints for spindle assembly and/or chromosome alignment whose efficiency fails upon advancing maternal age, or these and related checkpoints are intrinsically leaky relative to somatic cells or male germ cells and therefore predispose female germ cells to genetic imbalances that may have a long-term adaptive benefit for reproduction.[271]

Whatever the case may be, studies using mouse models have been informative in guiding research on human oocytes and will likely continue to be so. Studies in animal models have also raised concerns regarding current ART practices and how they may compromise oocyte or embryo quality. Examples of this again have focused on mitochondrial metabolism and the impact of in vitro maturation or controlled ovarian hyperstimulation,[272,273] a subject critically reviewed with respect to clinical considerations.[274] In this regard, it is interesting that work on cohesins in human oocytes obtained from women of different ages supports the findings in rodents cited above validating some aspects of oocyte aging worthy of further pursuit in humans and other species.[275]

The Oocyte in Human Assisted Reproductive Technologies

In a clinical context, many factors have been evaluated in an attempt to explain why of the many human oocytes collected for embryo production, so few give rise to embryos of high developmental competence and even fewer give rise to live offspring. This has raised a number of questions regarding the practice of human ARTs and how the procedures currently in use may alter egg quality either directly or as a result of hormonal manipulations involved in controlled ovarian hyperstimulation (COH). While current evidence suggests that offspring health is not adversely affected by human ARTs, the causes of inefficiency remain important to address and may provide insights into the unquiet biology of the human oocyte.[276]

Lifestyle Factors and Oocyte Quality

Although the impact of lifestyle has been rigorously studied in animal models, focus on the periconceptional period—that is, immediately prior to and following fertilization—has been receiving greater attention. Interest has centered on the role of diet during the preimplantation period of mammalian development and whether dietary changes or conditions such as diabetes would impact the metabolism of offspring and contribute to early-onset adult disease.[277] Obesity has been identified as a contributory factor to many forms of human infertility, sometimes linked to polycystic ovary syndrome, and the fact that altered metabolism during oogenesis influences oocyte quality brings to the table the increasing likelihood that preconceptional health may be as important as postconceptional.[278] Obviously, given the focus of this chapter, the manner in which lifestyle influences oocyte quality is of great importance to human

Vet-ebooks.com

reproduction. But how close are we to identifying a link between maternal health and oocyte quality?

Several laboratories have made progress in this arena. It appears that a diabetic state influences the process of oogenesis through impairments in mitochondrial biogenesis and function, likely the result of altered ovarian metabolism.[279] Secondary to metabolic perturbations are defects in the assembly and function of the meiotic spindle that predispose mouse oocytes to genetic instability. In the cow, hyperlipidemia during oocyte maturation leads to altered metabolism in resulting embryos.[280] And in one study, the adverse consequences of obesity on oocyte quality were found to be partially reversible after treatment with rosiglitazone.[281] Taken together, there is mounting evidence to suggest that the protracted period of ovarian oogenesis is subject to lifestyle interventions.

Controlled Ovarian Hyperstimulation—More Oocytes but are They Better?

Ovarian stimulation with gonadotropins has been used in experimental and clinical settings as a means to rescue follicles from atresia and thereby gain access to a greater number of oocytes than might be obtained from an unstimulated ovary (see Chapters 28 and 29). The widespread use of COH in the practice of human ARTs has increased oocyte retrieval efficiency, but for patients classified as poor responders due to low oocyte yields, multiple rounds of COH are often conducted in an effort to increase the number of embryos available for transfer. Concerns over the long-term effects of repeated COH have been raised with respect to increased cancer risks and premature follicle depletion, but the practice continues.[282] Because repeated COH accelerates the rate of follicle development while sensitivity to exogenous gonadotropins is retained, the potential negative consequences on egg quality have been the subject of many investigations in animal models.[283] In one study using mice subjected to four rounds of stimulation, a progressive decrease in oocyte ATP levels was noted in relation to the number of rounds of stimulation. It was further shown that while when oocytes were fertilized in vivo or in vitro, only embryos maintained in culture exhibited fetal defects after transfer to pseudopregnant animals, indicating that metabolic deficiencies affect in vitro developmental competence. Embryos allowed to develop in vivo were indistinguishable from one another despite multiple rounds of COH.[284] Studies of this kind suggest that altering the pace of follicle development with exogenous gonadotropins does not exert long-term effects on developmental competence unless additional challenges are imposed on embryos by maintaining them in culture. As mentioned earlier, one of the major determinants for successful completion of meiosis and egg activation is the ability to sustain calcium transients after fertilization. In fact, it is well established that if this competence for calcium oscillations is instilled in the oocyte during maturation, then many of the sequelae that launch early development will proceed on schedule.[285–288] Thus, as a biomarker of developmental competence, calcium oscillations emerge as a major property for oocyte quality.

This has been borne out further by studies linking the fidelity of metabolic changes during egg activation to adult body weight.[289] As the spermatozoon's contribution of phospholipase C zeta (PLCz) is known to trigger the onset of calcium oscillations (see Chapter 4), it is of special interest that in cases of male infertility, where intracytoplasmic sperm injection is unable to launch the program of developmental competence, replacement with purified PLCz can rescue human oocytes and sustain early development.[290] Manipulations such as these may in the future be used for the treatment of infertility where specific deficiencies are identified that compromise gametic quality.

In Vitro Maturation of Human Oocytes

In vitro maturation is likely to be used clinically as conditions for optimizing cytoplasmic and nuclear maturation are refined in the future. Already, some of the differences between in vivo and in vitro matured mouse oocytes have led to the identification of specific competency deficits that can be rectified using inhibitors or activators of signaling pathways.[291] As mentioned earlier, inhibitors of PDEs can improve the maturation and developmental competence of IVM human oocytes,[216] but concerns remain given that studies in primates suggest a delay or blockage in zygotic gene activation as a consequence of IVM.[292] Even though there is now solid evidence that recapitulation of all phases of oogenesis under in vitro conditions results in the birth of mice exhibiting normal adult health and lifespan, caution should be exercised when applying such approaches to human material for purposes of reproduction.[293] Thus, while live births have occurred after human oocyte IVM, careful follow-up of offspring health has yet to be evaluated.[294]

Human Oocyte Cryopreservation

Cryopreservation of human oocytes is becoming widely adopted in human ARTs when indicated for purposes of achieving or preserving fertility. In recent years, comparisons have been made between mature metaphase two oocytes cryopreserved by either vitrification[295] (rapid freezing) or slow-freeze methods where the effects of either approach have been evaluated based on oocyte survival after thawing and the ability to produce embryos.[296] There has been general agreement that vitrification is less damaging to mature human oocytes, and coupled with the convenience and expense associated with it, it has become the method of choice clinically.[297]

Oocyte Biology in the Context of Fertility Preservation

The increased survival of female cancer patients observed over the past 20 years has motivated scientists and clinicians alike to pursue avenues of research that might enhance prospects for preserving fertility. As noted above, the mechanisms by which mammalian oocytes die of natural causes or as a result of iatrogenic therapies indicated for cancer patients are gradually being understood to a level where it may be possible to preserve and/or protect the livelihood of oocytes.[298] It has been recognized that both chemotherapy and radiotherapy, alone or in combination, cause extensive damage to the oocyte and follicle pool in the human ovary.[299] To offer patients the prospect of preserving fertility, a number of strategies are under development to achieve this end, and these have been summarized by Woodruff[300] and are illustrated in Figure 2.18.

It has become possible to cryopreserve ovarian cortical strips from patients using either slow-freeze or vitrification technology and subsequently perform autologous grafting to those patients once they have fully recovered from their original malignancy. To date, 16 children have been born by transplantation of previously frozen ovarian cortical strips. Because the risk of reintroducing cancer cells is high, an alternative to this approach has been initiated that involves culturing ovarian strips to allow for the activation of primordial follicles and the attendant initiation of the growth phase of oogenesis (Figure 2.1). An ex vivo procedure has been developed by Telfer and colleagues recently.[301] This three-step procedure is designed to mimic the growth phase by culturing intact strips of ovarian cortex, followed by a prematurative phase when somatic cell contact is maintained outside the follicle, and finally subjecting oocytes to IVM. Thus far, small numbers of oocytes have been shown to initiate and complete meiotic maturation (Figure 2.18).

Oocyte Biology and Regenerative Medicine

Achieving totipotency is the *raison d'etre* for the mammalian oocyte. Thus, understanding how this cell acquires and sustains the ability to reprogram the genome brings it to center stage in the field of regenerative medicine. The most significant advance in the field of regenerative medicine has recently been achieved in the demonstration that human oocytes subjected to SCNT are capable of producing high-quality blastocysts with the competence to generate embryonic stem cells (ESCs).[302] On a more fundamental level, the possibility that stem cells could be coaxed back into the female germ line has been proffered as an experimental strategy for defining the molecular blueprints that guide and inform the process of oogenesis. The recent demonstration that ESCs or induced pluripotent stem cells (iPSCs) can be manipulated to form primordial-like germ cells, that if placed in the correct ovarian context proceed to acquire and express all of the competencies resulting in live offspring, establishes the feasibility of directing stem cells down the pathway of gametogenesis.[303] Other strategies have been proposed to recapitulate oogenesis de novo.

There has also been great interest in the field of oocyte biology with regard to prospects of identifying oogonial stem cells from which mature oocytes might be propagated, as originally suggested from the studies on mice by Johnson and colleagues.[304] While this work has elicited much debate and attention, more recent studies showing that more complete methodological approaches can be used to purify oogonial stem cells from mouse or human ovarian tissues offer some promise that the existence of such cells can be investigated in a broader context.[305] As

	Follicle stage			
	Germ cell cyst	Primordial	Primary & secondary	Antral
Technique				
Cryopreservation	NA	Cortical strips	NA	Oocytes; GV or MII
Culture	NA	Cortical strips	Intact follicles	In vitro maturation
Transplants	NA	Yes	No	NA

FIGURE 2.18 Summary of in vitro methods being used to support oocyte development in the field of fertility preservation. Figure illustrates application of techniques at specific stages of oogenesis represented by cortical strips containing primordial follicles, isolated follicles, or oocytes subjected to IVM. NA, not applicable. Cryostorage of cortical strips of ovary containing primordial follicles has been shown to result in live births following culture and autologous grafting in humans; and while oocyte cryopreservation is widely used, successful attempts for embryo production have yet to be accomplished cryopreserving follicles. For growing oocytes, methods have been used to culture primary or secondary follicles, but as yet, complete development and maturation in all mammals have not been achieved except in the mouse.[301]

Vet-ebooks.com

there is little direct evidence to suggest that such cells recapitulate the entire process of oogenesis in vivo or in vitro, earlier questions regarding the validity of this provocative idea remain.[306]

As advances in stem cell and germ cell plasticity continue to be made using mouse models, the prospects of achieving in vitro oogenesis remain a formidable challenge for the oocytes of other mammals.[307] Given that recent technological advances are showing some signs of progress that some aspects of oogenesis may indeed proceed ex vivo (Figure 2.18), a deepening understanding of the complexities of oogenesis looms as the next chapter in the study of mammalian oocytes.[301]

CONCLUSION

The above discussion of the mammalian oocyte summarizes the present state of knowledge on this remarkable cell. As noted in the introduction, the fundamental property of totipotency that allows the fertilized egg to develop into the conceptus and adult organism has spawned intense interest in the areas of reproductive physiology, stem cell biology, and human regenerative medicine. Many questions remain regarding the biological underpinnings of the oocyte whose resolution will be required to advance research at basic science and clinical levels. In the end, understanding how an organism draws upon the ovarian follicle reserve to support ovulation of a developmentally competent mature oocyte is the overarching question awaiting resolution.

Two outstanding questions prevail. First, how will the key determinants of oocyte quality be best defined using present and future technological innovations? The introduction of "omics" approaches has certainly opened new avenues for study, and the increased availability of databases on mammalian oocytes suggests that "deep" technologies and bioinformatics will foster mining of genomes, metabolomes, and transcriptomes in relevant animal models where functional outcome studies are feasible. Such efforts are likely to reveal the molecular and physiological determinants of oocyte competencies and for the first time permit the linking of each phase of oogenesis to specific events in early embryogenesis and beyond. Discovery of the array of maternal effect genes, in this regard, will provide a detailed biochemical roadmap with which to generate new hypotheses pertinent to reproductive health and well-being of females and their offspring.

Second, what is the difference between mammalian oocytes of good or bad quality? Human ARTs reinforce long held beliefs from studies on other mammals that ovulated oocytes are not equal in their ability to yield live young. To date, our perspective for defining oocyte quality has been largely restricted to understanding properties emerging at the time of ovulation when the oocyte is proceeding through the penultimate stages of oogenesis. But as discussed above, many of the properties essential for sustaining later development of the conceptus in fact are conferred at much earlier times in oogenesis, typically three or more ovarian cycles prior to ovulation. So, while the technology is in hand for monitoring the various competencies the oocyte must acquire during the protracted course of oogenesis, our understanding of how and when these events take place remains fragmentary.

The bulk of accumulated knowledge in this area has come from studies on the mouse and the introduction of technologies such as transgenesis. Hence, attributing functional phenotypes to oocyte-specific genes is now possible using conditional gene deletion strategies as well as siRNA knockdowns along the pathway of oogenesis. However, oocyte-specific Cre mice are limited in availability for most stages of oogenesis, and as noted above, must also be generated to tease apart the interdependence of oogenesis and folliculogenesis (see Chapter 21). Nonetheless, the mouse, and likely other species like the rat, afford animal models with great potential owing to their genetic tractability and development of novel transgenic technologies. While these technological advantages are unlikely to be realized for species more related to the human, both nonhuman primate and various domesticated species have served well in the domain of oocyte biology in the past, and all indications are that appropriate models will be exploited with the "omics" approaches required to systematically solve important questions such as: (1) how are maternal mRNAs differentially processed to direct the overlapping events of cell cycle control and cytoplasmic maturation in response to physiological signals propagated by the ovulatory surge of LH versus ex vivo maturation? (2) What are the immediate and delayed consequences of oocyte cryopreservation on mitochondrial function after fertilization? (3) What competing interests at the level of RNA or protein allocation are served by maternal versus zygotic gene products? and (4) How will the range of newly discovered RNA species play into the growth and maturative stages of oogenesis as genetic or epigenetic modifiers?

Several limitations of our current knowledge are in evidence. First, while much is known about the biology of the mouse oocyte, we are only now gaining insight into the ova of other mammalian forms. Second, almost all studies of oocytes, especially in rodents, involve analyses of somatic cell free systems that, as has been shown, greatly impact the maturation and postmaturative stages of oogenesis. Of course, this problem is the basis for the experimental intractability in this system due to the highly integrative nature of the cumulus oocyte complex. And third, the use of COH to obtain as many oocytes as possible, while serving a practical experimental need, is

Vet-ebooks.com

now recognized to severely compromise oocyte quality from bench studies with rodents to human ARTs. In fact, and as discussed earlier, gonadotropin stimulation of follicle development appears to disrupt the delicate balance of signaling pathways within the follicle, and what appears, at least on the surface, to be good for the follicle seems not to be so for the oocyte.

In the vein of clinical importance, the study of high-quality oocytes remain enigmatic and a source of frustration to patients and clinicians alike. Fewer than 5% of all oocytes retrieved for infertility treatments ever result in a live birth. Coupled with the severity of the aging problem in humans, and the desire to maintain fecundity in cancer patients, the sources of genetic and epigenetic instability remain poorly understood.[307] Are there intrinsic surveillance mechanisms that can detect and repair damaged DNA as a result of prolonged oxidative stress during aging, exposure to environmental toxins or endocrine disruptors, or manipulations from human ARTs (cryopreservation, culture). If molecular alterations can be identified that distinguish high- from low-quality oocytes, what measures can be devised that might restore and/or ameliorate the compromised performance of these oocytes? Will metabolomics approaches define these differences and will they be rectifiable by medium supplements? These and other questions in the realm of clinical practice will await the acquisition of basic knowledge obtained from studies in animal models.

The final prospect of oocyte biology that leaves many questions is that concerning the capability to manipulate the process of oogenesis in vivo or in vitro. Here, the power and potential of stem cell biology have already gained inroads in demonstrating proof of principle for the ability of ESCs and iPSCs to reenter the female germline and propagate oocytes after transplantation in murine models.[303] Such in vivo approaches emphasize the importance of the ovarian niche for directing appropriately primed stem cells to reenter meiosis and recapitulate oogenesis in a surrogate ovary, reinforcing the notion that somatic cell interactions with oocytes are essential for folliculogenesis to proceed.[31] But this approach is of low efficiency and long-term consequences on offspring health have yet to be fully evaluated. Will the generation of oocytes and the completion of oogenesis ever be possible in an ex vivo environment? Some steps have been recapitulated in in vitro experiments using cow and human materials, but only with the original support of the oocyte–follicle complex. Any attempts to recapitulate oogenesis from stem cells will require close attention to the detailed structural and functional requirements that establish and maintain the elaborate communication system between the oocyte and granulosa cells; the connectome, as it were, is emerging at the heart of many efforts to obtain some degree of ex vivo functionality for various organs. Herein lies a future for the biology of the mammalian oocyte that will likely contribute to the advancement of our basic understanding and at the same time continue to impact the fields of reproductive and regenerative medicine.

Acknowledgments

Some of the images used in this chapter were kindly provided by colleagues or were made possible by the late Dr Arthur T. Hertig while he was at the New England Regional Primate Research Center of Harvard Medical School. These include Figures 2.1, 2.4, 2.6, 2.7, and 2.8. Betsey Williams provided Figures 2.7(E) and 2.13(C); Alfredo Vitullo, Figure 2.1(A), Daniela Nogueira, Figure 2.4(B); and Virginia Rider, Figure 2.13(D).

Writing this chapter has brought back many fond memories of the people to whom I am indebted for initiating my interest in this subject and sustaining it over a 40-year period. Without the support, encouragement, and direction given by my mentors Everett Anderson, John D. Biggers, and the late Arthur T. Hertig, what started as a passing interest in reproduction would never have taken me on this incredible journey with such a remarkable cell. Over the years, many colleagues have sustained and molded my cogitation and commitment, including Pat Hunt, Richard Schultz, John Eppig, John Carroll, Carlos Plancha, Jon Van Blerkom, and Giovanni Coticchio. I especially want to recognize my friend and lab director, S. Darlene Limback, without whose direct involvement this chapter would not have been realized. Over the years, I have been fortunate to have received funding from the National Institutes of Health, National Science Foundation, March of Dimes, Eshe Fund, and the Hall Family Foundation, and appreciate their support.

INTRODUCTION

The term "sperm" is derived from the Greek word "sperma," meaning seed. The Dutch merchant Antonie van Leeuwenhoek is credited with using his handcrafted lenses and microscopes to be the first to observe live spermatozoa and to report in letters to the British Royal Society in 1637 that sperm have a head and a motile tail. Although initially controversial, the observations by van Leeuwenhoek and others led to the development of the cell theory: that all living organisms are made of cells, new cells are created by division of old cells, and cells are the basic building block of tissues, organs, and organisms. Another Dutch microscopist, Nicolaas Hartsoeker, who learned lens making from van Leeuwenhoek, is credited with observing in 1694 tiny men inside human sperm and calling them homunculi or animalcules. This led to the development of the spermists' theory explaining conception, that the sperm was a little man that grew into a child in the womb.

The German zoologist, Oscar Hertwig, is credited with discovering fertilization by observing in 1876 the penetration of a sperm into an egg cell in sea urchins. The many variations in the size and shape of sperm of different organisms were studied by biologists while the light microscope was the main research tool, but it was not until the development of the electron microscope that the remarkable complexity of spermatozoa was appreciated.

Studies beginning in the early 1960s by Don Fawcett and others, and continuing to the present, have led to a rich accumulation of knowledge regarding the nature and organization of the structural components of spermatozoa. Around this same time, biochemical studies began to identify enzymes responsible for the energy production in sperm needed by the flagellum to maintain motility and the major proteins of the acrosome, nucleus, and flagellum. It became possible to pinpoint the location of some of the proteins when antibodies to known proteins became available. The subsequent development of methods for generating monoclonal antibodies led to the identification and localization of previously unknown sperm components and to the definition of the restricted surface domains of spermatozoa. However, it has only been during the last 20 years that gene targeting methods have allowed studies to determine experimentally the roles of specific proteins in the structure and function of spermatozoa. Most of these studies have been carried out in the mouse for technical reasons, but have led to the identification of genes essential for fertility in the human male. One of the surprising findings of the genomic era has been that many of the proteins present in sperm are encoded by genes or variant transcripts that are not expressed in other cells of the body. Although there is a great deal to be learned about the regulation of expression of the genes and proteins that form the sperm and how they assemble and function, there is now a wealth of knowledge about the structure and physiology of sperm, as will be described in this chapter.

The spermatozoon is the end product of spermatogenesis proceeding through successive processes of mitotic, meiotic, and postmeiotic phases within the seminiferous tubules in the testis. During the mitotic phase, the germline stem cells undergo a series of divisions that expands the spermatogonial population. The DNA of male germ cells is reprogrammed in this phase. The first meiotic

Vet-ebooks.com

phase begins with the last cell cycle S phase and culminates in the second meiotic phase that rapidly occurs without DNA replication to produce haploid spermatids. Spermatozoa are formed during the postmeiotic phase characterized by extensive remodeling of spermatids into spermatozoa by formation of the acrosome, nuclear condensation, flagellar development, and shedding of the cytoplasm. These events result in production of a sperm cell highly differentiated in structure and function. It is developmentally totipotent and capable of combining with an egg to initiate the next generation. The spermatozoa have a small amount of cytoplasm and lack most organelles common to somatic cells.

The sperm head region is elaborately organized and efficiently leads to gamete fusion with the aid of flagellar motility. During the transit from the male to the oocyte, sperm DNA packaged very tightly in the nucleus is protected from damage by external conditions. Spermatozoa released from the testis are immature and in a transcriptionally and translationally silent state. They become mature to gain fertilizability and motility during passage through the epididymis and female reproductive tract. This maturation occurs in the absence of gene transcription and de novo protein synthesis, but depends upon posttranslational modifications and remodeling of constituent molecules under the influence of products of the epithelial cells lining the reproductive tract.

The main components of a sperm are the *head* and *flagellum* (tail), joined by the *connecting piece* or the neck (Figure 3.1). The head contains the nucleus, acrosome, and a small amount of cytoplasm, in which cytoskeletal structures are elaborately organized. The nucleus contains highly condensed chromatin and is capped anteriorly by the *acrosome*, a membrane-enclosed cytoplasmic vesicle containing hydrolytic enzymes and novel molecules required for fertilization. Starting from the connecting piece (neck), the flagellum is divided successively into the midpiece, principal piece, and endpiece regions. The connecting piece contains centriolar derivatives and the segmented columns. The flagellum contains a central complex of microtubules forming the *axoneme*, surrounded by *outer dense fibers* extending from the neck into the principal piece. The midpiece contains the *mitochondrial sheath*, a tightly wrapped helix of mitochondria surrounding the outer dense fibers and axoneme. Most of the length of the flagellum is the principal piece, defined by the presence of a *fibrous sheath* surrounding the outer dense fibers and axoneme. The outer dense fibers and the fibrous sheath are cytoskeletal structures novel to the sperm flagellum in higher vertebrates.[1] The endpiece is the final segment and contains only axonemal microtubules. The head and flagellum are tightly enclosed by the plasma membrane and contain a sparse amount of cytoplasm. There are substantial species-specific differences in the size and shape of the head, and in the length and relative amount of the different components of the flagellum. Spermatozoa from invertebrates usually have a head with an acrosome and a flagellum containing an axoneme and mitochondria, but lacking accessory cytoskeletal structures.[2]

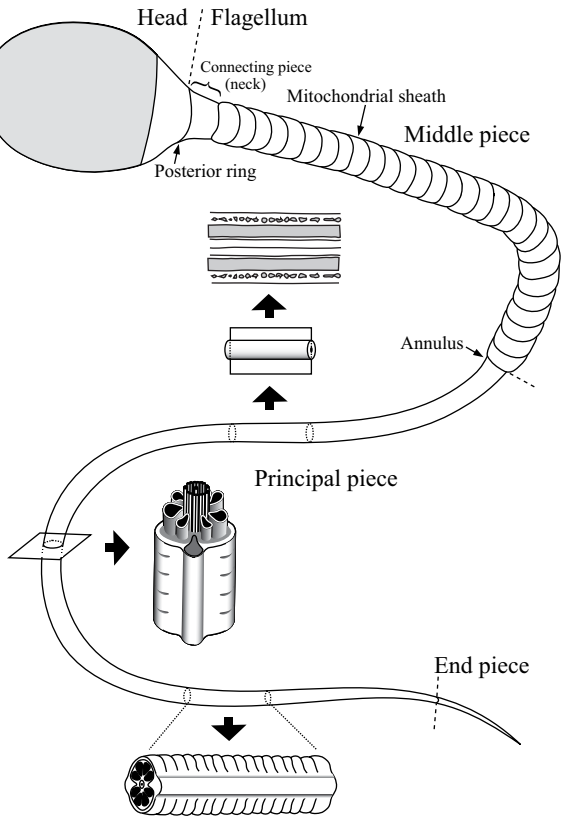

FIGURE 3.1 General features of the mammalian spermatozoon. The head of the sperm is attached to the flagellum by the connecting piece at a border termed the posterior ring. The regions of the flagellum are the middle piece, the principal piece, and the endpiece. The annulus forms a border between the middle piece and the principal piece. The middle piece contains the mitochondrial sheath, while the principal piece contains the fibrous sheath. Longitudinal and cross-sectional views of the principal piece and a segment of fibrous sheath are indicated by arrows. The internal components of the flagellum are identified in Figures 3.8–3.12.

The specialized structural features of mammalian spermatozoa reflect the unique functions required for fertilization. The acrosome contains specific enzymes and matrix molecules required for penetrating the egg investments and achieving competency to achieve fertilization, while the flagellum contains the energy sources and machinery to generate the motility necessary for the sperm to reach the egg. These functions are essential for delivery of the paternal genome to the ooplasm, where the haploid male and female pronuclei combine to produce the zygote and initiate development for the next generation. In most mammals, the sex chromosome carried in the haploid sperm nucleus determines the sex of the resulting animal. Both a paternal and a maternal

Vet-ebooks.com

genome are required for normal development to proceed to term, usually due to differential imprinting of genes during gametogenesis in males and females.[3]

This chapter focuses on the characteristics of mammalian spermatozoa,[4] with particular attention to the molecules currently known to contribute to their structures and functions. The major topics considered are the organization, composition, and function of the plasma membrane, the head, and the flagellum. Other chapters and the previous edition[5] should be consulted for fundamental and additional information, necessary for understanding the role of the structural and functional features of spermatozoa in reproductive processes.

THE SPERM PLASMA MEMBRANE

The Mosaic Sperm Surface

Spermatozoa have a characteristic polarized morphology and their surface is highly differentiated and subdivided into regional domains that differ in composition and function. Sperm surface differentiation and segregation are established during spermatogenesis. This segregation is presumably important for preventing the premature initiation of events such as the acquisition of motility, hypermotility, capacitation (acquisition of the ability to undergo the acrosome reaction and achieve hyperactivated motility), the acrosome reaction, and the sperm-egg interaction that should occur in the most appropriate timing during fertilization. However, even if once established, some molecules that are sequestrated in these domains can be redistributed within and between defined domains after release of mature spermatids into the seminiferous tubule lumen (spermiation). These changes cause selective mixing and shuffling of proteins between domains, which eventually induces coordinated protein interactions and specific signaling pathways that culminate in functional changes. Thus, the sperm functional domains are dynamic during the life of the cells.[6,7]

The major regions of the plasma membrane on the sperm heads of most mammals are the *acrosomal region* (anterior head) and the *postacrosomal region* (posterior head) (Figure 3.2). The plasma membrane of the acrosomal region can usually be subdivided into the *marginal segment* domain (apical segment, peripheral rim) over the anterior margin of the acrosome, *principal segment* domain (anterior acrosomal domain) over the major portion of the acrosome, and *equatorial segment* domain (posterior acrosomal domain) over the posterior part of the acrosome (Figure 3.3). The size and shape of these domains vary between species[5] (Figure 3.2). The marginal and anterior acrosomal domains together are referred to as the acrosomal cap. A central crescent

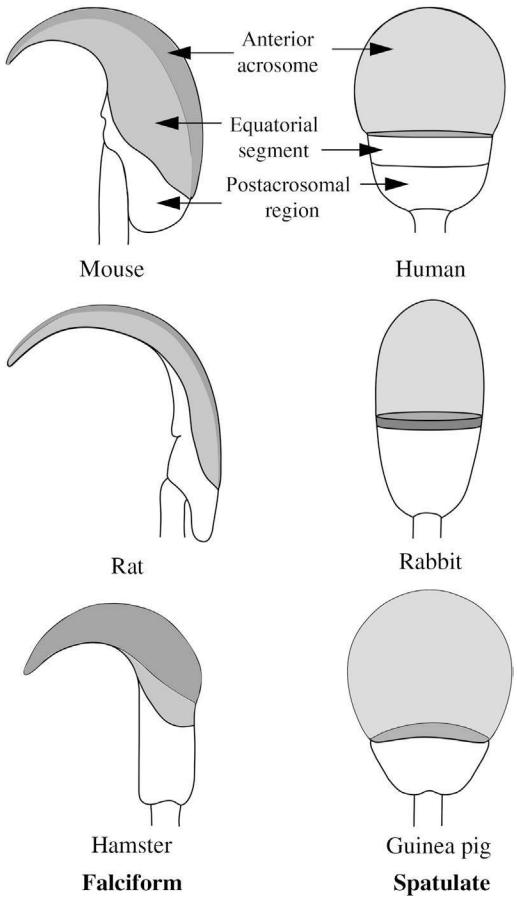

FIGURE 3.2 General features of the heads of falciform-shaped (mouse, rat, and hamster) and spatulate-shaped (human, rabbit, and guinea pig) spermatozoa. Lateral view. The size and shape of the spermatozoon head is specific to each species and varies considerably between species. The major regions of the sperm head are the acrosomal region or anterior head (anterior acrosome and equatorial segment (posterior acrosome)) and the postacrosomal region or posterior head. The acrosomal region of the falciform-shaped mouse sperm head has a relatively small anterior acrosome compared to the spatulate-shaped human sperm. The postacrosomal region is that portion of the sperm head not covered by the acrosome.

domain that separates the marginal and principal segment is found in the guinea pig.

The plasma membrane of the postacrosomal region (posterior head, postacrosomal segment) covers the region between the posterior margin of the acrosome and the connecting piece. The margin between the acrosomal and postacrosomal regions is delimited in some species by the serrated band (subacrosomal ring), which girdles the sperm head at the posterior margin of the equatorial segment.

The posterior ring (nuclear ring, striated ring) is located at the junction between head and connecting piece and believed to form a tight seal (barrier) between the cytoplasmic compartments of the head and flagellum (Figures 3.1, 3.3 and 3.4). The plasma membrane of the flagellum is divided into the middle piece (midpiece)

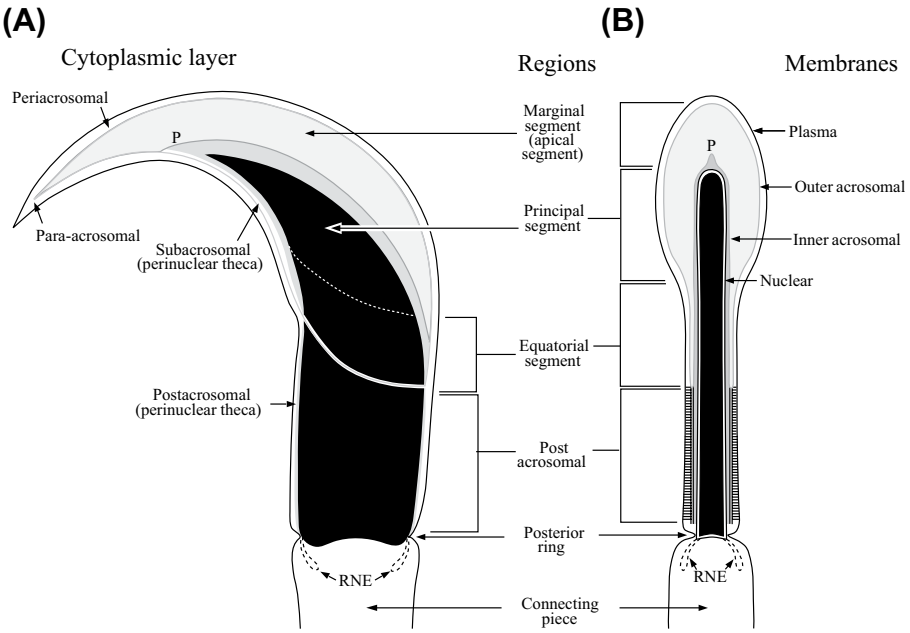

FIGURE 3.3 The distribution of the cytoplasmic layer, regions, and membranes on a falciform-shaped hamster sperm head is shown schematically. (A) Sagittal section. (B) Frontal section. The cytoplasmic layer includes the para-acrosomal layer, the subacrosomal layer, and the postacrosomal layer. The regions include the marginal segment (apical segment) and principal segment of the anterior acrosome, the equatorial segment or the posterior acrosome, and the postacrosomal region between the posterior margin of the acrosome and the posterior ring. The outermost plasma membrane encloses the entire spermatozoon, while the outer acrosomal and inner acrosomal membranes form a continuous enclosure of the acrosomal contents. The nuclear envelope is a double membrane enclosing the nucleus. The subacrosomal cytoskeleton (perforatorium) is located between the inner acrosomal membrane and the nuclear envelope. The postacrosomal cytoskeleton is located between the plasma membrane and the nuclear envelope. Together these are referred to as the perinuclear theca. *Source: Modified from Ref. 6.*

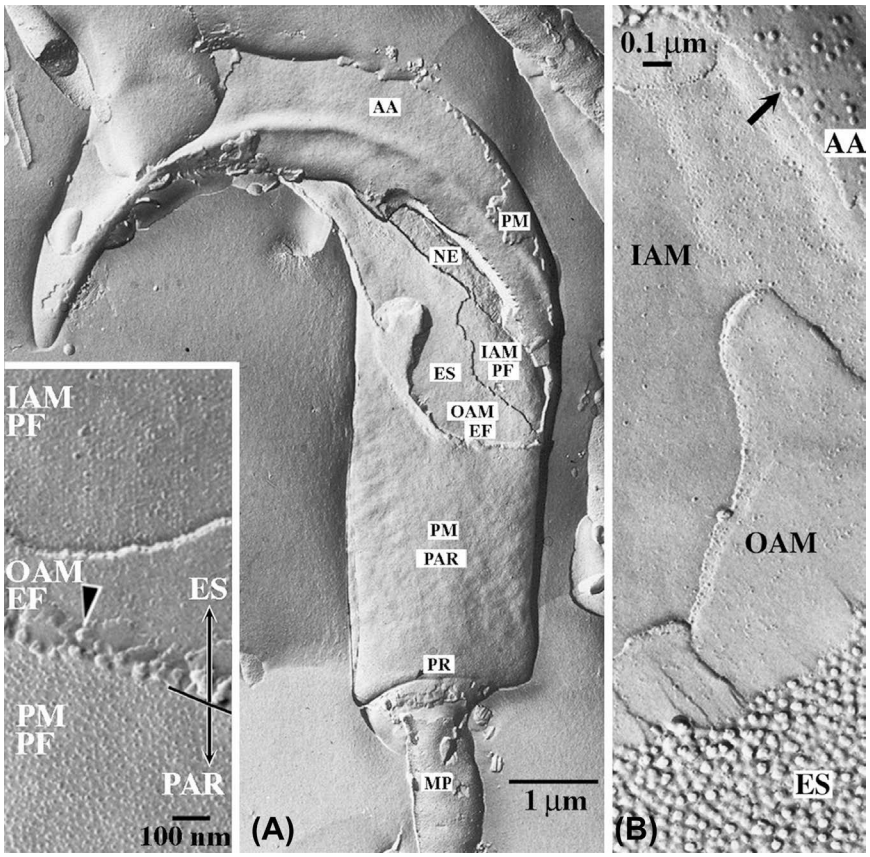

FIGURE 3.4 A freeze-fracture image of golden hamster sperm generated with a membrane cholesterol probe, filipin. (A) Lateral view. This image corresponds to that shown in Figure 3.3(A). Inset; freeze-fracture images of the plasma membrane, and outer and inner acrosomal membranes at the posterior acrosome (ES) and the postacrosomal region (PAR). (B) Freeze-fracture images of the plasma membrane, and outer and inner acrosomal membranes at the anterior acrosome (AA) and the equatorial segment (ES). The membrane features and compositions of the plasma membrane, outer and inner acrosomal membrane, and nuclear envelope appear to be different in the domains. Cholesterol is abundant in the equatorial segment (B), but low in amount in the postacrosomal region (A, inset). Arrowhead in the inset indicates the complex of filipin–cholesterol. An arrow in B indicates the border of the marginal domain and the principal domain of the anterior acrosome region. Vet-ebooks.com

region, principal piece region, and endpiece region. The middle piece and principal piece regions are separated by the annulus (Jensen's ring), a fibrous ring that is a cytoskeletal component adhered to the inner surface of the plasma membrane (Figure 3.1). Most sperm-surface domains are established during spermiogenesis as spermatids are remodeled into spermatozoa. However, spermatozoa undergo additional shape and surface changes during epididymal maturation, and some domains acquire their final form and composition. The middle piece is modified as sperm transit the epididymis by the cytoplasmic droplet migrating from the anterior to the posterior end and being shed. The cytoplasmic droplet does not move beyond the annulus. The shape and composition of the sperm head can change, the acrosome can undergo a reduction in size, and proteins on the surface of the sperm head can migrate to other domains.[6,7]

The surface of the sperm tail (also of the head) binds proteins secreted from the epithelial lining of the epididymal duct. Secretions from the epididymis, which contain a decapacitation factor and a variety of other components, coat the sperm surface. It is hypothesized that the temporal regulation of surface expression of surface components directs them to their correct surface domains, with newly synthesized proteins being inserted into sperm domains. Proteins might not diffuse into more posterior domains because they either are anchored in the anterior domain, or barriers exist to prevent diffusion between domains. Although this model suggests that localization of surface components to specific domains might not require a specific sorting mechanism, signals might exist that identify them for removal from inappropriate domains.

Identification of Domains

Surface Charge, Lectins, and Freeze-Fracture

Sperm domains have been identified using a variety of labeling methods.[5] These include surface charge labeling (e.g., net negative charge on the tail), lectin staining, freeze-fracture/freeze-etch/fracture-labeling, surface replication, and atomic force microscopy (AFM). In addition, specific membrane-intercalating agents such as a polyene that complexes β-hydroxysterols with sterol, filipin, and a fluorescent lipid analog, 1,1′-dihexadecyl-3,3′-tetramethyl-indocarbocyanine perchlorate (C_{16}diI),[5] have been used. For example, AFM revealed that the equatorial subsegment has a species-specific size and shape and that its topography is distinguishable from the plasma membrane overlying the anterior acrosome, equatorial segment, and postacrosome in *Artiodactyla* spermatozoa.[8] Filipin develops filipin-sterol complexes between plaques of intramembranous particles and clearly identifies the difference of sperm membrane domains (Figure 3.4). Domains are also observed using C_{16}diI, which intercalates into the outer leaflet of the plasma membrane. The acrosomal region of ram sperm is labeled more intensely than the postacrosomal region with this agent.[9] The difference in affinity of the probe for these regions apparently results from its interactions with lipids and proteins heterogeneously distributed within the plane of the membrane.

Antibodies and Green Fluorescent Protein

Antibodies can be conjugated directly with various labels and detected directly or indirectly with secondary antibodies for light or electron microscopy. Many antisera have been produced, but the multiple and variable specificities of these polyclonal antisera to whole cells or mixtures of antigens often has limited their usefulness for dissecting the distribution of specific sperm-surface components, for defining the biochemical characteristics and functional roles of such components, and for identifying the molecules recognized. Some of these problems were circumvented using monoclonal antibodies to identify molecules localized to subdomains of the sperm surface. Their use confirmed that the surface of sperm from many different species consists of well-defined domains and demonstrated that different proteins and glycoproteins may be either confined to individual domains or shared by multiple domains. However, attempts to use immunoprecipitation with monoclonal antibodies to identify specific proteins can also result in the isolation of multiple proteins that might either be subunits of a molecular complex or functionally unrelated molecules that share a common epitope. For example, a glycosphingolipid, GalNAcβ1-3Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-ceramide that is recognized by MC121 monoclonal antibody is present on different molecules, including the 54-kDa sialoglycoprotein in mouse cauda epididymal spermatozoa and lipids of human red blood cells.[10] Specific protein-tagged probes such as green fluorescent protein (GFP) used for GFP-transgenic mice have proven useful for determining the localization and behavior of specific molecules of plasma membrane domains under in vivo conditions.[11]

Localized Sperm Membrane Components

The sperm surface has a mosaic surface and reflects the localized distribution of different proteins. Ca^{2+} channel proteins localized to specific regions of the sperm plasma membrane are involved in regulating Ca^{2+} homeostasis required for various sperm functions. The CATSPER (cation channels, sperm associated) family contains four sperm-specific alkalinization-activated, voltage-gated Ca^{2+} channel proteins (CATSPER1, 2, 3, 4) and is highly conserved in humans and mice. CATSPER1 is a six transmembrane spanning, voltage-gated Ca^{2+}-channel protein necessary for regulation of Ca^{2+} entry,

Vet-ebooks.com

and is present in the plasma membrane of the principal piece region of the mouse sperm flagellum.[12] CATSPER2 is also located in the plasma membrane of the flagellum. Ca^{2+} ions entering the channels in the principal piece trigger intracellular Ca^{2+} concentration increases in the midpiece and head through unknown mechanisms.[13] Both CATSPER1- and CATSPER2-null male mouse are infertile due to failure of hyperactivation of spermatozoa, and the null sperm cannot fertilize zona-intact eggs in vivo.[12,14] CATSPER protein complex contains pore-forming proteins and three additional proteins, CATSPERB, CATSPERG, and CATSPERD. The trafficking and/or assembly of CATSPERB and CATSPERG depend on CATSPER1.[15,16] CATSPERD was identified as the product of the *Tmem146* gene.[17] In humans, at least two mutations in the *CATSPER1* gene are found to cause *CATSPER1*-related nonsyndromic male infertility.[18] Disruption of the gene for a subunit (alpha 1E) of $Ca_v2.3$ (*Cacna1e* gene) resulted in increased straight-line velocity and linearity parameters of sperm motility as determined by computer-assisted sperm analysis.[19] Another group of voltage-gated Ca^{2+}-channel proteins is present in the plasma membrane of the acrosome ($Ca_v1.2$ and $Ca_v2.2$), the postacrosomal region ($Ca_v2.3$), and the principal piece ($Ca_v1.2$, $Ca_v2.2$, and $Ca_v2.3$) of mouse sperm.[12] $Ca_v1.1$–$Ca_v1.4$, $Ca_v2.1$–Ca_v3 and $Ca_v3.1$–$Ca_v3.3$ are recently identified.[20]

Plasma membrane Ca^{2+}-transporting ATPase 4 (PMCA4, ATP2B4) is a widely expressed housekeeping enzyme that is a member of a family of proteins (PMCA1-4) that move Ca^{2+} from the cytosol across the plasma membrane, and is localized primarily to the principal piece and to a lesser extent to the acrosome of mouse spermatozoa. PMCA4 can be activated by PDC-109, a secretory protein of bovine seminal vesicles.[21] PDC-109 provokes a cholesterol and phospholipid efflux from membranes by binding to sperm surface choline lipids.[22] Deletion of the *Pcma4* gene resulted in a substantial increase in sperm intracellular Ca^{2+} concentrations and in male infertility due to a failure of hyperactivated sperm motility.[23–25] In the mouse, the major splice variants are PMCA4a and PMCA4b. PMCA4a differs from PMCA4b in the mechanism of calmodulin binding and activation, showing a much higher basal activity and being more effective than PMCA4b in returning Ca^{2+} to resting levels.[26] In the bull, PMCA4b is the major splice variant in testis, caput, and corpus epididymidis, but PMCA4a is the major variant in the cauda epididymidis for transferring Ca^{2+} across sperm membranes, suggesting the importance of isoform switching for facilitation of a higher Ca^{2+} turnover in epididymal spermatozoa.[26]

Other proteins are identified in restricted regions of the sperm surface. GLUT8 (*Slc2a8* gene) is a class three sugar transport facilitator predominantly expressed in testis and brain. Targeted disruption of *Slc2a8* reduces ATP levels, motility, and mitochondrial potential of spermatozoa.[27] Mouse GLUT9 protein (*Slc2a9* gene) has multiple splice variants. GLUT9a comprises a long form having 12 transmembrane segments, and GLUT9b comprises two short forms each having a deletion resulting in the loss of two transmembrane-spanning domains.[28] GLUT9a is present in the midpiece, while GLUT9b is present in the acrosome, midpiece, and principal piece.[28] Basigin (BSG, EMMPRIN, CE9, HT7) is involved in cell–cell interactions in the testis and is essential for the completion of spermatogenesis in mice, since deletion of the *Bsg* gene caused meiotic arrest.[29] BSG is expressed during spermatogenesis beginning in spermatocytes and associates primarily with the principal piece in caput epididymal spermatozoa and the middle piece in cauda epididymal spermatozoa.[30] BSG interacts with H^+-monocarboxylate co-transporters (MCT), MCT1 and MCT2, to locate them properly in the membrane of spermatogenic cells.[31] This suggests that BSG may enable sperm to utilize lactate as an energy substrate, contributing to sperm survival.

Some sperm proteins undergo chemical processing and modification of their location while sperm traverse the epididymis. In addition, proteins are attached to the sperm surface during epididymal maturation. They include chaperones calmegin (CLGN) and calreticulin (CALR, calsperin); a disintegrin-like and metallopeptidase (reprolysin type) with thrombospondin type 1 motif 10 (ADAMTS10); proprotein convertase subtilisin/kexin type 4 (PCSK4, PC4); cysteine-rich serine protein 1 (CRISP1); defensins; phospholipase C zeta 1 (PLCZ1); and the antigens SMA4 and T21.

Chaperones are cell stress-response or heat-shock proteins. Because molecular chaperones participate in normal cellular functions such as metabolism, growth, differentiation, and apoptosis,[32] they were initially thought to be restricted to intracellular organelles. However, molecular chaperones exist on the sperm surface and play secondary roles during functional transformation in the epididymis and female reproductive tract.[33–35] For example, testis-specific molecular chaperones, CLGN and CALR, are necessary for a disintegrin and metallopeptidase domain 1a (ADAM1A)—ADAM2 dimerization, subsequent maturation of ADAM3, and/or presentation on the sperm surface.[33,36] CLGN and CALR-null male mice are infertile with impaired sperm transport in the female reproductive tract in vivo and the loss of sperm–zona binding ability.[33,36] These phenotypes are the result of misexpression, misprocessing, and/or misfolding of fertilization-related proteins due to impairment of chaperone functions. A similar phenotype was documented by targeted deletion of *Adam1a* and *Adam3* genes.[37] These data suggest the link between ADAM protein expression and fertilization.

Vet-ebooks.com

ADAMTS10 is a novel sperm protein of the metalloprotease superfamily. ADAM family metalloproteases are known to mediate diverse cell and extracellular matrix adhesion events across a variety of cell types.[38] In the mouse, ADAMTS10 is initially expressed during the late stages of spermatogenesis and incorporated into the acrosomal domain of developing spermatids. This protein is chemically processed during sperm maturation and then expressed on the surface of the periacrosomal region.[35] ADAMTS10 is a candidate molecule for the functional redundancy involved in the mediation of sperm–oocyte interactions such as binding to zona pellucida.

PCSK4 originates in the testis and is integrated into the sperm surface. PCSK4 belongs to a nine-member family of Ca^{2+}-dependent serine endoproteinases involved in the proteolytic activation of secretory precursor proteins into their bioactive forms and is conserved in mammals. Deletion of the *Pcsk4* gene did not impair spermatogenesis but caused severe male subfertility, rendering sperm incapable of fertilizing oocytes.[39] In mouse sperm, PCSK4 is localized on the plasma membrane overlying the acrosome.[40] ADAM2 (fertilin beta) is a substrate for PCSK4.[41]

CRISP1 is secreted by the epididymal epithelium, and attached to the sperm surface. It is redistributed to the equatorial segment after capacitation in the rat.[42] CRISP1-null mouse sperm are fertile, but they showed lower levels of tyrosine phosphorylation than controls, suggesting a regulatory role during sperm capacitation.[43] CRISP4 is secreted predominantly in the mouse and rat epididymis as a soluble form associated with small membranous vesicles secreted into the epididymal lumen, called epididymosomes in the luminal fluid, and becomes bound to the sperm surface.[44] The CRISP domain of CRISP4 inhibits the transient receptor potential ion channel transient receptor potential cation channel, subfamily M, member 8 (TRPM8).[45] TRPM8 is a major cold receptor in the body and is found in the testis and on the tail and head of mouse and human sperm. CRISP4-null mouse spermatozoa are compromised in their ability to undergo the acrosome reaction in response to the physiological agonist progesterone, suggesting that CRISP4 is an endogenous regulator of TRPM8 in normal sperm function.[45] Defensin beta 126 (DEFB126) in macaques and defensin beta 22 (DEFB22) in mice are glycosylated peptides derived from the epididymis adsorbed onto the entire sperm surface.[46,47] DEFB126 has a conserved defensin beta core and a unique long glycosylated peptide tail. The carbohydrates of this domain contribute substantially to the surface glycoproteins that contribute to the sperm glycocalyx. DEFB126 loss is required for sperm recognition of the zona pellucida.[48] DEFB126 is critical for efficient transport of sperm in the female reproductive tract, preventing their recognition by the female immune system, and might facilitate the delivery of capacitated sperm to the site of fertilization.[47] Mouse DEFB22 is a 130-kDa protein, but migrates at 54–57 kDa under reducing conditions.[49] Although the presence of a cell coat is a common feature of many cell types, the carbohydrate structure of such coats and their contribution to the negative cell surface charge are yet to be clarified.

The T21 antigen, a 54-kDa glycoprotein recognized by T21 monoclonal antibody, is secreted from the epididymal epithelium and attaches to the mouse sperm tail.[50] It is heavily sialylated and the epitope (carbohydrate region) for T21 antibody is effectively masked.[50] The nature of the 54-kDa sialoglycoprotein is similar to DEFB22, but it is unclear whether the 54-kDa sialoglycoprotein is the same as DEFB22. The carbohydrate typically associated with a negative charge is sialic acid. The sialic acid is most often found as the terminal sugar in the oligosaccharide, thereby creating a negative shell around the molecule and extending its life.

Formation and Maintenance of Domains

The separation of different membrane proteins into specific domains allows the compartmentalization of responses by spermatozoa to external conditions and signals. In some cases, barriers to diffusion of plasma membrane proteins develop during spermiogenesis at the same time as membrane domains.[51] Most surface domains overlie distinct cytoplasmic organelles or features. In spermatozoa, transmembrane proteins stabilized by linkage through membrane skeleton proteins to cytoskeletal structures may be important for defining the boundaries and contents of different sperm-surface domains.

Actin and Associated Proteins

Cytoskeletal proteins in spermatozoa participate in the rearrangement and shaping of nuclear and cytoplasmic components, rearrangement of domains, and have a role in the acrosome reaction. The acrosomal region contains the testis-specific proteins, actin-related protein T2 (ACTRT2),[52] activity regulated cytoskeletal-associated protein (ARC),[53] and fascin homolog 3, actin-bundling protein, testicular (FSCN3).[54] Actin filaments were found in the subacrosomal space in rat sperm,[55] acrosome in guinea pigs,[56] the postacrosomal region of rat, rabbit, bull, and boar sperm, and in the connecting piece of hamster, rabbit, bull, and human sperm.[57] They also were detected in the posterior region of the head and in the connecting piece, middle piece, and principal piece of human sperm,[58,59] and along the concave margin of the hamster sperm head.[58] The testis-specific profilin 3 (PFN3)-actin related protein T3 (ACTRT3) complex was implicated in conformational changes in the organization of the sperm-specific nucleus.[60] In addition, myosin

Vet-ebooks.com

is a component of the nuclear plate that connects the acrosome with the nuclear envelope.[61] Also, the perinuclear theca contains actin-related proteins Arp-T1 and Arp-T2,[62] the actin-binding protein calicin (CCIN),[63] and the capping protein (actin filament) muscle Z-line, alpha 3 (CAPZA3, CPα3) and capping protein (actin filament) muscle Z-line, beta 3 (CAPZB3, CPβ3) subunits of a testis-specific actin-capping protein complex.[64] Furthermore, human spermatozoa contain spectrin in the anterior acrosome and principal piece regions[65] and rabbit sperm contain spectrin in the anterior acrosome region and postacrosomal region of the head and the principal piece of the tail.[66] Finally, Ca^{2+}-dependent protease, calpain-1 (CALPN1), originally located in the sperm cytoplasm, relocates from the cytoplasm to the plasma membrane during capacitation in guinea pigs, possibly serving to cleave spectrin and facilitating the acrosome reaction.[67]

Maintenance of Surface Domains

The maintenance of sperm-surface domains and the segregation of specific proteins into domains probably involves several processes: restriction of mobility of surface molecules in their final domain, existence of barriers to movement of surface components at the domain boundary, and thermodynamic partitioning of molecules into specific regions.[68] For example, ADAM2 is evenly distributed over the entire head of testicular sperm but becomes restricted to the posterior head as sperm transit the epididymis in the guinea pig probably due to proteolytic processing of the β fertilin subunit in the epididymis.

Associations between the plasma membrane and internal structures are believed to form barriers between domains and serve to restrict the movement of some proteins. The plasma membrane is closely associated with the posterior ring at the junction between the head and neck (connecting piece), and with the annulus at the junction of the middle piece and principal piece. Two antigens (2B1, 2D6) present over the whole surface of the flagellum of rat sperm showed antibody-induced patching, but did not migrate onto the head,[69] perhaps due to the posterior ring. However, BSG apparently was not restricted from redistribution by the posterior ring and annulus.[30] The PT-1 antigen exhibited free diffusion within the plasma membrane of the distal tail domain, but was prevented from migrating into the midpiece, possibly by the annulus.[70]

Other structures that might serve to constrain or anchor plasma membrane components are the groups of intramembranous particles seen in freeze-fracture studies. These include zipper-like array of particles associated with the ribs of the fibrous sheath and oblique strands of intramembranous particles associated with the underlying mitochondria.

Sperm Plasma Membrane Lipids

Lipid Composition

Sperm plasma membranes contain relatively high amounts of ether phospholipids known as plasmalogens (20–40%), other ether-linked phospholipids,[71] and lipids with long, polyunsaturated aliphatic chains.[72] Phospholipids make up about 70% of the total plasma membrane lipid in boar sperm,[73] and choline phospholipids account for almost two-thirds of phospholipids in the plasma membrane of the anterior head of ram sperm. Sterols are the next most abundant lipid, resulting in a cholesterol/phospholipid molar ratio of about 0.12.[73] The total cholesterol/total phospholipid ratio, the choline/ethanolamine glycerophospholipid ratio, and the proportion of plasmalogens within these two classes, were much larger in the head than in the tail in the rat.[74] It was suggested that the high cholesterol to phospholipid ratio accounts for the lack of thermotropic phase transitions in the plasma membrane of live human sperm detected by Laurdan fluorescence spectroscopy.[75] The amount of sterol is much higher in the anterior acrosome than in the postacrosomal region in mammalian sperm (Figure 3.4). The postacrosomal region contains few sterols or anionic lipids. Also, cholesterol sulfate makes up only a small fraction of the total sterol content, but is a major component of the plasma membrane over the acrosome of human sperm.[76]

Free fatty acids comprise a relatively small amount of the lipid in boar spermatozoa, whereas diacylglycerols are present in about the same amounts as glycolipids.[73] The phospholipid/protein ratio is approximately 0.68 on a weight basis in plasma membranes isolated from boar spermatozoa,[73] suggesting that the amounts of total lipid and protein are about the same. However, this is for the total plasma membrane, and the amounts and types of lipids and the lipid/protein ratios probably vary between different domains.

Glycolipids may have a significant role in lateral domain organization.[73,77] The major glycolipid in sperm, sulfogalactosylglycerolipid, is present in both the head and tail fractions of spermatozoa.[78]

Diffusion of Lipids

Fluorescence recovery after photobleaching (FRAP) measurements indicate that a large fraction of the plasma membrane lipids of mammalian sperm is not free to diffuse laterally.[9,79] The nondiffusing lipid pool increases to more than 50% of the lipid during epididymal maturation.[9] FRAP studies showed that the lipid diffusion rates were significantly higher over the acrosome and postacrosomal region than on the midpiece and principal piece in live bull, boar, ram, and mouse spermatozoa.[80] FRAP studies also observed a free exchange of a lipid analog by lateral diffusion in the plasma membrane between

Vet-ebooks.com

the head and midpiece regions of ram and boar sperm[81] and between the midpiece and distal tail of ram sperm.[9] However, studies using the method of fluorescence loss in photobleaching detected a diffusion barrier to ~200-nm particles between the equatorial segment and postacrosomal domains, but not between the principal and equatorial segments.[82]

When spermatozoa were subjected to hypo-osmotic shock to produce surface blebs, the diffusion rate for lipids were comparable on blebs and on untreated spermatozoa, suggesting that interactions of plasma membrane lipids with underlying cytoskeletal elements do not affect diffusion.[77] In addition, when artificial bilayers were formed from sperm plasma membrane lipid extracts, the fraction of nondiffusing lipid was about the same as that on intact spermatozoa, suggesting that lipid–lipid interactions are responsible for restricting lateral lipid movement.[77] Differential scanning calorimetry studies indicated that significant amounts of gel-phase lipids are present in the anterior region of the head of ram spermatozoa, which allows sperm plasma membrane lipids to segregate by lateral phase separation into coexisting fluid and gel domains at physiological temperatures.[71] The gel domains may contain the nondiffusing lipid fraction present in the sperm plasma membrane.

Lipid Rafts

Lipid rafts (also known as lipid microdomains) are discrete lipid domains present in the external leaflet of the plasma membrane. The rafts are enriched in cholesterol, glycosphingolipids, and glycosyl-phosphatidylinositol GPI-anchored proteins, and are insoluble in low concentrations of nonionic detergents. Lipid rafts are present throughout the surface of mammalian spermatozoa and not restricted to particular domains. Lipid raft-related proteins detected in spermatozoa include caveolin1 (CAV1) on the anterior acrosome and principal piece.[83] Transient receptor-1 homolog (TRPC1) was co-immunolocalized with CAV1.[84] Other lipid raft markers, CD59, GM1 ganglioside, and flotillin2 (FLOT2), were found on the posterior head, and FLOT2 was localized mainly on the posterior head and middle piece in human spermatozoa.[85] Serine protease 21 (PRSS21) was localized in the head, cytoplasmic droplet, and midpiece.[86] Sperm lipid raft dynamics are reviewed elsewhere in relation to sperm–zona binding and the zona pellucida-induced acrosome reaction.[87]

Changes in Lipids with Maturation and Capacitation

Changes in the lipid content and distribution in the spermatozoon plasma membrane occur during epididymal maturation and capacitation, and these may have substantial effects on the composition and function of the membrane in different domains. The total lipid and cholesterol content decreases during epididymal maturation in most species. In addition, the cholesterol/phospholipid ratio and concentration of phosphatidylserine, phosphatidylethanolamine, cardiolipin, and ethanolamine plasmalogen decreases. However, sulfoconjugated sterols and unsaturated fatty acids increased in hamster and human.[88] There was a decrease in the level of fatty acids and an increase in diacylglycerol, but no change in the degree of saturation of fatty acids. Plasma membrane from the anterior head region of ram sperm is particularly rich in ethanolamine and choline phosphoglycerides, and the amount of desmosterol and ethanolamine in this region of the plasma membrane decreases while the cholesterol to phospholipid ratio increases during epididymal maturation. The decrease of plasma membrane fluidity is regionally different, as evidenced by FRAP.[9] However, the diffusion rate of a fluorescent lipid analog increased in all regions of the sperm except the midpiece during maturation.

Cholesterol efflux from the sperm plasma membrane occurs during capacitation. A sulphogalactolipid analog incorporated into the marginal segment of ram sperm migrated to the equatorial segment with capacitation.[89] Capacitation also resulted in the redistribution of CRISP1 on rat spermatozoa,[42] ADAM2 on guinea pig spermatozoa,[90] and BSG on mouse spermatozoa.[30] Freeze-fracture studies of filipin-treated sperm showed a patch-like loss of cholesterol during capacitation from the plasma membrane overlying the acrosome in mouse spermatozoa. This cholesterol change alters the membrane fluidity and the lateral mobility of associated proteins and initiates the protein kinase A signal transduction pathway that promotes capacitation.[91] This membrane condition is presumed to lead to facilitating fusion between the plasma membrane and acrosomal membrane during the acrosome reaction, and between the plasma membrane overlying the equatorial segment and microvilli during gamete membrane fusion. ATP-binding cassette transporter G2 (ABCG2) is an efflux pump that belongs to the ABCG subfamily of the ATP-binding cassette (ABC) transporters and can extrude a wide variety of compounds, including cholesterol, from the cell using the energy produced from ATP hydrolysis. ABCG2 is present in the plasma membrane overlying the acrosomal membrane from bovine testis and epididymis.[92] This location of ABCG2 suggests its possible involvement in the translocation of cholesterol sulfate and its role in epididymal sperm maturation.

THE SPERM HEAD

The mammalian sperm head contains the nucleus and acrosome surrounded by moderate amounts of cytoskeletal components and a small amount of cytoplasm.

Vet-ebooks.com

The acrosome caps the anterior end of the nucleus and cytoskeletal components lie in the narrow space between the acrosome and the nucleus and between the acrosome and the plasma membrane. Spermatozoa of most mammalian species have a spatulate head (Figure 3.2), with the nucleus and acrosome flattened in the plane of the anterior–posterior axis of the spermatozoa. The acrosome and nucleus are symmetrical structures. In contrast, the sperm of some rodents have a falciform-shaped head (Figure 3.2), with the acrosome overlying the convex margin of the nucleus. Although spermatozoa are uniform in size and shape within most species, a third or more of human spermatozoa are abnormal in size and shape and frequently have various sizes of nuclear vacuoles or lacunae.

The Sperm Head Cytoplasm (Layer)

The head of the spermatozoon contains a thin layer of cytoplasm. The space between the anterior tip and convex surface of the acrosome and the plasma membrane of falciform sperm is the para-acrosomal space (Figure 3.3). The space between the outer acrosomal membrane and nuclear envelope is the subacrosomal space (perinuclear space) that contains perinuclear theca components. The subacrosomal space can be divided into two subspaces. One is the subacrosomal space of the anterior part of the head and the other is the postacrosomal space where the postacrosomal sheath is present. The cytoplasm or space between the plasma membrane and outer acrosomal membrane is the periacrosomal space. This space is narrow and not clearly visible in mature spermatozoa, but it may be important in maintaining acrosome shape and in early events of capacitation and the acrosome reaction or in sperm-egg membrane fusion.

The Sperm Nucleus

Sperm deliver the paternal genome to the embryo in a novel configuration. The chromatin is highly condensed to 1/13th that of the oocyte,[93] and the nuclear volume is considerably less than 5% of a somatic cell. Sperm chromatin is resistant to much greater mechanical disruption than somatic cells.

Nuclear Proteins

Mammalian sperm have two major nuclear proteins, protamines and histones. Protamines are the predominant nuclear proteins, composed of 27–65 amino acids, and are enriched in the highly basic amino acids arginine and cysteine. The mRNAs encoding mouse protamines are transcribed from the haploid genome in round spermatids and translation is delayed until spermatids are undergoing elongation.[94] The remaining histones are highly acetylated. Most mammals have only one active protamine gene, but mice and humans have two. Both protamines are essential for fertility; in mice heterozygous for a mutation in either gene, the amount of the protein was decreased and sperm DNA stability was disrupted.[95,96] Male mice null for testis-specific serine kinase 6 (TSSK6, SSTK) are sterile due to profound impairment in motility and morphology of spermatozoa resulting from a defect in DNA condensation.[97] Nuclear disruption occurs in elongating spermatids at a step in spermiogenesis coincident with chromatin displacement of histones by transition proteins.

It was suggested that the histones in human spermatozoa might be part of a sequence-specific component of the genome that is programmed for expression in early development. TSSK6 phosphorylated histones H1, H2A, H2AX, and H3, but not H2B or H4 or transition protein one in vitro.[97] The chromobox 1 protein (CBX1, M31) was detected in mouse total sperm proteins on western blots and presumably was associated with centromeres, but histone H1 was not detected.[98] Hamster sperm nuclei appear to contain a DNAse,[99] and enzymes involved in de novo pyrimidine biosynthesis were detected in the nucleus of human spermatozoa.[100]

There are two general models for the association of protamines with DNA. The more widely accepted model suggests that protamines are present in an extended configuration and lie in the major groove of the DNA helix, causing the DNA to become packaged into toroidal loops.[101] Most of the mammalian sperm chromatin is compacted into toroids that contain roughly 50 kb of DNA. Each protamine-DNA toroid forms a loop domain, and these are stacked side to side. The toroid configuration is thought to protect chromatin from oxidizing and from the effects of other harmful molecules within the reproductive tract.[102,103]

Although the large majority of DNA is packaged by protamines, a smaller amount (2–15%) retains histones and the DNA is attached to the proteinaceous nuclear matrix at roughly 50-kb intervals.[101,104] Histones are nonrandomly distributed in the sperm genome and are associated with specific genes.[105,106] Histone-bound segments of DNA are scattered throughout the paternal genome, largely at gene promoter regions.[105] This can allow spermatozoa to transmit histone-based chromatin structural features and histones with specific modifications in the sperm to newly fertilized oocytes,[107] including both histone-bound chromatin and matrix attachment regions in the newly formed paternal pronucleus. It is suggested that the nuclear matrix organization is required for DNA replication in the one-cell embryo, with the histone-bound chromatin identifying paternal genes important for embryonic development.[101,103] Chromatin is stabilized by the formation of covalent disulfide linkages between protamines

Vet-ebooks.com

on adjacent DNA strands. Defects in sperm DNA integrity are linked with DNA fragmentation and apoptosis.[108]

Epigenetics

Epigenesis is the heritable transmission of non-DNA-based information. Epigenetic modifications occur in the methylation recycling stages in primordial germ cells, gametogenesis (reprogramming), and postfertilization or embryogenesis.[109] Mammalian sperm carry the paternal genome to the oocyte, and each sperm contains one copy of each gene that bears epigenetic modifications. There are two types of heritable epigenetic changes, DNA methylation and histone modification.

DNA methylation is the status of methylation of cytosine nucleotides of DNA (examples are genomic imprinting and X-chromosome inactivation), leading to monoallelic expression. This occurs on cytosine residues within CpG dinucleotides that exist at differentially methylated regions, and is involved in regulation of gene expression. For example, the *H19* gene is normally methylated and silent in males (paternally methylated), and hypomethylated or unmethylated in females and expressed in the offsprings (maternally demethylated). However, the occurrence of abnormal methylation (e.g., incomplete methylation acquisition) at the *H19* locus was significantly increased in oligozoospermic patients compared with normozoospermic patients.[110] Similarly, unusual hypomethylation of the *H19* gene and hypermethylation of the *MEST* gene (paternally expressed gene) were observed at a higher frequency in oligozoospermic men than in normozoospermic controls.[111]

Histone modification occurs by acetylation, phosphorylation, methylation, sumoylation, and ubiquitylation. During spermatogenesis, canonical histones (H2A, H2B, H3, H4) are replaced with protamine, resulting in chromatin compaction. However, 5%–15% of the sperm genome in fertile men remains bound to histones rather than undergoing protamination.[109,112] During protamine replacement, histones and nucleosomes were retained on promoters of genes for transcription factors and signaling pathway components associated with early embryo development, and these regions also showed significant DNA hypomethylation in the sperm genome.[106,109] A study employing chromatin immunoprecipitation of DNA bound to histone H3 acetylated at lysine 12 (H3K12ac) showed that in human sperm H3K12ac was primarily localized in the subacrosomal region, and that in mouse sperm H3K12ac was more strongly observed in the male pronucleus than the female pronucleus.[113] A positive relationship was found between H3K12ac enrichment at specific gene promoters and an elevated level of mRNA transcription of those genes. Histone H4K12ac was localized in the nucleus at the postacrosomal region, while protamine-1 is present throughout the nucleus.[113] Because histones are retained for potential epigenetic regulatory control of the sperm genome postfertilization, aberrant histone acetylation (e.g., H4K12 deacetylation) that is found within developmentally important gene promoters in infertile men could reflect insufficient sperm chromatin compaction and result in inappropriate transfer of epigenetic information to the oocyte.[113]

Thus, the status of the sperm epigenome implies not only a poising of the paternal genome for embryogenesis and a possible role in the establishment of totipotency of the embryo, but also an association with different types of male infertility.[114]

RNA

Mature ejaculated mouse and human spermatozoa carry messenger RNA, antisense RNAs, and microRNAs.[115,116] For example, ropporin 1 (ROPN1) RNA is localized to the nuclear matrix, suggesting that paternal RNA could contribute to early embryonic development.[117]

Nuclear Envelope

The sperm nucleus is enclosed by an unusual nuclear envelope, which is established during spermiogenesis. Over most of the nucleus, nuclear pores are absent. Caudal to the posterior ring, in the redundant nuclear envelope, sperm nuclear pores are abundant (Figure 3.5).

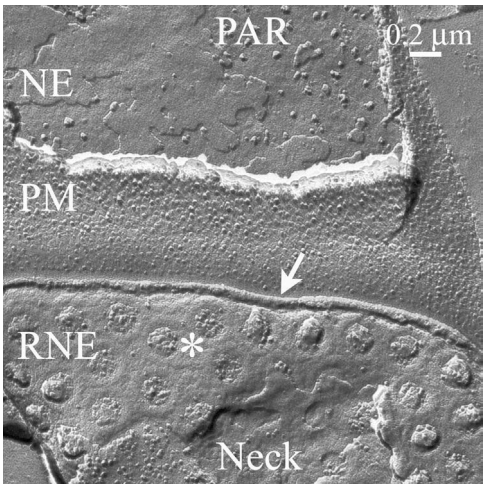

FIGURE 3.5 Freeze-fracture image of the membranes at the neck region. The neck region is connected to the postacrosomal region by the posterior ring. The nuclear pores (*) of the redundant nuclear envelope (RNE) are seen in the neck region. The plasma membrane covering the neck region is not seen because of detachment of the head from the neck region during sample preparation. Nuclear Lamina

The nuclear lamina is a protein meshwork lining the inner surface of the nuclear envelope and forms part of the nuclear skeletal network (karyoskeleton) anchoring the chromatin. It consists primarily of lamins, members of the intermediate filament protein family. This network contains lamins A and B (LMNA and LNMB), and splice variants of LMNA and LMNB, lamina-associated polypeptide 2 (LAP2), and the lamin B receptor (LBR). These proteins are detected during spermatogenesis, but except for lamin B1, usually are not detected in spermatozoa. Deletion of the *Lmna* gene resulted in a high level of apoptosis in pachytene spermatocytes and the disruption of spermatogenesis.[118] Deletion of the germ cell-less homolog 1 (*Gmcl1*) gene caused abnormally shaped spermatozoa, suggesting involvement for head shaping via the association between the nuclear lamin and perinuclear theca substance in mice.[119] The dpy-19-like-2 (DPL19l2) protein is located in the inner nuclear membrane. This new member of a family of structural transmembrane proteins was reported to anchor the acrosome to the nucleus.[120] In DPY19l2-null male mice, the acrosome and the manchette (a transient microtubular structure surrounding the elongating spermatid nucleus) failed to link to the nucleus. This led to the formation of round-headed sperm (globozoospermia) apparently caused by disruption of vesicular trafficking and destabilization of the nuclear dense lamina and the junction between the acroplaxome and the nuclear envelope.

Nuclear Pocket

During chromatin condensation in spermiogenesis, smaller areas of the nucleus (0.1–0.2 μm) remain uncondensed and manifest a fine granulofilamentous substructure. While this process takes place, pores move caudally and concentrate in the redundant nuclear envelope that demarcates the clear nuclear pocket around the sperm neck.[121] Polyubiquitinated proteins are found in the nucleus of rat spermatids and human spermatozoa, and proteasomes are present in the small uncondensed chromatin regions and nuclear pocket area.[122] In most cells, proteasomes are proteolytic macromolecular complexes that digest polyubiquitinated proteins.

Nuclear Lacunae or Vacuoles

When observed with the electron microscope, nuclear lacunae or vacuoles appear as large (1–3 μm) defects of irregular shapes. They are found in human sperm, but not in sperm of other primates and mammalian species. The vacuoles are sharply delimited from normally compacted chromatin.[121] The nuclear vacuoles sometimes contain cytoplasmic or acrosomal components.[123,124] Because surplus cytoplasm usually is phagocytosed by Sertoli cells and discarded during normal spermiogenesis, the nuclear vacuoles that contain surplus cytoplasm could have deleterious effects on the function of the paternal genome in the fertilizing sperm.[124]

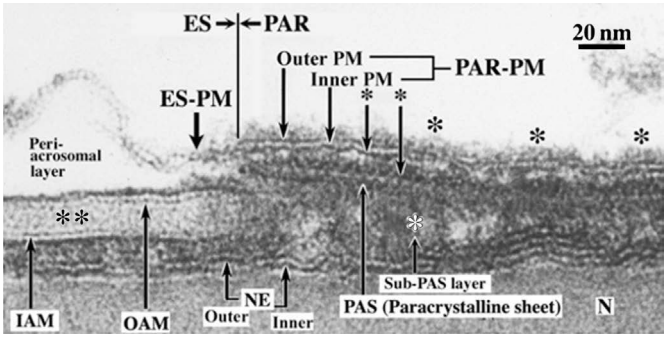

FIGURE 3.6 Transmission electron micrograph of the border between the equatorial segment (ES) and the postacrosomal region (PAR) in mouse sperm. In the ES, the periacrosomal layer is expanded and appears to be electron-lucent. The acrosomal lumen between the outer acrosomal membrane (OAM) and inner acrosomal membrane (IAM) at the equatorial segment is filled with the acrosomal matrix (**). The PAR has complex features. Glycocalyx-like substance (*) is seen over the postacrosomal plasma membrane (PAR-PM). The postacrosomal sheath (PAS) or the paracrystalline sheet is connected by an electron-dense periodic substructure (asterisks with arrows) to the plasma membrane. The sub-PAS layer is filled with electron-dense material (white asterisk), which is a component of the perinuclear theca surrounding the enitre nucleus (see Figure 3.3). N, nucleus; NE, nuclear envelope. *Source: Modified from Toshimori K, et al.* Mol Reprod Dev *1991;**29**(3):289–93.*

The Sperm Head Cytoskeleton

Cytoskeletal structures are associated with the different regions (domains) of the mammalian sperm head (Figure 3.3), including the *subacrosomal cytoskeleton* located in the subacrosomal space, the *postacrosomal cytoskeleton* in the postacrosomal space, and the *para-acrosomal cytoskeleton* in the para-acrosomal space in falciform sperm (Figures 3.6 and 3.7). The periacrosomal space is narrow, but molecules in this region could function in sperm–egg interactions.

Structural Aspect

The subacrosomal cytoskeleton, referred to as the *perforatorium* and postacrosomal cytoskeleton, is composed of amorphous, electron-dense material. These structures can be isolated together and are referred to as the *perinuclear theca* (Figure 3.3). The perforatorium is a prominent feature of falciform-shaped heads of rodent spermatozoa, but is a minor component of the spatula-shaped heads of spermatozoa in most mammalian species. The perforatorium becomes more resistant to solubilization during epididymal transit due to extensive disulfide bond formation, and may have a mechanical role in egg penetration.[125]

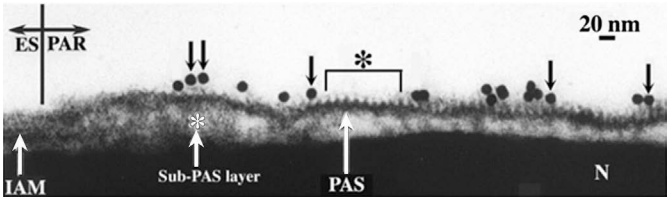

FIGURE 3.7 The cytoskeletal structure at the postacrosomal region. Immuno-electron microscopy with anti-MN13 monoclonal antibody. MN13 epitope regions (arrows) are present on the electron-dense periodic substructures (typically found on the part indicated by asterisk) that emerge from the postacrosomal sheath (PAS). The plasma membrane was removed with 0.1% Triton X-100 treatment before antibody application. The sub-PAS layer (white asterisk) is filled with electron-dense material. ES, equatorial segment; IAM, inner acrosomal membrane; N, nucleus; PAR, postacrosomal region. *Source: Modified from Toshimori K, et al.* Mol Reprod Dev *1991;**29**(3): 289–93.*

The perinuclear theca covers the external surface of the nuclear envelope and is divided into two components, the subacrosomal perinuclear theca and the postacrosomal sheath perinuclear theca. The postacrosomal sheath perinuclear theca is continuous with the posterior end of the subacrosomal perinuclear theca and extends caudally to the posterior ring. The ring region is a zone of close adhesion between the plasma membrane, the postacrosomal cytoskeleton, and the nuclear envelope (Figures 3.3–3.5). The isolated perinuclear theca retains the shape of the sperm nucleus in the absence of DNA and the acrosome.[126] In human spermatozoa, the perinuclear theca is composed of six proteins of variable molecular mass (16, 22, 29, 34, 50, and 68 kDa) similar to those previously described in other mammals.[63,127–131] In addition, the MN13 molecule is localized in the perinuclear theca just beneath the plasma membrane overlying the postacrosomal sheath (Figure 3.7). It is involved in maintaining the shape of the posterior head and is absent in round-headed spermatozoa (globozoospermia) in both human and in mouse spermatozoa deficient in the golgi-associated PDZ- and coiled-coil motif-containing protein GOPC.[132]

Composition

The evidence that the sperm-head cytoskeleton shows resistance to chemical treatments suggests that it has structural roles in defining the shape of the sperm head and functional roles in helping sperm penetration into the egg investment at fertilization, and presumably regulates other functional molecules required for the acrosome reaction.[125] The proteins of the sperm-head cytoskeleton are listed in Table 3.1.[133–146] In addition to these molecules, other proteins associated with the perinuclear theca include actin, spectrin, and calmodulin,[147] thecins,[148] DP71F isoform of dystrophin, β-dystrobrevins,[149] antigen AJ-p90,[150] and PLCZ1.[151] Of these, PLCZ1 is best-characterized and is a candidate for the sperm-borne oocyte activation factor. PLCZ1 is the smallest among the five or more phopholipase C (PLC) isoforms and lacks an N-terminal pleckstrin homology domain that is present in other PLC isoforms.[151] The reported location of PLCZ1 is variable from species to species, possibly due to the different antibodies used. Although PLCZ1 is initially thought to be a constituent of the detergent-resistant perinuclear theca, it is localized in the acrosomal region, equatorial segment, and postacrosomal region in human.[152] In humans and mice, PLCZ1 is incorporated into the acrosome and not detected in testicular sperm during spermatogenesis. However, a recent study showed that PLCZ1 is secreted by the epididymal epithelial cells, binds to the sperm surface during epididymal maturation, and disappears after the acrosome reaction.[153] In addition, PLCZ1 is not found in the detergent-resistant perinuclear theca fraction, which may not support a role for it as a sperm-borne oocyte activation factor. The postacrosomal sheath's other proteins include the WBP2 N-termina like protein (WBP2NL) localized to the postacrosomal sheath in the rat[154] and the MN13 antigen. An inhibition assay with the MN13 antibody blocked egg activation in the mouse.[155]

Function

Sperm-head cytoskeletal components have a structural role in defining the shape of the sperm head and have a functional role in aiding sperm penetration of the egg investments at fertilization.[156] In early spermiogenesis before the perforatorium forms, the para-acrosomal theca materials support acrosome biogenesis and apparently shield and shape the nucleus. At the end of spermiogenesis, the perforatorium and the postacrosomal sheath develop as a distinct structure after elongation and flattening of the spermatid head, and these postacrosomal sheath components provide structural reinforcement to maintain the acrosome and nuclear shapes.[157]

Because the anterior acrosome is involved in the acrosome reaction, the molecules including periacrosomal or para-acrosomal cytoskeletons are important in relation to the initiation of the acrosome reaction. The para-acrosomal cytoskeleton (filamentous cytoskeletal complex) is present in hamster sperm.[158] Complexins I and II (CPLX1, CPLX2) proteins are reported to bind tightly to the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex and regulate exocytosis. These proteins are found in the peri-acrosomal region of spermatozoa.[159] CPLX1-deficient sperm performed the acrosome reaction in response to a Ca^{2+} ionophore, but they did not respond to egg zona proteins and showed reduced fertilizing ability in vitro.[159] SNARE regulatory proteins, including *N*-ethylmaleimide sensitive fusion protein attachment protein alpha (NAPA, a-SNAP), *N*-ethylmaleimide sensitive fusion protein (NSF), ras oncogene family

member 3a (RAB3A), and synaptotagmins (SYT), are detected around the acrosomal region, suggesting involvement of the SNARE complex in regulation of acrosomal exocytosis.[160–162]

The perinuclear theca components presumably associate with the other matrix proteins and play roles in assembling the acrosome and shaping the nucleus (head) during spermatogenesis and in oocyte activation during fertilization.[132,163–165] If acrosome biogenesis and perinuclear theca formation are impaired, developing sperm become round (globozoospermia) and lack the ability to activate mouse or human oocytes.[165] In addition, the perinuclear theca appears to link the nuclear envelope to the postacrosomal plasma membrane. In round-headed sperm of GOPC-null males, the association between the nuclear envelope and the postacrosomal plasma membrane is weak due to the lack of a postacrosomal sheath and posterior ring, allowing the mitochondrial sheath to shift proximally to coil around the nucleus.[166]

The Acrosome

The acrosome is a unique sperm organelle that originates from the Golgi complex and contains enzymes necessary for the sperm to penetrate through the cumulus cells and zona pellucida of the egg to achieve fertilization. It is a membrane-enclosed vesicle sitting as a cap over the nucleus in the anterior part of the sperm head. Most of the acrosomal components are produced in haploid spermatids during spermiogenesis, but a few begin to be synthesized in late pachytene spermatocytes.

Structure

The shape of the acrosome is characteristic of the species (Figure 3.2). The inner acrosomal membrane overlies the anterior part of the outer membrane of the nuclear envelope and is continuous with the outer acrosomal membrane at the posterior end of the acrosome (Figure 3.3**)**. The outer acrosomal membrane lies close to the inner surface of the plasma membrane of the anterior sperm head. The acrosome consists of two segments, the acrosomal cap (anterior acrosome) and the equatorial segment (posterior acrosome), which corresponds in distribution to the plasma membrane domains with the same names. During the acrosome reaction, the outer acrosomal membrane and the overlying plasma membrane fuse and vesiculate, and most of the acrosomal contents are discharged. The inner acrosomal membrane and the contents at the equatorial segment persist until sperm–egg fusion in most species. Acrosome shape and size varies widely between species (Figure 3.2), and the distribution and relative prominence of these two segments differ accordingly.[167]

The portion of the acrosomal cap that extends beyond the anterior margin of the nucleus is referred to as the marginal segment (apical segment, peripheral rim), and the portion overlying the nucleus is referred to as the principal segment (acrosomal segment). In the human, monkey, bull, boar, rabbit, and bat the acrosome is relatively small, with no appreciable extension beyond the nucleus, whereas in the guinea pig, chinchilla, and ground squirrel the acrosome has a large apical segment.[167] The acrosome, particularly the marginal segment, often has a more complex shape than is obvious when examining sperm smeared onto a slide. The equatorial segment forms a band that approximately overlies the equator of spatulate head spermatozoa, while in falciform head sperm, the equatorial segment may cover much of the lateral surfaces of the head (Figure 3.2).

The anterior acrosome is subdivided into two or three subdomains as evidenced by immunocytochemical and electron microscopy methods. In mouse spermatozoa, the cortex domain faces the outer acrosomal membrane, while the medulla domain is deep and faces the inner acrosomal membrane. The MC101 molecules appear to locate at the border of these subdomains.[168] In guinea pig sperm, three subdomains (M1, M2, M3) are present.[169] Acrosomal molecules are present in these subdomains and integrated into the acrosomal membranes.

The final shape of the acrosome is influenced by extrinsic forces generated by cytoskeletal elements in the spermatid and/or Sertoli-cell cytoplasm or by forces intrinsic to the nucleus. Generally, mammalian acrosomes and their constituents continue to undergo differentiation structurally and chemically after spermatogenesis, and the definitive morphology is not achieved until sperm reach the distal portion of the epididymis.[170] Genetic factors influence acrosome formation and shape, as evidenced by disruption of this process in many genetically modified mice and in mutant mice.[171]

The membrane of the acrosome, particularly the equatorial segment, contains particles that form a crystalline array, giving the membrane a highly regular, granular appearance (Figure 3.4). These may be an indication of ordered structure in the underlying acrosomal components. The outer acrosomal membrane appears to be fragile and easily displaced at the time of the acrosome reaction. However, it has electron-dense coating substances on the inner (luminal) surface.[172] This inner surface coat of the outer acrosomal membrane is composed of glycoproteins, since lectin wheat germ agglutinin binds to the inner surface of the membrane. These glycosylated molecules at this site might help to stabilize the membrane or play a functional role in the membrane fusion events of the acrosome reaction.[173] Some of the membrane components could be phosphorylated in a cyclic adenosine monophosphate (cAMP)-independent manner and include calmodulin-binding proteins.[173] This coating may also function as protection, because the outer acrosomal membrane is greatly deformed

Vet-ebooks.com

to contact the plasma membrane, accompanying acrosomal swelling prior to the acrosome reaction in human sperm.[174] Zonadhesin (ZAN) is restricted to the outer acrosomal membrane of the apical and principal segments and to the contents of the posterior acrosome in mammals including humans.[175] ZAN is dissociated from the outer acrosomal membrane and becomes incorporated into the forming acrosomal matrix during sperm maturation in the epididymis.[176] ZAN is exposed to the sperm surface during capacitation to be involved in binding to the zona pellucida independently of the acrosome reaction by a rapid transient fusion ("kiss and run") mechanism.[175]

Development of the inner acrosomal membrane begins in early spermatids when the membrane of the proacrosomal granule abuts and then flattens against the nuclear envelope. The granule spreads over the apical end of the nucleus during acrosomal development and nuclear elongation.[177] The inner acrosomal membrane contains glycoproteins and is generally quite resistant to chemical and physical disruption. However, the inner acrosomal membrane appears to be fluid because antigens recognized by monoclonal antibody PH-20 (SPAM1) migrate from the plasma membrane of the postacrosomal region of the guinea pig sperm head to the inner acrosomal membrane following the acrosome reaction.[178] Acrosomal proteins equatorin (EQTN) and izumo (IZUMO1) are anchored on both the inner and outer acrosomal membranes and are translocated to the overlying equatorial plasma membrane.[179–181] IZUMO1 also moves to the postacrosomal plasma membrane.[180] In contrast, the equatorial segment is stabilized by the extensive scaffolding network that connects the outer acrosomal membrane to the inner acrosomeal membrane, but this cytoskeletal network is not seen before sperm entry into the oocyte, and becomes apparent upon fertilization, presumably due to the release of acrosomal contents.[125,155]

Contents

The acrosome contains multiple enzymes that serve a critical role in the process of fertilization in mammals (Table 3.2).[182–221] During the acrosome reaction, acrosomal contents are released by exocytosis in response to Ca^{2+} signals. Following the release and activation of acrosomal enzymes, spermatozoa penetrate the zona pellucida surrounding the oocyte, a process that can be blocked by protease inhibitors. Some of the acrosomal enzymes appear to associate with nuclear matrix structural proteins.

Acrosin (ACR) is a member of the serine protease superfamily and present only in spermatogenic cells (Table 3.2). It is synthesized as a precursor (proacrosin) predominantly in round spermatids, but proacrosin mRNA or protein are detected in pachytene spermatocytes of mouse, guinea pig, and human. Proacrosin is present mainly in the anterior acrosome in human, boar, bull, and rabbit spermatozoa and is localized to the inner acrosomal membrane.[186] ACR-null male sperm are fertile,[185] indicating that other serine proteases participate in this process. ACR appears to contribute to zona penetration because acrosin-null male mouse sperm are moderately slower to fertilize than wild-type sperm.[222]

Acrosin-binding protein (ACRBP, sp32) binds proacrosin, but not mature ACR, and is tyrosine phosphorylated during capacitation.[206] In PCSK4-null male mice, ACRBP, which normally undergoes processing from a 58.5-kDa precursor to a 27.5-kDa mature form, is not proteolytically processed, suggesting that ACRBP is a substrate for PCSK4.[175] A recent report showed that ACR and matrix metalloprotein 2 (MMP2) are bound to the inner acrosomal membrane.[186] ACR inhibitors are present both within the acrosome[223] and in seminal plasma.[224] Sperm-associated inhibitors in the boar resembling Kazal-type inhibitors are present in seminal plasma.[224] Another serine protease inhibitor closely related to the plasma protein C inhibitor is present in the acrosome of human spermatozoa.[225] Thus, both ACR and ACR inhibitors are present in the acrosome.

Sperm hyaluronidase is different from the common lysosomal form.[226] Although neither of the two sperm hyaluronidases, sperm adhesion molecule 1 (SPAM1, PH20) and hyaluronoglucosaminidase 5 (HYAL5), are essential for fertilization in the mouse, SPAM1/ACR-deficient and SPAM1/serine protease 21 (PRSS21 testisin, TESP5) deficient sperm have reduced ability to traverse the cumulus matrix compared to sperm lacking SPAM1. This suggests that ACR, PRSS21, or both may function cooperatively with SPAM1 in sperm/cumulus penetration.[227]

Other acrosomal enzymes that have been reported include β-galactosidase, β-*N*-acetylglucosaminidase, arylsulfatase, collagenase-like peptidase, a cathepsin D-like protease, cathepsin H, trypsin-like proteases distinct from acrosin, dipeptidyl peptidase II, calpain II, neuraminidase, nonspecific esterases, arylamidase, aspartylamidase, arylsulfatase A, acid phosphatase, β-*N*-acetylglucosaminidase, a phospholipase C, and phospholipase A_2.[5] Although it is generally believed that these enzymes are soluble components that are released when the acrosome reaction occurs, the genes encoding most of these enzymes have not been identified and they remain to be characterized at the molecular level. Testis-specific serine proteases 39 and 40 (PRSS39 and PRSS40)[210] and a ubiquitously expressed homolog of pancreatic trypsin, serine protease 2 (PRSS2),[211] are also present. PRSS21-deficient sperm are fertile, but are reduced in fertilizing ability in vitro.[212] Sperm acrosome associated 3 (SPACA3, SLLP1) is an acrosomal protein

			Interacts with GGN1 and SHTAP	189,190
β-galactosidase	*Bgal*	Ubiquitous	Soluble compartment; putative testis-specific isoform, differs in size and enzymatic properties from lysosomal form	182,191,192
Hyaluronidase SPAM1 (PH-20)	*Spam1*, *SPAM1*	Testis-specific, protein	Glyosylphopshatidylinopsitol-anchored plasma membrane, inner acrosomal membrane retained on acrosome-reacted sperm	193
			KO; fertile	194
HYAL5	*Hyal5*, *HYAL5*	Testis-specific, protein	Glyosylphopshatidylinopsitol-anchored plasma membrane, released during acrosome reaction	195
			KO; fertile	196
MC41	N.D.	Testis-specific epitope	Matrix of marginal segment; putative ZP2-binding protein	197
SPACA1 (SAMP32)	*Spaca1*, *SPACA1*	Testis-specific	Matrix; inner membrane in principal and equatorial segments	198
			KO; infertile (globozoospermia)	199
SPACA3 (SLLP1)	*Spaca3*, *SPACA3*	Abundant in testis, low in pancreas and Raji cells	Matrix, principal and equatorial segments; C lysozyme-like protein	200
			Novel binding partner for oocyte SAS1B	201
SPACA4 (SAMP14, Izumo4)	*Spaca4*, *SPACA4*	Testis-specific	Matrix; inner and outer membranes; similar to Ly6/urokinase plasminogen activator receptor superfamily protein	202
SPACA7	*Spaca7*, *SPACA7*	Testis-specific	Acrosomal protein; novel protein	203
SPESP1 (ESP)	*Spesp1*, *SPESP1*	Testis-specific	Matrix; equatorial segment	204
			KO; fertile, equatorin increased	205
sp32	*Acrbp*, *ACRBP*	Testis-specific	Matrix; proacrosin-binding protein	206
sp56 (AM67)	*Zp3r*, *SELENBP1*	Testis-specific, protein in late pachytene spermatocytes	Matrix; marginal segment; putative zona binding protein	207
			Zp3r KO; fertile	208
Sp-10	*ACRV1*, *Acrv1*	Testis-specific	Matrix, principal segment and posterior equatorial segment; putative zona binding protein	209

TABLE 3.2 Acrosome Components—cont'd

Protein	Gene	Expression	Features	References
Synaptotagmin VI	*Syt6*, *SYT9*	Ubiquitous	Outer acrosomal membrane; Ca^{2+}-binding protein	160
TESP1	*Press39*, *TESP1*	Testis-specific	Matrix, principal segment; serine protease, putative role in zona penetration	210
TESP2	*Press40*, *TESP2*	Testis-specific	Matrix, principal segment; serine protease, putative role in zona penetration	210
TESP4	*Prss2(Try2)*	Ubiquitous	Matrix, principal segment; pancreatic trypsin-like serine protease, putative role in zona penetration	211
TESP5 (testisin, esp-1)	*Prss21*	Testis-specific	Matrix; glyosylphopshatidylinopsitol-anchored serine protease, localize in head, cytoplasmic droplet, midpiece	86
			KO; fertile, but reduced fertility in vitro	212
TMEM190	*Tmem190*, *TMEM190*	Testis-specific	Matrix; inner acrosomal membranes, co-localize with Izumo1. Present in human pharynx and ovary KO; fertile	213
Zonadhesin	*Zan*, *ZAN*	Testis-specific	Matrix; inner and outer membranes in spermatids, matrix in sperm; zona binding protein, acrosomal matrix	176
			Zan KO; fertile	175
ADAM3 (cyritestin)	*ADAM3* (pseudogene in human)	Testis-specific	Matrix; inner and outer acrosomal membrane sperm migration into the uterus KO infertile	37
Izumo1 (OBF13)	*Izumo1*, *IZUMO1*	Testis-specific (from Japanese word for shrine for uniting) in sperm	Matrix; soluble compartment, inner and outer acrosomal membrane associated at apical segment	180,181
			KO; infertile	180
Equatorin (MN9, afaf)	*Eqtn*, *EQTN*	Testis-specific	Matrix; inner and outer crosome membrane	179
			N-*O*-sialoglycoprotein, acrosome reaction	214
			Acrosome formation-associated factor	215
CD9	*Cd9*, *CD9*	Ubiquitous	Matrix; inner acrosomal membrane	216
			KO; male fertile, female infertile	217
CD46 (MCP)	*Cd46*, *CD46*		Matrix; inner acrosomal membrane	
			KO; fertile	218
MC101	N.D.	Testis-specific epitope	Matrix; marginal segment border between cortex and medulla	168
MMP2	*Mmp2*, *MMP2*	Ubiquitous	Matrix; inner acrosomal membrane associated with protainase	186
ZPBP1 (SP38, IAM38)	*Zpbp1*, *ZPBP1*	Testis-specific?	Matrix; inner acrosomal membrane inner and outer acrosome membrane after acrosome reaction	219
			KO; infertile (astheno-globozoospermia)	220
			Mutation; abnormal head in infertile men	221

Vet-ebooks.com

exposed and retained on the inner acrosomal membrane in 90% of acrosome-reacted sperm.[201] In astacin-like metalloendopeptidase (M12 family) (ASTL, SAS1B)-null mice, oocytes showed a 34% reduction in fertility, suggesting that sperm ASTL functions as a binding partner for oocyte ASTL during fertilization.[228]

Some other partially characterized acrosomal proteins that might function during the acrosome reaction include inhibitory guanine nucleotide-binding regulatory proteins (G_i proteins) that function as signal transducing elements mediating this exocytotic event, acrogranin in guinea pig sperm, proenkephalin in rats, gastrin in humans, and the related cholecystokinin peptide in mouse, rat, and monkey.[5] The functional roles of these peptides during spermatogenesis or fertilization have not been determined. Soluble components that are released when the acrosome reaction occurs include AM50 (p50, apexin) in the guinea pig, which is similar to neuronal pentraxin II,[187] and the cystein-rich protein CRISP2.[188]

The majority of the non-enzymatic acrosomal proteins serve as components of the acrosomal matrix. The acrosomal matrix is relatively insoluble in nonionic detergents and largely remains associated with the sperm after the acrosome reaction. Proteins associated with the acrosomal membranes include sperm acrosome associated 1 (SPACA1, SAMP32),[198] synaptotagmin IV (STY4),[160] and ZAN.[229] Some matrix components that might be involved in zona binding include the MC41 antigen,[197] zona pellucida 3 receptor (ZP3R, SP56),[207] acrosomal vesicle protein 1 (ACVR1, SP-10),[209] and zona pellucida binding protein (ZPBP, Sp38, IAM38).[220] ZAN-deficient ($Zan^{-/-}$) male mice are fertile, although $Zan^{-/-}$ sperm have reduced species specificity for zona pellucida adhesion.[175] ZP3R is not essential in sperm–zona pellucida binding and/or penetration of zona pellucida, because ZP3R-deficient male mice were fertile.[208] Other matrix proteins that have been identified include ACRBP[230] and sperm acrosome associated 4 (SPACA4, SAMBP14), which has regions of sequence similarities to the plasminogen activators.[202] Equatorin (EQTN, Mn9),[179,215] IZUMO1, POU domain, class 2, and associating factor 1 (POU2AF1, OBF1)[180] are released during the acrosome reaction, and become relocated and retained on the overlying plasma membrane. IZUMO1 is a type one immunoglobulin superfamily protein localized in the anterior acrosome and becomes translocated onto the overlying plasma membrane of the whole sperm surface after the acrosome reaction.[180,181,199] IZUMO1-null sperm are infertile.[180] TSSK6-null sperm failed to relocate IZUMO1 during the acrosome reaction due to a failure of actin polymerization.[231] Sperm equatorial segment protein 1 (SPESP1) is localized to the equatorial segment of ejaculated human spermatozoa.[204] SPESP1 persists in the equatorial segment in the acrosome-reacted spermatozoa and to spermatozoa tightly bound to the oolemma of hamster eggs.[204,232] SPESP1 deficient male mice were fertile, although $Spesp1^{+/-}$ and $Spesp1^{-/-}$ sperm had a reduced fusing ability.[205] In SPESP1-null sperm, although various sperm proteins were aberrantly distributed, EQTN was increased in amount, suggesting a redundancy of EQTN. EQTN is expressed in spermatids, integrated into spermatids during spermatogenesis, and becomes a type 1 *N*,*O*-sialoglycoprotein anchored to the outer and inner acrosomal membrane in mammals, including human.[179,214] Anti-EQTN antibody MN9 inhibited the sperm–oocyte fusion or egg activation in vitro[179] and in vivo.[233] Transmembrane protein 190 (TMEM190) is an inner-acrosomal membrane protein in cauda epididymal sperm. TMEM190 also partly relocated onto the surface of the equatorial segment during the acrosome reaction. TMEM190 and IZUMO1 are co-localized in mouse sperm both before and after the acrosome reaction, but immunoprecipitates of TMEM190 did not include IZUMO1.[213]

Abnormal Sperm Heads

Teratozoospermia is a condition in which human spermatozoa have abnormal morphology, including abnormally shaped heads.[234] A widely accepted notion is that a well-conserved organization of sperm transcripts in the healthy male originates from a well-orchestrated process of spermatogenesis, and failures in that process result in abnormal spermatozoa without heads, called acephalic or decapitated sperm. Decapitated tails are detected in up to 10%–20% of spermatozoa in subfertile patients, but are rare in the semen of fertile men.[235,236] Round heads are formed by altered early acrosome biogenesis in mouse and human globozoospermia.[132,237] This alteration is related to the failure of perinuclear theca proteins to properly associate with the nuclear surface and significant deficiencies in specific perinuclear theca components that are necessary for proper acrosome formation, implantation, and expansion over the spermatid nucleus.[237] Round head formation is also related to disorganization of tail components. Mutations associated with the occurrence of round-headed sperm (globozoospermia) in humans have been identified.[238]

THE FLAGELLUM

The flagellum is connected to the head (nucleus) at the basal plate between the connecting piece and base of the nucleus. The indentation of the base of the sperm head containing the basal plate is known as the implantation fossa. The flagellum of the mammalian sperm consists of four distinct segments: the connecting piece (neck), the middle piece (midpiece), the principal piece,

Vet-ebooks.com

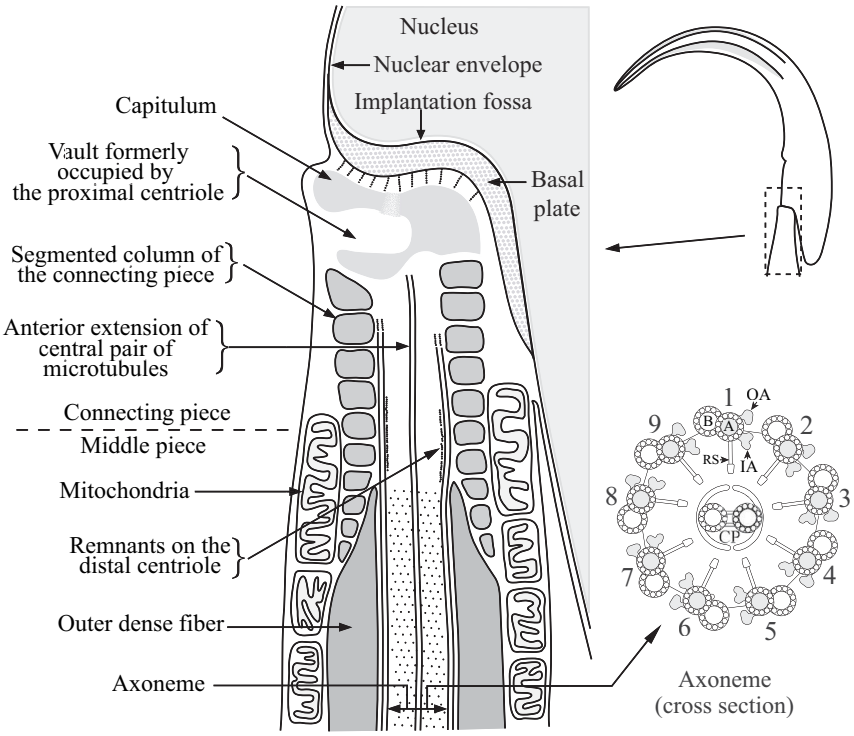

FIGURE 3.8 Connecting and proximal middle piece regions of sperm flagellum. Left schematic shows the internal details of the boxed area at the top of the right side of the diagram of a rat sperm head. The basal plate is adherent to the nuclear envelope, defining the implantation fossa and forming the site of attachment of the flagellum to the sperm head. The connecting piece is topped by the capitulum, with the segmented columns extending from it caudally to fuse with the outer dense fibers. The axoneme extends from the connecting piece to the distal tip of the flagellum. *(Source: This schematic drawing is modified from Ref. 239.)* The details of the axoneme are shown in bottom right diagram. The axoneme is composed of a nine-plus-two (9+2) complex of microtubules; 9 outer doublet microtubules (from 1 to 9) and a central pair of singlet microtubules (CP). When the axoneme is viewed from the sperm head towards to tail, the peripheral doublets are numbered 1 through 9. Number 1 is the doublet situated on a plane perpendicular to that bisecting the microtubules of the central pair, and the next clockwise doublet is number 2. Outer dynein arms (OA) and inner dynein arms (IA) extend from the A microtubule (A) towards the B microtubule (B) of the adjacent doublet.

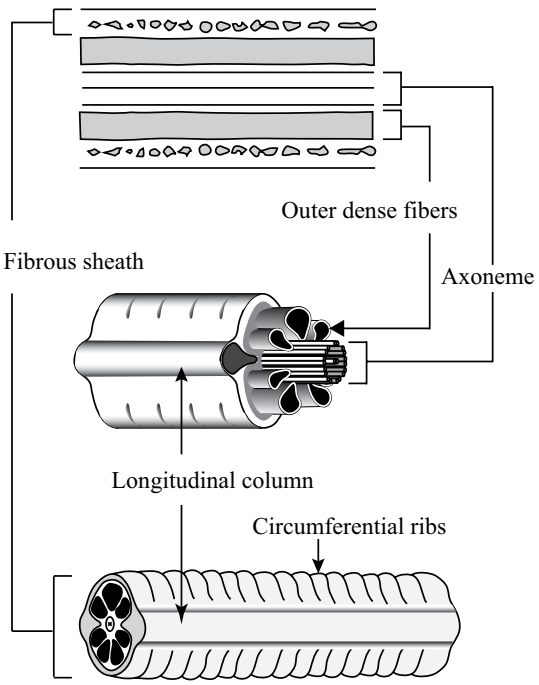

FIGURE 3.9 The cytoskeletal components in the principal piece region of the sperm flagellum. The outer dense fibers lie between the fibrous sheath and axoneme in the principal piece of the flagellum. The fibrous sheath is composed of two longitudinal columns connected by circumferential ribs and surrounds the axoneme and outer dense fibers in the principal piece region.

and the endpiece (Figure 3.1). The main structural components within the flagellum are the axoneme, the mitochondrial sheath, the outer dense fibers, and the fibrous sheath (Figures 3.8 and 3.9). The axoneme is composed of a nine-plus-two (9+2) complex of microtubules that extends from the connnecting piece through the full length of the flagellum. Early during spermiogenesis, sperm axonemal microtubules are recruited to the distal centriole as the proximal centriole migrates towards the spermatid nucleus. In mammalian sperm flagella, two accessory structures, the outer dense fiber and the fibrous sheath, surround the axoneme. Most flagellated sperm of lower organisms, such as sea urchins, do not contain either outer dense fiber or the fibrous sheath. The outer dense fibers are adjacent to the axoneme, and extend from the connecting piece to the posterior portion of the principal piece. The fibrous sheath begins anteriorly at the annulus and is a characteristic feature of the principal piece segment. The mitochondrial sheath defines the extent of the midpiece. It immediately surrounds the outer dense fibers, whereas the fibrous sheath surrounds the outer dense fibers. The endpiece lacks fibrous sheath or outer dense fiber components and contains only axonemal components. The components of these domains have unique functional roles.

The human sperm is about 60 μm long, and the flagellum is greater than 1 μm in diameter, 55 μm in length, and tapers towards the distal tip (Figure 3.1). However, sperm vary considerably in length between

Vet-ebooks.com

species: for example, 120 μm in the mouse, 190 μm in the rat, 250 μm in the Chinese hamster, 46 μm in the rabbit, and 50 μm in sea urchins.[5]

Connecting Piece

The connecting piece (the neck or head–tail coupling apparatus) comprises the capitulum (the dense fibrous plate-like structure) and the segmented (striated) columns (Figure 3.8). The capitulum conforms to the shape of the implantation fossa and connects to the top of the segmented column. The implantation fossa conforms to the basal plate, an electron-dense structure that is adherent to the outer membrane of the nuclear envelope. The connecting piece functions as a structural anchorage or articulation between the head and tail, retaining some centriolar proteins, to stabilize the proximal part of the tail. The elastic compliance of the connecting piece is thought to provide initiation of the sperm beat cycle and bend propagation in guinea pig sperm, suggesting the importance of the pale band region of the connecting piece.[240]

A recent electron cryotomography study revealed the three-dimensional structure of the connecting piece in bovine spermatozoa.[241] The connecting piece has asymmetrical architecture, with the segmented columns held together by filamentous linkages. At the proximal end, the segmented columns fuse with each other into structures that form the centriolar vault, where the structure reminiscent of the proximal centriole is localized, while at the distal end, the segmented columns fuse with the outer dense fibers to form the distal centriolar vault, where a novel bar structure associates with outer dense fibers 3 and 8. The architecture of these two outer dense fibers extending into the principal piece as part of the fibrous sheath suggests an intrinsic structural constraint on the waveform of sperm movement.

The segmented columns extend posteriorly from the capitulum, 1 to 2 μm in length, and connect to the outer dense fibers at their distal end (Figure 3.8). However, the segmented columns and outer dense fibers are different in their origin. During spermiogenesis, as centrioles initiate docking to the plasma membrane in an early stage of axonemal development, segmented structures form around the centrioles, presumably by the aid of a novel component of the connecting piece, speriolin (SPATC1).[242] The connecting piece region is strengthened by these molecules. Centrioles are involved in development of the connecting piece and the axoneme, but not required for sperm motility.[4,239] In humans and bovines, but not in rodents, the microtubule organizing center found in the fertilized egg arises from the sperm aster derived from the fertilizing sperm centrioles. Proteins that mediate the binding of the connecting piece to the sperm head are not known at present.

Centrosome

The centrosome is an amorphous cytoplasmic region, approximately 0.5 μm in length and 0.2 μm in diameter. The centrosome functions as the primary microtubule organizing center in animal cells and regulates the nucleation and spatial organization of microtubules. The centrosome is formed by the perpendicularly oriented proximal and distal centrioles and by the surrounding matrix of pericentriolar material. The proximal centriole retains its structure, but the distal centriole is disorganized in late spermatids in most species.[239] The pericentriolar material is a protein complex containing gamma 1 tubulin (TUBG1) and is involved in microtubule nucleation. Although information about the proteins found in the sperm centriolar region is limited, molecules found in the microtubule organizing center include TUBG1, nuclear mitotic apparatus protein 1 (NUMA1), and pericentrin (PCNT).[243] TUBG1 is found in germ cells in the mouse, rat, hamster, guinea pig, rabbit, bull, rhesus monkey, and human. It is shed during late spermatid differentiation in most species, but can be detected in human and bull sperm. Centrin (CETN1) is contained in the pericentriolar material associated with the proximal and distal centrioles in spermatids in the mouse, rabbit, pig, rhesus monkey, and human.

There are other proteins localized in the connecting piece region. SPATC1 is thought to provide architectural strength to the connecting piece region of mouse and human sperm.[242] SPATC1 is associated with the seventh tryptophan–aspartic acid (WD) protein structural motif of the CDC20 spindle checkpoint protein that activates the anaphase-promoting complex/cyclosome. SPATC1 surrounds the intact proximal centriole in human sperm and is localized at the periphery of the distal centriole in mouse sperm. Although the paternal centrioles enter the oocyte with the fertilizing sperm and form the sperm aster in humans and most other mammals, they are degenerated and not inherited by the oocyte in mice. SPATC1 is the first sperm centrosomal protein identified in the connecting piece region that is transmitted to the mouse zygote.[242]

The testis-specific serine kinase (TSSK) protein family is composed of six members (TSSK1-6). TSSK1, TSSK2, TSSK4, and TSSK6 (SSTK), but not TSSK3, are present in mouse testicular germ cells and in epididymal spermatozoa. TSSK1, TSSK2, and TSSK6, but not TSSK3, are detected in human spermatozoa.[244] Testis-specific serine kinase substrate (TSKS) is the substrate of TSSK1 and has two coiled-coil regions. The coiled-coil region is related to its centriolar localization, and through its binding activity with TSKS, TSSK2 is recruited to the spermatid centrioles to fulfill its essential function.[245] TSKS is localized during spermiogenesis to the centrioles, associating with TUBG1 of postmeiotic spermatids, and persists in

Vet-ebooks.com

ejaculated human spermatozoa, while centriolar TSKS diminishes in mouse spermatozoa.[245] Mouse TSKS and the TSSK2 persist and localize to the tail and acrosomal regions of epididymal spermatozoa, while human TSSK2 is found in the equatorial segment, neck, and midpiece. TSSK2 kinase is enzymatically active in both testis and mature spermatozoa. Male chimeras with a deletion of one allele of both of the closely located *Tsks* and *Tssk2* genes were unable to transmit the mutations to the next generation due to haploinsufficiency.[245] Testes of chimeras exhibited arrested spermatogenesis, failure to form elongated spermatids, increased apoptosis, and a greater number of round spermatogenic cells in the epididymides.[245] The TSSK6-null sperm exhibited impaired postmeiotic chromatin condensation and showed abnormal spermiogenesis.[97] Another group reported that the TSSK1/2 double knockout males are infertile, with the mitochondrial sheath severely disarranged, presumably due to impaired annulus migration, a process that is required for maturation of sperm mitochondria during late spermiogenesis.[246] This phenotype was somewhat similar to the feature of SEPT4 deficient mice.[247,248]

Ornithine decarboxylase antizymes (OAZs) control the intracellular concentration of polyamines. The rigid connection of the sperm head and tail are affected by the actions of OAZs.[249] OAZ-t/OAZ3 is expressed specifically in germline cells during spermiogenesis, while OAZ1 and OAZ2 are expressed ubiquitously. OAZ3 appears to play a role in haploid germ cell differentiation by binding to ornithine decarboxylase and inactivating it to regulate the local concentration of polyamines. OAZ3-deficient male mice are infertile, and the sperm heads and tails are easily separated.[249] Most of the headless tails contain all the components except the basal plate, indicating that the head-tail separation occurs at the plane between the basal plate and the capitulum. A similar separation is induced by trypsin treatment, but not by sonication, which causes cleavage at any place of the tail. The decapitated head that contains the nucleus and the basal plate fails to acrosome-react, but is capable of fertilizing eggs via intracytoplasmic sperm injection. OAZ3 may have a function other than as an antizyme that inactivates decarboxylase. However, a 12-kDa protein variant encoded by *Oaz3* lacks the antizyme domain that interacts with ornithine decarboxylase.[250] It is localized to the connecting piece, outer dense fibers, and fibrous sheath. In *Oaz3*-null male mice, the p12 variant does not affect ornithine decarboxylase levels and the testis does not display altered polyamine metabolism.[250] A major p12-interacting protein is myosin phosphatase targeting subunit 3 (MYPT3), a regulator of the protein phosphatase 1, catalytic subunit, beta isoform (PPP1CB). MYPT3 is present in sperm tails and its ankyrin repeat binds p12.

Centrobin (CNTROB, Nip2, Nek2-interacting protein 2, NIPS) was initially identified as a centrosome protein that is critical for centrosome duplication and spindle assembly. CNTROB is associated with daughter centrioles and implicated in microtubule stabilization. In the rat hypodactylous (*hd*) mutation males, the sperm head is detached from the tail. The mutation is caused by an insertion of an endogenous retrovirus into intron 10 of the *Cntrob* gene. In the *hd* mutant, spermatids fail to form an acroplaxome marginal ring and unusually separate the centrosome from the normal attachment site, which leads to spermatid decapitation during the final step of spermiogenesis.[251] Such *hd*/*hd* mutant spermatozoa resemble a type of (oligo)teratoasthenospermia in humans, with marked sperm tail fragility and decapitated sperm heads.

Axoneme

Microtubules

The organization of the axoneme (axial filament complex) is the same in the mammalian sperm tail and in the cilia and flagella of most plants and animals. Cytoskeletal tubulin and motor protein dynein are the major components. The typical axoneme nine-plus-two (9 + 2) axonemal structure is composed of 9 outer doublet microtubules (A and B microtubules) and 2 central singlet microtubules. Each doublet consists of a complete A microtubule, and a "C-shaped" B microtubule attaches onto the side of the A microtubule. Two dynein arms extend from the A microtubule toward the B microtubule of the anterior doublet. When the axoneme is viewed from the sperm head (proximal) towards the tail (distal), the arms project clockwise, and the doublets are numbered one through nine. Number one is the doublet situated on a plane perpendicular to that bisecting the microtubules of the central pair, and the next clockwise doublet is number two (Figure 3.8). In most mammals, the central pair of microtubules appears to extend into the connecting piece to the implantation fossa or capitulum, whereas the other microtubules appear to end on the remnants of the base of the distal centriole. Radial spokes are structures that extend from the base of A-tubules to the central pair apparatus.[252]

The microtubules are composed of dimers of β-tubulin (tubulin, alpha 1a, TUBA1A) (56 kDa) and α-tubulin (tubulin, alpha 1b, TUBA1B) (54 kDa). Multiple tubulin genes are expressed during spermiogenesis, including testis-specific isoforms, and the diversity of these proteins are further expanded by posttranslational modifications.[253] One of the first postmeiotically expressed genes identified was for a spermatid α-tubulin with a unique sequence.[254] This led to the prescient suggestion that the gene encoded a novel α-tubulin involved in determining special properties of the sperm axoneme.[254]

Vet-ebooks.com

Radial spokes are composed of at least 23 polypeptides (8–210 kDa) in *Chlamydomonas* flagella. These proteins include several components involved in Ca^{2+}/calmodulin (CALM) or (cAMP)-dependent intracellular signaling, such as CALM, a calmodulin-binding protein, a protein with an A-kinase anchor protein (AKAP) domain RSP3 (RS protein 3), a protein with a nucleoside diphosphate kinase domain and an isoleucine–glutamine motif, and a protein with a regulatory subunit (RII) alpha motif.[255]

The central pair apparatus contains at least 17 proteins, including CALM, CaM-binding protein primary ciliary dyskinesia protein 1, FAP221, AKAP-binding protein AAT-1 (FAP91), CPC1, a protein with an adenylate kinase domain, a CPC1-binding protein (enolase), WD-repeat protein paralyzed flagella PF20, Ala/Pro-rich protein PF6, a kinesin-like protein 1, the hydrocephalus-inducing gene product hydin, and armadillo-repeat containing protein PF16. The binding between spoke CaM and central apparatus CaM-binding protein and between the protein with an AKAP domain RSP3 and central apparatus AKAP-binding protein AAT-1 might mediate radial spoke/central pair apparatus interaction.[252]

Dyneins

The dyneins are a large family of motor proteins associated with microtubules, including the outer doublet microtubules in axonemes of cilia and flagella. Their ATPase activity generates force unidirectionally towards the minus (−) end of microtubules to generate sliding forces between adjacent doublets of microtubules during flagellar movement. Dyneins consist of heavy, intermediate, light intermediate, and light chains. The motor activity is associated with heavy chains and axonemal dyneins are present as heterotrimers, heterodimers, and monomers of heavy chains. Most of what is known about the function of axonemal dyneins comes from studies on ciliated unicellular organisms and sea urchin sperm and is presumed to apply to mammalian sperm. The targeted disruption of genes for axoneme components in mice that result in drastically altered sperm motility and male infertility are reviewed elsewhere.[252]

The flagellar movement that results from axonemal bending is generated by the active sliding of axonemal doublet microtubules by the action of two molecular motor dyneins, the outer and inner arm dyneins. They play different roles in the production and regulation of flagellar motility. Dynein itself contributes to the formation and propagation of flagellar bending, while the other axonemal structures, such as the radial spoke/central pair apparatus, also have essential roles in the regulation of flagellar bending.[252] Also, outer or inner arm dyneins are presumed to be involved in the elevation of microtubule sliding velocity (increasing beat frequency) and formation and propagation of flagellar bending, respectively.[256]

Tektins

Tektins, first identified in sea urchin sperm flagella, are a family of cytoskeletal proteins associated with microtubules and are expressed in spermatids. Tektins are coiled-coil proteins that form filaments in the walls of ciliary and flagellar microtubules.[257] At least five tektin proteins (TEKT1-5) have been identified in mammals. TEKT1 is localized to the centrosome in round spermatids and to the caudal end of elongating spermatids, but disappears as spermiogenesis proceeds. TEKT1 may be involved in the nucleation of the flagellar axoneme and is required for assembly of the basal body.[258] TEKT2 is localized to the axoneme. TEKT2-null male mice are infertile and TEKT2-null sperm display flagellar bending and reduced motility[259] due to a disruption in the dynein inner arm. TEKT3-deficient males are fertile and hyperactivation is intact, but TEKT3-null sperm have reduced motility and forward progression and increased flagellar structural bending defects.[260] TEKT4 is located on outer dense fibers and interacts with the outer dense fiber-associated protein, spermatogenesis associated 18 (SPATA18, SPETEX1), in rat sperm flagella,[261] but is not associated with the axonemal tubulins of flagella in mice.[260] TEKT4-null male mice are subfertile and TEKT4-null sperm have drastically reduced ATP levels and forward progressive velocity and uncoordinated waveform propagation along the flagellum.[262] In addition, the peri-outer dense fiber space is extended, the submitochondrial reticulum (Figure 3.10) is diminished,

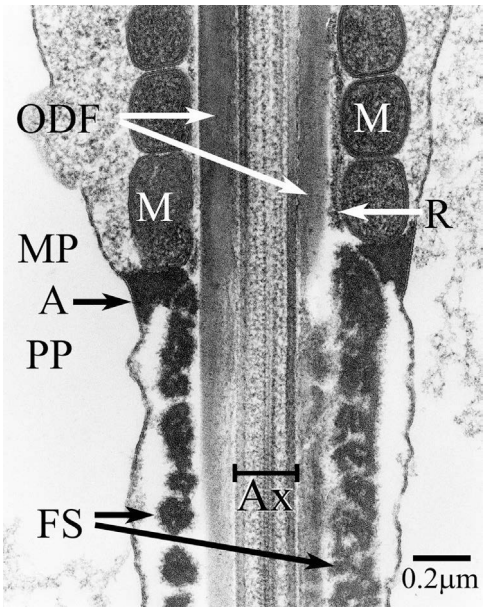

FIGURE 3.10 Transmission electron micrograph showing the annulus region. The mitochondrial sheath (M) is found in the middle piece (MP), and the fibrous sheath (FS) is found in the principal piece (PP). Outer dense fibers (ODF) and sub-mitochondrial reticulum (R) are found longitudinally between the mitochondrial sheath and the axoneme (Ax). A, annulus.

Vet-ebooks.com

and the circumferential ribs of the fibrous sheath frequently break, suggesting that the lack of TEKT4 causes a decrease in the tensile strength of flagella. Thus, TEKT4 likely functions in the transmission of the bending force from the axoneme through the outer dense fiber to the connecting piece.[262] TEKT5 is localized to the inner surface of the mitochondrial sheath in the rat sperm flagellar midpiece.[263]

Mitochondrial Sheath

The middle pieces differ considerably in length, and the organization of mitochondria is quite variable between species. The midpiece length is related to the length of the sperm, and in most mammals is between 5 and 12 μm (8.5 μm in rabbits, 9 μm in guinea pigs, 10 μm in rhesus monkeys, 12 μm in bulls, and 5.5 μm in humans), but is 64 μm in rats and 100 μm in Chinese hamsters.[5]

Sperm mitochondria are elongated, flattened, and arranged circumferentially in an end-to-end fashion to form a helically coiled sheath around the outer dense fibers (Figures 3.10 and 3.11). The number of helices, the number of spiral turns, and the length of the middle piece vary between species; for example, in the mouse, there are two parallel helices, with an average of 87 windings.[5] The morphogenesis of this mitochondrial arrangement occurs in the spermatid by (1) the migration of the annulus from the connecting piece down the flagellum to the beginning of the fibrous sheath, (2) the formation of a dextral helix of elongated mitochondria around the flagellum, (3) the division of these mitochondria into spherical mitochondria, and finally (4) the elongation and end-to-end apposition of these mitochondria into two tight sinistral helices.[264] In the mouse, the mitochondria are usually of variable length and abut end-to-end at random along the helix. The organization of the mitochondrial sheath is highly uniform in most species, but the precise numbers of mitochondria differ between species.[5]

The mitochondrial sheath adheres to an underlying complex of filaments named the sub-mitochondrial reticulum[265] (Figures 3.10 and 3.11). The sub-mitochondrial reticulum complex is a network of ribbons of filamentous material that are laterally interconnected and terminate to fuse with the annulus at the junction between the midpiece and the principal piece.

A structural protein, sperm mitochondria-associated cysteine-rich protein (SMCP), localizes to the capsule associated with the mitochondrial outer membranes and is thought to function in the organization and stabilization of the helical structure of the sperm mitochondrial sheath. SMCP is synthesized in elongating spermatids in the rat, but the levels of SMCP mRNA in humans are much lower than in other mammals. SMCP-null male mice on the 129/Sv background are

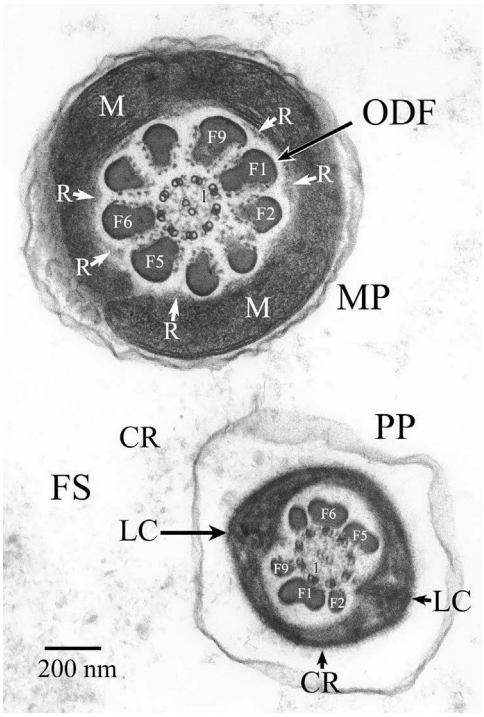

FIGURE 3.11 Cross-section of the middle piece and the principal piece. When the outer dense fibers (ODF) are viewed from the sperm head towards to tail, the outer dense fibers are numbered 1 (F1) through 9 (F9). Outer dense fiber number 1 (F1) is adjacent to microtubule doublet number 1 of the axoneme. It is situated on a plane perpendicular to that bisecting the microtubules of the central pair. The next clockwise outer dense fiber is number 2 (F2). The sub-mitochondrial reticulum (R) is located in the gap between the adjacent outer dense fibers and the indentation on the abaxial surface of outer dense fibers. The fibrous sheath (FS) is formed by two longitudinal columns (LC) connected by circumferential ribs (CR). M, mitochondria; MP, middle piece; ODF, outer dense fiber; PP, principal piece.

infertile due to asthenozoospermia (reduced sperm motility), and the decreased capability of sperm to penetrate oocytes.[266] Five triple gene knockout lines, *Acr/H1.1/Smcp*, *Acr/Tnp2/Smcp*, *Tnp2/H1.1/Smcp*, *Acr/H1t/Smcp*, and *Tnp2/H1t/Smcp*, displayed decreased fertility on mixed genetic backgrounds.[267] The decreased fertility is due to defects in sperm motility in vitro correlated with reduced migration in the female reproductive tract, and decreased fertilization due to defects in adhesion of sperm to the zona pellucida. SPATA19 (SPERGIN1) is localized to the midpiece and associated with the mitochondrial sheath as an adhesive molecule in the mouse and human.[268,269] Glutathione peroxidase 4 (GPX4, PHGPX) is a structural component of the mitochondrial capsule that serves to maintain normal sheath structure. Phospholipid hydroperoxide glutathione peroxidase (PHGPX) is an intracellular antioxidant enzyme that directly reduces peroxidized phospholipids produced in cell membranes.[270] GPX4, first described as an antioxidant enzyme, is the predominant selenoenzyme in testis and required for spermatogenesis. GPX4-deficient male

Vet-ebooks.com

mice are infertile and show multiple structural abnormalities such as bent tail, decaudated heads, dislocation of mitochondria along the midpiece, and extrusion of microtubules and outer dense fibers from the principal piece, features that likely would lead to infertility in humans.[271] In GOPC-null sperm, SPATA19 remains on the stratified mitochondria, while GPX4 is unevenly distributed on the mitochondrial sheath, suggesting that GPX4 is necessary to maintain normal sheath structure, and SPATA19 prevents dispersal of mitochondria.[166]

Outer Dense Fibers

General Features, Structure, and Formation

The outer dense fibers are cytoskeletal structures specifically found in the sperm tails of vertebrates but not in eukaryotic cilia and flagella.[4] The outer dense fibers are important for the stability and the elastic recoil of the sperm tail as well as for support of the flagellar beat, but they seem not to be involved in active motility.[272]

The outer dense fibers consist of nine fibers located between the mitochondrial sheath and the axoneme in the midpiece and surrounded by the outer dense fibers in the principal piece (Figures 3.10 and 3.11). The fiber shows a "9+2" complex numbered corresponding to the adjacent microtubule doublets. The fibers run longitudinally throughout the length of the middle piece and most of the principal piece of the flagellum of mammalian sperm, and are attached to doublet microtubules of the axoneme. Their cross-sectional profiles are not uniform at the ultrastructural level[4] (Figure 3.11). In general, the fibers 1, 5, 6, and 9 are larger than the others, and fibers are thickest in the proximal part of the middle piece and gradually taper in size toward the distal tip and terminate in the proximal half of the principal piece in human, macaque, and bat sperm, but extend to near the end of the principal piece in rat, hamster, guinea pig, and ground squirrel sperm.[4] Fibers 3 and 8 organize the distal centriolar vault, closely adhering to the connecting piece at the proximal end, whereas they terminate in the principal piece as the longitudinal columns of the fibrous sheath extend inwardly. The large fibers 1, 5, and 6 are usually the last to terminate.

The formation of outer dense fibers is best characterized in the rat, where it begins in spermatids; first as a small dense fiber immediately adjacent to microtubule doublets at the head–tail junction in step 8 spermatids, extends into the principal piece by step 14, and continues to be laid down in a proximal-to-distal direction during steps 15 to 19.[273] The precursor of the outer dense fibers apparently are synthesized in the cell body, and transported down the axoneme to the distal portion of the principal piece.

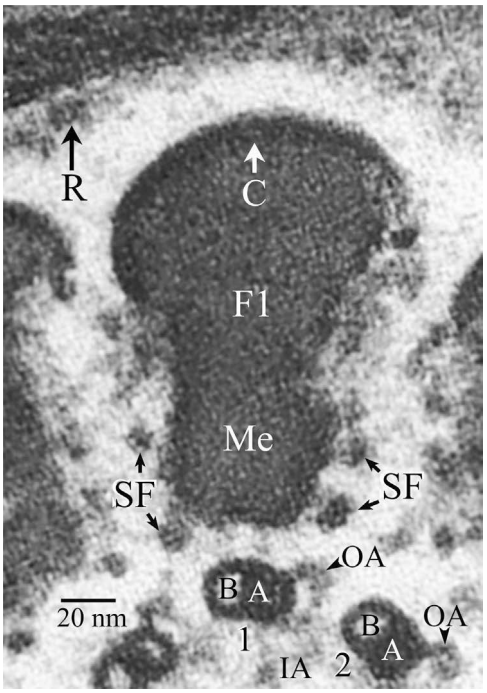

FIGURE 3.12 Higher magnification of outer dense fiber. Outer dense fiber 1 (F1), which is adjacent to peripheral microtubule doublet number 1, has cortex (C) and medulla (Me) regions. Satellite fibers (SF) are found associated with the medulla region at the adaxial surface of the outer dense fiber. A, A microtubule; B, B microtubule; IA, inner dynein arm; OA, outer dynein arm; R, sub-mitochondrial reticulum.

Each outer dense fiber is composed of cortex and medulla as determined by electron microscopy (Figure 3.12). The cortex is a thin layer stained more intensely than the medulla, and appears to be composed of a single lamina of globular particles 6–7 nm in diameter, whereas the medulla appears electron dense with no obvious substructure[274] (Figure 3.12). The cortex appears to be continuous with the satellite fibrils located at the adaxial surface of the outer dense fibers (Figure 3.12).

Composition

A number of the constituent proteins of the outer dense fibers and their genes have been identified and are listed in Table 3.3.[275–306] The outer dense fibers (ODF) are composed of two main ODF proteins, outer dense fiber of sperm tails 1 and 2 (ODF1 and ODF2).[288] The ODF1 protein interacts with ODF2, and both are located to the ODF, basal plate, capitulum, and segmented (striated) columns.[307] Linking of ODF to axonemal microtubules may be mediated via binding of ODF1 to sperm-associated antigens 4 and 5 (SPAG4, SPAG5) and of ODFs to mitochondria via kinase light chain 3 (KLC3) binding. ODF1 interacting proteins are SPAG4, KLC3, ODF1-interacting protein (OIP1), and SPAG5.[294] SPAG4 is located in the transient manchette and associated with the axoneme and manchette in elongating spermatids and epididymal sperm, and binds to ODF1 but not to

TABLE 3.3 Outer Dense Fiber-Associated Proteins

Protein	Gene	Features	References
ODF1 (RT7, Odf27, rts5/1)	*Odf1*	Outer dense fiber of sperm tails 1, also as HSPB10 in human structural protein, present only in medulla of ODF postmeiotic, high in testis and low in a few other tissues	275–283
ODF1/HSPB10	*HSPB10*	Self-interacting protein, family of small heat-shock protein KO; sperm head-tail detachment, dysarrangement of ODF and mitochondrial sheath	284
ODF2 (Odf84)	*Odf2*	Outer dense fiber of sperm tails 2, structural protein, also present in acroplaxome, connecting piece of sperm, centrosomes of other tissues interacts with ODF1, meiotic and postmeiotic, partial homology with cenexin	285–290
ODF3 (SHIPPO1)	*Odf3*	Outer dense fiber of sperm tails 3, structural protein, postmeiotic, high expression in testis, low in epididymis and brain	291
ODF4 (OPPO 1, Tisp-62)	*Odf4*	Outer dense fiber of sperm tails 4, oppo (from Japanese word for tail) 1, structural protein, meiotic and postmeiotic, testis-specific	292,293
Rhophilin (ODF5)	*RHPN1*	Outer dense fiber of sperm tails 5, also as rhophilin	
		Rhophilin-associated protein 1, AKAP-binding sperm protein, postmeiotic, testis-specific	291
Roppoein (ODF6)	*Ropn*, *ROPN1*	Outer dense fiber of sperm tails 6, also as ropporin-1	
Spag4	*Spag4*, *SPAG4*	Sperm associated antigen 4, structural protein, interacts with ODF1, present in manchette and axoneme, not in ODF, postmeiotic, testis-specific	294,295
Spag5 (deepest, Astrin)	*Spag5*	Sperm associated antigen 5, structural protein, interacts with ODF1, meiotic and postmeiotic, testis-specific	296,297
		KO; fertile	297
OIP1	*Rnf38*	ODF1 interacting protein, ring finger protein 38, structural protein, interacts with ODF1, localizes to sperm tail, meiotic and postmeiotic, high expression in testis, present in several other tissues	292
CRISP2 (Tpx-1)	*Crisp2*	Testis-specific protein 1, cysteine-rich secretory protein 2, also present in acrosome and connecting piece and longitudinal columns of FS, meiotic and postmeiotic, testis-specific	189,190
		Interacts with GGN1 and SHTAP	298
SAK57	*Krt5*	Sperm associated keratin of mass 57 kDa, keratin 5, keratin complex 2 gene 5, structural protein, also found in manchette and acroplaxome, meiotic and postmeiotic, expressed in many tissues	299
VDAC2	*Vdac2*	Voltage dependent anion channel 2, ubiquitously expressed, bind to KLC3	287,300,301
VDAC3	*Vdac3*	Voltage dependent anion channel 3, ubiquitously expressed	300
KLC3	*Klc3*	Kinase light chain 3, motor protein, interacts with ODF1 and VDAC2 postmeiotic, expressed in multiple tissues	302–305
Cdk5/p35	*Cdk5r1*	Cyclin-dependent kinase 5 regulatory subunit (p35) 1, regulator of proline directed serine/threonine kinase, associated with developing ODF, ubiquitously expressed	306

Vet-ebooks.com

ODF2.[294] SPAG4 has a leucine zipper that interacts with a leucine zipper in ODF1.[294] SPAG4 interacts with two microtubule-containing structures in spermatids, the manchette and the axoneme, but not outer dense fibers in epididymal spermatozoa. SPAG4 is presumably involved in outer dense fiber assembly by forming a link between ODF1 and axonemal microtubules.[294] SPAG5 associates with ODF, but not with the axonemal microtubules.[308] OIP1 binds to the conserved C-X-P motif in the C-terminal end of ODF1,[309] and ODF1-OIP1 interaction is enhanced by cyclin-dependent kinase 5 (CDK5), p35-mediated ODF1 phosphorylation.[310] ODF1 and ODF2 also are located in the manchette.[311]

The genes for ODF2, ODF3, and ODF4 are not homologous to each other or to the gene for ODF1. Their names relate only to their original source. The *Odf1* gene encodes a cysteine-proline-rich 27-kDa protein that is the major protein of rat ODFs. The *Odf1* gene encodes a protein highly conserved in evolution.[288] ODF1-null male mice are infertile, and the sperm show detachment of the head from the tail.[284] In addition, the organization of the mitochondrial sheath and the outer dense fibers are disturbed.

A major 84-kDa outer dense fiber protein encoded by the *Odf2* gene interacts through leucine zipper motifs.[289] ODF2 is also found in rat, mouse, and human. ODF1 was detected only in the medulla, but ODF2 was detected in both the cortex and the medulla of the outer dense fibers.[307] Although ODF2 is abundant in spermatogenic cells, it is also a cell-cycle dependent scaffold component of centrosomes in somatic cells.[290] ODF2 is known as a protein marker of the mother centriole and is a coiled-coil protein containing two leucine zipper motifs that mediate interactions with itself, ODF1 and microtubules.[290] In the testis, ODF2 is found localized to the acroplaxome, tail, connecting piece, and the nucleoli of Sertoli cells, spermatogonia, and spermatocytes.[137] ODF2 and cenexin 1 and 2 are the products of differential splicing of the *Odf2* gene consisting of 24 exons. ODF2 and cenexin 1 and cenexin 2 differ in a short stretch of amino acids at their N-terminal regions encoded by exon 3b. A peptide of 42 amino acids specific for cenexin is necessary for the formation of ODF2/cenexin fibers that are associated with acetylated microtubules and targets ODF2/cenexin to the centrosome and the primary cilium.[312] Conditional knockout (KO) mice have been generated, in which exons 6 and 7 of *Odf2* are disrupted.[313] In these conditional KO mice, multiple phenotypes such as coughing and sneezing were induced due to impaired structure and function of the basal bodies of cilia, but the effects on the flagellum of the sperm tail are unknown.

ODF3, a highly conserved 28-kDa protein is expressed only during the postmeiotic phase of spermatogenesis.[291] ODF4, a 33-kDa protein, is expressed only in the testis.[292] The human *ODF4* gene encodes a 30-kDa protein and differs from the mouse gene in genomic structure and in exon/intron usage.[293]

Three other ODF1-interacting proteins, SPAG4, SPAG5, and OIP1, are identified in rat sperm. SPAG5 also interacts with ODF1 via leucine zippers.[295] However, ODF2 does not interact with either SPAG4 or SPAG5, indicating that their interactions with ODF1 involve more than leucine zipper binding. The *Spag5* gene product, a 200-kDa protein, is synthesized in pachytene spermatocytes and spermatids. SPAG5 has a 73% similarity with DEEPEST, a putative mitotic spindle protein of unknown function.[296] SPAG5-null male mice are fertile[297] and the role of the protein remains unknown.

OIP1, a RING-finger family protein, is present in the outer dense fibers of rat sperm. It is encoded by the *Rnf38* gene, which appears to have biphasic expression during spermatogenesis, with one peak in spermatogonia and another in round spermatids. *Rnf38* also is expressed at lower levels in epididymis, heart, and smooth muscle.[309] ODF1 phosphorylation by CDK5 enhances ODF1 interaction with OIP1.[310]

Other proteins found in outer dense fibers are CRISP2, keratin 5 (KRT5, SAK57), voltage dependent anion channels 2 and 3 (VDAC2 and VDAC3), kinesin light chain 3 (KLC3), and the CDK5/p35 complex. CRISP2 is a member of the CRISP family including CRISP1, CRISP2, CRISP3, and CRISP4. They share 40%–80% sequence similarity at the protein level, and all are found in sperm. CRISP2 is a component of outer dense fibers and is present in the developing acrosome in spermatids, and in the perinuclear theca, connecting piece, and longitudinal columns of the fibrous sheath in rat sperm.[189] CRISP2 has a potential role in fertilization through the regulation of ion signaling in the acrosome reaction and sperm motility. The ion channel regulatory region within the CRISP domain of CRISP2 interacts with gametogenetin 1 (GGN1), a novel CRISP2-binding protein in the mouse sperm tail expressed during spermatogenesis, suggesting a role for the GGN1–CRISP2 complex in sperm tail development and/or motility.[190] In addition, CRISP2 specifically binds to multiple ~20–87 kDa isoforms of the sperm head and tail associated protein (SHTAP), a novel binding partner in the mouse.[314] SHTAP protein is localized to the periacrosomal region of round spermatids, and the head and tail of the elongated spermatids and sperm tail, where it co-localizes with CRISP2.

KRT5, an acidic keratin, is temporarily stored in the manchette, and then became a component of ODFs and the longitudinal columns of the fibrous sheath after the dispersion of the manchette.[299]

VDAC2 and VDAC3 are identified in bovine sperm outer dense fibers.[300] VDAC2 is located in the acrosomal membrane or plasma membrane of human spermatozoa and plays putative roles in sperm functions through mediating Ca^{2+} transmembrane transport.[315] VDAC2

Vet-ebooks.com

is also localized on the acrosomal region and principal piece, while VDAC3 is localized on the acrosomal region and midpiece.[301]

KLC3 binds to the surface of outer dense fibers in spermatids, isolated outer dense fibers, and to ODF1 in a microtubule-independent fashion. In a recent study using a transgenic mouse model in which a KLC3ΔHR (heptad repeat) mutant protein is specifically expressed in spermatids, KLC3 mutant protein bound mitochondrial protein VDAC2 and caused aggregate formation. It did not bind outer dense fibers,[304] but it was found to be localized between outer dense fibers and mitochondria,[305] suggesting it plays a role during the formation of sperm tail midpiece and in sperm function.

CDK5 is a proline-directed serine/threonine kinase that pairs with an activator, either p35 or p39. Both CDK5 and p35 are present in the outer dense fibers and in the basal plate, capitulum, and striated collar of the connecting piece.[306] ODF2 interacts with CDK5 and p35 but not with the CDK5/p35 heterodimer.[310] In addition, an in vitro phosphorylation assay showed that although CDK5/p35 did not phosphorylate ODF2, it phosphorylated ODF1.[306] Such phosphorylation of ODF1 enhanced ODF1–OIP1 interaction, suggesting that CDK5 may be important in promoting ODF1 degradation.

The germ cell-less homolog 1 (*Drosophila*)-like (GMCL1) protein is predominantly expressed in rat elongating spermatids and is integrated into outer dense fibers.[316] It is localized at the abaxial (convex) surface of outer dense fibers. TEKTIN4, TEKTIN5, and GMCL1 interact either with each other or with some molecules in the sub-mitochondrial reticulum to tether the axoneme–outer dense fiber complex to the mitochondrial sheath.

Satellite Fibers

Satellite fibers are present in the flagellar matrix between the outer dense fibers (Figure 3.12). These fibers form in step 19 of spermiogenesis in the rat, just before spermatozoa are released from the seminiferous epithelium.[273] The satellite fibers appear to separate from the edge of the outer dense fibers. SPETEX1, a protein with two coiled-coil motifs, appears to be associated with the satellite fibers and involved in the structural stability of the middle piece in cooperation with TEKTIN4.[317] It is also present in the capitulum and connecting piece in *Suncus*.[318]

Function

The outer dense fibers function in improving the bending torque of the tail,[272] and/or protecting the sperm tail against shear forces encountered during epididymal transport and ejaculation. The fibers are also important for the stability and the elastic recoil of the sperm tail, as well as for support of the flagellar beat, but are not involved in active motility. Stabilization of outer dense fiber proteins by abundant disulfide cross-linking may give them significant passive elastic properties that serve to stiffen or provide elastic recoil for the sperm tail.[4] The presence of VDAC2 and VDAC3,[300] and a serine/threonine kinase CDK5, its activator p35, and Cdk5/p35 activity[306] suggest that the outer dense fibers serve as scaffolds for proteins involved in regulating sperm function.

Annulus (Jansen's Ring)

The annulus is located at the junction of the midpiece and the principal piece in mammalian mature spermatozoa (Figure 3.10). It is essential for the structural and mechanical integrity of the flagellum. Cytoplasmic droplets do not move to distal regions beyond the annulus. During spermatogenesis when the axoneme starts to extend, the annulus is already formed as an electron-dense structure in the round spermatid phase, associating with the chromatoid body at the base of the flagellum. As sperm tails elongate, the annulus and the ring-shaped chromatoid body move distally along the axoneme towards its final position. During its migration, the annulus is located at the leading edge of the cytoplasm that encompasses the midpiece area of the axoneme.

Some of the biochemical components of the annulus have been identified in the mouse, bovine, and human.[247] Septin (SEPT) proteins, originally named from being in the "septin ring" in yeast, are localized at the annulus. Septins are generally regarded as cytoskeletal proteins involved in various cellular functions through interaction with tubulin or actin. Septins are members of the GTPase superfamily (polymerizing GTP-binding proteins), and there are at least 14 septin genes. Several are shown to be associated with male infertility and other diseases in humans.[319] In SEPT4-null sperm, the annulus is replaced by a loose fibrous network, beyond which kinesin-mediated intraflagellar transport is impaired (stalls). Although the ability of ATP usage by the dynein motor is decreased, the axonemal 9+2 structure is unchanged.[247] In addition, in SEPT4-deficient sperm, domain confinement was lost, allowing unrestricted lateral diffusion of BSG on the whole tail.[320] BSG is normally confined to the principal piece domain on testicular and caput sperm and is relocated into the midpiece during epididymal transit.[30] Thus, SEPT4 functions as a membrane diffusion barrier at the midpiece–principal piece junction. Decreased expression (haploinsufficiency) of SEPT12 (*Sept12*$^{+/-}$) results in maturation arrest at the spermatid stage, broken acrosomes, bent tails, disorganized mitochondria, and nuclear DNA damage.[321] SEPT4, SEPT5, and SEPT6 deficiencies, however, do not show overt phenotypes. In infertile men, two missense SEPT12 mutations, c.266C>T/p.Thr89Met and

Vet-ebooks.com

c.589G>A/p.Asp197Asn, were found inside the GTPase domain, implying alteration of the protein structure.[322] The SEPT12^{D197N} patient spermatozoa showed annulus defects with bent tail and loss of SEPT12 from the annulus.[322]

DnaJ (Hsp40) related, subfamily B, member 13 (DNAJB13) and solute carrier family 26, member 8(SLC26A8, TAT1) appear to associate with the annulus.[323,324] DNAJB13 is a member of the HSP40 cochaperone family produced in the mouse testis and located in the radial spokes of the flagellar axoneme in mature sperm and similarly in the flagella of *Chlamydomonas reinhardtii*.[325] DNAJB13 is co-localized with the annulus in late spermiogenesis and migrates towards the midpiece–principal piece junction. When the annulus reaches its final position, DNAJB13 appears to gradually disappear from this structure and persists as a radial spoke protein.[324]

SLC26A8 is a member of the SLC26 family of anion transporters that is specifically expressed in male germ cells.[326] SLC26A8 is localized to the annulus region in normal mouse and human spermatozoa. The structural defects in SLC26A8-deficient sperm are similar to those in SEPT4-null sperm, but SLC26A8-deficient sperm lack or have an incomplete oval annulus that is detached from the plasma membrane and the fibrous sheath, strongly reducing ATP consumption.[323]

During spermatogenesis, the annulus guides the growth of the flagellum to coordinately align the mitochondria along the axoneme. Then, the annulus/septin ring serves as a cortical scaffold to organize the fibrous sheath immediately distal to the mitochondrial array, and also serves as a barrier between the midpiece and principal piece, forming a complex of septins 1, 4, 6, 7, and 12 in mammals. This complex is associated with the co-chaperone DNAJB13 and possibly with integral protein SLC26A8, which could play a critical role in anchoring the annulus to the plasma membrane.[327]

Fibrous Sheath

General Features, Structure, and Formation

Most of the genes encoding the known fibrous sheath components are expressed during the postmeiotic period of spermatogenesis and found only in spermatogenic cells. Constituent proteins, features, and the genes associating to the fibrous sheath are listed in Table 3.4.[328–359]

Structure

The fibrous sheath defines the extent of the principal piece (Figure 3.1), by far the longest segment of the flagellum.[167] It is a cytoskeletal structure that is probably unique to the flagellum of spermatozoa in mammals and some birds. It closely underlies the plasma membrane, is attached to the annulus (Figure 3.10), and is a tapering cylinder formed by two longitudinal columns connected by circumferential ribs (Figures 3.9 and 3.11). The columns are formed by longitudinally oriented, loosely packed filamentous structures 15–20 nm in diameter. The longitudinal columns run peripheral to microtubule doublets 3 and 8 of the axoneme and are attached to outer dense fibers 3 and 8 in the proximal part of the principal piece. Distal to the termination of these two dense fibers, the tapered central edges of the longitudinal columns attach to ridges projecting from microtubule doublets 3 and 8.[167] The columns lie approximately in a plane sagittal to both of the inner doublet microtubules of the axoneme. The dorsal longitudinal column is nearest outer doublet 3, while the ventral column is nearest outer doublet 8 in sperm with a falciform shape.[167] The ribs broaden toward their ends, where they merge with the longitudinal columns and with each other. The thickness of the ribs diminishes toward the distal end of the principal piece, and the ribs and outer dense columns end abruptly at the posterior margin of the principal piece.[4,167] In human spermatozoa, the ribs are 10–20 nm apart and about 50 nm wide.

Formation

Fibrous sheath assembly, most thoroughly studied in the rat, proceeds throughout much of spermiogenesis from distal to proximal, opposite to the direction of outer dense fiber development.[273] The longitudinal columns first appear as thin rods joined to microtubule doublets 3 and 8 near the distal end of the flagellum in step 2 of spermiogenesis and increase in length until step 10. The ribs appear in step 11 as evenly spaced pairs of fibrous bands lying against the plasma membrane in the posterior part of the flagellum. The rib precursor associates with the columns in a distal to proximal direction during steps 12–14. During steps 15 and 16, additional ribs are formed and the longitudinal columns thicken to complete fibrous sheath development. Fibrous sheath proteins continue to be synthesized during the entire 15-day period of fibrous sheath formation in the rat.[273] This assembly occurs similarly in the mouse.[273]

Composition

The fibrous sheath is highly resistant to acid solubilization and contains disulfide bonds that cross-link the proteins for stabilizing the fibrous sheath. There are presumably more than 20 proteins that are located in or are closely related to the fibrous sheath of mammalian spermatozoa (Table 3.4).

Six cAMP-dependent protein kinase A (PRKA or PKA) anchoring proteins (AKAPs) have been identified in sperm, including AKAP1, AKAP3, AKAP4, AKAP11, microtubule-associated protein 2 (MAP2), and WAS protein family, member 1 (WASF1, WAVE1).[360] Of these,

Vet-ebooks.com

TABLE 3.4 Fibrous Sheath-Associated Proteins

Protein	Gene	Features	References
AKAP4 (p82, FSC1, AKAP82, FS75)	*Akap4*	"PRKA (PKA) anchoring protein 4," major structural protein, two kinase activity, PKA anchoring sites, postmeiotic, testis-specific	328–332
		Transmembrane receptor serine/threonine kinase signaling pathway	333
		KO male; infertile due to lack of sperm motility	331
AKAP3 (AKAP110, FSP95)	*Akap3*	"PRKA (PKA) anchoring protein 3," structural protein, PKA anchoring site, postmeiotic, testis-specific	334,335
TAKAP-80 (AKAP14)	N.D.	"Rat testis-specific, developmentally regulated, RII-binding protein," postmeiotic, testis and other tissues	336
FSIP1	*Fsip1*	Fibrous sheath interacting protein 1, binds to AKAP4, postmeiotic, testis-specific	332
FSIP2	*Fsip2*	Fibrous sheath interacting protein 2, binds to AKAP4, meiotic and postmeiotic, testis-specific	332
ASP (AKAP-asp)	*Ropn1l*	"AKAP-associated sperm protein," ropporin 1-like protein, binds to PKA anchoring site on AKAP3, testis-specific	337
Ropporin (RPPN, ODF6)	*Ropn1*	Rhophilin-associated protein 1, AKAP-binding sperm protein, postmeiotic, testis-specific	337
Rhophilin (rhophilin 1 or odf5)	*Rhpn1*	Rho GTPase binding protein 1, meiotic and postmeiotic, high expression in testis and low in some other tissues	338–340
Sp17	*Spa17*	Sperm protein 17, meiotic and postmeiotic, mainly in principal piece, detectable in middle piece and dorsal acrosome, testis-specific	339,341
CABYR (fibroushethin 2)	*Cabyr*	Ca^{2+}-binding tyrosine phosphorylation regulated protein, mainly expressed in testis, bind to AKAP3 and ropporin	342,343
FS39 (DDC8)	*Ddc8*	39-kDa fibrous sheath protein, postmeiotic, testis-specific	344
Tsga10		Testis-specific 10, meiotic and postmeiotic, testis and other tissues	345
HK1-S	*Hk1*	Hexokinase 1-S, spermatogenic cell HK-1 splice variants, meiotic and postmeiotic, mainly in principal piece, testis-specific tethered to PFKMS and GSTM5 and the fibrous sheath	346–349
GAPD-S (GAPD-2)	*Gapds*	Glyceraldehyde 3-phosphate dehydrogenase-S, sperm-specific glycolytic enzyme, postmeiotic, testis-specific	350–353
		KO male; infertile	354
GSTM5	*Gstm5*	Glutathione S-transferase mu 5, meiotic and postmeiotic, high expression in testis and low in other tissues	355
Sptrx-1 (TXNDC1)	*Txndc2*	Sperm thioredoxin-1, associated with assembling longitudinal columns of fibrous sheath in spermatids, not detected in sperm, postmeiotic, testis-specific	356
Sptrx-2	*Txndc3*	Sperm thioredoxin-2, present in longitudinal columns and ribs in fibrous sheath in sperm, postmeiotic, testis-specific	357
36K-A	*Pdhb*	Pyruvate dehydrogenase E1 component β subunit, possible testis-specific splice variant, meiotic and postmeiotic, multiple tissues	358
PDHA2	*Pdha2*	Pyruvate dehydrogenase E1 component α subunit, possible testis-specific splice variant, meiotic and postmeiotic, multiple tissues present in fibrous sheath and co-localize with AKAP4	359

Vet-ebooks.com

three AKAPs are identified in the fibrous sheath. PRKA are defined by their ability to bind one or more of the regulatory subunits (PRKAR1A, PRKAR2A, PRKAR1B, and PRKAR2B, formerly RIa, RIIa, RIb, and RIIb) of PRKA, and these subunits interact with an amphipathic helix on the AKAP.[360] The catalytic subunits are PRKACA, PRKACB, and PRKACG (formely Cα, Cβ, and Cγ).[361]

AKAP4, a ~80-kDa protein, is the most abundant AKAP and a major structural component.[328,329] AKAP4 is present in both the longitudinal columns and the ribs of the fibrous sheath of mouse spermatozoa. AKAP4 has two regions of homology with PKA-anchoring domains characteristic of AKAP proteins, one domain with dual specificity for binding either the PRKAR1A or PRKAR2A subunit of PKA and one domain that binds only PRKAR1A.[330] AKAP4-null males are infertile, and have reduced motility (one-eighth the level of sperm motility from wild-type male). In the absence of AKAP4, the framework of the fibrous sheath formed, but the fibrous sheath remained incompletely developed, and the flagellum was shortened.[331] Also, AKAP4-null sperm showed disruption in subcellular distributions of PRKA, phosphatidylinositol 3-kinase, and sperm autoantigenic protein 17 (SPA17), as well as significant alteration in activity and phosphorylation of PPP1CC.[361]

AKAP3, a ~110-kDa protein, has a single PRKAR2A binding site. In the mouse, *Akap3* mRNA and AKAP3 protein were both detected in step 2 round spermatids, but AKAP3 protein was not detected in the flagellum until the beginning of step 8 spermatid elongation.[332] In human sperm, the AKAP3 protein was detected by immunoelectron microscopy only in the circumferential ribs.[335] AKAP3 is involved in formation of the framework of the fibrous sheath, and AKAP4 is deposited on this framework late in spermiogenesis.[331]

Other proteins associated with the fibrous sheath include AKAP14 (TAKAP-80), a 55-kDa protein found in the rat, which has a single PRKAR2A binding site.[336] In addition, fibrous sheath interacting proteins 1 and 2 (FSIP1 and FSIP2) have been identified by yeast two-hybrid screening. FSIP1 binds to the C-terminal portion of AKAP4, and AKAP4 binds to a region at the C-terminal end of FSIP1.[332] The FSIP2 binding site on AKAP4 encompasses the dual PRKAR1A/PRKAR2A-binding domain, suggesting that FSIP2 might have a role in regulating PKA anchoring to AKAP4.

ROPN1 and roppolin 1-like protein (ROPN1L, ASP) interact with the PKA-binding domain of AKAP3.[337] ROPN1L is 39% identical to ROPN1 and both proteins have N-terminal regions similar to the AKAP-binding domain of the PRKAR2A subunit. Due to the sequence similarity of ROPN1 and ROPN1L to the N-terminal dimerization and docking domain of PRKAR2A, these proteins are named R2D2 proteins.[362] The R2D2 domain is also contained in SPA17 and Ca^{2+}-binding tyrosine phosphorylation-regulated protein (CABYR, formerly FSII).[343] ROPN1 was identified previously as a rhophilin-binding protein and forms a heterodimer with SPA17.[339] Rhophilin (RHPN1) contains a binding motif for the ras homolog protein (RHO), a small GTPase that triggers reorganization of the cytoskeleton and regulates motility and cell-substrate adhesion.[340] Ultrastructurally, ROPN1 is mainly on the inner surface of the fibrous sheath, while RHPN1 is tightly bound to the outer surface of the fibrous sheath.[339]

SPA17 and CABYR contain regions similar to the N-terminus of the AKAP binding region of PRKAR2A.[337] SPA17 is found in the principal piece, middle piece, and equatorial region of the acrosome, co-localizes with AKAP3 in the fibrous sheath of mouse sperm and binds to AKAP3 in vitro, but SPA17 is expressed more widely. CABYR is expressed mainly in the testis.[343] Multiple variants of CABYR were identified in human testis, not all of which contained the RII-like domain or the Ca^{2+}-binding EF-hand domain. Some of the variants gained Ca^{2+}-binding capacity when phosphorylated during capacitation.[343] Recent yeast two-hybrid assays showed that CABYR variants form a complex with AKAP3 and ROPN1 in human sperm fibrous sheath.[244] This binding to AKAP3 may reflect a functional need for Ca^{2+} signaling transduction and it may play a role in motility at sites along the fibrous sheath.

Protein FS39 (gene unknown) is testis-specific in the mouse and has similarities to myosin and intermediate filament-related protein.[344] The testis-specific 10 protein (TSGA10) contains a myosin-like domain similar to the Ezrin/radixin/moesin family domain. The gene is expressed at high levels in mouse testis, but the transcript is also present in some fetal tissues and tumor cells.[345] Mouse TSGA10 is a 65-kDa protein synthesized in elongating spermatids and processed to a 27-kDa protein in the purified mature fibrous sheath.[345]

Testis-specific isozymes or proteins associated with enzymatic activity also are found in fibrous sheath. They include three glycolytic pathway enzymes, hexokinase type 1, spermatogenic cell variant (HK1S), glyceraldehyde 3-phosphated dehydrogenase, spermatogenic (GAPDHS), and pyruvate dehydrogenase subunits (PDHA E1α and E1β subunits; PDHB).[5] In addition, there are enzymes associated with free radical metaolism, including mu-class glutathione S-transferase (GSTM5) and two thioredoxins, thioredoxin-related transmembrane protein 1 (TMX1, TXNDC1, SPTRX1) and thioredoxin domain containing 2 (spermatozoa) (TXNDC2, SPTRX2).

HK1S and GAPDHS are associated with the principal piece. Alternate transcripts of HK1 (hexokinase type 1) are present in spermatogenic cells, and the N-terminal porin-binding domain usually present in HK1 is absent and replaced with a spermatogenic cell-specific region

Vet-ebooks.com

(SSR).[348] There are at least three alternatively spliced transcripts that encode the same protein. HK1S is present mainly as a monomer in motile sperm with an increase of hexokinase activity accompanied by dephosphorylation and reduction of the disulfide bond in HK1S.[349] A yeast two-hybrid assay using the SSR as bait determined that HK1S is tethered to a sperm variant isozyme of muscle-type phosphofructokinase (PFKMS), which in turn is bound tightly to GSTM5 in the fibrous sheath.[363] Thus, direct interactions occur between two glycolytic enzymes and between a glycolytic enzyme and a fibrous sheath protein. A hierarchy of binding affinities exists from low to high between HK1S and PFKMS, between PFKMS and GSTM5, and between GSTM5 and other fibrous sheath components.[363]

GAPDHS is as a testis-specific ortholog of GAPDH (glyceraldehyde 3-phosphate dehydrogenase) that is integrated into the fibrous sheath and is encoded by the *Gapdhs* gene.[353] GAPDHS-null male mice are infertile, and the motility of the null sperm was reduced to a weak, twitching motion.[354] Oxygen consumption of the GAPDHS-null sperm was unchanged, but ATP levels were greatly reduced. Thus, the energy required for sperm motility is derived primarily from ATP produced by glycolysis in the principal piece and not by oxidative phosphorylation in mitochondria.[354] A recent study showed that active metabolism of glucose, rather than mitochondrial ATP production, results in hyperactivated motility of spermatozoa, by affecting sperm redox pathways that could play a role in regulating sperm changes that occur during capacitation.[364]

GSTM5 is a member of the mu-class glutathione S-transferase family. The GST proteins are scavengers of cytotoxic substances, such as electrophilic compounds and peroxides. GSTM5 found in the fibrous sheath of mouse sperm[329] might serve to protect sperm from damage by such agents.

Thioredoxins are able to reduce disulfide bonds in the presence of thioredoxin reductase. Thioredoxin family SPTRX1 protein is associated primarily with the longitudinal columns of the fibrous sheath during flagellar formation in rat spermatids, but little SPTRX1 was detected in rat epididymal spermatozoa. Thus, SPTRX1 is suggested to be a transient component whose role is to participate in the formation of the longitudinal columns of the fibrous sheath, but the SPTRX2 protein is an integral component of the fibrous sheath in epididymal spermatozoa.[357]

PDHB was identified in associated with the fibrous sheath in hamster sperm.[358] PDHA has two active sites and requires thiamine pyrophosphate (TPP) and Mg^{++} as cofactors for its enzymatic activity. PDHA co-localized with AKAP4 in the fibrous sheath and exhibited tyrosine phosphorylation during hamster sperm capacitation.[359] Using a proteomics approach, eight peptide fragments were found to match regions covering 32% of the sequence of PDHB.[358] PDHA catalyzes the decarboxylation of pyruvate, thereby forming a tightly bound enzyme intermediate and liberating carbon dioxide. PDHA is a component of pyruvate dehydrogenase complex that exhibits tyrosine phosphorylation during hamster sperm capacitation.[365]

Function

The fibrous sheath serves as a mechanoelastic structure involved in shaping the flagellar waveform.[4] The fibrous sheath serves as a scaffold for both glycolytic enzymes and constituents of signaling cascades mediated by tyrosine phosphorylations, plays a role in the regulation of sperm motility, and also is involved in sperm maturation, capacitation, and hyperactivation.[331,366,367] Glycolytic enzymes associated with the fibrous sheath include GAPDHS, HK1S, aldolase a (ALDOA), lactate dehydrogenase A (LDHA), triose phosphate isomerase (TPI), pyruvate kinase (PK), lactate dehydrogenase-C (LDHC), sorbitol dehydrogenase (SORD), and ADP/ATP carrier protein 4 (SLC25A4).[5] Several signaling proteins localized in the fibrous sheath include SPA17, CABYR, AKAP3, AKAP4, AKAP14, ROPN1, and GSTM5.[336,339,343,367,368]

The attachment of axonemal doublets 3 and 8 to the longitudinal columns of the fibrous sheath seems to restrict their participation in microtubule sliding and axoneme binding during flagellar motion. The longitudinal columns themselves also limit bending of the flagellum in this same plane, whereas these features would not restrict flagellar bending perpendicular to this plane.[4] Although sperm appear to swim with a planar effective stroke and recovery stroke somewhat like cilia, they also rotate, and the propagated waves have a three-dimensional component in the distal portion of the tail when viewed in a microscope.[4]

The cAMP-signaling pathway participates in the regulation of processes associated with sperm maturation, motility, capacitation, hyperactivation, and the acrosome reaction.[125,369] PKA is the predominant target for cAMP, synthesized from ATP by adenylate cyclase in response to HCO_3^- and Ca^{2+} stimuli, and PKA in turn phosphorylates proteins on serine and threonine residues. The downstream targets for PKA in this cascade are tyrosine kinases that modify proteins in the flagellum associated with these processes.[369] The presence of AKAP4, AKAP3, and AKAP14 in the fibrous sheath strongly suggests that one of its main roles is to anchor the PKA involved in such processes.

Components of the Rho-GTPase signaling pathway also are associated with the fibrous sheath. RHOPN1 binds to Rho, a small GTPase that acts through effector molecules to modulate reorganization of cytoskeletal components. ROPN1 and ROPN1L bind to the RII-anchoring

Vet-ebooks.com

site on AKAP3 and contain an N-terminal domain similar to the AKAP-binding region of PKAR2A.[337] Other proteins associated with the fibrous sheath that also have similar domains are SPA17, and CABYR.[337] This led to the suggestion that AKAPs serve as scaffolding proteins for the Rho-GTPase pathway and that Rho activates kinases and phosphatases involved in regulating sperm motility.[332,337] The evidence that Rho GTPases (RhoA, RhoB, Rac1, and Cdc42), as well as the effectors RhoGDI, PI(4)P5K, and ROCK-1, were present in the sperm head in boar, human, rat, ram, bull, and elephant sperm suggests that Rho GTPases in spermatozoa are conserved throughout mammalian evolution and Rho GTPase is involved in regulating the acrosome reaction in the sperm of several mammalian species as well as in motility of bovine sperm.

Although glycolysis is a highly conserved process, several of the glycolytic enzymes in sperm have biochemical or enzymatic properties that differ from those of glycolytic enzymes in somatic cells.[370] Four glycolytic enzymes in sperm that have been examined closely to determine the basis for these differences are PGK2, GAPDHS, LDHC, and HK1S. Sperm require glucose for in vitro fertilization and are not able to use pyruvate or lactate as energy substrates. Since blocking mitochondrial oxidative phosphorylation with oligomycin does not inhibit fertilization, sperm do not depend on mitochondria for their energy. Indeed, targeted disruption of the *Gapdhs* gene drastically reduced ATP levels and sperm motility, leading to male infertility.[354]

Abnormal Flagella

Spermatozoa with abnormal flagella are not common in many mammals, but are relatively common in humans. Asthenozoospermia is found frequently in infertile men.

Two categories of flagellar defects have been defined.[371,372] One category includes nonspecific or nonsystematic defects, seen as heterogeneous combinations of alterations affecting variable percentages of sperm among different individuals. These are usually acquired secondary to pathological conditions that affect the testis or duct system. The second category includes systematic defects, often seen as a particular sperm phenotype that predominates in a sample from an individual and resembles the phenotype of sperm from other individuals. These are likely to have a genetic origin and tend to show family clustering.[372] These two categories are recently described as nonspecific flagellar anomalies (NSFAs) and various genetic disorders including primary ciliary diskinesia and the dysplasia of the fibrous sheath, and are reviewed in sperm pathologies affecting the head, neck, and tail.[121]

Heritable Effects on Human Sperm Flagellar Structure

One hereditary condition causing sperm flagellar defects is referred to as immotile-cilia syndrome (ICS),[373] Kartagener's syndrome, or primary ciliary dyskinesia (PCD).[374] It often results in male sterility, situs inversus (major visceral organs are reversed from their normal position), chronic respiratory problems, and sinositis.[373] These conditions are directly or indirectly a consequence of an autosomal recessive trait that makes cilia or flagella unable to perform normal and coordinated movements.[375] Sperm from men with the syndrome have defective axonemes with such alterations as a partial or complete lack of dynein arms, a lack of outer dynein arms, a lack of inner arms, or abnormally short spokes, and a lack of the central sheath.[375] Because of the different types of defects seen in sperm and cilia, mutations in multiple genes might contribute to the syndrome.[373] Over 200 axonemal proteins are present in human cilia[376] and many of these probably are present in the sperm flagellum. However, the relatively low incidence of ICS suggests that a smaller number of genes are involved.[377] Two strategies being applied to identify such genes include screening for mutation in candidate genes selected on the basis of their expected function in axonemes, and genetic linkage analysis in families with ICS to map chromosomal regions associated with the disease.[377] Such studies have led to the identification of two genes for components of the outer dynein arms that are associated with ICS and the elimination of other candidate genes.[377]

A different type of flagellar defect probably of genetic origin is known as dysplasia of the fibrous sheath (DFS). This syndrome is characterized by severe asthenozoospermia and by the sperm having hyperplastic and disorganized fibrous sheaths and short, rigid, thick, and immotile tails.[372] Other associated changes seen include distortion or severe disruption of the axoneme, extension of outer dense fibers 3 and 8 into the principal piece, and failure of the annulus to migrate caudally. The occurrence of this syndrome in brothers suggests that DFS can be caused by recessive mutations in autosomal genes involved directly or indirectly in the assembly and organization of the fibrous sheath. If DFS is the only symptom present, the mutations might occur in spermatogenic cell-specific genes expressed in spermatids. However, about 20% of DFS patients have respiratory symptoms from early childhood, suggesting that their sperm defects might be due to ICS,[371] that mutations in some genes might cause both ICS and DFS, or that these individuals have mutations in multiple genes associated with these syndromes.

An additional type of flagellar defect that occurs in sperm from infertile men is called flagellar dyskinesia.[378] It has been observed in brothers, suggesting that it can

Vet-ebooks.com

have a genetic cause.[379] The sperm have normal axonemes but altered placement of periaxonemal structures. These include abnormal extension of individual dense fibers along the axoneme, altered order of termination of these structures, and a modified number and location of longitudinal columns of the fibrous sheath.[378] The outer dense fibers have abnormal positions with respect to each other, being placed symmetrically with respect to a plane that passes through microtubule doublet 1 and between doublets 5 and 6. The most common defect of the longitudinal columns of the fibrous sheath is the presence of only one column adjacent to doublets 3 or 8.[378] One suggestion was that this might be due to a defect in the A microtubules of the outer doublets that affects the adjacent formation or assembly of the outer dense fibers and longitudinal columns of the fibrous sheath.[380]

Heritable Effects on Mouse Sperm Flagellar Structure

Several spontaneous mutations affecting formation of the flagellum have been identified in mice. The mutations usually are pleiotropic, causing defects in other tissues in addition to the seminiferous epithelium.[381] This is known because they were identified by other effects of the mutation and subsequently found to cause defects in sperm. Homozygous mice with the wobbler mutation, caused by a nonsense point mutation in the leucine rich repeat containing 32 (*Lrrc32*) gene and characterized by spinal muscular atrophy and defective spermiogenesis, apparently produce normal numbers of sperm, but few sperm are motile.[382] The sperm appear to have average-length tails and normal heads, but 70% of the sperm in the vas deferens have ultrastructural defects in the flagellum. These defects include the absence of one to four outer doublets and the corresponding dense fibers, most commonly those from positions 4 through 7. Other defects seen less frequently are supernumerary microtubules or the absence of central pair tubules in the axoneme.[383] Defective sperm are common in mice heterozygous for a mutation in the T-locus that causes a shortened tail and/or defects in sacral vertebrae,[384] with the most frequent flagellar defects seen in sterile mice being a lack of four outer dense fibers and doublets. The male-sterile mutation, hydrocephalic-polydactyl (*hpy*), results in the absence of a flagellum or in partially assembled axonemal structures and/or poorly organized aggregates of other tail components.[381] The axoneme usually is absent or abnormally formed and the outer dense fibers and fibrous sheath are morphologically atypical, when present. The axoneme dysgenesis might be due to failure to form stabile structures because of defective subunits.[381]

A defect often seen in an abnormal or degenerating flagellum is the absence of microtubule doublets 4 through 7 and the associated dense fibers. Doublets 3 through 8 and the associated dense fibers appear to remain firmly attached to the fibrous sheath, while doublets 4 through 7 are extruded from the sperm tail.[385] This suggests that sperm seen with this defect may be degenerating. In some situations, the flagellar axoneme appears to form normally and then to become progressively disorganized, as occurs during spermiogenesis in quaking[386] and in hpy/hpy mice.[381] However, in wobbler mice, the percentage of abnormal sperm increases as they transit the male tract. Only about 5% of sperm tails are abnormal in the testis, while nearly 70% of sperm from the vas deferens have abnormal flagella.[382]

Gene Knockouts Affecting Mouse Sperm Flagellar Structure and Function

Sperm flagellar defects and dysfunctions found in gene knockout mice models have been reviewed in detail elsewhere.[252,387] This accumulated evidence shows various mutants generate different phenotypes relating to the axoneme, fibrous sheath, outer dense fibers, motility, and other parameters, sometime affecting head components. More than 400 mutant mouse models with an altered reproductive phenotype have been generated.[388] Only about 10% of knockout mouse models that disrupt male fertility have spermatozoa with impaired motility and/or sperm flagellum structure anomalies, with the remainder being infertile due to disruption of developmental, spermatogenic, or endocrine functions.

Flagellar Motion

The Flagellar Wave

The evidence that the proximal part of the midpiece remains collinear with the axis of the head suggests that motion of the head is minimal with respect to the connecting piece or within the connecting piece itself.[241]

The flagellar wave is propagated in a plane perpendicular to the central pair of microtubules of the axoneme. It passes through doublet 1 and between doublets 5 and 6, with the active stroke being toward doublet 1.[389] The flagellum twists during bend propagation, with the plane of bending moving toward doublet 2.[390] The part of the axoneme containing doublets 1 through 5 is thought to be active during this phase of flagellar motion.[390] The outer dense fibers and fibrous sheath appear to play a passive role in flagellar motion. The tapering architecture of the dense fibers appears to relate to the progressive increase in the amplitude of curvature observed during flagellar wave propagation.

As sperm mature while passing through the epididymis, sperm gain a vigorous motion that results in rapid forward movement, referred to as progressive motility. With this change, sperm flagella appear to become more rigid due to the increased disulfide bond formation that

Vet-ebooks.com

occurs in outer dense fibers and the fibrous sheath and reduce the arc of curvature in swimming pattern. However, cauda sperm from different species show different patterns of motility, flagellar beat, and flagellar rigidity.

Regulation of Sperm Motility

Sperm undergo two types of motility: progressive motility and hyperactivated motility. The beating mode of sperm flagella can be categorized into two different types: symmetrical waves and asymmetrical waves. Progressive motility is generated by symmetrical waves propagating down the flagellum with net linear propulsion. Hyperactivation is associated with asymmetrical waves propagating down the flagellum with higher amplitude, resulting in circular trajectories.[391] Hyperactivation is characterized by a whip-like beating showing a vigorous figure-eight pattern of the flagellum. It occurs with the capacitation process leading to the acrosome reaction and is found in sperm during ascending of the female reproductive tract.[125,392] The details are still unclear concerning whether hyperactivation is a consequence of capacitation or whether hyperactivation and capacitation are separate processes that occur in parallel. However, hyperactivation mediated by Ca^{2+} signaling is regulated by similar yet distinct signaling events that distinguish it from capacitation that involves cross-talk between the cAMP/PKA and tyrosine kinase/phosphatase signaling pathways.[393]

ACTIVATION OF MOTILITY

Physiological factors such as Ca^{2+}, HCO_3^-, and cAMP are essential for the initiation and maintenance of progressive motility and hyperactivated motility. Ca^{2+} plays a major role in regulating hyperactivated motility by acting on the axoneme. Demembranated sperm produced by disruption of the plasma membrane and mitochondrial membranes with Triton-X100, leaving the axoneme and cytoskeletal support intact, show hyperactivation. However, it is poorly understood how Ca^{2+} reaches the axoneme in the flagellum to switch on hyperactivation. Sperm motility quiescence factors such as immobilin are present in rat epididymal fluid, suggesting that sperm motility is prevented in the epididymis.[394]

There is limited information about receptors on the sperm surface that might be involved in triggering progressive or hyperactivated motility. Olfactory receptors are a large family of membrane-associated G-protein-coupled receptors, some of which are found on the sperm surface. They are suggested to be involved in triggering progressive or hyperactivated motility as well as chemotaxis. Olfactory receptors are localized in the midpiece of mature sperm. Bourgeonal (a ligand for human olfactory receptor 1D2 (OR1D2)) causes an increase in intracellular Ca^{2+} as well as chemotaxis in human sperm.[395] Sperm from transgenic mice overexpressing the olfactory receptor 16 (OLFR16, MOR23) showed positive chemotactic swimming behavior.[396] In mammals, 29 olfactory receptors were identified in the testis by RNAse protection assays, northern blotting, RT-PCR, western blotting, in situ hybridization, DNA arrays, and bioinformatics.[397]

Gamma-aminobutyric acid (GABA) receptors are present in the sperm membrane, and exposure of human sperm to GABA causes changes in sperm motility parameters and hyperactivation.[398] Bicuculline and picrotoxin, antagonists of GABA, blocked the effects of both GABA and progesterone on the acceleration of rat sperm capacitation and hyperactivation, and sperm capacitation required both Cl^- and HCO_3^-.[399] This suggests that activation of a GABA receptor contributes to sperm capacitation and hyperactivation and that both HCl^- and HCO_3^- are essential for its function.

CALCIUM AND MOTILITY

Ca^{2+} has important roles in motility, especially hyperactivation. CATSPER1, CATSPER2, $Ca_v2.3$, and PMCA4 participate in the regulation of intracellular Ca^{2+} levels, and are involved in the initiation of sperm motility. CATSPER1 is a testis-specific voltage-gated Ca^{2+} entry channel localized to the sperm principal piece. CATSPER1-null male mice are infertile and have reduced progressive motility.[400] CATSPER2, another voltage-gated ion channel, is closely related to CATSPER1 and is present in the flagellum. CATSPER1- and CATSPER2-null mouse sperm fail to hyperactivate but exhibit normal protein tyrosine phosphorylation.[12,14]

Ca^{2+} channels have important roles in regulating sperm motility. Disruption of the gene for the Ca^{2+} channel, voltage-dependent, T type, alpha 1G subunit (CACNG1) resulted in increases in straight-line velocity and linearity in mutant sperm.[19] Disruption of the gene for PMCA4, a Ca^{2+}-dependent ATPase involved in Ca^{2+} efflux, also resulted in male infertility. One research group reported that there were no differences in motility of sperm with or without PMCA4 when incubated in a medium that did not induce capacitation, but sperm without PMCA4 became immotile when incubated in capacitation medium.[23] However, another group reported that the majority of sperm lacking PMCA4 were immotile.[24] In addition, the latter group indicated that the motile sperm present had decreased average velocity, progressive velocity, and track speed, and intracellular Ca^{2+} levels over two times higher than normal sperm.

Other regulators of ion movements across the plasma membrane also are known to be important in sperm motility. Disruption of the gene for a voltage-dependent anion channel (*Vdac3*) resulted in markedly reduced sperm motility, frequently causing alterations in the axoneme structure.[401] A sperm-specific sodium–hydrogen exchanger called solute carrier family 9, subfamily C (Na^+-transporting carboxylic acid decarboxylase),

Vet-ebooks.com

member 1 (SCLNC1) is also involved in regulating intracellular pH and is located in the principal piece. Disruption of its gene (*Sclnc1*, formerly *Slc9a10*) resulted in male infertility and markedly reduced sperm motility.[402] This immotility phenotype of SCLNC1-null spermatozoa appeared to result from an intimate association of SCLMC1 and the atypical spermatogenic cell adenylyl cyclase (ADCY10, sAC).[403] Furthermore, a unique Na,K-ATPase alpha4 isoform subunit (ATP1A4) found only in testis and located in the midpiece, is also required for sperm motility. It is responsible for transporting Na^+ out and K^+ into the cell. Specific inhibition of the alpha4 isoform with the cardiac glycoside ouabain substantially reduced the percentage of motile sperm over time.[404] In addition, an inositol 1,4,5-triphosphase (IP_3) receptor-gated release of Ca^{2+} from an intracellular store in the sperm neck region was suggested to regulate hyperactivated motility.[405]

cAMP AND MOTILITY

cAMP is a key second messenger to regulate sperm motility. cAMP levels increase when adenylyl cyclase is stimulated to convert ATP to cAMP. This results in activation of PKA to trigger a cascade of phosphorylation of serine and threonine residues on neighboring proteins. This occurs primarily in the flagellum and in turn results predominantly in phosphorylation of proteins on tyrosine residues.

Plasma membrane-bound adenylyl cyclases (ADCYs) are regulated by G proteins in response to external stimuli. There is evidence for G-protein activated ADCYs in mouse sperm that are involved in the acrosome reaction and in human sperm that are involved in olfactory receptor-mediated chemotaxis and hyperactivation.[406] However, sperm appear to depend primarily on the soluble adenylate cyclase ADCY10 that lacks a putative transmembrane domain and is not G-protein regulated.[407] Two alternatively spliced transcripts are expressed in rat testis, which encode a 187-kDa and a C-terminal truncated 52-kDa form.[407,408] The 187-kDa form is present predominantly in soluble fractions from rat testis.

HCO_3^- and Ca^{2+} are involved in the cAMP-regulated activation of sperm motility.[409] HCO_3^- directly stimulated ADCY10 of spermatozoa.[410] This elevates intracellular pH, increasing sperm intracellular cAMP, and activating protein kinase A, which in turn initiates a downstream signaling cascade that enhances tyrosine phosphorylation. Increased tyrosine phosphorylation is an indication that spermatozoa are undergoing capacitation.[410,411] HCO_3^- increased ADCY10 activity in vitro by increasing the rate of the enzyme reaction and by relieving substrate inhibition that occurs at high ATP-Mg^{2+} concentrations.[409] The evidence that HCO_3^- concentration in the epididymis is low suggests that sAC activity is limited in sperm stored in the epididymis.[409] Ca^{2+} acts directly on ADCY10 and acts synergistically with HCO_3^-.[409]

ADCY10-null male mice were infertile and their sperm showed only a trembling movement in the midpiece and no forward motility, and this motility was restored by loading the sperm with a cAMP analog.[412] ADCY10-null spermatozoa, adenylyl cyclase activity and cAMP content are greatly diminished, and HCO_3^- is unable to rapidly accelerate the flagellar beat or facilitate evoked Ca^{2+} entry into sperm.[413] Thus, ADCY10 and cAMP coordinate cellular energy balance in sperm, and ADCY10 plays a critical role in cAMP signaling in spermatozoa.

PKA AND MOTILITY

PKA phosphorylation of proteins on serine and threonine residues activates a signaling cascade leading to tyrosine phosphorylation of flagellar proteins. The presence of PKA anchoring sites (AKAP3, AKAP4, and AKAP14) in the fibrous sheath strongly suggests that one of the major roles of this structure is to anchor PKA in the principal piece region. The defining characteristic of an AKAP is the presence of an amphipathic helix region that binds PKA, usually in a subcellular location that places it close to its target proteins.[414] The PKA holoenzyme consists of two catalytic I subunits and two regulatoI(R) subunits. Genes have been identified for three C subunits (PRKACA, PRKACB, PRKACC) in humans and two C subunits (PRKACA, PRKACB) in mouse, and for four R subunits (PRKAR1A, PRAKR1B, PRKAR2A, and PRKAR2B) in humans and mice. There are at least three isoforms for PRKACB and two isoforms for PRKACA in mice, one of which (PRKACA2) lacks the N-terminal myristoylation signal and is present only in the testis.[415] The R subunits dimerize by their N-terminal domains and bind to AKAPs by this region. The R and C subunits have a cAMP-binding site and when cAMP binds to the R subunits, the C subunits are released and their catalytic activity is triggered by cAMP. PRKAR2A was present mainly in the axonemal region of the flagellum of bovine sperm and in the middle piece and distal portion of the principal piece of the flagellum of mouse sperm,[416] while PRKAR1A was seen in association with outer dense fibers and the fibrous sheath of boar sperm.

In PRKAR2A-null male mouse sperm, the majority of the PKA was not anchored in the flagellum, and sperm motility and fertility were not changed.[416] RI appears to be present in low amounts in the flagellum,[416] and bind to a PRKAR1A-specific domain and a dual PRKAR1A/PRKAR2A domain of AKAP4 in vitro.[330] Although significant amounts are present in specific locations within the flagellum, the PRKAR1A knockout is an embryonic lethal[417] and the role of PRKAR1A in sperm motility was unclear.

PRKAR2A is present in the midpiece and axoneme of ovine and mouse sperm.[418] $C\alpha_2$-null male mice generated

Vet-ebooks.com

from the targeted disruption of exon 1b of the Cα gene using a conditional Cre-loxP knockout system produced normal numbers of sperm, but were infertile.[419] The null sperm have progressive motility, but failed to hyperactivate or to accumulate tyrosine-phosphorylated proteins.[419] The level of PRKAR1A in sperm was reduced considerably, while the level of RIIα was reduced somewhat. The PRKAR2A remaining was most abundant in the principal piece, suggesting that it anchors to AKAPs in that region in the absence of C subunits.

PHOSPHORYLATION AND MOTILITY

Increased protein tyrosine phosphorylation is found in the flagellum and associated with capacitation, but not hyperactivation. Capacitation and protein tyrosine phosphorylation are regulated by cAMP at the level of PKA.

Studies defining the correlation between capacitation and the pattern of changes in tyrosine phosphorylation have greatly facilitated studies leading to a better understanding of the roles of bovine serum albumin (BSA), Ca^{2+}, HCO_3^- and other factors involved in the regulation of protein phosphorylation during capacitation.[420]

A number of changes need to occur in the sperm before the tyrosine phosphorylation begins, and the time course is relatively slow. Newly phosphorylated proteins are first seen in mouse sperm after 30–45 min in capacitation medium and the maximum level of phosphorylation is reached at about 90 min. Although some of the increases in phosphorylation might be involved in regulating hyperactivated motility, initiation of progressive motility occurs within a few seconds after exposure to medium containing HCO_3^-.[421] This suggests that rapid PKA-mediated serine/threonine phosphorylation events are involved in initiation of progressive motility.

A few sperm proteins have been identified that are serine/threonine phosphorylated in response to HCO_3^-. These include 96-, 64-, and 59-kDa bands recognizable on western blots of boar sperm extracts with an antibody against the consensus target sequence for PKA.[422] Proteomics approaches indicated that the 96- and 59-kDa bands were ODF2. It was suggested that PKA phosphorylation of target sites within a leucine zipper domain might result in changes in protein–protein interactions to alter mechanical properties of outer dense fibers.[422] In addition, AKAP4, AKAP3, and valosin-containing protein (VCP), the homolog of a SNARE-interacting protein, were found to be serine and tyrosine phosphorylated in human sperm.[423] Another sperm protein that is serine phosphorylated is glycogen synthase kinase 3 beta (GSK3B). Stimulation of bovine sperm motility with a general phosphodiesterase inhibitor (IBMX) or a serine/threonine-specific phosphatase inhibitor (calyculin A) resulted in a dramatic increase in GSK3B serine phosphorylation and a decrease in its catalytic activity.[424] In addition, the pyruvate dehydrogenase E1 component β (PDHB) associated with the fibrous sheath in hamster sperm is serine phosphorylated in a cAMP-dependent manner in association with the initiation of motility.[358] However, it is not obvious how serine/threonine phosphorylation of these proteins affects motility.

Several of the proteins that undergo changes in tyrosine phosphorylation during capacitation include the fibrous sheath proteins AKAP3,[423,425] AKAP4,[328,335,423] and CABYR.[343] Others reported are VCP[423,426] and NSF, another homolog of the SNARE-interacting protein.[423] Fifteen additional human sperm proteins that undergo tyrosine phosphorylation were identified by microsequencing.[423] These include proteins that are axonemal (α-tubulin) and fibrous sheath or outer dense fiber components (ODF1, VDAC2, GSTM3, PDHB) (Tables 3.3 and 3.4). Some of these also were identified (previous paragraph) as serine and threonine phosphorylated proteins.

Kinases responsible for tyrosine phosphorylation during capacitation must be present in sperm that are either direct targets of PKA or in the downstream signaling cascade. A 42-kDa tyrosine kinase (sp42) was isolated and purified from ejaculated boar sperm.[427] It is male germ cell-specific and localized to the midpiece. Another tyrosine kinase isolated from boar sperm (TK-32) was shown by an in-gel tyrosine kinase activity assay to require Ca^{2+} and HCO_3^- in the incubation medium. An additional tyrosine kinase identified is present in the connecting piece and principal piece of the boar sperm flagellum.[428] This 72-kDa protein is not extracted by NP-40, indicating it is bound to cytoskeletal components of the sperm. It is recognized by an anti-phospho-Sky antibody and is likely to be protein tyrosine kinase 3 (TYRO3, SKY), a Src family protein tyrosine kinase. It was shown to respond to cAMP-PKA signaling by tyrosine phosphorylating proteins mainly in the connecting and middle pieces. In addition, Yamaguchi sarcoma viral (v-yes) oncogene homolog 1 (YES1, c-Yes), another member of the Src family, has been identified in human sperm.[429] However, it was shown by immunohistochemistry to be present in the sperm head and unlikely to be involved directly in regulation of motility.

Although the primary signaling pathway for protein phosphorylation passes through PKA, other routes for the initiation of this process are present. Stimulation of sperm motility occurred when human sperm were treated with an inhibitor (LY294002) of phosphatidylinositol 3-kinase (ataxia telangiectasia mutated homolog, ATM). This resulted in an increase in cAMP production and tyrosine phosphorylation of AKAP3, leading to the suggestion that PI3-kinase is a negative regulator of sperm motility.[425] Treating sperm with the inhibitor also resulted in stimulation of binding of PKA to AKAP3 through PRKA2B, apparently due to tyrosine phosphorylation of AKAP3. This was interpreted

Vet-ebooks.com

to indicate that PI3-kinase negatively regulates sperm motility by interfering with binding of PKA to AKAP3. PI3-kinase also might be an upstream regulator of GSK3B, also a negative regulator of sperm motility. In somatic cells, PI3-kinase-generated phosphoinositol lipids activate pyruvate dehydrogenase kinase, isoenzyme 1 (PDK1), causing it to phosphorylate thymoma viral proto-oncogene 1 (AKT1), which in turn phosphorylates GSK3B. Treating bovine sperm with protein phosphatase inhibitors (calyculin A, IBMX) resulted in phosphorylation of serine 21 of GSK3Aα, reduced GSK3B kinase activity, and initiation and stimulation bovine sperm motility.[430] Thus, GSK3B also acts as a negative regulator of motility. GSK3B is located in the principal piece region (and postacrosomal region) of bovine sperm, where it could participate in the regulation of motility.

In addition, the proline-directed serine/threonine kinase CDK5 and its activator p35 are present in the outer dense fibers and in the basal plate, capitulum, and striated collar of the connecting piece in mouse sperm.[305] The substrates for CDK5 in the brain include actin, microtubule-associated proteins, and other cytoskeletal proteins, suggesting that CDK5 could have a significant role in modifying axonemal proteins in association with initiation of progressive or hyperactivated motility.

The inhibition of phosphatase activity results in the stimulation of motility, strongly suggesting that phosphatases have an important role in regulating this and other processes in sperm. While phosphatases are important components of signaling and regulatory pathways in other cell types, little is known about phosphatases in sperm. A sperm phosphatase isoform that has received some attention is protein phosphatase 1, catalytic subunit, gamma isoform (PPP1CC). It is a proline-directed serine/threonine phosphatase and thus could serve to buffer the serine/threonine kinase activity of PKA. It is a testis-specific isoform and the only PP1 present in spermatozoa of several mammalian species. There is an inverse relationship between PPP1CC activity and the motility of sperm from different regions of the epididymis, suggesting that PP1γ2 limits motility of sperm in the epididymis. PPP1CC is regulated by a homolog of the yeast protein phosphatase binding protein, protein phosphatase 1, regulatory (inhibitor) subunit 7 (PPP1R7, SDS22), and PPP1CC complexed with PPP1R7 is catalytically inactive.[431] A phosphorylated form of PPP1CC is present predominantly in the sperm head and may be involved in signaling events associated with fertilization.[432] The PPP1CC-null males were infertile due to spermatogenesis failure and only a few motile sperm were present in the epididymis, but the details are unknown.[433]

CONCLUSION

A rich knowledge of the structural and functional features of spermatozoa has been gained since 2006 (3rd edition) by a combination of studies using both modern molecular technologies and classical methods of light and electron microscopy. This information provides the foundation on which current studies are continuing to build an understanding of the molecular composition and functional mechanisms responsible for the unique properties of spermatozoa. The use of newer visualizing tools such as nanoscopy and live imaging techniques in addition to molecular tools have led to advances during the last decade in understanding the molecular components responsible for the novel structural and functional features of spermatozoa. Although earlier studies provide information valuable for interpreting the results of current investigation, they often are no longer readily accessible and therefore overlooked. This chapter has included information gained both in earlier and in recent studies that have led to the current understanding of the biology of the spermatozoon.

The role of the spermatozoon is of course to deliver the male haploid genome to the egg so that it can combine with the female haploid genome to initiate development of the next generation. The novel structural and functional features of spermatozoa are exquisitely well designed for this purpose. The major features of spermatozoa were divided here into three arbitrary categories: the plasma membrane, the head, and the flagellum. They can be considered analogous in some ways to a space ship: (1) the plasma membrane forms a barrier to a hostile environment; (2) the head contains the payload being delivered; and (3) the flagellum provides the propulsion required for delivery of the payload.

Since 2006, significant advances in knowledge about spermatozoa have come from the large expansion of the use of the tools of molecular biology and proteomics to identify the genes and proteins responsible for its composition, and of gene targeting methods for determining the role of specific proteins in sperm functions. Some of these advances concern (1) the basic information of structures and molecules during spermatogenesis that affect sperm morphology and function; (2) the identification of acrosomal proteins that have essential roles in fertilization; (3) dynamic redistribution of constituent proteins from a domain to different domains to play essential roles; (4) how the nuclear elememts are inherited by the next generation; (5) how surface molecules are posttranslationally modified in the male reproductive tract and in the female reproductive tract; (6) the identification of Ca^{2+} channels that have an essential role in sperm motility; (7) the further identification of a novel bicarbonate activated adenylyl cyclase; (8) the further findings that capacitation is accompanied by the

Vet-ebooks.com

tyrosine phosphorylation of a characteristic subset of flagellar proteins; (9) the expansion of the identification of genes encoding proteins that contribute to the structure and function of cytoskeletal elements in the head and flagellum; (10) the identification of heritable effects on the structure and function of the flagella of human spermatozoa and the genes responsible for similar effects on mouse spermatozoa; and (11) the demonstration that many of the proteins that comprise the features specific to spermatozoa are the products of novel genes or alternative transcripts that are expressed during the postmeiotic phase of spermatogenesis.

Notwithstanding a very active research period in the last three decades, the molecular basis controlling gamete adhesion and species specificity in mammals remains a conundrum. There also are large holes in our knowledge of how different molecular components are assembled into the complex structures of spermatozoa, the mechanisms responsible for sperm function, and how these mechanisms are regulated. Although great progress has been achieved particularly at the molecular and gene levels, the following questions still remain: (1) How are sperm-surface domains established and maintained? (2) What mechanisms are involved in delivery of surface components to specific domains? (3) What is the role of surface domain and lipid raft components in plasma membrane function? (4) What are the mechanisms responsible for producing and maintaining the species-specific sperm head shapes? (5) What are the roles of the sperm head cytoskeletal components or the other cytoplasmic substances? (6) Are the acrosomal enzymes identical to lysosomal enzymes, or are they products of novel genes or alternative transcripts? (7) How do acrosomal membrane and matrix proteins affect fertilization events? (8) How is assembly of the complex cytoskeletal structures of the flagellum regulated? (9) Are the components of the outer dense fibers and fibrous sheath found only in mammals, or are there homologs in nonmammalian vertebrates? (10) What mechanisms regulate the initiation of progressive motility and hyperactivated motility? (11) What are the targets of PKA, and what are the components of the downstream signal transduction pathways that lead to initiation of motility, capacitation, hyperactivation, and the acrosome reaction? Newly emerged questions are: (l) In human sperm, how do sperm nuclear changes such as epigenetic modifications and DNA fragmentation affect fertilization or early embryonal development? (2) What are the roles of carbohydrates and lipids on sperm proteins that are composed of a myriad of unknown combinations?

Although there have been considerable advances in knowledge, clearly there is a great deal more to be learned that is important to human male reproductive health. More knowledge is required to understand the long-term effects of assisted reproductive technologies, particularly intracytoplasmic sperm injection, on the integrity of the sperm genome and the risk of transmitting genes causing infertility in males to their male offspring. There is a need to identify the gene mutations detrimental to sperm function to allow identification of patients who will or will not benefit from further medical treatment. A better knowledge of the composition, organization, and function of spermatozoa is also needed to allow development of highly specific approaches to regulating sperm function in ways beneficial to family planning, either to improve sperm function and male fertility or to inhibit sperm function and disrupt male fertility. Furthermore, additional knowledge about mechanisms regulating function of spermatozoa is also essential for identifying the effects of environmental agents on male fertility and the genetic integrity of spermatozoa. There clearly are many important reasons for learning much more about the structure and function of the mammalian spermatozoon.

Fertilization in Mammals

Harvey M. Florman

Department of Cell and Developmental Biology, University of Massachusetts Medical School, Worcester, MA, USA

Rafael A. Fissore

Department of Veterinary and Animal Science, University of Massachusetts, Amherst, MA, USA

INTRODUCTION

Fertilization is the process by which haploid gametes, sperm and egg, unite to produce a genetically distinct individual. Interest in this process extends back more than two millennia,[1–3] but recently research in this area has exploded. Here are some numbers: a query of the PubMed database (htttp://www.ncbi.nlm.nih.gov/pubmed) lists more than 62,500 publications on *fertilization*; in 1967, for the first time there were more than a hundred new articles in a single year, in 1987 more than 1000, and since 2003 more than 2000 reports each year. A philosophical interest in the beginnings of development is ancient and longstanding, but several factors contribute to this more recent growth in the study of fertilization. An understanding of the mechanisms of fertilization may hold the key to both population control, where expansion past 7 billion has refocused efforts to develop effective contraceptive methods, and infertility, where there is an increased reliance on and concern about the therapeutic interventions that comprise assisted reproductive technologies.

In order for fertilization to occur, sperm must attain a fertile state through the process of capacitation (see below and Chapter 3). Sperm and egg must interact so that gamete fusion and the introduction of paternal information into the egg occurs, and the program of development must be activated. As we discuss these events, our focus will be narrow. First, we concentrate on these processes in eutherian mammals, although it is not possible to tell this story without reference to nonmammalian models. Second, we will not address the related areas of gametogenesis and meiotic regulation, sperm maturation within the epididymis, gamete transport, or preimplantation development after the first cell cycle. Those issues are considered in depth in other chapters of this volume (Chapters 1-3, 5,6 and 17). Finally, we will concentrate on developments that have occurred since the third edition of this series appeared in 2006.[4] Context for recent progress requires discussion of earlier results, but in those cases we will attribute only the initial observations and then point readers to relevant reviews. This is particularly the case for the unusually fertile period of approximately four decades beginning in the mid-to-late 1940s, during which many of the foundations of this field were established. It was during this time that the key events of mammalian fertilization, such as capacitation, the acrosome reaction (an exocytotic event in sperm that is required for fertilization), and the block to polyspermy, were discovered; methods for analysis of fertilization in vitro were developed; the first "test tube babies" were produced; and the oral contraceptive "Pill" was developed. The pioneering work of Chang, Austin, and numerous others who ended their research careers within that time frame will, of necessity, be referred to briefly herein. Yet their work remains highly relevant for the continued progress of this field. A more thorough discussion of that foundational period can be found in the magisterial reviews by Yanagimachi in 1988 and 1994 in the first two editions of this series.[5,6]

SPERM CAPACITATION

Definitions and General Comments

Mammalian sperm that await ejaculation in the cauda epididymis are not able to fertilize eggs (Chapter 17). The requirement for additional maturation was

first reported in 1951 by Austin[7] and by Chang,[8] who observed that sperm must reside in the female reproductive tract in order to fertilize eggs. A similar conclusion was reported by Noyes and coworkers in 1953,[9] although Yanagimachi suggests that those experiments were completed in the late 1940s but not reported for several years.[6] The process by which sperm develop fertility under instruction from the female is referred to as "capacitation".[10] The importance of capacitation should not be understated. It was the last key step that needed to be understood in the effort to fertilize mammalian eggs in vitro, which began with the work of Schenk in 1878 but produced equivocal results for a variety of reasons.[11] Once the requirement for capacitation was recognized, it was a relatively brief 8 years until rabbit eggs were fertilized in vitro using sperm recovered from the uterus, and hence at least partially capacitated in vivo,[12] and 4 years further until the report by Yanagimachi and Chang in 1963 of the fertilization of ovulated hamster eggs in vitro using cauda epididymal sperm capacitated in vitro.[13] This set the stage for the analysis of sperm–egg interaction and fertilization under controlled conditions. In addition, capacitation is a factor in evolution through postcopulatory sexual selection[14,15] and a plausible target for contraceptive intervention.[16]

A characteristic feature of capacitation is a relatively long time course. This varies among mammalian species in vivo, from ~1 h in mice to >6 h in some primates, but in all cases sperm must reside for a prolonged period within the female reproductive tract.[6,17] In contrast, sperm of some well-studied nonmammalian model systems fertilize eggs soon after release from the male; for example, in echinoderms fertilization may occur in <1 min after spawning.[18–20] This difference may suggest that capacitation is restricted to mammals. Yet the general phenomenon of capacitation—the control of sperm function by factors from eggs or from the female reproductive tract—is not unique to mammals but instead similar to events in a wide range of animals and plants. In the hydroid *Campanularia flexuosa*, sperm fertility requires the secretion of factors from epithelial cells surrounding the egg.[21] A jelly coat, secreted by the oviduct, is required for fertilization of amphibian eggs,[22,23] and the intracellular signaling pathways that are activated in sperm by jelly are similar to those that participate in mammalian sperm capacitation in vitro.[24] In sea urchins the egg jelly coat contains chemokinetic and chemoattractant regulators of sperm motility, as well as stimulators of sperm metabolism,[19,25,26] and females of other vertebrate and invertebrate animals also produce egg-derived sperm chemoattractants.[27–29] Similar events occur in mammals and are regulated by capacitation (see below).

The notion that, as Austin states, "sperm must undergo some form of physiological change or capacitation before it is capable of penetrating the egg,"[10] and so linking capacitation to fertilizing potential, has been difficult to approach experimentally. Fertilization assays in vitro require sperm:egg ratios of 100–1000:1, and so one can only assess the capacitation state of the small fraction of the sperm population that enter eggs. Mammalian sperm are functionally heterogeneous,[6,30–33] and it is difficult to correlate the physiological status of the few fertilizing sperm with population-averaged biochemical or molecular properties. Related problems are presented by in vivo studies. Only a small fraction of the ejaculate reaches the oviduct ampulla and are available to fertilize eggs[34–36] (see Chapter 5 in this volume for additional details.). Those sperm that reach the ampulla exhibit hyperactivated motility[37] and are strongly capacitated, but they are difficult to study due to the low numbers involved and inaccessibility within the oviduct.

One effort to resolve these experimental difficulties has been to develop a set of markers that permit the identification, and possible purification, of a capacitated subpopulation. In this regard, many events during capacitation can be followed with fluorescence probes or by observing changes in sperm behavior. Monitoring such capacitation-associated changes, in conjunction with methods of fertilization in vitro using small numbers of sperm (sperm:egg ratios <10:1),[38,39] may provide some resolution. However, a comprehensive set of appropriate markers is not yet available.

Several general features of capacitation should be emphasized:

1. Capacitation is usually thought to reflect the functional reprogramming of sperm within the female reproductive tract. However, it may be that capacitation begins when sperm are exposed to seminal fluids during the ejaculation. Sperm are quiescent during storage in the cauda epididymis and activate progressive motility rapidly upon release.[6,40] This process, which is essential for fertility, is driven in part by HCO_3^- concentrations in seminal fluids through a cAMP/protein kinase A (PKA) pathway[41,42] and continues within the female reproductive tract.[6,43–45] The significance of seminal plasma-induced capacitation has not been fully explored and is likely to vary among mammalian species depending on the degree of sperm mixing with seminal fluids and the time of sperm exposure.[6,46,47] Capacitation is completed in vivo in the oviduct.[6,48]
2. As a consequence of capacitation, sperm express the ability to interact with eggs, exhibit unique patterns of flagellar motility, and display novel responses to external signals (see the section Consequences of Capacitation). Many of the biochemical and biophysical changes that accompany capacitation are likely to relate to these behavioral modifications.

Vet-ebooks.com

3. Capacitation is not a unitary process but rather the sum of several component reactions that proceed with separate time courses and regulation.[4,6,49,50] The notion of multiple distinct reactions is illustrated by the elegant chemical genetic study of Morgan et al., in which a genetically modified Cα2, the sperm-specific isoform of the catalytic subunit of protein kinase A,[51,52] was used to show that the cAMP/PKA pathway has separate early and late roles in capacitation.[53]
4. Sperm within a population capacitate in a highly asynchronous manner, such that the representation of strongly capacitated sperm in a population at any one time may be low both in vitro and in vivo.[30–32,54,55] This might plausibly extend the fertile lifespan of an ejaculate by continually replenishing a pool of capacitated sperm and so may be essential for efficient reproduction in species where ovulation and sexual receptivity of the female are not tightly coupled.[6,14,30] In any case, this heterogeneity complicates an analysis of the underlying mechanisms.
5. Capacitation in vitro and in vivo may differ in important regards. Studies in rodent models use cauda epididymal sperm that have not been mixed with seminal fluids. Those fluids contain: negative modulators of fertility (so-called "decapacitation factors");[6,56–58] positive modulators of fertility, including *c*ysteine-*ri*ch *s*ecretory *p*roteins (CRISP) family proteins; Fn-2 domain proteins; spermadhesins; other secreted proteins and peptides; as well as prostaglandins.[47,59–62] Also contained in these fluids are exosomes, shed by the epithelium in distal regions of the male reproductive tract after sperm release from the cauda epididymis, that regulate sperm function,[63,64] including some properties that may be involved in capacitation.[65] Even when ejaculated sperm are used, in vitro culture conditions represent a simplification of the environment within the female reproductive tract. For example, Yanagimachi noted that the ionic composition of the female reproductive tract fluids differs from the standard culture media used for capacitation, and this may influence sperm physiology.[6] In addition, female reproductive tract fluids contain an array of bioactive molecules that may affect sperm function but which are not present in simple culture medium. Stated differently, the development of culture conditions that support sperm fertility in vitro has provided valuable information on the intracellular pathways mediating capacitation, but does not necessarily inform us of the extracellular triggers that activate these pathways in vivo.

In the next sections, we consider the physiological process of capacitation and current thoughts regarding the underlying mechanisms. For additional details of the understanding of these events up through 1994, readers should consult Yanagimachi.[6] Recent progress in specific aspects of capacitation is discussed in a number of reviews.[29,66–70]

Consequences of Capacitation

Capacitation is associated with widespread changes in the biochemical and biophysical properties of sperm cells. These include alterations in the following: plasma membrane and cell surface properties through such processes as desorption of noncovalently attached (glyco) proteins,[71–73] redistribution of integral plasma membrane proteins, altered rates of membrane protein and lipid diffusion,[74–76] reorganization of detergent-resistant membrane domains,[77–79] alterations in the asymmetric distribution of plasma membrane phospholipids, and loss of membrane cholesterol;[76,80,81] altered cAMP metabolism;[82,83] increased phosphorylation state of a range of proteins through the regulation of both protein kinases and phosphatases;[84–86] changes in metabolism;[87,88] a strong hyperpolarization of membrane potential;[31,89] and an altered internal ionic environment, including changes in pH, intracellular calcium concentrations (Ca^{2+}_i) and other ion activities.[68,90] This extensive reprogramming takes place in both the sperm head and flagellum.[4,6,49,50]

As a consequence of capacitation, sperm exhibit at least three modifications in behavior that appear related to fertility: hyperactivation of flagellar motility; regulation of signal transduction pathways permitting responses to chemoattractants; and expression of the ability to acrosome react and to interact with eggs. These are considered separately as, at present, there is not a unified mechanism that accounts for the range of behavioral changes in sperm during capacitation.

Hyperactivated Motility

Sperm are immotile during storage in the cauda epididymis and initiate motility upon release either into culture medium in vitro or into seminal fluids. This initial pattern of motility (referred to as "progressive" or "activated" motility) consists of relatively symmetrical, low amplitude flagellar bends that produce linear, forwardly progressive sperm movement in aqueous media. In contrast, a different type of motility is observed in sperm that were incubated under capacitating conditions in vitro,[91–94] recovered from the oviduct,[95] or observed through transilluminated, explanted oviducts following mating or artificial insemination.[94,96,97] Sperm in the hyperactivated state display a number of behaviors, including (but not restricted to) vigorous, deep, asymmetric flagellar bending that produces nonprogressive cell movement and that alternates with periods of progressive motility during observations in culture media

Vet-ebooks.com

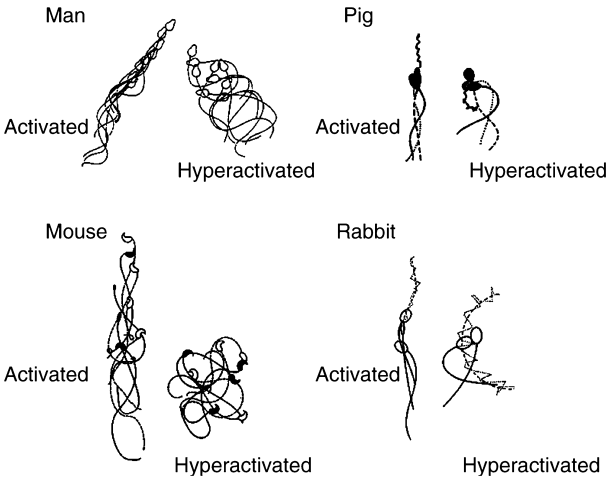

FIGURE 4.1 Progressive and hyperactivated motility of mammalian sperm. Motility patterns of mammalian sperm are displayed in time-lapse drawings. Activated (or progressive) motility is characteristic of uncapacitated sperm, while hyperactivated motility is observed in sperm incubated under capacitating conditions in vitro and in sperm recovered from the oviduct. Note that sperm in the activated state exhibit low amplitude and relatively symmetrical flagellar bends, and linearly progressive path of the sperm head. The hyperactivated mode consists of transitions to deeper and less symmetrical flagellar bending and results in a path of the sperm head that is less linear than that of activated state motility. *Reprinted from Ref. 4 with permission from Elsevier, Inc. Courtesy of Dr Ryuzo Yanagimachi.*

(Figure 4.1). However, there are species differences in the particular details of flagellar bending and in the frequency of nonprogressive/progressive transitions.[4,6,96,98–100]

Fertility depends on the timely development of hyperactivated motility. Hamster sperm that were incubated under noncapacitating conditions in vitro and did not display hyperactivated motility were able to penetrate into the oviduct from the uterus following artificial insemination, while sperm that had been subjected to preincubation in a capacitating medium, and that displayed high levels of hyperactivation, failed to enter the oviduct in appreciable numbers.[101] This suggests that the transit through the uterotubal junction into the oviduct may act as physiological filter and select sperm that have not completed capacitation prematurely (see Chapter 5). Hyperactivation increases the thrust and force generated by sperm[102] and has been suggested to facilitate release of sperm from oviduct storage sites in the lower isthmus.[103,104] Additionally, it permits sperm to move through viscous media more readily[105] and may be essential for progression along the surface of the female reproductive tract and for penetration of cervical mucus, the cumulus oophorus matrix, and zona pellucida, each of which is a formidable barrier to fertilization.[106–113] Finally, mode switching between hyperactivated and progressive motility is linked to sperm chemotaxis in vitro (see the section Sperm Chemotaxis).[114,115]

Hyperactivation is dependent on elevated Ca^{2+}_i,[100,116] and can be evoked by treatment of intact sperm with Ca^{2+} ionophore or of demembranated sperm with elevated Ca^{2+}.[100] CATSPER (cation channel, sperm associated), an evolutionarily conserved ion channel, is the major Ca^{2+} entry pathway controlling sperm hyperactivation.[68,108,117–121] Loss of function mutations of any of the channel subunits result in loss of male fertility in mouse models and have been linked to cases of human male infertility.[68,117,122,123] Sperm with defective CATSPER activity fail to ascend the oviduct to the site of fertilization in vivo[124] or penetrate the zona pellucida in vitro.[117]

The channel is constructed from pore-forming subunits that have the architecture of a classic voltage-sensitive ion channel,[68,117,118] with six transmembrane α-helices (S1–S6) consisting of a voltage sensor domain (S1–S4) with a set register of fixed positive charges in the S4 helix and an ion conductance domain (S5–S6).[125,126] CATSPER exhibits weak voltage sensitivity.[127] Sperm with a slightly acidic internal pH (pH_i), a characteristic of uncapacitated cauda epididymal sperm,[4,128,129] require depolarization to strongly positive potentials to activate CATSPER conductance.[127] There is no evidence that sperm generate such strongly positive membrane potentials.[4,31,67,89,130,131]

How then is CATSPER activated? A variety of factors have been shown to modulate CATSPER channels and facilitate conductance. First, sperm pH_i rises during capacitation[128,132] and will shift the conductance–voltage relationship such that CATSPER can be activated by physiological membrane potentials.[127] Several mechanisms may contribute to this internal alkalinization. These include: SLC9A10, a sperm-specific Na^+-H^+ exchanger regulated by membrane potential[133,134] and related to the voltage-sensitive Na^+-H^+ exchanger of sea urchin sperm;[135] HVCN1, a voltage-sensitive proton channel mediating acid efflux from human sperm[136] that participates in pH_i regulation; and HCO_3^- entry pathways, such as CFTR (*cystic fibrosis transmembrane conductance regulator*)[137–139] and other anion transporters;[129,140,141] as well as formation of HCO_3^- by sperm carbonic anhydrase[142] following diffusion of the CO_2 that is reported to be present in the oviduct during the periovulatory period at high levels.[44] Second, CATSPER is a ligand-gated channel that can be directly activated by progesterone and by prostaglandins, which are present in the oviduct,[143] and certain odorants and other small molecules.[144–146] This will be discussed in greater detail in the next section.

The emerging model is that CATSPER is essential for hyperactivation and is designed to be activated by the environment of the oviduct, where capacitation is completed.[6,48] However, the reader should be cautious—CATSPER may do more than simply control the switch to hyperactivated motility, as indicated by the sluggish

Vet-ebooks.com

motility of sperm from nullizygous mice[117] and some aspects of the behavior of human sperm,[147] and so all aspects of the phenotype of CATSPER nullizygous mice may not reflect a failure of hyperactivation. Alternatively, ligands that activate CATSPER may also have additional, CATSPER-independent mechanisms of action.

Sperm Chemoattraction

That male gametes orient motility in gradients of factors released by eggs or by the female reproductive tract is a widely conserved phenomenon. The earliest report in plants was in 1884 for the case of bracken fern sperm,[148] and in animals in 1912, for the cases of an echinoderm, *Arbacia punctulate*, and a polychaete worm, *Nereis limbata*.[149] However, the chemical nature of attractants in taxa examined to date varies and includes proteins, peptides, amino acids, olefins and other lipids, and gases; thus, it is likely that the chemoattraction process has evolved independently on multiple occasions. The focus here is on events in mammals and their relationship to capacitation. Events in other taxa and the cellular mechanisms by which sperm receive attractant signals and respond to those signals are detailed elsewhere.[27–29,54,150,151]

Chemotaxis of mammalian sperm was first reported in 1958 in a study using human sperm and (among other attractants) follicular fluid,[152] and was soon followed by a study of rabbit sperm.[153] Interest in this area was reignited following reports that human sperm reorient swimming direction in vitro toward sources of follicular fluid or media conditioned by oocyte–cumulus complexes in a manner that correlated with the ability of oocytes to be fertilized in vitro.[154,155] In addition, assay systems were developed that differentiate chemoattraction from other mechanisms of sperm accumulation.[54] Finally, an expanding understanding of the complex environment and the physiological roles of the oviduct has mitigated concerns of functional relevance.[36,156,157] Current models suggest that sperm are guided through the mammalian female reproductive tract by several mechanisms: processes such as rheotaxis[113] and thermotaxis[158,159] may operate over long distances, while chemotaxis operates when sperm are in the vicinity of the egg/cumulus complex.[54] Chemotaxis has been studied more extensively than other processes and will be discussed here.

Soluble sperm attractant activity is present in the follicular and oviductal fluids from a number of mammalian species,[154,155,160–162] as well as from the egg/cumulus complex.[163] Figure 4.2 shows that human sperm reorient motility toward a medium conditioned by human eggs and containing follicular fluid.[155] In human sperm preparations, which have been studied extensively in recent years, the proportion of responsive sperm was low (~10%), consistent with observations that a small fraction of human sperm populations reside in a capacitated

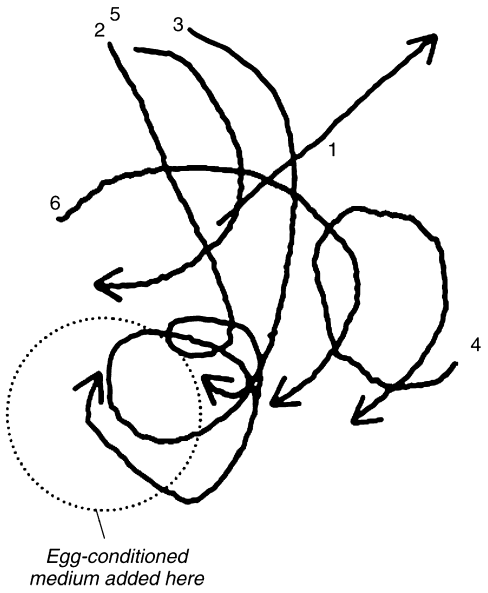

FIGURE 4.2 Diagram of mammalian sperm chemotaxis. Capacitation is associated with the ability of sperm to reorient motility toward chemoattractants. Culture medium was conditioned by incubation with human oocyte/cumulus complexes and also contained ~5% follicular fluid (which was recovered with oocytes during aspiration from follicles). Aliquots of conditioned medium were added to fields of human sperm (site of addition shown by dotted line). Human sperm motility was tracked using video microscopy. Paths of six sperm are shown, of which five reorient toward the conditioned medium. *Adapted from Ref. 155 with permission from Elsevier, Inc. and is provided through the courtesy of Dr Michael Eisenbach.*

state at any one time, and that only capacitated sperm execute taxis in response to chemoattractants.[30,54,164,165]

At least one of the active factors in follicular fluid and oviduct fluid appears to be progesterone,[166–169] although other factors may also be present.[54,163,170] Cumulus cells synthesize progesterone during the periovulatory period and apparently retain this activity following ovulation.[167,171–175] One model predicts that progesterone from cumulus cells at the site of fertilization (lower ampulla region of the oviduct) establishes a local gradient that guides sperm from the side channels formed by the highly arborized projections of the oviductal mucosa toward the egg.

The behavioral mechanism of taxis in response to chemoattractant gradients appears to be regulated by switching between progressive and hyperactivated motility modes, as demonstrated in gradients of the floral odorant, bourgeonal, and of progesterone.[114,115] Human sperm exhibit progressive motility during ascent of spatial gradients but initiate episodes of hyperactivation when they are moving down the concentration gradient (Figure 4.3). This permits a directional change in that sperm emerging from transient hyperactivation will enter a progressive run if pointing up the gradient but reinitiate a hyperactivated phase if moving to zones of lower attractant concentration. Armon and Eisenbach

Vet-ebooks.com

point out that, despite mechanistic differences, this mode switching serves the same purpose as bacterial tumbling in driving a directional reorientation in a spatial gradient.[115]

A plausible mechanism of mode switching is through modulation of CATSPER channel activity. Bourgeonal (a chemoattractant of human sperm in vitro that is unlikely to play a role in vivo) and progesterone are CATSPER agonists that act in a direct and membrane delimited fashion on the channel, either by interacting with one of the identified channel subunits or with another protein intimately associated with the channel.[144–146] Inhibition of hyperactivation occurs during sperm ascent of spatial gradients of progesterone.[115] While CATSPER mediates hyperactivation,[108,119] the channel may also exhibit agonist-induced desensitization in a spatial gradient, similar to that reported following repetitive agonist stimulations, and so continue to ascend the spatial gradient.[123]

A number of questions must be resolved in order to explain this sperm behavior. First, taxis toward chemoattractants has been demonstrated in stable gradients in vitro, but do stable gradients exist in vivo in the presence of the reported enhanced fluid flow following coitus[113] and the high beat rate of motile cilia on the epithelium lining the ampulla of the oviduct?[176] Second, in addition to progesterone, many candidate mammalian sperm chemoattractants have been identified, including *N*-formyl peptides,[177,178] chemokines,[179] atrial natriuretic factor,[180,181] and odorants.[114,182,183] The reader is directed toward focused reviews for additional detail.[54,170,184]

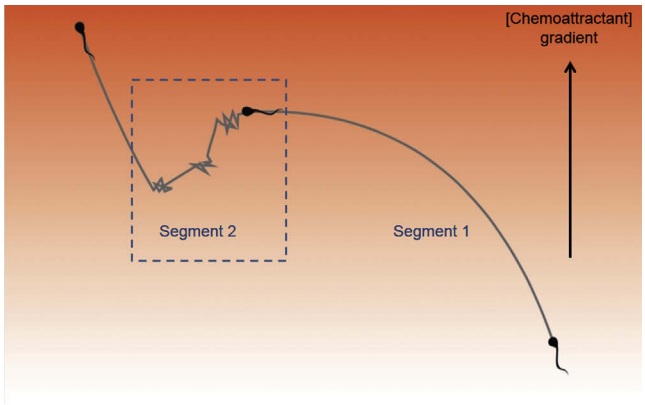

FIGURE 4.3 A model of sperm behavior in a spatial gradient of a chemoattractant. This model is based on mode switching between progressive and hyperactivated motility. The local chemoattractant concentration is indicated by the intensity of the background shading. *Segment 1*: Sperm that sense an increasing local chemoattractant concentration suppress hyperactivation turns, resulting in swimming along approximately a straight path. *Segment 2*: Sperm cease to sense an increasing concentration gradient of chemoattractant switch motility modes transiently from progressive to hyperactivated, resulting in turns. One or more episodes of hyperactivation reorient sperm movement so that they once again ascend the spatial gradient of chemoattractant. This behavior can be based on the activation of the CATSPER ion channel and suggests that this channel may adapt to increasing chemoattractant concentrations. *This figure is adapted from Ref. 115 through the open access license policy of the Public Library of Science and* PLoS One, *and is provided through the courtesy of Dr Michael Eisenbach.*

Are all of these bona fide chemoattractants, and, if so, how does CATSPER integrate such diverse signals? For example, we have discussed the case of bourgeonal, an odorant that can activate CATSPER directly. Yet sperm also appear to have G protein-coupled odorant receptors.[182,185–187] Are these functional and do they also transmit chemoattractant (or other) information?

Regulation of Sperm–Egg Interaction by Capacitation

Uncapacitated sperm cannot interact with eggs in vivo as their failure to hyperactivate motility precludes ascent to the site of fertilization. However, in vitro studies suggest additional layers of direct modulation of gamete interaction. Following capacitation, sperm develop the ability to penetrate the cumulus oophorus.[188] This reflects, at least in part, a role of hyperactivation in the penetration process. There is also an enhanced ability to adhere tenaciously to the zona pellucida[189,190] and to undergo acrosome reactions evoked by zona pellucida agonists.[191,192] This is discussed in greater detail elsewhere.[4,6]

Some Considerations of the Mechanisms of Capacitation

Our view is that capacitation is a cluster of processes running in parallel and that a single, unified mechanism is not apparent at present. That said, there are several well-established mediators of capacitation that are likely to provide an entrée to the underlying mechanisms.

Ion-mediated events. It has been suggested that altered activities of a number of different intracellular ions are essential for capacitation. It may be premature to design mechanistic pathways, but at least the key components may have been identified.

There is strong evidence for a role of Ca^{2+} entry in capacitation,[6,84] as underscored by the recent demonstration that elevation of Ca^{2+}_i activity is sufficient for fertilization in vitro.[193] CATSPER is the major influx pathway for this ion that can be observed in electrophysiological experiments[68] and plays an important role in hyperactivation and mechanisms of activation as noted above. In addition, data from gene disruption models and fluorescent probe experiments indicate that $Ca_v2.3$, a member of the family of high-voltage activated Ca^{2+} channels, is present and is regulated during capacitation.[194] Other Ca^{2+} entry pathways may be present,[67,195] although not evident in electrophysiological recordings due to channel

Vet-ebooks.com

density, restriction to small but functionally important membrane domains,[194] or to a lack of voltage sensitivity.

In addition, sperm membrane potential is hyperpolarized,[31,68,89] and pH_i shifts in an alkaline direction rise during capacitation.[68,128,129,195] These may be linked as membrane potential is set, at least in mouse sperm,[196] by KCNU1, a pH-dependent K^+ conductance channel.[197–199] A number of potential regulators of sperm pH have been discussed previously, including extracellular pH, the sperm-specific Na^+-H^+ exchanger SLC9A10, and the voltage-sensitive proton channel HVCN1, which conducts a proton current in sperm and may regulate pH_i.

A number of other ion activities and transport pathways are also implicated in capacitation.[67,68,195] In considering these events, the reader should view the ion milieu in any cell, including sperm, as a dynamic network in which changes in any one component drive the whole system to reset at a different equilibrium point. As such, treatments that focus on a single ion (for example, the effects of ionophore addition or depletion of a single extracellular ion) should be interpreted cautiously.

Sperm phosphoproteins. The phosphorylation state of an array of sperm proteins increases during capacitation, and both in vitro studies and gene disruption models suggest that these are important regulators of sperm functional state.[66,82,84,195,200] Efforts are focused on the identification of these phosphoproteins and their role in capacitation, as well as on the protein kinases and phosphatases that ultimately control phosphorylation state.

Sperm membrane changes. Membrane remodeling accompanies capacitation, including: cholesterol efflux and the associated alterations in membrane domains; phospholipase activation, with the potential generation of lipid regulators of ion channels and other membrane proteins.[49,76,201]

Final considerations. A wide range of factors control the capacitation state of sperm in vitro. Readers are directed to other issues in this series for earlier thoughts and References 4 and 6, and to more recent reviews for a more detailed examination of the role of protein phosphorylation, ion channels, and sperm membrane state in this process.[66,68,195,201] An increased understanding of the physiological environment for capacitation, as established in the periovulatory oviduct, should provide insight into the relevant mechanisms.

SPERM–EGG INTERACTION

Models of Gamete Interaction

The development of well-controlled methodologies for the study of fertilization in vivo and the application of new and powerful microscopic tools (phase contrast and transmission electron microscopy) lead to the identification of core principles for gamete transport in the female, capacitation and the acrosome reaction, and the cortical reaction and zona block to polyspermy. This initial phase led to the articulation of the first coherent model of mammalian fertilization in the early 1960s.[5,6]

The first version of this model (referred to here as Model 1; Figure 4.4) was based on the following observations: that ovulated eggs in the oviduct are surrounded by a cumulus mass;[202] that the cumulus mass can be dispersed by a sperm-derived enzyme[203,204] shown later to be hyaluronidase;[205,206] that mammalian sperm undergo an acrosome reaction (Figure 4.4(A)) before penetration of the zona pellucida;[207,208] and that hyaluronidase is within the acrosome and released during the acrosome reaction.[206,209] Based on these observations it was proposed that: (1) capacitated sperm initiate, and possibly complete, the acrosome reaction immediately before or during penetration of the cumulus mass; (2) the acrosome reaction releases hyaluronidase, which is essential for sperm penetration of the cumulus mass; and (3) sperm attached to the zona pellucida have at least initiated, and possibly completed, the acrosome reaction.[5,6,209]

This model was subsequently modified during two overlapping historical periods. First, the systematic study of the cellular events of fertilization began in earnest with the development of methods for the fertilization of eggs in vitro using sperm capacitated in vitro.[13] Controlled in vitro gamete interaction studies were carried out using then-novel tools (hybridoma reagents, ion selective fluorescent probes, and single-cell imaging). In particular, a structure/function analysis of the zona pellucida led, by the mid-1980s, to a reformulation of Model 1 of sperm–egg interaction (Model 2; Figure 4.4). The core elements in Model 2 include: (1) capacitated sperm with intact acrosomes are able to penetrate the cumulus mass, possibly by means of a cell surface hyaluronidase;[210] (2) sperm with intact acrosomes bind to the zona pellucida (ZP)[211] through the interaction of an unknown sperm adhesion site and an oligosaccharide domain of ZP3;[212–216] (3) ZP3 then triggers the sperm acrosome reaction;[217] (4) following the acrosome reaction, sperm penetrate the zona pellucida and fuse with the egg plasma membrane; and (5) the block to polyspermy includes the release of the ovastacin,[218] which catalyzes the proteolytic modification of ZP2[219] thought to prevent sperm penetration of the zona pellucida, as well as triggers an unknown modification of ZP3,[212,214] preventing additional sperm from binding to the matrix and acrosome reacting. Additional descriptions of the ZP proteins and their roles in fertilization are given later in this chapter.

Finally, two separate experimental threads are brought together in a competing model (Model 3; Figure 4.4), which states: (1) the fertilizing sperm begin, and possibly complete, acrosome reactions during transit through the cumulus;[220] (2) sperm that are completely[39]

Vet-ebooks.com

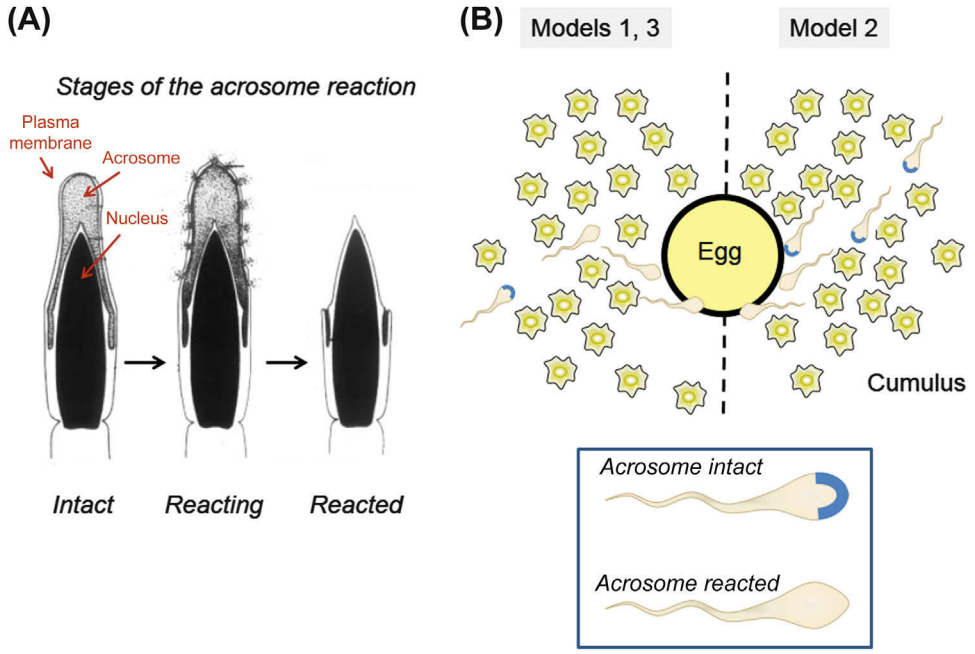

FIGURE 4.4 Models of sperm interaction with the zona pellucida. (A) Drawings of the sperm head are shown with the plasma membrane, acrosome, and nucleus indicated (*intact*). During early stages of the acrosome reaction, the plasma and acrosomal membranes fuse at multiple points, permitting release of acrosomal vesicle contents (*reacting*). The completion of the acrosome reaction is marked by complete release of vesicle contents, sloughing of acrosomal/plasma membrane hybrid vesicles, and the exposure of a new cell surface domain in the apical sperm head. Sperm must complete the acrosome reaction to penetrate the zona pellucida and fuse with the egg plasma membrane. (B) Models of the cellular events of sperm–zona pellucida interaction. Models 1 and 3 both propose that sperm acrosome react within the cumulus mass, that acrosome reaction-inducing agonists are found within the cumulus mass, and that acrosome reacted sperm bind to the zona pellucida. Model 2 proposes that sperm with intact acrosomes penetrate the cumulus mass, bind to the zona pellucida, and then initiate acrosome reactions on the surface of the zona pellucida. *Inset*: key for acrosome intact and acrosome-reacted sperm for Panel B.

or partially acrosome reacted adhere to the zona pellucida by the association of adhesion sites, either on the inner acrosomal membrane or within the acrosomal matrix,[221,222] with domains on ZP2;[223] (3) following adhesion sperm penetrate the zona pellucida and fuse with the egg plasma membrane; and (4) the block to polyspermy includes proteolytic cleavage of ZP2 by ovastacin.[218] Note that Model 3 is, in fact, Model 1 with additional molecular details.

The thumbnail description above identifies the salient elements of these models. More details, including additional data, are available in numerous reviews.[4,6,224–229] In the following discussion we focus on two questions raised by these models: (1) Do sperm acrosome react in the cumulus matrix (Model 3) or on the zona pellucida (Model 2)? (2) How do sperm establish initial interactions with the zona pellucida?

Sperm Interaction with the Cumulus Oophorus

Eggs of eutherian mammals are ovulated and enter the oviduct surrounded by several thousand cumulus cells.[6,202] Initially, a number of passive roles were suggested for the cumulus, including: enhancement of the efficiency of fertilization by increasing the target size (relative to a denuded egg) and by orienting sperm that enter the cumulus toward the egg; and functioning as a sperm barrier that may minimize polyspermy.[230] It is now understood that the cumulus is a more dynamic structure that, in in vitro experiments, may be both regulated by the presence of sperm and also secrete factors that regulate sperm function. Such factors include progesterone,[54,167–169,231] chemokines[232,233] and possibly other proteins,[234] prostaglandins,[233,235] extracellular matrix components such as hyaluronic acid fragments,[232,236] and other bioactive components.[237]

Do these or other factors trigger acrosome reactions during sperm transit through the cumulus in vivo? Acrosome-reacted sperm have been observed within the cumulus by phase contrast[208] and transmission electron microscopy,[238] but it was not certain whether these were trapped cells in the process of dying or fertilizing sperm captured en route to the egg.[6,228] Recently, Jin and coworkers followed living, acrosome reacted mouse sperm penetrating the cumulus and fertilizing eggs in vitro.[220] In addition, acrosome-reacted sperm recovered from the perivitelline space can penetrate the zona pellucida and fertilize new, zona-intact eggs.[39,239–241]

Vet-ebooks.com

These reinsemination experiments clearly indicate that acrosome-reacted sperm can penetrate the cumulus mass and fertilize eggs in vitro.

Several cumulus-derived factors, including hyaluronan fragments, progesterone, and chemokines, elevate sperm Ca^{2+}_i.[144–146,236] It is well known that Ca^{2+}_i elevations in the sperm head, whether driven by agonists or ionophores, can initiate acrosome reactions in vitro.[6] There is cytosolic continuity between the sperm head and flagellum,[127] and so it follows that elevations of Ca^{2+}_i arising anywhere in sperm, if sufficiently large to override the intrinsic Ca^{2+}_i clearance mechanisms,[242,243] may initiate acrosome reactions during in vitro experiments. Whether such acrosome reactions are physiologically relevant will depend on such factors as the kinetics of stimulation. This is illustrated by the case of progesterone: in low (pM–nM) concentration gradients it regulates motility and can be a chemoattractant, but does not evoke acrosome reactions,[167,244–247] whereas the stepwise presentation at higher doses (μM) triggers acrosome reactions.[248] Whether acrosome reactions are evoked in sperm transiting the cumulus by progesterone, or by other cumulus-derived factors, will depend on how the agonist is presented.

Thus, candidate agonists for induction of the acrosome reaction are present in the cumulus, but the physiological relevance of these molecules is unresolved. The question of how this impacts the models of gamete interaction will be discussed in a subsequent section.

Sperm Interaction with the Zona Pellucida

The zona pellucida is the extracellular coat of the mammalian oocyte. It acts as a selective filter before fertilization that can only be penetrated by sperm that have completed the acrosome reaction.[6,208] Sperm interaction with the zona pellucida has been examined extensively using two distinct strategies and two distinct models (mouse and a mouse/human hybrid). These models (Model 2 and Model 3, Figure 4.4) were discussed above (see the section Models of Gamete Interaction) and in greater detail in the references cited there. Here, we consider the strengths and assumptions of those strategies.

A reductionist approach, pioneered by Wassarman and his coworkers, starts with the assumptions that (1) the biological activities of the intact zona pellucida can be recapitulated from the properties of its component constituents; (2) purification of those zona pellucida glycoproteins from an insoluble matrix and subsequent examination of their actions on sperm in solution does not alter essential biological properties of those glycoproteins; and (3) the cumulus-denuded egg that is used to study interactions with the zona pellucida is an appropriate model for gamete interaction in vivo. This approach led to the core data supporting Model 2 (Figure 4.4). As noted previously, the core data led to proposals that sperm adhere to the zona pellucida by interacting with a glycan chain that (at least in mouse) is on ZP3, that ZP3 triggers acrosome reactions in bound sperm, and these bioactivities are lost following fertilization and contribute, along with a proteolytic modification of ZP2, to the block to polyspermy.[4,225,249,250]

A different proposal for sperm–zona pellucida interaction is presented in Model 3 (Figure 4.4). Dean and his colleagues studied the biological properties of the structurally intact zona pellucida. A knockout/knockin strategy was used to replace mouse ZP proteins with their human orthologs, and the interactions of human sperm with this modified matrix were then examined. The assumption in this case is that the hybrid zonae pellucidae, containing mouse and human glycoproteins, is a useful model for sperm interaction with native structures. Although conserved cysteine residues in the ZP domain indicate similar protein folding patterns,[251–255] the primary sequences of mouse and human ZP2 and ZP3 are only 56% and 67% identical, respectively. The effects of these sequence differences on the structure and behavior of hybrid zonae pellucidae are not known. Finally, glycosylation is specified by the host cell, and so human proteins synthesized in mouse oocytes will have mouse glycans.[256,257] The genetic manipulation approach that is the basis for Model 3 assumes that these factors can be accounted for and do not alter the properties of the hybrid zona pellucida. The core features of Model 3, as it pertains to sperm–zona pellucida interaction, are that human sperm bind to the zona pellucida by interactions with an N-terminal domain of ZP2,[223] that this adhesion depends inversely on the proteolytic cleavage state of ZP2 (as does Model 2),[258,259] and that this adhesion does not trigger the acrosome reaction.[260]

These models are internally complete and coherent, and agree on certain points (for example, that ZP2 proteolysis is associated with downregulation of sperm adhesion to the zona pellucida), but it may be instructive to focus on points where they disagree. First, different approaches to solid-phase assays have yielded different results; in one case, human sperm bind only to beads conjugated with fragments of human ZP2 synthesized in mouse oocytes,[223] consistent with Model 3, and in the other mouse sperm bind only to beads coated with native ZP3,[261] consistent with Model 2. Second, isolated glycans from human zonae pellucidae[216] and glycans or low molecular weight glycopeptides from mouse ZP3[213,214] bind directly to sperm and inhibit sperm binding to the zona pellucida, consistent with Model 2 and inconsistent with Model 3. Finally, Model 2 asserts that an acrosome reaction-inducing agonist is present in the zona pellucida, as has been reported in mouse,[217,262,263] bull,[192] and human.[263–267] However, experiments supporting Model 3 assert that sperm do not acrosome react

Vet-ebooks.com

on the zona pellucida surface.[260] An examination of the experimental points at which these models depart from each other may provide a means of resolving this apparent impasse.

Is There an Obligatory Sequence of the Early Events of Fertilization?

There is general agreement that sperm must acrosome react before penetrating the zona pellucida. However, disagreement exists regarding where the exocytotic reaction begins, on how it is triggered (in the cumulus or at the zona pellucida surface), and on the cellular and molecular mechanisms of sperm interaction with the zona pellucida (acrosome intact or reacted sperm binding to ZP2 or ZP3, and whether interaction is mediated by zona pellucida glycans or a protein domain). The underlying premise is that there is a single conserved sequence of events during sperm–egg interaction. However, reproduction is characterized by diversity,[268] and this may clarify the understanding of mammalian fertilization.

First, we have considered the question of whether acrosome reactions are initiated in the cumulus or at the surface of the zona pellucida. It should be recalled that eutherian eggs enter the oviduct within a cumulus, but this cellular investment disperses with time in the oviduct. In those species in which the female displays a restricted period of sexual interest and receptivity, and in which the period of interest is regulated such that capacitated sperm arrive in the ampulla either before or at approximately the same time as eggs, it is likely that sperm are confronted with a cumulus mass that has not started to disperse, and that may be an obstacle to sperm penetration. This is the situation in, for example, the mouse, but it is not the case for all eutherians. There are reports of the absence of adherent cumulus cells around the egg within the oviduct in cows, sheep, horse, goat, and other species.[6,269] In particular, this may be the case when there are long periods of sexual receptivity by the female, and where ovulation occurs early in that receptive period. There are additional examples (such as human) in which sexual receptivity is not restricted to the periovulatory period. It then seems likely that there will be many cases in eutheria in which sperm must be capable of fertilizing eggs irrespective of the presence of the cumulus. The presence of an acrosome-reaction evoking agonist in the zona pellucida is expected as acrosome-intact sperm cannot proceed past the zona pellucida surface. Potential agonists are also present in the cumulus, but their functional significance may vary across species and depend on reproductive behavior and other factors.

Similarly, sperm interactions with the zona pellucida may also be characterized by diversity. Four genes encode mammalian zona pellucida proteins (ZP1-4), but there are extensive differences in the composition of these egg coats. Eutherian mammals can be divided into three classes based on the composition of the zona pellucida: those assembled using four glycoproteins (human, chimpanzee, macaque, and rat); those built from ZP2, ZP3, and ZP4 (dog, cattle, and possibly pig, cat, and rabbit); and those using ZP1, ZP2, and ZP3 (mouse).[270] These categories may simplify as ZP1 is most closely related to ZP4,[270,271] yet the possibility of functional differences in eutherian zonae pellucidae cannot be discounted.

The suggestion here is that there may not be a canonical reaction sequence for mammalian fertilization. If there is extensive diversity in the process of sperm–egg interaction, then these questions should be examined in a wide range of species. This was the case to some extent during an early period that began approximately with the discovery of capacitation (1951) and ended during the 1980s. Since then the choice of model systems has narrowed to mouse (where genetic and other tools became available first), human, and a limited number of domestic species (where studies have high translational value). Generalized conclusions may be more evident when our knowledge base is more generalized.

SPERM–EGG PLASMA MEMBRANE INTERACTIONS

Plasma Membrane Domains and Factors that Affect Fusion

Only acrosome-reacted sperm undergo fusion, and the acquisition of a fusogenic capacity occurs within minutes of initiation of the acrosome reaction.[6] Fusion is preceded by adhesion, and experimental methods have been designed to evaluate and distinguish these processes, such as strength of sperm attachment to the oolemma and transfer of nuclear dyes between gametes.[6,272] These techniques and others have made possible the determination of whether adhesion or fusion has taken place, but they do not provide insight into the mechanisms or molecules that underlie these events. The availability of proteomic and genetic approaches is progressively filling this gap.[272,273]

Mere contact anywhere at the gamete surface is not sufficient to ensure fertilization. The sperm membrane is highly regionalized, and specific domains must come into intimate association with the egg surface. Initial contact and adhesion is followed by fusion in neighboring regions.[6] Evidence for the specialization of the membranes involved in gamete interaction also comes from antibody studies demonstrating specific localization of proteins and inhibition of fertilization.[274,275]

Indirect evidence for an initial binding step prior to fusion comes from studies in which bound, non-fused sperm on eggs can be identified, and the two processes

Vet-ebooks.com

(binding and fusion) can be dissociated. After fertilization in vitro of zona-free eggs, fusion failure of residual surface-bound sperm is inferred from the absence of the transfer of a DNA dye from the egg cytoplasm to the sperm nucleus.[276] Experimental conditions have been found in which gamete binding occurs but fusion does not. For example, despite the fact that media requirements for sperm-oolemma fusion are minimal compared to those required for capacitation, it was observed that the absence of glucose or presence of glycolytic inhibitors, or in an acidic external pH, sperm–egg binding occurs without fusion.[6,277] Reduced binding also occurs in the absence of extracellular Ca^{2+}, and restoration of Ca^{2+} or glucose or pH levels allows some bound sperm to fuse.

Identification of the membrane interactions and the structures involved in both the initial association of sperm and egg membranes, as well as in the subsequent steps that result in the incorporation of the sperm head, were revealed by electron microscopic examination of the acrosome reaction and fertilization.[278] These formative observations have been recently expanded upon by studies using time-lapse confocal microscopy of fluorophore-tagged proteins.[279,280] The sperm-acrosome reaction exposes the inner acrosomal membrane (IAM), where initial interactions with the oolemma occur,[281] but it is the sperm's equatorial segment and posterior head regions that become closely associated with the egg surface and undergo fusion with the oolemma (Figure 4.5(A)–(D)).[6] The IAM is subsequently

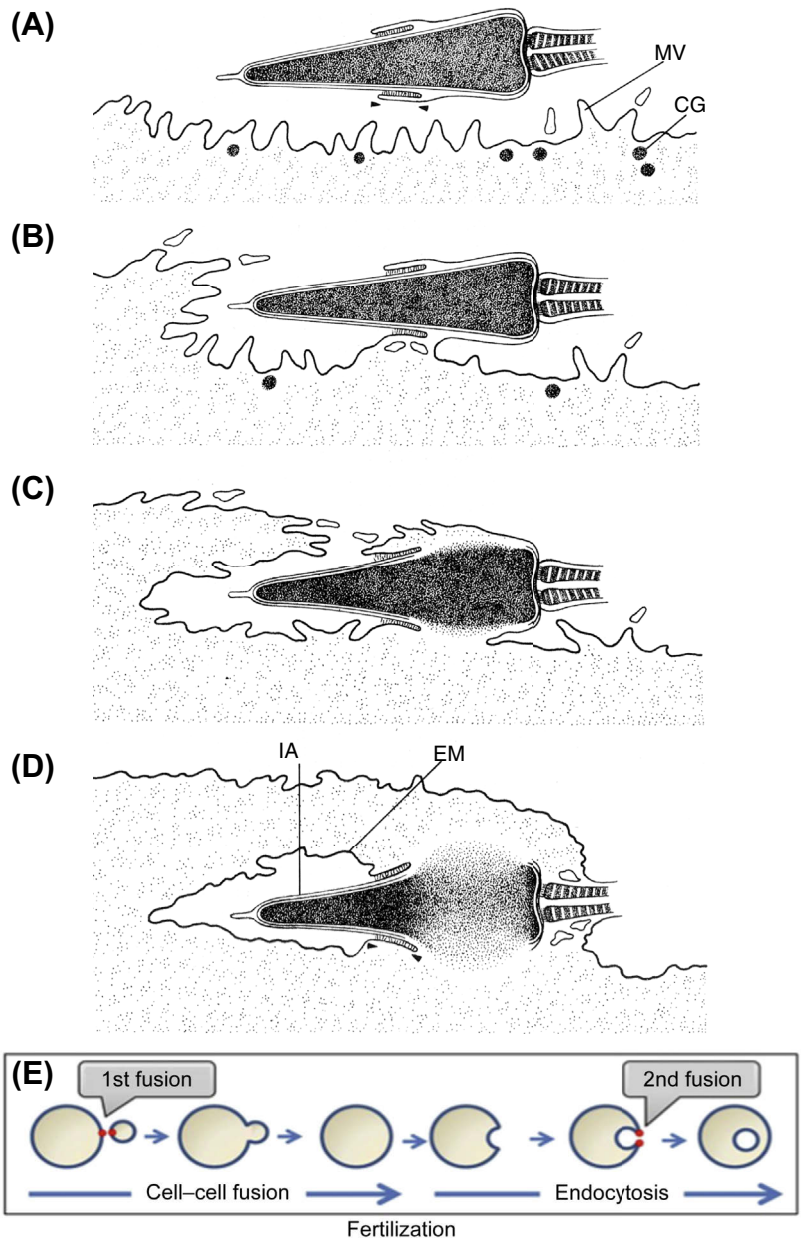

FIGURE 4.5 Diagram of the early stages of sperm interaction with the egg plasma membrane. (A–D). Although the inner acrosomal membrane (IA) of the sperm may make initial contact with egg microvilli, this region does not seem to undergo fusion. The equatorial segment of the head of an acrosome-reacted sperm undergoes the initial fusion with the egg plasma membrane (A–B). The amount of continuity between the sperm and egg cytoplasm increases in a posterior direction on the sperm head. Anteriorly, the inner acrosomal membrane and egg plasma membrane (EM) form a vesicle inside the egg cytoplasm (C, D), whose internalization requires a second round of fusion (E). The loss of cortical granules can be observed to occur during the initial process of sperm incorporation (A–C). *(Reprinted from Ref. 4 with permission from Elsevier, Inc. Courtesy of Dr Michael Bedford.)* (E) The two distinct fusion processes during fertilization are shown in a diagram. The first, cell–cell fusion, combines two independent membranes (sperm and egg) into one. Second, a second round of fusion is required to incorporate the vesicle. Dots indicate where fusion occurs. Vet-ebooks.com

internalized[6,282] through a second membrane fusion event (Figure 4.5(E)).[280] Sperm enter a fusion competent state immediately before interaction with the oolemma; in contrast, competence develops in oocytes well before ovulation.[283]

Mammalian sperm fuse with microvilli on the egg surface,[6] consistent with the notion that membrane fusion is facilitated by the regions of high curvature,[284,285] and conditions that alter the integrity of microvilli, including destabilization of actin microfilaments, prevent fusion.[286,287] The egg surface may be further regionalized. In rodents, a non-microvillous membrane domain is established over the metaphase II spindle during oocyte maturation[288] through a process that involves signaling through FYN kinase-dependent pathways.[289] This domain does not seem to participate in fusion.[6,290] However, such morphological and functional regionalization is not observed in all mammalian eggs, as human eggs display uniform distribution of microvilli.[291]

Candidate Sperm Proteins for Binding and Fusion

The observation that gamete plasma membranes exhibit specialized domains involved in adhesion and fusion provided a strategy for identifying specific molecules that mediate gamete interaction. These molecules were characterized and localized initially using anti-gamete monoclonal antibodies that inhibit fertilization in vitro,[292,293] and later by application of proteomic[290,294]

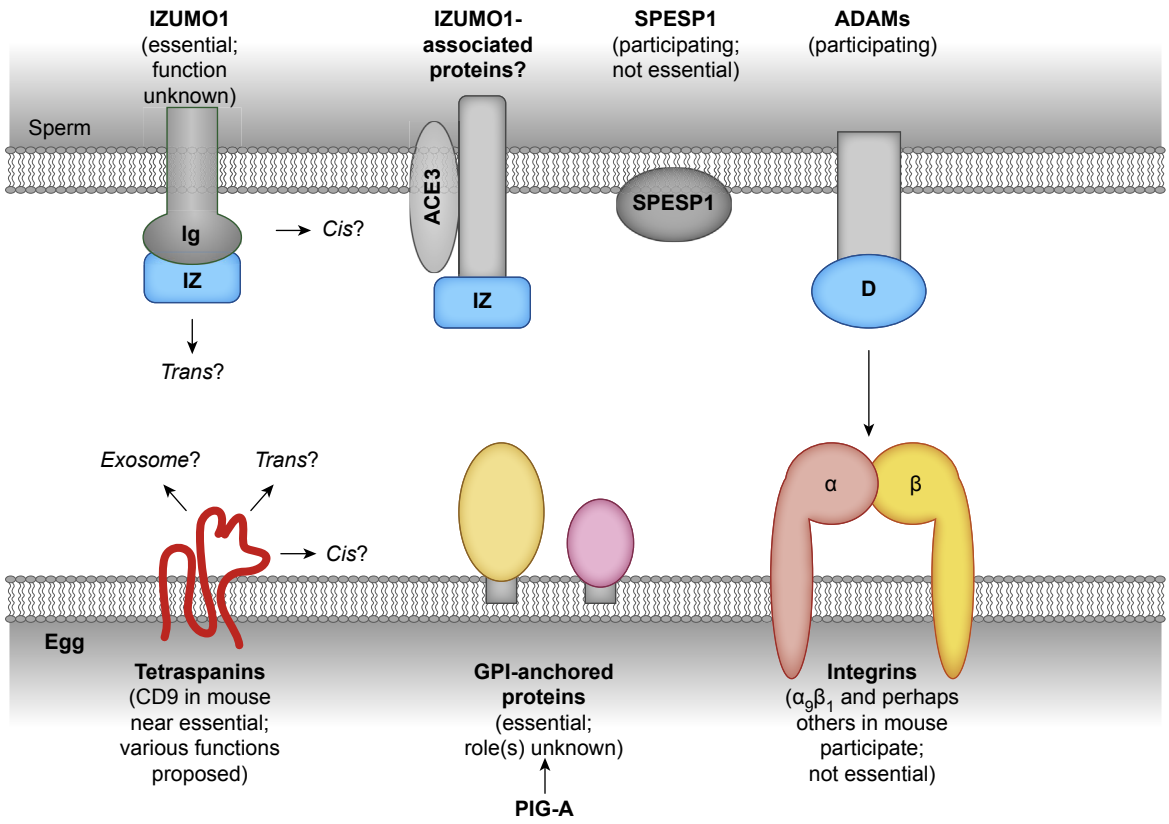

FIGURE 4.6 Sperm and egg molecules implicated in gamete membrane interactions. This diagram illustrates the molecules proposed to participate in sperm–egg membrane interactions. IZUMO1 is essential for sperm–oocyte fusion. ACE3 (angiotensin-converting enzyme 3) is one of IZUMO1-associated proteins recently identified. The position of the Izumo domain (IZ), which has been detected in other proteins, is noted in the diagram. The tetraspanin CD9 is the major player identified thus far on the mouse egg and is likely to function in conjunction with another tetraspanin, CD81. The two extracellular loops, a small and a large one, characteristic of this family are noted. Also noted are the different ways in which the CD9 may interact with putative partner proteins, cis, trans, and exosomes. Glycosyl phosphatidylinositol (GPI)-anchored proteins on the egg are also implicated on the basis of the phenotype of the oocyte-specific conditional knockout of phosphatidylinositol glycan anchor biosynthesis, class A (PIG-A). Other proteins both in sperm and eggs that for their location and/or antibody-blocking studies have been suggested to participate in sperm–egg fusion are also shown. For most of these proteins, knockout lines have not yet been done or if available have failed to confirm the need of the specific protein in the fusion process. Among those proteins are the sperm equatorial segment protein 1 (SPESP1) and several sperm ADAMs, where ADAM stands for a disintegrin and a metalloprotease domain and the D in the diagram depicts the disintegrin domain thought to mediate interactions with their putative partners, the integrins, which are membrane proteins composed of an α subunit and a β subunit. Refer to the text for specific citations and experimental data of the proteins presented in the diagram. *Figure adapted from Ref. 272 with permission from Annual Reviews. Courtesy of Dr Janice P. Evans. See Addendum.*

Vet-ebooks.com

and gene knockout technologies.[295] These efforts identified an array of sperm/male reproductive tract proteins thought to participate in adhesion and fusion, however, subsequent in vitro and in vivo studies ruled out most of these candidates. A comprehensive list of these early contenders is discussed in earlier editions of this series,[4,6] while more recent candidates are considered in specialized reviews[272,295] and discussed below.

Candidate fusion protein were identified in rodents by the inhibition of fertilization in vitro by function-blocking antibodies, although subsequent studies found in some cases that these proteins participated in preliminary events antecedent to fusion[272,295] (Figure 4.6). The first strong candidate sperm proteins were members of the ADAM family (*A D*isintegrin *A*nd *M*etalloprotease domain).[296,297] Fertilin, the founder member of this group, is a membrane-anchored heterodimer composed of fertilin-α (ADAM1B) and fertilin-β (ADAM2) subunits. Fertilin is distributed on the entire sperm head in testicular sperm, but during transport through the epididymis it relocalizes to the posterior head, where sperm bind to the oolemma, and both subunits undergo proteolytic processing exposing N-terminal disintegrin domains.[298] ADAM2 was suggested to participate in sperm–egg binding and fusion based on the following observations: (1) it contained a Gln/Thr-Asp-Glu peptide motif that could mediate interactions with integrin(s)[299] on the egg suface;[300] (2) it also contained a 20-residue amphipathic α-helix with a diprolyl motif that was similar to viral fusion peptides;[301] and (3) addition of peptides that interact with integrins, antibodies, native fertilin-β, or recombinant fertilin inhibited sperm binding and fusion with zona-free eggs.[302,303]

However, the assignment of a function to sperm ADAM2 is complicated by the pleiotropic effects of gene disruption. Nullizygous *Adam2* male mice lack fertilin and are infertile, but this infertility is associated with defects in sperm migration into the oviduct and in interaction with the zona pellucida, as well as reduced interaction with the oolemma.[304] More telling, disruption of *Adam1b* also resulted in a loss of sperm surface fertilin, but in this case there was no associated fertility phenotype. In addition, deletions of *Adam2* were associated with compensatory downregulation of other ADAM family members in sperm.[305] These results were consistent with the notion that fertilin was not required for sperm–oolemma fusion and that another, possibly ADAM-related protein, might underlie the fertility defects of *Adam2*-deficient mice. Further studies showed that disruption of two other ADAM family members, *Adam1a* and *Adam3*,[306,307] as well as other unrelated genes, phenocopied the fertility defect associated with *Adam2* deficiency and also resulted in a loss of sperm surface ADAM3.[295,308] Finally, eggs are fertilized in vivo when sperm from *Adam3*$^{-/-}$ mice were injected directly into oviducts at a point distal to the uterotubal junction, and in vitro.[309,310] The emerging picture is that fertilin and other ADAM family genes do not mediate gamete fusion, but that Adam3 or an associated protein plays an essential role in uterotubal transport.

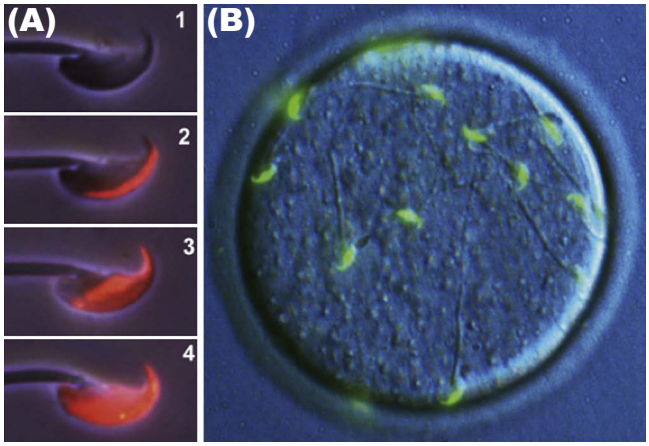

FIGURE 4.7 Gamete fusion-related factor IZUMO1 and localization in sperm. This figure is reproduced in color in the color plate section. (A) IZUMO1 is an acrosomal membrane protein that is not exposed before the completion of an acrosome reaction (1). Acrosome-reacted sperm can be classified into three major groups by their IZUMO1-staining pattern: acrosomal cap (2), equatorial (3), and whole-head (4). (B) Accumulation of many sperm in the perivitelline space of the eggs recovered from females mated with *Izumo1*$^{-/-}$ males. Sperm in the perivitelline space were labeled with acrosome-reacted sperm-specific monoclonal antibody MN9. *Figure reprinted from Ref. 273 with permission from the* Asian Journal of Andrology. *Courtesy of Dr Masaru Okabe.*

A stronger case can be made for a second candidate: IZUMO1. Antibodies against this protein block fertilization and *Izumo1* nullizygous male mice are infertile.[311,312] IZUMO1 remains the only sperm protein required for gamete fusion in the mouse. A role in other species has not been explored extensively; addition of antihuman IZUMO1 antibodies prevented fusion of human sperm to zona-free hamster eggs, but sperm binding to the oolemma was also disturbed.[312]

IZUMO1 is a testis-specific member of the immunoglobulin (Ig) superfamily of proteins, and there are three other closely related members of the family: IZUMO2–4. IZUMO1 is a type I membrane protein with a single extracellular Ig domain and shares a unique "Izumo domain" with other IZUMO proteins.[313] IZUMO1 is located in the acrosomal membrane before the acrosome reaction.[273,314] Following the acrosome reaction, IZUMO1 relocalizes in one of three patterns (Figure 4.7), and the functional consequences of this process are to relocate IZUMO1 from the anterior sperm head to the equatorial segment or to the complete sperm head, where sperm–egg fusion starts and progresses, respectively.[273,280] Sperm from *Izumo1* nullizygous mice display normal morphology, penetrate the zona pellucida, and attach to the oolemma in vitro,

Vet-ebooks.com

although are unable to fuse with the oolemma and therefore accumulate in the perivitelline space (Figure 4.7).[39] Importantly, sperm from *Izumo*-disrupted males used for intracytoplasmic sperm injection (ICSI) fertilize and promote development to term, which suggests that the function of IZUMO1 is exclusively associated with sperm–oolemma fusion.

It is unclear whether IZUMO1 is the fusogen, as it lacks the characteristic features of a viral fusion protein. However, it may be of interest that Ig domain proteins are implicated in osteoclast cell–cell fusion.[315,316] Alternatively, IZUMO1 may be more responsible for organizing the membrane and providing the appropriate framework for the sperm membrane fusion machinery to operate.[313] One approach to resolving the mechanism of IZUMO1 action has been to identify interacting partners. When *Izumo1* was reintroduced into an *Izumo1*$^{-/-}$ background, the protein interacted with angiotensin-converting enzyme-3 (ACE3), an acrosomal protein. The functional significance of this association is unknown, and generation of *Ace3*-deficient mice had no fertility defect.[308] Interestingly, disruption of the genes that encode SPESP1 (sperm equatorial segment protein-1) and TSSK6 (testis-specific serine kinase-6) altered the localization and/or redistribution of IZUMO1, compromised the ability of sperm to fuse with the oolemma, and impaired male fertility in mice.[317,318] Disruption of *Spesp1* altered the organization of the equatorial segment membrane, as assessed by scanning electron microscopy, and modified the localization of other equatorial segment resident proteins.[318] Disruption of *Tssk6* leads to defects in actin polymerization in the posterior sperm head, suggesting that redistribution of IZUMO1 during the acrosome reaction may be regulated by the actin cytoskeleton.[317] At present, IZUMO1 is believed to mediate gamete fusion either directly or through its association with a fusogenic partner.[318] (See Addendum.)

The equatorial segment protein equatorin is another candidate sperm protein to mediate gamete fusion. Addition of the MN9 antibody, which recognizes equatorin, prevents fertilization in vivo and in vitro by blocking fusion, but had no effect on sperm penetration of the zona pellucida.[319] Equatorin is an acrosome protein that redistributes to the equatorial region after the acrosome reaction. The N-terminal region of the protein, which contains the MN9 epitope and is *O*-glycosylated, is present on the acrosomal membrane facing the acrosome lumen.[320] Further studies of equatorin are required to establish its function during fertilization and fusion.

The CRISP family of sperm proteins are also candidate mediators of gamete fusion. CRISP proteins are synthesized in the epididymis and deposited on the sperm surface.[321] The evidence for their participation in fusion includes: (1) antibodies against these proteins reduced fertilization rates in vitro, largely by inhibiting sperm–egg fusion; and, (2) recombinant CRISP1 protein also inhibited gamete fusion. *Crisp1*$^{-/-}$ males had normal fertility, although their sperm showed reduced capacitation parameters and some reduction of fertilization in vitro.[322] Complete assessment of the role of CRISP family proteins is complicated by the presence of other family members that may compensate for *Crisp1* gene disruption, and therefore must await the generation of more comprehensive genetic models.

In summary, a single sperm protein, IZUMO1, has emerged as essential in the pathway leading to gamete fusion. It remains uncertain whether this acts directly as a fusion protein, or indirectly. Finally, it is worth noting that while dismissed as fusogen candidates, several members of the ADAM family play essential functions in fertilization. Therefore, besides identifying additional key effectors of sperm–oolemma fusion, future studies should ascertain the role and mechanisms of action of proteins such as ADAM3.

Candidate Egg Proteins for Binding and Fusion

Interest in identifying oolemmal molecule(s) that participate in gamete fusion has been hampered by the limited availability of oocytes. To date, only three families of proteins remain as possible candidates/effectors for gamete binding and fusion: integrins, glycosyl phosphatidylinositol (GPI)-anchored proteins, and tetraspanins; only the last two are known to be required for gamete fusion[272,273] (Figure 4.6). Interest in the role of integrins was sparked upon the discovery of the ADAM family proteins in sperm and the presence in ADAM2 of an integrin-binding domain.[301] Integrins are a large family of heterodimeric proteins mediating cell interaction with extracellular matrix and with other cells, as well as intracellular signaling.[323] Consistent with their proposed role in gamete interaction, mouse eggs express several α and β integrin subunits, making possible the presentation of multiple αβ pairs on the surface of eggs; integrins have been detected in other mammalian eggs as well.[272,324] Their functional role in gamete interaction was supported by the inhibition of sperm binding to and fusion with oocytes by integrin-targeted antibodies and by peptide studies.[300,303] In addition, integrin α6β1 was shown to be associated on the oolemma with CD9, one of the tetraspanins required for sperm–oolemma fusion (see below).[325] However, subsequent studies involving animals or eggs with disrupted expression of single integrins displayed normal fertility in vivo or in vitro, casting doubts on the importance of these proteins in fertilization.[326,327] Collectively, this work suggests that individual loss from the egg surface of most integrin family members expressed in eggs is dispensable for sperm–oolemma fusion and fertility, although ancillary roles for these proteins cannot be fully ruled out by genetic

Vet-ebooks.com

studies due to possible redundancy, incomplete knockdown, and/or compensatory mechanisms.[272]

A family of proteins involved in mediating sperm-oolema fusion in mouse eggs is the GPI-anchored proteins. Initial studies by Hirao and Yanagimachi noted that treatment of eggs with phosphatidylinositol-specific phospholipase C (PI-PLC), which cleaves the phosphatidylinositol link and releases proteins from the oolemma, prevented gamete fusion in hamsters.[328] While the authors themselves questioned the results, comparable experiments by Coonrod and colleagues with more purified versions of the enzyme produced similar results and narrowed down the fertilization phenotype to defects of fusion.[329] Proteomic analysis of exudates of PI-PLC-treated eggs revealed that one of the proteins released was CD55, although mice null for this protein are fertile.[330,331] Nevertheless, widespread removal of GPI-anchored proteins from the oolemma accomplished by conditional targeting of the *p*hosphat*i*dylinositol *g*lycan *a*nchor biosynthesis, class A gene (*Piga*), which participates in the initial steps of GPI synthesis, generated females that were sterile and displayed lack of sperm–oolemma fusion in vitro.[332] However, the precise GPI-anchored protein(s) responsible for the fusion defect was not uncovered. What also remains obscure is how the absence of GPI-anchored protein(s) affects fusion. GPI-anchored proteins usually associate with lipid rafts, where signaling molecules congregate. A possibility is that in the absence of these proteins, productive interactions between sperm and the oolemma are not possible and appropriate signaling pathways are not engaged. It is also possible that without these proteins, the oolemma becomes widely disorganized and prevents fusion, although this seems less likely, as acute removal of these proteins produces similar outcomes than those caused by persistent absence of these proteins, as in the case of the knockout model where oocyte membrane is organized in the absence of GPI-anchored proteins.[331] (See Addendum.)

CD9 is to date the only identified egg plasma membrane protein required for gamete fusion in mammals. Tetraspanins display four transmembrane domains: two extracellular loops, a small and a large one; and two intracellular tails, which can interact with cytoskeletal components and with molecules involved in signal transduction[333] (Figure 4.6). Tetraspanins interact with other tetraspanins as well as with other transmembrane and cytoplasmic proteins forming "tetraspanin webs", which are specialized membrane microdomains.[331] Tetraspanin proteins are widely expressed and participate in myriad cell functions, including cell proliferation, signaling, cell–cell interaction and fusion.[334] Regarding the latter, CD9 interacts in various cell types with several β1 integrins including α6β1,[333] which is also the case in mouse eggs.[335] A monoclonal antibody raised against the extracellular loop of CD9, JF9, proved highly potent at inhibiting sperm–oolemma adhesion and fusion.[335] Subsequent genetic studies showed that eggs from females with disrupted CD9 rarely fused with wild-type sperm, even in zona-free assays in vitro, and females were nearly infertile;[286,336,337] disruption of another tetraspanin, CD81, showed similar, albeit less severe, phenotype.[338] Importantly, the fusion defects observed in CD9 null eggs were partly overcome by injections of mRNAs encoding for CD9 or CD81,[339] and fertilization of these eggs by ICSI caused egg activation and supported development to term, demonstrating that CD9 null eggs are developmentally competent.[286] CD9 appears to play a role in gamete interaction in other mammalian species,[340] and CD151 appears to be one of the tetraspanins involved in human sperm–oolemma interaction and fusion.[341]

The mechanism by which CD9 modulates gamete fusion is not known.[272,331] One possibility is that, via its numerous interactions, one of its associated proteins effects fusion. Consistent with this prospect is the finding that preincubation of recombinant peptides representing the large extracellular loop of CD9 prevents fertilization when incubated with eggs but not with sperm.[342] In addition, proteomic studies support this notion, as one of the few known CD9-associated proteins in eggs, EWI-2 (also known as immunoglobulin superfamily member 8, or IgSF8), is absent from the surfaces of CD9-null eggs, and similar fates may befall other currently unknown CD9-partner proteins. Such protein losses may undermine the fusion competence of CD9-null eggs. This remains a possibility, but it should be noted that IgSF8 knockout mice did not show a fertility phenotype.[343] CD9 may also be critical in determining overall membrane topology and thereby enhancing the interaction between gametes. In support of this view, the shape and density of the microvilli is severely altered in CD9 null mice,[344] and a recent, more exhaustive assessment of sperm–oolemma interactions showed that while the number of adhesion opportunities between sperm and eggs was unaffected by the absence of CD9, the strongest adhesion interactions were decreased.[345] These results suggest that on the plasma membrane CD9 may favor the formation of sites responsible for stronger adhesion events that facilitate the subsequent fusion process. The underlying mechanism(s) responsible for the superior adhesion properties of CD9-containing membranes is unknown. CD9 is also reportedly released from oocytes in cell-derived vesicles (exosomes) into the perivitelline space, where it can be adsorbed onto surrounding sperm.[346] Adsorption may render sperm fusion competent,[279] although this has been disputed.[347] Lastly, CD9 may interact with sperm proteins, thereby facilitating adhesion and fusion between gametes. There is evidence for this type of association in other cell types, although such interactions have not been found in sperm. In summary, research over the

Vet-ebooks.com

last decade on both sperm and eggs has identified key molecules that participate in sperm–oolemma adhesion and fusion. Nevertheless, how these and other yet-to-be-discovered molecules function in mediating gamete adhesion and fusion remains a significant challenge for present and future investigators interested in this field.

Incorporation of the Fertilizing Sperm into the Egg and Fate of Sperm Components

One indication that gamete fusion is underway is the sudden reduction of the movements of the sperm tail,[348] a property of fertilizing sperm shared by mammals and invertebrates.[6] In mammals, fusion results in the entire sperm, including the tail, being incorporated into the ooplasm.[349] Sperm incorporation induces modifications of the oolemma and of the underlining egg cortex, causing the formation of an actin-rich fertilization cone[350] that progressively expands to engulf the sperm head (Figure 4.5(B) and (C)). The anterior portion of the fused membranes form a vesicle derived from the inner acrosomal and oolemmal membranes, which is endocytosed and requires a second round of membrane fusion, as already pointed out (Figure 4.5(D) and (E)).[280,351] Nevertheless, the role of actin in the process of sperm entry in mammals is not yet settled. Some reports show no inhibitory effects of actin inhibitors,[352] others find that the organization of oocyte actin is essential and required for sperm head entry, decondensation, and for incorporation of the axoneme;[353,354] the blunted $Ca^{2+}{}_i$ responses induced by fertilization of mouse eggs with disrupted microfilament organization confirm the pivotal role of actin in promoting complete and timely sperm incorporation in these species.[354] PYK2, a calcium-sensitive tyrosine kinase from the focal adhesion kinase (FAK) family, reportedly participates in the reorganization of actin at the site of sperm entry.[355]

Once in the ooplasm, the components of the sperm undergo different fates. Simultaneous with sperm head decondensation, which is brought about in part by the reducing environment of the ooplasm, the mitochondrial sheath is separated from the connective piece, making possible access of ooplasm material to the sperm centriole. Recruitment of pericentriolar material to this site and assembly of microtubules leads to formation of the sperm aster, which guides the apposition of the male and female pronucleus and brings both genomes in close proximity in preparation for the first mitotic cleavage.[6,356,357] This sequence of events occurs in most mammals, although in rodents, which lack a sperm centriole, centrosomes made up of egg pericentriolar material serve as the microtubule-organizing center.[358] Centrosomes organize meiotic spindles, and their function during the initial stages of development appears to be more important than centrioles, as parthenogenetically activated diploid embryos can commence embryo development and reach early fetal stages without sperm contribution.[359] Given that centrosomes and centrioles can form "de novo" from egg extracts and during early cleavage stages,[358] the significance of paternal centrioles and components of both maternal and paternal centrosomes to the early embryos remains to be determined. The displaced paternal mitochondria, which are ubiquitinated during spermatogenesis, are targeted for degradation in the ooplasm and do not persist more than 2 or 3 days, although it is possible that some may evade degradation and fuse with the egg's mitochondria;[356,357] their elimination seems determined by certain developmental events rather than by time postfertilization, and it appears to be species specific, as it is not seen in cases of interspecies crosses.[357] Other components of the sperm tail and principal piece also undergo degradation, with loss of the fibrous sheath preceding the disintegration of the outer fibers and axoneme microtubules.[356,360]

Other sperm components delivered during fertilization include plasma membrane and RNA.[4] Remnants of the sperm plasma membrane are detectable on the surface of marine and mammalian eggs on the site of entry,[361,362] from where they disperse into the oolemma.[363] The role of this exchange is unknown, although it may contribute to the membrane block to polyspermy, which in mammals is observed after fertilization but not after ICSI.[364,365] However, prophase-I stage oocytes do not mount such a block following fertilization with sperm, raising questions regarding the contribution of the donated sperm membrane.[366] In terms of RNAs, it is now widely accepted that sperm carry and deliver into the ooplasm diverse RNA populations, including rRNAs, mRNAs of genes actively transcribed during spermatogenesis, and miRNAs;[367] sperm also carry an endogenous reverse transcriptase, which reportedly may be active both prior and after fertilization.[368] While the implications of this type of genetic transmission to fertilization and early embryo development remain tantalizing,[369,370] additional studies are needed to demonstrate the scope of their functions as well as their possible application as a diagnostic method.

EVENTS FOLLOWING SPERM–EGG MEMBRANE FUSION

The onset of zygote development depends on completion of a series of so-called "events of egg activation" that are induced by fertilization and occur sequentially prior to the first cleavage. The early events include secretion of egg cortical granules (see loss of cortical granules from the egg cortex in the diagram of Figure 4.5(B) and (C)), the blocks to polyspermy (see below) and onset of paternal chromatin decondensation. In most mammals,

Vet-ebooks.com

these events are well underway within the first hour of fertilization. Later events include completion of maternal meiosis, maternal chromatin decondensation, male and female pronuclear formation, and recruitment of maternal mRNAs resulting in expression of new proteins. Before the first cleavage, the zygote also undergoes the onset of genomic reprogramming and limited zygotic genome activation. Egg activation is universally induced by an increase in the concentration of free Ca^{2+}_i, and all events of egg activation are directly stimulated by Ca^{2+}_i or rely on changes in the activity of specific kinases brought about by the release of Ca^{2+}.

Block(s) to Polyspermic Fertilization

Mammalian females employ several mechanisms to prevent incorporation of extra sperm into the ooplasm, "block(s)" to polyspermic fertilization,[4,371,372] as polyploidy caused by entrance of more than one sperm results in abnormal development. The blocks to polyspermy occur sequentially and arise from two sources: the oviduct and the egg itself. Despite these barriers, low rates of polyspermic fertilization are observed under in vivo conditions in all mammals, including humans.[373] Rates of polyspermy increase considerably when fertilization is performed in the absence of oviductal fluids and in the presence of excess numbers of sperm, which is the case when assisted reproductive technologies (ART) such as in vitro fertilization (IVF) are applied. For example, in the case of human IVF, reported rates of polyspermy are between 5% and 10%,[374] and similar rates are reported for most other mammals including bovines, sheep, rodents, and rabbits, although in the case of porcine eggs polyspermic fertilization following IVF can reach levels higher than 50%.[6,375]

The oviduct contributes to the polyspermy block in two manners (Figure 4.8). The best-characterized effect is the physical barrier imposed by transport through the uterotubal junction, which limits the number of sperm available for storage in the isthmus and posterior release to the ampulla.[6,376] This mechanism in several species reportedly achieves sperm/egg ratios in the ampulla of <10:1,[377] which considerably lowers the risk of multiple sperm penetration.[378]

A less-characterized oviduct-based mechanism is predominantly functional in ungulates and relies on molecular components of the oviductal fluid. This effect is evidenced in in vitro matured porcine and bovine oocytes that when incubated with tubal fluids for different periods of time prior to IVF show greatly reduced rates of polyspermy.[375,379] Exposure of eggs to tubal fluids in these species render the zona pellucida resistant to proteolysis, a change that is not induced by fertilization or by release of cortical granules,[375,380] as it occurs in rodents; human eggs seem insensitive to the effects of oviductal fluids.[381] This mechanism has therefore been called prefertilization zona hardening (see below for more details for postfertilization zona hardening), and it does not interfere with sperm penetration.[382] Remarkably, this process is reversible, restricted to the fluids of the periovulatory period[382,383] and thought to be mediated by the combined and sequential action of oviduct-specific glycoprotein 1 (OVGP1) and sulfated-glycosaminoglycans

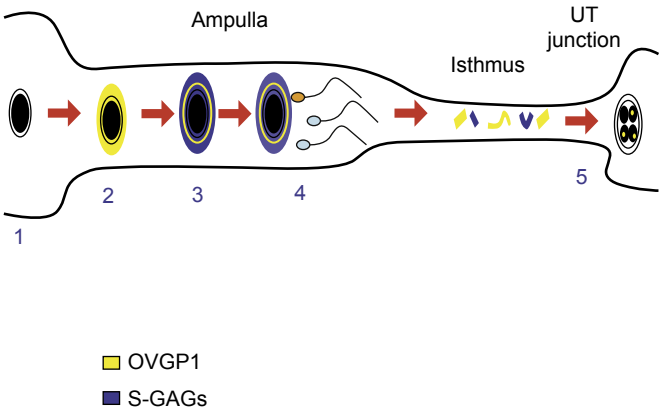

FIGURE 4.8 Depiction of the proposed role of oviductal contents in preventing polyspermy in ungulates. This figure is reproduced in color in the color plate section. After the egg is shed into the ampulla following ovulation (1), oviduct-specific glycoprotein (OVGP1) surrounds it in a "shell" that renders the zona pellucida (ZP) resistant to proteolysis (2). Other oviduct molecules such as heparin-like glycosaminoglycans (S-GAGs) are thought to aid and strengthen the binding of OVGP1 to the ZP (3), modifying interaction with spermatozoa (4). As the zygote advances to the uterus, the aforementioned factors are shed or absorbed into the egg (5). *Figure reprinted and legend adapted from Ref. 375 with permission from John Wiley & Sons. (S-GAGs) (Figure 4.8), although the expression of these proteins in specific regions of the oviduct and the structural modifications imposed on the ZP are unknown and remain to be characterized.[384]

The egg-based blocks to polyspermy have been thoroughly investigated in mammals and consist of the zona and plasma membrane blocks. The relative contributions of these two blocks vary in different species[4,6] (Table 4.1) with the plasma membrane block unfolding earlier than the zona pellucida block. The membrane block reportedly unfolds within a few minutes after sperm–egg fusion in eggs of mice[385] and hamsters,[386] although a more recent study suggests a slower block.[287] The goal of the plasma membrane block is to prevent binding/fusion of additional sperm, as demonstrated by in vitro fertilization of zona-free eggs that have large numbers of bound sperm but remain (in >50% of eggs) monospermic even after many hours of culture. Little is known about the biochemical basis of the membrane block,[6,287,366] which lacks the membrane depolarization component observed in marine eggs.[371] Nevertheless, the observation that this block is induced following sperm–egg fusion but not after ICSI[364,365] suggests contribution of a sperm membrane component, although participation of oocyte/egg factors is required, as it is only engaged in metaphase II stage eggs.[366] (See Addendum.)

The zona block is intended to prevent sperm penetration and/or binding;[229] inhibition of penetration unfolds rapidly after fusion,[6,385–387] while prevention of sperm binding occurs after several hours.[219,229] Several mechanisms have been proposed to account for the zona block, including those that might cause specific modifications in key sperm-binding residues,[388] or changes in the organization of the zona or of its components,[219,229,389] and/or by addition of new proteins following the release of cortical granules (see below).[390] Ultrastructural studies in human eggs and those from other mammals showed changes in zona filaments and structure after fertilization,[391–393] although unfertilized human eggs display significant variability in these parameters, raising questions about their contributions to the zona block.[391,394] Initial studies to elucidate the molecular basis of the zona block focused on modifications of presumed sperm binding residues such as *O*- and *N*-linked glycans on ZP3, as studies with purified ZP3 from unfertilized eggs but not from two-cell embryos demonstrated that it, but not ZP1 or ZP2, abrogated sperm binding to the zona, and it induced acrosome reaction.[212,217] Further, ZP3 glycopeptides and purified ZP3 *O*-glycans retained sperm-binding ability but not the capacity to induce the acrosome reaction.[213,214] The glycan model (Figure 4.9(A)), as this theory is known, envisions release of glycosidases following the cortical granule reaction that removes *O*-linked glycans from ZP3 thereby preventing sperm binding.[214,395] Nevertheless, the proposed glycan composition has thus far not been detected in native zonae pellucidae,[396] hindering further characterization of the model. In addition, demonstration that sperm binding to the zona continues unimpeded in transgenic mice where candidate *O*-glycans residues have been eliminated raises the prospect that other mechanism(s) may underlie the zona block.[397] The ZP2 cleavage model (Figure 4.9(A)) arises from observations in mice showing that after fertilization ZP2 undergoes cleavage, after which sperm are no longer able to bind the zona pellucida.[219] More specifically, this model proposes that after fertilization the N-terminal domain of ZP2, which is where sperm binding is thought to occur, undergoes a series of cleavages eliminating the binding site.[258,259] While ZP2 fragments remain bound by disulfide bonds and are undetectable during fertilization, they can be visualized by electrophoretic methods[219] even in human eggs;[398] it is speculated that these modifications change the higher-ordered structure of the zona pellucida. Studies using transgenic and genetic models where human zona pellucida proteins were used to replace their mouse counterparts provide support for this model, including: (1) human sperm only bind eggs that express human ZP2 (Figure 4.9(B)); and (2) human sperm bind to beads decorated with human ZP2 N-terminal peptides, and excess of these peptides prevents binding of human sperm to ZP2 humanized zonae pellucidae.[223] Therefore, these studies suggest that proteolytic cleavage of ZP2 prevents sperm binding and underlies the slow developing zona block in mouse and most likely in other mammals. While it is speculated that structural reorganization of the zona pellucida accounts for the downregulation of sperm binding, there is no available biophysical or biochemical evidence supporting such conformational shifts.

The zona pellucida block results from the action of proteins secreted by the egg upon fertilization. This evidence is well established in marine and amphibian eggs where the secreted proteins are known to contribute to the extracellular matrix-level block.[399] A major source of secretion is the exocytosis of thousands of egg cortical granules. These granules undergo reorganization during oocyte maturation, which includes migration to the cortex and acquisition of exocytosis competence.[4] In fact, during late stages of maturation, some granules undergo premature exocytosis and their contents are found in the perivitelline space; the role of this prefertilization release is not well established. In mammalian eggs, thousands of 0.1- to 1.0-μm-diameter, membrane-delimited cortical granules are found in the peripheral cortex underlying the plasma membrane.[400] The major wave of cortical granule exocytosis occurs within 15 min of sperm entry, as the egg initiates the "cortical reaction", and it is triggered by the Ca^{2+}_i rises induced by fertilization.[386,401] The cortical granule exudate diffuses across the perivitelline space, where it removes or masks sperm

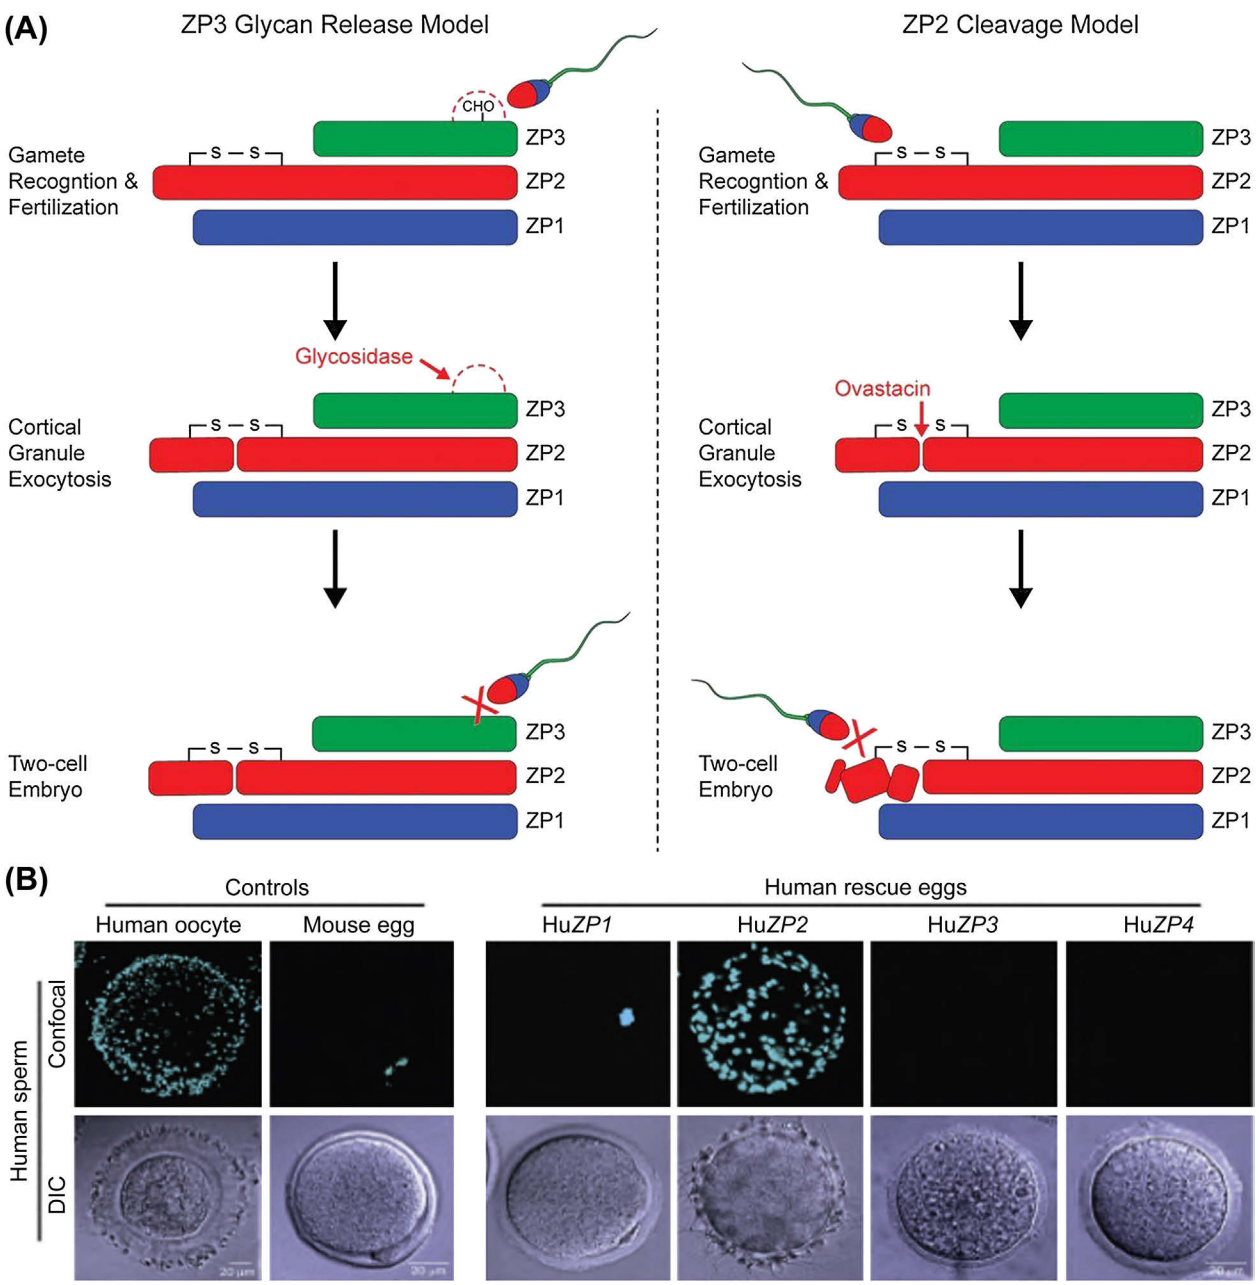

FIGURE 4.9 **Models of zona pellucida block to polyspermy.** This figure is reproduced in color in the color plate section. (A) A specific glycan-release model (left panel) proposes that *O*-glycans on ZP3 Ser^{332} and Ser^{334} or possible others act as ligands for a sperm surface receptor. Following fertilization, cortical granules would release a glycosidase that would remove the *O*-glycans and account for the inability of sperm to bind to two-cell embryos. The ZP2 cleavage model (right panel) proposes that sperm bind to an N-terminal domain of ZP2. Following fertilization, ovastacin, a cortical granule metalloendoprotease, is exocytosed and the proteolytic destruction of the ZP2 docking site prevents sperm from binding to two-cell embryos. (B) Human sperm bind to mouse eggs from transgenic strains expressing human ZP2, but not other human ZP proteins, in the ZP. Confocal and differential interference contrast images of capacitated human sperm binding to the ZP of mice expressing human ZP1, human ZP2, human ZP3, or human ZP4, in the absence of the corresponding mouse protein. Human oocytes and mouse eggs served as positive and negative controls, respectively. Specific references and experimental details can be found in the text. *Figure reprinted from Ref. 229 with permission from Oxford Journals. Courtesy of Dr Jurien Dean.*

receptors in the egg's extracellular investments, or otherwise modifies those investments.[390] Some of the cortical granule-derived macromolecules that remain in the perivitelline space have been suggested to form a "cortical granule envelope",[390,402] although the function and molecular composition of this envelope warrant further investigation.

Cortical granules in mammals are estimated to contain up to 14 different proteins.[400,403] A number of enzymatic activities are present, including trypsin-like and

Vet-ebooks.com

tissue-type plasminogen activator activities, an ovoperoxidase and an *N*-acetylglycosaminidase activity that is thought to use ZP3 as a substrate,[4,6] but these activities were not directly linked to the zona pellucida block. Recently, characterization of the ZP2 cleavage site led to a focus on an astacin family of metalloendoproteases,[259] and to the identification of ovastacin, an oocyte-specific astacin,[404] which localizes to mouse cortical granules and is released by exocytosis.[218] Transgenic expression of ZP2 with a mutated cleavage site or ablation of the *Astl* gene, which encodes ovastacin, left ZP2 intact, even after cortical granule release, and prevented the inhibition of sperm binding component of the zona pellucida block to polyspermy.[218,259]

Targeted deletion of the liver-derived plasma protein fetuin-B confirmed the role of ZP2 cleavage in the deployment of the zona block under in vivo conditions.

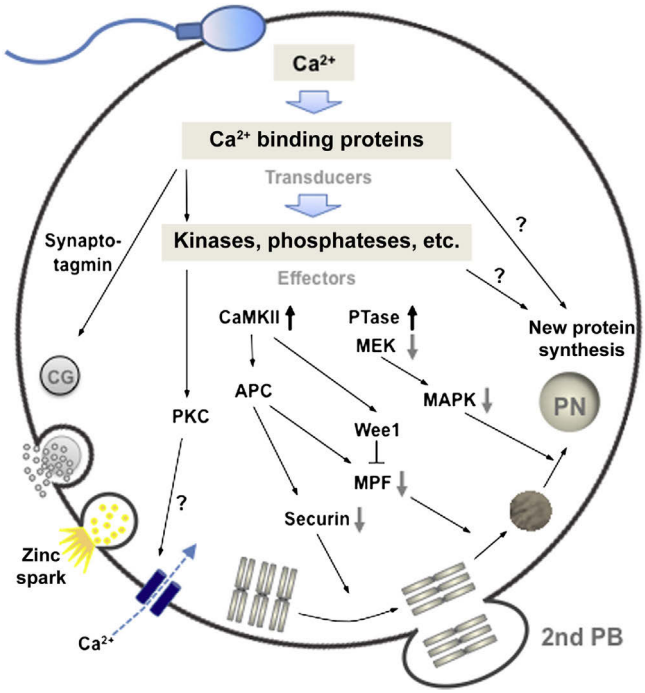

FIGURE 4.10 Signaling diagram of egg activation. The model includes the pathway downstream of multiple elevations of $Ca^{2+}{}_i$ and the events of egg activation initiated by these rises. Some Ca^{2+}-sensitive transducers (e.g., calmodulin, not shown) and effectors (CaMKII) have important roles (see text). Others, for example those promoting new protein expression, which is Ca^{2+} dependent, are yet to be identified. Small vertical arrows indicate whether the activity of an effector increases or decreases to promote the pathway with which it is associated. New protein synthesis results from the recruitment of maternal mRNAs. APC, anaphase promoting complex; Ptase, phosphatase; MAPK, MAP kinase; MEK, MAPK kinase; 2nd PB, second polar body; PN, pronucleus; CG, cortical granule; CaMKII, calmodulin-dependent protein kinase II; MPF, maturation promoting factor, PKC, protein kinase C. Synaptotagmin is a Ca^{2+}-sensitive protein that regulates secretion in other cells. *Modified from Ref. 410 with permission from Elsevier, Inc.*

The so-called zona pellucida hardening, a descriptive term for the zona block and so named for the diminished susceptibility of zona pellucida to proteolytic digestion, occurs naturally after fertilization, and prematurely when oocytes are matured in vitro in the absence of serum;[4,6,405] in both cases, it is associated with ZP2 cleavage.[219,404] Addition of serum, or fetuin prevents in vitro hardening of the zona including cleavage of ZP2,[406] although the molecular target was unknown. Fetuins are part of the cystatin superfamily, which are structurally related to protease inhibitors.[407] Consistent with this, in vitro studies showed that fetuin-B directly inhibits ovastacin, and eggs of *Fetub*$^{-/-}$ mice showed preovulatory ZP2 cleavage, which prevented sperm from penetrating the zona pellucida and caused female infertility.[408] This indicates that plasma fetuin-B restricts the activity of ovastacin in vivo, thereby rendering the zona pellucida permissive to sperm penetration. It is worth noting that ZP2 cleavage is observed in human eggs that fail to fertilize during clinical IVF procedures, but it is unknown if ZP2 changes were responsible for the lack of fertilization or arose due to the prolonged in vitro culture.[409]

Cell Cycle Progression and Completion of Meiosis

Sperm entry promotes cell cycle progression that entails the transition from meiosis to mitosis. In temporal order, these include the completion of meiosis and extrusion of the second polar body, formation of male and female pronuclei, DNA replication, pronuclear envelope breakdown, and the first mitotic metaphase prior to first cleavage. This review will focus more attention on the mechanisms responsible for early events in this series because they are more directly regulated by fertilization (Figure 4.10).

Fertilization of most (but not all) mammalian eggs occurs at metaphase II (MII) of meiosis. This arrest coordinates completion of meiosis with fertilization: ovulated mammalian eggs are arrested at MII by the elevated maturation-promoting factor (MPF) activity, whose two components are cyclin-dependent kinase 1 (CDK1) and cyclin B. MPF activation is necessary for promoting entry into the M-phase stage in all cells. In mitotic cell cycles, MPF levels rise transiently during metaphase and then decrease following cyclin B degradation with each cell cycle.[411] In oocytes (Figure 4.11), activation of MPF promotes the transition from the germinal vesicle stage to metaphase I. Complete activation of MPF requires association of CDK1 with cyclin B, site-specific phosphorylations/dephosphorylations of CDK1, and increasing concentrations of cyclin B.[4,411–414] Oocytes that reach MI transition to MII following decrease in MPF activity and cyclin B degradation, which are prematurely terminated by increasing levels of early mitotic inhibitor 2

Vet-ebooks.com

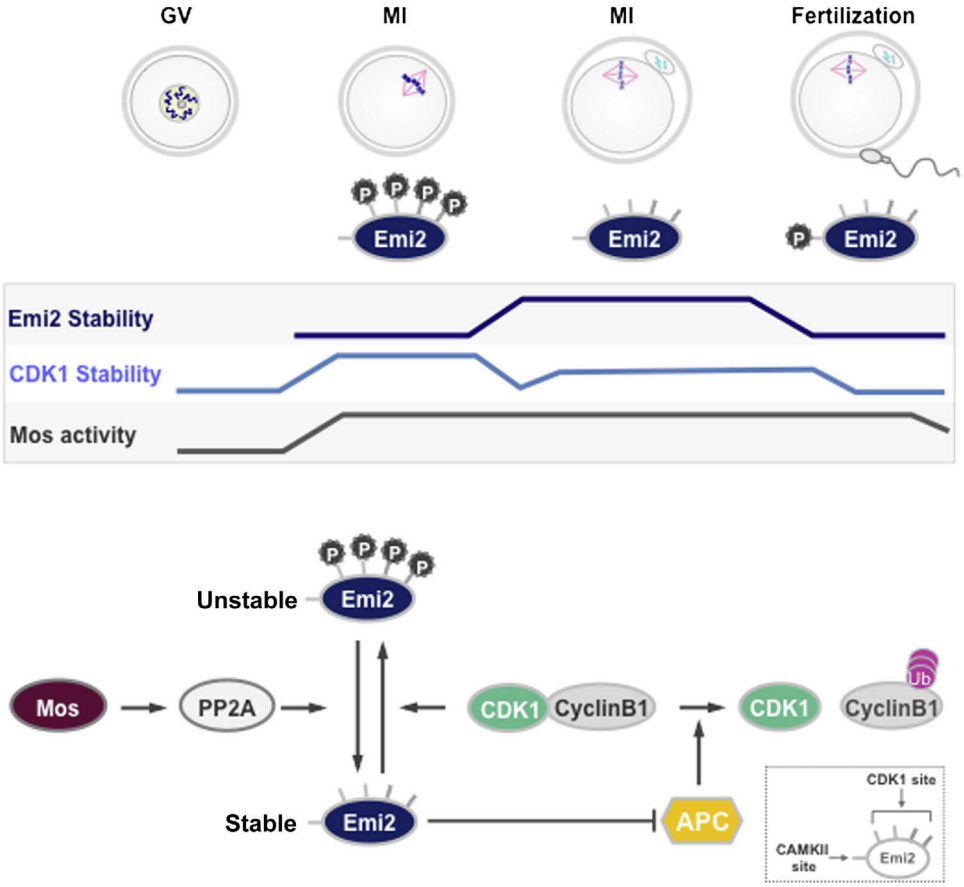

FIGURE 4.11 Molecular effectors that contribute to resumption of meiosis and MII arrest in vertebrate eggs. Stages of oocyte maturation are depicted in the top panel. Phosphorylation controls EMI2 stability during oocyte maturation. At MI, CDK1 phosphorylates amino-terminal sites on EMI2, at least in *Xenopus* oocytes, and this triggers EMI2 degradation, required for MI exit. At MI anaphase, cyclin B is degraded, leading to a drop in CDK1 activity. EMI2 is stabilized by dephosphorylation triggered by Mos signaling and mediated by PP2A type of phosphatase. EMI2 accumulates, resulting in APC inhibition, critical for S phase block and MII entry. CDK1 activity is low in MII relative to MI. EMI2 is stable in MII, as required for CSF-mediated arrest. At fertilization, EMI2 is quickly degraded through a CaMKII-mediated pathway, allowing for activation of the APC and exit from MII. At the onset of MI anaphase, APC-mediated cyclin B degradation results in decreased CDK1 activity. With the Mos-PP2A pathway predominant, dephosphorylated and stabilized EMI2 protein prevents complete ubiquitylation of cyclin B by the APC. This is essential for the inhibition of S phase between MI and MII. *Figure and legend adapted from Ref. 412 with permission from CSHLP. Courtesy of Dr Sally Kornbluth.*

(EMI2), an inhibitor of the anaphase-promoting complex cyclosome (APC/C)[415] that stalls cyclin B proteolysis, promoting instead its accumulation, increase in MPF activity and transition into MII with formation of a bipolar spindle.[416] Unlike mitosis, the activity of MPF at MII remains elevated for hours. The so-called "cytostatic factor" or CSF stabilizes MPF by restraining the proteolytic activity of APC/C.[417,418] EMI2, a component of CSF, is mostly responsible for inhibiting the APC/C, although the precise mechanism(s) of inhibition is not entirely resolved.[419,420] EMI2's activity and stability during vertebrate meiosis are regulated by activation of the c-MOS/MEK/MAPK/p90RSK pathway, which phosphorylates it on several key residues;[411] in mice, the function of p90RSK seems assumed by another substrate of MAPK, the stress-mediated mitogen-activated protein kinase.[421] A PP2-type of phosphatase binds phosphorylated EMI2 and modulates its inhibition of the APC/C by erasing destabilizing CDK1-mediated phosphorylations and in this manner maintains stable levels of MPF activity despite continuous synthesis of cyclin B (Figure 4.11, lower panel).[411] Downregulation of EMI2 or pharmacological inactivation of PP2A in mouse eggs causes the release of the CSF-dependent MII arrest and induces changes associated with fertilization, confirming the role of these molecules in mammalian eggs.[416,422] PP2A, at least in *Xenopus* eggs, seems to be negatively regulated by the action of the Greatwall kinase by means of the small peptide ARPP19 (cAMP-regulated phosphoprotein-19) and α-endosulfine[423] (Figure 4.12, right panel); the timely regulation of PP2A is required both for the arrest and exit of MII.[424]

The stability of MPF ceases after fertilization, which causes inactivation of CSF and release from the MII

Vet-ebooks.com

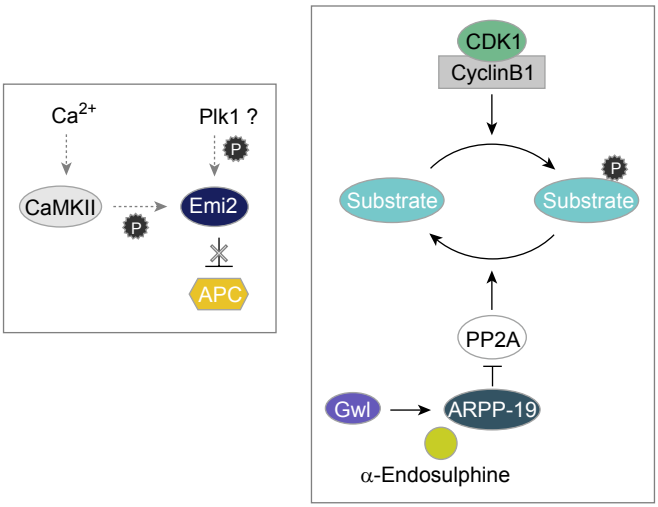

FIGURE 4.12 Molecular events induced by Ca^{2+} release promote MII exit and progression into interphase in vertebrate eggs. As a consequence of a $Ca^{2+}{}_i$ rise, CaMKII is activated, which induces phosphorylation at a conserved consensus site of EMI2. Phosphorylation of EMI2 promotes Plx1 binding and phosphorylation, which triggers SCFb-TrCP-dependent degradation of EMI2 and consequent reactivation of the APC in *Xenopus* eggs; in mouse eggs, a phosphodegron is present, although its position shifted, and therefore the molecular intermediaries from CaMKII to EMI2 degradation remain to be determined in these species (Plk?). Following inactivation of MPF, progression into interphase is facilitated by inactivation of the Greatwall kinase (Gwl), which via ARPP-19 and alpha-endosulphine negatively regulates PP2A, which dephosphorylates many of the M phase CDK1 substrates. *Figure modified from Ref. 412 with permission from CSHLP Dr Sally Kornbluth.*

arrest.[410,425] Sperm entry and the increase in the concentration of free $Ca^{2+}{}_i$ associated with it induce EMI2 degradation[426,427] (Figure 4.12, left panel). $Ca^{2+}{}_i$ increases are transduced by the calcium-responsive protein calmodulin (CaM), which activates several signaling cascades (Figure 4.10). One pathway involved is calcineurin/PP2B, which reverses previous phosphorylations by MPF, thereby facilitating resumption of meiosis and release of the second polar body;[428,429] the function of calcineurin is seemingly not required in mouse eggs.[430] CaM also activates CaM-dependent protein kinase II (CaMKII), which is responsible for proteolysis of EMI2, subsequent APC-mediated destruction of cyclin B, and loss of MPF activity (Figure 4.11; Figure 4.12, left panel).[426,427] CaMKII phosphorylates EMI2 promoting binding by polo-like kinase, whose phosphorylation of EMI2 renders it a substrate for SCFβ-TRCP-mediated ubiquitylation and complete destruction.[426,427,431] Consistent with this, expression in mouse eggs of cRNAs encoding constitutively active CaMKII induced MII exit and egg activation,[432] although in vitro phosphorylation studies by others failed to show phosphorylation of EMI2 by CaMKII.[430] Further, the polo-like kinase phosphodegron in mouse EMI2 is shifted to a different position than in *Xenopus*, therefore making it unclear how CaMKII targets EMI2 for degradation and what is the E3 ligase involved.[430] Nevertheless, the role of CaMKII on MII exit was confirmed by studies where eggs devoid of CaMKIIγ, the predominant isoform on the enzyme in mouse eggs, failed to exit MII following fertilization or activation by $SrCl_2$.[433,434] Another target of CaMKII is WEE1B, which phosphorylates and inhibits CDK1, inactivating MPF and facilitating exit from MII.[435] Once fully active, the APC/C, which targets proteins for destruction via ubiquitylation, also degrades securin, making possible the cleavage of cohesins, which are the proteins that hold sister chromatids together, allowing anaphase onset[436,437] (Figure 4.10 and Chapter 1). Therefore, the current Ca^{2+}-CaM-CaMKII model of EMI2 inactivation and MII release that has been comprehensively characterized in *Xenopus* eggs is largely conserved in mammals, although additional studies are needed to identify the molecular players and pathways that execute the program in the latter species.

Given the cortical location of the second meiotic spindle and small constriction required for extrusion, the second polar body forms relatively rapidly after fertilization. In preparation for polar body extrusion, the meiotic chromosomes cause remodeling of the cortex above the spindle, which includes the formation of the F-actin cap[288] and differential accumulation of several proteins such as myosin IIA and B, PAR proteins, and the small GTPase RAC.[4] A RAN-GTP gradient emanating from the meiotic spindle is responsible for recruiting actin filaments and the actin nucleating machinery to the cortex and for the organization the F-actin cap,[438] which is necessary to maintain the eccentric location of the spindle.[439] The RAN-GTP gradient also controls the polarized distribution of the RHO-GTPase CDC42,[438] which regulates the function of the actin nucleating machinery[439] and whose inactivation prevents extrusion of the second polar body.[440] Following the $Ca^{2+}{}_i$ response induced by fertilization and progression to anaphase but prior to the telophase stage, the cortical spindle must rotate to attain a perpendicular position relative to the surface of the egg. The myosin-light chain kinase (MYLK), which is another target of CaM and the upstream regulator of myosin II, a protein involved in cytokinesis, controls rotation of the spindle and constriction of the cytokinesis ring, as pharmacological inhibition of either protein prevents these events and release of the second polar body. The molecular mechanism(s) that regulates MYLK during these processes remains to be demonstrated.[441]

The Pronuclear Stage

In mammalian fertilization, the haploid genome of each gamete becomes surrounded by its own nuclear ("pronuclear") envelope, in which the first mitotic "S"

Vet-ebooks.com

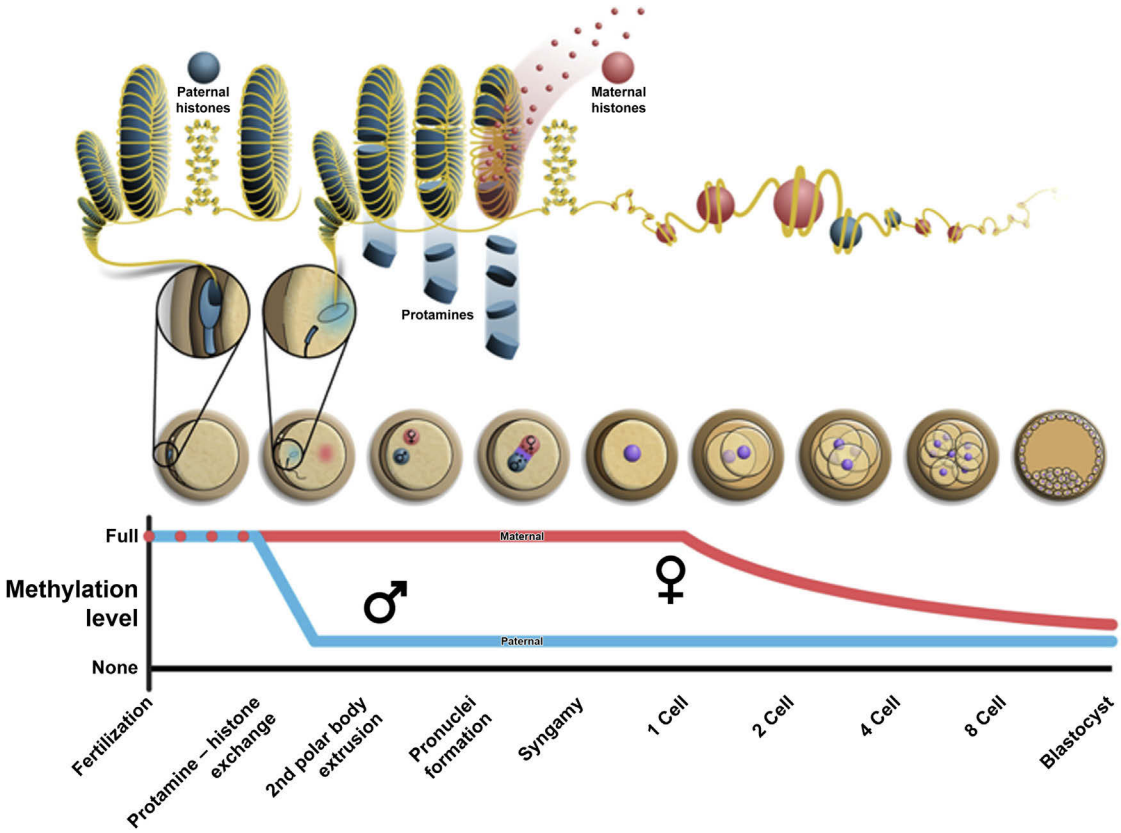

FIGURE 4.13 Reorganization of the male chromatin after fertilization and alterations to the epigenome postfertilization. This figure is reproduced in color in the color plate section. The top panel illustrates the chromatin structure of the mature sperm immediately following fertilization (highly protaminated with some retention of paternally derived histones). Soon after sperm entry, the protamine to histone transition takes place where maternally derived histones replace protamines resulting in the decondensation of the sperm head. The middle panel illustrates the various stages of early embryonic development. The bottom panel shows the methylation changes that occur over time in the maternal and paternal pronucleus, where the paternal pronucleus undergoes active demethylation and the maternal DNA is demethylated passively in a replication-dependent manner. The approximate chronology of major events in the early embryo is outlined along the bottom of the figure and correlates to the illustrations of embryos above. *Figure reprinted from Ref. 444 with permission from Frontiers. Courtesy of Dr Douglas Carrell.*

phase takes place to generate two copies of each chromosome. Thus, there are two distinct pronuclei. Examination of this pronuclear stage has been crucial for human IVF programs, because the large size of the pronucleus allows for rapid identification of fertilized eggs, and on occasion, if required, removal of abnormal polyspermic or triploid embryos (with >2 pronuclei). Following this transient pronuclear stage, the pronuclear envelope disassembles and chromosome condensation reoccurs to set up the first mitotic cleavage division. Despite assembling in a single metaphase plate, the two sets of chromosomes remain separated according to parental origin, and this organization is maintained up to the four-cell stage in mouse embryos. It is speculated that chromatin segregation may be required to accommodate the extensive and distinct reprogramming that occurs in both genomes early in embryogenesis.[442]

Pronuclear formation is dependent upon factors in the egg cytoplasm that accumulate during maturation and require protein synthesis.[443] The male chromatin is organized in a highly compact manner, toroid complex, and is associated with protamines, which are sperm-specific basic proteins that replace the majority of histones during late spermatogenesis (Figure 4.13).[444,445] Prior to becoming a male pronucleus, the sperm nucleus undergoes a multistep reprogramming, which consists of an initial phase of chromatin dispersal, followed by a brief recondensation, and finally a complete decondensation into the male pronucleus. Upon gaining access to the ooplasm, the sperm's nuclear envelope, which lacks a lamin lining and is poreless except on its posterior region, undergoes breakdown. Egg kinases, especially PKC and possibly M-phase associated kinases, are thought to regulate this process, although findings that paternal chromatin decondensation continues unimpeded in the presence of PKC inhibitors and the sperm nucleus can undergo decondensation during interphase suggest participation of additional molecular regulators.[4] The loss of nuclear envelope exposes the sperm head contents to the ooplasm, leading to limited sperm

Vet-ebooks.com

head decondensation, which coincides with reduction of the protamines' disulfide bonds. This relaxation of the toroid complex enables the egg's histones to associate with the sperm DNA, causing the formation of nucleosomes and inducing recondensation of the sperm nucleus. Finally, once the deposition of histones is complete, the paternal chromatin fully expands into the male pronucleus (Figure 4.13),[446] whose formation is also associated with incorporation of other proteins.[445]

The exchange of protamines and histones in the ooplasm is regulated by different mechanisms. The required reduction of disulfide bonds is primarily controlled by the egg's glutathione content, which increases during maturation, and abrogation of this increase prevents sperm chromatin decondensation.[4] The nucleoprotein exchange also involves phosphorylation events[447] as well participation of chaperone proteins. In *Xenopus*, an oocyte-specific acidic protein, nucleoplasmin (NPM), assists both with the removal of protamines and deposition of histones onto the paternal chromatin.[448] The mammalian homologues NPM1, NPM2, and NPM3 are expressed in oocytes, and recent in vitro studies showed that NPM1 and the complex NPM1-3 efficiently promoted sperm nuclear decondensation and nucleosome organization.[447] Earlier studies have shown that mouse oocytes with deletion of NPM2, which is the most abundant isoform, underwent fertilization and sperm nucleus decondensation, although females displayed fertility defects associated with chromatin organization during failed preimplantation development.[449] Thus, in mammals, NPM1 and 3 are likely additional sperm head decondensation factors. Other proteins are likely to contribute to nuclear reprogramming as well, such as the NAP/SET family of proteins, the histone chaperone HIRA[450] and the chromatin remodeling protein CHD1,[451] both of which associate with the histone H3.3 replacement variant in the paternal genome until DNA replication.[452] Given that several of these factors contribute to sperm nucleus remodeling, future studies should ascertain their relative contribution.

The formation of the female pronucleus also requires chromatin decondensation, although this process is simpler, as the DNA remains associated with maternal histones and without a pronuclear envelope. At the time of fertilization, the MII-stage chromatin is condensed from the high levels of CSF activity reigning in the ooplasm, and remains in this condensed state until the completion of meiosis and extrusion of the second polar body. Decondensation and entry into interphase requires a sustained decrease in MPF activity, which is triggered by the oscillations in $Ca^{2+}{}_i$ levels induced by fertilization.[453]

Despite the different pathways involved in chromatin remodeling, the formation of the male and female pronuclear envelopes occurs at approximately the same time. Pronuclear envelope assembly begins at the periphery of decondensing chromatin,[454] and in sea urchins forms by ATP-dependent recruitment of vesicles to chromatin and GTP-dependent processes.[455] The latter studies provide evidence that a lamin B receptor-like protein, an integral membrane protein of the interphase nuclear envelope, mediates targeting of the nuclear envelope precursor vesicles to chromatin.[456] Pronuclei appear to draw on a reserve of egg endoplasmic reticulum to generate the large surface area that each pronucleus requires, which is not surprising given the extensive endoplasmic reticulum that is present in oocytes and zygotes. Remnants of the sperm envelope persist in zygotes at the tip and on the base of the sperm head, and these structures are thought to be important for the assembly of the new male nuclear envelope. These nuclear remnants are rich in sterols, contain polyunsaturated phospholipids, and are enriched in polyphosphoinositides and other phospholipids.[457] In sea urchins, fusion of the nuclear envelope precursors seems to be promoted by vesicles containing PLCγ and polyphosphoinositides that produce diacylglycerol, promoting localized fusion and formation of the pronuclear envelope.[458] In zebrafish, fusion of individual chromatin masses, which are surrounded by nuclear envelope, into a large mononucleus relies on a newly discovered maternal-effect protein named Brambleberry.[459] In mouse zygotes, the ooplasm has strong propensity to form nuclear envelopes around individual chromosomes, resulting in the formation of micronuclei and multinucleated cells, a condition that negatively affects fertility.[460,461] This tendency is prevented by the chromokinesin Kid/kinesin10, a plus-end directed microtubule-based motor with both microtubule and DNA binding domains, which is responsible for compacting chromosomes at the anaphase stage, thereby favoring the formation of large pronuclei.[462] Pronuclear envelope assembly also occurs in the presence of decreasing MAPK activity,[463] and studies suggested that inactivation of MAPK was required for pronuclear formation.[463,464] MAPK inactivation follows the drop in MPF activity by several hours or more, depending on the species. The decrease in MAPK activity and formation of pronuclei are Ca^{2+} dependent and require a greater number of $Ca^{2+}{}_i$ rises than do the decrease in MPF activity and anaphase II onset.[453] In spite of these findings, recent studies performed on individual oocytes where inactivation of MAPK and pronuclear formation were evaluated simultaneously showed that pronuclear formation precedes inactivation of MAPK, and can even occur in the presence of high MAPK activity, suggesting that other factor(s), most likely Ser/Thr protein phosphatases, also play a role in pronuclear assembly.[465]

The pronuclei are far from merely a passive staging area for the two parental genomes prior to assembling the zygotic genome. Both sets of chromatin undergo asynchronous DNA synthesis at the pronuclear stage,

Vet-ebooks.com

generating the 4C amount of DNA required for the ensuing first mitosis.[466] In addition, they undergo changes in DNA methylation, with the paternal genome appearing to experience earlier and "active" demethylation (Figure 4.13 and Chapter 52) that occurs prior to and during DNA replication[467] and is mediated by oxidation of the 5-methylcytosine by the DNA dioxygenase ten-eleven translocation 3 (TET-3);[468,469] but see Ref. 470. In spite of this so-called global demethylation, specific paternal sequences such as those containing paternally imprinted genes, intracisternal A particle elements (IAPs), retrotransposons, and centromeric regions, avoid demethylation and preservation of these marks is important for embryo development.[471] The maternal genome also avoids demethylation at the zygotic stage, an effect that seems mediated by the specific binding of the maternal factor STELLA or DPPA3.[472] The maternal genome, however, experiences passive demethylation over the course of subsequent cleavages.[444,473] Other differences found in the paternal pronucleus include the presence of inherited sperm histones (Figure 4.13), which are significantly enriched at loci of developmental importance,[474,475] higher levels of acetylated histone (H)4,[476] and hypomethylation, which is specifically reflected by lower levels of methylation on H3 at lysine(K)-9 and H4K20me3.[477–479] Further, the histone variant H3.3 is predominantly associated with the paternal genome, and mutation of lysine 27 on H3.3 but not on H3.1 prevents embryo development.[467] Of note, the paternal genome retains binding of the heterochromatin protein 1β HP1β, which is also associated with the maternal genome.[479] Thus, these differences in methylation, acetylation, and histone composition may be the basis for the earlier initiation of transcriptional activity from the male than female pronucleus in the mouse.[478,480,481] The acquisition of transcriptional permissiveness and activation of the zygotic genome, which is first detected approximately at the mid S-phase in mouse zygotes[477,481] and coincides with massive degradation of maternal RNAs,[481] is made possible by multiple maternal factors,[482,483] and requires recruitment of maternal mRNAs[484] and protein synthesis.[485] Activation of the zygotic genome is vital for preimplantation development, as demonstrated by the early developmental arrest caused by the elimination of any of the genes encoding for maternal factors (for recent review, see References 483,486; also see table of maternal effect genes and products in Chapter 2). Other factors important for the regulation of zygotic/early embryonic gene expression are those that control chromatin remodeling and structure and DNA replication. Chromatin remodeling is important to ensure specific patterns of gene expression during early development, as demonstrated by the finding that mutation or elimination of remodeling or transcription factors such as BRG1, a homologue of the brahma protein of *Drosophila*, or transcriptional intermediary factor 1α, TIF1α, cause early cleavage arrest.[487,488] The role of DNA replication was elucidated in studies that showed that while inhibition of the first or second round of DNA replication did not prevent activation of the zygotic genome, it reduced expression of genes transiently expressed during the two-cell stage and reduced BrUTP incorporation (RNA production), respectively, suggesting that it is required to impose the repressive chromatin state during the few embryonic cleavages.[489,490]

While some of these molecular events are underway, the two pronuclei migrate toward each other to become apposed prior to lining up for the first mitosis. Actin microfilaments and microtubules are required for pronuclear apposition in sea urchin and mouse eggs,[352,491] although in humans and other large domestic animals, pronuclear migration and apposition relies exclusively on microtubules.[492] The molecular mechanism by which the cytoskeleton actually translocates these relatively large pronuclei, compared to other organelles, a distance of 50–100 μm from opposite directions, remains to be established. However, it is likely to involve cytoplasmic, microtubule-associated motor proteins found in eggs.[493]

The pronuclear stage ends when MPF levels rise again, resulting in nuclear envelope breakdown and chromosome condensation. While CDK1 is responsible for phosphorylation of the lamin A/C proteins that results in nuclear/pronuclear envelop breakdown, recent studies have shown that inhibition of poly(ADP-ribosylation), a process that involves transferring negatively charged poly ADP ribose polymers to proteins, causes zygote arrest at the pronuclear envelope breakdown stage, suggesting that poly(ADP-ribosylation) may contribute to the regulation of this process; the precise role of poly(ADP-ribosylation) in pronuclear envelope breakdown remains to be determined.[494] With meiosis completed, the duplicated chromosomes line up for the first mitotic cleavage. In contrast to the previous meiotic divisions, the spindle is centrally placed, resulting, after first cleavage, in two blastomeres of similar size. An F-actin cloud-like structure that surrounds the anastral spindle, and possibly the lack of MAP kinase activity at this stage, are responsible for the central location of the first mitotic spindle.[495]

Other Cytoplasmic Events

The recruitment of maternal mRNAs is another event of egg activation, and translated products are known to contribute to several zygote functions, including conferring transcriptional competence that underlies the activation of the zygotic genome.[483,484] Other proteins that accumulate in mouse zygotes are those associated with

Vet-ebooks.com

protein synthesis[496] and degradation,[497] especially components of the ubiquitination pathway and the proteasome, which may assist with the degradation of maternal proteins that occurs soon after fertilization.[496] The molecular mechanism(s) whereby maternal mRNAs are recruited for translation after fertilization remains unknown, although increases in $Ca^{2+}{}_i$ as well as cell cycle progression are necessary, unlike CaMKII activity that seems dispensable.[434,453] Despite recent progress in the recognition of proteins produced at this stage,[4,498] the identity of most translated zygotic proteins remain unknown, and their contribution to the activation of embryonic genome and preimplantation development needs to be ascertained.

The aforementioned degradation of mRNAs that occurs during maturation and post fertilization[499] is also vital for activation of the zygotic genome.[498] The decapping complex proteins DCP1A and 2, which are maternal products, assist in this process, and reduction of their levels reduces activation of the zygotic genome.[498] Micro RNAs are also associated with message degradation, but they are inactivated in oocytes and embryos.[500]

In many organisms, the polarity of the unfertilized egg, i.e., the orientation of the axis that runs through the animal pole, corresponding to the spindle region and the vegetal pole, the animal–vegetal (A–V) axis, provides positional cues for the organization of the body pattern of the early

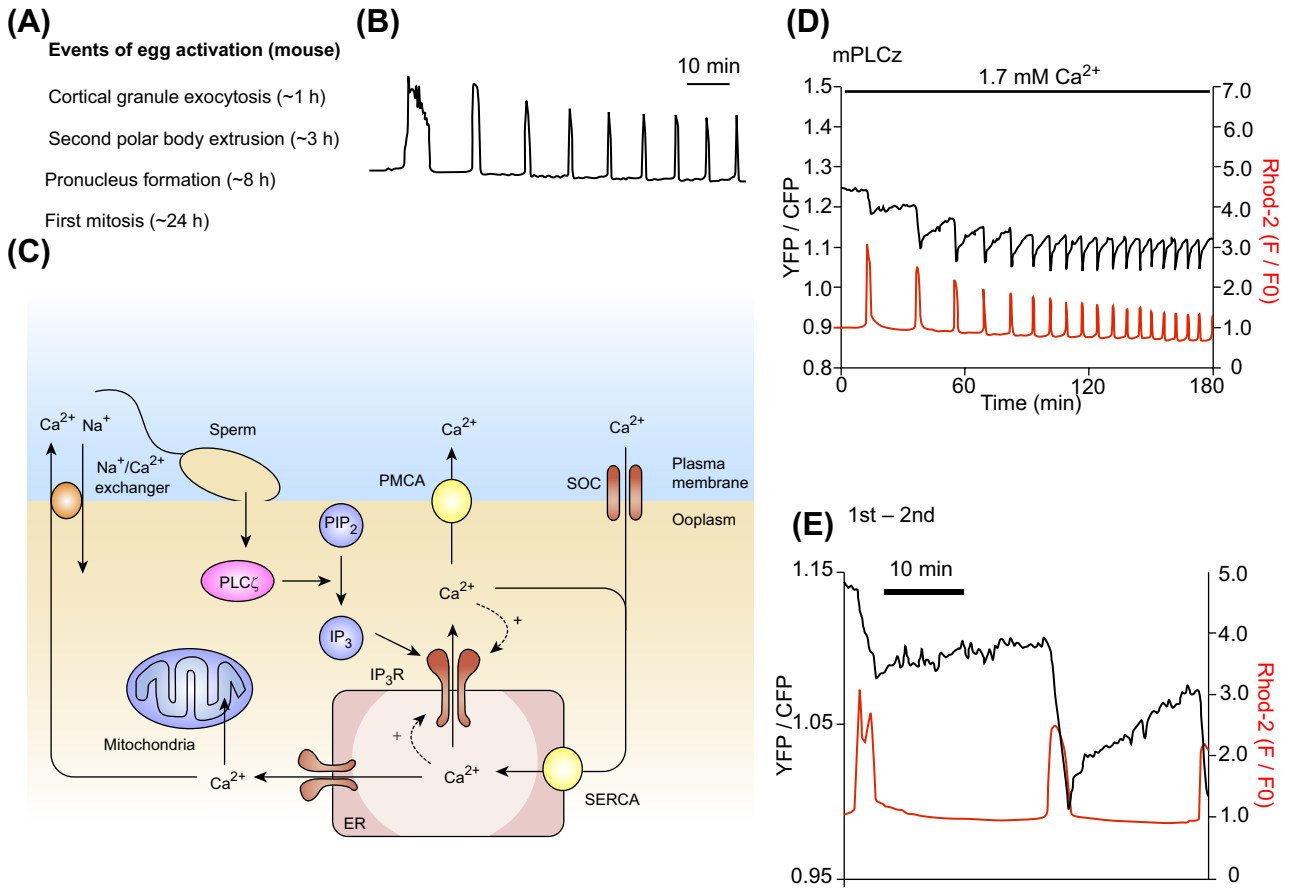

FIGURE 4.14 Temporal course of activation events in mouse eggs with a characteristic Ca^{2+} response and candidate molecules involved in the initiation oscillations and in Ca^{2+} homeostasis. This figure is reproduced in color in the color plate section. (A) Main cellular events of egg activation after sperm entry and approximate time in hours (h) required for their completion. (B) A typical pattern of $Ca^{2+}{}_i$ oscillations associated with fertilization or with injection of PLCζ cRNA. Note that recordings were terminated prematurely. (C) Upon fusion, the sperm is thought to deliver phospholipase C (PLC) ζ, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol 1,4,5-trisphospahte (IP_3) and diacylglycerol (DAG). IP_3 binds its receptor, IP_3R1, causing Ca^{2+} release out of the endoplasmic reticulum (ER). Following Ca^{2+} release, basal $Ca^{2+}{}_i$ levels are regulated by the combined action of the sarcoendoplasmic reticulum Ca^{2+} ATPase (SERCA), plasma membrane Ca^{2+} pump (PMCA), Na/Ca^{2+} exchanger, and mitochondria. Store operated Ca^{2+} channels (SOC) or other Ca^{2+} channels are proposed to mediate Ca^{2+} influx, which is required to fill the ER and maintain oscillations. Broken lines suggest feedback action of Ca^{2+} on IP_3R1. *(Adapted from Ref. 507 with permission of CSHLP.)* (D) $Ca^{2+}{}_{ER}$ and $Ca^{2+}{}_i$ undergo simultaneous but opposite changes in concentration during oscillations in mouse MII eggs. $Ca^{2+}{}_i$ responses were induced by injection of 0.05 μg/μl mouse PLCζ cRNA into MII eggs. In vitro transcribed D1ER cRNA was injected into eggs 5h before the initiation of $Ca^{2+}{}_i$ measurements. The emission ratio of D1ER (YFP/CFP) was used to estimate relative changes in $[Ca^{2+}]_{ER}$ (left axis, black trace). $[Ca^{2+}]_i$ (right axis, red trace) was recorded using Rhod-2. (E) The first and second $Ca^{2+}{}_i$ rises do not elicit significant refilling of the ER, but subsequent rises, especially after ~ the sixth rise do (D). *Adapted from Ref. 508 with permission from The Company of Biologists.*

embryo.[501] Other positional determinants have been suggested in mammals such as the point of sperm entry[502] or the plane of first cleavage, which is defined by the second polar body and the sperm point of entry.[503] Nevertheless, equally significant literature contradicts these findings.[504,505] Therefore, whereas bias in the pattern and lineage contribution in early cleavage stage mammalian embryos is observed after the two-cell stage,[506] the emerging notion is that mammalian embryos are developmentally flexible and that patterning driven by differential intrinsic concentration of molecules is not and does not need to be established by the egg or zygote.[504,506]

SIGNALING PATHWAYS RESPONSIBLE FOR THE EVENTS OF EGG ACTIVATION

Ca^{2+} is the Predominant Messenger of Activation

Over the last decades, steady progress has been made in elucidating the underlying pathways of egg activation, although mechanistic details remain to be worked out in all animal and plant systems. A universal step in the signaling cascade leading to egg activation is the increase in the intra-oocyte/egg levels of free Ca^{2+}_i, which initiates a multitude of cellular responses, including the previously described events of egg activation that render eggs into zygotes and meiotic cells into mitotic blastomeres (Figure 4.10; Figure 4.14 (A) and (B)).[509] Work by Loeb and colleagues at the end of the nineteenth century associated egg activation with changes in the intracellular concentration of several ions, as egg activation and initiation of development in sea urchin eggs was accomplished by varying the concentration and composition of the fertilizing medium.[510] Nevertheless, a few decades later concrete evidence started to emerge regarding the role of Ca^{2+} in fertilization. Ca^{2+} signaling is important for many cellular processes,[511,512] and many of the parameters that make it such a widespread signaling mechanism have been worked out in somatic cells. Significant for its function is the steep gradient between its intracellular and extracellular concentrations, 10,000 to 100,000-fold greater concentrations in the extracellular milieu, and the energy-dependent mechanisms that cells use to restore Ca^{2+}_i levels to ~100 nM, which is the basal level in most cells.[511] In eggs, the activating Ca^{2+} signal is generally associated with sperm–egg interaction/fusion, which occurs at different stages of meiosis depending on the species,[513] although in insects, where fertilization is dissociated from activation and where embryos can develop parthenogenetically, the presumed Ca^{2+}_i increase is thought to be induced by mechanical stimulation during ovulation/oviductal transport.[514,515] Therefore, regardless of the mode in which Ca^{2+}_i is increased in oocytes and eggs, Ca^{2+} signaling is thought to drive the majority of the events of egg activation with the possible exception of the initial decondensation of sperm chromatin. For an updated and comprehensive review of the signaling pathways associated with Ca^{2+} release during fertilization in a number of model species, please refer to a special issue of *Cell Calcium* "Ca^{2+} signaling and ionic homeostasis in gamete maturation and function".[516]

The role of Ca^{2+} ions as the pivotal change responsible for driving all events of egg activation was established by studies where the calcium ionophore A23187, a reagent capable of mobilizing Ca^{2+}, was used to activate sea urchin eggs as well as eggs from other invertebrates and vertebrates species.[517] These studies also showed that most of the Ca^{2+} required for egg activation was from intracellular stores, as activation was unaffected by the absence of extracellular Ca^{2+}.[518] Follow-up studies focused on determining the spatial and temporal characteristics of the activating Ca^{2+} signal. Using the then recently synthesized luminescent protein aequorin, explosive Ca^{2+}_i rises were detected following fertilization or addition of Ca^{2+} ionophore in medaka fish eggs.[519] Subsequent studies showed that the Ca^{2+}_i rise propagated as a wave starting from the point of the sperm entry,[520] an observation that was later extended to several other species, including mammals.[513,521]

Unlike the single Ca^{2+}_i increases detected in fertilized sea urchin and medaka eggs, measurements of Ca^{2+}_i changes in mammals revealed that their eggs displayed repeated Ca^{2+}_i responses, also known as oscillations.[522] Ca^{2+}_i oscillations were subsequently reported in non-mammalian species, although the duration in these species rarely exceeded 30 min, whereas in mammals they last for many hours.[513] These oscillations are required for egg activation, as their abrogation, which can be accomplished by a Ca^{2+} chelator such as BAPTA, prevents egg activation and thwarts the initiation of development in mouse zygotes.[523] In mammals, the first Ca^{2+}_i rise is of greater magnitude and duration than subsequent ones, which are mostly uniform, last approximately 1 min and occur at intervals between 10 and 40 min according to the species[507,521,524] (Figure 4.14(A) and (B)). Information is apparently encoded in the number of Ca^{2+}_i rises, as different egg activation events require different numbers of oscillations for their initiation, and, for most events, more rises are required for their completion than for their initiation.[453] Changing the Ca^{2+}_i oscillation parameters also alters the extent of parthenogenetic mammalian development.[359,525] These periodic Ca^{2+}_i increases generate nearly synchronous oscillations of activity of the kinase CaMKII,[526] which regulates the resumption of meiosis, as previously discussed (Figure 4.12, left panel). It is worth noting that the Ca^{2+}_i rises induced by fertilization cause coordinated cytoplasmic contractions that can be detected by advanced imaging technology,[521] providing a noninvasive method to assess in real time the presence and frequency of oscillations; analysis of

Vet-ebooks.com

these cytoplasmic contractions has been successfully used to predict the developmental competence of mouse zygotes.[527] Also associated with sperm-initiated Ca^{2+}_i oscillations, and especially with the first few rises, is extrusion of intracellular zinc into the extracellular milieu, which lowers the levels of zinc in the ooplasm. This extrusion can be visualized with fluorescent dyes and is generically termed as zinc sparks. Zinc sparks, which also occur around the time of cortical granule exocytosis (Figure 4.10), are thought to facilitate the resumption and completion of meiosis following fertilization.[528]

The universal and indispensable role of Ca^{2+} release for egg activation[513] as well as the diverse temporospatial configuration in which the responses are deployed, provoked interest in understanding the underlying mechanisms responsible for their initiation and regulation. Several hypotheses have been put forth, including sperm–egg contact or receptor-mediated activation and various fusion models, invoking the addition of sperm membrane ion channels, or the passage of Ca^{2+} from the sperm into the egg, or the release of a sperm-signaling protein (for reviews see References 4, 529, 530). Although initially it was thought that a single mechanism could underlie initiation of Ca^{2+} signaling in all species, it became apparent that this was not the case, and the more accepted view is that signaling mechanisms have been adapted according to the species' Ca^{2+}_i profile of egg activation. Therefore, in species that display single Ca^{2+}_i rises, i.e., *Xenopus* and sea urchin, signals emanating at the site of interaction between sperm and egg initiate the signaling cascade,[530,531] whereas in species that rely on protracted Ca^{2+}_i signaling such as mammals, the initiation depends on the release of a sperm-signaling molecule, most commonly known as the "sperm factor" into the ooplasm.[532] For more details and supporting data on these hypotheses, see specific reviews on the subject.[533–535]

IP_3, IP_3R, and Other Components of the Ca^{2+} Tool Kit

1,4,5-Inositol trisphosphate (IP_3)-mediated Ca^{2+} release from the endoplasmic reticulum (ER), the main cellular Ca^{2+} reservoir, is associated with Ca^{2+} release and cellular events in myriad cell types (reviewed in References 512, 536) (Figure 4.14(C)). It is also primarily responsible for the initial Ca^{2+}_i wave and oscillations during fertilization in most species studied to date.[522,537] Its cognate receptor, IP_3R, is the main intracellular Ca^{2+} release channel in nonmuscle cells and is appropriately located in the ER. The ER and IP_3Rs undergo reorganization during oocyte maturation,[538,539] and by the MII stage, IP_3Rs are organized in cortical clusters, near the entry point of the sperm, which is the site from where the first Ca^{2+}_i wave is initiated. Abnormal ER reorganization at the end of maturation affects Ca^{2+}_{ER} content and the ability to initiate persistent oscillations, as recently demonstrated in oocytes deficient in the maternal effect protein Mater.[540]

The suggestion that IP_3 may play a role during fertilization arose from studies in sea urchin and amphibian eggs where an increase in phosphoinositide metabolism was associated with fertilization,[541,542] an observation that was soon followed by the demonstration that injection of IP_3 triggered Ca^{2+}_i release.[541] IP_3 production requires phosphatidylinositol-4,5-bisphosphate (PIP2) hydrolysis by a PLC,[544] and injection of antibodies against PIP2 in *Xenopus* eggs inhibited the sperm-initiated Ca^{2+}_i wave, suggesting that this sequence of events is conserved in fertilization.[545] Measuring IP_3 changes during mammalian fertilization has proven difficult due to the small size of eggs and asynchrony of fertilization, although an increase in intrazygote concentrations of IP_3 has been observed during Ca^{2+}_i oscillations using fluorescence resonance energy transfer (FRET) technology.[546] In addition, injection of IP_3 and guanine nucleotides into mammalian eggs initiated Ca^{2+} release from intracellular stores,[547] albeit of short duration, but injection of a nonhydrolyzable analogue of IP_3 such as adenophostin A[548] or repeated release of caged IP_3 generated long-lasting Ca^{2+}_i responses and triggered all events of egg activation.[549] Another channel thought to participate in Ca^{2+} release during fertilization is the ryanodine receptor (RyR), the main Ca^{2+} channel of muscle cells, which is also expressed in oocytes and eggs of vertebrate and nonvertebrate species.[550,553] Despite studies reporting Ca^{2+}_i responses induced by RyR agonists in mammalian eggs, their role remains largely undefined and is likely minor, as inhibitors of these channels have no effect on egg activation.[550,554]

The overwhelming evidence for the phosphoinositide pathway in mammalian fertilization led to the search for expression of IP_3Rs in oocytes and eggs. The IP_3R is a large protein with distinct domains, which functions as a tetramer.[555] There are three IP_3R isoforms,[512] and mammalian oocytes and eggs and their surrounding cells express all isoforms,[556,557] although the type I IP_3R isoform is overwhelmingly the most commonly expressed version.[556,558,559] Besides IP_3, gating of IP_3R1 requires Ca^{2+}, although at high concentrations Ca^{2+} inhibits the channel's conductivity,[560,561] and this biphasic regulation of IP_3R1 makes it especially suited to mediate oscillations. The function of IP_3R1 is enhanced during oocyte maturation by its increase in concentration, its own phosphorylation, redistribution to the cortex, and increased levels of Ca^{2+} in ER, all of which optimize Ca^{2+} release at the time of fertilization.[507,562] As oscillations persist after sperm entry, IP_3R1 undergoes protracted degradation, which is solely induced by the production of IP_3, whose persistent production is required to underlie the

Vet-ebooks.com

oscillations.[559] Lastly, the essential role of IP_3R1 in mammalian fertilization was also demonstrated by injection of a functional blocking antibody, which blocked both initiation of Ca^{2+}_i oscillations[537] and egg activation.[563] Subsequent studies confirmed the role of IP_3R1 in fertilization in other species.[564–568]

For long-lasting oscillations to unfold, besides IP_3 production, Ca^{2+}_i levels must be returned to baseline after each Ca^{2+}_i rise and stores refilled (Figure 4.14(D)) as oscillations cease prematurely without external Ca^{2+}.[569,570] Cells use a variety of mechanisms to maintain basal Ca^{2+}_i levels, including sarcoendoplasmic reticulum Ca^{2+} ATPases (SERCAs), which uptake Ca^{2+} into the ER, plasma membrane (PM) Ca^{2+} ATPases (PMCAs), and Na^+/Ca^{2+} exchangers, which extrude/exchange Ca^{2+} out of the cell (Figure 4.14(C)).[512,571] These mechanisms are functional in mammalian eggs,[507] as revealed by pharmacological inhibition of SERCAs or PMCAs, which profoundly alter and/or terminate oscillations,[507,572,573] by the recent demonstration of SERCA1B protein expression in these cells,[507] and by the transient effects on Ca^{2+}_i responses caused by culturing eggs in Na^+-free conditions.[574] Because only a fraction of Ca^{2+} from each Ca^{2+}_i rise is returned to the ER during oscillations in mammalian eggs,[508] internal stores must be refilled to maintain oscillations. Somatic cells as well as oocytes and eggs use a variety of plasma membrane channels to influx Ca^{2+},[507,573] but which of these channels operates in mammalian eggs remains unknown. Unlike fertilization in sea urchins,[575] the changes in membrane potential during mammalian fertilization are negligible, which likely limits the role of voltage-gated channels during this process. More recently, mammalian oocytes and eggs have been shown to express components of the store-operated Ca^{2+} entry (SOCE) mechanism,[576] stromal interaction molecule 1 (STIM1)[577,578] and ORAI1.[579,580] SOCE is based on the notion that stores refill following their depletion, and this function relies on a Ca^{2+} sensor in the ER, STIM1, which when Ca^{2+} in the stores falls below a certain threshold, it engages ORAI1 in the plasma membrane, which mediates Ca^{2+} influx. Functional studies show that depletion of the Ca^{2+} stores occurs during sperm-initiated oscillations (Figure 4.14(D)) or after inhibition of SERCA by pharmacological methods, both of which induce Ca^{2+} influx.[508,581] Nevertheless, the role of SOCE in mammalian fertilization needs to be further investigated, as while its inactivation precluded oscillations in porcine oocytes,[582] it was without effect in mouse eggs.[573,583] Other channels that might contribute to Ca^{2+} influx in mammalian eggs are the transient receptor potential (TRP) ion channels, which are widely expressed, nonselective cation channels[584] for which transcripts have been found in mammalian oocytes.[585,586] Their contribution to Ca^{2+} homeostasis in mammalian oocytes and eggs, however, remains to be demonstrated, although a member of the vanilloid family of TRP channels, TRPV3, is expressed in mouse oocytes during the late stages of maturation.[587] Genetic deletion of TRPV3 did not modify sperm-initiated oscillations but abolished $SrCl_2$ influx and egg activation associated with exposure to this commonly used parthenogenetic agent;[587] a more formal role in sperm-induced oscillations cannot be discounted for other members of the TRP-family of ion channels. Elucidating the channels that underlie influx in oocytes and eggs will have broad implications, as this knowledge might be applied to parthenogenetic activation, enhancing developmental competence and contraception.

Egg Phospholipase C and SRC Family Kinases

The involvement of IP_3, IP_3R, and diacylglycerol (DAG) in the events of egg activation implied the participation of PLCs. Besides being involved in the production of IP_3 and DAG, PLCs are a large family of enzymes that are capable of responding to a variety of stimuli, as they can be activated by interacting with plasma membrane receptors, either guanine nucleotide-binding protein (G-protein)-coupled-receptors or tyrosine kinase receptors, or by other means.[544,588] Transcripts for nearly all members of each of the PLC families have been detected in mammalian eggs,[589] and protein expression has been demonstrated for a few isoforms.[533,590,591] Evidence for their functional presence in eggs was initially gathered from pharmacological studies, as injection of GTP-γS and activation of trimeric G proteins resulted in Ca^{2+}_i transients, whereas GDP-βS, a nonhydrolyzable GDP analogue that inhibits G-protein function, prevented sperm-induced Ca^{2+}_i oscillations.[547,592] Expression of exogenous m1 muscarinic receptor followed by addition of its ligand acetylcholine[593] led to oscillations and events of egg activation, confirming the presence of target PLC(s) and the G-protein-signaling machinery in eggs. Nevertheless, other studies do not support a role for G-protein-coupled receptors, including those using ADP-ribosyltransferase exotoxins such as cholera toxin, an activator of Gs function, and pertussis toxin, an antagonist of Gi, both of which failed to prevent egg activation.[547,593,594] The role of the Gq-protein family members, Gq, G11, G14, and G15,[595] which are insensitive to the mentioned exotoxins but are capable of activating PLCβ isoforms,[596,597] was also examined. Despite expression of Gq and G11 in mouse eggs, their inhibition failed to modify fertilization-induced Ca^{2+}_i oscillations.[598] Intriguingly, deletion of PLC-β1 and PLC-β3 genes[533,599] resulted in female infertility, although follow-up studies including oocyte-specific downregulation of PLC-β1 did not eliminate Ca^{2+}_i

Vet-ebooks.com

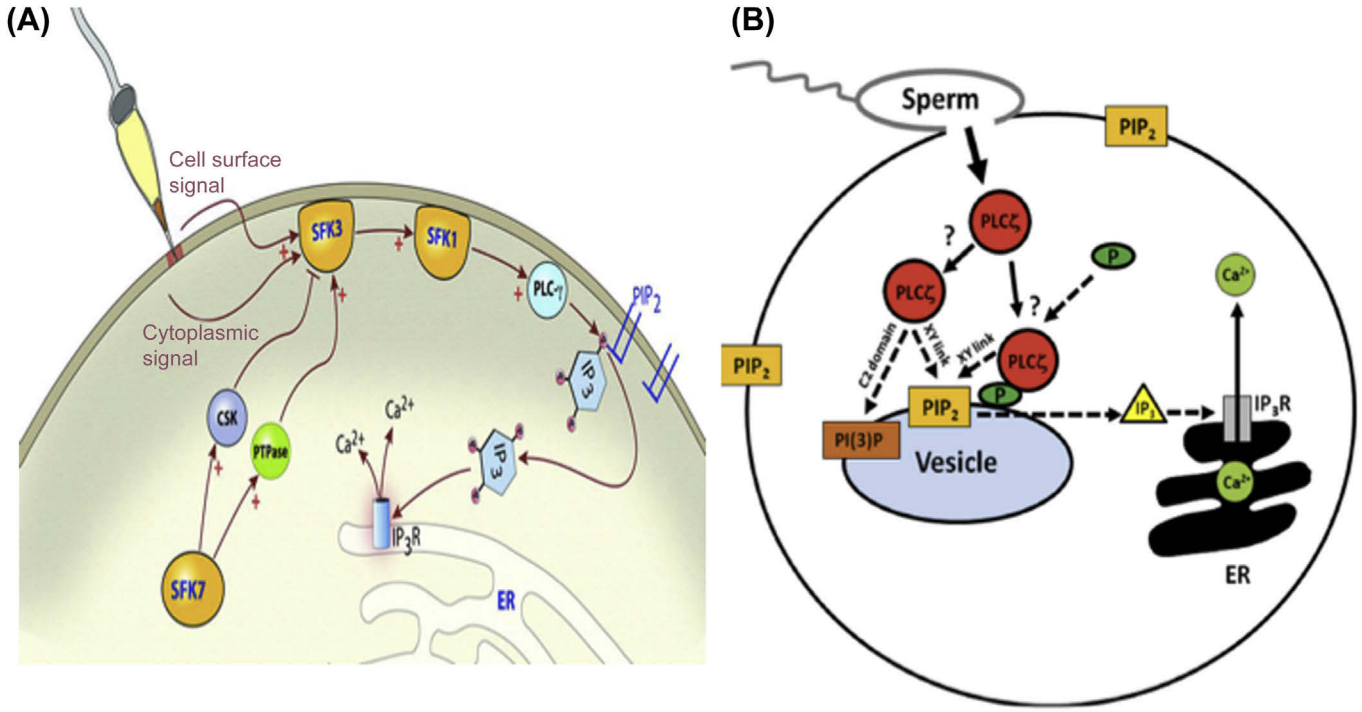

FIGURE 4.15 Model for initiation of Ca2+ signaling at fertilization in echinoderm and mammalian eggs. (A) In echinoderms, the initial signal leads to activation of a Src family kinase 3, SFK3, which binds and activates SFK1 that in turn activates PLCγ. This is followed by production of IP_3 and $Ca^{2+}{}_i$ release, which activates multiple aspects of oocyte function. New data suggest that this pathway could be regulated in several ways. SFK7 could affect calcium release either via phosphorylation of CSK, a negative regulator of SFK3, or via a hypothesized phosphatase that would activate SFK3. *(Adapted from Ref. 604 with permission of John Wiley & Sons. Courtesy of Dr William Kinsey.)* (B) Hypothetical mechanism of PLCζ domain regulation of function based on studies on sperm PLCζ. After sperm–egg fusion, PLCζ diffuses from the sperm head into the egg cytosol and targets a distinct intracellular vesicular PIP_2-containing membrane. The EF hand domains of PLCζ confer its high Ca^{2+} sensitivity, enabling the enzyme to be active at resting $Ca^{2+}{}_i$ levels (nM) in the egg. Association of PLCζ with its specific membrane target may be mediated by interaction of the C2 domain with either PI(3)P and/or an unidentified egg membrane-targeting protein (P). The positively charged amino acids in the XY-linker region (XY link) further assist the anchoring of PLCζ to the membrane, thus enhancing the local PIP_2 concentration adjacent to the catalytic domain via electrostatic interactions with the negatively charged PIP_2. Once PLCζ is associated with the membrane PIP_2 the catalytic X/Y barrel binds and hydrolyzes its substrate to produce IP_3 that in turn induces Ca^{2+} release from the ER. *(Adapted from Ref. 529 with permission of John Wiley & Sons. Courtesy of Dr Karl Swann.)*

oscillations,[589] which is consistent with results demonstrating that the infertility of PLCβ1 knockout female mice is mostly associated with implantation defects.[600] PLCβ isoforms can also be activated by monomeric small GTP-binding proteins such as RHO GTPases, which although present in mouse eggs, seem to participate in sperm incorporation rather than in the generation of oscillations.[354]

PLCγs are downstream of tyrosine kinase receptors and are expressed in mouse eggs.[590,601] A burst of protein tyrosine kinase activity accompanies fertilization in sea urchin and *Xenopus* eggs, and PLCγ is among the phosphorylated targets in these eggs[602,603] (Figure 4.15(A)). Consistent with these results, inhibition of PLCγ activity by expression of own SH2 domains delayed or prevented fertilization-induced Ca^{2+} release in sea urchin and ascidian eggs,[604] but not in *Xenopus* or mouse eggs.[566,601] Nevertheless, the role of PLCγ is indispensable for Ca^{2+} release and fertilization in *Xenopus*,[601] suggesting that in this species the enzyme might have a different mechanism of activation, which is consistent with the recently reported role of phosphatidic acid during *Xenopus* fertilization.[605] Conversely, inhibition of PLCγ in mouse eggs either by pharmacological[606] or dominant negative constructs against nonreceptor SRC family kinases (SFKs), the upstream activator of PLCγs, did not prevent oscillations,[607] suggesting that this pathway does not contribute to the initiation of the sperm-induced $Ca^{2+}{}_i$ responses in the mouse and possibly all mammals. It is noteworthy that mouse oocytes and eggs abundantly express several protein tyrosine kinases such as the SFKs FYN and YES, FAK kinases as well as FER,[604,607] and injection of recombinant c-FYN-induced mouse egg activation, although evidence that it does by causing Ca^{2+} release has not been shown.[608,609] Therefore, the expression and presence of PLCγs, SFKs, and FAK suggests important roles for these pathways in oocyte maturation and fertilization in mammals, although the effects in these species seem more a consequence of their role in actin and cortical

Vet-ebooks.com

organization than in the regulation of Ca^{2+} release and oscillations.[604,610]

Sperm Phospholipase C

The inability of egg PLCs to replicate sperm-initiated oscillations,[592,611] the evidence that sperm–oolemma interactions are brief,[6] and the demonstration that oscillations start seconds after fusion of the gametes[612,613] raised the prospect that an alternative mechanism(s) might underlie oscillations in mammalian eggs. Prompted by the studies of Dale and colleagues, one of the mechanisms examined was that a sperm-derived product, the sperm factor (SF), might cause oscillations. Toward this end, observations first in sea urchins and then in ascidian eggs reported that injection of sperm extracts caused plasma membrane currents similar to those observed in fertilization,[614,615] although more recent studies cast doubts on the role for a sperm factor in sea urchin fertilization.[616] More convincingly, injections of mammalian sperm extracts into mouse, rabbit, and hamster eggs induced oscillations highly similar to those of fertilization as well as caused egg activation.[617,618] Subsequent studies extended these results by demonstrating that sperm extracts initiated oscillations in eggs of other mammalian and nonmammalian species.[532,619,620] Additional evidence for a sperm-based factor came from clinical studies, as ICSI, which bypassed any interaction of the gametes' membranes, produced offspring in humans.[621] Later, it was shown that fertilization by ICSI initiated fertilization-like oscillations in eggs of numerous mammalian species.[622–624] This sperm activity is associated with demembranated sperm heads, as it was present after light sonication and it was lost after residence in the ooplasm.[625,626] Function-blocking antibodies to IP_3R1 inhibited sperm extract-induced oscillations, indicating that it acts upstream of IP_3R1.[627] These studies consolidated the concept that a sperm component participates in the initiation of oscillations, although the active principle remained unknown.

Several small molecules and proteins were proposed as the active candidate(s) in the sperm extracts,[533,628,629] although earlier studies have shown that the Ca^{2+}-inducing activity was dependent upon a protein component(s).[617,618] Injection of the candidate factors caused egg activation in some studies, but without exception they failed to initiate sperm-like $Ca^{2+}{}_i$ oscillations, a result that undermined their proposed role.[533,629] This was in contrast to the significant PLC activity displayed by mammalian sperm extracts in in vitro assays.[630,631] Importantly, this activity was highly sensitive to Ca^{2+},[632] which implied that the putative PLC(s) should be active at the reigning basal $Ca^{2+}{}_i$ levels of approximately 100 nM Ca^{2+}; this is in contrast to most other PLCs that require $Ca^{2+}{}_i$ levels of approximately 1 mM,[544,633] which are not compatible with MII arrest. Not surprisingly, injection of recombinant proteins representing most of the known isoforms expressed in sperm[631,634,635] failed to initiate oscillations in mouse eggs[635] or did so at nonphysiological concentrations,[636] which suggested that the PLC(s) in sperm extracts must contain especial properties.

A novel sperm-specific PLCζ[637] was identified in a homology screen of mouse testis – expressed sequence tags. Results from this and other subsequent studies point at this molecule as the sperm's Ca^{2+} active component (Figure 4.15(B)), as PLCζ is present almost exclusively in active fractions of sperm extracts,[637,638] its removal by specific antibodies abrogates their activity,[637,639] injection of PLCζ cRNAs induced sperm-like oscillations in mouse, rat, human, bovine, porcine, and equine eggs;[535] injection of recombinant PLCζs in mouse or human eggs induced similar responses.[529,640–642] Further, in vitro PLC assays with recombinant PLCζ confirmed the enzyme's high sensitivity to Ca^{2+},[641] and its accumulation in the postacrosomal area of mouse sperm[640] and in the equatorial area of bull and human sperm,[643,644] which at the time of gamete fusion are the regions to first come in contact with the ooplasm, respectively,[645] reinforced the hypothesis of PLCζ as the initiator of oscillations. In this context, lower PLCζ expression should compromise fertility. Although this association has not yet been examined using knockout models due to abrogation of spermatogenesis caused by deletion of PLCζ, a knockdown approach using transgenic RNAi produced males whose sperm displayed reduced $Ca^{2+}{}_i$ oscillatory activity and produced smaller litters.[646] More significantly, the sperm of human patients that repeatedly fail to fertilize after ICSI, besides being incapable of initiating $Ca^{2+}{}_i$ responses when injected into mouse eggs, also display severely reduced or absent expression of PLCζ,[643] and point mutations in the catalytic regions of the molecule that inactivate the enzyme have been found in other infertile males.[647] Patients with globozoospermia, an affliction characterized by round-headed, acrosomeless sperm that repeatedly fail ICSI and have low PLCζ expression, have their infertility overcome by artificial activation.[648,649] These results suggest that the impediment to fertility in these patients is most likely their inability to induce egg activation because of abnormal expression of PLCζ. Of note, recent studies have shown that these patients and a mouse model of the disease have deletions or lack expression of the Dpy19l2 gene, which encodes for a novel inner nuclear membrane protein whose presence is required for anchoring the acrosome to the nucleus and for the organization of the perinuclear theca, the site of storage of PLCζ in the sperm.[650,651]

The structure of PLCζ is similar to that of other PLCs in that it has a domain-based structure with two pairs of EF-hand domains, X and Y catalytic regions, which are the active sites of the enzyme, and a C2 domain.

Vet-ebooks.com

Prominently, it lacks a pleckstrin homology domain, which makes it soluble, and other regulatory domains present in other PLC family members, and therefore its regulation is presently not well known.[529,637] Nevertheless, PLCζ is more than 20 times more effective at inducing oscillations in eggs than PLCδ, its closest relative,[641] and this is possibly due to its high Ca^{2+} sensitivity, which is conferred by the first pair of EF-hand domain, as its deletion greatly decreases PLCζ EC50 for Ca^{2+}.[633,652] Another unique feature of PLCζ is its longer and more basic linker domain,[637] which is the region joining the X and Y domains. It is thought that this domain together with the C2 domain contribute to the localization of PLCζ in the egg, which is uniformly distributed in the ooplasm.[653,654] These domains via electrostatic and/or low affinity interaction with membrane phospholipids are thought to target PLCζ to internal sites and/or vesicles whose membranes are enriched in PiP2, the enzyme's substrate (Figure 4.15(B)). Therefore, several features of PLCζ makes it uniquely qualified to be the trigger of oscillations in mammalian eggs and possibly in other vertebrate species.[655] Nevertheless, future studies should establish the mechanism(s) that limit the function of this enzyme in sperm, and the mechanism(s) regulating its function and localization in the egg, as answers to these questions may have applications in both overcoming infertility and developing novel contraception methods in humans and animals alike.

CONCLUSION

This chapter highlights progress in our understanding of the complex process of mammalian fertilization. We have focused on the cellular and molecular events associated with gamete interaction, sperm–egg fusion, and the activation of development. Since the third edition of this series in 2006, some of these topics are better understood. The understanding that CATSPER is a ligand-gated channel and a target for oviduct factors, including progesterone, clarifies a number of issues and points to a potential mechanism for the control of sperm motility during capacitation. The discovery of ovastacin opens new avenues for the examination of the ZP block to polyspermy.

In contrast, a number of unresolved questions remain and are targets for future studies. A partial list of these unanswered questions is as follows. We do not understand how the oviduct capacitates, and possibly selects, sperm. In particular, the environment within the oviduct is not understood in detail, despite the essential role of that environment in supporting capacitation, fertilization, and the first days of embryonic development. The early events of sperm–egg interaction, from entry into the cumulus matrix to association with the ZP, have not been resolved completely. It is understood that sperm IZUMO and egg CD9 are essential for gamete fusion, but the specific roles of these proteins and their interacting partners have not yet been revealed. Ovastacin permits a detailed study of the molecular and biophysical events of the ZP block to polyspermy, but events of the plasma membrane-level block remain elusive. We understand that in mammalian eggs, as in the eggs of other taxa, Ca^{2+} responses are required for the activation of development, and key regulators such as PLCζ and IP3R1 have been identified, but we have an incomplete vision of how those Ca^{2+} oscillations are sculpted and interpreted. Important proteins, such as EMI2, have been identified, but questions remain about the regulation of its stability and of how it, and other components, that control the imposition and release of MII arrest. Finally, the events of sperm nuclear decondensation and the epigenetic remodeling of chromatin are key unresolved issues. We anticipate that these and other aspects of fertilization may be understood in greater detail when the fifth edition of this series appears.

ADDENDUM

Candidate Egg Proteins for Binding and Fusion

The sperm's IZUMO1 binding partner(s) in the egg plasma membrane and its mechanism(s) of action during mammalian fertilization remain unknown. A recent manuscript by Bianchi et al.[656] shows that the folate receptor 4 (FOLR4) is the required egg receptor for IZUMO1. FOLR4 does not bind folate and given its expression in eggs and role in fertility, it is proposed to be renamed JUNO, after the Roman goddess of fertility and marriage. JUNO's cellular distribution and participation in fertilization suggests that it is the long sought-after binding partner for IZUMO1. (1) JUNO is a GPI-anchored protein expressed on the surface of mouse eggs, which is consistent with the requirement for these types of proteins for gamete fusion during mammalian fertilization. (2) Anti-JUNO antibodies prevented fertilization in in vitro trials. (3) JUNO -/- females but not males are sterile. (4) JUNO is rapidly shed from the plasma membrane after fertilization, a finding that suggests participation on the membrane block to polyspermy. The molecular underpinning(s) of the membrane block are unknown, and the role of JUNO provides the first evidence towards its understanding. This is also consistent with the evidence that ICSI, which does not induce the membrane block, does not induce shedding of JUNO. (5) In vitro binding studies showed that among members of the Folr family only JUNO, which contains a single globular domain, binds IZUMO1 and not other IZUMO isoforms. (7) JUNO-IZUMO1 interaction,

Vet-ebooks.com

which is conserved among mammals, is proposed to mediate the initial adhesion step between gametes but not their fusion.

Acknowledgments

The authors wish to thank the following colleagues for their insightful suggestions or for reading parts of the manuscript: Drs Michael Bedford, Luca Jovine, Melissa Jungnickel, Ana Maria Saliconi, Paula Stein, Bayard Storey, Keith Sutton, Carmen Williams, Janice Evans, and Pablo Visconti. We also appreciate the contribution of the Fissore laboratory for their generous contributions and suggestions. The assistance of Ms. Banyoon Cheon in preparing the figures is also highly appreciated. Due to space constraints, it was not possible to cite all relevant work nor to refer to important contributions by means of review articles, and for this we apologize.

This work was supported by the National Institute of Child Health and Human Development (HD046948 and HD058631 to H.M.F.; HD051872 to R.A.F.) and by NIFA/USDA (to R.A.F.).

CHAPTER

5

Gamete and Zygote Transport

Susan S. Suarez

Department of Biomedical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, NY, USA

INTRODUCTION

Overview

How do mammalian sperm and oocytes reach each other? It might seem a simple matter of chance, because millions of sperm are usually deposited in the female by the male. Nevertheless, there is strong evidence for the existence of mechanisms that regulate the passage of sperm and oocytes through the female reproductive tract. These mechanisms not only promote successful fertilization but also tend to select morphologically normal and vigorously motile sperm for passage to the oocyte.

In mammals, oocytes are usually fertilized within hours of ovulation.[1] Sperm, however, may be stored within the female for days or even months before the arrival of the oocyte in the oviduct. In mice, fertilization takes place within 7 h of mating,[2,3] but in some bats, sperm are stored throughout winter hibernation.[4,5] Because sperm are terminally differentiated cells deprived of an active nucleus and a synthetic apparatus, they must survive the wait without benefit of transcription and translation.

Sperm are subjected to physical stresses during ejaculation and some phases of transport through the female tract, and they may sustain oxidative damage. Furthermore, because sperm are allogenic to the female, they must endure or avoid the defenses of the female immune system.[6] Thus, in order to succeed, sperm must somehow overcome these challenges. On the other hand, it is also advantageous to the female to promote the successful migration of sperm all the way to the site of fertilization, yet without promoting the invasion of disease organisms.

The major consideration for oocyte transport is to get the ovulating oocyte directly and quickly from the surface of the ovary into the ampulla of the oviduct. Speed is crucial, because oocytes of at least some mammalian species are known to age within hours of ovulation in vivo.[1]

Historical Aspects

It has been challenging to learn about gamete transport, because of the tremendous amount of variation among species with regard to gross and microscopic anatomy of the female reproductive tract, site of insemination, timing of reproductive cycles, mechanisms of ovulation induction, numbers of oocytes ovulated per cycle, level of intensity of sperm competition, and more. Information obtained from one species cannot be reliably translated to another species.

In the first half of the last century, attempts to understand the processes involved in transport of sperm and oocytes relied primarily on three approaches: (1) preparing histological sections of the female reproductive tract at various times after insemination to examine distribution of gametes; (2) removing the tract, dividing it into segments, and flushing each segment to assess distribution of gametes in the tract and the motility patterns of sperm in each segment; and (3) surgically ligating the tract at various points along its length and at various times after insemination in order to ascertain when sperm reach regions above the point of ligation in sufficient quantities to enable fertilization to occur. Although much information was obtained using these approaches, handling the tract can often cause redistribution of gametes, particularly by stimulating contraction of smooth muscles in the walls of the tract; therefore, results obtained were not always reliable.

In the 1950s, cinematography became a valuable tool for examining the process of transferring the oocyte–cumulus complex from the surface of the ovary to the ostium of the oviduct. Richard Blandau pioneered the use of cinematography to study transfer, particularly in the rabbit, where the process can be visually accessed in anesthetized animals via surgery.[7] In 1980, Katz and Yanagimachi adapted high speed cinemicrography to study the movement of sperm within the oviductal ampulla of the golden hamster.[8] This was possible

because the oviduct could be removed from the hamster after mating, placed in a chamber on a warm microscope stage, and transilluminated to reveal the movement of sperm within the oviductal lumen. Sperm would continue to swim vigorously in the ampulla for several minutes. Later, sperm behavior throughout the entire oviduct of the mouse could be recorded in this fashion, enabling the study of the oviductal reservoir of sperm.[9]

In the first decade of this century, the development by Masaru Okabe's group of gene-modified mice that produce fluorescent sperm made it possible to use epifluorescence with highly sensitive digital video cameras in order to see sperm more clearly within the oviduct. Sperm with green fluorescent acrosomes made it possible to ascertain where acrosome reactions take place in the oviduct.[10,11] Other uses of the tools of gene manipulation, particularly gene disruption, have contributed to our understanding of various mechanisms driving and regulating gamete transport, including semen coagulation,[12] passage of sperm through the uterotubal junction,[13] and the role of the cumulus matrix in oocyte transport.[14,15] Selection of genes for manipulation has been aided by advances in microarray analysis and mass spectrometry.[16]

In order to understand fully the regulation of movement of gametes in the female reproductive tract, studies of biochemical factors must be complemented by studies of the physical aspects of interactions of gametes with the reproductive tract. The development of mathematical models to describe swimming of organisms the size of sperm (micron scale) began in the latter half of the 1800s with calculations of Reynolds numbers, which indicated that inertial forces acting on sperm are negligible compared with viscous forces.[17] Interest of biophysicists and mathematicians in understanding movement of sperm was stimulated in 1951 by Sir Geoffrey Taylor, who developed the analysis of an infinite sheet, which could be idealized as a swimmer (for example, a sperm flagellum) that was much longer than its radius.[18] In 1976, James Lighthill proposed a mathematical approach for analyzing the hydrodynamics of the movements of eukaryotic flagella.[19] Application of physics to sperm interactions with mucus in the female tract was pioneered by David Katz[20] in the late 1970s. In 1995 and beyond, mathematical modeling was used by Lisa Fauci to explain the interaction of sperm with boundaries, such as the walls of the female reproductive tract.[21] More recently, development of the technology to produce microfluidics devices enabled Denissenko et al. to design microchannels that could actually guide the movement of human sperm.[22] The current explosion in the advances of biophysics, microfluidics technology, and mathematical modeling should rapidly advance our understanding of how sperm move through the female reproductive tract and inspire development of new treatments for infertility and of more effective contraceptives.

In the second edition of this book, Michael J. K. Harper,[23] a leader in the study of gamete transport, provided more detailed information on the earlier work on gamete transport.

SPERM TRANSPORT

Sperm Competition and Cooperation

For the males of many species, the ability to reach the site of fertilization in the oviduct is not enough to ensure success, because their sperm may be forced to compete with the sperm of other males.[24] There is strong evidence in a variety of species that increased competition among males correlates with increased velocity of their sperm.[24] In some lineages, the increased competition appears to have selected for evolution of longer flagella that produce faster sperm; however, in other lineages, competition appears to have selected for increased production of sperm, suggesting that evolutionary tradeoffs occur between production of larger, faster sperm and production of greater numbers of sperm.[24]

In some species, sperm appear to cooperate by joining with each other to form aggregates that move with greater speed than individual sperm. In the wood mouse, *Apodemus sylvaticus*, sperm have small hooks on their heads that latch them onto each other, resulting in the formation of trains of several (Figure 5.1), or even thousands, of cells[25]. The trains swim faster than solitary sperm.[26] Furthermore, in the highly promiscuous deer mouse, *Peromyscus maniculatus*, sperm aggregate preferentially with sperm from the same male over sperm from other males; whereas, sperm from the monogamous species, *Peromyscus polionotus*, aggregate indiscriminately with sperm from other males.[25] The nature of the tendency of sperm to aggregate preferentially with others from the same male is unknown, but proposed to be due to a homophilic adhesion protein.

There are other examples of sperm joining with each other by their heads. Sperm of new world marsupials, such as the opossum species *Didelphis virginiana*[27] and *Monodelphis domestica*,[28] form pairs that break apart

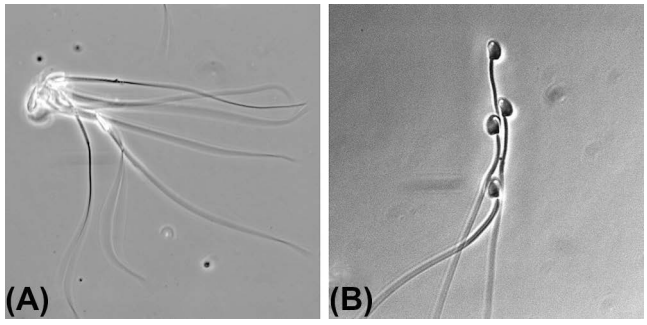

FIGURE 5.1 Phase contrast images of deer mouse (*Peromyscus maniculatus*) sperm (230×). (A) Sperm aggregates attached at heads. (B) Sperm attached head hook to midpiece. *Source: From Ref. 25.*

Vet-ebooks.com

shortly before fertilization. Pairing enhances passage of marsupial sperm through viscous media and thus may provide an advantage for sperm swimming in the viscous fluids of the female tract.[29] Guinea pig (*Cavia porcellus*) sperm heads stack together in rouleaux in the epididymis, and the rouleaux are maintained in the female tract, even into the oviduct.[30–32] Sperm of flying squirrels (*Glaucomys volans*)[33] and armadillos (*Cabassous unicinctus*)[34] also form rouleaux. Hamster sperm (*Mesocricetus auratus* and *Cricetulus griceus*) retrieved from the caudal epididymis agglutinate by their heads when incubated under capacitating conditions in vitro, then break apart as they become hyperactivated,[35–37] although it is not known whether this behavior occurs in vivo. Whether or not these last examples represent sperm cooperation, it is evident that cooperation has evolved in sperm of diverse species.

Timing of Insemination with Respect to Ovulation

Sperm may be required to survive in the female tract for a long time in species that spend several days in estrus or that delay ovulation during hibernation. Prolonged survival is promoted by adaptations of the female for storing sperm. Mares (*Equus caballus*) ovulate about five days after the onset of estrus and must therefore be able to store sperm for that period.[38] Many species of hibernating vesperilionid and rhinolophid bats mate before they enter hibernation in the autumn, and their sperm are stored until spring, when ovulation occurs shortly after arousal.[39,40]

One solution to shorten the length of time that sperm must survive in the female tract is coitus-induced ovulation. Female rabbits, for example, remain in estrus for long periods of time until they mate, which triggers ovulation about 12 h later.[41] In the Sumatran rhinoceros (*Dicerorhinus sumatrensis*), mating activity induces an LH surge within 1–2 h, followed by ovulation.[42] Other induced ovulators include domestic cats and other feline species,[43,44] camels,[45] the American black bear (*Ursus americanus*),[46] the grasscutter (*Thryonomys swinderianus*),[47] voles,[43] hedgehogs, moles, and shrews.[48]

Insemination

Vaginal Insemination

The site of semen deposition is not easy to establish, because it must be determined by examining the female immediately after coitus and by considering the anatomy of the penis, vagina, and cervix during coitus. This has been accomplished for humans, in which semen has been observed pooled in the anterior vagina near the cervical os shortly after coitus (Figure 5.2). Within minutes

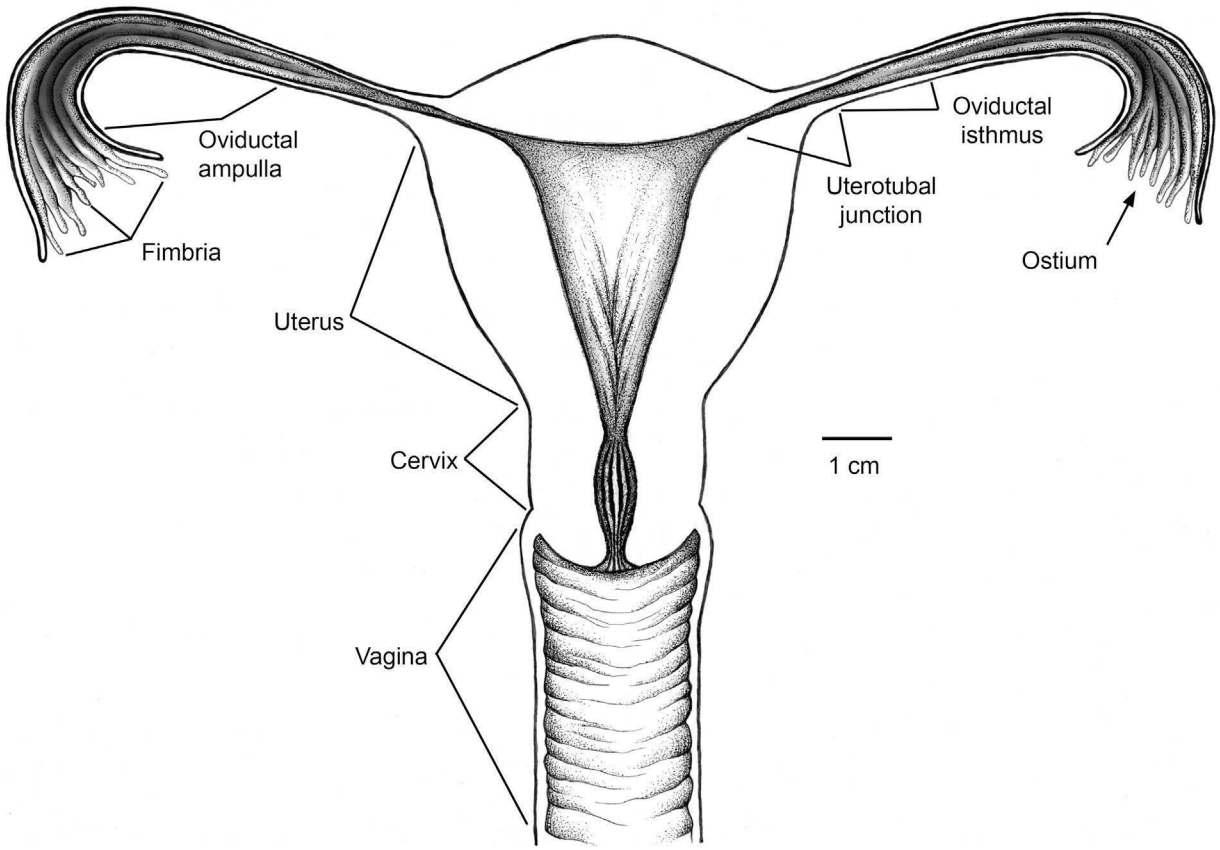

FIGURE 5.2 Human female reproductive tract. *Source: Adapted from Ref. 49.*

Vet-ebooks.com

of vaginal deposition, however, human sperm begin to leave the seminal pool and enter the cervix.[50] Semen of rabbits (*Oryctolagus cuniculus*) is also deposited in the anterior vagina, but a few million sperm have been recovered from the cervix 1 min after coitus.[51]

Rats (*Rattus norvegicus*) and hamsters (*M. auratus*) have been classified by some as uterine depositors of semen, because their sperm can be found in the uterine horns minutes after coitus. Nevertheless, results of a careful study by Bedford and Yanagimachi[52] revealed that the sperm are deposited in the vagina but transported through the cervix into the uterus within a few minutes. At the time of vaginal deposition, the sperm are immotile or only weakly motile[52]; therefore, it is assumed that they are swept through a relaxed cervix into the uterus by muscular contractions of the female tract. In support of this assumption, Carballada and Esponda[53] detected several seminal plasma proteins in rat uterine fluid. As in the rat, the mouse uterine lumen is distended only minutes after coitus by a dense mass containing sperm and bacteria,[3] indicating that mouse semen is rapidly swept through the cervix into the uterus as well.

Copulatory Plugs and Gels

Whereas most of the semen of murine rodents is rapidly transported into the uterine cavity, some remains in the vagina where it coagulates to form a copulatory plug. The plug forms a cervical cap that promotes sperm transport into the uterus.[7,53,54] The plugs formed by semen of guinea pigs and mice extend into the cervical canals and thus would seem to form a seal against retrograde sperm loss[7] (Figure 5.3). Ligation of the vesicular and coagulating glands of rats prevented the formation of plugs and the transport of sperm into the uterus.[55] The major protein components of the copulatory plugs of rodents are a family of seminal vesicle-secreted proteins (SVS) family.[56–58] A transglutaminase secreted by the mouse coagulating gland polymerizes SVS1-3 and is thought to be responsible for plug formation in vivo.[56,59]

Male mice deficient for the gene encoding the protease inhibitor known as protease nexin-1 (PN-1) show a marked impairment in fertility.[12] Vaginal plugs formed in females after mating with PN-1 null males were small, soft, and fibrous, and did not lodge tightly in the dual cervical canals. When proteins extracted from plugs produced by mutant and wild-type males were compared by SDS/PAGE analysis, significantly fewer protein bands were detected in the mutant extracts, suggesting that, in the mutant, many of the proteins normally forming the plug had been degraded into peptides too small to be retained by the gel. No sperm could be found in the uterus 15 min after mating with PN-1 null males, demonstrating the importance of the plug for promoting transport of mouse sperm into the uterus.[12]

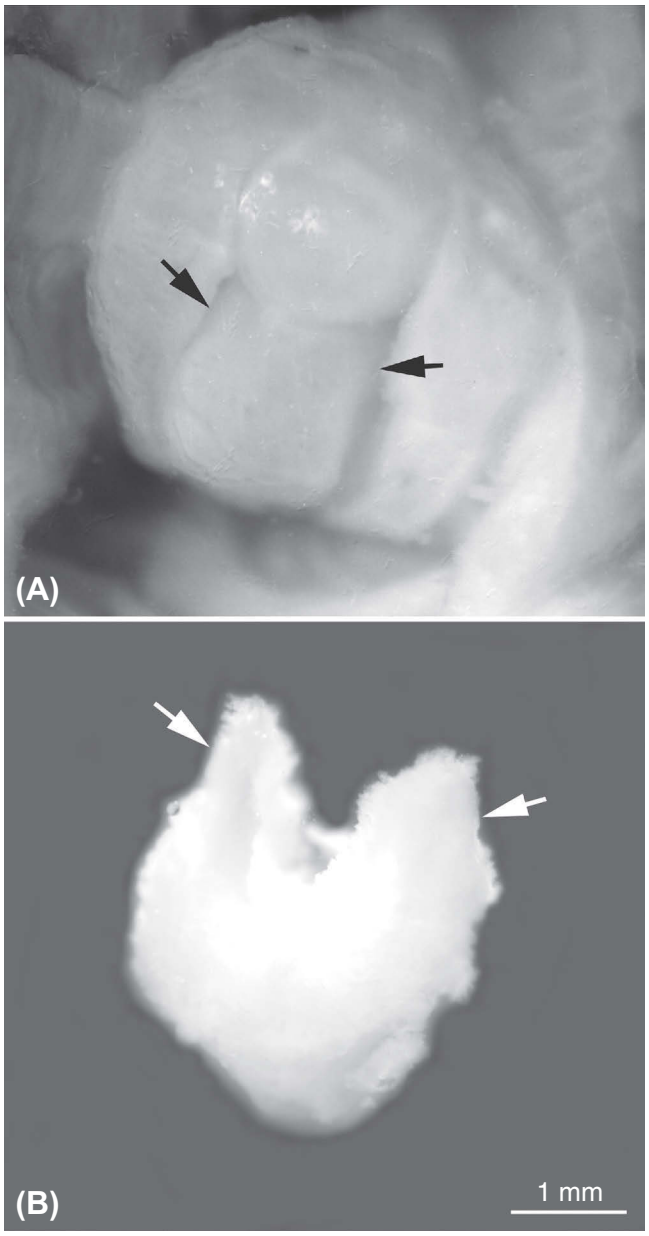

FIGURE 5.3 Copulatory plugs. (A) External os of mouse cervix. *Arrows* indicate openings. (B) Anterior portion of a mouse copulatory plug removed from the vagina. *Arrows* indicate projections that fit into cervical openings. *Source: Photomicrographs by S. S. Suarez.*

The semen of humans also coagulates, although it forms a loose gel rather than the compact fibrous plug seen in rodents. The coagulum forms within a minute of coitus and soon is enzymatically degraded[50] by prostate-specific antigen (PSA), a serine protease secreted by the prostate gland.[60] The predominant structural proteins of the gel are the 50 kDa semenogelin I (SEMG1) and the 63 kDa semenogelin II (SEMG2), as well as a glycosylated form of SEMG2, all of which are secreted primarily by the seminal vesicles.[60] The semenogelin genes, *SEMG1* and *SEMG2*, are considered homologous to the mouse genes that encode SVSI and SVSII.[60]

Vet-ebooks.com

SEMG1 binds to epididymal protease inhibitor (EPPIN) on the surface of sperm. Sperm acquire a coating of EPPIN in the testis, where it is produced by Sertoli cells, and in the efferent ductules and epididymis, where it is produced by the epithelial linings.[61]

It has been proposed that temporary entrapment of human sperm in the coagulum serves to keep the sperm at the cervical os and protects them from the acidic environment of the vagina. EPPIN has strong bacteriocidal activity, and may also serve to protect sperm from vaginal bacteria and help to prevent bacterial transport into the cervix.[61]

Like humans, some primates produce semen that forms a soft gel. However, in chimpanzees (*Pan troglodytes*), a species in which females mate with more than one male in a brief time, the semen coagulates into a compact plug resembling that of rodents.[62,63]

Some carnivores (e.g., domestic dogs, *Canis familiaris*) and some rat and mouse species of the family Cricetidae use the penis as a copulatory plug; i.e., the mating pair remains joined together for a period of time after coitus.[64] About a minute after a dog has mounted and locked with a bitch, he turns around, such that the two animals face opposite poles. They remain locked together in this position for 5–45 min. Close examination of the anatomy of the joined genitalia led Grandage[65] to propose that locking serves to "encourage uterine insemination".

Uterine Insemination

Some species bypass the vagina altogether and deposit semen directly into the uterine cavity, where sperm may quickly gain access to the oviduct. In the pig (*Sus scrofa*), the penis is shaped like a corkscrew and the cervix contains complementary furrows. During copulation, the penis fits into the cervix and passes a large volume of semen (about 250 ml) into the uterine cavity.[66–68]

Even those species that do not pass the penis through the cervix may use the penis to open the cervical canals. The glans of the rat penis contains projections that seem designed to push open flaps guarding the cervical canals.[55]

Artificial Insemination

In dairy cattle (*Bos taurus*), bypassing the vagina and cervix has proven advantageous for artificial insemination. Whereas a bull normally deposits several billion sperm into the vagina (Table 5.1), artificial inseminators deposit 5–20 million frozen/thawed sperm directly into the body of the uterus.[69–71]

Artificial insemination into the peritoneal cavity, near the ovary, can result in pregnancy and has been used to treat infertility in humans and repeat breeding syndrome in dairy cows.[72] Access to the peritoneal cavity is obtained through the abdominal wall or vaginal wall.[72] Evidently, inseminated sperm are swept into the ostium or picked up by the cilia on the surface of the oviductal fimbria and transported into the ampulla to fertilize oocytes. Oviductal pickup of sperm from the peritoneal cavity may also occur naturally. To demonstrate that sperm can exit an oviduct via the ostium of the ampulla, enter the peritoneal cavity, and then enter the contralateral oviduct through its ostium, Larsson[73] ligated and resected a 2–3 cm segment of isthmus of one oviduct of dairy heifers (virgin cows), then deposited semen into the uterus at estrus. Sperm were recovered only 2 h after insemination from the resected oviducts, cranial to the resected segment. Presumably, these sperm had reached the resected segment via the peritoneal cavity.

There are case reports of human tubal pregnancies that arose in spite of lack of access of sperm from the uterus into the oviduct on the side of ovulation.[74–76] The only route available to the sperm in these cases was through the peritoneal cavity.

TABLE 5.1 Semen Characteristics in Domestic Animals

	Bull	Stallion	Ram (Buck)	Boar	Dog	Cat
Volume (ml)	4[a] (1–15)[b]	70 (30–250)	1 (0.7–3.0)	250 (125–500)	10 (1.0–25.0)	0.04 (0.01–0.12)

Vaginal Defenses

The vagina is open to the exterior and therefore to infection, especially at the time of coitus; therefore, it is well equipped with antimicrobial defenses that can work against sperm as well as against pathogens. To enable fertilization to take place, both the female and the male have adopted mechanisms for protecting sperm from these defenses. As discussed before, some species bypass the vagina and deposit semen directly into the uterus, whereas, in all other species, vaginal deposition occurs right at the entrance to the cervix.

Vaginal pH

For vaginal inseminators, sperm must contend with the acidic pH of vaginal fluid. The vaginal pH of women is normally 5 or lower, which is microbicidal for many sexually transmitted disease pathogens, including those that cause bacterial vaginosis, yeast infections, urinary tract infections, and HIV/AIDS.[77] Evidence indicates that the acidity is maintained through lactic acid production by anaerobic lactobacilli that feed on glycogen present in sloughed vaginal epithelial cells.[78] Lowering pH with lactic acid has been demonstrated to immobilize bull sperm.[79,80] The pH of seminal plasma ranges from 6.7 to 7.4 in common domestic species (Table 5.1)[68] and has the potential to neutralize vaginal acid. Vaginal pH was measured by radiotelemetry in a fertile human couple during coitus. The pH rose from 4.3 to 7.2 within 8 s of the arrival of semen; whereas, no change was detected when the partner used a condom.[81]

The bacteria that inhabit the vagina of healthy women consist of a number of species. The composition of the vaginal microbial ecosystem was examined in samples from asymptomatic sexually active women using a high throughput method of pyrosequencing of barcoded 16S rRNA genes. The samples were acquired from 396 North American women, equally representing Asian, white, black, and Hispanic communities. A total of 282 taxa were detected among the microbiota of these samples. The majority of vaginal communities were dominated by *Lactobacillus* species. The remaining types were other anaerobic species of bacteria; however, all communities contained species that are known to produce lactic acid,[77] indicating that lactic acid plays an important role in cervical function, presumably for its toxicity against a number of aggressively infectious microbes.

Leukocytic Response in the Vagina

In addition to providing protective substances for sperm in seminal plasma, males may also overcome female immunological defenses by inseminating millions or even billions of sperm. This strategy would be particularly effective in overcoming a cellular immune response. In the rabbit, deposition of semen results in an invasion of neutrophils into the vagina. This invasion takes time, however, to build to an effective level. Numerous leukocytes, many containing ingested sperm, were observed in the vaginas of rabbits 3–24 h post coitus.[82,83] By that time, however, thousands of sperm had already reached the oviduct.[84]

Sperm Transport Through the Cervix

Cervical Mucus

After deposition in the cranial vagina, sperm of humans and dairy cows enter the cervical canal rapidly, where they encounter large volumes of cervical mucus produced when systemic levels of estrogen are high. Under the influence of estradiol, the cervix produces highly hydrated mucus, with a water content that often exceeds 96% in women.[85] The extent of hydration is correlated with penetrability to sperm.[86] Coitus on the day of maximal mucus hydration in women, which occurs within the six-day window prior to the day of ovulation, is more closely correlated with incidence of pregnancy than coitus timed with respect to ovulation detected using basal body temperature.[87]

The viscoelastic nature of cervical mucus is due to the presence of large, polymeric, glycosylated proteins in the mucin family that range from 2 to 50 MDa in mass.[88] RNAseq analysis of bovine endocervical linings indicated that transcription of some genes associated with mucus production was higher during estrogen dominance than during progesterone dominance, including *Muc5B*, *Muc1*, *Muc16*, and *Muc20. Muc5B* encodes secreted mucin, while the other three *Muc* genes encode transmembrane mucins. Some genes involved in glycosylation of mucins were upregulated at estrus, whereas others were downregulated, suggesting that the glycosylation patterns of mucins differ between the time that cervical mucus is watery and accessible to sperm and the time that it is inaccessible to sperm.[88] Staining of histological sections of bovine cervix with lectins indicated that the presence of some terminal sialic acids is maximal during estrus, while that of terminal fucose is lowest.[89] Because bovine sperm bind to fucosylated molecules,[90] the reduction in fucosylation of mucin molecules would facilitate sperm passage through the cervix.

Proteomic and glycomic analyses of samples of secreted human cervical mucus collected from 12 Caucasian women did not detect cyclical changes in mucin glycoproteins; however, glycosylation changes were detected and were associated with ovulation. MUC5B

Vet-ebooks.com

was the most abundantly secreted, gel-forming mucin, but MUC5AC and MUC6 were also detected, along with two transmembrane mucins, MUC16 and MUC1. Sialylated oligosaccharides were the predominant forms identified in mucins before and after the ovulatory period, but the dominant oligosaccharides detected during the ovulatory period were neutral oligosaccharides.[91]

Cervical mucus presents a greater barrier to abnormal sperm that cannot swim properly or that present a poor hydrodynamic profile than it does to morphologically normal, vigorously motile sperm, and is therefore thought to be one means of sperm selection.[85,92–94]

The greatest barrier to sperm penetration through cervical mucus is at its border, because here the structure is more compact.[95] Components of seminal plasma may assist sperm in penetrating the mucus border. More human sperm were found to enter cervical mucus in vitro when an inseminate was diluted 1:1 with whole seminal plasma than when it was diluted with Tyrode's medium, even though the sperm swam faster in the Tyrode's dilution. It was concluded that components of seminal plasma facilitate penetration of sperm into cervical mucus.[96]

A role for penetration of cervical mucus has been attributed by Tollner et al.[97] to the coating of sperm by specific members of the defensin family of proteins, namely DEFB126 in humans and rhesus macaques, and DEFB22 in mice and rats. Defensins are cationic peptides comprised of 29–42 amino acids. They contain six conserved cysteine residues that form three intramolecular disulfide bonds, which fold the peptide into a conformation that resists protease cleavage. Defensins have been detected in a wide array of animal and plant species, where they are known to play a role in innate immunity and to possess microbicidal activity against bacteria, fungi, and some viruses. DEFB126 and DEFB22 are large defensins (32–35 kDa) that have extended carboxyl tails with numerous glycosylation sites. DEFB126 is secreted in the epididymis and coats the entire surface of macaque sperm. Removal of the DEFB126 coating reduced the ease by which macaque sperm swam through watery estrous cervical mucus, but regained the ease when the supernatant, which contained DEFB126, was added back to sperm.[97,98] A similar reduction in mucus penetration occurred when the macaque sperm were treated by neuraminidase, which was proposed to remove terminal sialic acid groups from the DEFB126 coating.

Homozygosity for a sequence variant of the *DEFB126* gene in humans has been associated with reduced fertility. The variant consists of a deletion of two nucleotides that creates a nonstop mutation. Sperm of men who are homozygous for the delection variant do not penetrate hyaluronate gels as well as men who are heterozygous or homozygous for the wild-type allele. Hyaluronate gel is supposed to serve as a model for cervical mucus. The variant allele is common in Asian, European, and African populations, suggesting that the allele is old and has not been subjected to significant negative selection. Nevertheless, because the incidence of heterozygotes is more frequent than expected, heterozygosity may confer a selective advantage to the variant.[97]

Immune Responses in the Cervix

The cervix is immunologically competent. In rabbits and humans, vaginal insemination stimulates the migration of leukocytes, particularly neutrophils and macrophages, into the cervix as well as into the vagina.[99,100] Neutrophils migrate readily through midcycle human cervical mucus.[101] In rabbits, neutrophils heavily infiltrate the posterior region of the cervical canal near the external os within a half hour of mating or artificial insemination.[99] Interestingly, it was discovered that if female rabbits were mated to a second male during the neutrophilic infiltration induced by an earlier mating, sperm from the second male were still able to fertilize.[102] Thus, although the cervix is capable of mounting a leukocytic response, and neutrophils may migrate into cervical mucus, the leukocytes may not present a significant barrier to sperm, at least in the rabbit. It has been demonstrated that neutrophils will bind to human sperm and ingest them only if serum that contains both serological complement and complement-fixing antisperm antibodies is present.[103] This can happen if the female somehow becomes immunized against sperm antigens. In conclusion, the evidence indicates that leukocytic invasion serves to protect against microbes that accompany semen and does not normally present a barrier to normal motile sperm, at least not shortly after coitus.

Immunoglobulins IgG and IgA have been detected in human cervical mucus. Secretory IgA is produced locally by plasma cells in subepithelial connective tissue. The amount of IgG and IgA increases in the follicular phase and then decreases at about the time of ovulation.[104] The immunoglobulins provide greater protection against microbes at the time when the cervical mucus is highly hydrated and offers the least resistance to penetration. However, when there are antibodies present that recognize antigens on the surface of ejaculated sperm, infertility can result.[6]

TGF-β and other components of human seminal plasma induce cervical epithelium to activate cytokine and chemokine gene expression, including genes that encode GMC-SF and IL-6.[105] This results in recruitment of macrophages, dendritic cells, and memory T cells to the cervical epithelium and underlying connective tissue.[105] The recruited cells may serve to protect the female against infectious disease microbes that accompany semen; however, the infiltration process is too slow to affect the rapid migration of many thousands of sperm through the cervix into the uterus.

Preferential Pathways Through the Cervix for Sperm

An elegant three-dimensional reconstruction of serial sections of the bovine cervix produced by Mullins and Saacke[106] led them to conclude that there are narrow channels in the cervix, not much wider than the heads of sperm, that lead to the uterine cavity (Figure 5.4(A–D)).

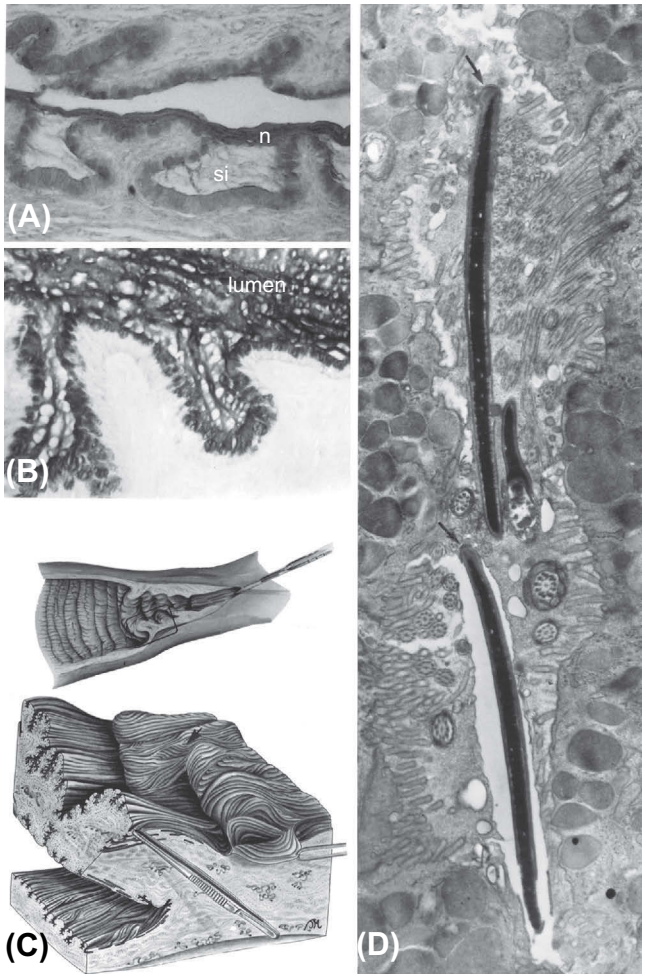

FIGURE 5.4 The bovine cervix (*Bos taurus*). (A) A section of a primary fold of cervical mucosa taken from a cow in the follicular phase of the estrous cycle. The tissue was fixed in Bouin's solution, dehydrated, embedded in paraffin, sectioned, and stained with Alcian blue (AB) and high-iron diamine (HID). AB-positive sialomucins (si) predominate in basal areas of minor grooves in the mucosa, underneath a layer of denser-staining HID-positive neutral (n) and sulfomucins. This staining pattern demonstrates that sperm encounter a different type of mucus in the base of grooves (magnification × 170). (B) In a similar section, taken from a cow in the luteal phase, the AB and HID staining reveal a loss in the layered organization seen in the estrous cow (magnification × 170). (C) An illustration by K. J. Mullins of the three-dimensional structure of the folds of cervical mucosa, derived from stereomicroscopical examination of tissue stained on its mucosal surface and from three-dimensional reconstruction of serial sections. (D) Transmission electron micrograph of cervical tissue showing sperm within grooves of cervical mucosa. *Arrows* indicate the rostral tips of the heads of sperm (magnification × 17,850). *Source: Adapted from Ref. 106.*

Furthermore, based on histochemical staining characteristics of the mucus in tissue sections of cervix, they concluded that mucus in the channels is different in composition and less dense than that in the cervical lumen during the follicular phase (Figure 5.4(A) and (B)). They proposed that sperm reach the uterine cavity by traveling through the narrow channels and avoiding the more viscous mucus in the center of the cervical lumen that serves to discharge uterine contents and perhaps also to prevent the ascent of pathogens. Mattner[107] found that when he flushed the cervices of goats and cows 19–24 h after mating at the onset of estrus he recovered approximately 90% of the mucus and more than 90% of the luminal leukocytes but only about half of the sperm. The remaining half of the sperm were found in the periphery of the cervical lumen, at the base of mucosal folds and within small channels. Recent histochemical staining of sections of bovine cervix with an array of lectins revealed differential distribution of glycans between the apical and basal regions of mucosal folds.[89]

Sperm may also be guided through the cervix by the microarchitecture of the cervical mucus itself. Mucins, the chief glycoproteins comprising cervical mucus, are long, flexible linear molecules. It is thought that these long molecules become aligned as they are secreted by the flow of secretions through mucosal channels and thus serve to guide sperm. Human[108] and bull[109] sperm have been demonstrated to orient themselves along the long axis of threads of bovine cervical mucus. Human sperm swimming through cervical mucus swim in a straighter path than they do in seminal plasma or medium (Figure 5.5(A) and (B)).[110]

Are Sperm Stored in the Cervix?

Little is known about how long sperm spend traversing the cervix or whether sperm are stored there. About one day after natural mating, a few million sperm were recovered from the cervices of cows and goats, and more than 60% of these sperm were motile.[107] Vigorously motile sperm have been recovered from the human cervix up to five days after insemination.[111] Nevertheless, it is not known whether sperm collected from cervices this long after coitus would reach the oviducts and succeed in fertilizing, nor could it be known whether these sperm had re-entered the cervix from the uterus. In vitro, human sperm swim through estrous cervical mucus at a rate of 2–3 mm/min.[110] At this rate, the time for traversing the cervical canal would be about 10–15 min.

Sperm Transport Through the Uterus

Rate of Transport

In uterine semen depositors, some sperm leave the uterus rapidly to enter the uterotubal junction. In pigs, for example, ligation of the uterotubal junction at various times after mating revealed that sperm in numbers sufficient to achieve fertilization reach the oviduct within 30 min of coitus.[66] The large volume of porcine semen could ensure that sperm are washed up against the uterotubal junction shortly after coitus. In mice, rats, and hamsters, even though semen is deposited in the cranial vagina, enough sperm-filled seminal fluid is soon transported into the uterine horns to cause visible distension.[52,112] Mouse sperm move beyond the uterus to reach the oviduct in substantial numbers within 30 min of mating.[3]

At only a few centimeters in length, the human uterine cavity is relatively small and could be passed through in less than 10 min by sperm swimming at about 5 mm/min, which is the swimming speed of human sperm in aqueous medium.[113] The actual rate of passage of human sperm through the uterus is difficult to determine, due to experimental limitations. In studies of sperm distribution in reproductive tracts of women, variation of data was high among individuals.[114] In one set of experiments, fertile women were inseminated into the cranial vagina shortly before surgical excision of both fallopian tubes. Sperm were recovered from the fimbrial segment of the ampulla in two women whose tubes were removed 5 min after insemination. Sperm were recovered all along the tubes of two more women 10 min after insemination.[115] Unfortunately, the condition of these sperm was not assessed; therefore, it could not be determined whether the sperm were capable of fertilizing. In another study,[116] several motile sperm were recovered from fallopian tubes following hysterectomy 30 min after insemination in one patient and 1 h after insemination in three out of seven patients; however, these women underwent surgery for treatment of fibroids, polyps, or endometriosis and therefore sperm transport may have been abnormal.

In contrast to human sperm, bovine sperm must pass through a uterine body 2.5–4 cm long and uterine horns that are 20–40 cm long before reaching the uterotubal junction (Figure 5.6).[68] At an approximate swimming speed of 7 mm/min, bull sperm would require about an hour to reach the uterotubal junction if they swam directly from the internal os of the cervix to the uterotubal junction. Hunter and Wilmut[117–119] ligated the uterotubal junction at various times after mating and later flushed the oviduct to recover embryos. Their results indicate that about 8 h are required for bull sperm to reach the oviduct in sufficient numbers to achieve fertilization. A similar experiment in sheep also indicated that 8–10 h are required for sufficient numbers of sperm to reach the oviduct.[120]

Uterine Peristalsis

Transport of sperm through the uterus is likely aided in some species by pro-ovarian contractions of the myometrium. Ultrasonography of the human uterus has revealed cranially directed waves of uterine smooth muscle contractions that increase in intensity during the late follicular phase.[121,122] The uterine contractions occurring in women during the periovulatory period are limited to the layer of myometrium directly beneath the endometrium.[121,123] This is in contrast to contractions occurring during menses, which involve all layers of the myometrium. In cows and ewes, electromyography has indicated that strong contractile activity occurs during estrus, while contractions are weak and localized during the luteal phase.[124]

Kunz et al.[122] deposited 5–40 μm albumin microspheres radioactively tagged with technetium into the cranial vaginas of women to determine how such contractions might transport sperm. They found that spheres were rapidly and maximally transported into the uterine cavity and even into the oviductal isthmus during the late follicular phase. Interestingly, transport of the spheres was greater to the isthmus ipsilateral to the dominant follicle than to the contralateral isthmus. This preferential transport may result from signals passed via a vascular communication between the preovulatory follicle and the uterus and oviduct. An arterial anastomosis lies between the ovarian and uterine arteries (which also supply the oviduct) in the corneal region of the human uterus. Doppler flow sonography revealed increased perfusion of the anastomosing vessels on the side of the preovulatory follicle.[125] It is thought that these vessels carry hormones from the dominant follicle directly to the uterus and oviduct without first passing through the systemic circulation, because the ovarian artery associates closely with the ovarian vein. This association is thought to enable a countercurrent transfer of ovarian hormones from the venous drainage of the ovary to the ovarian artery and then to the arterial supply of the uterus and oviduct.[126,127] In addition, lymphatic drainage of the ovary might transfer hormones to the ovarian artery.[127] Although these anatomical relationships appear to be widespread in mammals, the data demonstrating transfer of hormones or other signals along this route are still preliminary.

Studies of uterine contractions during estrus should be interpreted with caution if the females were not mated. Video laparoscopic examination of mated and unmated rats revealed significant changes in contractile patterns of the uterine horns after mating. Unexpectedly, the change consisted of several-fold increases in both cranially and caudally propagating contractions.[128] Caudally directed peristalsis would be expected to carry sperm away from the uterotubal junction. In estrous domestic cats, both ascending and

descending contractions were observed by fluoroscopy.[129] Perhaps the ebb and flow of contractions direct fresh waves of sperm to the junction.

Myometrial contractions may be stimulated by seminal components. When female rats were mated with vasectomized males, the incidence of strong uterine contractions was lower than when they were mated with intact males, indicating that sperm or testicular or epididymal secretions have stimulatory activity.[128] The secretions of male accessory sex glands may also play a role, because removal of the seminal vesicles significantly reduced the pregnancy rate in mice.[112] In boars, there is evidence that estrogens, which may reach 11.5 μg in an ejaculate, increase myometrial contraction frequency.[130] Since boar semen is deposited directly into the uterine cavity, the uterus is exposed to the full amount of estrogens in the semen. There is evidence that the estrogens enhance contraction by stimulating secretion of PGF-2α.[130]

Immunological Responses in the Uterus

Rapid transport of sperm through the uterus by myometrial contractions can enhance sperm survival by propelling them past the immunological defenses of the female. Particularly in species in which seminal plasma rapidly enters the uterus, coitus induces a leukocytic infiltration of the uterine cavity, which reaches a peak several hours after mating in mice.[3] The leukocytes are primarily neutrophils and have been observed phagocytizing uterine sperm in mice, rats, and rabbits.[3,131] This phagocytosis was observed several hours after insemination and therefore might be directed primarily against damaged sperm.

Sperm of rhesus monkeys retain the protective coating of the protein DEFB126 after migrating through the mucus of the cervix. This coating has been proposed to mask highly antigenic proteins of the sperm plasma membrane.[97] Because DEFB126 is highly conserved among mammals, this proposal likely applies to many other species. As time passes, the leukocytes in the uterine lumen begin to outnumber the sperm and phagocytosis of sperm occurs. Loss of the DEFB126 coating, which occurs during capacitation of sperm,[97] could accelerate the killing and phagocytosis of uterine sperm by leukocytes. (Note: capacitation is broadly defined as physiological changes in sperm that confer on them the ability to fertilize oocytes. The processes associated with capacitation are described in Chapter 4. Thus, it is imperative that sperm pass through the uterine cavity before significant numbers of leukocytes arrive.

In addition to phagocytosing uterine sperm, uterine neutrophils also trap sperm by extruding nuclear contents, particularly DNA, which form neutrophil extracellular traps (NETs).[132] NETs were initially discovered as part of the response of neutrophils to bacteria,[133] but neutrophils have also been demonstrated to respond

Vet-ebooks.com

similarly to sperm. Interestingly, DNase activity has been detected in equine seminal plasma and is capable of breaking down NETs.[132] Since equine seminal plasma enters the uterus during mating, the DNase activity could offer sperm some protection from NETS.

Sperm Transport Through the Uterotubal Junction

The Junction as a Regulated Entrance to the Oviduct

The uterotubal junction presents anatomical, physiological, and/or mucous barriers to sperm passage in most eutherian mammals. Anatomically, the lumen in species as distantly related as dairy cattle and mice is particularly tortuous and narrow.[134–138] The narrowness of the lumen is especially apparent in living tissue[9] and in frozen sections (Figure 5.7), in which tissue does not shrink as it does during standard preparation of paraffin-embedded sections.[138]

The entrance to the junction is fairly simple in humans; whereas, it is complicated by mucosal folds in cows, pigs, rabbits and many other species (Figure 5.8).[134–137] In mice and rats, the entrance forms a projection into the uterus called a colliculus tubarius (Figure 5.9).[3,9,140]

The mucosal folds that line the uterotubal junction vary in amplitude, architecture, and complexity among species. When the junction of the cow is slit open longitudinally and laid flat, the mucosal folds appear to form cul-de-sacs that would seem to block ascent of sperm[137,141] (Figure 5.10). Nevertheless, when the tube is intact, the cul-de-sacs might actually form funnels that direct sperm to the center of the channel for rapid passage.

In cattle and other species, a physiological valve may be created by a vascular plexus in the lamina propria/submucosal layer of the wall of the junction. When engorged, the plexus can compress the lumen.[137] The walls of the bovine junction and adjacent tubal isthmus also contain a thick muscular layer that could further constrict the lumen. The bovine uterotubal junction is sigmoidal in shape and supported by muscular ligaments that appear capable of increasing the flexure of the curve to compress the lumen.[134,135] Altogether, these structures could control the diameter of the lumenal channel and accessibility of the oviduct to sperm. The human junction traverses a thick muscular layer of uterine wall.[135] In the mouse, the junction (Figure 5.11) was reported to be patent shortly after coitus, but to close tightly about an hour later.[3,9]

In some species, the junctional lumen is filled with a viscous mucus that could impede the progress of sperm (Figures 5.7 and 5.12). Mucus has been found in the uterotubal junction in rabbits,[142,143] pigs,[144] cattle,[138,145]

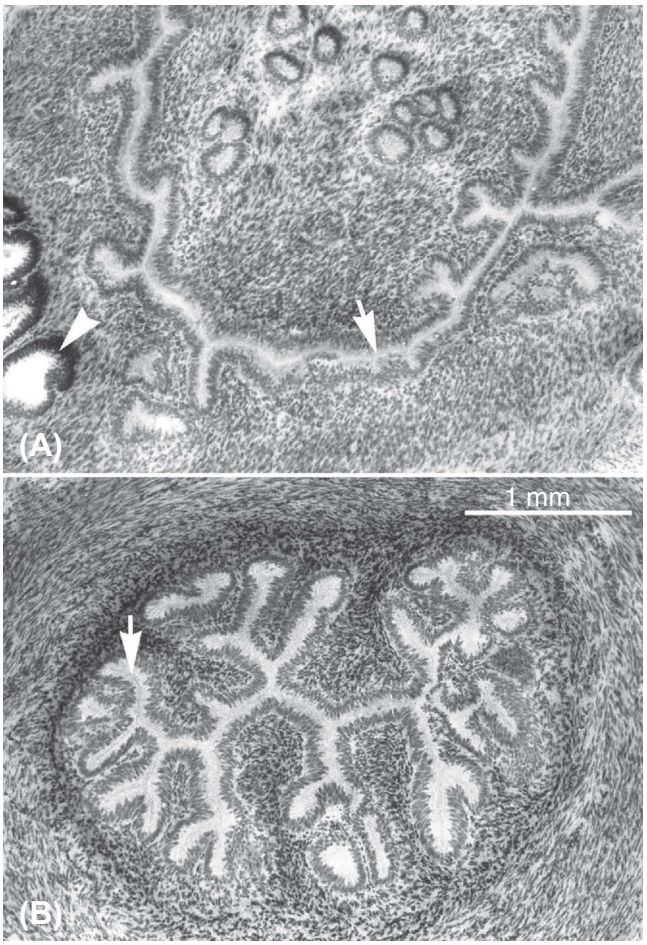

FIGURE 5.7 Frozen sections of the bovine uterotubal junction and caudal isthmus, stained with periodic-acid Schiff reagent and counterstained with hematoxylin. and humans.[146] In pigs at estrus, the mucus becomes watery, similar in appearance to that of human midcycle cervical mucus (Suarez, personal observation).

The Junction as a Filter

For uterine semen depositors, the uterotubal junction, particularly when filled with mucus, can serve the filtration function served by the cervix in vaginal depositors. That is, it may filter out pathogens introduced with the semen, as well as morphologically abnormal sperm or sperm with poor motility. In pigs,[147] rats,[140] and hamsters[148] motile sperm pass through the uterotubal junction much more successfully than immotile sperm. Sperm demonstrating linear, progressive motility are more successful at passing through the uterotubal junction than are sperm swimming in nonlinear patterns,

such as those circling due to an asymmetrical flagellar beating pattern.[140,149] In species in which whole semen is deposited in the uterus, the uterotubal junction may also serve to filter out seminal plasma. Seminal plasma components are left behind in the uterus and are not detected in the oviducts of rats.[150]

Proteins Required for Passage of Sperm Through the Junction

Male mice that are null mutants for the genes *Adam3*,[151] *Clgn*,[152,153] *Ace*,[154,155] *Adam2*,[156] *Adam1a*,[157] *Calr3*,[158] *Tpst2*,[159] or *Pdilt*[13] are infertile because their sperm cannot pass through the uterotubal junction. In these null mutants, both the motility and morphology of the sperm are normal when examined in vitro. The sperm are unable to bind to the zonae of cumulus-free oocytes; however, sperm from *Adam1a–/–*, *Adam3–/–*, and *Pdilt–/–* males have been reported to fertilize cumulus-intact oocytes in vitro. Therefore, the main cause of infertility in vivo is failure of sperm to pass through the uterotubal junction. All of the aforementioned gene products are proteins that are involved, directly or indirectly, in correct folding and disulfide bond formation of ADAM3 (a disintegrin and metalloprotease 3) in the endoplasmic reticulum of developing male germ cells in the testis, such that ADAM3 is placed in a proper configuration in the sperm plasma membrane.[16]

So far, the protein that is most indirectly involved in the proper placement of a properly folded ADAM3

Vet-ebooks.com

in sperm membranes is ACE (angiotensin I-converting enzyme). ACE is normally shed from mouse sperm when they enter the epididymis; therefore, it has been proposed that it has an enzymatic effect on the surface of maturing sperm that somehow enables them to pass through the uterotubal junction.[160] The testis-specific isoform of ACE has dipeptidase activity similar to that of somatic ACE, but it also has GPI-anchored protein-releasing activity (GPIase). Although ACE does not act directly on ADAM3, removal of the GPI-anchored protein TEX101 from developing male germ cells by ACE in the testis has been shown to be necessary for normal distribution of ADAM3 in sperm membranes and for passage of sperm through the uterotubal junction.[161]

Although there is strong evidence that ADAM3 is required in sperm plasma membranes in order for sperm to pass through the uterotubal junction, little is known about how ADAM3 serves this purpose. Some indication of how ADAM3 functions was obtained using mice that are null mutants for *Clgn*. CLGN acts as a chaperone protein in testicular male germ cells and mediates the heterodimerization of ADAM1A with ADAM2. In turn, the ADAM1A/2 dimer is required for correct folding of ADAM3. The role of CLGN in enabling sperm to pass into the oviduct was examined more closely using chimeric males that produced a mixture of testicular germ cells with intact and disrupted *Clgn*. The question addressed was whether CLGN-chaperoned proteins are required by individual sperm in order to pass through the uterotubal junction, or would the presence of wild-type sperm enable the mutant sperm to pass? Such would be the case, for example, if the proteins on the sperm surface signaled the uterotubal junction to open. Chimeric males were created by fusing embryos from wild-type mice that had normal *Clgn* genes with those from a double transgenic line of mice that were homozygous null for *Clgn* and expressed enhanced green fluorescent protein in their acrosomes. The resulting chimeric XY/XY males produced a mixture of sperm, about half of which were derived from mutant germ cells, as identified by the presence of the fluorescent acrosomes. When these males were mated with wild-type females, only

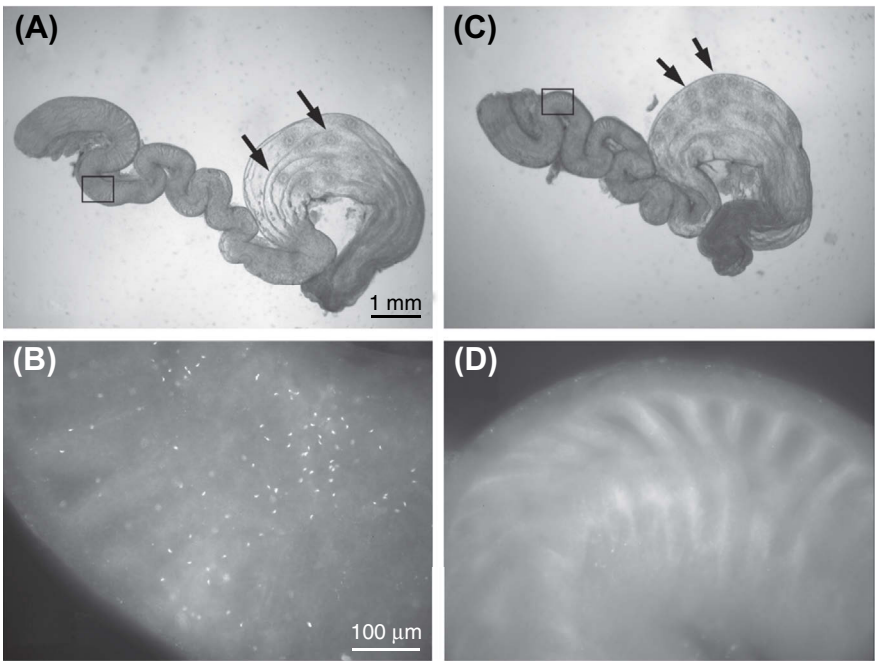

FIGURE 5.13 Comparison of oviductal colonization by sperm from *Clgn–/–* and *Clgn+/–* male mice. Vet-ebooks.com

wild-type sperm could be found within the oviduct.[10] This indicates that normal morphology and motility are not sufficient for enabling sperm to enter the oviduct. An additional factor, likely a sperm surface protein or proteins (such as ADAM3), is required by each sperm in order to pass through the junction. In videos of the behavior of mouse sperm in the uterotubal junction, the sperm do appear to attach transiently to the mucosal lining of the junction (Suarez, personal observation); however, the nature of this interaction remains largely unknown.

To identify other proteins dependent on CLGN for placement in the sperm plasma membrane, 2D gels of Triton X114-extracted proteins from sperm of *Clgn* knockout mice were compared with extracts from wild-type mouse sperm. Two proteins were identified, PMIS1 and PMIS2. When the genes for these proteins were knocked out, *Pmis1*–/– mice were fertile, but *Pmis2*–/– males showed the same infertility phenotype as Clgn–/– males. ADAM3 was missing from the sperm of *Pmis2*–/– males and PMIS2 was severely reduced in sperm of *Adam3*–/– males.[16] Consequently, it was proposed that either PMIS2 or ADAM3 or another protein, perhaps complexed with PMIS2 or ADAM3, is directly responsible for the sperm interaction with the uterotubal junction that enables sperm to pass into the oviduct.

Rapid Transport of Sperm Through the Junction

Sperm have been recovered from the cranial reaches of the ampulla only minutes after coitus or insemination in humans[115] and several other species of mammals.[51,124,162] This phenomenon has been termed rapid sperm transport.[51] Rapid transport of sperm into the oviduct would seem to counter the proposed model of sperm swimming one by one through the uterotubal junction. Nevertheless, when the conditions of rabbit sperm recovered from the cranial ampulla shortly after mating were evaluated by Overstreet and Cooper,[51] they found that most sperm were damaged and immotile. They proposed that the waves of contractions that are stimulated by insemination force some sperm all the way to the cranial ampulla; however, those sperm are unlikely to fertilize because they are damaged by the sheer stress of rapid transport. The contractions might serve primarily to draw sperm into the cervix and/or uterus, but some sperm are forced beyond the uterus. Later, motile sperm gradually pass through the uterotubal junction to establish an oviductal population capable of fertilizing. Rapid transport resulting in sperm damage has not been studied this carefully in other species, but it is likely to apply in cases where sperm are found near the ovary within a few minutes of coitus.

Oviductal Sperm Reservoir

The Reservoir Stores Sperm and Prevents Polyspermy

Many sperm that enter the oviduct do not immediately continue to the site of fertilization but are instead held in a storage reservoir. The mammalian oviductal sperm reservoir was first reported in hamsters by Yanagimachi and Chang[163] and has since been reported to exist in a variety of species (mice,[9] hamsters,[164] rabbits,[51,165] cows,[119] pigs,[66] and sheep[166]).

The oviduct provides a safe haven for sperm. Unlike the vagina, cervix, and uterus, the oviduct does not respond to insemination with an influx of leukocytes.[167] However, the oviduct seems to be more than simply a safe haven for sperm; in addition, it somehow acts to maintain the fertility of sperm between the onset of estrus and the time of ovulation. Sperm fertility and motility are maintained longer in vitro if the sperm are incubated with oviductal epithelium (bovine,[168,169] porcine,[145] human,[170] and canine[171]).

The holding of sperm in the oviductal isthmus may also serve to prevent polyspermic fertilization by allowing only a few sperm at a time to reach the oocyte in the ampulla. Sperm numbers have been artificially increased at the site of fertilization in the pig by surgical insemination directly into the oviduct,[172,173] by resecting the oviduct to bypass the reservoir,[174] or by administering progesterone into the muscularis to inhibit smooth muscle constriction of the lumen.[175,176] Each of these treatments raised the incidence of polyspermic fertilization.

How Sperm are Held in the Reservoir

There is strong evidence from multiple species that the oviductal reservoir is created in eutherian mammals when sperm bind to oviductal epithelium. Motile sperm have been observed to bind by their heads to the oviductal epithelium in cattle (Figure 5.14),[145] mice,[9] hamsters,[178] pigs,[144] horses,[179] and dogs.[180] The opportunity for binding could be enhanced because the mucus-filled, narrow lumens of the uterotubal junction and isthmus slow the sperm and increase their contact with the epithelium.

Guinea pig sperm have been observed stacked in large rouleaux in pockets in the wall of the uterotubal junction 1–12 h after copulation,[30,31] indicating that sperm-to-sperm binding also plays a role in sperm storage in some species.

Rabbit sperm flushed from the oviductal isthmus with oil showed only sluggish motility, but could be revived by dilution in medium. This led to the proposal that motility suppression is also a mechanism for trapping and storing sperm.[181–183]

In hamsters[184] and mice,[9] immotile sperm have been seen in the central part of the isthmic lumen; however,

Vet-ebooks.com

(C) A high magnification view of a sperm cell associated with the cilia of the epithelium (bar = 1 μm). *Source: From Ref. 177.*

when hamster oviducts were flushed 2–8 h after mating, most of the unattached sperm recovered from the central lumen were dead, whereas most of the sperm that were attached to epithelium were motile.[184] In this case, binding of sperm to the epithelium seemed to be required for maintenance of viability during storage of sperm in the oviduct.

Sperm Bind to Carbohydrates on Oviductal Epithelium

Sperm binding to oviductal epithelium involves carbohydrate recognition. Fetuin and its terminal sugar, sialic acid, were found to competitively inhibit binding of hamster sperm inseminated directly into oviducts, whereas desialylated fetuin did not.[185] The sperm could be labeled over the rostral portion of the head by colloidal gold-tagged fetuin, indicating that they bind fetuin in the same region by which they bind to epithelium. Gold-tagged fetuin also labeled certain protein bands on western blots of membrane extracts from hamster sperm.[185] These observations indicate that there is a carbohydrate-binding molecule on the heads of hamster sperm that binds sialic acid and is responsible for attachment of sperm to the epithelium.

Binding of other species of sperm to conspecific epithelium was also reported to be competitively inhibited by specific carbohydrates. Binding of stallion sperm to explants of oviductal epithelium was inhibited by asialofetuin and its terminal sugar, galactose.[186,187] Bull sperm binding was blocked by fucoidan and its component fucose.[90] Pretreatment of bovine oviductal epithelium with fucosidase, but not galactosidase, also reduced sperm binding.[90]

The binding of bull sperm to oviductal epithelium was the first to be more fully characterized. Fucose in an *alpha* 1–4 linkage to *N*-acetylglucosamine, as in the trisaccharide Lewis-a, inhibited binding to oviductal epithelium more efficiently than fucose in monosaccharide form or other linkages. Furthermore, Lewis-a tagged by conjugation to fluorescein-labeled polyacrylamide bound to the heads of live bull sperm.[188]

Recently, the development of glycan arrays enabled rapid and detailed identification of glycan motifs to which boar sperm bound. Boar sperm bound directly to variants of Lewis-X trisaccharide and also to a branched structure with a mannose core and antennae terminating in sialylated or unsialylated lactosamine.[189] Mass spectrometric analysis of extracts of isthmic epithelium from porcine oviducts identified these motifs in *N*- and *O*-linked glycans and glycolipids. Sialylated lactosamine was identified by SNA lectin on apical surfaces of mucosal epithelium in both the isthmus and ampulla of the porcine oviduct. Labeled sialylated lactosamine bound to heads of boar sperm; labeling was reduced after capacitation, indicating that loss of sialylated lactosamine groups from sperm heads could play a role in release of sperm from the reservoir.[189]

Altogether, studies of carbohydrate involvement in sperm binding to epithelium indicate that the phenomenon is widespread among eutherian mammals, although the particular carbohydrate moiety comprising the binding site varies according to species. These species differences may not seem so unusual when one considers that a single amino acid residue can determine the ligand specificity of a lectin[190,191] and that closely related animal lectins have different carbohydrate specificities.[192]

Sperm Ligands and Oviductal Receptors

In order to identify the ligand on bull sperm that binds them to oviductal receptors, the oligosaccharide that blocked sperm binding to oviductal epithelium, Lewis-a,

Vet-ebooks.com

was used to affinity purify potential ligands from extracts of bull sperm plasma membranes. A protein of approximately 16.5 kDa was pulled down from the extracts and identified by amino acid sequencing as BSP1 (Binder of SPerm 1, formerly known as PDC-109), which is a secretion of bovine seminal vesicles that becomes adsorbed onto sperm (Figure 5.15 (A–D)).[194] BSP1 purified from seminal plasma competitively inhibited bull sperm binding to oviductal epithelium. Bovine epididymal sperm lack BSP1 on their membranes (Figure 5.15) and, indeed, show only minimal binding to oviductal epithelium in vitro. However, when epididymal sperm were incubated with purified BSP1, then washed to remove unadsorbed protein, and then added to explants of oviductal epithelium, incidence of sperm binding was raised to the level of ejaculated sperm.[193]

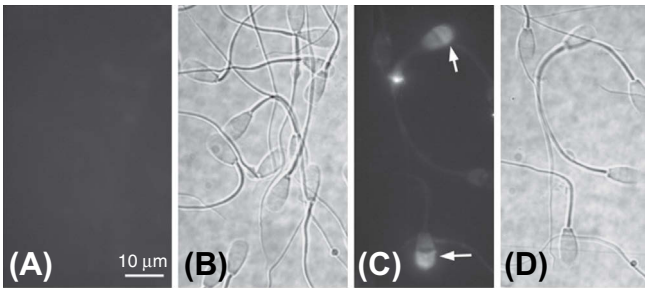

FIGURE 5.15 Bovine epididymal sperm adsorbed BSP1 over the acrosomal region of the head plasma membrane, shown using anti-BSP1. (A) Epididymal sperm without BSP1 show no antibody label. (B) Brightfield image of (A). (C) Epididymal sperm previously treated with BSP1 are labeled over the acrosomal region (*arrows*). (D) Brightfield of (C). *Source: From Ref. 193.*

BSP1 is the most abundant protein in bovine seminal plasma, present at concentrations of 15–20 mg/ml.[195] It occurs in two forms: BSP-A1 and BSP-A2. BSP-A1 possesses a single trisaccharide, NeuNAc-Gal-GalNAc, that is *O*-linked via GalNAc to threonine on residue number 11 in the N-terminal domain,[196] while BSP-A2 lacks the trisaccharide. The N-terminal domain is followed by two fibronection type II (FN2) domains.[197] BSP1 binds to choline phospholipids via short hydrophobic sequences within its fibronectin domains.[198] This is thought to be the mechanism by which it adsorbs onto epididymal sperm when they are exposed to secretions of the seminal vesicles.[199,200]

It was later reported that two other BSP proteins, BSP3 (formerly known as BSPA3) and BSP5 (formerly known as BSP30K), each acting alone, can also induce sperm binding to oviductal epithelium.[201] BSP1, BSP3, and BSP5 are each comprised of a unique N terminal domain, followed by two FN2 domains with heparin and phospholipid binding sites (Figure 5.16).[201] BSP3 and BSP5 are also produced exclusively by the seminal vesicles, but in concentrations only about one-tenth that of BSP1.[202] Because each BSP can act alone to bind sperm to epithelium, it is not required that they form a complex in order to do so. If each BSP acts alone, each may play a slightly different role in holding sperm in the reservoir, maintaining sperm functionality during storage in the reservoir, or in regulating the release of sperm from storage.

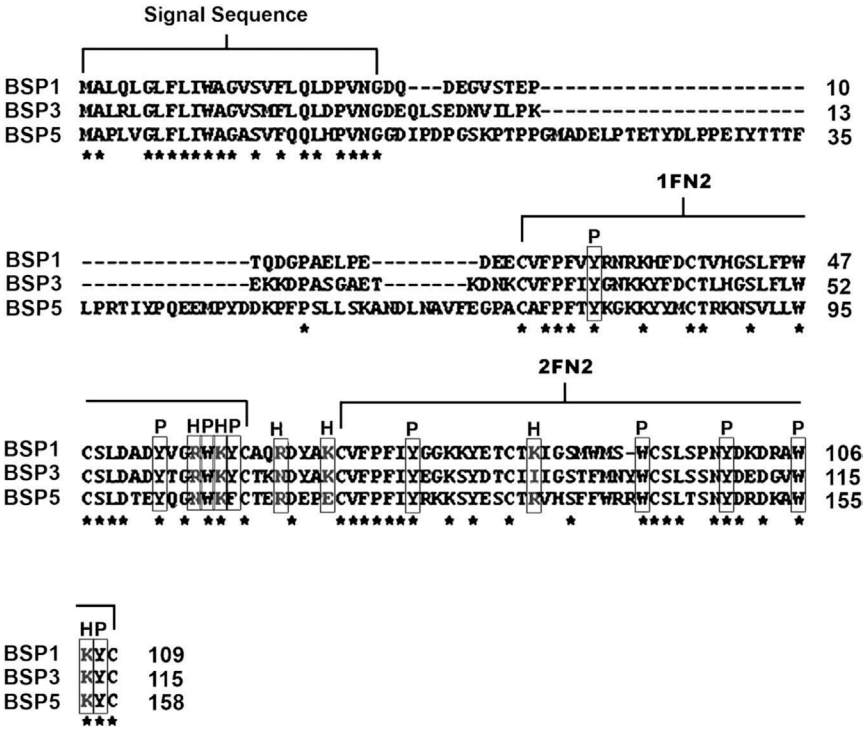

FIGURE 5.16 Amino acid sequence alignments of BSP1, BSP3, and BSP5. Residues conserved among all three proteins are indicated by asterisks. The FN2 domains are indicated above the sequences. P, aromatic residues that bind phosphorylcholine; H, heparin-binding residues. *Source: From Ref. 201.*

Vet-ebooks.com

Homologs of the bovine BSP proteins have been identified in a wide array of mammalian species, including rodents, ruminants, and humans. The homologs of humans and mice are expressed in the epididymis rather than in the seminal vesicles and would therefore coat epididymal sperm.[203]

Oviductal receptors for the BSP proteins on sperm were tentatively identified by using each BSP protein as bait in affinity columns to pull proteins from extracts of apical membranes of bovine oviductal epithelium. Oviductal protein bands of approximately 34 and 38 kDa were obtained from the columns and identified by tandem mass spectrometry as annexins (ANXA) 1, 2, 4, and 5. Antibodies to each of the four ANXA proteins blocked sperm binding to explants of oviductal epithelium and labeled the apical surfaces and cilia of the mucosal epithelium in histological sections of bovine oviduct.[204] Western blots confirmed the presence of annexins in apical plasma membranes of oviductal epithelium.[204]

Preserving Sperm Fertility during Storage

The oviductal mucosa protects sperm against aging damage during storage. Sperm incubated with oviductal epithelium in vitro remain viable longer than when they are incubated in medium alone (porcine,[145] equine,[205] human,[170] canine[171]) or with tracheal epithelium (bovine[168]). Viability can even be extended by incubating sperm with vesicles prepared from the apical membranes of oviductal epithelium (rabbit,[206] equine,[207] human[208]), indicating that the epithelium can produce the effect by direct contact with sperm. It was reported that equine sperm binding to epithelium or membrane vesicles maintained low levels of cytoplasmic Ca^{2+} when compared with free-swimming sperm, sperm attached to Matrigel, or sperm incubated with vesicles made from kidney membranes.[207] Equine and human sperm incubated with oviduct membrane vesicles also capacitated more slowly than sperm incubated in capacitating medium alone, when capacitation was assessed by chlortetracycline fluorescence patterns.[207,208] Possibly, sperm viability is maintained by inhibition of capacitation and its concomitant rise in cytoplasmic Ca^{2+}. The mechanism for preventing rises of cytoplasmic Ca^{2+} in sperm are not known, but one suggestion is that catalase, which is present in the oviduct, serves to protect against peroxidative damage to the sperm membranes,[209] which could increase the permeability of membranes to Ca^{2+}.

The oviductal binding protein on bull sperm, BSP1, probably preserves sperm by acting to stabilize sperm plasma membranes. By adding spin-labeled lipids to membranes in order to assess membrane fluidity by electron spin resonance spectroscopy, it was determined that addition of BSP1 to phospholipid membranes reduces membrane fluidity and immobilizes cholesterol in artificial membranes and in membranes of epididymal sperm.[210,211] BSP1 can also contribute to membrane stability by inhibiting the activity of phospholipase A_2.[212,213] Thus, BSP1 may play a role in preserving sperm fertility while they are stored in the reservoir.

Release of Sperm from the Reservoir

Theoretically, sperm could be released from the reservoir either by loss or alteration of receptors on the epithelium or by loss or alteration of ligands on sperm. Changes in the hormonal state of oviductal epithelium related to impending ovulation were not found to affect the density of oviductal binding sites for bull sperm[177]; therefore, it appears that epithelium does not release sperm by reducing available binding sites, at least in cattle. Instead, current evidence indicates that a change in the sperm brings about its release.

As part of the complex process of capacitation, which prepares sperm to fertilize oocytes, sperm undergo two changes that may play a role in their release from the reservoir: modification of the plasma membrane and motility hyperactivation (see Chapter 4). Modification of proteins on the surface of the plasma membrane overlying the acrosome could reduce binding affinity for receptors on the oviductal epithelium. Motility hyperactivation is a change in the flagellar beating pattern of sperm that is characterized by increased flagellar bend amplitude and asymmetry of the beat (Figures 5.17 and 5.18).[214,215] Hyperactivation could provide the force necessary for overcoming the adhesion between sperm and oviductal epithelium.[215]

Hamster sperm that had undergone both capacitation and hyperactivation in vitro did not bind to epithelium when infused into hamster oviducts, while uncapacitated/unhyperactivated sperm did bind.[178] When bull sperm were incubated in bovine sperm capacitation medium[216] (a buffered balanced salts medium containing energy substrates, bovine serum albumin, Ca^{2+}, bicarbonate, and heparin) and were then added to explants of oviductal epithelium, binding was significantly reduced.[217] In this case, the sperm were capacitated in the sense that they could undergo physiological acrosome reactions, but they were not hyperactivated; therefore, it was concluded that capacitation reduces binding affinity of sperm for epithelium. Taken together, these observations indicate that capacitation-induced changes in the surface of the sperm head are responsible for loss of binding affinity, although the pulling force produced by hyperactivation can enhance the ability of bound sperm to detach from the epithelium.

Oviducts removed from mated mice can be transilluminated in order to examine the behavior of sperm within the reservoir. Under these conditions, it was noted that only hyperactivated mouse sperm detached from epithelium.[218] Hyperactivated mouse sperm appeared

Vet-ebooks.com

to use a rocking motion to tear themselves off of the cilia on the epithelial surface.[219]

Hyperactivation of sperm can also assist their escape from the reservoir by propelling them through mucus in the oviductal lumen. Mucus that fills the uterotubal junction also extends into the isthmus in rabbits,[142,143] pigs,[144] dairy cattle,[138,145] and humans.[146] Hyperactivated sperm penetrate artificial mucus, such as viscoelastic solutions of long-chain polyacrylamide or methyl cellulose, far more effectively than nonhyperactivated sperm[220–222]; therefore, they are better equipped to swim through oviductal mucus (Figure 5.17).

Even in the absence of mucus, hyperactivation can assist escape from the reservoir, because it endows sperm with greater flexibility for turning around in the pockets formed by folds in the oviductal mucosa (Figure 5.18).[214,215,223,224]

While evidence is lacking for a release mechanism involving reduction in binding sites on the epithelium, the epithelium could play a role in sperm release by secreting factors that affect sperm. For example, hormonal signals that induce ovulation or signals from the preovulatory follicle could stimulate the oviductal epithelium to secrete factors that hasten sperm capacitation and trigger hyperactivation, thereby bringing about sperm release. Soluble oviductal factors have been reported to enhance capacitation of bull sperm in vitro.[225,226]

As sperm undergo capacitation, the carbohydrate-binding molecules responsible for binding sperm to the epithelium may be lost from the sperm surface or modified so as to lose affinity for specific receptors on

the oviductal epithelium. Hamster sperm capacitated in vitro no longer labeled over the acrosomal region with fetuin,[185] indicating that they had lost the ability to bind to oviductal epithelium via sialic acid. Similarly, electrophoretically resolved proteins extracted from capacitated hamster sperm showed diminished fetuin labeling on blots, compared with proteins extracted from uncapacitated sperm.[185]

Capacitated bull sperm showed reduced binding to oviductal epithelium,[217] as well as to fucose, as measured using fluorescein-labeled fucosylated bovine serum albumin.[194,227] The loss of binding affinity for the oviductal epithelium could be accounted for by a loss of the adsorbed BSP proteins from the sperm head. When BSP1 coats sperm by binding to choline phospholipids in the plasma membrane, it forms homodimers with heparin-binding sites exposed.[196,228] Heparin is used to capacitate bull sperm in vitro,[216,229,230] and there is some evidence that BSP1 is lost from the sperm surface during heparin-induced capacitation.[231] BSP3 and BSP5 also have heparin binding sites.[201] Addition of heparin to cocultures of bovine sperm and oviductal epithelium enhance the release of sperm from epithelium.[232] In vivo, as the time of ovulation approaches, an increase of heparin-like glycosaminoglycans in oviduct fluid could serve to release sperm. Oviduct fluid collected from cows in the periovulatory period showed a peak in heparin-like biochemical activity, as well as a peak in capacitation-inducing activity.[229]

Although BSP1, BSP3, and BSP5 can each attach sperm to oviductal epithelium, their response to capacitation and the specific roles they may play in holding and releasing sperm could vary due to differences in their amino acid sequences. The N-terminal domain of each of the three BSP proteins is unique. The two FN2 domains, each of which contains binding sites for membrane phospholipids and heparin, differ somewhat in sequence.[203] In fact, like many proteins specific to the reproductive system, members of the BSP protein family are undergoing rapid evolutionary change.[203] It was proposed that reduced binding to oviductal epithelium is due in part to loss of BSP proteins during capacitation. Because of differences in amino acid sequences, it was predicted that each BSP would respond differently to capacitating conditions. To test whether all three BSP proteins were lost from sperm during capacitation and whether the kinetics of loss differed among the three bovine BSP proteins, ejaculated bull sperm were incubated under various capacitating conditions, and then the amounts of BSP proteins remaining on the sperm were assayed by western blotting. Capacitation was assayed by analysis of protein tyrosine phosphorylation. While loss of BSP1 was not detected in these experiments, most BSP5 was lost from sperm even during incubation under minimally capacitating conditions. Surprisingly, antibodies against BSP3 detected a new protein band of reduced molecular mass in extracts of incubated sperm. Its identity was confirmed as BSP3 by mass spectrometry, indicating that BSP3 undergoes modification while on the sperm surface.[233] Because BSP3 is not glycosylated, the reduction in size cannot be attributed to deglycosylation. Metalloproteases and serine proteases have been identified on the surface of sperm[233,234]; therefore, the mass reduction could be due to proteolytic cleavage. Altogether, the different responses of the three BSP proteins on bull sperm indicate that a complex process is involved in the release of sperm from the reservoir.

The development of Acr-EGFP mutant mice that produce sperm with fluorescent acrosomes[11] facilitated the study of sperm movement into the ampulla of the oviduct. Periovulatory wild-type female mice were mated with males who produced the fluorescent sperm and the oviducts were removed 3 h later for observation of sperm. Hyperactivated sperm in the isthmic reservoir detached frequently from the epithelium and then reattached. Unexpectedly, most of the few sperm found in the ampulla were also attached to epithelium, often for several minutes (Figure 5.19). Some sperm detached from epithelium in both the ampulla and isthmus during strong contractions of the oviduct. Blockage of oviduct contractions with nicardipine, however, did not prevent sperm from reaching the ampulla, indicating that contractions are not required for moving sperm. These observations show that sperm continue to bind to oviductal epithelium as they move up the oviduct,[219] and they agree with earlier reports that bull sperm can bind to ampullar epithelium.[144,177,179]

Summary: Entrapment and Release of Sperm in the Reservoir

In summary of what is known about sperm movement in the oviduct, the following picture emerges. The sperm reservoir forms in the uterotubal junction and/or the

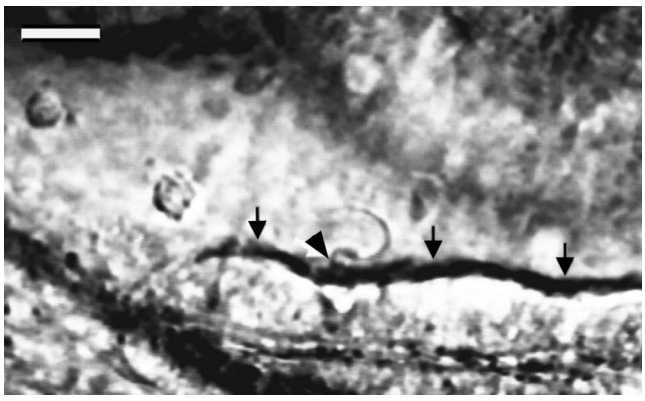

FIGURE 5.19 A mouse sperm attached by the hook of the head (*arrowhead*) to cilia on a ridge of epithelium (*arrows*) in the oviductal ampulla. Bar = 20 µm. *Source: From Ref. 219.*

caudal isthmus when a carbohydrate-binding molecule on the sperm head adheres to a glycosylated receptor on the oviductal epithelium. The narrowness of the oviductal lumen and mucus within the lumen can enhance sperm binding by slowing their progress and increasing their contact with the epithelial surface. Binding to the mucosal epithelium prolongs sperm survival and delays capacitation. As the time of ovulation approaches, capacitation is likely initiated by secretions in the oviduct fluid. The coating of oviduct-binding molecules on the surface of sperm is modified during capacitation, thereby changing binding affinity of sperm for the epithelium. As the binding affinity of sperm is modified, hyperactivation provides them with the force necessary to pull away from the oviductal epithelium. Nevertheless, sperm continue to bind intermittently to oviductal epithelium as they move toward the site of fertilization.

Oviductal Sperm Storage in Marsupials and Insectivores

In some marsupial mammals,[235,236] sperm are stored in special mucosal crypts in the oviduct (Figures 5.20 and 5.21). However, sperm within the crypts do not attach to the epithelium. Many of the sperm in the crypts of the marsupial *Sminthopsis crassicuadata* were observed to be immotile[237]; therefore, motility suppression may serve to keep sperm in the crypts until ovulation. In other marsupials, however, sperm appear to attach to oviductal epithelium.[239]

In primitive eutherian mammals in the order Insectivora, some species of shrews and moles possess isthmic sperm storage crypts,[240] while others store sperm in bubble-like outpocketings of the ampullar wall (Figure 5.22).[241,242] Sperm found within these structures do not bind to the epithelium. Perhaps the most complex oviductal sperm storage system is that of the white-toothed shrew (*Crocidura russula*) and the African shrew (*Myosorex varius*). In these insectivores, sperm inhabit crypts in the isthmus prior to ovulation and move up to bubble-shaped outpocketings in the ampulla at about the time of ovulation (Figure 5.23). Sperm seen in the isthmic crypts have slowly beating flagella; whereas, sperm in the ampullar structures have rapidly beating flagella.[243,244]

Another insectivore, the African pygmy hedgehog (*Atelerix albiventris*), lacks distinctive oviductal sperm storage structures, but little is known about how it stores sperm.[245] More advanced eutherian mammals, such as mice, cows, and pigs, also lack distinctive storage structures. In the "advanced" species, sperm bind to epithelium primarily in grooves created by folds of mucosa. It is curious that distinctive storage structures would be lost and sperm binding would evolve to replace them as a mechanism of sperm storage.

Sperm Storage in Women

So far, no conclusive evidence has emerged for a distinct oviductal sperm reservoir in humans.[246] While associations of human sperm with oviductal epithelium have been observed in vitro, the sperm do not seem to bind as quickly or as tightly to the epithelium as those of nonprimate mammals.[208,247–250] On the other hand, human sperm viability is maintained by incubation with oviductal epithelium,[208] as it is in species in which there is immediate and strong binding of sperm to epithelium.[168,169,171]

The human cervix has been designated a sperm reservoir; however, as discussed previously, the evidence is not robust. Leukocytic infiltration of the uterus becomes significant several hours after coitus, with leukocytes outnumbering sperm at about 24 h postcoitus.[251] Unless sperm are protected from phagocytosis (and they might be!), it is unlikely that they could be stored for more than a few hours in the cervix and still reach the site of fertilization in the oviduct.

Human sperm could be stored for long periods of time in the oviduct, but not in a distinct reservoir and not as a result of binding tightly to the mucosal surface. The

mucosal folds of the human oviductal lumen increase in height and complexity toward the ovary (Figure 5.24), thereby producing increasingly greater obstacles to the advancement of sperm. Sperm progress could also be slowed by the mucus in the lumen[146] and by sperm sticking lightly to the epithelium.[248,249] So, rather than having a distinct reservoir, human sperm advancement to the

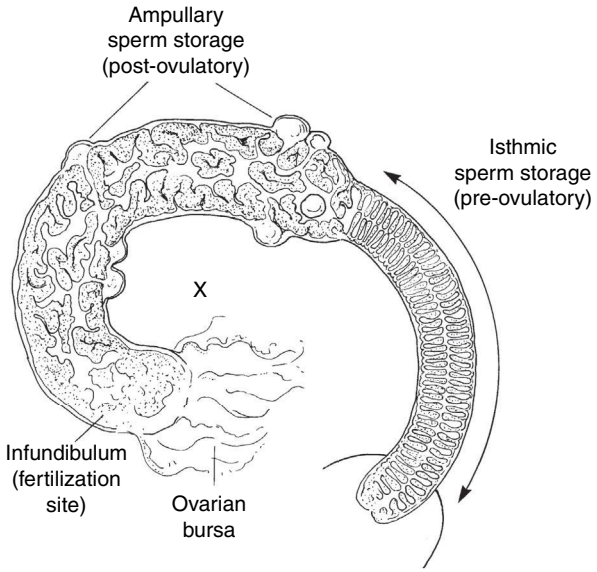

FIGURE 5.23 Diagram of the main features of the oviduct of the shrew, *Crocidura russula* monacha. site of fertilization could be slowed in such a manner so as to increase the chances that a few will be present at the site of fertilization when ovulation occurs hours to days after insemination. Muscular contractions and secretions at the time of ovulation could move or activate sperm and increase chances of encountering the oocyte.

Reports of sperm distribution in the oviducts of women have not provided a clear picture of the events of sperm transport. Numbers of sperm recovered at various times in different regions of the human oviduct have varied so much that the data do not permit the construction of a model for the pattern of sperm storage and transport in women.[246] Perhaps fertilization is a relatively inefficient and unregulated process in humans, because coitus has taken on an additional role of promoting long-term pair bonding in addition to promoting fertilization success.

The Fate of Nonfertilizing Sperm in the Oviduct

After fertilization, mammalian sperm may be phagocytosed by isthmic epithelial cells (Figure 5.25)[243,253,254] or may be eliminated into the peritoneal cavity[255] and then phagocytosed. Phagocytosis within the oviduct may be employed by species, such as mice, which have an extensive ovarian bursa that would limit passage of sperm into the peritoneal cavity.

Sperm Chemotaxis in the Oviduct

Chemotaxis is the directional movement of a cell or organism along a gradient of an attractant produced

Vet-ebooks.com

by another cell or organism. In vitro, human and rabbit sperm have been reported to turn toward or accumulate in a gradient of follicular fluid.[252,256–259] Progesterone, which is present in follicular fluid and also secreted by the cells of the cumulus oophorus, has been proposed to be a chemoattractant for human and rabbit sperm.[260,261]

Odorant receptors unique to sperm have been localized to a spot on the base of the flagellum of canine,[262] rat,[263] and human sperm.[264] Mark Spehr's group screened components of a complex mixture of 100 odorants to see if any evoked a physiological response in human sperm. Eventually, they identified the floral odorant "bourgeonal" as a potential chemoattractant for human sperm.[264] The results of their first experiments have been validated; however, neither bourgeonal, nor an equivalent odorant compound with sperm chemoattractive activity, has been identified in mammalian eggs or reproductive tracts.

Sperm are equipped with mechanisms for turning. One is that they can switch back and forth between symmetrical flagellar beating and the asymmetrical flagellar beating of hyperactivation. Hyperactivation is triggered by a rise in cytoplasmic Ca^{2+} and has been reversed in mouse sperm in vitro.[265] Reversing and reinitiating hyperactivation by lowering and raising cytoplasmic Ca^{2+} levels would enable sperm to alternate between turning and swimming straight ahead. A second mechanism for turning has been observed in mouse sperm, that is, the switching of the orientation of the deep asymmetrical bends of hyperactivation from one side of the flagellum to the other. In vitro, treatment of mouse sperm with procaine or 4-amino pyridine to trigger Ca^{2+} influx induces hyperactivation characterized by the formation of deep bends in the same orientation as the hook of the sperm head; whereas, treatment with thimerosal to trigger release of Ca^{2+} from internal stores induces formation of deep flagellar bends in the direction opposite to the orientation of the hook of the sperm head.[219] Nevertheless, the identities of signal or signals from the egg or oviduct that trigger switching between symmetrical and asymmetrical flagellar beating patterns, or switching the direction of the deep asymmetrical flagellar bends, have not been established.

Chemotactic guidance of mammalian sperm toward oocytes, if it exists, is likely to be limited to short distances within the oviduct, because gradients established in oviductal fluids would be disrupted over longer distances by the loops of the oviduct, the folds in the lining of the oviduct, muscular contractions, and ciliary

Vet-ebooks.com

currents. In the well-established example of chemotaxis of sperm of the sea urchin *Arbaci punctulata* in gradients of resact, a peptide from the jelly layer of the egg, the calculated effective range of resact diffusing radially out from the egg is only about 0.4 cm, even though the sperm can respond to as little as a single molecule of resact.[266] If translated to humans, this effective distance would not reach the lower isthmus from the fertilization site. Babcock[267] suggested that human sperm could be guided into the cumulus mass from nearby mucosal pockets in the oviductal ampulla. In other species, such as mice, large cumulus masses fill the width of the ampullar lumen (Figure 5.13). In these species, chemoattraction could serve to guide sperm from the edge of the cumulus mass to the oocytes deep within the mass, if the oocyte released an attractant that formed a gradient within the cumulus.

Chemotaxis has been well established in several species of marine invertebrates. This is because the phenomenon is easily observed in vitro. When a gradient of chemoattractant is introduced into a dish containing high concentrations of sperm, a swarm of sperm can immediately be seen to move up the gradient.[266] No movies or images of this kind of behavior have yet been published for mammalian sperm. It has been proposed that the reason for this is that only a small fraction of sperm is capable of responding to chemoattractant at any given time. If this hypothesis is correct, then it is challenging to obtain an adequate sample size to detect small but significant differences between control and treatment samples. Recently, block bootstrapping statistical procedures have been adapted for detecting differences in the distribution of angles of sperm swimming direction with respect to the orientation of a chemotactic gradient. These procedures were used to detect chemotactic responses of human sperm to progesterone in gradients where the maximum progesterone concentrations were 10 and 100 pM.[268]

On the other hand, the very low percentages of chemotactic responses reported for samples of mammalian sperm could be due to the conditions of the experiments performed in vitro. Some experiments have been carried out at room temperature, rather than the temperature of the oviduct, and this could reduce the ability of sperm to respond. Other experiments have been carried out using putative attractants under conditions that could induce acrosome reactions and therefore cause sperm to stick to the walls of the chemoattractant chamber in the regions of high concentrations. Still other experiments have been carried out in chambers in which chemotaxis is assayed by the number of sperm that pass through a screen into a separate chamber. These experiments could be measuring entrapment rather than chemotaxis. If the agent being tested triggers continuous hyperactivation, rather than true chemotaxis, sperm that become hyperactivated in the separate chamber could become trapped there. Lastly, it has been reported that sperm must be capacitated in order to respond to chemoattractants. In vitro, sperm do not capacitate synchronously, which could explain the low incidence of chemotaxis detected in experiments. Nevertheless, the synchronicity of capacitation of sperm in the oviductal reservoir is unknown at present.

In addition to possible chemoattractants already mentioned, a variety of other potential chemoattractants have to date been put forth in a number of publications. As improved chambers and statistical methods become available to test for chemotaxis, one or more of the proposed attractants may turn out to be true physiological chemoattractants.

An alternative, or additional, mechanism for guiding sperm to the site of fertilization is that of chemical guidance provided by molecules on the mucosal surface of the oviduct. For example, three different BSP proteins have been reported to bind sperm to the oviductal wall, and four different annexin proteins have been tentatively identified as receptors for the BSP proteins. Because the composition of the coat of BSP proteins changes during capacitation in vitro,[233] the interaction of sperm with the oviductal epithelium would change concurrently, perhaps resulting in release and then reattachment of sperm further up the oviduct. Sperm have been observed to attach to epithelium in both the isthmus and ampulla.[144,177,179] In the mouse oviduct, sperm have been observed to detach from and reattach to the oviductal epithelium as far up the oviduct as the ampulla.[219] These observations provide preliminary evidence for a solid phase chemical guidance system for sperm.

To date, the reports of chemotaxis in mammalian sperm have been intriguing and have justifiably stirred up excitement; however, much remains to be learned about whether and how the chemotaxis occurs.

In addition to chemical attractants, the movement of sperm could be guided by physical factors. The tendencies of sperm to move along walls and against gentle fluid flows could be utilized by the female to guide sperm to and through the oviduct. Microchannels designed on the basis of observed sperm interactions with wall geometries have succeeded in guiding the movement of human sperm (Figure 5.26).[22] Evidence has been presented to demonstrate that sperm are thermotaxic; however, there is controversy about whether sperm could be guided by thermotaxis in vivo.[269] Physical factors might function less efficiently than chemical gradients but could still be sufficient to ensure that enough sperm reach the oocytes in a timely manner.

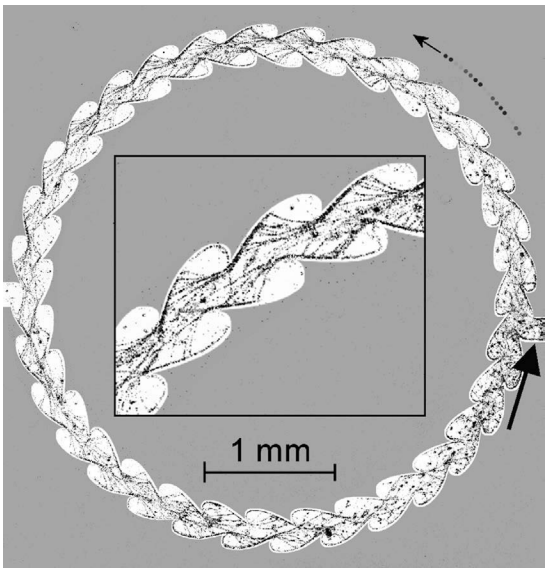

FIGURE 5.26 Human sperm in a microchannel designed to funnel them to swim in a counterclockwise direction (*curved arrow*). The gray shading indicates the position of the walls, but is placed 10–20 μm back from the actual walls so as not to interfere with viewing the tracks of the sperm. The input channel for sperm is on the right (*large, straight arrow*). The insert shows a higher magnification of tracks of sperm swimming within the microchannel. The dots represent locations of sperm heads. Images were collected at four frames per second, and the location of sperm heads in 200 consecutive images were summed to produce this figure. Notice that sperm tend to swim in a certain pattern in the channel. *Source: From Ref. 22.*

OOCYTE AND EMBRYO TRANSPORT IN THE OVIDUCT

In many mammalian species, oocytes progress from prophase of the first meiotic division to metaphase of the second meiotic division just before ovulation (see Chapter 1). Most then arrest in the second metaphase until fertilization activates completion of meiosis.[270] Oocytes are usually fertilized soon after entering the oviduct. If mating or artificial insemination is delayed until the time of ovulation or after, the incidence of pregnancy is reduced and the occurrence of developmental anomalies is increased.[271] The most common anomalies detected after delayed insemination are polyspermy (multiple sperm fertilizing a single oocyte), polygyny (failure to complete the second meiotic division and extrude the second polar body), and disintegration of the oocyte chromosomes.[271,272] Aged unfertilized oocytes may undergo a spontaneous, though abnormal, form of activation, eventually leading to cell death.[273,274] Aging reduces developmental competence of oocytes by altering Ca^{2+} homeostasis and signaling, including reduction of Ca^{2+} levels in the endoplasmic reticulum and of IP_3-induced release of Ca^{2+} from intracellular stores.[275] Mitochondrial function and actin distribution in the oocyte cytoplasm are also altered by aging.[275]

Female mice inseminated 10 h after ovulation had shortened gestation length and decreased litter size. Their pups had a higher perinatal death rate, growth retardation, and other developmental delays.[276] In the CF-1 mouse strain, oocyte abnormalities begin to appear about 4 h after ovulation or about 16 h after hCG administration,[273] although the fertile lifespan of oocytes in Swiss Webster mice may be 15 h or more.[272]

Early reports indicated that the fertile lifespan of oocytes is about 6 h in the rabbit,[277] 12 h in the rat,[278] 9 h in the golden hamster,[279] and 20 h in the guinea pig.[280] Ferret (*Mustela* sp.) oocytes may be fertilizable for 30–36 h.[281,282]

Oocyte Pickup

Muscle and Ciliary Action in Oocyte Pickup

There are two steps involved in oocyte transport. The first is the picking up of the oocyte from the surface of the ovary or from the ovarian bursa by the fimbria. The second is transport of the oocyte through the oviductal ampulla.

Richard Blandau's pioneering films of ovulation and oocyte pickup in rabbits inspired an appreciation of the process. The films revealed that the mesosalpinx (the segment of the broad ligament of the uterus that suspends the oviduct in the pelvic cavity) contracts rhythmically during ovulation, causing the fimbria to slide over the surface of the ovary.[7] Smooth muscle in various regions of the broad ligament moves the oviduct and ovary to aid in the positioning of the fimbria over the ovary, as do contractions of smooth muscle in the wall of the fimbria.

In some species, such as rats and hamsters, the fimbria are small and cannot sweep over the surface of the ovary. In these species, the space between the ovary and oviductal ostium is nearly completely enclosed by the mesovarium and mesosalpinx, which together form a bursa. The cumulus mass is actually ovulated into the bursa, where it is jostled by movement of the ovary and oviduct until it comes into contact with cilia on the fimbrial surface and is picked up.[7,283,284] At ovulation in the hamster, follicular contents are extruded as a long, sticky strand of cumulus, matrix, and oocyte. The strand soon makes contact with the cilia on the surface of the fimbria, drawing the rest of the mass away from the surface of the ovary. The mass is then rapidly transported over the fimbrial surface toward the ostium (Figure 5.27). Upon reaching the ostium, the mass churns in the entrance and becomes compacted before it enters the ampulla.[284,285]

Adhesive Interactions

Ciliary currents alone cannot sweep an object the size of a cumulus mass or even an oocyte into the ostium of the ampulla; such currents can only move small particles, such as *Lycopodium* spores.[286] In the eutherian

mammals studied so far, adhesion of the cumulus mass to the cilia is required for successful pickup. The sites of interaction on the surface of the fimbria are the tips of its cilia (Figure 5.28).[284,287]

Adhesion between the cilia and cumulus-enclosed oocyte is mediated by the negative charge of sialic acid glycosyl moieties on the surface of the cilia. Polycationic molecules block oocyte pickup in the rabbit and hamster.[283,286,287] Neuraminidase pretreatment of hamster fimbria to remove sialic acid reduces pickup.[283]

On the oocyte side of the adhesive interaction, presence of cumulus is required for pickup. In rabbits and hamsters, if the cumulus and its matrix are removed from the oocyte, it is not picked up by the fimbria.[283,284]

Hyaluronic acid is the chief component of the extracellular cumulus matrix; however, it is unlikely to be the molecule directly responsible for sticking the cumulus to the fimbrial cilia. When placed on the surface of hamster fimbria, hyaluronate gel was not picked up. Furthermore, a solution of hyaluronate did not block pickup, nor did pretreatment of the cumulus with hyaluronidase prevent pickup. Cumulus-free oocytes were not picked up, even if they were coated with Na-hyaluronate.[283] In contrast, coating the cumulus-free oocytes with egg white restored pickup.[283]

Fertility of female mice was severely reduced by targeted disruption of the bikunin gene.[288] Bikunin is the light chain of proteins in the IαI family (inter-alpha-trypsin inhibitors). Heavy chains in the family, called SHAPs (serum-derived hyaluronan-associated proteins) bind directly to hyaluronic acid. IαI proteins formed from the light and heavy chains link hyaluronic acid and associated molecules together to form gels. In the mutant mice, cumulus formation was abnormal but could be significantly improved if bikunin was infused into the peritoneal cavity.[288]

TNFAIP6 (hyaladherin tumor necrosis factor-α-induced protein 6) binds to hyaluronan and forms a complex with IαI proteins.[289] It acts as a catalyst to covalently link the heavy chains of IαI to hyaluronan. Disruption of the gene encoding TNFAIP6 also severely reduced fertility of female mice. Fertility was significantly improved by injecting mouse recombinant TNFAIP6 protein into the peritoneal cavity at the time of ovulation induction

Vet-ebooks.com

by hCG.[289] Similarly, disruption of the gene for PTX3 (pentraxin 3) resulted in abnormal cumulus formation and female subfertility. PTX3 binds cumulus matrix protein to TNFAIP6.[14,15] In vitro fertilization was normal in *Ptx3*–/– mice, indicating that while a normal matrix is not required in vitro, it is critical in vivo. PTX3 is also present in human cumulus matrix.[15] The exact roles of these molecules in adhesion to the fimbria are unknown. They may either interact directly with molecules of the ciliary plasma membranes or they may assemble other cumulus matrix molecules into the proper molecular structure for adhesion to the cilia.

In hamsters, the adhesive attraction between cumulus mass and oviductal cilia increases 10- to 40-fold when the mass reaches the ostium. After compaction of the cumulus in the ostium, adhesive strength of the interaction decreases precipitously.[284]

While the cumulus is undoubtedly important for egg pickup in the eutherian mammals studied, a cumulus oophorus has not been found in marsupial mammals. The granulosa cells do not accompany the oocyte at ovulation.[235,238,290] In some shrews, which are considered primitive eutherian mammals, the cumulus does not have a visible matrix at the time of ovulation, although a matrix may be produced after fertilization, when the zygote is in the oviduct.[241,291]

Oocyte Transport in the Oviduct

Ovulatory Products Fit the Oviductal Lumen

Bedford noted that the diameter of the central lumen of the oviduct matches the size of the ovulatory products in mammals.[290] In most eutherian mammals, there is a large, expanded cumulus mass surrounding the oocytes, which fills a segment of the ampulla or the central channel of the ampullar lumen (Figure 5.29). Cumulus expansion is accomplished by the secretion of hyaluronic acid and other matrix materials, followed by hydration. In marsupial mammals, there is no cumulus surrounding the ovulated egg and the ampulla is narrower than those of eutherian mammals.[238] In shrews, an intermediate situation exists; that is, there is a cumulus around the ovulating oocytes, but it is not expanded.[241,243,291] Correspondingly, the ampullar lumen of shrews is intermediate in diameter and fits closely around the compact cumulus mass (Figure 5.29). So, in all cases, the oocyte and its vestments fit snugly in the ampullar lumen or central channel. These observations raise an interesting question: why did the vestments of the oocyte increase and expand? Bedford and Kim have proposed that the expanded cumulus evolved to serve to sequester sperm.[292]

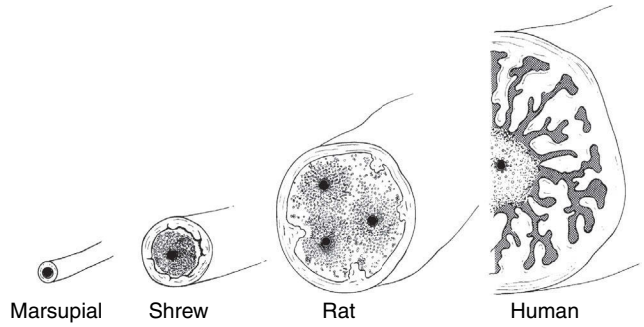

FIGURE 5.29 Diagram of the spatial relationship between the egg or egg–cumulus complex and the site of fertilization in the oviduct of various representative mammals. Where the oviduct is much larger than the egg, then the ability of the cumulus to fill the space is maximized by a variable degree of cumulus expansion. *Source: From Ref. 290.*

Muscle and Ciliary Action in Oocyte Transport

In eutherian mammals, once the cumulus mass containing one or more oocytes enters the ampulla, it moves rapidly to the ampullary-isthmic junction. Potential effectors of this movement are the oviductal musculature and the cilia.

Cilia lining the oviductal ampulla of dairy cows, sheep, guinea pigs, rats, and rabbits beat toward the uterus.[293,294] When rabbit oviductal smooth muscle contractions were blocked by isoproterenol, an agonist of beta-adrenergic receptors, the net rate of transport of cumulus-oocyte masses down the ampulla (about 0.12 mm/s) was not affected.[295] Isoproterenol was also tested in rats, where it inhibited muscle contractile activity without affecting ciliary activity or transport of surrogate ova (polystyrene microspheres suspended in egg white).[296] These observations indicate that cilia alone can move the cumulus/oocyte mass to its destination. When muscular contraction was allowed, back-and-forth motion of the mass was observed in the lower ampulla, although net movement was toward the uterus. When muscular contractions were blocked by isoproteronol, the mass moved smoothly down the ampulla.[296] Thus, while the overall rate of transport is not affected by inhibiting muscular action, the pattern of transport is affected. The back-and-forth movement could serve to enhance infiltration of the cumulus matrix with ovarian secretions or to initiate the process of cumulus removal.

In the transparent oviduct of the mouse, movement of oocytes in a cumulus mass has also been reported to move in a back-and-forth fashion through the ampulla toward the uterus. However, in contrast to the aforementioned descriptions of oocyte movement in rabbits and rats, smooth muscle contractions in the wall were shown to be required for oocyte transport. When contractions of the smooth muscle in the oviduct wall were inhibited by nicardipine, a Ca^{2+} channel blocker, movement of cumulus oocyte complexes ceased; however movement of 15–25 micron particles of apparent cellular

Vet-ebooks.com

debris were unaffected.[297] This indicates that, while cilia are capable of moving small particles down the oviduct, ciliary motion alone is not sufficient to move cumulus oocyte complexes at normal rates in mice. The contrasting reports of the relative roles of cilia and smooth muscles could be attributed to species differences or to differences in the spectrum of effects produced by nicardipine and isoproteronol.

There is evidence that the pendular muscle contractions of the mouse oviduct are controlled autonomously by interstitial cells of Cajal in the muscular layer of the oviductal wall, because treatment with tetrodotoxin to block nerve input did not inhibit contractions in mouse oviducts, whereas contractions were inhibited by treatment with nicardipine.[297]

Some women diagnosed as having Kartagener's syndrome (immotile cilia syndrome) are infertile,[298,299] while others are fertile.[300] This suggests that cilia are not absolutely necessary for oocyte transport in humans. Nevertheless, Kartagener's syndrome is a genetically heterogenous disorder, and some affected women have been reported to have some motile cilia.[298,299]

Embryo Transport in the Oviduct

In most eutherian mammals, the cumulus disperses soon after fertilization, while the zona pellucida remains intact. The fertilized ovum usually pauses at the ampullary-isthmic junction before resuming transport toward the uterus.[301] At the time of resumption of transport, the amplitude of isthmic contractions decreases in the rabbit, detected by insertion of a pressure-sensitive microballoon.[302]

Oviductal transport of embryos differs from that of unfertilized oocytes in some species. In the mare, unfertilized oocytes remain in the oviduct for several estrous cycles, while embryos pass into the uterus 5–6 days after ovulation.[303,304] In rats, unfertilized oocytes reach the uterus about 72 h after ovulation, while fertilized oocytes take about 96 h.[305] These observations indicate that the early embryo interacts differently with the oviductal mucosa than the unfertilized oocyte in some species, perhaps initiating signaling pathways that modulate its transport to the uterus.

In horses, there is evidence that early embryos secrete prostaglandin E2 (PGE_2), which acts to hasten the transport of embryos into the uterus. Infusion of PGE_2 into the oviducts of pregnant mares hastened the transport of both oocytes and embryos into the uterus.[306,307]

Platelet activating factor (PAF) bioactivity was detected in early hamster embryos, and PAF antagonists were found to prevent hastening of embryo transport into the uterus.[308] PAF is also produced by human embryos,[309] and receptors for PAF have been detected in the mucosal epithelium of human oviducts.[310]

The evidence supporting roles for estradiol (E2), PAF, and PGE_2 indicate that smooth muscle contraction plays a role in transport of the early embryo toward the uterus. The isthmus of the oviduct is generally lined by far fewer ciliated cells than the ampulla[293] and possesses a thicker muscular tunic.

In contrast to these findings, porcine ova fertilized by intrauterine insemination were not found to traverse the isthmus and reach the uterus any faster than unfertilized oocytes in uninseminated sows.[311]

In the rat, the time of embryo transport into the uterus is 72–94 h from the approximate time of fertilization.[312] Systemic administration of E2 at noon on day 1 of the estrous cycle in mated rats reduced the time of transport to 11–23 h.[312] Evidence indicates that E2 acts on the oviduct via both genomic and nongenomic pathways.[313–315] Nongenomic effects mainly depend on conversion of E2 to 2-methoxyestradiol, which activates cAMP-PKA and PLC-IP_3 signaling pathways in the oviduct.[315,316] Microarray analysis of gene expression revealed that the effects of E2 on the oviduct change after mating, decreasing activation of the nongenomic pathway and increasing gene expression through the genomic pathway.[316]

Rabbit embryos acquire a visible mucoid coat as they move down the oviduct.[317] The oviductal epithelium of many species of eutherian mammals secretes an oviduct-specific group of glycoproteins with mucin-like domains; these glycoproteins adhere to the zona pellucidae of oocytes and early embryos.[318–320] As marsupial embryos roll down the oviduct, they are wrapped in strands of mucin that form concentric layers.[321] However, the role mucoid coats play in embryo transport is unknown.

Little is known about the passage of the embryo through the uterotubal junction, although relaxation of the smooth muscle is likely to open the lumen for passage of the embryos. In dairy cows the sigmoid flexure at the junction must relax and the vascular plexus surrounding the junction must drain fluids out of the wall to open the lumen.[134,137]

Cigarette Smoke Interferes with Oocyte and Embryo Transport

Epidemiological data have revealed a correlation between smoking and ectopic pregnancy in women.[322,323] In a hamster model, the soluble components of mainstream cigarette smoke inhibited ciliary activity in the oviduct and oocyte pickup.[324–326] Of the components of cigarette smoke, nicotine, pyridines, and pyrazine were found to interfere with oviductal functions. Pyridines and pyrazine and some of its derivatives were effective in picomolar or nannomolar doses at reducing oocyte pickup rate, ciliary beat frequency, and smooth muscle contractions in vitro in fresh preparations of hamster oviductal infundibula.[327,328]

Vet-ebooks.com

Exposure of female hamsters to mainstream or sidestream cigarette smoke delays the arrival of embryos into the uterus.[329] Some of the delay could be attributed to impaired oocyte transport as well as embryo transport.

CONCLUSION

What has been learned to date about gamete transport can be summarized as follows. Sperm are deposited at coitus into the anterior vagina or uterus. Those deposited in the vagina swim through the cervix or are drawn through by uterine contractions. Muscular contractions assist in moving sperm through the uterine cavity. Then, a few thousand sperm enter the uterotubal junction. While still within the junction, or upon reaching the caudal isthmus, sperm are trapped by binding to the mucosal epithelium, forming a storage reservoir. As the time of ovulation approaches, sperm become capacitated and hyperactivated, which enables them to release from the epithelium and escape from the reservoir. Meanwhile, oocytes, surrounded in some species by cumulus cells in a sticky, viscoelastic matrix, are released from the ovary. The cumulus mass adheres lightly to cilia on the mucosal surface of the fimbria and is transported into the oviductal ampulla and then toward the ampullary-isthmic junction by ciliary action. During this time, a few sperm reach the cumulus mass. Fertilization occurs soon thereafter, as sperm penetrate the cumulus, reach and penetrate the zona pellucida, and finally fuse with the oocyte plasma membrane. After pausing at fertilization, the embryo resumes transport, probably by the actions of smooth muscle in the oviductal wall, and reaches the uterus in a few days.

Much remains to be learned about molecules and physical factors that regulate and guide transport of gametes. If the female tract is indeed adapted for enabling sperm transport to the oocyte while impeding the ascent of infectious microorganisms, elucidating these adaptations could inspire development of more effective nonhormonal contraceptives, as well as improved diagnosis and treatment of infertility. In the past, attention has been directed at the roles of female immune responses; however, more remains to be learned about innate and adaptive immune responses, as well as structural adaptations at the micron scale that could guide sperm. Another largely unknown story is how sperm in the uterus find the entrance to the uterotubal junction and why they require certain surface proteins to move through the junction. Yet another set of questions revolves around the oviductal sperm reservoir: how does binding to the oviductal epithelium benefit sperm and what triggers their release to continue ascending the oviduct? Once sperm are released from the reservoir, are there chemical and/or physical mechanisms that guide them to the cumulus-oocyte complex and to the oocyte? If so, what are they?

Transport of the oocyte into the oviduct and down the ampulla has been closely observed in a few species; however, we have only scratched the surface of understanding the chemical and physical interactions between the cumulus-oocyte complex and the oviduct. Of particular interest is how molecular interactions between the ovulatory products and the oviduct change with fertilization and with activation of the zygote genome. Also, although this subject is beyond the scope of this chapter, much more needs to be known about how the embryo benefits from interaction with the oviductal fluid and epithelium. This information could provide critical improvements to embryo culture prior to embryo transfer.

The species diversity seen in the details of gamete and embryo transport is wonderful to see and yet challenging for researchers who are trying to use animal models to study basic mechanisms. Recent advances in the technology of gene modification, such as the injection of CRISPR/Cas9 (clustered regularly interspaced short palindromic repeat/CRISPR-associated proteins) or TALENs (transcription activator-like effector nucleases) into zygotes to generate mutants in a single generation,[330] opens up the opportunity of efficiently creating mutants in a broad array of mammalian species. Applications of these new technologies to the study of gamete transport in a variety of species have great potential to uncover critical new information.

Acknowledgments

This chapter in the fourth edition was inspired by its predecessor in the 1994 edition, which was written by Michael J. Harper.[23] The author's work described herein was supported by grants from the USDA, NSF, and NIH. Thanks to Pei-hsuan Hung, Florencia Ardon, and Sarah Olson for reviewing the manuscript of the 4th edition and to Jennifer Patterson for editing the references.

INTRODUCTION

Key Concepts

Historically, preimplantation embryo development has been poorly understood; early scientists and philosophers vigorously debated whether development originated via enlargement of fully preformed tiny beings delivered by the father as originally promoted by Pythagoras and later by Leeuwenhoek or whether epigenesis (the derivation of form from the egg) was the central tenet of development as first suggested by Aristotle.[1] Much of the debate was settled during the Renaissance when diverse Italian embryologists produced elaborate drawings of the oocyte to embryo transition and subsequent fetal stages of development that suggested a gradual and predictable change in form most consistent with epigenesis.[2] Since these early discoveries, more mechanistic details of preimplantation embryo development, including the major developmental stages and metabolic requirements of early embryogenesis, have been uncovered by several individuals working with different mammalian species.[3–7] These and subsequent studies discussed in greater detail later have shown substantial similarities in preimplantation development between species as well as significant species-specific differences such as the timing of embryonic genome activation (EGA) or the frequency of chromosomal abnormalities. Our most current understanding of preimplantation development has been enhanced by technological advances in imaging, molecular, genetic, and epigenetic analyses and the conceptual strides integrally linked to fundamental principles of developmental and stem cell biology.[8–13] Scientists have attempted to tackle tough questions regarding when symmetry in embryonic developmental potential is first disrupted[14,15] and what factors might contribute to success and failure of embryos to thrive.[8,16] In recent years, the derivation of pluripotent stem cells has also provided a new system to model human embryo and germ line development for the first time.[17]

Purpose and Scope

In this chapter we review the fundamentals of mammalian preimplantation embryogenesis, including epigenetic reprogramming, genetic (chromosomal) instability, timing and mechanisms of embryonic gene activation, early miotic divisions, compaction, and cavitation. We then examine lineage specification, first with a discussion of trophectoderm (TE) formation and later with a focus on germ line development. This subject matter then naturally leads to consideration of the derivation of human embryonic stem cells (hESCs), their biological properties, and the closely related induced pluripotent stem cells (iPSCs) derived via nuclear reprogramming of a nonpluripotent cell type, typically an adult somatic cell. Finally, we return to the beginning—the formation of the

germ line, its properties, and the use of pluripotent hESCs and iPSCs to probe fundamental aspects of germ line formation and gametogenesis. The scope is thus focused on events that initiate during the first two weeks of human development and track with the germ line through gametogenesis. Note that other chapters provide greater detail of gametogenesis, while the focus here is on understanding gametogenesis in light of stem cell biology. We conclude by discussing the clinical need for knowledge of early human development as it relates to infertility, assisted reproduction, and regenerative medicine.

Overview of Mammalian Preimplantation Development

Mammalian preimplantation embryo development begins under transcriptional silence with an oocyte-to-embryo transition that encompasses the migration and fusion of the maternal and paternal pronuclei at the one-cell stage, genetic and epigenetic reprogramming, activation of the embryonic genome, and a series of mitotic, or cleavage, divisions that result in the formation of a compacted morula, which further develops into a compartmentalized blastocyst primed for implantation (Figure 6.1). Details regarding mammalian preimplantation development have been extrapolated from studies in model organisms, predominantly the mouse.[18,19] Additional insight has been provided by an examination of other mammalian species, particularly as conditions for in vitro culture of preimplantation embryos were established and improved.[20–22] Moreover, early characterization of human embryos following natural conception[3,4] and more recent studies in the context of in vitro fertilization (IVF) have also afforded an understanding of human embryogenesis.[23,24] While mammalian embryos may appear morphologically similar at this stage of development, it is clear that certain aspects, such as the inheritance of maternal and/or paternal factors, timing of EGA, patterns of gene expression and epigenetic modifications, and susceptibility to chromosomal instability are likely species-specific and may limit extrapolation between species. Nonetheless, early pioneering studies[3,4,18,19] and recent technological advances in imaging, genomic and molecular analyses,[8–13] have greatly contributed to our knowledge of mammalian preimplantation development. It is important to note that the mammalian preimplantation embryo does not necessarily develop by itself and there are several extrinsic cues provided by the oviduct in vivo or replaced by culture media in vitro.[25] However, this section will primarily focus on the major events and underlying mechanisms regulating proper growth and development of the embryo itself throughout the pre- and peri-implantation period as discussed in further detail as follows.

Overview of Germ Line Development

The establishment of early germ cells and their successful maturation are complex processes that require continual changes in physiology, location, and transcriptional profiles of involved cells. In lower organisms such as flies (*Drosophila melanogaster*) and worms (*Caenorhabditis elegans*), primitive germ cell formation first arises within the heterogenous cells of the developing embryo by the segregation of cells destined to be germ cells from cells destined to become the soma.[26] In the worm, this mechanism occurs after four asymmetric divisions resulting in primordial germ cells (PGCs), while in flies, the segregation of PGCs occurs during embryogenesis to the poles of the developing embryo.[27] Despite the slight differences, it is considered that the embryonic material contains instructive signals for germ line specification (germ "plasm") and that the subset of cells containing the germ plasm commit to a PGC-like fate. Concurrently, the coordinated suppression of transcriptional programs by RNA polymerase II inhibition in PGCs prevents their entry into somatic lineages. In this manner, germ cell formation is endowed upon physically segregated cells, specifically, in the fly and worm.

In contrast, germ line establishment in mammals occurs via "inductive" signaling involving specific signaling molecules that instruct a germ cell fate in cells of the epiblast.[28–30] In rodents and humans, the first glimpses of PGC formation are observed in the embryo after implantation and gastrulation, when the epiblast, endoderm, mesoderm, and ectoderm are first established (Figure 6.2, right).[31] At this time, in response to molecular cues including bone morphogenetic proteins (BMP4 and BMP8a) from the yolk sac, a population of pluripotent stem cells is segregated from the inner cell mass (ICM) and set physically apart from the extraembryonic ectoderm or yolk sac of the embryo (Figure 6.2, middle).[32–34] While BMPs provide the inductive signal to epiblast stem cells to supply PGCs, it is not clear what signals control the size of the PGC founder population or what molecules signal the termination of PGC specification. BMPs are crucial to specification of PGCs due to their activation of the ALK2 receptor and Smad-1/5 signaling pathways, as evidenced in mice.[35] Importantly, the function of BMPs in inducing PGC formation is conserved in the early human embryo. Subsequently, mouse and human PGCs embark on a remarkable physical journey, encompassing important events such as migration via the hindgut and arrival at the primitive genital ridge (Figure 6.2, left). During this remarkable migratory process, PGCs repress their somatic gene program and undergo genome-wide DNA demethylation, histone modifications, and establishment of sex-specific imprints. After sexual divergence of the indifferent fetal gonad, acquisition of spermatogonial and oogonial

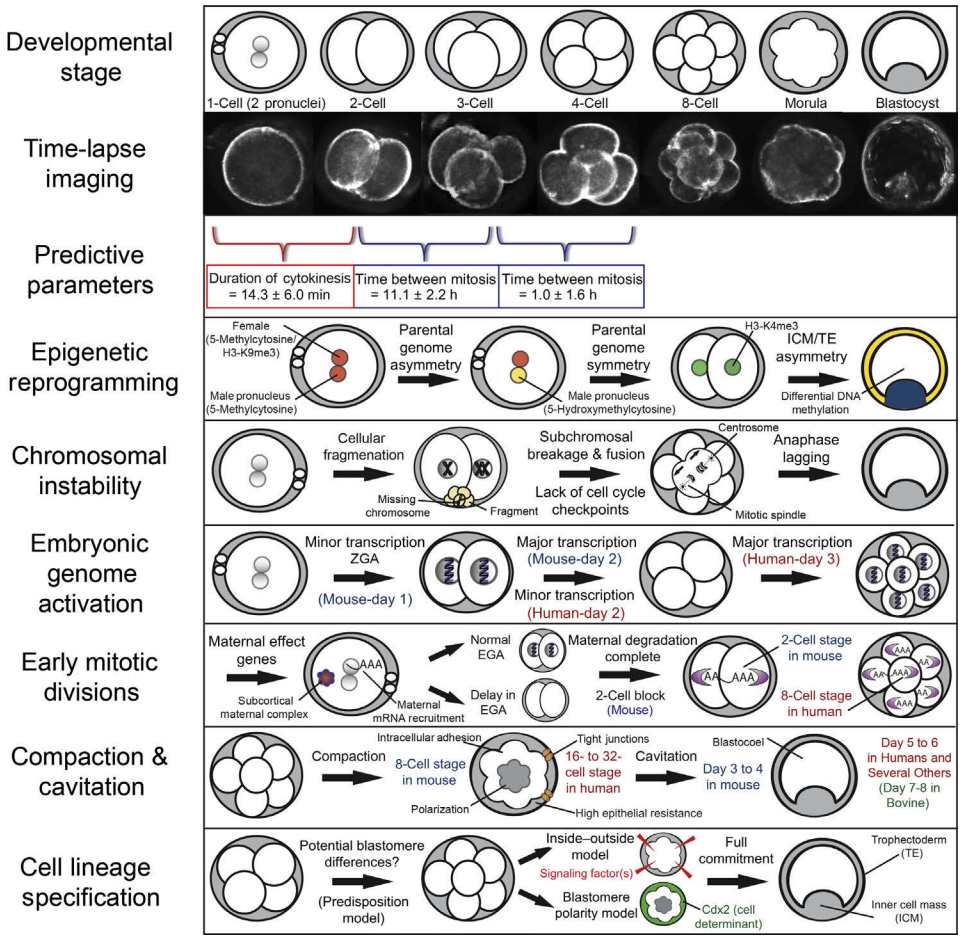

FIGURE 6.1 Summary model of fundamental aspects of mammalian preimplantation development. Recent technological advances in embryology, including time-lapse imaging, whole genome and transcriptome approaches, and single cell molecular analysis have provided insight into key characteristics of mammalian preimplantation development. Assessment of each embryonic developmental stage via time-lapse imaging has shown that the timing windows of certain cell cycle parameters, namely the duration of the first cytokinesis, time between the first and second mitosis, and time between the second and third mitosis is highly predictive of which embryos will successfully reach the blastocyst stage. This oocyte-to-embryo transition is characterized by two phases of epigenetic reprogramming and asymmetry: the asymmetry of epigenetic marks in maternal and paternal pro-nuclei at the zygote stage, which become more symmetrical beginning at the 2-cell stage, and the asymmetry in species-specific DNA methylation patterns between the inner cell mass (ICM) and trophectoderm (TE) at the blastocyst stage. There are several underlying factors that contribute to the generation of chromosome instability, particularly in human embryos, including cellular fragmentation, subchromosomal breakage and fusion, a lack of cell cycle checkpoints, and chromosomal lagging during anaphase. While the major wave of embryonic genome activation (EGA) occurs in the mouse at the 2-cell stage, the major wave of human EGA begins on day 3 at approximately the 8-cell stage and is independent of cell number. In preparation for EGA, maternal effect genes, which were synthesized during oogenesis, are passed to the embryo during the early mitotic divisions. Besides individual maternal proteins, multiprotein complexes, including the subcortical maternal complex (SCMC), are important for embryonic progression beyond the 2-cell stage. Without these maternally provided cytoplasmic components, mouse embryos may undergo a delay in EGA and subsequently exhibit a phenomenon known as the "in vitro 2-cell block". A select group of maternal mRNAs are recruited via poly(A) tail adenylation for translation following fertilization, while the remaining maternal mRNAs are degraded, a process that is essentially complete by the 2-cell stage in mouse embryos and the 8-cell stage in human embryos. The processes of compaction, intracellular adhesion, and polarization result in the formation of a morula at the 8-cell and 16- to 32-cell stage in mouse and human embryos, respectively. The majority of mammalian species, including humans, undergo cavitation to form a fluid-filled cavity called a blastocoel between days 5 and 6, whereas mouse embryos begin blastulation earlier between days 3 and 4, and bovine embryos later between days 7 and 8. It remains unclear as to when differences in blastomere developmental potential are first observed, however, it is thought that blastomeres become fully committed to form either the ICM or TE cells at the morula stage. Two models of cell lineage specification have been proposed: the inside-outside model, which suggests that the location of cells within the embryos determines the signal(s) they receive; and the blastomere polarity model, whereby cell determinants such as Cdx2 are inherited or precluded from symmetric versus asymmetric divisions to confer cell fate. *Source: Shawn Chavez, unpublished.*

Vet-ebooks.com

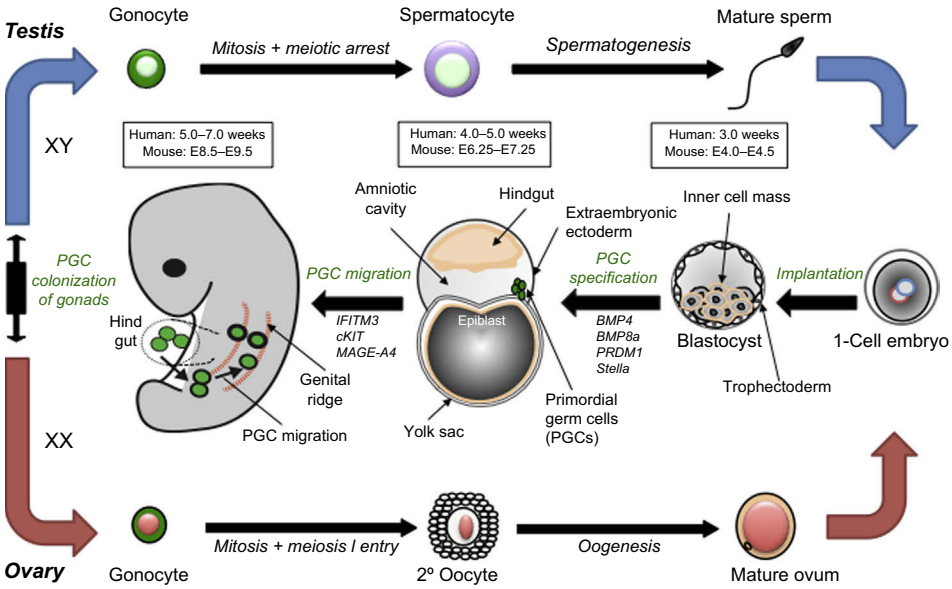

FIGURE 6.2 Life cycle of mammalian germ cells from PGC specification to fertilization. Fertilization of an oocyte by a sperm promotes the formation of a 1-cell zygote that undergoes several cell divisions to form a specialized embryo called a blastocyst. The outer layer of blastocyst will give rise to the trophectoderm, whereas the inner cell mass (ICM) will form the embryo proper later in development. Following implantation, the embryo undergoes gastrulation (E6.25–7.25 in mouse; 4.0–5.0 weeks in human), to form the epiblast, which will differentiate into the three embryonic germ layers, as well as the germ line. Primordial germ cells (PGCs) are specified at the base of the allantois and localize near the extraembryonic ectoderm. Once specified, the PGCs migrate from the invaginating hindgut to the genital ridges (arrows), which eventually develop into fetal gonads. The primitive gonads are formed when PGCs are encircled by somatic cells to form either testicular cord-like structures in the male or primitive follicular structures in the female. PGCs enclosed in either the testis or ovary undergo sex-specific development and maturation to male and female gonocytes, respectively. While male gonocytes arrest meiosis and undergo spermatogenesis to form mature sperm, female gonocytes enter meiotic prophase I and begin oogenesis, which is completed upon ovulation of a mature ovum. At the time of fertilization, the mature germ cells together transmit genetic information to the next generation, thus completing the cycle. Molecules that are involved in regulation of each PGC specification stage are listed. XY = male lineage, XX = female lineage. *Source: Adapted from Ref. 17.*

features and transcriptomes sets the stage for sex-specific mitotic expansion and meiosis of the resultant gametes (Figures 6.2 and 6.3). In this chapter, the processes outlined will be broadly defined with focus on PGC specification in the developing embryo, PGC migration, and developmental remodeling of PGCs. We will briefly discuss studies on gonadal stem cells in the mouse and human models with emphasis on human development. A summary of efforts using human fetal tissue and germ cells derived in vitro to overcome lack of access to early human tissue is also presented.

EMBRYOGENESIS

Epigenetic Reprogramming

Epigenetics is the study of alterations in gene expression or cellular phenotype caused by other mechanisms besides changes in DNA sequence; it was first described by C.H. Waddington as an explanation of how cells with the same genetic makeup could express different genes to determine cell fate.[36] Epigenetic reprogramming, or the erasure, conversion, and reestablishment of epigenetic marks, is initiated in mammals during early embryogenesis and continues through gametogenesis.[37,38] Following fertilization, the paternal and maternal genomes are predominantly erased and/or epigenetically modified and subsequently reset around the time of implantation[39–41] (Figure 6.1), which is thought to be required for the totipotency of the newly formed embryo.[42] The two main types of epigenetic mechanisms are DNA methylation and histone modifications (please refer to Chapter 52), which influence gene expression and chromatin structure in a potentially heritable manner without altering DNA sequence.[43–45] DNA methylation is mediated by a family of DNA methyltransferases (DNMTs) that catalyze the transfer of a methyl group to the 5′-position of cytosine residues within CpG dinucleotides, usually resulting in effective gene silencing through the recruitment of methyl-CpG-binding proteins and inhibition of transcription factor binding.[46] Histone modifications include, but are not limited to, the phosphorylation of serine residues, acetylation of lysine residues, and the methylation of either lysine or arginine residues, all of which are mediated by distinct histone-modifying enzymes. As covalent modifications, these histone marks can alter the interaction between DNA and

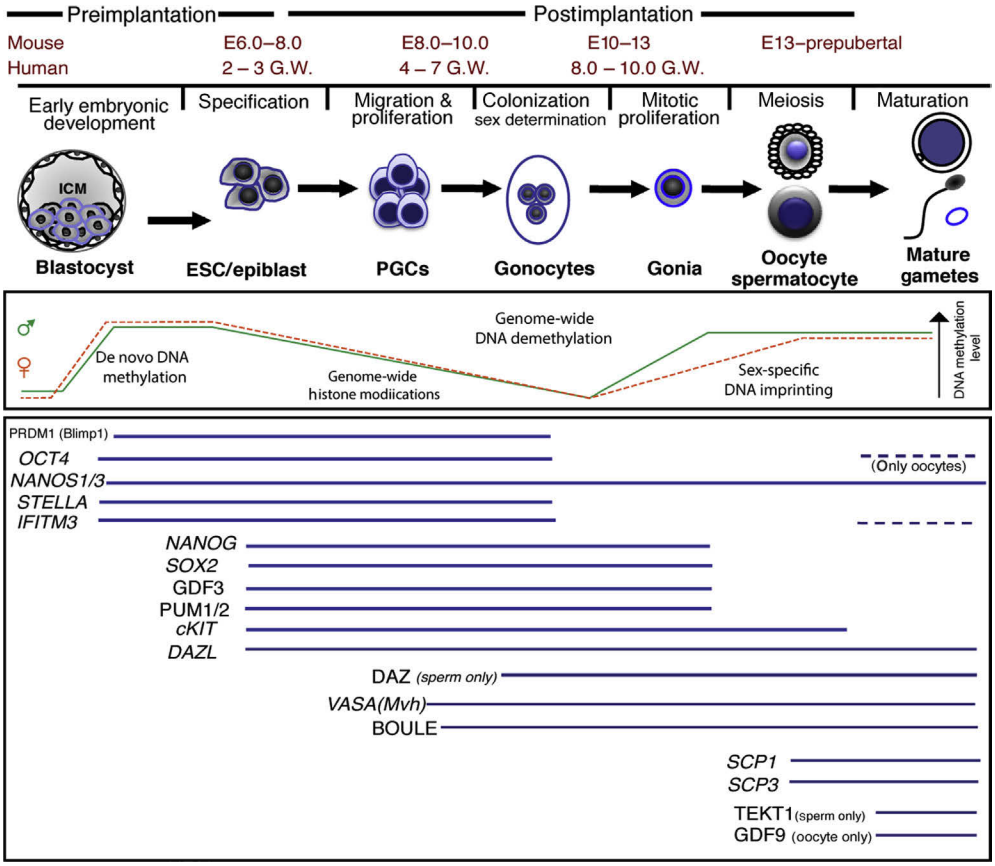

FIGURE 6.3 **Timeline of germ line specification with stage-specific germ cell marker expression.** A temporal representation of the different stages of human and mouse germ line differentiation during pre- and postimplantation in vivo. The approximate time in development for both humans and mice is indicated at the top with the major stages pictured below. An examination of global DNA methylation as assessed by five methylcytosine levels in both males and females demonstrates a period of de novo methylation for male (continuous line) and female (broken line) occurring in the blastocyst prior to, and during, implantation. This is followed by genome-wide DNA demethylation in the ESCs and epiblast stages and proceeding to PGC specification. In the mouse, and largely true for the human, genome-wide changes in histone modifications occur concurrently with DNA demethylation between the time of primordial germ cell (PGC) specification, migration, and colonization of the gonads. Sex-specific DNA methylation and imprinting are reestablished later during male and female gametogenesis, albeit at different times. Specific molecular markers for germ cell identification are indicated on the left with lines depicting the duration of expression from the blastocyst stage to the formation of mature gametes. Genes that are italicized are present in both mouse and human germ cells. *Source: Adapted from Ref. 17.*

nuclear proteins and, together with DNA methylation, ensure appropriate gene activation during preimplantation development.[47]

Besides being associated with the epigenetic silencing of genes, DNA methylation and histone modifications have also been shown to be important for normal embryogenesis, X-chromosome inactivation, and genomic imprinting.[26,48–50] Unlike the vast majority of autosomal genes, whereby gene expression occurs from two alleles simultaneously, a subset of approximately 80 or more known imprinted genes vary in expression according to the maternal or paternal origin and escape the epigenetic reprogramming that occurs during this period of development.[51] Genomic imprinting is thought to represent a barrier to parthenogenesis and has been shown to play an important role in normal embryo growth and development, placental function, as well as neurobehavioral processes.[52] As development of the mammalian zygote proceeds, the paternal genome must undergo dramatic structural and epigenetic changes such as chromosome decondensation, protamine replacement by histones, and rapid DNA demethylation. It was originally thought that the methylation of DNA is almost completely erased by the morula stage of development, with the exception of maternal and paternal DNA imprints.[40,53] However, more recent studies have shown that 5-methylcytosine, a marker of global DNA methylation levels, is actually converted to 5-hydroxymethylcytosine in the paternal pronucleus to directly or indirectly influence transcription and/or DNA replication, whereas the maternal pronucleus is protected from this conversion in several mammalian species[41] (Figure 6.1). In conjunction with the asymmetric DNA methylation reprogramming of the parental genomes, certain histone modifications such as

Vet-ebooks.com

histone H3 lysine 9 methylation mark the female pronucleus during the oocyte-to-embryo transition.[54] This epigenetic asymmetry of parental genomes is thought to remain until at least the two-cell stage when other histone marks, including histone H3 lysine 4 methylation, begins to appear more similar between the two genomes.[55] By the time of implantation, DNA methylation is subsequently reestablished during a period of de novo methylation at the blastocyst stage, and a second wave of asymmetric epigenetic marks is observed to coincide with the commitment of blastomeres to form either ICM or TE cells.[37] Additionally, cells of the early female embryo display marks of X-chromosome inactivation, such as X-inactive specific transcript (*XIST*) and histone H3 lysine 27 methylation, at or around the time implantation.[56,57]

Despite conservation of certain epigenetic marks between species during preimplantation development, there are clear species-specific distinctions in DNA methylation and histone modification dynamics in different mammalian embryos. For instance, there are different degrees at which the paternal genome is demethylated and/or modified upon fertilization, and the ICM and TE cells of blastocysts are known to exhibit differential methylation levels across mammalian species[58–62] (Figure 6.1). This may be related to distinctions in developmental timing, activation of the embryonic genome, cellular differentiation, and/or the chromosomal status of the embryo. Future work should enhance our understanding of how epigenetic mechanisms are cooperatively regulated to achieve normal embryogenesis and how perturbations in this process during preimplantation development may contribute to adverse outcomes such as birth defects.

Chromosomal Instability

Studies using whole genome approaches have demonstrated that aneuploidy, or an abnormal number of chromosomes, is present in the blastomeres of between 50% and 80% of cleavage-stage human embryos, including those from fertile couples and regardless of cryopreservation.[12,16,63] The high incidence of human embryonic aneuploidy observed in vitro may also be reflected in vivo considering that approximately 30% of natural human conceptions result in live births and chromosomal abnormalities have been reported in as many as 70% of spontaneous miscarriage cases.[64–70] In several instances, the embryo may successfully implant but does not develop further and results in early miscarriage, often before detection of pregnancy, and is historically termed a blighted ovum.[71] This is in contrast to other mammalian species, particularly the mouse, which is estimated to exhibit less than 1% embryonic aneuploidy rates at this stage of development.[72] However, arrays for the detection of copy number variants are far more utilized for humans than other mammalian species due, in part, to preimplantation genetic screening (PGS) of human embryos in IVF clinics and genetic testing centers.[73–75] Thus, it will be interesting to determine the overall aneuploidy rates via similar cytogenetic approaches in preimplantation embryos from additional species, especially those more closely related to humans.

It is thought that chromosomal errors most commonly occur on the meiotic spindle during oogenesis or the mitotic spindle during embryonic cleavage divisions,[76] which could be perpetuated due to the apparent lack of cell cycle checkpoints in cleaving human embryos,[13,77] as well as anaphase lagging, or the failure of one or more chromosomes to connect to the spindle during mitosis at the blastocyst stage[78] (Figure 6.1). Indeed, estimates of meiotic error rates in humans are relatively high at 5–20% of oocytes compared with other species such as the mouse, whereby only 0.05–1% of oocytes are typically aneuploid.[79] Therefore, it is not surprising that maternal meiotic errors are much more frequent than paternal meiotic errors in human embryos determined to be chromosomally abnormal.[63] However, it is important to note that the centrosome and potentially other spindle components, which mediate the first mitotic division(s) in embryos, are paternally inherited in the majority of mammalian species.[80,81] In contrast, it appears that the centrosome is maternally inherited in the mouse embryo,[82] the only known exception to date. This may help explain the relatively low aneuploidy rates observed in mouse embryos[72] and suggests that paternal contribution to human embryonic aneuploidy is likely greater than expected and invokes consideration of paternal age as maternal age-related aneuploidy does.[63,76] Additional studies have supported this notion by demonstrating that the generation of chromosomal errors during early human embryo development is very often mitotic in origin.[12,37] Moreover, Chavez and colleagues also revealed via single cell analysis of whole embryos that the high frequency of human embryonic aneuploidy may have contributions from chromosome-containing embryonic micronuclei that arise via cellular fragmentation, particularly during or following the first mitotic division[16] (Figures 6.1 and 6.4). While the cause of cellular fragmentation has been disputed for several years and was previously thought to represent anucleate cytoplasmic components,[83] it is estimated to occur in greater than 50% of human embryos cultured in vitro[84] and is distinct from the DNA fragmentation that can occur following cell death later in preimplantation development.[85–87] There is also evidence to suggest that cellular fragmentation occurs in human embryos in vivo, indicating it is not just a consequence of in vitro culture[88,89] and that it may negatively correlate with implantation potential.[90,91] It is also important to note that not all fragments contain

Vet-ebooks.com

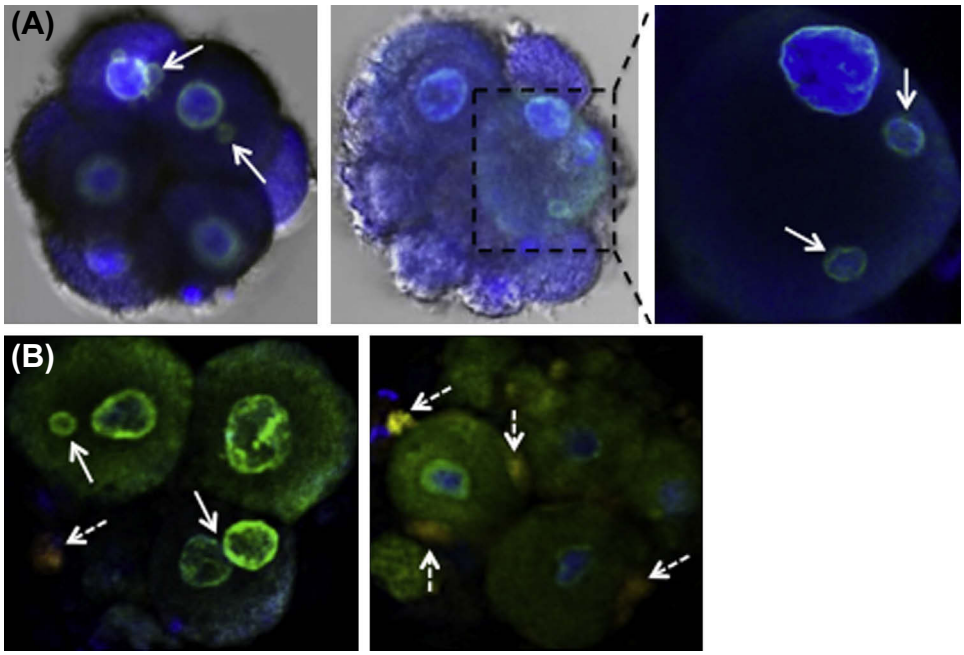

FIGURE 6.4 Detection of embryonic micronuclei in cleavage-stage human embryos. This figure is reproduced in color in the color plate section. (A) Expression of the nuclear envelope marker, LAMIN-B1 (green), in 4′,6-diamidino-2-phenylindole (DAPI)-stained (blue) cleavage-stage human embryos visualized by immunofluorescent confocal microscopy and differential interference contrast (DIC) imaging at 20× (left and middle) and 40× (right) reveals the presence of several embryonic micronuclei (indicated by white solid arrows) distinct from primary nuclei in human blastomeres. (B) Similarly evaluated additional cleavage-stage human embryos with low (left) and high (right) fragmentation also immunostained for centromere protein E (CENP-E; orange) in the absence of DIC imaging identifies multiple missing chromosomes in cellular fragments (indicated by white dashed arrows) adjacent to blastomeres at this stage of development. *Source: Adapted from Ref. 16.*

missing chromosomes (Figures 6.1 and 6.4), which may partially explain how certain fragmented embryos can still result in successful pregnancy outcome.[83] Regardless of its origins, cellular fragmentation is observed, although to a lesser extent, in preimplantation embryos from other mammalian species,[92,93] and it will be important to determine the mechanism(s) by which it occurs and how dynamic events such as the timing, degree, and resorption of chromosome-containing fragments contributes to the generation of embryonic aneuploidy.[16,94–96]

Notably, aneuploid human embryos at the cleavage stage have also been shown to exhibit frequent chromosome segmental deletions, duplications, and/or amplifications that are balanced between presumptive sister blastomeres.[12,16] Not only does this suggest that chromosome breakage and fusion often arises during early cleavage divisions but it also indicates that there is a relationship between aneuploidy and subchromosomal instability in human embryos (Figure 6.1). There is some evidence to suggest that chromosomal correction can occasionally occur during embryo development based on PGS and biopsy of an aneuploid blastomere on day 3, followed by euploid TE cells on day 5.[97–99] While blastocysts may exhibit less mosaicism, defined as the presence of two or more cell populations with different chromosomal makeup, and contain fewer aneuploid cells than cleavage-stage embryos,[100] frequent findings of complex mosaicism, whereby multiple chromosomes are affected, in embryos without a single euploid blastomere indicate that it is unlikely that most chromosomal abnormalities can be corrected through development.[12,16] Nevertheless, some groups have proposed that euploid cells may exhibit advantageous growth over aneuploid cells in embryos or, perhaps, there is preferential contribution of chromosomally normal cells to the ICM and chromosomally abnormal cells to the TE layer.[97,101,102] More recent studies, however, have shown no preferential distribution of chromosomally abnormal cells between the ICM and TE.[103,104] Thus, while ICM and TE chromosomal asymmetry may not explain the so-called "embryo self-correction," there remains the possibility that alternative mechanisms such as blastomere exclusion or DNA replication in the absence of cell division, called endoreduplication, followed by abnormal mitotic divisions with multipolar spindles may play a role and future studies will assist in deciphering this phenomenon.[103]

Embryonic Genome Activation

Perhaps the most compelling species-specific difference between mammalian preimplantation embryos is the developmental stage at which EGA occurs. The

Vet-ebooks.com

mouse preimplantation embryo exhibits the earliest transition from maternal to embryonic transcriptional control at the beginning of the 2-cell stage with a few mRNAs being transcribed at the 1-cell stage and is therefore an event often referred to as zygote gene activation (ZGA)[105] (Figure 6.1). Rat EGA begins at the 2- to 4-cell stage,[106] the 4-cell stage in pigs,[107] and in humans on day 3 at the 4- to 8-cell stage,[108] which is similar to nonhuman primates as EGA occurs at the 6- to 8-cell stage in rhesus macaque embryos.[109] For other mammalian species, including cow, rabbit, and sheep, EGA begins later in preimplantation development at the 8- to 16-cell stage[110–112] and may coincide with delayed implantation timing. Regardless of the stage, all mammalian embryos begin preimplantation development under relative transcriptional silence, and it is clear that the duration of this quiescence differs between species. Thus, the mammalian preimplantation embryo must rely predominantly on maternally-derived RNAs and proteins for the first day(s) of life in order to survive, although previous findings have demonstrated the importance of a small population of paternal transcripts inherited from the sperm beginning at the 3- to 4-cell stage in human embryos.[113,114]

In preparation for ZGA/EGA, the majority of maternal mRNAs and proteins are degraded, a process that is largely complete by the 2-cell stage in mouse embryos and the 8-cell stage in human embryos.[11,115,116] These maternally stored factors are subsequently replaced by newly synthesized embryonic gene products,[117] which are important for establishing the totipotency of each blastomere in the cleavage-stage embryo.[118] Thus, ZGA is required for the oocyte-to-embryo transition[119] as well as development to the 4-cell stage at least in mouse embryos.[120] Failure of embryos to progress beyond the 2-cell stage is referred to as the "in vitro 2-cell block".[121] It had long been assumed that this block in early murine development was due to the failure of ZGA based on the timing of ZGA as described before and frequent findings of embryo arrest in certain mouse strains at the 2-cell stage. The utilization of blocking and nonblocking mouse strains, however, has shown that embryos with 2-cell block still initiate ZGA, and it is therefore not due to the inability to begin ZGA. More specifically, Qui et al. demonstrated via analysis of the transcription-requiring complex (TRC), a subset of proteins whose expression is a hallmark of ZGA; it is a delay in ZGA that contributes to the 2-cell block phenomenon in the mouse.[122] Nevertheless, additional studies have identified specific genes, including heat shock 70 kDa protein 1 (*Hsp70.1*),[123] eukaryotic initiation factor-IA (*eIF-IA*),[124] as well as zinc finger and SCAN domain containing 4 (*Zcan4*)[125] that are actively transcribed at the onset of ZGA.

While it is generally accepted that the human embryo activates its genome on day 3, data from a recent study suggesting early waves of transcriptional activation at the 2-cell stage has prompted disagreement as to when EGA actually begins in the human preimplantation embryo.[126] Although a few genes may be expressed as early as the 2-cell stage, genome-wide transcriptional analyses of human preimplantation embryos have shown that the major wave of EGA does indeed occur on day 3 at the 4- to 8-cell stage[9–11] (Figure 6.1). Further support for this time course is provided by early studies demonstrating via uridine radiolabeling that nucleolar RNA synthesis takes place no earlier than the fourth cell cycle and embryonic cleavage divisions are not sensitive to inhibition of transcription by alpha-amanitin until after the 4-cell stage.[108,127] More recently, the first whole transcriptome analysis of preimplantation human embryos demonstrated that the expression of approximately 1800 mRNAs is modulated during the first three days of development and that the vast majority of transcripts were targeted for destruction and downregulated.[9] However, Dobson and colleagues also showed that a small group of mRNAs were upregulated between days 1 and 2, and a much larger group of transcripts increased in abundance on day 3. The authors suggested that the increase in mRNA levels prior to day 3 likely represented minor transcriptional activity or preferentially stable transcripts in a pool of rapidly degrading maternal mRNAs. In addition, they demonstrated that the major wave of EGA was independent of cell number since embryos that arrested with fewer than eight cells still exhibited EGA on day 3.[9] Additional studies using global genome assays have revealed similar findings of major EGA in human embryos at the 4- to 8-cell stage,[10,11] at the 6- to 8-cell stage in rhesus monkey embryos,[128] and at the 8-cell stage in bovine embryos[129] (Figure 6.1). Thus, it remains unclear whether apparent changes in gene expression prior to the 4- to 8-cell stage are the result of maternal mRNA degradation, actual gene activation, or associated with embryo arrest and/or other aspects of abnormal embryogenesis, which may affect embryo quality and the interpretation of the results.[126] Given that blastomeres of the cleavage stage human embryo appear to develop cell autonomously, divergent findings may also be attributed to differences in gene expression between whole embryos and single blastomeres.[8,11] Nevertheless, more extensive transcriptional analysis of individual embryos and blastomeres throughout mammalian preimplantation development are still warranted and together with confirmation at the protein level, may help determine the importance of dynamic gene expression patterns at different stages.

Early Mitotic Divisions

Following fertilization, the 1-cell zygote undergoes a series of mitotic cell divisions to produce an increasing number of progressively smaller cells without changing

Vet-ebooks.com

the overall size of the embryo.[119] Notably, several studies have shown that male mammalian preimplantation embryos may cleave faster than female embryos cultured in vitro,[130–132] although other studies have shown no difference in the sex ratios between early or late-cleaving human embryos.[133,134] This suggests that potential sex-related differences in the cleavage rate of male versus female human embryos does not occur until later in development or is a phenomenon that is restricted to only certain mammalian species. Nevertheless, early cleavage appears to be a strong indicator of embryo viability as human embryos that undergo the first mitotic division sooner have greater potential for successful implantation and possible pregnancy outcome.[134] A more recent study has demonstrated that it is the duration of the first mitosis together with the time between the first and second as well as second and third mitotic division that is highly predictive of which human embryos will reach the blastocyst stage[11] (Figure 6.1, Predictive Parameters), which is further discussed in a later section. Whether the first three mitotic divisions are similarly predictive for other mammalian species besides the human remains to be determined, but an examination of early mitotic timing in mouse[135] and bovine embryos[136] has suggested that this may be the case.

As described earlier, cellular fragmentation has been observed to occur most often in human embryos during or following the division from one cell to two cells.[16,96] In many instances, this emergence of fragments is resolved by the 8-cell stage or later in development, which may be explained by frequent findings of fragment resorption in cleavage-stage human embryos.[10,94–96] Therefore, it is not surprising that the incidence of cellular fragmentation itself is an unreliable indicator as to whether an embryo will successfully develop to the blastocyst stage.[18,137] Given the poor prognostic value of fragmentation in human embryos and findings that removal of acellular debris promotes blastocyst hatching in mouse models,[138] the practice of fragment removal via laser-assisted microsurgery was introduced.[139–141] However, as discussed earlier, cellular fragments can contain genetic information, and, thus, the elimination of fragments may potentially be deleterious for an embryo.[10] Regardless of micronuclei formation, subsequent findings have demonstrated that fragment removal provides no benefit to the developing embryo at least to the blastocyst stage,[140] and, as such, surgical removal of cellular fragments is generally no longer promoted.

Besides varying degrees of cellular fragmentation, as discussed earlier, another hallmark of early cleavage divisions in mammalian preimplantation embryos is the degradation of maternally deposited factors in preparation for the oocyte-to-embryo transition. There must be, however, a certain amount of selectivity in the destruction of maternal mRNAs and proteins in order to facilitate the successful shift from maternal to embryonic control of development.[142] In support of this, it was shown that several maternal mRNAs are recruited via polyadenylation of their poly(A) tails for translation following fertilization but prior to the activation of the embryonic genome[143] (Figure 6.1). Further evidence has been provided by findings that the injection of cytoplasm from a nonblocking mouse strain into a strain with 2-cell block rescues the defect,[144] suggesting that the block is mediated by a cytoplasmic component. Additional studies have demonstrated that rescue occurs in the absence of maternal chromosomes to indicate that stored, rather than newly synthesized factors, are responsible for overcoming this block in development.[145] Although the identities of the specific maternally provided cytoplasmic proteins are still largely unknown, factors that are thought to originate from the oocyte and persist in the embryo are termed maternal effect genes and are transcribed during oogenesis. However, some maternal effect genes are not expressed until after activation of the embryonic genome to complicate the differentiation between maternal and embryonic effects.[117] Several maternal effect genes have been identified and include factors involved in maternal mRNA degradation, transcription, chromatin remodeling, and DNA methylation. In addition to individual maternal proteins, multiprotein complexes such as the subcortical maternal complex (SCMC) have also been shown to be important for embryonic progression beyond the 2-cell stage in mouse embryos.[146] One of the first members of this complex to be reported was maternal antigen that embryos require (Mater/Nlrp5), which by definition is not expressed by the embryonic genome.[147] Thus, the depletion of *Mater* prevents SCMC formation and results in preimplantation embryonic lethality in both mice[146] and monkeys.[148] A similar phenotype is observed in mouse embryos lacking factor located in oocytes permitting embryonic development (*Floped/Ooep*), another member of the SCMC complex. The absence of other SCMC proteins such as *Filia (RIKEN)*, on the other hand, results in less pronounced phenotypic effects.[149] Given the conservation of the SCMC genes in humans, it will be important to determine whether these maternal effect proteins play an analogous role in human preimplantation development.

Compaction and Cavitation

Mitosis continues during preimplantation development until the embryo undergoes compaction, or intracellular adhesion, as first described by Mulard[150] and further characterized by several others in different mammalian species,[151–153] to form a morula (Figure 6.1). The formation of a morula represents the first morphological indication of disruption in radial symmetry, or

Vet-ebooks.com

the symmetrical arrangement of components emanating from a central point, in the embryo during preimplantation development. It is thought that compaction is essential for later morphogenetic events such as lineage specification, but how the process of compaction is initiated is not well understood.[154,155] In conjunction with cell adhesion, intracellular polarization occurs, whereby the outward-facing (apical) domains of each blastomere become distinct from inward-facing (basolateral) regions. More specifically, the cell nuclei move basolaterally, whereas actin and microtubules accumulate apically concomitant with differential localization of membrane and polarity protein complexes.[156–158] While cell–cell contact does appear to be important for establishing the orientation of polarity since blastomeres polarize along the axis perpendicular to the cell contact and apical poles form farthest from the contact point, additional mechanisms are likely to be involved.[151,159] Nevertheless, once the morula has compacted and polarized, subsequent cell divisions are influenced by the orientation of the cleavage plane so that polarity is inherited in the daughter cells. If a blastomere divides at an angle perpendicular to its axis of polarity, both daughter cells will be polar and remain on the outside of the embryo. In contrast, if a blastomere undergoes mitosis parallel to its axis of polarity, one daughter cell will be polarized and the other apical, and thus they will be located on the outside and inside of the embryo, respectively.[160,161] These symmetric versus asymmetric cleavage divisions result in the generation of two distinct cell populations: the cells on the inside will become a part of the ICM and the cells on the outside will contribute to the TE layer.

The processes of compaction and polarization together with symmetric versus asymmetric cell division eventually lead to the formation of a blastocyst that comprises a fluid-filled cavity called a blastocoel and an ICM surrounded by TE cells beginning on day 4.5 during human preimplantation development.[162] While the ICM will eventually give rise to the embryo proper, the TE will form the fetal portions of the placenta later in development. Blastocoel formation is initiated almost immediately after compaction by the assembly of tight junctions, which includes occludin, cingluin, as well as other components, and the establishment of high epithelial resistance in TE cells until the 32-cell stage.[163–165] As the blastocoel forms, which is essential for proper ICM development,[166] water may enter the embryo via osmosis until tight junctions in TE cells are fully functional to prevent fluid loss.[164,167] In preparation for implantation into the uterus, the blastocyst "hatches" from the zona pellucida, a glycoprotein layer that encapsulates and protects the oocyte during fertilization and transition to an embryo. Blastocyst hatching allows for increased embryo growth and development as well as TE cell access to the lining of the uterine wall to allow adhesion to occur. Just prior to implantation, which occurs on day 7 of human embryonic development, a second lineage decision is made, whereby the ICM of the blastocyst differentiates into either early epiblast or primitive endoderm to form the future fetus and parietal/visceral endoderm, respectively, the latter of which will contribute to the yolk sac.[168]

Much of what we know about embryo compaction and cavitation has been derived from studies in the mouse, and relatively little is known of these processes in other mammalian species, including humans. Although in vitro studies have shown that different preimplantation embryos closely resemble each other at this stage of development, there are a few notable species-dependent exceptions. For example, compaction often occurs much earlier in mouse embryos at the 8-cell stage than in humans, which begins at the 16-cell stage.[162,169] Thus, it remains unclear how the timing of compaction may affect polarization and asymmetric cell divisions in the human embryo.[168] In addition, human embryos are likely to undergo at least one additional round of cell division to form a ~256-cell blastocyst, whereas mouse blastocysts typically comprise ~164 cells.[170] However, morphological changes such as compaction or cavitation have been shown to be a function of timing in development rather than cell number, at least in the human preimplantation embryo. Finally, human embryos show delayed blastocyst development compared with mouse embryos; the mouse blastocyst forms between days 3 and 4 (Figure 6.1). Analogous to humans, the vast majority of other mammalian species, including rhesus, ovine, porcine, rabbit, and rat, form blastocysts on days 5 to 6,[171–174] but bovine embryos exhibit blastocyst formation on days 7 to 8,[175] which might be due to differences in embryo energy requirements and metabolism and/or the extent of placental invasion.[176,177]

TE Lineage Specification

The first cell lineage to be specified in the mammalian preimplantation embryo is the TE layer, but how this decision is made is not entirely clear. In the mouse embryo, blastomeres become fully committed to form either the TE or ICM lineage at the 32-cell stage.[166,178] Based on the location of TE cells on the outside and the ICM on the inside of the embryo, as well as the observation that changing the position of a cell may change its fate, the inside–outside model of lineage specification was initially proposed[179] (Figure 6.1). According to this model, cells on the outside would receive different signaling factors, including components of the Hippo signaling pathway such as Nf2/Merlin, than cells on the inside of the embryo and signal to the downstream factors, large tumor suppressor homolog1 (Lat1), Lat2, and yes-associated protein 1 (Yap1), to result in differences

Vet-ebooks.com

in cell fate. Both Lat1 and Lat2 are serine–threonine kinases that are functionally redundant, whereas Yap1 is a transcriptional activator that is required by the transcription factor, TEA domain family member 4 (Tead4), for TE specification.[180,181] Once blastomere polarization was discovered, however, the cell polarity model was established and the inheritance of polarity was suggested to determine TE fate.[160] For this model, certain cell fate determinant(s) such as caudal type homeobox 2 (*Cdx2*) may be restricted to or separated from polarized cells during cell division. Since it localizes to the apical region of blastomeres at the 8-cell stage and is necessary for murine trophoblast development, Cdx2 is thought to play a role in cell fate determination at least in the mouse.[14,182] However, more recent studies have shown that the initiation of TE lineage specification is independent of both maternal and zygotic *Cdx2* mRNA[183] and that with the use of an endogenous Cdx2 fusion protein, outer TE cells may change their fates by migrating inward and losing Cdx2 expression as late as the 32-cell stage.[184] Thus, regardless of whether TE lineage specification is due to cell position and/or blastomere polarity, additional signaling pathways and transcription factors are likely required to determine cell fate. Indeed, other factors such as suppressor of defective silencing 3 (Suds3) and TCFAP2C/AP-2γ as well as Hippo-independent pathways via angiomotin have recently been shown to play an important role in early lineage specification.[185–188] How all these factors are temporally, spatially, and/or cooperatively regulated throughout preimplantation development, and whether there is differential regulation at the mRNA and protein level or between mammalian species, should be the focus of future studies.

Besides the uncertainty regarding the molecular mechanism(s) mediating cell fate determination, it is also unclear as to how early in development individual cells of the mammalian embryo acquire the first developmental differences predictive of lineage specification. While certain studies have suggested that lineage allocation is decided stochastically by cell–cell interactions at the 16- to 32-cell stage of mammalian development as previously described with the inside-outside and blastomere polarity models,[15,189,190] others have argued that cells are predisposed to form either the ICM or TE cells beginning at the 4-cell stage to suggest a potential third model of cell lineage specification[14,191] (Figure 6.1). In this model, the levels or kinetics of Cdx2 and the pluripotency-related transcription factor, octamer-binding transcription factor 4 (Oct4)/Pou5f1, in individual blastomeres may promote symmetric versus asymmetric cell divisions in the embryo, which ultimately determines cell fate. However, whether molecular differences between blastomeres are the cause or a consequence of lineage commitment is not known and continues to be debated.[192] Nevertheless, there remains the possibility that intrinsic differences between cells, irrespective of mechanism, stage, or lineage-defining factor, may be reflected from particular epigenetic modifications in individual blastomeres as previously suggested.[193,194]

As expected, it is likely that the timing and developmental stage of distinctions in blastomere potential are species specific. Similar to the mouse, cell fate has been suggested to be determined as early as the 4-cell stage in human embryos, even without transcription, based on the localization of TE markers such as human chorionic gonadotropin (hCG) to particular blastomeres[195,196] (Figure 6.1). In contrast, subsequent studies using whole-genome approaches or single cell quantitative-PCR analysis demonstrated that human blastomeres are transcriptionally similar up to the 8-cell stage and do not express TE-associated genes.[8,11] Wong et al., however, did observe differences in the molecular programs of maternal mRNA degradation and EGA between individual blastomeres to suggest that they develop by themselves.[8,11] Moreover, species-dependent differences have been noted not only for the expression of CDX2 but also for OCT4 during human, rhesus monkey, bovine, and mouse preimplantation development. More specifically, both human and bovine embryos exhibit prolonged OCT4 and CDX2 co-localization in the TE layer,[197,198] as compared to mouse and rhesus embryos,[190,199,200] suggesting a lack of evolutionary conservation in the formation of ICM and TE. There is also evidence to suggest that species-specific mechanisms exist for the specification of epiblast and primitive endoderm lineages later in development. For instance, mouse and bovine embryos require fibroblast growth factor (FGF)/mitogen-activated protein kinase (MAPK) signaling for the formation of primitive endoderm cells, whereas the development of primitive endoderm in human embryos is unaffected by FGF and MAPK inhibition.[201–203] More detailed analysis of the molecular mechanisms mediating lineage restriction in the early human embryo will undoubtedly lead to a better understanding of human preimplantation development as well as assist in the determination of the similarities and differences between humans and other mammalian species.

Recent Advances in Understanding Embryology

As discussed in detail earlier, new developments in whole genome and transcriptome analysis of individual embryos and single blastomeres have greatly contributed to our knowledge of mammalian preimplantation development.[8–13] In addition, the implementation of time-lapse imaging to monitor human embryos throughout development has provided a noninvasive approach to potentially assess embryo viability[8,94,204,205] (Figure 6.5(A) and (B)). Once it was confirmed that time-lapse

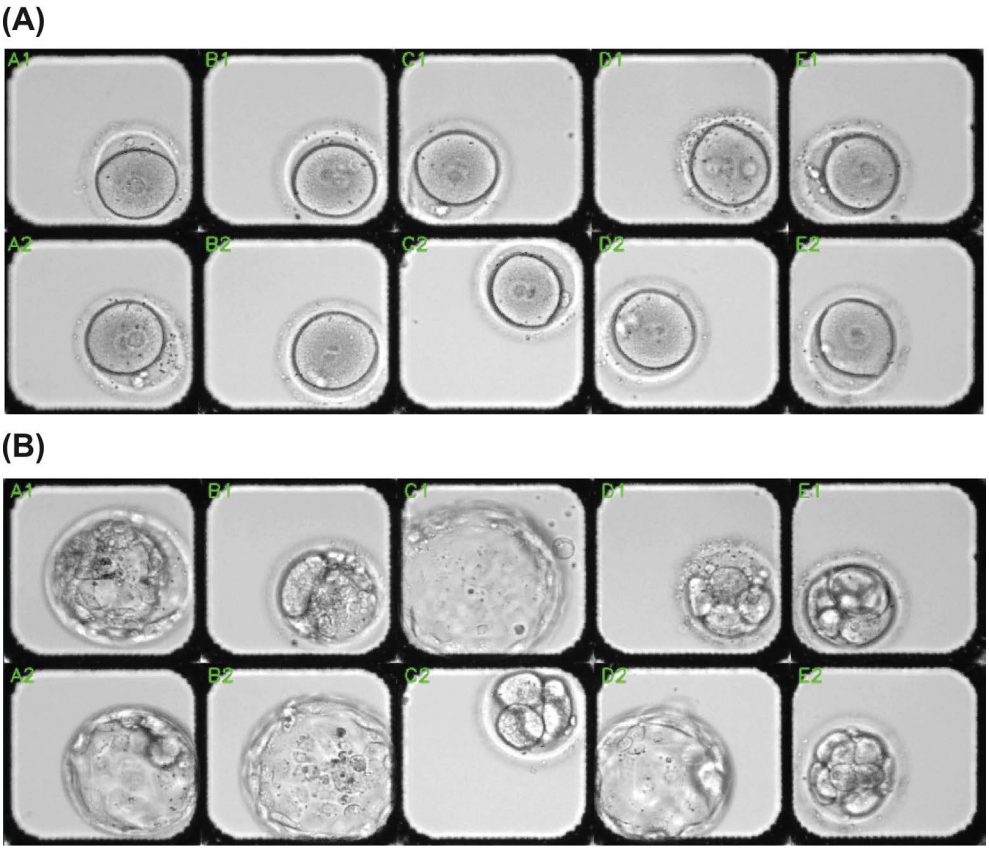

FIGURE 6.5 Time-lapse image analysis of human preimplantation development. (A) 10 human zygotes were thawed on day 1 and cultured together in alphabetically and numerically labeled microwell-containing Petri dishes. (B) Time-lapse imaging was performed in a standard incubator until day 6 when the majority of embryos had reached the blastocyst stage. Embryo imaging behavior was monitored by measuring dynamic imaging parameters between the first and last frame of an image sequence compiled into a time-lapse movie with well identification labels and time stamps. *Source: Brooke Friedman and Shawn Chavez, unpublished.*

imaging was not detrimental to embryo development, several groups began conducting morphological, spatial, and temporal studies to determine if there were correlates between imaging behavior and embryo quality.[8,206,207] In 2010, Wong and colleagues demonstrated that time-lapse image analysis can be used to predict blastocyst fate prior to EGA by measuring the duration and time between the first three mitotic divisions. By evaluating the correlation between imaging and gene expression analysis, it was determined that embryos with normal gene expression patterns followed strict cytokinesis and mitotic division timing, whereas arrested embryos exhibited abnormal gene expression profiles and one or more parameter values outside the timing windows of normal embryos[8] (Figure 6.1). More recently, Chavez et al. demonstrated that the timing of the first three mitotic divisions, in conjunction with dynamic cellular fragmentation analysis, may also be used to distinguish euploid from aneuploid human embryos.[16] Obviously, clinical validation of these findings is required, and recent retrospective studies of patient embryos have confirmed the importance of these and additional cell cycle parameters in predicting embryo viability and/or aneuploidy risk.[208,209] Given the significance of preimplantation embryo development in human biology and pathology, further investigation of the cellular dynamics, underlying molecular programs, as well as genetic and epigenetic profiling of normal and abnormal human development is clearly warranted.

EMBRYONIC STEM CELLS

Biology of Embryonic Stem Cells

Questions about human origins and human development have always been important centerpieces of scientific and public discourse. The significance and impact of embryonic stem cells (ESCs) on the public has fluctuated considerably over the last 50 years, but always invigorated the scientific community. Early observations with mouse teratocarcinomas and embryonal carcinomas demonstrated the sheer developmental power of stem cells to become virtually any other cell type. However, interest remained limited until scientists isolated and harnessed the potential of mouse embryonic stem cells (mESCs) for the generation of genetically modified mice. With the advent of hESCs isolation from discarded embryos, the scientific and public community increasingly shifted their attention to ESC biology. Moreover, recent innovations in resetting cells to an embryonic-like state developed by Nobel prize recipient Shinya Yamanaka and colleagues incorporated 50-year-old concepts developed by his Nobel corecipient, John Gurdon (2012 Nobel Prize

Vet-ebooks.com

in Physiology or Medicine), about somatic cell cloning and have refocused a multidecade topic on the prospect of stem cell-based therapies for regenerative medicine. More importantly, the use of ESCs and the aforementioned iPSCs have helped us understand the molecular control of self-renewal and introduced new concepts in preimplantation human development such as trophoblast function, germ line specification, and neuronal lineage formation. Some of these historical breakthroughs encompass the analysis of primitive embryonic tumors, germ cell tumors, and ESCs and are discussed next.[210]

Early efforts at understanding pluripotency in the mammalian embryo began with rather simple experiments in which pieces of mouse germ cell tumors known as teratocarcinomas were grown in culture and a variety of pluripotent cell types emerged.[210] One cell type, embryonal carcinoma cells, produced all three germ layers as well as the original tumorigenic cells when isolated and transplanted into host mice. This established, for the first time, the pluripotent nature of embryonic cells. mESCs from the preimplantation embryo initially form within the ICM. In studies by Evans and Kauffman and others, cells of the ICM were isolated from late blastocysts and grown in culture.[211,212] These cells proliferated and demonstrated the capacity for self-renewal. The subsequent addition of leukemia inhibitory factor (LIF) promoted the self-renewal of mESCs in culture by acting through the Stat3 pathway.[213] Further studies showed that the ICM-derived cells could, if reintroduced into an embryo lacking an ICM, recolonize and form all three germ layers of the embryo, including the germ line.[214] mESCs are characterized by the strong and persistent expression of important pluripotency genes such as POU domain, class 5, transcription factor 1 (*Pou5f1/Oct4*), SRY-containing box-2 (*Sox2*), NANOG homebox protein (*Nanog*), and transcription factor 4 or 8 (*Tcf-4/Tcf8* among others).[215] In general, mESCs are considered to have a more naïve ground state of pluripotency, meaning their potential for differentiation to all cell lineages, including the epiblast, is greater than hESCs.[216,217] However, mESCs still possess important differences from cells of the mouse ICM in their hypermethylated DNA composition and their capacity for self-renewal.[217,218] Meanwhile, hESCs share some properties with mouse epiblast stem cells (mEpiSCs) (pluripotency) but may be more restricted than mESCs.[219] This may be the case because current hESC derivation methods from the ICM could actually select for cells in a different developmental stage than that from the mouse ICM.[216]

hESCs are derived in a very similar manner to mESCs from explants of ICM of in vitro, fertilized blastocysts that bear features of a transient epiblast-like state.[220] Thomson et al. first isolated hESCs from preimplantation human blastocysts and analyzed their morphology and expression of pluripotency genes.[221] Although they express high levels of pluripotency genes, hESCs share a morphology that is more consistent with that of early mEpiSCs. Specifically, they are "flattened", possess large nuclear to cytoplasmic ratios, and respond less favorably to single cell clonability in contrast to mESCs.[219,222] In addition, they depend on basic FGF (bFGF) and activin signaling for self-renewal. While the signaling pathways of the TGFβ superfamily (TGFβ/activin/nodal) are undoubtedly important for hESC pluripotency, the molecular mechanisms underlying these observations have yet to be explained. Nevertheless, the transcription factors OCT4, NANOG, and SOX2 are clearly all involved in hESC pluripotency, and more recently identified molecules such as the WNTs (wingless-type MMTV integration site family members) have been implicated to drive hESC self-renewal through canonical signaling pathways.[223] The functions of OCT4, NANOG, and SOX2 are regarded as indispensable for hESC self-renewal as their expression typically reduces when hESCs differentiate. Additionally, activation of activin and nodal signaling pathways are thought to be essential for controlling hESC cell fate. Specifically, the high expression of activin and nodal is thought to either directly maintain pluripotency via their downstream receptors, ACTRIIB and ALK4 receptors and SMAD coactivators, or prevent the spontaneous differentiation of hESCs to neuroectodermal pathways.[157] Finally, hESCs and mESCs are similar in that they both express a repertoire of cell surface proteins that distinguish them from other cell types, including the stage-specific embryonic antigen-3 and -4 (SSEA-3 & SSEA-4) and the proteoglycan receptors TRA1-60 and TRA1-81. However, mESCs and mouse iPSCs (miPSCs) express SSEA1 and SSEA3, but not SSEA4. Together with OCT4, NANOG, and SOX2 protein expression, these markers are routinely used for characterization of hESCs, mESCs, and iPSCs (see following) cell lines. Additionally, it has been observed that ESCS and embryonic germ cells (EGCs) share several biomarkers, making it difficult to distinguish between the embryonic, pluripotent, and primitive germ cells.[224,225] The intimate relationship that exists between the germ line and ESCs in mice and humans is critically important to decipher in the future and will greatly inform current and future efforts to derive "artificial" gametes. In fact, derivation of functional gametes from pluripotent stem cells in the mouse has been accomplished with considerable success and is discussed later in this chapter. However, insights into human germ line specification are lagging behind those of the mouse field largely because more efficient models of human PGC specification from pluripotent stem cells are still being designed and tested. Nevertheless, there is an overall emphasis for derivation of male and female gametes in order to advance our understanding of the genetic and nongenetic origins of human infertility.

Nuclear Reprogramming and Induced Pluripotency

A set of landmark studies conducted by Yamanaka and Gurdon and supported by work from other laboratories revealed that just four factors normally produced in the embryo are sufficient to reprogram differentiated, non-embryonic cells into pluripotent stem cells. This important finding enables many of the ethical issues associated with the use of human embryos to be bypassed and also evades potential problems with immune rejection that might affect patients upon stem cell transplantation. The four Yamanaka reprogramming factors—*Oct4, Sox2, Klf4*, and *C-myc*—when introduced into differentiated cells in excess amounts, change cell fate by inducing these cells to revert back to a progenitor-like or ESC-like state. It is believed that this is a stochastic process whose mechanisms lie in the ability of these four transcription factors to induce epigenetic restructuring of the genome, thereby enabling expression of previously silenced genes.[217,226] These artificially created pluripotent stem cells were first described by Takahashi and Yamanaka in rats in 2006.[227] The same researchers also demonstrated that they could derive iPSCs from adult human cells, a finding subsequently confirmed by others.[228–231]

A major concern with iPSCs is the level of genomic disruption that occurs with viral delivery of the reprogramming factors using retroviral or lentiviral vectors. Theoretically, these viral vectors, by integrating randomly into the host genome, may cause chromosomal translocations or transform reprogrammed cells into malignant cells. There are now several initiatives underway that seek to understand the degree of genome-wide mutations and changes in gene function that occur in iPSCs.[232] The art of generating pluripotent cells now involves making iPSCs with reprogramming proteins using techniques that both avoid the use of embryos and the downstream hazards of viral vectors. Additionally, it is now possible to employ just the reprogramming proteins of these factors without the use of viral vectors to create iPSCs.[233] Several gene delivery systems that have been described, including those that employ excisable polycistronic cassettes,[234,235] *piggy*BAC introduction,[236] transfection and/or nucleofection of plasmids,[237] and most recently, mRNA and miRNA delivery.[238] There is also evidence that cocktails of small chemicals including forskolin, valporoic acid, and CHIR99021 (a glycogen synthetase kinase 3 inhibitor) can be used as agents to induce reprogramming in somatic cells.[239] As per these reports, mechanisms by which small molecules induce pluripotency may include the initial activation of a transcription factor, sal4, which may assist in oct4 promoter demethylation and activation of oct4 transcription. Finally, direct reprogramming methods wherein cells from one lineage are directly transdifferentiated to another lineage (e.g., fibroblast to neural-like lineage) are gaining in popularity. Specifically, terminally differentiated cells like skin fibroblasts can be exposed to a cocktail of factors that simultaneously enable a potential reversal of cell fate and induce differentiation to the second lineage.[240–242] It is not clear if these cells transit through an ESC-like state before acquisition of their eventual cell fate. The use of these exciting approaches further highlights the plasticity in the fate of somatic cells that was previously treated as irreversible and suggests that acquisition of complete pluripotency may not be a requisite for full function of the desired cell type.[243] In sum, the use of human, patient-specific iPSCs in cell lineage tracing, cell fate alteration, and cell-based therapies has set the stage for revolutionary clinical breakthroughs in regenerative medicine.

Ethical and Technical Concerns in the Use of Stem Cells

Among the many ethical, technical, and safety concerns associated with the clinical application of stem cells, the primary concern surrounds the stem cell source. hESCs have generated the most controversy because the procedure of deriving a hESC line involves the sacrifice of a donated human embryo, even though the donated embryos would have likely been discarded (reviewed in Refs 244,245). Therefore, alternative sources of stem cells, such as iPSCs, which might achieve similar therapeutic goals, could be very valuable and bear fewer ethical issues than hESCs. Since one of the standard measures of a pluripotent stem cell is that it reliably forms teratomas when transplanted into animal models, careful long-term analysis and follow-up after transplantation will be needed in animal models before stem cells or directed differentiated cells are applied to humans. Yet, hESCs still represent the best model system with which to study early human development because of their robust differentiation potential and relatively permissive epigenetic status, and therefore remain the standard for studying stem cell properties. However, their suitability for transplantation studies is questionable mainly because of the risk of immune rejection from host human tissues.[246] In contrast, patient-autologous iPSCs are considered more suitable for clinical transplantation due to better immunological suitability, but their differentiation profiles, epigenetic status, and potential for tumor formation are far less characterized than are hESCs.[247] Therefore, it is imperative that studies with hESCs continue to allow better definition of the true potential of all other stem cell sources, including human iPSCs. Fortunately, there is currently considerable research devoted to deciphering the molecular mechanisms that underlie the cell fate reprogramming process. In parallel, many laboratories are now developing iPSC-based disease models

Vet-ebooks.com

for human degenerative diseases and cancers. These in vitro studies should provide the research community with insight into the mechanisms of disease progression and illuminate avenues of therapeutic potential. Consequently, hESCs will likely remain the gold standard stem cell type for developing basic scientific and clinical therapeutic protocols, and to which iPSCs and adult stem cells will be carefully compared for their therapeutic potential.

GERM LINE DEVELOPMENT

PGC Specification

As defined in the introduction, germ line establishment in mammals occurs via "inductive" signaling, in contrast to lower organisms such as flies and worms where the germ cell identity is transmitted via the inheritance of germ plasm.[28–30] In rodents and humans, PGC formation is first observed in the proximal epiblast region and near the extraembryonic ectoderm (ExE) region of the embryo (E6.5 in mouse) after implantation and gastrulation (Figure 6.2).[30,31] Coincident with the formation of epiblast, endoderm, mesoderm, and ectoderm, molecular cues including BMP4 and BMP8a are produced from the yolk sac. BMP signals induce a population of pluripotent stem cells to be segregated from the ICM and set physically apart from the extraembryonic ectoderm or yolk sac of the embryo.[32–34] Additional mechanisms that may assist germ line specification are the activation of molecules and pathways that either promote PGC survival such as the cytokines, fibroblast growth factor 9 (FGF9), LIF, and kit ligand (*KITLG*), or via modulation of signaling molecules such as AKT kinase and interleukin 6 pathways. Germ line specification can also be controlled by the inhibition of molecules that promote somatic differentiation of PGCs including the WNT/beta-catenin pathway and p53 activation. These mechanisms have been greatly elucidated in the mouse and are comprehensively reviewed in Ref. 248. Although several of these molecules and pathways are conserved in humans, their contribution to germ line specification is yet to be confirmed. As such, mouse and human PGCs retain expression of several biomarkers of pluripotency, including OCT4, NANOG, and SOX2, which underlies their close resemblance to other pluripotent stem cells (Figure 6.3).[225,249,250] Interestingly, the transcription factor SOX2 is expressed in both mouse and hESCs, but unlike in the mouse, human SOX2 expression is diminished when PGCs migrate to the fetal gonad.[251] Concomitant with the timing of germ line specification in the mouse (E7.5), PGCs near the extraembryonic ectoderm begin to express germ cell-specific markers such as *Blimp-1* (*PRDM1* in human), *Stella* (*DPPA3* in human) and deleted-in-azoospermia-like (*DAZL*) as well as acquire alkaline phosphatase (AP) activity (Figure 6.3). BLIMP-1/PRDM-1 is a transcriptional repressor whose activity is restricted to the germ lineage and appears to be critical for maintaining a PGC fate. There is strong evidence to suggest that in the mouse, BLIMP-1 actively represses the somatic fate of PGCs by inhibiting expression of key somatic regulators during development.[35,252,253] It is unclear whether PRDM1 carries out a similar function in human germ line formation. Once cell–cell communication has been established, the interferon-induced transmembrane proteins (IFITM1 and IFITM3) and STELLA/DDPA3 proteins promote further development of PGCs and may do so in a similar fashion as BLIMP-1 in mice.[30,254]

While several studies have documented how mESCs give rise to the PGC lineage in the mouse embryo, the lineage tracing of hESCs is difficult. Specifically, molecular data documenting the induction and specification of PGCs is severely affected by the lack of pregastrulation embryos. Nevertheless, early efforts of tracing human PGC development utilized three-week-old embryos in which a cluster of extragonadal PGC-like cells were observed as dense, rounded cells that were distinct from somatic cells (reviewed in Ref. 255). However, to remedy the lack of early lineage markers and developmental events of human PGCs, several groups have embarked on in vitro-based strategies to derive PGCs from human ESCs and iPSCs and then use these in vitro-derived germ cells for marker analysis (Figure 6.3). These efforts will be discussed in detail later in this chapter. Interestingly, hESCs may share some features with PGCs, and a subset of hESCs may be "primed" for a germ cell fate.[224,225] This observation has further underlined the unique biology of human germ cell development.

To develop more sustainable models for the study of molecular mechanisms of early germ cell development, considerable efforts have been made to culture mouse and human PGCs and gonocytes in vitro. In the case of mouse germ cells, the addition of endogenous factors known to affect germ cell development such as BMPs, RA, LIF, and forskolin have produced mixed results in maintaining PGCs in culture. For example, adding LIF enhanced PGC survival, but the observations with the use of other factors is not as clear. PGCs may also behave erratically in culture (showing low survival rates and nonsex-specific behavior) because of the lack of a normal somatic environment.[256] However, a landmark study has recently shown that supplementation of LIF in a "2i" cocktail for mESC growth can induce an epiblast-like cell stage of mESCs and set the stage for PGC development.[257] The 2i cocktail consists of serum-free medium and the use of two small molecules, PD0325901 and CHIR99021, that inhibit activation of MAP kinase and glycogen synthetase kinase 3, respectively. These inhibitors modulate cell

Vet-ebooks.com

turnover and differentiation potential in favor of overall stability of mESC cultures. Efforts to culture human fetal gonocytes by Shamblott et al., Turnpenny et al., and Tu et al. resulted in a mixture of cellular phenotypes. Some gonocytes appeared rounded, while others took on an elongated or spindly appearance. In addition, they appeared to have different proliferation rates.[258–260] Currently, it is not at all clear that these cells resemble their germ cell counterparts in vivo, but improvements in culture conditions and the cellular microenvironment will certainly help in this regard. The difficulties in growing these cells have led several researchers to turn attention to the isolation and in vitro culture of prospective spermatogonial stem cells (SSCs) from human tissue, which will be discussed later in this chapter.

Germ Cell Colonization of Gonads

Migration of germ cells to the gonad begins at E8.5 in the mouse and during weeks 4–6 of human gestation (first trimester). At this stage, PGCs accumulating at the base of the allantois exit the extraembryonic ectoderm and begin migration to the developing gonads, also known as the genital ridge (Figure 6.2). Specifically, PGCs are brought to the genital ridges by way of invagination of the hindgut and passage through the dorsal mesentery (Figure 6.2, left, arrows). Because of the remarkable journey undertaken by PGCs through several somatic tissue environments, it is plausible that PGCs are responsive to several different signaling environments that instruct their motility. It is thought that IFITM1 and/or IFITM3 are largely responsible in initiating PGC migration into the endoderm and to the future hindgut (Figures 6.2 and 6.3). However, mouse knockout studies have yielded conflicting results on the role of this molecule.[254,261] Other molecules expressed during migration include the CXCR4 receptor on the surface of mouse PGCs and the proto-oncogene c-KIT and its ligand, KITL, in both mice and humans.[262,263] DAZL is also expressed on migrating PGCs in mice[264] and on postmigratory human PGCs in the testis.[265,266] In support of a model of directed migration of PGCs in mouse and human embryos, it is considered that extracellular proteins such as collagen I/II/IV, fibronectin, and laminin all play a passive role in guiding PGCs to their destinations. Accordingly, it follows that adhesion molecules such as integrin α and β receptors on PGCs and in the cells of the hindgut are important guidance cues.[267,268] In the mouse, migratory PGCs display pseudopodia that may assist in movement through the hindgut, and it is plausible that human germ cells behave similarly since they are also observed in the hindgut during migration.[269,270] Indeed, studies using electron micrographs of 4–6-week-old human embryos revealed irregular structures that resembled pseudopodia on PGCs.[270,271] Various somatic tissues interact with PGCs during the migratory path to the gonad. It is therefore likely that these tissues express molecules and factors that guide or "cue" the PGCs and help maintain their survival. Several candidate molecules have been identified in the mouse, including receptors such as β-1 integrin and extracellular matrix components such as collagen I.[272,273]

Although migration of PGCs is less well understood in human development, germ cells have been histologically observed during the late first trimester, when they undergo migration to the hindgut.[271,274,275] In another study, histological evaluation of first-trimester fetuses revealed that human PGCs intimately contact with and migrate along nerve fibers and Schwann cells to arrive at the gonadal ridge.[276] Male and female PGCs have been isolated from 10-week old fetuses and were observed to express AP, a marker of PGCs.[275] The morphology of human PGCs also resembles the rounded shape of mouse PGCs. Female-specific germ cells have also been visualized at the ultrastructural level during gonadal development in human fetuses.[277] Finally, recent studies by Kerr et al. with human fetal gonads (testis and ovary) provide a detailed analysis of pluripotency and germ cell-specific markers. The germ cells of the fetal testis are OCT4+/NANOG+/C-KIT+ from week 7–15, after which these cells become localized to the periphery of the testis. Meanwhile, the presumptive gonocytes in the week-15 testis show strong expression of pumilio RNA-binding family member 2 (PUM2), VASA, a cytoplasmic protein that is implicated in translational regulation and DAZL and express low to no pluripotency markers (OCT4, NANOG, C-KIT, TRA1-60, TRA1-81).[265] In the human fetal ovary, as in the testis, the expression of pluripotency markers peaks by week 8 and then declines after week 9, as oocytes enter meiosis. Interestingly, the cell surface markers SSEA-1 and SSEA-4, which are also negative and positive cell surface markers of hESCs, respectively, are co-expressed on the female germ cells from week 5 onwards, although only SSEA-1 is restricted to the germ cell lineage.

Upon arrival at the genital ridge, mouse and human germ cells begin to express VASA (Figure 6.3). The gene encoding VASA expression, *DDX4* (*Mvh* in mouse), is highly conserved among species and is expressed exclusively in both male and female pre-meiotic germ cells.[278] This finding underlines the importance of the VASA protein in germ line function and makes it an attractive candidate for further study. Along with VASA, other factors produced in the mouse are germ cell nuclear antigen-1 (GCNA-1) and E-cadherin. The sex-specific character of the developing gonad is controlled by the chromosomal constitution of gonadal somatic cells as discussed in Chapter 7. In particular, the *Sry* gene expressed on the Y chromosome in mammals is thought to be an essential regulator of various downstream targets, including the *Sox9* gene that controls male gonadal development.[279,280] Once within the

Vet-ebooks.com

gonad, germ cells associate with Sertoli cells to form testis cords, and this interaction induces the expression of VASA in postmigratory PGCs. VASA expression is induced in both male and female PGCs and persists until these cells enter meiosis, after which its levels diminish.[281,282]

Developmental Remodeling of PGCs

During embryonic and germ line development, an extensive remodeling of the epigenetic landscape occurs (Figure 6.3). This takes place by global DNA demethylation at the transition from morula to blastocyst stages of embryogenesis followed by reestablishment of DNA methylation in the blastocyst during implantation as discussed earlier. When PGCs are specified from ESCs or epiblast at about 2 to 3 gestational weeks in human and E6.0–E8.0 in mice, they begin to undergo global DNA methylation erasure.[250] Postimplantation, de novo methylation of DNA continues exclusively in PGCs during their specification period. Finally, migrating PGCs undergo a genome-wide DNA demethylation period, presumably induced by the local environmental changes around PGCs in the hindgut and genital ridges.[283–285] This phase occurs only in germ cells and may help to prime them for sex-specific DNA remethylation, when their developmental programs are established.[286] In the mouse, the reestablishment of imprints takes place prior to birth in the male prospermatogonia (E15) and only after birth in oocytes.[287] In addition to DNA methylation changes, male and female germ cells also undergo posttranslational histone modifications such as increased methylation of histone H3 at lysines 27 and decreased methylation at lysine 9 on histone H3, which may regulate transcriptional regulation of germ line-specific genes. Additionally, RNA-mediated silencing and X chromosome inactivation also participate in epigenetic remodeling of male and female germ cells (reviewed in Refs 250,288).

Hypomethylated PGCs in primitive gonads undergo sex-specific methylation changes during oogenesis and spermatogenesis. However, establishment of male and female imprints does not take place until after gonadal differentiation and at different time points in male and female development (Figure 6.3).[289] The DNMT enzymes DNMT1, DNMT3A, and DNMT3B are considered to be the principal catalysts of DNA methylation of cytosines at the 5- position (5-methylcytosine). The specific roles of DNMTs in human PGCs is not clear due to the lack of access to migratory PGCs, but mouse studies have yielded important insights about DNMT1 maintaining methylation globally, while DNMTs 3A and 3B serve as de novo methylators of DNA (reviewed in Ref. 283). Recently, the modification of 5-methylcytosine to 5-hydroxymethycysotosine (5-hmC) by the TET family of enzymes has illuminated an additional level of regulation of DNA methylation erasure in PGCs.[290] The precise role of 5-hmC as an intermediate modification or source of additional molecular recognition is being actively explored. Meanwhile, core histone modifications may also aid in the DNA demethylation process. Specifically, dimethylation of histone H3 at lysine 9 (H3K9), a repressive mark, appears to be reduced in PGCs over time, while the permissive marks of H3K27 trimethylation and H3K4 dimethylation increase up until the eventual G2 arrest of PGCs in gonads (Figure 6.3). Therefore, a working model of epigenetic remodeling is a passive mechanism involving de novo methylation followed by widespread DNA demethylation at imprinted and nonimprinted loci, resulting in activation of sex-specific gene expression and commitment to the spermatogenesis or oogenesis pathways.

The successful passage of germ cells through meiosis is a unique and highly rigorous process as detailed in Chapter 1. However, in general, between male and female embryos, the timing and mechanisms of meiotic entry bear similarities and key differences.[266] Male germ cells are restricted from entering meiosis, while female germ cells enter meiosis within the embryo. Female germ cells destined to become oocytes eventually arrest during meiosis I prior to fetal birth and will only resume meiosis upon receiving hormonal signals during adulthood.[291] Meanwhile, male germ cells transition from primordial status to the gonocyte stage, stop proliferating, and remain quiescent in the fetal seminiferous tubules until after birth. The postnatal gonocytes then commit to a SSC fate and amplify through self-renewal or enter meiosis to initiate spermatogenesis. In both male and female germ cells, the synaptonemal complex proteins (SCPs) SCP-1, SCP-2, and SCP-3 are critical components of the meiotic machinery during chromosomal segregation (Figure 6.3).[292–294] The completion of meiosis signals that germ cells have matured into haploid male and female gametes. At this stage, oocytes exclusively express growth differentiation factor-9 (GDF9) and spermatocytes express tektin 1 (TEKT1).

GONADAL STEM CELLS

Guided by the premise that male gametes must be replenished, several investigators have sought the identity of germ line stem cells (GSCs) in the testis. In females, a finite supply of follicles endowed upon birth in women and in mice argues against the existence of oogonial stem cells, although this concept has been revisited recently.[295–297] Moreover, the pluripotency potential of EGCs and their similarity to ESCs has fueled the speculation about the similarities between gonadal stem cells such as SSCs and ESCs in vitro and in vivo. There is compelling data proving the existence and plasticity of testicular GSCs in the mouse and more recently the human testis. Functional evidence for stem cells in the rodent

Vet-ebooks.com

adult testis was first provided by Brinster and colleagues in 1994 when they transplanted a putative SSC population extracted from a prepubertal mouse testis into completely sterile *W/W* recipient mice and observed chain-like colonies of donor-derived cells, indicating complete spermatogenesis with transplanted cells.[298] Brinster and colleagues followed up their studies with transplantations of primate SSCs and human testicular cell suspensions into seminiferous tubules and observed colonization and survival of donor cells two months after transplantation, which solidifies the use of this assay for testing SSC function.[299,300] Recent research has sought to characterize the true stem cell potential of early spermatogonia within the seminiferous tubule. Kanatsu-Shinohara et al. first reported the generation of pluripotent stem cells from the mouse testis.[301] In their study, a population of cells termed GSCs was isolated from neonatal mouse testis and propagated in culture.[302] Subsequently, they found that cell colonies with morphology quite distinct from GSCs, termed ESC-like cells, also appeared in culture. The formation of both GSCs and ESC-like cells depended on a GDNF signal, and only ESC-like cells expanded in regular mESC media. The expression profile and imprinting profiles indicated that the ESC-like cells had gene expression and imprinting profiles that closely matched those of mESCs. Interestingly, transplantation of ESC-like cells into seminiferous tubules gave rise to teratomas, while GSC transplants led to spermatogenesis without teratomas.

In 2006, pluripotent stem cells were derived from the adult mouse testis.[303] With the introduction of a *Stra8-eGFP* reporter in which GFP expression was regulated by *Stra8* promoter activity, ES-like cells were separated from a heterogenous population of testicular cells. When these isolated ES-like cells were grown on mouse embryonic fibroblasts or cultured in medium containing LIF, they evolved into a subpopulation of cells that the authors termed multipotent adult germ line stem cells (maGSCs). Another transplantation study by Nakagawa et al. in 2007 employed the neurogenin 3 (*Neurog3*) promoter to induce GFP expression and thereby enrich for two populations of undifferentiated spermatogonia.[304] The researchers took advantage of the expression of NEUROG3 on undifferentiated spermatogonia, and, from their sorting studies, the first population of cells maintained the SSC progenitor pool through self-renewal while the second population revealed a pool of SSCs that diminished with age. In parallel to these studies of mice multipotent GSCs, several groups have reported a collection of genes and biomarkers that are nonexclusively expressed by mouse SSCs.[305,306]

Motivated by the successful discovery of SSCs in the adult rodent testes, several investigators have attempted the same types of studies in the human. In a landmark study, Conrad and colleagues harvested THY1-positive SSCs from adult human testes and subsequently reprogrammed them into pluripotent cells.[307] The single-cell suspension was then cultured in vitro in the presence of the self-renewal factor, GDNF. SSCs were purified from the mixed population by magnetic-activated cell separation with CD49-bound beads. Overall, the authors observed significantly different expression profiles in human maGCSs (hmaGSCs) compared to the parent spermatogonial cells. They also noted that hmaGSCs acquired expression profiles similar to hESCs. Although the foregoing study represents a complete analysis of a novel cell population in the human testis, several caveats to this research exist. Entire testicles were used to derive spermatogonial cells, bringing into question the feasibility of this approach for clinical use.[308] In addition, the global gene expression patterns of pluripotency markers obtained from these hmaGSCs have been challenged as being more closely associated with fibroblasts than hESCs.[309] Nevertheless, the above experiments were corroborated by other groups, who used THY1 as a marker for isolation of prospective SSCs.[310,311]

To address the issue of limited availability of starting material, two similar approaches were used for generating human pluripotent stem cells from testicular biopsies as reported by Kossack et al. and Golastaneh et al.[312,313] After enzymatic digestion of the adult testis biopsy, cells were plated with or without mouse feeder cells, and hESC-like colonies were observed after about 7–10 days. Subsequently, hESC-like cells in colonies were propagated by manual dissection onto fresh mouse embryonic fibroblasts in hESC culture conditions, supplemented with FGF. Under these conditions, the spermatogonial cells maintained an hESC-like morphology, were karyotypically normal, expressed both pluripotency and early germ cell markers, and contained a generally hypomethylated DNA pattern consistent with hESCs rather than somatic cells. However, hmaGSCs isolated in this study did not successfully form large teratomas in vivo. Therefore, even with limited substrate, this study suggested that hmaGSCs, unlike true hESCs, might be only multipotent and not fully pluripotent. In more recent experiments, at least two other markers, SSEA4 and the CD9 receptor, have been used to test for the presence of SSCs in the human testis. CD9 is a matrix metalloproteinase that binds to extracellular matrix molecules and is expressed on the surface of human spermatogonia. Following transplantation of CD9-positive human spermatogonia into mouse testes, long-term survival of donor cells was observed.[314] Meanwhile SSEA4-positive cells isolated from human testicular biopsies were enriched for SSCs as evidenced by their survival and localization to the basement membrane after transplantation to mouse seminiferous tubules.[315] Collectively, these studies highlight the existence of a multipotent stem cell population that bears resemblance to mouse SSCs by virtue of colonization of the seminiferous tubules and their clonogenic properties.

The exploration of GSCs in the human ovary has gained interest recently because of findings that challenged

Vet-ebooks.com

the long-held notion that women are endowed with a finite supply of oocytes. For instance, Johnson and colleagues observed that a small population of GSCs reside in the ovarian surface epithelium in the mouse and can undergo self-renewal of the follicular pool within 24 h.[316] The source of these GSCs was proposed to be from the bone marrow and via the vasculature.[317] Despite the proof of successful transplantation in this study, they failed to demonstrate meiosis in the oocytes generated from ovarian stem cells (OSCs) or bone marrow-derived stem cells.[318] Furthermore, it was not clear whether these OSC-derived oocytes could be artificially fertilized. Based on these findings, the existence of GSCs in the adult ovary remained unknown until a follow-up study by the same group in 2012. In their latest efforts, Tilly and colleagues established a method by which adult human OSCs can be isolated using a FACs-based approach to target the N-termini of VASA.[319] They went on to characterize the germ cell behavior of OSCs, their meiotic competence, and potential for follicle formation in vivo following xenotransplantation with human ovarian cortical tissue into mouse ovaries. Yet, questions remain as to the efficiency of OSC derivation, their ability to mature in vitro, and, more importantly, the veracity of their transformation in vivo after their exposure to artificial in vitro manipulation.[320] If OSCs can be isolated from adult ovarian biopsies, as these studies claimed, it seems reasonable to expect that immature ovaries from neonatal or prepubertal mice or adolescent girls would produce far greater numbers of OSCs by the methods described.[319,321] However, the studies by Tilly and colleagues did not examine this possibility, and if the future strategy is to preserve OSCs from young women or adolescent girls prior to extensive follicle loss or before chemotherapeutic exposure, then it seems worthwhile to quantify and document the OSCs at those stages. Nevertheless, these proof-of-principle studies are illuminating about the possible existence of an ovarian progenitor cell type.

GENERATION OF GAMETES FROM PLURIPOTENT STEM CELLS

Our knowledge about mouse embryo and germ line development from mESCs has allowed for in vivo and in vitro modeling of germ line development. However, very limited access to early stage human embryos and especially human PGCs has greatly reduced the ability to conduct similar investigations into human germ line development, let alone modeling it in vitro (Figure 6.6).

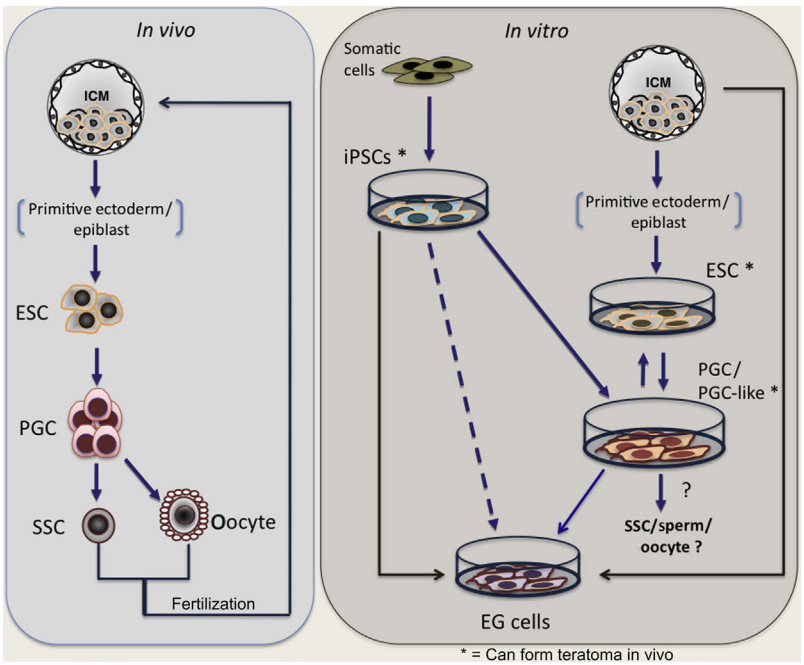

FIGURE 6.6 Comparison of in vivo germ line development and in vitro germ cell derivation from ESCs and iPSCs. A depiction of in vivo development of germ cells and gametes from the mammalian embryo is shown on the left to demonstrate that embryonic stem cells (ESCs) originate from primitive ectoderm (epiblast) by way of the inner cell mass (ICM). Primordial germ cells (PGCs) then migrate to gonads where they undergo self-renewal in the form of spermatogonial stem cells (SSCs) in the testis or further differentiate to oocytes in the ovary. On the right is a schematic of the different cell lineages that can be derived in vitro. ESCs cultured in dishes can be differentiated to PGCs via methods summarized in Table 6.1. PGCs cultured in vitro, at least in the mouse, can transform to embryonic germ cells (EGCs). There is also evidence to suggest that a subpopulation of hESCs cultured in vitro behave like EGCs. Finally, somatic cells can be reprogrammed to iPSCs with addition of the transcription factors, OCT4, SOX2, KLF4, and MYC to induce a stem cell-like fate. iPSCs can then be induced to form PGC-like cells or EG-like cells by in vitro and in vivo methods. Those cell types marked with an asterisk indicate that ESCs, PGCs, and iPSCs can all form teratomas when injected in vivo as demonstration of their pluripotency. *Source: Adapted from Ref. 17.*

This section reviews the highlights of experiments conducted during the last decade using in vitro model systems of mouse and human germ line development from mESCs and hESCs (Table 6.1).

Derivation of Germ Cells from Mouse and hESCs

The mouse has proven to be a robust and dependable system for analysis of germ line development. Studies conducted in vivo during early mouse development have greatly provided information for subsequent in vitro investigations and have generated promising prospects for creating gametes from nongonadal stem cells. The earliest in vivo evidence for ESC-derived germ cells was suggested from experiments performed by Bradley et al. in 1984. They generated germ line chimeras after injecting mESCs into mouse blastocysts.[214] This work suggests that mESCs, if cultured under the right conditions, could be differentiated to PGCs. We now know that mESC share many developmental features and markers with PGCs, which further supports the use of mESCs as a starting point. This is most convenient as mouse PGCs are difficult to grow and differentiate in vitro.

The first report on the creation of putative germ cells in vitro was reported in 2003. In this study, mESCs were transfected with a reporter green fluorescent protein (GFP) under the control of an oct4 enhancer sequence.[322] The withdrawal of LIF, a factor that promotes self-renewal in mESCs, promoted PGC development and resulted in an increase in GFP-positive cells that resembled a follicle-like appearance. Tooyaka et al. used a mouse VASA homologous gene promoter *Mvh* to drive GFP or LacZ expression in mESCs, which then spontaneously differentiated to embryoid bodies (EBs) with supplementation of BMP4 and in the absence of LIF. EBs were subsequently dissociated and cells expressing GFP were separated from the bulk population using fluorescence-activated cell sorting (FACS) and found to be positive for Mvh. Subsequently, MVH-driven LacZ+ cells were derived, aggregated with mouse embryonic gonadal tissue, and transplanted under a mouse neonatal testis capsule. These cells differentiated to give rise to LacZ-positive spermatozoa.[323] These two landmark studies set the stage for further investigation of deriving gametogenesis from mESC.

In 2004, Geijsen et al. derived male gametes from mouse EBs in retinoic acid-enriched medium. These germ cells were capable of entering meiosis and fertilizing a mouse oocyte.[324] Other studies have employed slightly different approaches to derive putative oocytes such as cocultures of PGCs made from cultured EBs with fetal ovarian granulosa cells.[325] In an alternative approach developed by Salvador et al., a *Gdf9*-driven GFP reporter transgene was introduced into mESC. The mESCs were then differentiated to EBs and GFP-positive cells were isolated from the EBs to isolate PGCs.[326] It was later shown by Kerkis et al. that the divergence of male and female germ cell programs during spontaneous differentiation of EBs in vitro was dependent on the length of culture time.[327] Several attempts at oocyte or follicle derivation from mESC have been made using the EB-based approach with various culture and attachment conditions, all of which yielded oocyte-like cells that lacked critical structural features such as the zona pellucida or expression of meiotic molecular machinery.[328,329] In summary, these latter studies may have derived primitive oocytes from mESCs but failed to accomplish meiotic entry in the final cell products. An alternative approach to deriving female germ cells was employed by Nicholas et al. using a germ cell-specific reporter *ΔPE:Oct4:GFP*.[330] GFP-positive cells exhibited a higher expression of germ cell and oocyte markers, and when aggregated with fetal ovarian tissue and transplanted under a mouse kidney capsule, gave rise to mature oocytes in vivo.

The first study to show virtually complete gametogenesis in vitro was conducted by Nayernia et al. in 2006. A two-stage approach was employed to first derive pre-meiotic PGCs from mESCs with a *Stra8*-driven GFP reporter induced with retinoic acid (RA) addition.[331] GFP-positive cells were then separated by FACS, grown in RA-supplemented medium, and transfected with a second reporter, *Prm1-Dsred*. The second reporter enriched for PGCs that had undergone meiosis and formed red-fluorescing, haploid cells. After further RA treatment, the haploid sperm-like cells were then injected into mouse oocytes by intracytoplasmic sperm injection (ICSI) to test the functionality of the derived germ cells. Indeed, blastocysts formed and viable offspring were born that eventually succumbed to developmental complications and died prematurely. Potentially, the epigenetic reprogramming of the derived germ cells may not have been complete. Nevertheless, these efforts provided functional proof of gametogenesis in vitro.

To further demonstrate in vitro spermatogenesis, researchers have also employed the use of organ culture systems. This is best exemplified by a very recent study by Sato et al. in which functional mouse sperm were generated in vitro by employing a novel organ culture method.[332] Specifically, they improved on existing organ culture methods by placing neonatal (mouse pup) testis fragments in serum-free or FBS-soaked agar plugs in culture. Within these plugs, they had the ability to control the gas:liquid interface while also adding exogenous factors such as BMPs, activin A, hepatocyte growth factor, and testosterone. Their study conclusively showed through an analysis of reporter expression before and after meiosis that functional haploid spermatozoa were generated that could fertilize oocytes and give rise to viable, healthy pups. Moreover, the generated pups

TABLE 6.1 A Summary of the Recent Efforts to Derive Gametes from ESCs and iPSCs—cont'd

Source of Cells	Germ Line Differentiation Strategy	Endpoint			Reference	Reference #
		Cell Types Formed	Gametes	Fertilization		
hESC	Low-density adherent culture differentiation with laminin substrate	CXCR4+ germ cells and Sertoli cells	N	ND	Bucay et al., 2008	305
hESC—XX	EB formation and adherent culture differentiation, selection of SSEA-1 positive cells	Immature germ cells with PGC-like imprinting status	N	ND	Tilgner et al., 2008	301
hESC—XX, XY hiPSC—XY	Coculture of hESCs and hiPSCs with human fetal gonadal cells, selection with SSEA-1 and c-Kit	Double-positive germ cells with PGC-like imprinting status (only with hESCs)	N	ND	Park et al., 2009	302
hESC—XX, XY	Overexpression of DAZ, DAZL, BOULE and adherent culture differentiation +/− BMPs	Haploid germ cells expressing germ line markers and PGC-like imprinting	Y	ND	Kee et al., 2009	306
hESC—XY	Adherent culture differentiation on KITL KO/WT feeders with addition of BMP4	Early germ-like cells expressing VASA and OCT4	N	ND	West et al., 2010a	304
hESC—XY	Adherent culture differentiation on MEF feeders	VASA+/OCT4+ clonally expanded early germ-like cells	Y	ND	West et al., 2010b	307
hESC—XX, XY hiPSC—XX, XY	*VASA-GFP* reporter or overexpression of DAZ, DAZL, BOULE and adherent culture differentiation + BMPs	Haploid, sperm-like germ cells expressing germ line markers and PGC-like imprinting	Y	ND	Panula et al. 2010	310
hESC—XX, XY hiPSC—XX, XY	Overexpression of VASA and DAZL and adherent culture differentiation + BMPs	Haploid, sperm-like germ cells expressing germ line markers and incomplete imprinting	Y	ND	Medrano et al., 2011	308

mESC, mouse embryonic stem cells; hESC, human embryonic stem cells; EB, embryoid body; BMP, bone morphogenetic protein; Mvh, mouse Vasa homolog; RA, retinoic acid; ICSI, intracytoplasmic sperm injection; IVF, in vitro fertilization; MEF, mouse embryonic feeders; Y, Yes; N, No; ND, not determined.

were also shown to be naturally fertile as adults. In summary, attempts to generate germ cells from mESCs have yielded cells that resemble sperm or oocytes in gene expression, ploidy, epigenetic reprogramming, and fertilization ability. However, these studies have also revealed irregularities in the duration of meiosis in culture, the morphological features of oocytes, the viability of generated offspring, and in the germ line transmission of exogenous genes to the offspring.[333] Saitou and colleagues recently achieved the most advanced derivation of functional male and female gametes from mECS and miPSCs.[257,334] In these studies, mESCs were induced into an epiblast-like cell stage (EpiLCs), enriched by selection for the STELLA germ cell marker and then further induced to produce PGCs. When transplanted to empty mouse seminiferous tubules of infertile male mice (*W/W* strain), PGCs made in vitro differentiated and formed spermatozoa. Similarly, to produce oocytes, PGCs derived in vitro were co-aggregated with embryonic gonadal somatic cells (that were depleted of PGCs) and transplanted under the ovarian bursa of neonatal recipient mice. These "reconstituted" ovaries enabled proliferation of female PGCs, meiotic entry, and completion of oogenesis, which when fertilized in vitro yielded healthy pups.[334] In both male and female ESC-derived gametes, the mating of donor cell recipient mice led to successful germ line transmission to progeny mice that appeared normal. Most recently, the same group has uncovered a mechanism by which mouse PGC formation from EpiLCs can be enhanced by the overexpression of STELLA (PRDM1), PRDM14, and TFAP2C transcription factors.[335] These fascinating results have provided

Vet-ebooks.com

an impressive system with which to query germ cell developmental stages in mice.

The evidence for germ line differentiation from hESCs lags severely behind the progress made in the mouse system; as such, literature is more preliminary than that from the mouse primarily due to the low efficiencies in derivation of human germ cells. Furthermore, doubts regarding the extent of pluripotency in hESCs versus mESCs and the ethical constraints of testing the functionality of human germ cells are legitimate concerns of this research. Despite this, there is a tremendous need to understand human germ line formation, the genes that control spermatogenesis and oogenesis, and, from a clinical standpoint, the requirement for in vitro-derived functional gametes. Efforts to derive human germ cells began with a study by Clark et al. in 2004 in which spontaneously differentiated hESCs were used to create EBs.[225] Within the mixed cell population of the EBs, they identified several known germ cell markers such as DAZL, STELLA, and c-KIT. Additionally, they observed that VASA levels were induced within a putative PGC population, and other markers of meiosis were also upregulated. Collectively, their data indicated that PGCs had formed but had not entered meiosis. An important facet of their study was the identification of germ line–associated genes such as DAZL and c-KIT, which are expressed at low levels in undifferentiated hESCs. The methods of Clark et al. were optimized in a follow-up study in which BMP-4, -7, and -8 were added exogenously during EB formation from hESCs, and higher VASA expression was observed in the putative PGC population.[336] Therefore, similar to the mouse model, the role of BMPs in human germ line specification may be important. More recent studies using mESCs in vitro by Young et al. have illustrated how BMP2 and BMP4 but not BMP8b are important inductive agents for specifying the germ cell lineage in EBs.[337] These results help to clarify our understanding of BMP action in the germ line as the goal of deriving haploid germ cells is pursued.

Chen et al. and Tilgner et al. also derived human PGCs from substrate EBs in independent studies. They observed that their EBs contained small structures that resembled ovarian follicles that tested positive for c-KIT and expressed low amounts of VASA protein.[338] They also observed these follicle-like structures in hESCs that were attached on matrigel-coated tissue culture plates and then spontaneously differentiated. This finding was important in suggesting that EB formation may not be essential for germ cell differentiation from hESCs, at least in the female lineage. Meanwhile, Tilgner et al. used a more sophisticated strategy to separate germ cells from EBs and adherent cultures through FACs sorting for cells expressing the surface marker SSEA-1, a protein associated with very early germ cells.[339] Despite evidence of complete epigenetic reprogramming in these early germ cells, the authors did not observe meiosis. In 2009, Park et al. built upon the findings of Tilgner et al. by differentiating iPSCs and hESCs and isolating putative germ cells enriched in SSEA-1 as well as c-KIT expression. However, they used an alternative differentiation strategy and cocultured hESC colonies with stromal cells from the human fetal gonad.[340] In this model, the paracrine factors produced from fetal stromal cells would ideally resemble those made in vivo, thereby theoretically inducing hESCs and iPSCs to differentiate into PGCs. Their efforts were successful, yielding SSEA-1/c-KIT-positive PGCs that expressed numerous germ cell markers such as VASA, PRDM1, and DAZL, and revealed evidence of partial epigenetic reprogramming.

Based on the findings of spontaneous differentiation of hESCs to PGCs, researchers have entertained the possibility that a small population of cells within a typical hESC population constitutes a primitive germ cell population or a subpopulation that is developmentally "primed" to become germ cells (Figure 6.6). Based on this hypothesis, several groups have explored whether simply optimizing culture conditions of hESCs can promote or induce germ line differentiation. Stice and colleagues first reported that by the simple addition of bFGF to hESCs growing on inactivated MEF feeder cells they could produce approximately 69% VASA-positive cells with increased expression of germ line and meiotic markers.[341] These data seem rather optimistic given that most other groups have reported much lower germ cell numbers under similar culture conditions. In recent studies, West et al. explored the effect of modulating KIT ligand (KIT-L) and BMP4 activities in culture of hESCs and observed that these are required for early germ-like cell (GLC) derivation.[342] Concurrently, Bucay et al. modified their culture conditions by lowering the confluency of hESC colonies and observed a subpopulation of cells expressing CXCR4, a membrane receptor implicated in PGC migration.[343] Upon purification, the CXCR4-expressing cells could be grown on a laminin substrate and gave rise to putative PGCs and Sertoli cells.

A major milestone in germ line differentiation of both male and female human PGCs is the initiation and completion of meiosis. Deriving haploid gametes in vitro is a significant feat and one that researchers have struggled with for years in human germ line differentiation. Kee and colleagues derived human haploid gametes for the first time in 2009 by introducing three major germ cell-specific genes of the deleted-in-azoospermia family—*DAZ2*, *DAZL*, and *BOLL*— that encodes for the protein BOULE in hESCs, and then differentiating the cells spontaneously in adherent culture conditions.[344] Although a low number of haploid cells were observed (~2%) 7 days after differentiation, they expressed numerous germ cell-specific markers, and chromosomal spreads indicated the presence of SCP3, a key member of the

Vet-ebooks.com

synaptonemal complex that forms during meiosis. These data also reinforce the importance of the DAZ family of genes for early (*DAZL*) and late (*BOLL*, *DAZ*) PGC formation. Since this work was published, another group has demonstrated meiosis in in vitro-derived PGCs; West et al. had previously shown that they could isolate early VASA-positive GLCs and were able to subclone three populations of these cells from their mixed cultures and propagate them through at least 50 serial passages.[345] These cells were then differentiated with FBS into a more homogenous population, and the majority of cells entered meiosis (~71%) while also expressing germ line and meiotic markers. Taken together, these studies offer alternative and compelling strategies for derivation of PGCs from hESCs. While the latter study suggests that GLCs are a natural clonal subpopulation of hESCs that can be propagated in vitro, the former argues in favor of an active, gene-driven induction of germ line differentiation with the addition of BMPs. The concept of genetic control of germ cell induction has been further explored through the derivation of germ cells from hESCs by the overexpression of the RNA-binding proteins DAZL and VASA.[346]

The composition of medium used for differentiation of hESCs is also important, as was revealed by a recent study in which hESCs were exposed to a medium composition that is known to promote mouse SSC survival and self-renewal in vitro.[347] Without the use of genetic modifications and reporter-based enrichment, this unique approach revealed that hESCs adapt to conditions favoring spermatogonial development and that a subpopulation of hESCs appeared to differentiate to germ cells capable of entering and completing meiosis in vitro.

Germ Line Differentiation from Human iPSCs

Ongoing advances in reprogramming of human somatic cell to iPSCs or direct reprogramming of somatic cells to specific cell lineages are legitimate avenues for autologous, patient-derived stem cell therapies (Figure 6.6; Table 6.1). By applying similar genetic approaches used for hESCs, iPSCs can now be directed to give rise to cells of the germ cell lineage such as PGCs (iPGCs). Moreover, the use of iPSCs derived from infertile, azoospermic men offers a viable avenue by which to explore patient-specific developmental changes during germ line development. We summarize here some of the recent efforts in this growing area of exploration. The use of human iPSCs to derive gametes was first shown by Park et al. in a study that also compared the derivation efficiency to hESCs.[340] In short, they grew iPSCs on a feeder layer of fetal gonad stromal cells and subsequently isolated SSEA-1+/c-KIT+ cells, which they characterized as a putative PGC population. These human iPGCs expressed several germ line markers but did not show evidence of imprinting erasure, a key feature of early PGCs. Further evidence for the creation of haploid iPGCs from male and female iPSCs was provided recently by Panula et al. wherein they used a GFP reporter under the control of the *VASA* promoter to select for putative germ cells from spontaneously differentiated cultures.[348] The *VASA*-GFP transduced human iPSCs were differentiated adherently in feeder-free conditions in the presence of BMPs, giving rise to approximately 5% GFP-positive PGCs. These PGCs expressed a number of germ cell markers such as *PRDM1A*, *ACTC*, *GATA6*, *PELOTA*, and *IFITM3*. More importantly, the GFP-positive iPGCs expressed the meiotic marker SCP3 in both punctate and elongated patterns, indicative of early and late meiosis, respectively. Interestingly, when compared to PGCs derived from both male or female hESCs, the efficiency of iPGC derivation appears higher, suggesting that iPSCs may be a better starting substrate for germ line differentiation. The roles of RNA-binding proteins VASA and DAZL were further explored as modulators of germ cell fate by overexpressing them in human iPSCs and inducing germ cell formation with BMPs.[346] The derivation of low numbers of putative haploid germ cells from these experiments confirmed the importance of genetic regulation of germ cell differentiation in humans. Despite offering novel insights into mechanisms of germ cell differentiation, the efficiency of human PGC derivation remained low. In summary, the above investigations provide encouraging results about the ability to use iPSCs to derive gametes in vitro. Although the differentiation potential of iPSCs may vary greatly from one cell line to another, they appear to have strong potential as a genetic model system to study human germ cell development.

Clinical Need and Applications for In vitro-Derived Gametes

Currently, many men suffer from nonobstructive azoospermia, as described earlier, that results in complete sterility. In addition, in the United States alone, there are 55,000 childhood cancer survivors annually, many of whom were unable to bank sperm before receiving sterilizing treatments. Similarly, women have a finite supply of reproductively competent oocytes, while others undergo premature ovarian failure, making childbearing difficult or impossible. Alternative options for parenthood in these cases are not always simple or inexpensive. Although sperm donation is economical, oocyte donation is quite expensive and the use of donated embryos is unusual.[250] For men, recent strategies such as extracting low numbers of testis sperm after

Vet-ebooks.com

prior localization with fine needle aspiration mapping offer the hope of fatherhood for some candidates.[349,350]

Although such strategies are gaining in popularity, the pregnancy success rate remains at about 30–40% using sophisticated IVF techniques (Centers for Disease Control, 2008). In addition, with these reproductive technologies, there remain important safety concerns about de novo sex chromosome disorders, birth defects, and imprinting-related disorders such as Beckwith–Wiedeman syndrome in offspring.[256] Therefore, there is an obvious clinical need for high quality, in vitro-derived gametes. However, the prospect of employing current protocols and reagents to derive human gametes from hESCs appears unlikely at this time. On the other hand, the use of iPSCs and alternative stem cell sources such as adult stem cells hold great promise in this regard. In the foreseeable future, patients who have undergone chemotherapy and/or patients with genetic disorders affecting fertility could theoretically donate somatic cell biopsies that could then be reprogrammed into iPSCs, genetically modified if required, and subsequently utilized for gametogenesis in vitro.

In sum, the low efficiency of meiotic potential in vitro and the incomplete epigenetic reprogramming of PGC-like cells have thwarted studies of germ line derivation from hESCs. A new avenue of exploration is required, and current efforts are focused on utilizing existing xenograft technologies to derive PGCs from human iPSCs and hESCs in vivo in the environment of the mouse gonad or kidney capsule. These efforts, if successful, will pave the way for better xenograft models that resemble human physiology more accurately and subsequently lead to cell-based therapies for infertile men and women.

CONCLUSION

Humans have long pondered the mechanisms and meanings that underlie the formation of a new individual. Since the days of debate between preformation and epigenesis, several scientific discoveries have addressed many complexities in human development. More specifically, the underlying programs mediating epigenetic erasure and reestablishment of methylation and histone modification marks, which genes are first expressed during development, and the timing of cell lineage differentiation have been revealed in recent years. In addition, systems and technologies such as whole genome and epigenome analysis, as well as imaging and transplantation techniques to probe fundamentals of embryo and germ line development, have been extensively elaborated and hold promise to provide the means to discover new molecules and mechanisms.

Future Challenges

Although much has been accomplished and revealed in the fields of human embryology and gametogenesis in recent years, many challenges and questions surrounding early human development still persist. In particular, the possible origins and consequences of embryonic chromosomal abnormalities, the long-term effects of epigenetic changes during early embryogenesis, and whether the completion of human germ cell meiosis in vitro or in vivo following xenotransplantation will ever be attainable remain elusive. As noted before, most studies of embryo development are conducted in the mouse or non-mammalian species, requiring extrapolation of results to human development. However, given extensive species-specific differences, even comparison between closely related mammalian species may be difficult. Moreover, most data on human embryo development by necessity is limited to that obtained from infertility clinics and embryos produced with germ cells that may be compromised. Thus, while such studies have proven to be invaluable, the interpretation of results and what should be considered "baseline" must be approached cautiously. Further, data specific to segments of human populations, or cohorts, and the similarities or differences between populations that may translate to disease risk or other factors is limited. In large part, these limitations are linked to a lack of tools, historically, to probe imaging, molecular, genetic, and epigenetic determinants of human development especially on a small scale such as at the single embryo or blastomere level. It is likely that as tools for single cell analysis continue to be developed, along with computational means to integrate different types of data, and continued improvements in the differentiation of stem cells to germ cells in vitro and/or in vivo, that understanding of human embryo and germ line development will be dramatically improved and translate to clinical applications.

Perspectives on the Future of Reproductive Medicine

Infertility is common, with IVF and other forms of assisted reproduction increasingly being used to treat this disorder. Fundamental problems in identifying embryos that are likely to be successful in development, reducing embryo loss, and examining development at the cellular basis should be a focus of studies in human reproduction over the next several years. It is envisioned that with knowledge of human embryonic preimplantation development, three outcomes might be realized in assisted reproduction: (1) Predominant transfer of single embryos, (2) improvements in success rates, and (3) reduction in adverse outcomes associated with multiple embryo transfer/births.

Vet-ebooks.com

In summary, over the last decade human preimplantation development has been the subject of much inquiry, resulting in greatly increased knowledge of fundamentals. The coming decade is likely to witness genetic and epigenetic studies at the single embryo and/or single cell level that further improve our understanding of basic human development, including the genes and proteins required for reprogramming through the oocyte to embryo transition and activation of the embryonic genome, clinical applications in reproductive medicine that allow transfer of single embryos cultured under optimal conditions, and translation to other pluripotent cell types important to stem cell biology and regenerative medicine.

CHAPTER

7

Sex Determination and Differentiation

Jennifer R. Gardiner, Amanda Swain

Division of Cancer Biology, Institute of Cancer Research, London, UK

INTRODUCTION

Sex determination is the fundamental step that an animal takes to become male or female. Although this decision is common to most species, the mechanism that determines sexual dimorphism is highly diverse. The question of how sex is determined has puzzled scientists and philosophers for centuries.

Aristotle predicted in 335 BC that sex was determined by environmental factors—specifically, by the temperature of both partners during intercourse. The theory that environmental sex determination occurred in all species remained popular until the turn of the twentieth century. In 1891, it was observed that wasp sperm cells contained unequal numbers of chromosomes. Some of the sperm cells contained an unidentified 12th chromosome, which was named the X element, and later the accessory chromosome. In 1902, two separate papers hypothesized that this chromosome was involved in sex determination.[1,2] Further observations led to the realization in 1910 that this unequal distribution of sex chromosomes only occurred in some animals; in others, the same number of chromosomes appeared, although one set was morphologically different in males and females.[3] This was the first observation of the XY sex determination system that is found in humans. In the mid twentieth century, experiments demonstrated that a "testis determining factor" present on the Y chromosome was critical for male development in mammals. This factor was finally identified in 1990,[4] cementing the modern view of mammalian sex determination.

In mammals, sex determination is classically divided into three hierarchical, irreversible stages. The first step is the establishment of chromosomal sex at fertilization. For the most part, the initial stages of fetal development do not show any morphological differences between the sexes until the gonad develops. The second step in sexual differentiation is the choice of the bipotential gonad to become an ovary or a testis. The third step is the development of the sexual phenotype of the fetus, some aspects of which are controlled by diffusible substances produced by the gonads. In recent years, advances in genomics have resulted in an influx of data on sex determination in many species, providing insights into the dynamic and rapid evolution of this process. Furthermore, recent data have challenged the simple stepwise model of sex determination, indicating that sex in mammals is more plastic than previously thought; indeed, sex can be altered even into adulthood. This chapter will discuss the three stages of sex determination and differentiation, focusing primarily on mammals, and examining how mouse models and human disease have expanded and challenged our understanding of the meaning of sex.

CHROMOSOMAL SEX

Mammalian species rely on genetic factors to determine sex. In eutherian (placental) mammals such as humans and mice, heterogametic chromosomes determine sex. Homogametic individuals—those possessing two X chromosomes—are genetically female, while heterogametic individuals possessing one X and one Y chromosome are male. This is due to the presence of a single gene on the Y chromosome, *SRY* (Sex-determining region on the Y chromosome), which is necessary and sufficient to determine male development.[5,6]

Evolution of Heteromorphic Sex Determination

Heterogamety is often viewed as the standard mode of chromosomal sex determination. As such, heteromorphism—a difference in morphology between male and female members of the same species—is evident in many of the model species studied by developmental biologists, including mice, rats, chicks, and *Drosophila*.

Knobil and Neill's Physiology of Reproduction, Fourth Edition

In most cases, male heterogamety is the norm, the notable exception being birds, in which the female exhibits ZW heterogamety. Heteromorphic chromosomes have evolved on multiple occasions. Evidence from lower vertebrate groups such as the teleosts and amphibians, in which both male and female heterogamety have evolved in separate populations, suggests that environmental rather than genetic pressure may drive evolution of heteromorphism.[7,8] However, the reasons for evolution of male versus female heterogamety remain unknown.

Heteromorphic sex chromosomes like the X and Y are thought to have evolved from an identical pair of autosomes. Several evolutionary theories propose that the first step in the evolution of sex chromosomes is the appearance of an autosomal gene with two different alleles, where homozygosity leads to the development of one sex and heterozygosity to the other. Once this occurs, there is a suppression of recombination between the chromosomes, probably initiated by the reduced crossing over at the sex-determination locus due to chromosomal rearrangements such as inversions around the sex-determining locus. This leads to a degeneration of the sex-linked loci in the heterogametic sex[9] (Figure 7.1(A)). This process may be driven by sexual antagonism. In this model, an allele on the same chromosome as the sex-determining locus that is beneficial to the heterogametic sex will become fixed into the population even if this allele has no effect or is disadvantageous to the other sex. This happens because natural selection will favor suppression of recombination between the chromosomes to keep the sex-determining locus and the sexually antagonistic locus together. Thus, in XY species, an allele may become fixed in the population even if it is harmful to the female. For example, in the fruitfly, *Drosophila melanogaster*, genes are fixed in the population that are beneficial to male fertilization rates but disadvantageous to female ability to reproduce.[10] This model of sex chromosome evolution is complicated by unequal distribution of the chromosomes between the sexes, and thus cannot be determined by a straightforward weighing up of advantage versus harm. This was demonstrated by recent experiments that showed that a novel gene with the above properties could become fixed into a population of *D. melanogaster*, despite the allele conferring twice as much harm to the female as benefit to the male.[11] To date, however, little is known about the mechanisms by which sexual antagonism acts.

Evolution of heteromorphic chromosomes due to suppression of recombination should in theory lead to the accumulation of deleterious mutations on the Y/W chromosome, and even gene deletion. This is indeed observed on the mammalian Y. It is far smaller than the X chromosome and consists of two main regions. One is a relatively short region, named the pseudoautosomal region, which is found at either end of the chromosome and is identical to the corresponding regions of the X chromosome. This is the only place where the X and Y chromosomes still recombine during male meiosis, ensuring sequence identity (discussed in detail in Chapter 1).[12] The remainder of the chromosome, the male-specific region (MSY), comprises 95% of the chromosome and is Y-specific (Figure 7.1(B)). Deletion of deleterious genes is thought to be counteracted by gene conversion of necessary testis-specific genes within the MSY, leading to regions of duplication within the Y chromosome. Indeed, this region is a mosaic of heterochromatin—highly repetitive DNA that is thought to be nonfunctional—and euchromatin sequences.[13] In some species, such as certain types of mole vole, deleterious

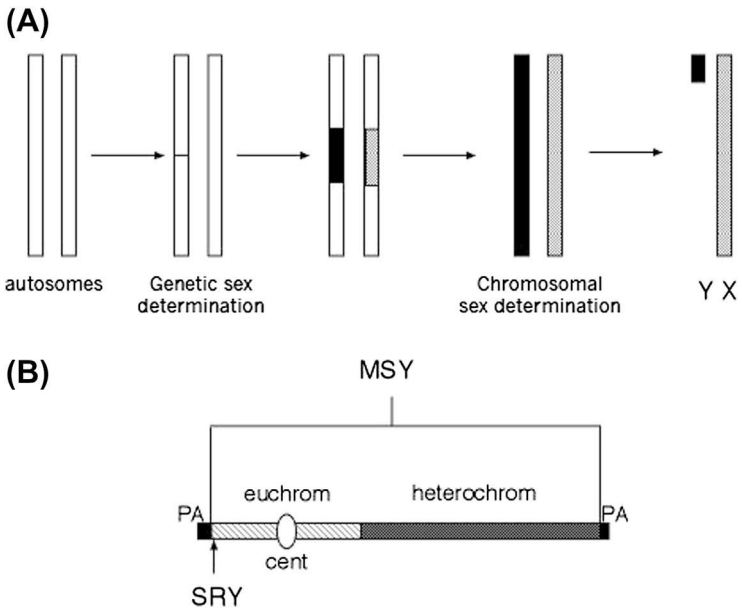

FIGURE 7.1 (A) Proposed mechanism for the evolution of sex chromosomes from a pair of autosomes. (B) Structure of the human Y chromosome indicating the position of the SRY gene. mutation and subsequent gene deletion occurs to such an extent that the entire Y chromosome is lost.[14]

These evolutionary theories of heterogametic emergence and subsequent gene deletion indicate that it should be possible to date divergence of heteromorphic chromosomes. The determination of the physical map of the Y chromosome and the sequencing of the euchromatic portion of MSY provided evidence for the model that the human X and Y originated about 300 million years ago with the emergence of *SRY* as the primary sex determinant.[13,15,16] X and Y recombination was then suppressed in a series of steps, probably through chromosomal inversions, which led to the differentiation of each chromosome. Selection then occurred on the Y chromosome for a group of testis-specific genes that enhanced male fertility, which are maintained by Y–Y gene conversion.[17]

Dosage Compensation

An inevitable consequence of heteromorphic sex determination is that in the homogametic sex, twice as many alleles will be expressed from the X/Z chromosome as the Y/W. Thus, dosage compensation is critical to maintain normal regulation of genes on sex chromosomes. This is not well conserved evolutionarily, and as such is achieved in different ways in different organisms, as exemplified by comparison of model organisms. In mammals, silencing the transcription of genes from one X chromosome occurs when two are present, a process called X inactivation.[18] In *Caenorhabditis elegans*, instead of silencing one chromosome, gene expression from both is downregulated in the XX hermaphrodite.[19] In the *D. melanogaster* fruitfly, gene expression from the male X chromosome is upregulated by a male-specific dosage compensation complex. Although all three organisms modulate sex-linked gene expression in different ways, all use chromatin remodeling to achieve a similar result.

A major component of silencing in humans is the non-protein-coding *XIST* gene, which maps to the X chromosome inactivation center, Xic, and is preferentially expressed by the inactive X chromosome.[20,21] *Xist* RNA expression has been shown to be necessary for X inactivation in mouse models.[22] It appears that localization of *Xist* RNA to the Xic may be mediated by binding to the nuclear scaffold, via the nuclear scaffold protein SAFA.[23] Circumstantial evidence suggests that silencing then "spreads" along the chromosome from the Xic via long interspersed element 1 (LINE1) repeats, nuclear "relay" elements, which are enriched on the X chromosome.[24] This hypothesis is supported by mouse data showing that misexpression of *Xist* on an autosome causes only partial silencing.[25] Furthermore, all genes on the X chromosome should be subject to X inactivation, yet reports show that up to 15% of X-linked genes in humans might escape this control[26,27]; these "escaper" genes tend to cluster together in areas that have fewer than average LINE1 elements. LINE1 elements are not sufficient for complete silencing,[28] however, and thus other as yet undetermined factors must also be involved. The mechanism by which *XIST* triggers X inactivation is not fully understood and is a subject of intense study. It is thought likely that transcriptional machinery is excluded from the Xic, although how this is achieved is unknown. Subsequently, two repressive complexes, apparently acting redundantly with one another, are recruited to the chromosome.[29,30] These complexes contain polycomb group proteins, which have the ability to remodel chromatin in order to impose epigenetic silencing on target regions of the genome. The final result is the formation of facultative heterochromatin, which is transcriptionally repressed and epigenetically silenced down the cell lineage.

Inactivation of the X chromosome in XX embryos occurs at different stages in different species, and in different cell types within each species. In the mouse, cells initially undergo paternal X inactivation at the four-cell stage.[31] This situation is temporarily reversed in inner mass cells that will give rise to the embryo, while extraembryonic cells escape reversal.[31,32] The embryonic cells then undergo random X inactivation at the blastocyst stage.[33,34] In humans, X inactivation is believed to occur after the blastocyst stage, although the exact timing has not been defined (reviewed in Ref. 35). After the blastocyst stage, the majority of murine embryonic cells maintain their inactivated status throughout life. The exceptions to this rule are the XX primordial germ cells (PGCs), which undergo X reactivation at some point between E7 and E10.5, during which time they migrate to the genital ridge.[36–38] Once the cells undergo meiosis they become haploid and thus X inactivation is no longer a requirement.

Sex Chromosome-Related Disease

Disorders of sexual development (DSDs) are among the most common congenital disorders in humans. DSDs can encompass a wide range of phenotypes, from mild androgen insensitivity in males or primary ovarian insufficiency in females to complete sex reversal (termed XX,46 DSD in the case of genetic females who are phenotypically male, and XY,46 DSD in the opposing case). As sexual development is not identical in humans and mouse models, mutations that cause complete sex reversal in humans may be associated with intermediate phenotypes in the mouse, or vice versa. Many of the genes associated with DSDs are found on the sex chromosomes.

SRY

Inactivating mutations in the testis-determining gene, *SRY*, are associated with XY,46 female sex reversal in humans. The study of DNA from XX male individuals

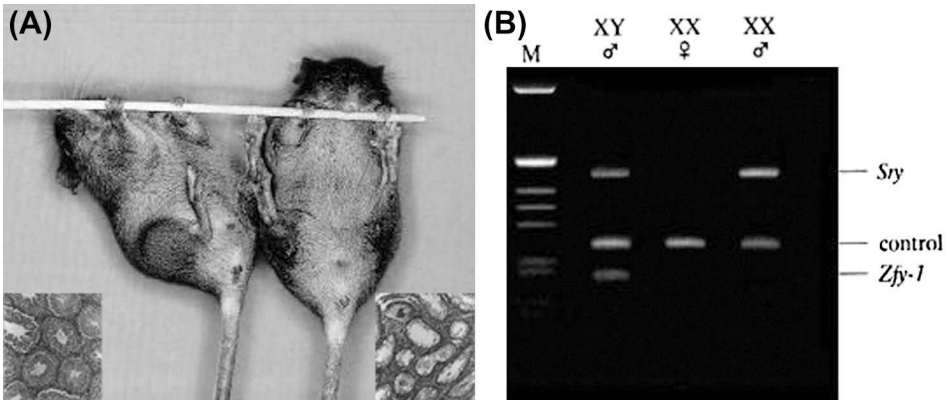

FIGURE 7.2 XX male sex reversal with an *Sry* transgene. (A) On the left is a control XY male and on the right is his littermate, an XX transgenic carrying a 14-kb genomic fragment containing the mouse *Sry* gene. The external and internal genitalia are indistinguishable except for the testis, which is smaller in the transgenic animal due to the lack of germ cells (see insets, in which cross-sections through the testis of each mouse are shown). (B) PCR analysis of genomic DNA from these mice as well as an XX sibling control. Bands for *Sry* and the DNA loading control (myogenin) are present in the XX transgenic animal but the Y chromosome marker *Zfy-1* is missing. M, size marker. *Soure: Adapted from Ref. 6.*

identified small regions of the Y chromosome that had transferred onto the X chromosome by abnormal X-Y interchange during male meiosis. The *SRY* gene was found within the minimum region of Y-specific DNA required for male development.[4] Confirmation of its role was found by the analysis of XY female patients with mutations within this gene.[5,39]

The mouse has been an important working model to study the process of mammalian sex determination. As in the case of human patients, XX mice carrying the *Sxr* mutation develop as males and it was shown that the X chromosome in these mice carried a small portion of the Y chromosome containing the *Sry* gene.[40] Conversely, a mouse mutation that produced XY females was shown to have an 11-kb deletion on the Y chromosome that included the *Sry* gene.[41] Direct evidence that *SRY* is the only gene on the Y chromosome to be necessary and sufficient for establishing male development came from transgenic experiments in the mouse. XX mice carrying a 14-kb fragment of Y chromosome DNA that contains the mouse *Sry* gene and no other gene developed as males[6] (Figure 7.2). These transgenic animals were infertile, however, because of a block in spermatogenesis due to the presence of two X chromosomes and the lack of other Y-linked genes. The SRY protein contains an evolutionarily conserved HMG box type of DNA-binding domain found in a number of other transcription factors. This is believed to be important for SRY function because almost all mutations found in human XY females cluster within this region.[39,42]

SRY is thought to have evolved around 300 million years ago due to duplication of SOX3, resulting in the primary sex determinant present in mammals today.[43] The two proteins share a highly similar HMG box domain.[44] Despite its location on the X chromosome, *Sox3* is not required for normal sex determination in mice and loss of function mutations have not been documented in DSD patients.[45] However, misexpression of *Sox3* in the gonads of XX mice causes sex reversal. In vitro experiments indicate that SOX3 is capable of activating downstream targets of *Sry*.[46] Analysis of 16 XX male sex reversal cases revealed three patients with chromosomal rearrangements in and around the *Sox3* locus.[46] Furthermore, a separate case has since been reported,[47] implying that *Sox3* mutations may well be a clinically relevant cause of XX male sex reversal. Together, these data suggest that SOX3 can act in a manner analogous to that of SRY in mammals.

The master regulator role of *Sry* has been used in mouse models to genetically differentiate between chromosomal and gonadal regulation of sexual characteristics. In the four core genotypes (FCG) model, generation of a Y chromosome lacking *Sry* (Y^-)[48] and a transgenic *Sry* expressed from an autosome[49] allows separation of gonadal and chromosomal male determination. Thus, mice can be one of four "core" genotypes: phenotypic female with XX or XY (abbreviated to XYF) chromosomes, or phenotypic male with XX*Sry* (abbreviated to XXM) or XY-*Sry* (XYM) chromosomes (Figure 7.3(A)).[50] The sexual traits controlled by gonadal sex can be established by comparison of animals of different phenotypic sexes (XXF/XYF versus XXM/XYM). Conversely, sexual traits governed by chromosome complement can be elucidated by observation of differences between XX and XY animals, regardless of *Sry* status (Figure 7.3(B)). The FCG model should therefore also determine traits in which both chromosomal and gonadal sex have a role to play. However, caution must be used when interpreting the data gained from these mouse models, as animals of the same phenotypic sex still have some differences; for example, XXM mice are azoospermic (lacking in sperm production), as spermatogenesis requires genes on the

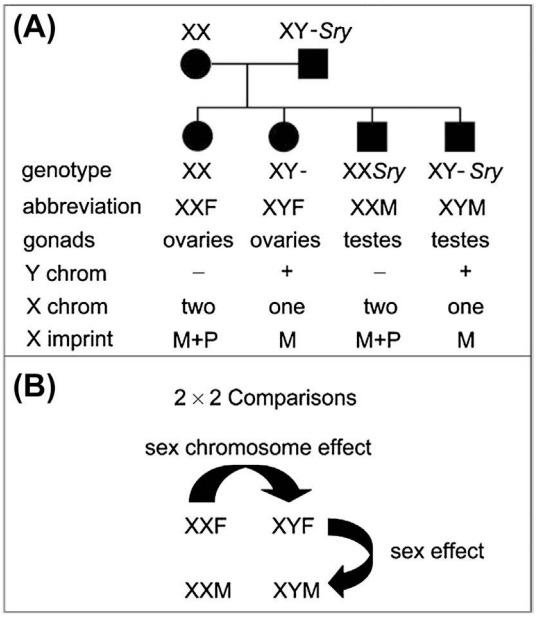

FIGURE 7.3 The four core genotypes (FCG) model separates the effects of chromosome complement from those of gonadal sex. (A) Breeding scheme for generation of FCG mice. XX female mice are crossed with XY male mice in which *Sry* has been deleted from the Y chromosome (Y^-) and reinserted on an autosome (*Sry*). Progeny of four different genotypes are generated. Their phenotype, chromosome complement, and X imprinting status are listed below. (B) A 2 × 2 schematic demonstrates how the FCG mice can be used to determine the cause of phenotypic differences observed. *Source: Figure reprinted with permission from Ref. 249.*

Y chromosome. Furthermore, these mice have different genetic imprints. For example, XXF mice have both maternal and paternal imprints, while XYF mice have only one maternally imprinted X chromosome. As genetic imprinting can determine expression of certain genes, this status needs to be taken into account when comparing phenotypically similar mice. Experiments using FCG mutants have shown that, although *Sry* is necessary and sufficient for male sex determination, X chromosome dosage plays a role in multiple aspects of sexual dimorphism despite X inactivation[50–52]—perhaps not surprising as the "escaper" genes on the inactive X are expected to be expressed at a higher level in XX mice than XY.[26,53]

Y-Specific Genes

Many of the genes on the Y chromosome are involved in male fertility, in particular in the regulation of spermatogenesis. Consistent with this, most XX,46 men are azoospermic and therefore infertile. Microdeletions in three regions of the long arm of the Y chromosome (azoospermia factor, AZF, a, b, and c) have been associated with reduced sperm production (oligospermia) or azoospermia in humans.[54] Due to the large repeats and multicopy gene sequences in this region, it has been difficult to establish which genes are responsible for the spermatogenic failure in each case. The variable phenotype of patients with AZF microdeletions implies that multiple genes in each region are involved in male fertility. Deletions of regions of the Y chromosome in the mouse also lead to a block in spermatogenesis. These animal models have been used to define multiple genes on Y that are involved in spermatogenesis. For example, deletion of the long arm of Y, MSYq, revealed that genes in this region are required for sperm differentiation.[55,56] Deletion of smaller regions on this arm results in reduced fertility, and an increase in transcription from sex chromosomes in spermatids.[55,57] Transgenic mice harboring siRNA constructs were used to identify which candidate genes within this region were responsible for the infertility phenotype. Reduction in levels of the *Sly* genes led to defects in sperm differentiation, resulting in reduced fertility. Furthermore, *Sly* was found to drive repression of genes from sex chromosomes following meiosis in the germ cells.[58] This type of targeted gene disruption will be important in dissecting the roles of other multicopy genes on the Y chromosome.

X-Dosage

XO

In humans the loss of one X chromosome gives rise to Turner syndrome. In most cases XO fetuses are lost, but some survive, with a frequency of 1 in 2500 to 3000 female births. The phenotypes of the affected individuals include short stature, a webbed neck, broad chest, and cognitive defects. Genes escaping X inactivation have been proposed to be responsible for these defects, as only one copy of these genes is expressed in these individuals. Consistent with this, fewer genes in the mouse escape X inactivation and XO mice have a less severe phenotype.[59] Turner patients show gonadal dysgenesis, which is characterized by the loss of oocytes. XO mice also show a reduced number of oocytes at birth, and analysis of these mice suggests that this is due to the lack of chromosome pairing of the single X during meiosis.[60,61]

XXY

Males with Klinefelter syndrome are characterized by an XXY genotype, increased stature and infertility. Loss of germ cells in these individuals occurs prior to puberty, and a similar situation is seen in the mouse. It has been proposed that the loss of germ cells in these individuals is due to the presence of two X chromosomes. Prior to entry into meiosis, germ cells with two X chromosomes undergo X chromosome reactivation, giving rise to a double dose of X-linked genes. If this occurs in the testis, the X chromosome dosage acts to impair germ cell development.[62]

GONADAL SEX

The action of SRY that determines male sex differentiation occurs within the developing gonad. The gonads are part of the urogenital system, which is derived from the intermediate mesoderm of the embryo. They initially develop as thickenings on the ventromedial surface of the mesonephros on either side of the midline at around 4 weeks in the human fetus and 9.5 days in the mouse. The somatic cells of the gonad are derived from the mesonephros and the coelomic epithelium that lines the coelomic cavity. The primordial germ cells originate at earlier stages of embryogenesis at the base of the allantois, and migrate through the hindgut to join the gonad as it develops. This gonadal primordium is a unique aspect of embryogenesis as it is bipotential; it has the potential to become either male or female. Adrenal cortical cells also derive from this primordium, which is therefore called the adrenogonadal primordium (AGP).[63]

This initial development is identical between males and females but at early stages, around E10.5–11 in the mouse, SRY acts in the XY embryo to initiate testis development. Without SRY the gonad will develop as an ovary; therefore the mammalian embryo is programmed to develop as a female and the male-specific pathway is imposed on this basic body plan.

Sex Determination

Sry was first identified as a regulator of sex determination in 1990. Studies in the mouse have shown that *Sry* is expressed almost exclusively in the somatic cells of the gonad of XY embryos as it begins to develop. Transcript levels reach a peak around E11.5 and then decline to undetectable levels by E12.5.[64,65] This transient pattern of expression suggests that *SRY* acts as a trigger for testis differentiation but is not required for the subsequent development of the organ or maintenance of testis-specific gene expression.

As discussed above, *Sry* contains an evolutionarily conserved HMG box domain, believed to be important for its DNA binding activity. Most human *SRY* mutations implicated in DSDs cluster in the HMG box.[39,42] However, other domains within the protein have also been implicated in its function. Experiments using transgenic mice in which stop codons were introduced into different regions of *Sry* revealed that the HMG domain alone was not sufficient for male sex differentiation in XX mice. Furthermore, insertion of a stop codon that caused production of a truncated protein lacking only a glutamine-rich region at the C-terminal of SRY produced the same phenotype.[66] This domain may be required for protein interactions in the mouse, although it is not conserved in other mammals. Alternatively, this mutation may simply decrease the stability of the protein. Transgenic expression of human or goat *SRY* in mice can drive male sex determination in XX mice.[67,68] Although this may implicate the well-conserved HMG domain in SRY function, an alternative explanation is that the other regions, although not conserved in sequence, may have similar functions. This is supported by evidence indicating that, as in the mouse, human SRY must be full-length to function properly.[69]

It has been proposed that the main role of SRY is to activate the expression of *Sry-related HMG box-containing gene 9 (Sox9)* within the male gonad. SOX9 expression leads to the differentiation of Sertoli cells, which then direct the differentiation of other male-specific cell lineages within the gonad.[70] Transgenic mice studies identified a 3.2-kb testis-specific enhancer element (TES) that was sufficient to promote initiation and maintenance of *Sox9* expression.[71] This was subsequently narrowed down to a 1.4-kb region known as the testis-specific core element, TESCO, to which SRY directly binds via the HMG box. Initiation of *Sox9* expression is induced by the synergistic action of SRY and steroidogenic factor 1 (SF1), an orphan nuclear hormone receptor (Figure 7.4(A) and (B)).[71] The TESCO enhancer was reported to be well conserved in mammals. Subsequently, an 180-bp region of TESCO was found to be conserved in mammals, reptiles, birds, and amphibians, suggesting that *Sox9* expression in the gonad is regulated in a similar manner in many vertebrates.[72]

Studies in chimeric mice derived from aggregations of early XX and XY embryos showed that Sertoli cells were the only cell type in the testis to have a bias towards an XY genotype. Consistent with this, cell fate studies in transgenic mice have shown that *Sry* is expressed in Sertoli cell precursors.[73,74] These data show that *Sry* initiates the differentiation of the Sertoli cell lineage within the developing gonad and that these cells direct the differentiation of the rest of the cell lineages along the male pathway.[70]

Genes Implicated in Sex Determination and Their Associated Defects

There is a window of time during gonad development when SRY needs to achieve a certain level of expression to ensure testis differentiation. If this is not the case, testis development is delayed and ovary development will occur. In some cases this will give rise to the development of ovotestes, where testicular cords are found in the middle portion of the gonad surrounded by ovarian tissue on either side (Figure 7.5). This property of sex determination implies that genes that act to affect the levels of expression of SRY or interfere with SRY action, either directly or indirectly, are also involved in the process of sex determination.

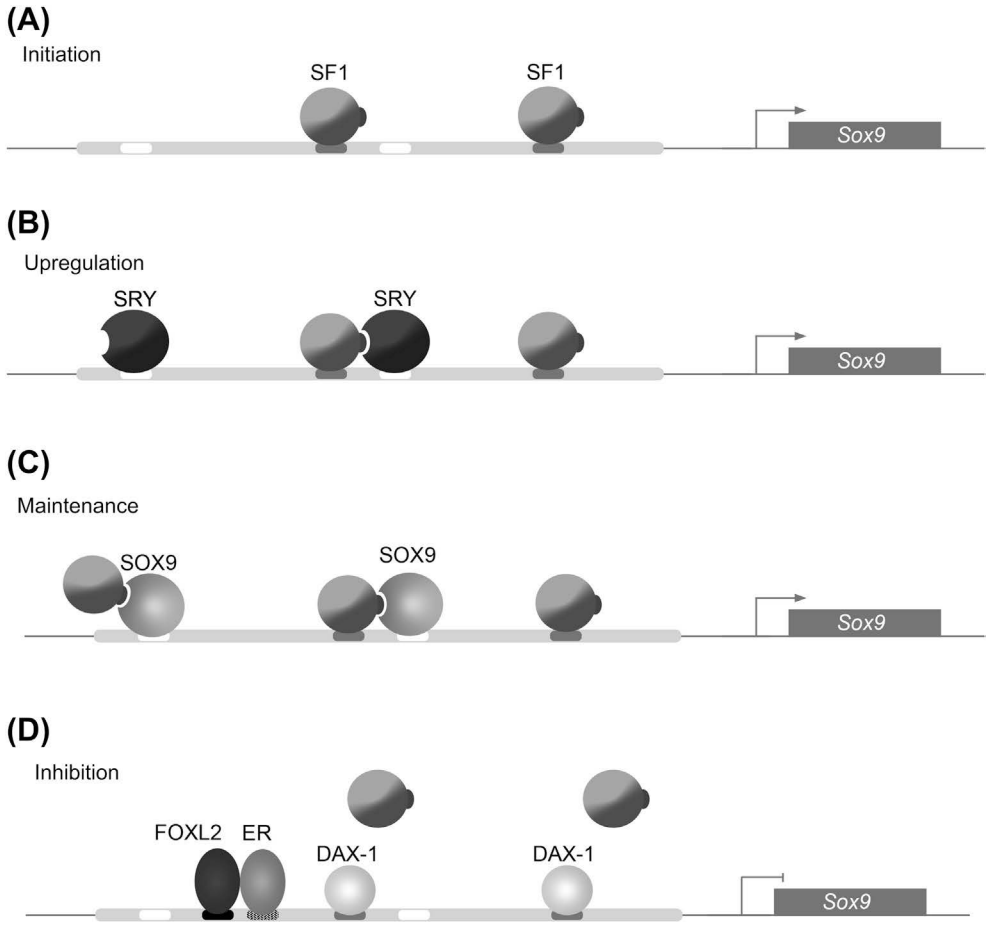

FIGURE 7.4 Regulation of *Sox9* expression at the TESCO enhancer. (A) Binding of SF1 to the TESCO enhancer is sufficient for initiation of *Sox9* expression. (B) Expression is subsequently upregulated by synergistic action of SF1 and SRY, which may physically interact at the enhancer. (C) Once SRY expression ceases, *Sox9* expression is maintained by an autoregulatory loop in which SOX9 itself binds to TESCO and interacts with SF1 to promote expression. (D) In female embryos, FOXL2 and estrogen receptor (ER) bind to TESCO, acting synergistically to inhibit *Sox9* expression. In addition, DAX1 competes with SF1 for binding sites on TESCO, preventing *Sox9* expression. *Source: Adapted from Sekido and Lovell-Badge, 2008.*[251]

GENETIC BACKGROUND AND TDA LOCI

A well-studied sex reversal system in mice is that of the *Sry* allele derived from a subspecies of *Mus musculus domesticus* from the Val Poschiavino in Switzerland. This allele (Sry^{POS}) is not able to trigger testis differentiation as efficiently as other alleles and causes a 14-h delay in the activation of the testicular pathway within the gonad. On a particular inbred mouse strain background, C57BL/6, Sry^{POS} is unable to initiate proper testis development and the gonads of these animals develop as ovotestes, with both ovarian and testicular components, or as ovaries[75] (Figure 7.5). Eicher et al. have mapped the C57Bl/6 loci involved in this effect to three regions: testis determining autosomal 1 (tda1) on chromosome 4, tda 2 on chromosome 2, and tda 3 on chromosome 5.[76] The genes associated with these loci have not yet been identified but it is likely that they encode factors that are involved in the regulation of *Sry* expression and/or that promote ovary development.[77] It has been posited that *Sf1* and Wilm's tumor 1 (*Wt1*) may be good candidates for tda2, and *Wnt4* for tda1.[78] These genes map to the tda loci, and are known to be dose-sensitive determinants of sex.

These studies highlight the importance of genetic background on the process of sex determination. Consistent with this, several mutant strains of mice, including those carrying mutations in *Fgf9* and *Dax1*, only show a sex reversal phenotype when the genetic background is derived from the C57Bl/6 background. This suggests that allelic variations that might have a small effect on available levels of active SRY could have a significant impact on phenotype due to the delicate balance that controls the decision to become male or female. Indeed, transcriptome analysis of E11.5 XY gonads in C57Bl/6J and 129S1/SvImJ mice revealed that the C57Bl/6J gonads had a more "female-like" transcriptome, explaining the propensity for XY sex reversal on this genetic background.[79]

Comparisons between human and mouse suggest that this balance is set up slightly differently between the two species such that mutations in the same gene can give different phenotypes, as mentioned below in the case of *WT1*. Thus it may be that analysis of sex determination in mouse models is best performed with the C57Bl/6 background, which may better mimic the state in humans.

WT1 AND CITED2

WT1 was first identified as one of the genes mutated in nephroblastomas found in newborns. This gene was

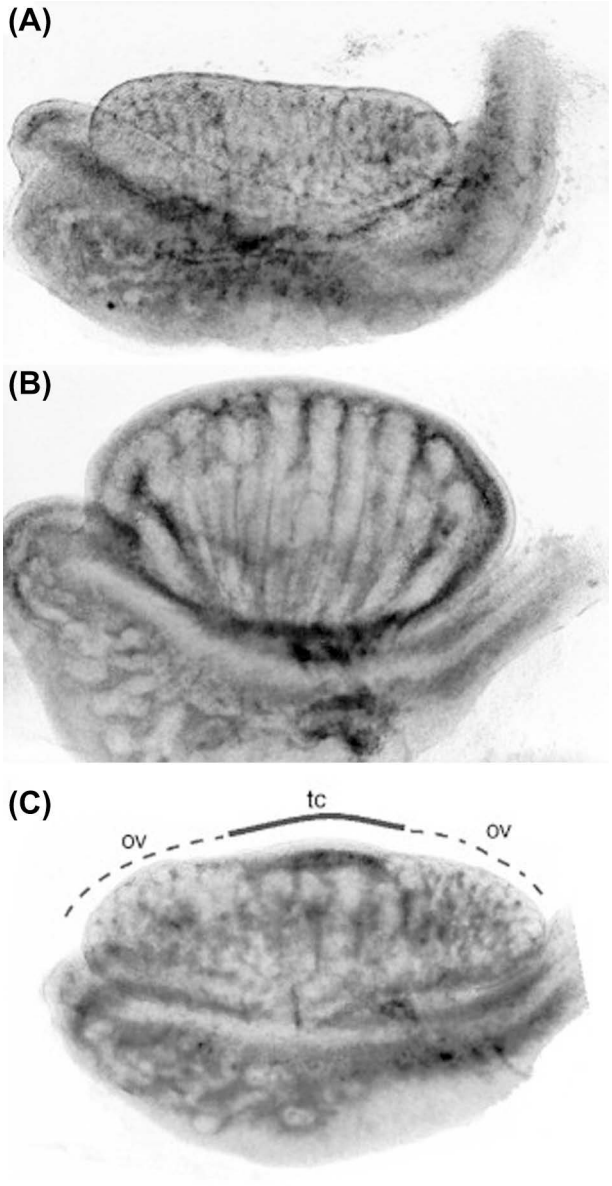

FIGURE 7.5 XY^{POS} mice on a C57Bl/6 background exhibit ovotestis formation. Brightfield images of wild-type female (A) and male (B) gonads from embryos at E14.5. Testicular cords are clearly visible in the male gonad at this stage. (C) Ovotestis formation in XY^{POS} mice on a C57Bl/6 background. Male testicular cords can be seen in the central portion of the gonad while the ovarian portion is found at both poles. *Source: Pictures taken from Ref. 250.*

also associated with defects in urogenital development in both mouse and man. During embryo development, WT1 is expressed throughout the intermediate mesoderm at early stages of urogenital development including the gonad.[80,81] Mice with a disrupted *Wt1* gene show absence of gonad and adrenal and arrested kidney development.[82] Studies on genetically modified mice have shown that not only is WT1 important in the development of the early genital ridge in both sexes but it also has a role in sex determination in the XY gonad.

The WT1 locus encodes a series of variant transcripts due to alternative splicing, alternative transcriptional start sites and RNA editing. These variants encode two main proteins containing a zinc finger domain that differ in the presence or absence of three amino acids (KTS) between two zinc fingers (designated +KTS or −KTS isoforms). Cell culture studies showed that these two proteins had different functions within the nucleus.[83] The −KTS isoform was associated with transcriptional regulation while the +KTS isoform co-localized with splicing factors and could bind RNA. Hammes et al. generated two strains of mice with mutations in the *Wt1* gene that inhibit the splicing events that give rise to the different isoforms such that the modified mice only expressed one variant or the other.[84] These two mouse strains showed different phenotypes in the gonad. The mice lacking the −KTS isoform showed a lack of proper gonad development in both sexes, while the mice lacking the +KTS isoform showed relatively normal gonad development but the XY gonad developed as an ovary. *Sry* expression in the gonad was significantly reduced in the latter case, accounting for the sex reversal phenotype.[85] These data suggest that WT1 regulates the levels of *Sry* within the gonad, possibly post-transcriptionally, through the action of the +KTS isoform.

Human patients with Frasier syndrome carry a heterozygous mutation in the splice site of WT1 that prevents the production of the +KTS isoform, shifting the ratio of the two isoforms within cells.[86] Consistent with the mouse studies, the XY Frasier individuals develop as females. However, the sex reversal phenotype observed in mice that lack the +KTS isoform is only observed in the human when the mutation is present in a homozygous state. Differences between human and mice phenotypes have been found for mutations in various genes involved in early sexual development, suggesting that the sensitivities to the levels of different factors are particular to each species.

CITED2 is a transcriptional cofactor that activates *Sry* via genetic interaction with WT1 and SF1. This is achieved by binding to WT1 and regulating SF1 levels within the AGP. *Cited2*$^{-/-}$ mice exhibit adrenal aplasia.[87] Similarly, compound mutant mice lacking *Cited2* and heterozygous for *Wt1* or *Sf1* lack adrenal glands and in addition exhibit partial XY sex reversal. Furthermore, loss of *Cited2* on an *Sry*^{POS} background produces complete XY sex reversal.[88] Thus, a WT1/CITED2/SF1 regulatory cascade mediates *Sry* expression.

SF1

SF1 is an orphan member of the nuclear receptor superfamily. *Sf1* expression in the early embryo is restricted to the genital ridge and adrenal and is the earliest marker of these tissues. Mice with a mutation

in *Sf1* lack gonads and adrenals and develop as female embryos.[89,90] This early phenotype prevents easy analysis of the role of SF1 in sex determination and gonad differentiation. Deletion using tissue-specific Cre drivers has allowed researchers to overcome this early phenotype to dissect the roles of SF1. Using this technique, it has been shown that *Sf1* is critical at multiple stages of sex determination and differentiation. As described above, SF1 acts with SRY to activate *Sox9* expression, triggering the male cascade.[71] Subsequent to this, *Sf1* expression in Sertoli cells is required for regulation of anti-Müllerian hormone (AMH), leading to degeneration of the Müllerian ducts in male embryos.[91] SF1 is a master regulator of steroidogenesis, required for normal steroid production in the Leydig cells of the testis, the stromal and theca cells of the ovary, and the cortical cells of the adrenal[92] (reviewed in Ref. 93). In addition, SF1 expression is required for normal differentiation of the ovary.[94] SF1 has been shown to be dosage sensitive, as mice heterozygous for *Sf1* exhibit impaired testis differentiation on an Sry^{POS} genetic background,[78] while sexual development occurs normally on a mixed background.

In accordance with the critical role of SF1, its expression is stringently regulated at both the gene and protein level. As discussed above, WT1 and CITED2 interact to regulate expression of *Sf1*.[87,88] POD1, a basic helix-loop-helix transcription factor, is also reported to regulate *Sf1* expression in the developing gonad.[95] DAX1, a female fate-promoting protein discussed in depth below, interacts antagonistically with SF1 at the protein level.[96] At the post-translational level, SUMOylation of SF1 has been shown to be required for normal gonadal and adrenal development. Inhibition of SUMOylation causes a change in the set of genes regulated by SF1 expression, resulting in an under-differentiated and mixed phenotype in the gonad and adrenals.[97] Regulation of *Sf1* expression is reviewed in more detail elsewhere.[98–100]

This requirement for stringent regulation is reflected in the clinical importance of normal SF1 expression. Heterozygous *Sf1* mutation in human disease was first observed in a patient with XY sex reversal.[101] Since this identification, many human SF1 mutations have been reported.[102–104] Although a small number of patients exhibit complete sex reversal, the majority fall elsewhere within the DSD spectrum (reviewed in Ref. 104).

INSULIN RECEPTOR FAMILY

The insulin receptor family is a set of receptor tyrosine kinase (RTK) proteins. Signals received by the insulin receptors are transduced by phosphoinositide-three kinase. Targeted mutagenesis in the mouse has uncovered a role for the insulin family signaling pathway in sex determination. XY mice with simultaneous mutations in all insulin receptors (*Insr, Igf1r*, and *Irr*) show complete sex reversal, with gonads developing into ovaries.[105] *Sry* expression during gonad development in these mice was found to be significantly reduced, accounting for the sex reversal phenotype. However, cell proliferation and the size of the gonads in both sexes was reduced in these mutant animals. Cell proliferation has been shown to be important in sex determination, as inhibition of proliferation at particular stages of gonad development can prevent testis determination.[106] Therefore the phenotype observed in the mutant mice was probably due to a defect in proliferation of cells of the gonad at the time when *Sry* is acting to determine testis development. Recently, it has been shown that mice with mutations in both *Igfr* and *Insr* have the same phenotype, indicating that *Irr* may not be required for sexual development.[107] Gonads remain undifferentiated until E16.5, when female-specific gene expression is detected, supporting the hypothesis that defects in these mutants are due to abnormal proliferation.

GATA4/FOG2

Members of the GATA family of transcription factors are important in many processes during embryogenesis. These factors contain a zinc finger DNA binding domain and interact with FOG (Friend of GATA) proteins that contain multitype zinc finger domains. Expression analysis of *GATA* and *FOG* genes during urogenital development show that GATA4 and FOG2 are expressed in the somatic cells of gonad.[108,109] Mouse XY embryos with a mutation in *Fog2* show sex reversal.[110] Analysis of the gonads of these mutant mice shows a reduction in *Sry* expression when compared to wild-type XY embryos. Ovary development was also seen in XY embryos with a mutation in *Gata4* that abrogates the interaction of GATA4 with FOG2, showing that both proteins are required for sex determination.[110] Mutations in GATA4 that prevent binding with FOG2 have been found in patients with XY,46 female DSDs.[111] Studies are underway to determine a direct role for GATA4 in the regulation of *Sry* transcription.

MAPK SIGNALING

RTK signaling is of critical importance in a large number of developmental settings. Recent research has revealed that RTK signaling via the Ras/Mapk pathway is critical for normal male development.[112,113] p38-MAPK signaling lies upstream of *Gata4* and *Sry* in murine sex determination.[112] This cascade is regulated by the stress-response protein GADD45G, which is expressed in a pattern similar to, but earlier than, that of *Sry*. Mice lacking *Gadd45g* exhibit reduced *Sry* expression and XY sex reversal. These phenotypes are mimicked in mice lacking *Map3k4* and *p38α+β*. GADD45G has been shown to functionally interact with MAP3K4 to activate p38-MAPK signaling.[114,115] Although the exact mechanism by which this cascade acts to activate *Sry* is unknown, it has been shown that demethylation of the *Sry* promoter, which precedes *Sry* gene expression by several hours,

still occurs in *Gadd45g* mutants; thus *Sry* is primed for activation, but lacking the stimuli required for expression.[114] Mutation in *MAP3K1* results in XY DSDs in both humans and mice.[113,116] Although a relationship between MAP3K1 and GADD45G has not yet been proven, this data implicates MAPK signaling as a clinically relevant factor in human sex determination.

CHROMATIN REMODELING FACTORS

Two factors involved in chromatin domain organization, M33 and ATRX, have been implicated in sex determination. M33 is a member of the Polycomb Group Gene family, and a general repressor of transcription. XY mice mutant for this gene show sex reversal.[117] However, the phenotype was variable and gonad development was retarded. Microarray analysis of these mutants indicated that *Sry* and other downstream male-specific genes were downregulated in M33 null mice. Forced expression of *Sry* rescued the sex reversal defects, although development of the gonad was still somewhat retarded. Thus, M33 acts upstream of *Sry*, although additional roles in gonad development are also probable.[118] Human XY individuals with mutations in the X-linked gene *ATRX* show sex reversal.[119,120] The role of this factor in gonad development has not yet been studied in any detail. Interestingly a homolog of the *ATRX* gene was found on the marsupial Y chromosome.[120] This gene was found to have a testis-specific expression, in contrast to *ATRX*, that is expressed in many tissues, suggesting that it has a role in marsupial testis development.

Testis and Ovary Development

The undifferentiated gonad is made up of four bipotential cell types: the supporting cells, interstitial cells, PGCs, and connective tissue (Figure 7.6). Upon sex

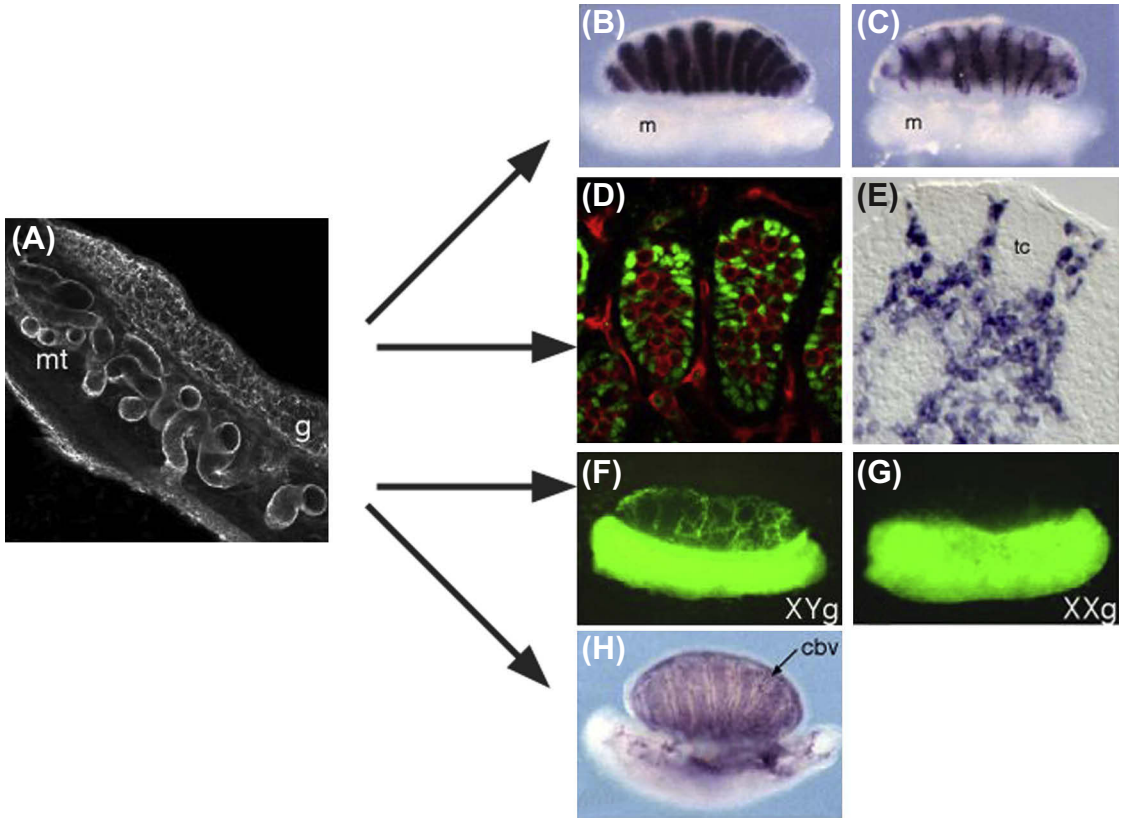

FIGURE 7.6 Differentiation of the embryonic testis from a bipotential precursor. This figure is reproduced in color in the color plate section. (A) Confocal image of a gonad and mesonephros stained with an antibody to laminin at a stage before morphological changes take place (E11.5). (B–H) Morphology of the embryonic testis. (B, C) The Sertoli and Leydig cells of the E13.5 gonad are marked by whole-mount in situ hybridization for the expression of the Sertoli cell marker AMH (B) and the Leydig cell marker *Cyp11a1* (C). The structure of the testicular cords is seen in the confocal image of an E12.5 gonad that was stained with an antibody against SOX9 in green (D). Germ cells are found within the testicular cords as marked by the antibody stain for PECAM in red (D). In the interstitium, epithelial cells, as marked by the antibody stain for PECAM in red (D), and Leydig cells, as marked by the section of the whole mount in situ hybridization on a gonad from a E14 embryo for the expression of *Cyp11a1* (E), are found. (F, G) Mesonephric cell migration is observed in the XY (F) but not the XX (G) gonad, as shown by organ culture samples where the mesonephros but not the gonad is derived from transgenic mice that express GFP ubiquitously. (H) The formation of male-specific vasculature as shown by a whole-mount antibody stain to PECAM, which marks endothelial cells, of gonad and mesonephros from an E14 embryo. mt, mesonephric tubules; g, gonad; m, mesonephros; tc, testis cord; cbv, coelomic blood vessel. *Source: Adapted from Ref. 252; confocal image (D) courtesy of Blanche Capel.*

determination, these cells types differentiate, assuming sex-specific fates. The supporting cells are the first male cell type to undergo differentiation, to give rise to the Sertoli cells. In the female, differentiation occurs postnatally, at which time the supporting cells give rise to the granulosa cells of the ovary. The interstitial cells of the male undergo differentiation to give rise to Leydig cells, while the same cells give rise to theca cells in the female at postnatal stages. The germ cells become sperm or egg cells (oocytes), while the connective cells encompass the rest of the cell types such as ovarian stromal and testicular peritubular myoid cells and the differing patterns of vasculature in the male or female gonad. In this section we will describe in detail the differentiation of each of the four cell types, discussing the cellular and molecular pathways that are activated in the developing male and female gonad.

Supporting Cell Differentiation

As the name suggests, the supporting cells are vital to nurture the germ cells during their development until their release. The Sertoli cells are also believed to direct Leydig cell differentiation and hence testicular development. Initiation of differentiation along a male or female path is determined by expression of SRY, or lack thereof, respectively. Subsequently, expression of different genes mediates supporting cell differentiation and maintenance.

SOX9 IS REQUIRED FOR SERTOLI CELL DIFFERENTIATION

Differentiation of the supporting cells into Sertoli cells is the first stage of male gonadal differentiation. This process is mediated by *Sox9*, which must be activated by the synergistic action of SRY and SF1 between E10.5 and E12.5 in order to direct the gonad to become a testis, rather than an ovary.[71,74] Expression analyses in the mouse have shown that *Sox9* is one of the first genes upregulated in the male gonad compared to the female, at around E11.5, and its expression is then associated with Sertoli cells throughout testis development.[121,122] Indeed, SOX9 is vital for definition and maintenance of Sertoli cell identity. In humans, heterozygous mutations in *SOX9* give rise to XY female sex reversal associated with the severe dwarfism syndrome campomelic dysplasia,[123,124] while translocation or mutation 5′ of *SOX9* has been reported to cause XY female sex reversal with or without the associated syndromes in several cases.[125–128] Mice that lack *Sox9* in the developing testis showed defects in testis differentiation, giving rise to ovotestis-like gonads.[129] Transgenic experiments in mice showed that SOX9 can induce Sertoli cell differentiation and testis development in XX gonads.[130] In one case, a chance integration of a transgenic construct 1.3 Mb from the *Sox9* locus resulted in the induction of the expression of this gene within the embryonic XX gonad.[131] Consistent with this, duplications of the *SOX9* locus in humans are associated with XX male sex reversal.[132,133]

Binding of SRY and SF1 at the TESCO enhancer initiates *Sox9* expression (Figure 7.4(A) and (B)), but *Sry* is only expressed for a brief period. Therefore, maintenance of *Sox9* expression must involve other transcriptional activators. In vitro, SF1 can recruit SOX9 to the TESCO element (Figure 7.4(C)), where the proteins are capable of acting in synergy to promote expression of *Sox9* itself. Thus it appears that maintenance of *Sox9* is achieved via an autoregulatory feed-forward loop. FGF9 has been implicated in maintenance of *Sox9* expression in Sertoli cells. *Fgf9* is expressed in the bipotential gonad at E11.5, but becomes restricted to the XY gonad by E12.5.[134] Expression begins at the center of the gonad and radiates out, in a manner similar to that of *Sry* and *Sox9*.[135] Loss of *Fgf9* causes XY sex reversal in mice, a phenotype that arises due to failure of Sertoli cell differentiation, measured by lack of desert hedgehog (*Dhh*) and *Amh* expression.[134,136] *Sry* expression is normal in these mutants, indicating that *Fgf9* is downstream of *Sry* in sex determination. In most mutants, *Sox9* expression is lost, but a small proportion retain a low level of *Sox9* expression, implying that FGF9 is not required for initiation of *Sox9* expression.[137] In cell culture, FGF9 promotes expression of *Sox9*, indicating that FGF9 is involved in maintenance of gene expression.[134] Furthermore, expression of *Fgf9* is lost in *Sox9*$^{-/-}$ gonads. Thus, *Fgf9* and *Sox9* act in a feed-forward loop in which SOX9 activates *Fgf9* expression, which then promotes continued expression of *Sox9*. FGF9 appears to act through FGFR2, which is expressed in the coelomic epithelium—where FGF9 promotes proliferation specifically in the male—and in Sertoli cell precursors. Deletion of *Fgfr2* in mouse models causes XY sex reversal and a decrease in proliferation within the coelomic epithelium.[138]

Prostaglandin D2 (PGD2) has been implicated as a paracrine positive regulator of *Sox9* in Sertoli cells. PGD2 is capable of inducing *Sox9* expression in XX gonads in organ culture, while *Fgf9* is not,[139] implying that *Sox9* is downstream of PGD2. This was supported by in vivo data demonstrating that mice lacking the enzyme responsible from production of PGD2, lipocalin prostaglandin D synthase (L-PGDS), exhibit downregulation of *Sox9*.[140] Furthermore, SOX9 was found to be required for *L-pdgs* expression. Thus, PGD2 and SOX9 also function in a positive regulatory loop. Analysis of *Fgf9*$^{-/-}$ and *L-pgds*$^{-/-}$ mice indicated that the two loops are independent from one another, and act additively to promote *Sox9* expression.[140]

The defects observed in *Sox9* mutant mice were shown to be more severe when these mice also lacked the related gene *Sox8*, which is upregulated in Sertoli cells of the developing gonad slightly after *Sox9*.[141]

Duplication of chromosome 22q13, where *SOX10* is located in humans, causes XX male sex reversal.[142] A gain-of-function mutation in *Sox10* in mice was shown to cause dose-dependent sex reversal, the severity of the phenotype corresponding to the level of *Sox10* expression.[143] This suggests that these *Sox* genes may have similar functions and therefore are part of a reinforced redundant system to ensure the differentiation of Sertoli cells, implying that conservation of *Sox9* function is vital for differentiation.

EVOLUTIONARY CONSERVATION OF REGULATION OF SERTOLI CELL DEVELOPMENT

SOX9 protein is related to SRY in that it also contains an HMG box type of DNA binding domain. Outside this domain it differs from SRY in that it contains a strong transcriptional activation domain. Evolutionary studies have shown that the *SOX9* gene is highly conserved in vertebrates and in many cases its expression is associated with early testis differentiation.[121,122,144–146] This suggests that there is a common pathway for ensuring Sertoli cell differentiation in vertebrates and that different sex determination mechanisms have evolved to control this process.[147] Consistent with this model, conserved members of the DMRT family of proteins are found in the developing gonad of all vertebrates that have been studied.

DMRT1 is a transcription factor expressed in the germ and Sertoli cells of the developing mouse testis.[148] DMRT1 homologs, those proteins possessing a zinc finger-like DM DNA-binding domain, are highly conserved factors in sexual determination and differentiation. Indeed, DM domain proteins play a role in these processes in virtually all metazoans analyzed (although their role is not always limited to regulation of sexual dimorphism). In the vast majority of metazoans, DM proteins appear to act immediately downstream of sex determination, at the top of the sexual differentiation cascade. This produces what may be termed an "evolutionary bottleneck" in sexual development. Many different mechanisms act upstream of primary sex determination in different species. Downstream of *Dmrt1*, once again a wide variety of signaling pathways act to enforce varying sexual dimorphisms on the different species, such as horns, plumage, mating behaviors, and many more.[149]

In humans, *DMRT1* is located on chromosome 9p24.3, a locus whose deletion results in DSDs and often sex reversal.[150,151] In mice, *Dmrt1* deletion does not cause congenital sex reversal,[152] although *Dmrt1* expression is required for normal adult development of both the Sertoli and germ cells.[153,154] As the deletions reported in humans affect multiple genes, it is possible that another gene at this locus is responsible for the resulting phenotypes. However, there are several alternative explanations for this difference; differences in the role of DMRT1 between species or a genetic background effect in the mouse, for example. Interestingly, in non-mammalian vertebrates, DMRT1 homologs have evolved multiple times to represent the top of the sex determination cascade. In both teleosts and some amphibians, duplication of *Dmrt1* has given rise to a primary sex determinant much like the mammalian *SRY*.[155–157] Thus, *Dmrt1* is important for sexual development throughout the animal kingdom. Together the genetic and functional conservation of *Sox9* and *Dmrt1* in vertebrates, and in particular in mammals, indicates that regulation of Sertoli cell development is critical for normal development of the testis.

DIFFERENTIATION OF FOLLICLE CELLS

Until fairly recently it was assumed that the default pathway for sexual development was female, and that SRY, as the primary male determinant was the only factor preventing this fate. While it is true that SRY is necessary and sufficient for male development, it has become apparent that the female pathway is also active, rather than default, and that the two fates repress one another. Activation of the female pathway in the absence of SRY causes differentiation of supporting cells into granulosa cells that, together with the interstitial theca cells, will make up the follicles within which germ cells are located. Normal folliculogenesis is vital to support development of oocytes from PGCs.

The exact stage at which follicle differentiation occurs is ill defined, as reorganization into female-specific structures is not evident by histological analysis until as late as E18.5, although female-specific markers such as the forkhead transcription factor *Foxl2* are expressed in the supporting cells of the XX gonad as early as E12.5.[158,159] *Foxl2* is evolutionarily well conserved in vertebrates.[160] Deletion in mice causes ovarian failure; thus the gene has been implicated as a primary female-determining gene.[158,159,161] However, *Foxl2* mutation does not cause complete sex reversal in humans or mice. FOXL2 has been shown in vitro to bind to the TESCO enhancer of *Sox9*, preventing upregulation of *Sox9* in Sertoli cells (Figure 7.4(D)).[162] Mice lacking *Foxl2* show sex reversal postnatally, implicating FOXL2 in maintenance of female sex programs via *Sox9* inhibition. This phenotype is discussed in more detail below. Together these data indicate that *Foxl2* is unlikely to be the primary determinant of female development. An alternative candidate is the Wnt signaling pathway.

Canonical Wnt signaling promotes female sexual differentiation via *Wnt4* and *R-spondin1 (Rspo1)*. R-spondins are a group of four secreted ligands that act to stabilize beta-catenin in a manner analogous to that of canonical Wnt ligands. Mice lacking either *Wnt4* or *Rspo1* show partial XX sex reversal.[163–165] In the case of *Rspo1* this was demonstrated to be due to alteration in beta-catenin signaling.[163] XY mice in which *Wnt4* is overexpressed undergo improper patterning of the vasculature in the testis, and abnormal Leydig cell recruitment, indicating that *Wnt4* alone is not a primary sex-determining

factor.[166,167] In humans, mutation of *Rspo1* has been documented in complete 46,XX male sex reversal.[168]

While loss of Wnt signaling affects female development, normal regulation of canonical Wnt signaling is also important for male development. In humans, duplication of chromosome 1p, where both *Wnt4* and *Rspo1* are located, results in complete XY,46 sex reversal.[169] This requirement was further demonstrated in mice in which a stabilized form of beta-catenin was expressed under control of an *Sf1Cre* driver. Stablilization of beta-catenin in this manner caused constitutive activation of canonical Wnt signaling in the somatic cells of the bipotential gonad. The XY mutant embryos showed development of follicles and upregulation of female-specific genes, including *Foxl2*.[170] Despite this phenotype, some aspects of initial testis formation were observed, including formation of the coelomic vessel. This indicates that Wnt signaling likely acts downstream *Sry* expression. Indeed, downregulation of *Sox9* was observed from E11.5 onwards. Data suggest that beta-catenin, like FOXL2, acts to induce female development by repressing binding between SF1 and the TES enhancer of *Sox9*.[171] Thus it is probable that canonical Wnt signaling in the XX gonad acts to modulate the effect of SRY on *Sox9*, repressing the male and activating the female fate.

BALANCING MALE VERSUS FEMALE GENE EXPRESSION

The above data show that canonical Wnt signaling via *Wnt4* plays an active role in female development, rather than female fate being a default pathway. WNT4 and the male-promoting FGF9 have been shown to antagonize one another upstream of *Sox9* expression. Although expression of these genes is ordinarily sex-specific from E12.5 onwards, *Fgf9* and *Sox9* are expressed in *Wnt4*$^{-/-}$ XX gonads, and *Wnt4* and Rpso are expressed in *Fgf9*$^{-/-}$ XY gonads.[134,172] In embryonic gonad organ culture, addition of exogenous FGF9 can induce *Sox9* expression and cause downregulation of *Wnt4*.[134] Furthermore, deletion of *Wnt4* in *Fgf9* or *Fgfr2* null XY mutant mice rescues the sex reversal phenotype, although the reverse is not true of the partially sex reversed XX *Wnt4* null mice.[172] Together, these data indicate that *Wnt4* and *Fgf9* are responsible for inhibition of one another once sex is determined by expression (or lack thereof) of *Sry*.

Although many genes are characteristically viewed as male- or female-promoting, the role of the X-linked gene *DAX1* (Nr0b1) has long puzzled researchers. *DAX1* has been implicated in sex determination and gonad and adrenal development. *DAX1* is an unusual member of the nuclear hormone receptor family because it lacks the classic zinc finger DNA binding domain but contains instead a novel domain with a repeated motif.[173] In many respects, *DAX1* is a classic female fate-promoting gene. *Sox9* is downregulated in transgenic mice overexpressing *Dax1*, and overexpression of *Dax1* in *Sox9*$^{+/-}$ mice results in partial XY sex reversal. However, the role of *Dax1* in sex determination is thought to be complex. XY mice with a targeted mutation in this gene showed defective testis cord development. Moreover, in certain genetic backgrounds these mutant mice showed complete male to female sex reversal.[174,175] *Sry* expression was not affected in these sex-reversed mice, suggesting that this gene acts downstream of *Sry* in the gonad. Mutations in *DAX1* in XY human individuals gave rise to adrenal deficiencies and hypogonadotrophic hypogonadism, where their testes were reduced in size but no sex reversal was observed.[176,177]

Human XY individuals with a duplication in the region of the X chromosome that contains *DAX1* show sex reversal, called the dosage-sensitive sex reversal syndrome.[178] Consistent with this, transgenic XY mice with extra levels of *Dax1* show sex reversal, although only in certain genetic backgrounds.[179] These studies show that although DAX1 is required for testis development, at high levels it can act antagonistically to SRY and promote sex reversal.

Tissue culture studies showed that DAX1 can act as a repressor of transcriptional activation by other classic nuclear hormone receptors.[177,180,181] DAX1 expression within the early gonad correlates with that of SF1. In vitro evidence indicates that the sex reversal observed in *Sox9*$^{+/-}$*; Dax1TG* mice is due to competition between DAX1 and SF1 at the TESCO enhancer of *Sox9* (Figure 7.4(D)).[96] Thus DAX1 promotes the female pathway via antagonistic interactions with SF1.

Cell Migration and Vasculature Formation

Once sex determination has occurred, the size of the male gonad increases relative to the female gonad, due to FGF signaling acting downstream of SRY in the gonad.[73,136,138] In addition, cell migration and vasculature formation occur in a sex-biased manner (Figure 7.6(F) and (G)).

The characterization of the cellular processes involved in gonad development has been possible due to the development of in vitro organ culture systems. Tissues from genetically modified mice have been used in recombinants to determine the molecules involved in the different processes. This type of study has shown that cells from the mesonephros migrate into the gonad during development, and that this only occurs in the male gonad.[182,183] The migrating cells are endothelial cells that instruct testis cord formation; blocking this process in organ cultures impairs the proper formation of cords.[184,185] Several growth factors, including FGF9, VEGF, and PDGFs, were able to induce migration of mesonephric cells into an XX gonad in culture.[137,186,187] These data were subsequently supported by in vivo

work. Repression of FGF signaling by the gain-of-function mutation in the RTK inhibitor *Sprouty2* in mice inhibited migration from the mesonephros, and prevented normal testis cord formation.[188]

Normal endothelial cell migration is a requirement for formation of the male vasculature. Testis cord formation in the XY gonad is accompanied by the formation of a prominent blood vessel running along the periphery of the testis, just under the coelomic epithelium. Although vascular formation is an active process in the gonad of both sexes during development, this coelmic blood vessel (CBV) is only found in the male. The endothelial cells associated with this vessel were found to express arterial markers, suggesting that a male-specific circulatory system that promotes the export of testosterone (T) produced by Leydig cells needs to form to ensure the masculinization of the embryo during its development.[189] Mice lacking PDGFRa show a defect in CBV assembly and branching in the testis.[186] VEGF inhibition in gonad culture also prevents normal vasculature formation due to lack of endothelial migration. PGDF signaling is proposed to act downstream of VEGF in this process, as addition of PDGF to VEGF-inhibited gonads can rescue the proliferation, but not the vascular formation defects.[187] In addition, mice lacking the gene inhibin beta B *(Inhbb)*, which encodes activin B, exhibit mild defects in CBV formation. *Inhbb* expression is sex-biased from E12.5, when it is detectable only in XY gonads.[190] The phenotypes observed, such as a thin CBV, differ from those seen in the PDGFR and VEGF mutants, and likely represent a different pathway.

The XX gonad does not normally form a CBV. An active repressive pathway is present in the ovary to prevent the migration of endothelial cells from the mesonephros and the formation of a CBV. Mice with mutations in the genes encoding either WNT4 or follistatin (*Fst*) showed the presence of an ectopic CBV in the ovary, similar to that found in the normal XY gonad.[166,191] WNT4 was found to act upstream of *Fst* in this process. Loss of *Inhbb* in $Wnt4^{-/-}$ or $Fst^{-/-}$ mice prevented formation of the CBV, indicating that activin B is responsible for ectopic CBV formation in these mutants.

Interstitial Cell Differentiation

The indifferent interstitial cells of the bipotential gonad are believed to give rise to the steroid producing cells of the adult reproductive organs; the Leydig or theca cells in the male or female, respectively. In the male gonad, the Leydig cells arise from the interstitium in the days succeeding Sertoli cell differentiation. Differentiation of the interstitial cell population is stimulated by signals from the forming testis cords. Subsequently, the Leydig cells produce enzymes that catalyze the conversion of cholesterol to androgen. Gonadal steroidogenesis is discussed in depth in Chapter 8. Theca cell differentiation is less well understood and occurs after birth. Interstitial cells surrounding the follicle are believed to differentiate into theca cells upon ill-defined signals from the granulosa cells during folliculogenesis. The theca cells then surround the follicle and produce androgens, which are subsequently converted to estrogens by the underlying granulosa cells (see Chapter 28 for details).

Adrenal cortical cells, which also produce steroids, are, like the testis and ovaries, derived from the AGP.[63] These cells arise when the genital ridge first forms, and separate into adrenal and gonadal populations as development proceeds. Although the expression of genes involved in steroidogenesis is observed in the fetal adrenal cells at early stages, it is not until after cord formation that this gene expression is seen in the testis. Steroidogenesis is not apparent until postnatal stages in the ovary. Either different pathways must activate the steroidogenic cascade in each organ, or different control mechanisms release the brakes on these pathways at different times, permitting differentiation of the interstitial population and subsequent steroidogenesis. Sex-biased roles in interstitial cell differentiation have been documented for the hedgehog signaling pathway.

The cell-signaling molecule DHH is a candidate factor for the activation of Leydig cell differentiation. DHH is produced by Sertoli cells at early stages of testis development, and mice that lack this gene showed a severe reduction in Leydig cell numbers during development in certain genetic backgrounds.[192,193] Furthermore, on a particular mixed background, the mutant testis cords were disorganized; therefore Dhh is required for normal cord formation. Downstream targets *Patched1*, *Gli1*, and *Gli2* are expressed not in the Sertoli cells but throughout the interstitium, indicating that hedgehog signaling is transduced in the Leydig and myoid cells of the testis rather than the Sertoli or germ cells.[193,194] DHH and its downstream targets are not expressed in the developing XX gonad.[194,195] Both Leydig cell differentiation and testis cord formation were affected in *Patched1* mutant mice, suggesting that hedgehog signaling has a general role during testis development.[193] Consistent with this, human individuals with mutations in DHH show variable gonadal phenotypes.[196] $Sf1^{+/-}$; $Dhh^{-/-}$ mice undergo XY external sex reversal. Testis cords and germ cells are present, but Leydig cells fail to differentiate, as measured by expression of *Cyp11a1*, a gene encoding the steroidogenic enzyme p450SCC.[197] Constitutive activation of Smoothened, a transducer of hedgehog signaling, in SF1-positive cells in the XX gonad resulted in the differentiation of steroidogenic cells but not of other testicular cell types.[198] This indicates firstly that hedgehog signaling can instruct differentiation of fetal Leydig cells, and secondly that hedgehog signaling is disruptive to normal female gonadal development.

Although absent during embryogenesis, it is possible that the hedgehog signaling pathway is involved in female steroidogenesis postnatally. DHH and its sister ligand Indian hedgehog (IHH) are both expressed in the granulosa cells of the adult ovary and are thought to signal to the theca cells, in which *Patched* and *Gli* expression has been documented.[199,200] Inhibition of hedgehog signaling with cyclopamine in organ culture experiments did not appear to affect the ovary, although the short duration of culture might be insufficient for phenotypes to arise. Therefore, any functional role for this signaling pathway in theca cells remains undefined.[200] Furthermore, other signals responsible for theca cell differentiation are also poorly understood. Proteins implicated include IGF1 and luteinizing hormone, as well as factors produced by the granulosa cells.[201] Addition of these proteins to an interstitial cell culture system induced differentiation of theca cells and steroidogenesis. However, this in vitro result has yet to be confirmed in vivo. Together, these data provide some insight into the potential cues governing thecal cell differentiation, but much more work is needed to achieve a good understanding of this process.

Although thecal cell development remains ill defined, Leydig cell differentiation has been more thoroughly studied. Mutation in the X-linked aristaless related homeobox (*Arx*) gene in both XY mice and humans results in similar phenotypes to those documented in DHH mutation.[202] *Arx* is expressed in interstitial and peritubular myoid cells of the developing testis, and Leydig cell differentiation is severely affected in the mutant mouse embryos. However, *Arx* is not expressed in Leydig cells, indicating that the differentiation and compartmentalization of the interstitial cells during development is important for the induction of steroid production. In humans, mutations in *ARX* are associated with the XLAG (X-linked lissencephaly with abnormal genitalia) syndrome, as this gene also has a function in forebrain development.[202]

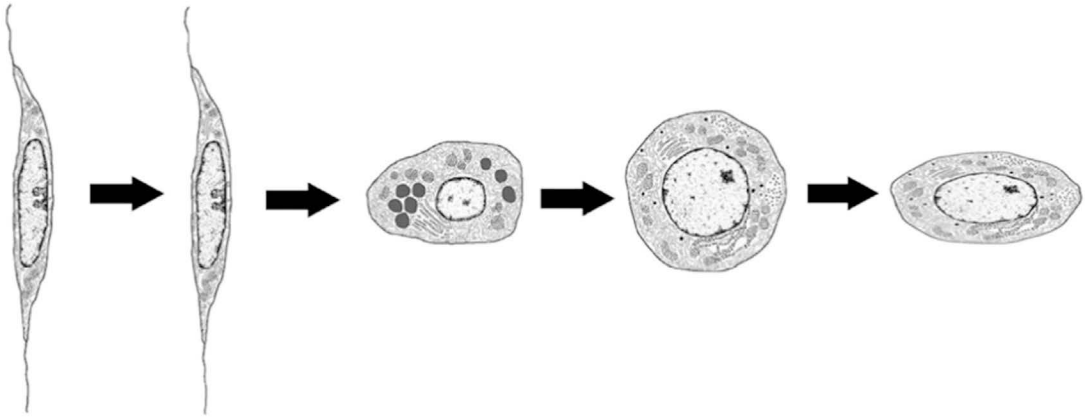
Notch signaling has also been implicated in Leydig cell differentiation. The Notch genes are expressed in a sex-biased manner in the XY gonad during development. Downstream targets *Hairy/Enhancer-of-split1 (Hes1)* and *Hes5* are expressed in the developing interstitium and Sertoli cells, respectively. Inhibition of Notch signaling results in an increase in the number of Leydig cells, while Sertoli cell number is unaffected. Conversely, constitutive activation of Notch signaling in the mouse causes a decrease in Leydig cell number, due to maintenance of a progenitor interstitial cell population in preference to differentiation into Leydig cells. Notch was not capable of reverting differentiated Leydig cells to a progenitor phenotype, indicating a specific requirement in the process of fetal Leydig cell differentiation.[203]

The genes described above have largely been studied during embryogenesis, and thus have been shown to be required for fetal Leydig cell differentiation. However, fetal Leydig cells are believed to be a separate population from adult Leydig cells. It is thought that fetal Leydig cells originate from two sources. Lineage tracing using Mitotracker dye showed that Leydig cells can derive from both the coelomic epithelium and the gonad-mesonephros border.[204] It is unclear whether the Leydig cells deriving from the gonad-mesonephros border represent true Leydig cells or the so-called adrenal-like cells, a population of steroidogenic cells in the fetal testis that express genes involved in adrenal steroidogenesis.[205]

The origin of adult Leydig cells remains unclear, although an adult Leydig stem cell population likely exists in the testis (see also Chapter 14). Studies suggest that onset of differentiation of the adult Leydig stem cell population occurs at different stages in different organism (reviewed in Ref. 206). Hardy described passage of the stem Leydig cell (SLC) through two intermediate stages to give rise to a terminally differentiated Leydig cell (Figure 7.7).[207] The SLC population proliferates to give rise to spindle-shaped progenitor Leydig cells (PLC), which begin to produce some enzymes associated with steroidogenesis, such at 3β-hydroxysteroid dehydrogenase (3β-HSD) (encoded by the gene *Hsd3b*).[208,209] Over time, the PLCs assume a rounded morphology, characteristic of Leydig cells, and upregulate expression of steroidogenic genes such as *Hsd3b* and *Cyp11a1*.[209,210] This population is referred to as the immature Leydig cell population (ILCs). Finally, one cell division in each ILC gives rise to the full complement of terminally differentiated adult Leydig cells. Although these stages of development have been documented histologically, they are hard to define on a stage-by-stage basis, as there are no known markers that distinguish each stage. Indeed, since the process was described almost 20 years ago, little data has been produced to improve our understanding of the process. Multiple attempts to characterize the adult Leydig stem cell population have been published.[211–213] However, contradictory evidence and a lack of markers mean that the population has yet to be defined.

Germ Cells

In mammals, germ cell fate is determined by induction; that is, signals from the surrounding environment induce multipotent embryonic stem cells to become germ cells. Thus, up until the blastocyst stage any cell is capable of becoming a germ cell if it is placed in the correct environment. This is in contrast to animals such as *Drosophila* and zebrafish, in which maternal factors predetermine which cells will become germ cells, a mechanism known as preformation. Once specified, germ cell fate is maintained by stringent transcriptional



Cellular attributes	Stem Leydig cell	Progenitor Leydig cell	Immature Leydig cell	Adult Leydig cell	Aged Leydig cell
Mitotic activity	Low	high	Once	Probably none	Probably none
Morphology	Spindle	Spindle	Round with large lipid droplets	Round with small lipid droplets	Round with small lipid droplets
Smooth ER	Low	Low	High	Highest	High
Testosterone metabolism	None	High	Highest	Low	Low
Testosterone synthesis	None	Low	Intermediate	High	Intermediate
Age when cell is typical	7 days	21 days	35 days	90 days	20 months
LH receptor number	None	Low	Intermediate	High	Intermediate
Androgen receptor number	?	High	High	Low	?

FIGURE 7.7 Stages of adult Leydig cell development. Pictorial representations of the morphology of the developing adult Leydig cell, with defining characteristics tabulated below. *Source: Taken from Ref. 253.*

repression, via chromatin modification and, in some species, repression of RNA polymerase. These processes are reviewed in detail elsewhere.[214]

In the mouse, germ cells migrate into the gonad from the proximal epiblast after specification. Upon arrival, transcriptional repression is lifted somewhat in order to allow a process known as licensing, which allows germ cells to respond to sex-specific signaling, and so enter meiosis or mitotic arrest. Although the signals determining a female versus male fate are extrinsic, the ability of the germ cell to respond is an intrinsic property. Intrinsic licensing is controlled by an RNA-binding protein, Deleted in Azoospermia-Like (DAZL). *Dazl* expression is restricted solely to germ cells.[215] In *Dazl* null mice, the germ cells maintain the primordial state normally found during migration. Thus the cells remain sexually undifferentiated and do not enter meiosis.[216,217]

Germ cells within the developing mammalian gonad follow a sexually dimorphic pathway. In the ovary, they enter meiosis at around E13.5, but in the male, they arrest in mitosis at about the same time and remain in G0 until neonate stage. This difference is dependent not upon the chromosomal sex of the germ cells but upon the somatic environment of the gonad.[218] The factor controlling entry into meiosis is the helix-loop-helix protein stimulated by retinoic acid 8 (STRA8). In the XX mouse, deletion of *Stra8* causes loss of germ cells by E16.5, as the cells cannot complete the transition to meiotic prophase, although they appear normal until E13.5.[219] The same phenotype is observed postnatally in the male mutants.[220]

Evidence indicates that *Stra8* expression in the gonad is downstream of retinoic acid (RA) signaling.[221] However, recent work has indicated that other pathways are also capable of activating *Stra8* in this setting, as deletion of *Raldh* genes does not result in a loss of *Stra8* expression in the early female gonad.[222] In the female gonad, RA signaling from the mesonephros occurs from E12.[221,223] In the male gonad, CYP26B1 in Sertoli cells degrades retinoic acid, thus inhibiting expression of *Stra8* and delaying entry into meiosis. *Cyp26b1* is not expressed in the female gonad at this time. After birth, *Cyp26b1* is downregulated in the male, permitting expression of *Stra8*. In XY mice lacking *Cyp26b1*, the germ cells enter meiosis at the same time as those of wild-type females.[223]

Interestingly, analysis of *Cyp26b1* mutants revealed that the level of *Stra8* expression was higher in XX than XY gonads, indicating the likely presence of an additional, male-promoting pathway.[224] FGF9 signaling through FGFR2 acts independently of RA signaling to inhibit *Stra8* expression and thus prevent meiosis in the embryonic male gonad. On some genetic backgrounds, loss of *Fgf9* causes germ cell apoptosis in the XY gonad.[225] Furthermore, treatment of XX gonads with FGF9 in culture induced expression of male germ cell markers including *Nanos2*, indicating that FGF9 actively promotes a male fate in the germ cells.[224] NANOS2 itself is a meiotic repressor in male germ cells.[226] Nodal/activin signaling has recently been proposed to act as a downstream target of FGF9, mediating expression of *Nanos2*. Loss of nodal/activin signaling causes apoptosis in male germ cells, a phenotype also seen in *Nanos2* mutants. This signaling cascade also appears to act to inhibit RA signaling.[227]

The data above indicate that the formation of male versus female germ cells is an active process with antagonistic/agonistic signaling pathways converging on the same target. Thus, progenitor cells would be expected to be unbiased. However, transcriptome-wide expression analysis of germ cells has recently revealed that prior to E13.5 this population is primed towards a male fate, indicating that the process may be incompletely understood.[228] Indeed, *DMRT1*, traditionally viewed as a "male" gene, has been implicated as a direct transcriptional activator of *Stra8* in the XX gonad, contrary to its role as an inhibitor of *Stra8* in the postnatal male testis.[229]

Plasticity of Gonadal Sex

Classically, sex determination in metazoans has been viewed as a largely irreversible process. Gonadal sex is determined embryonically and phenotypic sex cements the gonadal phenotype. However, recent data have challenged this dogma.

In 2011, it was shown that XY *Dmrt1*$^{-/-}$ mice exhibit feminization of the somatic and germ cells of the gonads postnatally. In the four weeks after birth, the somatic cells of the gonad switch off *Sox9* and instead begin to express *Foxl2* and other ovary-enriched genes. The germ cells adopt an oocyte-like phenotype. Furthermore, inducible deletion of *Dmrt1* in adult males causes the same phenotypes to arise.[230] As DMRT1 is capable of binding upstream of both male and female fate-promoting genes, these data suggest a model whereby DMRT1 activates male programming while inhibiting female-promoting gene expression throughout adult life.

Foxl2 has been implicated as a primary female-determining gene, as *Foxl2* deletion causes ovarian failure.[158,159,161] Furthermore, mutation of the gene has been implicated in XX male sex reversal in goats.[231] However, *Foxl2* mutation does not cause complete sex reversal in humans or mice. Loss of function mutation in humans leads to blepharophimosis/ptosis/epicanthus inversus syndrome associated with premature ovarian failure in females.[232,233] Mice with loss-of-function mutations in *Foxl2* exhibit impaired ovarian development, including loss of the granulosa cells.[158,159,161] In these mice, female sex reversal as such is not documented during development, although testis-specific genes are upregulated in the ovary.

Although not a master regulator during embryogenesis, conditional ablation of *Foxl2* in the adult ovary can cause masculinization.[162] In these mice, testis cords form from the somatic cells of the follicles, and Leydig cells are observed that produce levels of T equivalent to that of XY littermates. These are posited to derive from non-cell autonomous lineage reprogramming of the female steroid-producing theca cells, which did not express the *Cre* driver. *Sox9* upregulation was observed soon after deletion of *Foxl2* in these mutants, suggesting that FOXL2 might repress *Sox9*. Several lines of experimentation in vitro support this hypothesis, indicating that FOXL2 negatively regulates *Sox9* by direct binding to the TESCO enhancer. FOXL2 appears to be physically and genetically interacting with estrogen receptors (ERα and β mutation), which causes similar, but less severe phenotypes in the adult ovary.[234] ERβ and ERβ also have binding sites in the TESCO, and in vivo mutation of both the FOXL2 and the ERβ binding site in the TESCO enhancer is required for complete sex reversal in the adult ovary (Figure 7.5(D)).[162]

Together, these data from *Dmrt1* and *Foxl2* mutant mice indicate that sex in mammals is much more plastic than previously thought, with maintenance of sex vital after determination and differentiation have taken place (Figure 7.8). The extent to which this is true remains to be determined; it seems likely that other genes that are involved in initial sexual differentiation, such as *Sox9* in the XY gonad and components of Wnt signaling in the XX gonad, may continue to play a role in maintaining these phenotypes in the adult. Temporal deletion

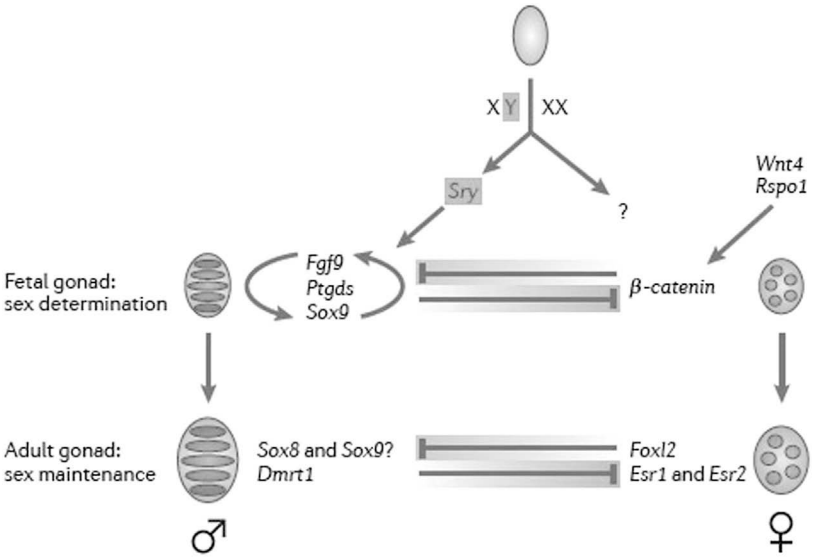


FIGURE 7.8 Initiation and maintenance of sex-specific gonadal phenotypes. Initially, a male versus female gonadal fate is dependent upon expression of *Sry* from the Y chromosome, and genes including *Sox9*, *Fgf9*, and *Pgd2* promote testis organogenesis. Male-promoting genes negatively regulate female-promoting genes including members of the Wnt pathway, and vice versa. In the adult, negative regulatory loops remain, and are now thought to involve female fate-promoting *Foxl2* and *ERα/β* genes, and male-specific *Dmrt1*. *Source: Taken from Ref. 149.*

of these genes in the mouse will be required to define the signaling cascades involved in maintenance of sex through adult life.

PHENOTYPIC SEX

Sexual Differentiation of Reproductive Organs

Experiments conducted by Jost in the 1950s on rabbit fetuses showed that male embryos that have been castrated develop as females. Jost postulated that secretions from the fetal testis induced the development of male sexual characteristics.[235] Today we know of at least three diffusible factors produced by the fetal testis with these properties: AMH, insulin-like factor 3 (Insl3), and T (Figure 7.9). As mentioned above, AMH is produced by Sertoli cells and its role is to activate the regression of the Müllerian duct, which gives rise to the oviduct, uterus, and the vagina in the female. Leydig cells produce Insl3 that, together with T, regulates the descent of the testis from a location next to the kidney to the region where the scrotum is developing.[236,237]

The development of most male-specific structures is dependent on T produced by the Leydig cells of the embryonic testis. T regulates three main aspects of male phenotypic development: the conversion of the Wolffian ducts into the epididymis, vas deferens, and seminal vesicles; the formation of the male urethra and prostate from the urogenital sinus; and the formation of the phallus and scrotum from the genital tubercle. In some of these target tissues, T is not the acting hormone but is converted to a more potent androgen, dihydrotestosterone (DHT), through the action of the enzyme 5α reductase found in these tissues. In marsupials it was found that the male-specific circulating androgen during the stage of development of male-specific organs was not DHT or T but a 3 α reduced derivative of DHT, 5 α-androstane-3α, 17β-diol (5α-adiol). However, 5α-adiol is considered a weak androgen and therefore it is thought that it converts back to DHT to induce virilization.[238]

Both T and DHT act through the androgen receptor, an X-linked member of the nuclear hormone receptor family, with DHT having approximately a 10-fold higher affinity.[239] Mutations in the androgen receptor gene and in genes encoding any of the enzymes required for DHT synthesis give rise to defects in the development of all male-specific structures in both mouse and man.[240] These defects can be highly variable depending on the nature of the mutation and the importance of the gene involved in the process. Analysis of these mutations showed that not all of male-specific structures require DHT for development as human individuals with 5α reductase deficiencies show virilization of the Wolffian duct but absence of other male-specific structures.[240] In the mouse, males lacking both isoforms of the 5α reductase enzyme showed proper internal and external genitalia, although the prostate and the seminal vesicles were smaller, showing that T is able to induce most male sexual development in this species.[241]

The development of sexual reproductive organs in the female is less dependent on diffusible factors made by the gonad. The exact role of steroids in female development has been hard to determine, because although the ovary does not produce steroids during embryogenesis, the fetus is bathed in female hormones derived from the mother. Mice lacking both ERα and ERβ develop proper

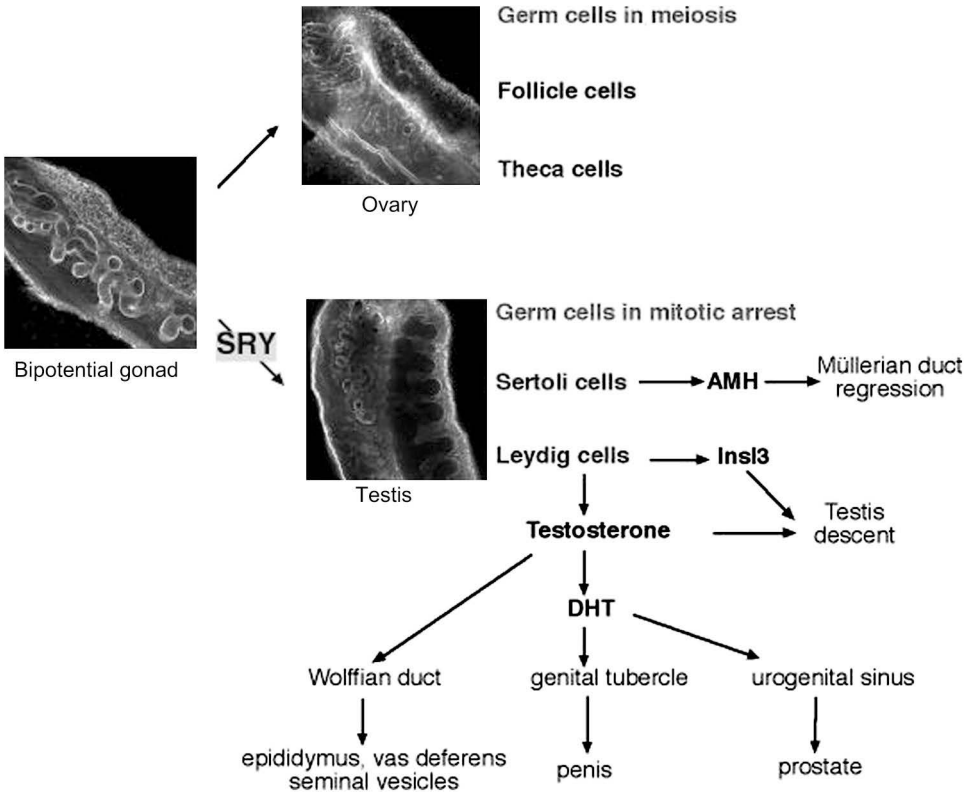

FIGURE 7.9 Sexual differentiation of the internal and external genitalia. The bipotential gonad develops into an ovary in the absence of SRY or a testis if SRY is present. Three main sexually dimorphic cell types are found in the gonad: germ cells, supporting cells (Sertoli cells and follicle cells), and steroidogenic cells (Leydig and theca cells). In the male, products from the testis, AMH, Insl3, and testosterone, induce the differentiation of the male-specific internal and external genitalia. *Source: Confocal images of laminin stained gonads were adapted from Ref. 254.*

Müllerian duct derivatives and ovary development is not affected initially. However, in adulthood these animals show uterine hypoplasia and testis-like cords within the ovary, showing that estrogen does play a role in late development of female reproductive organs.[234] As expected from Jost's postulate, female embryos that have been treated with androgens show virilization of their reproductive organs. A similar situation occurs in XX human individuals with congenital adrenal hyperplasia. These individuals carry mutations in the genes encoding enzymes in the final steps of adrenal steroid synthesis, the most common of which is a mutation in *CYP21*. This mutation causes steroid 21-hydroxylase deficiency, which results in a reduced level of corticosteroid production. This in turn activates feedback mechanisms in the pituitary, causing release of ACTH. This high level of ACTH stimulates the adrenal cortex, increasing production of steroidogenic intermediates with androgenic properties.

Sexual Differentiation of the Nervous System

Androgens have been shown to have a role in the sexual differentiation of the nervous system. Several regions of the rodent brain including the sexually dimorphic nucleus of the preoptic area (SDN-POA), the anteroventral periventricular nucleus (AVPV), and the spinal nucleus of the bulbocavernosus (SNB) show sexual differences, which are dependent on the presence or absence of androgens during fetal or neonatal stages.[242–244] In some cases it was found that androgens were not acting through the androgen receptor but were converted into estrogen in the brain by the enzyme aromatase, which was acting through the estrogen receptor. Consistent with these differences in brain structure between the sexes, behavior can be dependent on the level of androgens during fetal life. This was first demonstrated in guinea pigs, where females were exposed to T in utero and this interfered with their female pattern of reproductive behavior in adulthood.[245] Detailed descriptions of the role of steroids in different aspects of reproductive function and behavior are found in other chapters of this book.

Although many of the sex differences found in the brain are due to the effect of steroids, evidence has shown genetic contributions to these differences. Most of these differences are expected to be derived from the sex chromosomes, as these will contribute to gene differences between sexes. For example, females lack Y-linked genes; males may have lower doses of X-linked genes that escape X inactivation; and as males only inherit their X chromosome from their mothers, they will lack paternal imprinting effects. Experiments using the FCG mice were designed to uncover the effects of sex chromosomes independently of the sex of the gonad[50] (discussed in more detail in Chapter 47). Using these mice it was shown that the density of vasopressin innervation of the lateral septum was different between XX and XY animals independently of

the phenotype of the gonad. A difference was also seen in the number of dopamine neurons in cultures from embryonic mesencephalic cells.[246] Further characterization is needed to determine the importance of genetic effects in the development of brain structure and function and what effects these might have on behavior.

CONCLUSION

The study of sex determination and differentiation has provided great insight into different aspects of reproductive biology. The analysis of disorders of human sexual differentiation has been essential in the identification of genes regulating this process. In addition, the mouse has been an important model system with the advent of genetic technology such as targeted mutagenesis and transgenesis. In the last decade, the increasing use of genomics has proved a powerful tool for identification of evolutionarily conserved factors in sex determination, as well as for dissecting aspects of the process that are unique to mammals, leading to an influx of new discoveries in the field. However, many questions remain to be answered.

- New genes involved in sex determination continue to be discovered each year, yet many patients suffering from DSDs still have unknown mutations. New techniques must be employed in order to identify the full complement of genes involved in human DSDs. Improvements in genomics have already helped uncover new candidate genes, such as *Sox3*.
- It is still unclear how each lineage in the gonad is specified. Could induced pluripotent stem (iPS) cell technology be used to define the pathways involved in lineage specification? Such trials are currently underway.
- With the discovery of new genes involved in DSDs comes the challenge of characterizing their role in sex determination, and of understanding how their mutation causes disease. Generation of iPS cell lines from DSD patients could be used to study unknown mutations, or to analyze genetic modifiers that are likely partially responsible for the spectrum of DSDs seen in patients. These cell lines could also be used in drug discovery and testing. These techniques have already been used in research into heart disease and disorders of the nervous system (reviewed in Ref. 247).
- Recent data has revealed that the gonad is more plastic than previously realized. Exactly how is sex maintained in the adult gonad? Further analysis of gene function in the adult testis and ovary is likely to pinpoint more genes critical in maintaining each sex.

CHAPTER

8

Human Steroid Biosynthesis

Richard J. Auchus

Division of Metabolism, Endocrinology, and Diabetes, Department of Internal Medicine, University of Michigan Medical Center, Ann Arbor, MI, USA

INTRODUCTION

Heinrich Wieland received the Nobel Prize in Chemistry 1927 for determining the chemical structure of bile acids, and Adolf Windaus received the Nobel Prize in Chemistry 1928 for the chemical structure of cholesterol and sterols related to vitamins. Although their structures, alas, were not quite correct, this work prompted intense efforts to isolate similar compounds responsible for the biological activities of certain endocrine glands and their extracts. In the mid-1800s, Addison found that adrenal destruction was fatal in human beings, and Brown-Sequard showed that adrenalectomy was fatal in laboratory animals. Consequently, there must be a factor, which was essential for life, derived from the adrenal cortex.

Rosenheim and King determined the correct structure of the cyclopenanoperhydrophenanthrene steroid nucleus in 1932 (Figure 8.1(A)). In the ensuing years, Leopold Ruzicka and Adolf Butenandt isolated and determined the structures of estrone (E1), progesterone (P4), and androsterone, and these feats were likewise recognized with the Nobel Prize in Chemistry 1939. Their findings, which showed a diversity of hydrocarbon hormones bearing a common general structure, began to codify the field of steroid biology and to beg the question of how such a repertoire of compounds could be formed efficiently. Many compounds with the basic steroid structure were found in the adrenal gland, and epinephrine, which was the first hormone isolated from the adrenal, did not prevent death in adrenalectomized animals. Thus began the quest that ultimately led to the discovery of cortisone.

The elucidation of the structures of the first steroids inspired the work of Henry Kendall at Mayo Clinic; W.W. Swingle and J.J. Pfiffner at Princeton and later Columbia University; G.F. Cartland and M.H. Kuizenga at Upjohn; and Tadeus Reichstein in Zurich. These laboratories extracted massive amounts of animal adrenal cortex, painstakingly isolating and characterizing an alphabet soup of 29 adrenal steroids, which differed primarily on the location of a few hydroxyl and ketone groups. Once cortisone was isolated and synthesized, Phillip Hench at Mayo Clinic treated rheumatoid arthritis patients with cortisone and showed dramatic and unprecedented responses. Given the validation of cortisone (actually cortisol, formed in the liver from cortisone) as a hormone and vital factor, attention turned to its genesis.

In reviewing Reichstein's 29 compounds, one could logically propose some precursor–product relationships based on chemical thermodynamics. The more heavily oxidized or hydroxylated the compound, the lower its free energy, and the farther downstream in a pathway. The Δ^4-steroids with the enone structure are more stable than Δ^5-steroids and likely to be downstream in these pathways. Clues to the order of the adrenal pathways derived from patients with defects in specific reactions. The first such disorder was Luigi de Crecchio's description of a "man" with genital ambiguity at birth who lived as a male, but following death during a diarrheal illness of an apparent adrenal crisis, he was found to have female internal reproductive structures and enlarged adrenals at autopsy. He probably had a 46,XX karyotype and 21-hydroxylase deficiency (21OHD), the most common form of congenital adrenal hyperplasia (CAH). Joseph Jailer and Seymour Lieberman,[1] as well as Albert Bongiovanni in independent work, studied steroid production in similar patients in the 1950s. By identifying the steroids, which were unusually high or low, they correctly deduced that these patients had a defect in the steroid 21-hydroxylase enzyme, the most common human genetic enzyme deficiency. Similarly, Bongiovanni found high 11-deoxycortisol in patients

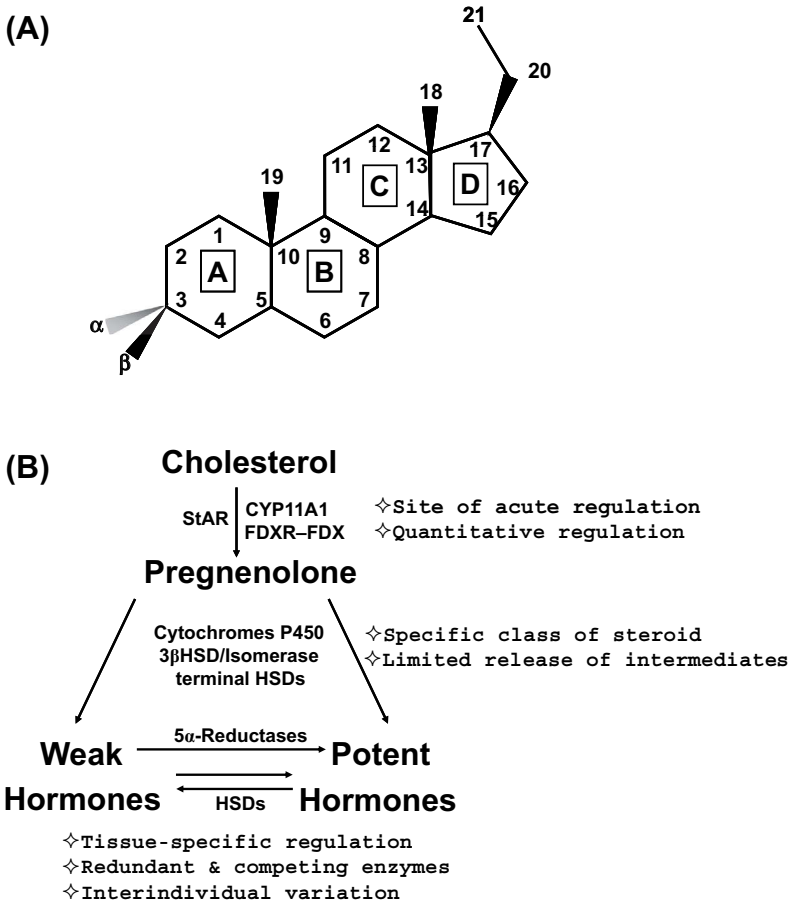

FIGURE 8.1 Conceptual model for steroidogenesis. (A) Cyclopentanoperhydrophenanthrene steroid nucleus, with boxed letters indicating rings A–D and numbers for carbon atoms 1–21. Substituents (see carbon 3) projecting in front of the page (dark wedge) are β-configuration, and those projecting behind the page (light wedge) are α-configuration. (B) The conversion of cholesterol to pregnenolone is the quantitative and acutely regulated step, involving StAR and CYP11A1. The downstream enzymes determine the major steroid products of each steroidogenic cell. The hydroxysteroid dehydrogenases dominate the terminal reactions in the steroidogenic cells and in peripheral tissues and target cells. Additional enzymes, including the sulfotransferases, 5α-reductases, and UGTs, participate in various biosynthetic and degradative processes, including enzymes not traditionally considered steroidogenic, such as CYP3A4.

with a hypertensive form of CAH and therefore ascribed this disorder to 11β-hydroxylase deficiency,[2] and he also described 3β-hydroxysteroid dehydrogenase/isomerase deficiency based on high Δ^5-steroids but low Δ^4-steroids in these patients.[3]

The formal birth of the field of biochemistry was in 1897, when Eduard Buchner showed that a yeast culture killed by grinding with sand continued to produce carbon dioxide—for which he too won a Nobel Prize in 1907. The concept of enzymes as biological catalysts was well advanced by 1950, following the purification of pepsin and urease in the 1940s. The important steroid-metabolizing enzymes, however, are mostly intrinsic membrane proteins, which dampened the interest of biochemists of that day, who were more comfortable studying soluble proteins. The first progress in the elucidation of the nature of the 21-hydroxylase enzyme came in the early 1960s, when David Cooper and Otto Rosenthal in Ron Estabrook's laboratory showed that carbon monoxide inhibited this activity in adrenal microsomes.[4] Around this time, Omura and Sato showed that the carbon monoxide–binding pigment of liver microsomes was responsible for oxidative xenobiotic metabolism, which became known as the cytochrome P450 enzymes. Radiolabeled steroids became commercially available in the 1950s, which facilitated experiments to confirm precursor–product relationships. Despite these initial advances, further progress was slow, due to low abundance of enzymes, the need to obtain animal adrenals as the source, the tedious nature of the assays, and the inability to purify the enzymes, which limited the interpretation of messy experiments.

By the mid-1960s, detergents were being used to solubilize proteins from membranes, and some enzymes retained activity despite this previously unthinkable manipulation. In 1969, Anthony Lu in Jud Coon's laboratory described the components of the P450 system: the P450 protein, the flavoprotein reductase, and phospholipid.[5] They showed that these components could be solubilized, purified, and reconstituted to restore activity with NADPH and oxygen. This work paved the way for the isolation of the steroidogenic P450 enzymes, which was still a daunting task, so investigators instead relied mainly on crude microsomal and mitochondrial preparations for many years. The DNA double helix was described in 1953, and the field of molecular genetics had developed the model that one gene encodes one enzyme by the 1960s. Consequently, by the early 1970s, the concept that 21OHD was a defect in the 21-hydroxylase enzyme due to a mutation in the 21-hydroxylase gene

was well accepted. This simple paradigm, however, does not account for several bizarre features of human steroidogenesis, which took many years to resolve, including:

1. discrepancies between activities and pathways in animal models and human beings;
2. multiple activities of one enzyme;
3. multiple enzymes catalyzing the same reactions;
4. similar enzymes with different directional preferences in intact cells;
5. activity regulation via cofactor proteins;
6. how a mutation in one protein can affect several enzymes;
7. how a single biochemical phenotype can result from mutations in three different proteins; and
8. the difference in clinical phenotype between severe and partial deficiency states.

With this framework, one of the seminal advances in steroidogenesis came at the end of the 1970s when Shizuo Nakajin and Peter Hall showed that the 17-hydroxylase and 17,20-lyase activities required for androgen biosynthesis co-purified from neonatal pig testis.[6] The reconstitution of 17-hydroxylase activity required phospholipid and flavoprotein reductase, while Makodo Onoda with Hall showed soon afterwards that restoration of maximal 17,20-lyase activity also required addition of cytochrome b_5.[7] As the field of molecular biology was developing during this time, purification and partial sequencing of porcine 17-hydroxylase/17,20-lyase led to cloning of partial and then complete cDNAs. Mario Zuber and Michael Waterman showed the expression of a single cDNA in non-steroidogenic COS-1 cells conferred both 17-hydroxylase and 17,20-lyase activities,[8] validating beyond any doubt the biochemical studies from Hall's laboratory. The cloning of other cDNAs and genes for the steroid hydroxylases followed (for review, see Ref. 9).

Ferdinand Labrie's group in Canada, including Van Luu-The, Jacques Simard, and many other talented investigators, spent over a decade during the 1980s and 1990s characterizing the molecular genetics and biochemistry of the multiple hydroxysteroid and dehydrogenases,[10,11] which turned out to be far more complex than anyone imagined (at least 15 17β-hydroxysteroid dehydrogenases have been identified to date). The first crystal structures of steroidogenic enzymes were of hydroxysteroid dehydrogenases (HSDs) and were solved in the early 1990s. Deb Ghosh and Bill Duax solved the structure of a bacterial 3α,20β-hydroxysteroid dehydrogenase[12] and with Shin Lin the structure of human placental estrogenic 17β-hydroxysteroid dehydrogenase.[13] Trevor Penning and Mitch Lewis solved the structure of rat liver 3α-hydroxysteroid dehydrogenase,[14] which revealed a second type of structural fold for these enzymes, the β-barrel. The structures of the steroid hydroxylases and other important proteins are still under study.

With the identification of the genes encoding different enzymes and ancillary proteins, diseases could be assigned to specific gene mutations, such as 21OHD, 5α-reductase type 2 deficiency, steroidogenic acute regulatory protein (StAR) deficiency, which is called lipoid CAH, and most recently cytochrome P450-oxidoreductase (POR) deficiency, which was reported in 2004.[15,16] Our understanding of pathways and key enzymes has led to the development of targeted therapies, such as aromatase inhibitors in breast cancer and 17-hydroxylase/17,20-lyase inhibitors in prostate cancer. This chapter will explore the basic principles and intricacies of human steroidogenesis, which is a fundamental and indispensable component of reproductive physiology. Additional details and references are found in recent comprehensive reviews of steroidogenesis[17] and its history.[18]

GENERAL CONCEPTS

Cholesterol is the 27-carbon precursor of all steroids, which share the common four-ring perhydrocyclopentanophenanthrene skeleton with sterols. The first committed step in steroidogenesis is the cleavage of cholesterol to 21-carbon pregnenolone, the common precursor of all other steroids. The capacity to convert significant amounts of cholesterol to pregnenolone is restricted to the cells of the adrenal cortex, the testicular Leydig cells, the ovarian theca and granulosa cells, and placental trophoblast cells. Some other cells might also produce enough pregnenolone for autocrine generation of specific steroid hormones acting on that cell. The first step is also the site of acute regulation and under most circumstances the rate-limiting step, thus determining quantitatively how much steroids are made. In contrast, the downstream enzymes determine the characteristic products of a given cell, or which steroids are made (Figure 8.1(B)).

Steroidogenic enzymes and other key proteins can be heuristically divided into three basic categories (Table 8.1). The first category contains the cytochromes P450, which are the steroid hydroxylases. In human beings, three P450s are mitochondrial and three are located in the smooth endoplasmic reticulum (microsomal). The mitochondrial enzymes use as electron transfer proteins the flavoprotein ferredoxin reductase (FDXR) and the iron–sulfur protein ferredoxin (FDX1), while the microsomal enzymes use only the flavoprotein POR, which contains both a flavin adenine dinucleotide (FAD) and a flavin mononucleotide (FMN). In addition, CYP17A1 (P450c17, steroid 17-hydroxylase/17,20-lyase) employs cytochrome b_5 (CYB5A) for the 17,20-lyase reaction. The second

TABLE 8.1 Classes of Human Steroidogenic Enzymes and Other Proteins

1. Cytochromes P450
   a. Mitochondrial: CYP11A1, CYP11B1, CYP11B2
   b. Microsomal: CYP17A1, CYP21A2, CYP19A1
   c. Redox proteins: FDX1, FDXR, POR, CYB5A
2. Oxidoreductases
   a. Hydroxysteroid dehydrogenases: 17βHSDs, 11βHSDs, 3βHSDs, 3αHSDs

   b. Sulfotransferases and sulfatases
   c. Uridyldiphosphate glucuronyltransferases

category, the oxidoreductases, is dominated by the HSDs, named for the carbon atoms for which their activity is best characterized and the order of their discovery. The HSDs are structurally grouped as short-chain dehydrogenase/reductases (SDRs), with a β-α-β weave,[12,13] or as aldo-keto reductases (AKR), with a β-barrel or triosephosphate isomerase (TIM-barrel) fold.[14] Steroid 5β-reductase (AKR1D1), which also participates in bile acid synthesis, is an AKR enzyme,[19] while the 5α-reductases are a unique subgroup of oxidoreductases. I have arbitrarily grouped all of the other key proteins in the third category, including the conjugating enzymes and StAR, which mobilizes cholesterol into the steroidogenic pathways.

Most steroid-metabolizing enzymes have K_m values near 1 μM, which is much higher than the circulating concentrations of most steroids. Consequently, the high intracellular concentration of upstream steroids generated in these specialized cells is critical for the completion of steroid synthesis. One corollary of this principle is that negligible amounts of circulating steroids enter the adrenal cortex and gonads for further metabolism, but large tissues such as the placenta, liver, and skin have greater capacity to metabolize steroids present in the circulation in low concentrations. In addition, target tissues might further metabolize circulating steroid to more potent or less active products. Testosterone (T) 5α-reduction in prostate to 5α-dihydrotestosterone (DHT) is a classic example of intracellular hormone amplification via an enzymatic conversion.

Most of the steps in steroidogenesis are irreversible transformations, including the cytochrome P450-catalyzed oxygenations, the 3βHSD/$\Delta^5 \rightarrow \Delta^4$-isomerase (3βHSD) reactions, and the 5α- and 5β-reductase reactions proceed only in one direction. The 3α-, 3β-, 11β-, 17β-, and 20αHSD reactions are reversible both in vitro and in vivo, although these reactions have a strong directional preference in intact cells.[20,21] A composite pathway is shown in Figure 8.2; however, this complete repertoire of enzymes is never present in any one cell. Instead, individual pathways leading to specific products are optimized within individual steroidogenic cell types. These specific pathways will be developed in subsequent sections.

THE CONVERSION OF CHOLESTEROL TO PREGNENOLONE AND MITOCHONDRIAL STEROID METABOLISM

In addition to being the step subjected to acute regulation, the conversion of cholesterol to pregnenolone is ordinarily the rate-limiting step. The cholesterol side-chain cleavage enzyme (P450scc, CYP11A1) catalyzes the three oxygenations required for this transformation in the mitochondria. CYP11A1 resides on the inner mitochondrial membrane (IMM) with FDXR, while FDX1 is a soluble protein in the mitochondrial matrix. The outer mitochondrial membrane (OMM) contains a pool of cholesterol, which is available for steroidogenesis within the specialized mitochondria of these cells. The access of CYP11A1 to this cholesterol pool requires transfer across the intercisternal space. The StAR protein mediates this transfer of cholesterol from the OMM to the IMM (Figure 8.3), which enables the acute regulation of steroid production within minutes of the tropic stimulus.[22] In most cells of the adrenal cortex and gonads, cyclic AMP (cAMP) is the second messenger responsible for StAR activation. In the zona glomerulosa (ZG) cells, the stimulus is intracellular calcium; in the placenta, steroidogenesis is StAR independent. The rate of StAR-stimulated steroidogenesis is about sevenfold above the StAR-independent rate.[23]

The episodic activation of cholesterol transfer via StAR accounts for the pulsatile secretion of testosterone by Leydig cells following each pulse of luteinizing hormone (LH) and the rapid increase in cortisol following a stress-induced adrenocorticotropin (ACTH) rise or during a cosyntropin (synthetic ACTH[1–24]) stimulation test. The acute rise in the end-product steroids rather than pregnenolone demonstrates that the downstream enzymes are present already and that these subsequent transformations are more rapid than pregnenolone generation.

The mechanism of StAR action has been studied extensively, and several features are now known. StAR expression increases acutely with the rise in cAMP, but the augmented expression is not fast enough to account for its action. StAR phosphorylation is probably the most rapid event and might initiate the action of preformed StAR,[24] which nascent StAR then amplifies. StAR is imported into the mitochondrion and degraded, which

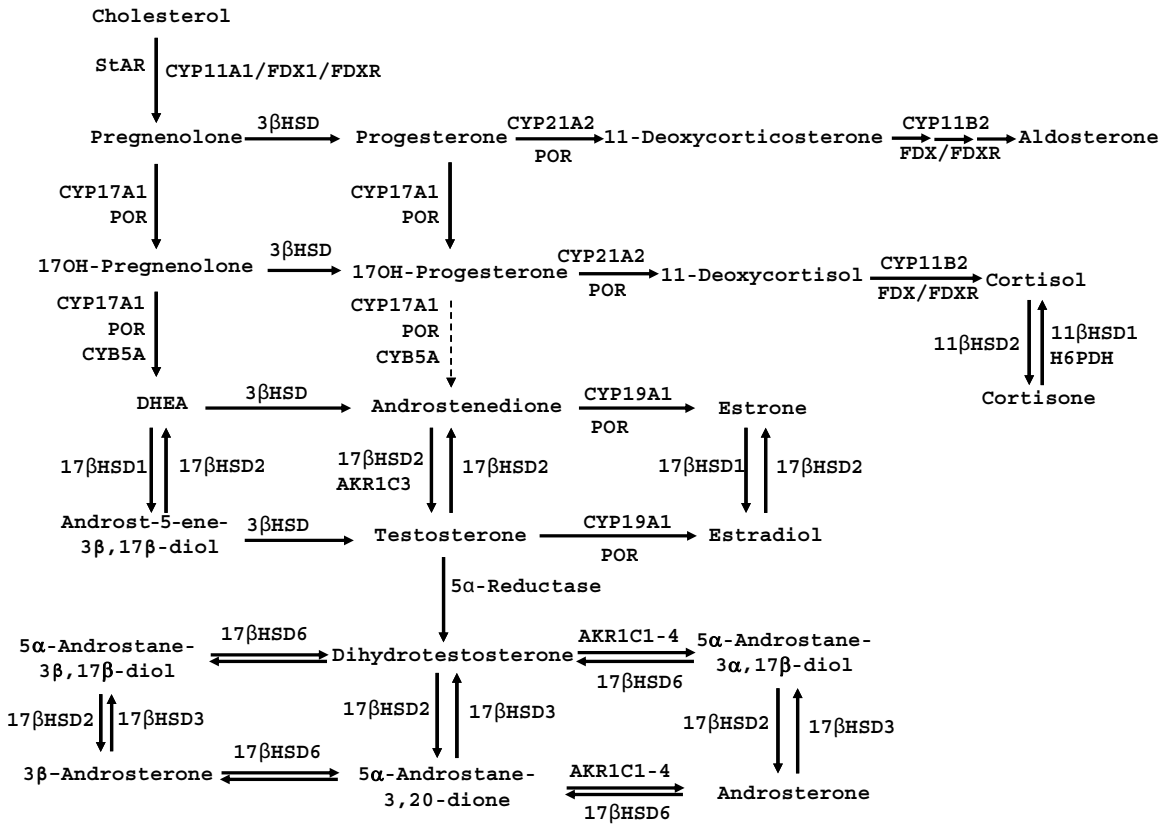

FIGURE 8.2 **A canonical, composite steroidogenic pathway.** In this rendering, progesterone and aldosterone pathways are at the top, cortisol synthesis is in the second row, and androgen and estrogens are in the lower half. The major enzyme is shown with each arrow, although additional enzymes might catalyze individual reactions. The dashed arrow indicates minor pathway.

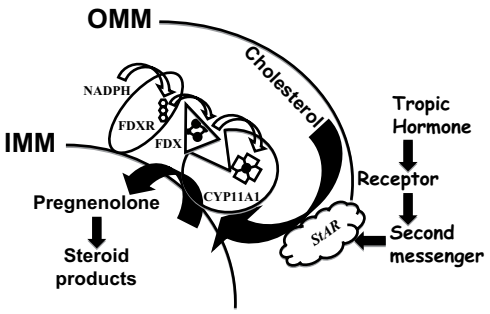

FIGURE 8.3 **The conversion of cholesterol to pregnenolone.** The StAR protein (cloud-shaped image) is required to transfer cholesterol in the outer mitochondrial membrane (OMM) to the inner mitochondrial membrane (IMM), where CYP11A1 resides. Electrons flow (open block arrows) from NADPH to the flavin (three fused hexagons) of FDXR (oval) to the iron–sulfur cluster (rhombus with filled circles at vertices) of FDX1 (triangle) to heme (Maltese cross with central filled circle, representing iron atom) of CYP11A1 (circle with wedge-shaped indentation), to support catalysis.

terminates its action. Considerable evidence suggests that StAR acts at the OMM and that its residence time is proportionate to its cholesterol transfer activity.[25] The structure of the START domain of MLN64, a StAR homolog, contains a molecule of bound cholesterol in a pocket lined with β-sheets,[26] which suggests that StAR binds and transports cholesterol to the IMM and CYP11A1. StAR appears to function catalytically, transporting many molecules of cholesterol per molecule of StAR. The exact route of cholesterol movement and the kinetic details of StAR action, as well as other participating proteins, are incompletely understood.

The side-chain cleavage reaction is somewhat more complex than the typical mitochondrial cytochrome P450 oxygenation in that it is actually three consecutive reactions, which ultimately yields isocaprioaldehyde and pregnenolone. During each catalytic cycle, one molecule of both NADPH and oxygen are consumed. The electrons from NADPH pass first to FDXR and then to FDX1 before flowing one at a time to CYP11A1 according to the canonical P450 reaction cycle (Figure 8.4). In the X-ray crystal structure of the CYP11A1 complex with FDX1,[27] cholesterol binds at about a 45° angle with the heme ring. The side chain is extended across the heme near the steroid D-ring. This structure is consistent with order of reactions, first the formation of 22(*R*)-hydroxycholesterol, then 20(*R*),22(*R*)-dihydroxycholesterol, and finally the pregnenolone product. Only a fraction of the hydroxycholesterol intermediates accumulate during turnover, suggesting that they rarely dissociate from

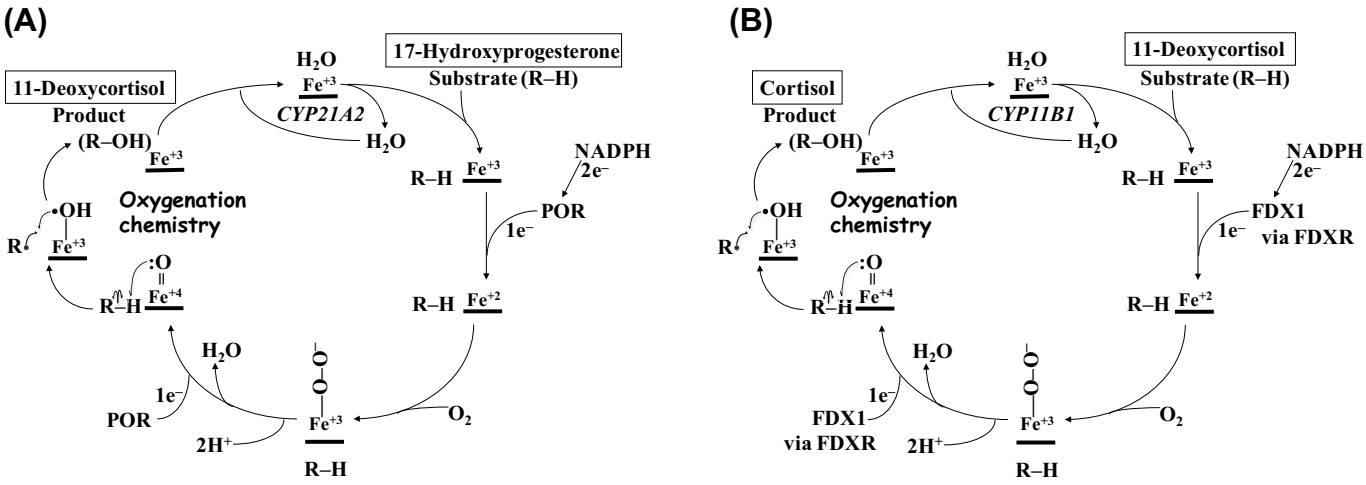

FIGURE 8.4 The cytochrome P450 reaction cycle. Examples shown here are the final two steps in the biosynthesis of cortisol. (A) CYP21A2-catalyzed 21-hydroxylation of 17-hydroxyprogesterone (substrate in box, "R–H") to 11-deoxycortisol (product in box, "R–OH"), a microsomal P450 reaction. (B) CYP11B1-catalyzed 11β-hydroxylation of 11-deoxycortisol (substrate in box, "R–H") to cortisol (product in box, "R–OH"), a mitochondrial P450 reaction. The two reaction cycles are identical except for the electron transfer proteins, which are POR for CYP21A2 and FDX1 (which receives electrons from FDXR) for CYP11B1. In each case, the heme is shown as a thick, short horizontal line with Fe above. In the resting state, the sixth ligand of the ferric iron (Fe^{+3}) is water. Substrate binding (R–H) displaces this water and lowers the redox potential of the heme, which favors one-electron reduction via POR or FDX1. In the ferrous (Fe^{+2}) state, the iron binds molecular oxygen avidly, and the oxyferrous P450 receives a second electron. Protonation of the iron-peroxide allows cleavage of the O–O bond, releasing water, and generating the reactive iron-oxide species with radical or odd-electron character. Electrons are shown as dots (i.e., R·, :O), and single-barbed arrows or "fishhooks" show single-electron movements, such as cleavage of R–H bond to form R· and ·H. The reactive heme-oxygen species performs a hydrogen atom abstraction, removing H· from substrate and forming R· and an iron-bound hydroxide radical (Fe–·OH). The final step of the hydroxylation chemistry is radical recombination, in which R· reacts with ·OH to form R–OH, the hydroxylated product, 11-deoxycortisol or cortisol, respectively. The mechanism is the same for all steroid hydroxylation reactions. The mechanisms of the carbon–carbon bond cleavage reactions, which CYP11A1, CYP17A1, and CYP19A1 all catalyze, probably share some similarities with the normal reaction cycle but must also account for the unique products and transformations.

the enzyme before subsequent reactions. This phenomenon is used experimentally to estimate P450scc activity, because the hydroxycholesterols bypass StAR and are directly converted to pregnenolone.[23]

A similar process occurs via one cycle for the CYP11B1-catalyzed 11β-hydroxylase reaction and three times for the CYP11B2-catalyzed aldosterone synthase sequence, one oxygenation at C-11 and two at C-18. These other mitochondrial P450s are required for cortisol and aldosterone synthesis and are expressed almost exclusively in the zona fasciculata (ZF) and ZG of the adrenal cortex, respectively. The cognate genes of these enzymes, which share 93% amino acid identity, are located in tandem on chromosome 8q (Table 8.2). Their proximity and similar activities explains the origin of the disease familial hyperaldosteronism type 1 (FHA1), also known as glucocorticoid-remediable aldosteronism. An unequal crossing over links the ACTH-responsive regulatory elements of CYP11B1 with a hybrid enzyme bearing aldosterone synthase activity.[28]

Both CYP11B1 and CYP11B2 enzymes catalyze the 11β-hydroxylation of 11-deoxycorticosterone (DOC) to corticosterone (B), and CYP11B1 has a small amount of 18-oxygenase activity. The X-ray crystal structure of human CYP11B2 with bound DOC illustrates the proximity of the hydrogen atoms at C-11 and C-18 to the heme iron.[29] Biochemical assays with purified proteins suggest that the intermediate 18-hydroxycorticosterone (18OHB) is a poor substrate for CYP11B2, whereas some DOC and B substrates are converted to aldosterone. The explanation for these data is that all the aldosterone product of CYP11B2 derives from 18OHB, which has not dissociated from the active site prior to the final 18-oxidation reaction.[29] These observations might explain why circulating concentrations of 18OHB exceed those of aldosterone by at least a factor of two under most circumstances.

STEROID HYDROXYLATION AND THE MICROSOMAL P450 ENZYMES

Nascent 21-carbon pregnenolone in a steroidogenic cell has only two primary fates (Figure 8.2). The first route is conversion to progesterone (P4) via 3β-HSD. This pathway limits flux to P4, as occurs in the corpus luteum or placenta, and to mineralocorticoids and glucocorticoids, with low flux to androgens and estrogens. The other route is 17-hydroxylation via CYP17A1 to 17-hydroxypregnenolone (17Preg), a cortisol precursor, and if CYB5A is present, the 17,20-lyase activity of CYP17A1 produces the 19-carbon steroid dehydroepiandrosterone (DHEA) from 17Preg. Viewed in this manner,

TABLE 8.2 Properties of Human Steroidogenic Enzymes and Other Proteins

Protein	Gene Size (kb)	mRNA Size (kb)	Chromosome Locus	Molecular	
				Exons	Weight (kDa)
StAR	8	1.6	8p11.2	8	32

the presence of CYP17A1 activities regulates the classes of steroids made in a given cell.

CYP17A1 is a typical microsomal P450 of approximate molecular mass 57 kDa. Its catalytic cycle involves one molecule of NADPH and oxygen for each turnover, similar to the mitochondrial P450s, but rather than FDXR and FDX1, it is POR that funnels electrons from NADPH to the microsomal P450s. The human *CYP17A1* gene is expressed in both the adrenal cortex and gonads, yielding the same protein in both glands.[30] Human CYP17A1 performs the 17-hydroxylase reaction well with both pregnenolone and P4 substrates, as well as the 5α-reduced homologs 5α-dihydroprogesterone and allopregnanolone.[31] With P4 substrate, 20–25% of the product is 16α-hydroxylated,[32] due to the presence of alanine at residue 105,[33] and a trace of 21-hydroxylation also occurs, yielding DOC.[34] Unlike bacterial P450 enzymes, which are much faster catalysts, C–H bond breaking is substantially rate limiting for the overall hydroxylation reactions.[34]

The 17,20-lyase reaction is not as robust or promiscuous as the CYP17A1-catalyzed hydroxylations. Human CYP17A1 performs the 17,20-lyase reaction about 50 times more efficiently with 17Preg than with 17-hydroxyprogesterone (17OHP), favoring the Δ^5-pathway to 19-carbon steroid formation (Figure 8.2),[35,36] and 17-hydroxyallopregnanolone (5α-pregnan-3α,17α-diol-20-one, Pdiol) is the best substrate yet identified.[31] The discovery of mutations in CYP17A1[37,38] or POR,[39] which minimally impair the 17-hydroxylase activity but markedly impair the 17,20-lyase activity and lead clinically to isolated 17,20-lyase deficiency, illustrates the vulnerability of the latter activity to subtle changes in enzyme structure. In reconstituted systems, the 17,20-lyase activity is very sensitive to phospholipid composition,[40] and phosphorylation also regulates this activity.[41,42] Most significantly, the presence of CYB5A stimulates the 17,20-lyase reaction 10-fold with 17Preg and 17OHP[35] and 3-fold with Pdiol.[31] This phenomenon, which was first demonstrated in recombinant systems in vitro,[43] has been substantiated with the discovery of patients having isolated 17,20-lyase deficiency due to mutations in CYB5A.[44,45] Although CYB5A functions as an alternate electron donor for the second electron transfer of some P450-catalyzed reactions, apo-CYB5A lacking the heme redox center stimulates the 17,20-lyase of human CYP17A1 as well as holo-CYB5A, suggesting an allosteric mechanism of activation.[35] The CYB5A mutation E48G+E49G retains normal electron transfer kinetics but fails to stimulate 17,20-lyase activity,[46] suggesting that residues E48 and E49 of CYB5A are essential for this stimulation and supporting an allosteric mechanism. In the presence of CYB5A, a small amount of pregnenolone and allopregnanolone are directly cleaved to Δ^{16}-19-carbon products without the intermediacy of the 17-hydroxylation products.[47]

The most similar steroidogenic enzyme to CYP17A1 is CYP21A2, steroid 21-hydroxylase. The two enzymes share 29% amino acid identity and up to 50% identity near the C-terminus, very similar hydropathy profiles, identical gene structures, and common substrates, yet their catalytic strategies and functions in human physiology are nearly

orthogonal. CYP21A2 hydroxylates the electron-deficient 21-methyl group of 17OHP and P4 (Figure 8.2). With P4 substrate, a trace of 16α-hydroxylation occurs,[34] and mutations to progressively reduce the bulk of V359 (V359A, V359G) increase the fraction of 16α-hydroxylation.[48] As with CYP17A1, C–H bond breaking is also partially rate determining for CYP21A2.[34]

Although its enzymology is more limited than CYP17A1, the molecular genetics of CYP21A2 are unique, which makes 21OHD the most common form of CAH. The classic or severe form of 21OHD occurs in 1:16,000 live births worldwide,[49] while the nonclassic or partial form is 10 times more common or even more prevalent in some populations. The reason for the high prevalence of 21OHD is the juxtaposition of the *CYP21A2* gene in a duplicated locus with the *CYP21A1P* pseudogene.[50] The vast majority of 21OHD cases arise from the process of gene conversion, in which all or part of the *CYP21A1P* pseudogene replaces the corresponding region of the *CYP21A2* gene.

The final microsomal P450 of steroid biosynthesis is CYP19A1, commonly named aromatase (P450aro) because it forms the aromatic A-ring of 18-carbon estrogens from 19-carbon androgens (Figure 8.2). CYP19A1, like CYP11A1, performs three cycles of oxygenation, ultimately releasing the C-19 methyl group as formic acid with the estrogen product. Unlike the restricted expression of CYP21A2 to the adrenal cortex and of CYP17A1 to the adrenal cortex and gonads, CYP19A1 is expressed in biologically significant amounts in many cells and tissues.[51] The enormous 130 kb *CYP19A1* gene contains at least five distinct promoters, which orchestrate the diverse regulation of its expression in tissues such as brain, bone, adipose, placenta, and ovary.

The X-ray crystal structures of modified human CYP17A1, human CYP19A1, and bovine CYP21A2 have all been recently solved and described. For CYP19A1, androstenedione (AD) fits tightly in the pocket above the heme ring with the A-ring and C-19 methyl group closest the iron center.[52] The positioning of the steroid is only slightly different than that of DOC in the CYP11B2 structure,[29] as the chemistry is shifted along the steroid by two rings, about 4 Å. This similarity explains why isomers of fadrozole bind to and inhibit both enzymes. If AD is removed from the structure of CYP19A1, clinically used aromatase inhibitors such as anastrozole and letrozole do not fit in the pocket where steroid was found. This observation suggests that the enzyme retains considerable flexibility and that the active site undergoes substantial conformational changes depending on ligand. The crystal structure of CYP17A1[53] was obtained on a modified CYP17A1 protein in a complex with abiraterone acetate, a steroidal azole inhibitor used in the treatment of prostate cancer,[54,55] which tightly binds to the iron of the heme. The steroid nucleus drapes along the I-helix, which contains residues critical for catalysis. Although a structure with bound pregnenolone has not been published, a pregnenolone molecule fits in the space occupied by abiraterone, and this orientation places the 17α-hydrogen atom near the heme iron.[53] The structure of bovine CYP21A2 contains two molecules of bound 17OHP.[56] One molecule is bound distant from the heme and is unlikely to be the molecule undergoing hydroxylation, but a structural or allosteric function is possible. The second 17OHP molecule is likely the catalytically relevant steroid. The steroid nucleus of this 17OHP molecule is positioned nearly orthogonal to the heme ring with the A-ring farthest away and the 21-methyl group dangling above the iron center. This orientation restricts chemistry only to the 21-position, as other more reactive hydrogen atoms are too far away to undergo hydroxylation without expansion of the active site.[48]

HSDs, THE TERMINAL STEPS, AND PERIPHERAL METABOLISM

The HSDs catalyze the terminal steps of steroidogenesis and dominate steroid metabolism in peripheral tissues and target organs. For each conversion, a pair of enzymes drives steroid flux in one direction or the other, with one enzyme favoring hydroxysteroid oxidation to ketosteroid and the other favoring ketosteroid reduction to hydroxysteroid. Often, more than one enzyme catalyzes the same reaction, such as AD reduction to T via 17βHSD3 and AKR1C3 and estradiol (E2) oxidation to E1 via 17βHSD2 and 17βHSD10. Some HSDs catalyze reactions at more than one site on steroids, but all of these enzymes have a strong directional preference in intact cells.

All of the HSDs catalyze both oxidation and reduction reactions in vitro, depending on the pH and nicotinamide cofactor(s) present, but in intact cells, each enzyme has a strong directional preference. In cell culture models, the reactions reach a steady-state or pseudoequilibrium, in which individual steroid molecules continue to undergo oxidation and reduction at the same rate, without any net flux of steroids.[20,21] The main reason for this discrepancy between reactions in intact cells and in vitro is that the nicotinamide cofactor (NAD[P][H]) abundance and usage determines the directional preference in intact cells.[57] In normal physiology, steroid concentrations are in the nanomolar to micromolar range, whereas the nicotinamide cofactors inside cells are at millimolar concentrations. In the cytoplasm of respiring cells with a normal glucose supply, [NADPH] exceeds [$NADP^+$] by three orders of magnitude, because cells regenerate NADPH via glucose-6-phosphate dehydrogenases and isocitrate dehydrogenases, subsequently using NADPH as a common source of electrons for various intracellular

reductions. Conversely, [NAD^+] exceeds [NADH] by a similar factor, because NADH provides reducing equivalents to molecular oxygen via the mitochondrial electron transport chain during oxidative phosphorylation. Consequently, HSDs that use NADP(H) favor ketosteroid reduction by NADPH via mass action, and HSDs that use NAD(H) favor hydroxysteroid oxidation with abundant NAD^+ cofactor.

For both SDR and AKR enzymes, a single residue provides the major structural feature favoring NADP(H) usage. In the crystal structure of 17βHSD1,[13] amino acid R38 forms a salt bridge with the 2′-phosphate, which distinguishes NADP(H) from NAD(H). Mutation of this R38 to G or D neutralizes and reverses, respectively, the positive charge of this residue and alters in parallel the directional preference for E1 reduction to E2 in intact cells.[58] The affinity of wild-type 17βHSD1 for NADP(H) is less than a factor of 10 stronger than for NAD(H), and these R38 mutations alter this preference only slightly, yet markedly alter steroid distributions in the steady-state.[58] Similarly, AKR1C9 has much greater affinity for NADP(H) than for NAD(H) compared to 17βHSD1, and this preference is driven by R276, which forms a salt bridge with the 2′-phosphate of NADP(H)[14] and is important for cofactor binding.[59] Mutation R276G changes the directional preference little, while introduction of a negative charge in mutation R276E reverses the directional preference to oxidation in intact cells.[60]

A similar attenuation and reversal of directional preference occurs when cells are depleted of NADPH. Glucose deprivation with 2-deoxyglucose in glucose-free medium, which lowers but does not eliminate NADPH regeneration, reduces the directional preference for cells expressing 17βHSD1[58] but not AKR1C9. Addition of methylene blue, which severely depletes cells of NADPH, reverses steroid flux from ketosteroid reduction to hydroxysteroid oxidation for both 17βHSD1 and AKR1C9.[60] Intracellular compartmentalization is another mechanism to favor hydroxysteroid oxidation. The lumen of the endoplasmic reticulum is strongly oxidative, favoring disulfide bond formation and other oxidation reactions, and the catalytic domains of some HSDs with oxidative directional preference such as 17βHSD2 are found in this environment.[61] The exception is 11βHSD1, which favors cortisone (E) reduction to cortisol (F) in this oxidizing compartment.[62] The mechanism of this paradox is via hexose-6-phosphate dehydrogenase (H6PDH), which regenerates NADPH within the endoplasmic reticulum lumen and supplies NADPH to 11βHSD1.[63,64]

In human physiology, the SDR isoenzymes are all membrane bound, the most active HSDs, and the forms associated with disease when deficient. The tissue-specific expression of these isoforms also parallels the sites of synthesis or inactivation known to be important endocrinologically. Mutations in the genes encoding 11βHSD1[65] or H6PDH,[66,67] 11βHSD2,[68] and 17βHSD3[69] all cause disease, whereas disease-causing mutations in 17βHSD2 and 17βHSD6 have not been described. Combined mutations in AKR1C2 and AKR1C4, however, have been found in two kindred with 46,XY disorder of sex development (DSD).[70] The catalytic efficiencies of the SDR enzymes are much higher than for the AKR enzymes, because the rates of both catalysis and product release from the AKR1C1-4 isoenzymes is very slow,[71] even compared to the rat homolog AKR1C9.[72]

One important HSD activity upstream of several of the steroid hydroxylases in most pathways is the 3βHSD reaction, which is coupled to the $\Delta^5 \rightarrow \Delta^4$-isomerase activity. There are two human 3βHSD isoenzymes[10]: the type 2 enzyme, which is expressed in the adrenal cortex, testis, and ovary—and is defective in 3βHSD deficiency leading to DSD in both males and females[73]; and the type 1 enzyme, which is expressed in the placenta as well as peripheral tissues such as liver and skin. The 3βHSD enzymes belong to the SDR family and share 94% amino acid identity.

The K_m of 3βHSD2 for the composite reaction is 1–5 μM using its three major substrates: pregnenolone, 17Preg, and DHEA.[74] When the dehydrogenase and isomerase activities are assayed individually using proteins engineered to be soluble, the K_m values of 3βHSD1 for the dehydrogenase reaction with these substrates is lower than for 3βHSD2 by an order of magnitude,[75] suggesting that 3βHSD1 is a high affinity/low capacity enzyme suitable for peripheral conversion, where steroid concentrations are not as high as in the adrenal cells. The 3βHSD1 isoenzyme also has higher affinity for inhibitors such as trilostane than 3βHSD2. The isomerase activity is linked to the dehydrogenase activity, in that the bound nascent NADH activates this second activity of the enzymes. The second, peripheral 3βHSD1 isoenzyme is responsible for the metabolism of orally ingested DHEA to T and explains why girls with 3βHSD2 deficiency have androgen excess in the face of cortisol deficiency.

STEROID SULFONATION

Steroids containing one or more free hydroxyl groups are subject to conjugation reactions, yielding steroid conjugates. One important reaction in the adrenal cortex is steroid sulfonation, which the enzyme SULT2A1 catalyzes. Over 99% of DHEA in the circulation exists as the sulfate conjugate (DHEAS), which is the major product of the zona reticularis (ZR). This sulfotransferase activity is also abundant in liver, which explains why orally administered DHEA is rapidly converted almost completely to DHEAS.[76] Sulfonation increases protein binding and prolongs the half-life of steroids; consequently,

the circulating concentration of DHEAS has little diurnal variation unlike free DHEA. The majority of the other Δ^5-steroids, such as pregnenolone, also circulate as their sulfates, although these conjugates are not normally measured in clinical laboratories. Another consequence of sulfonation is that it blocks conversion to the corresponding Δ^4-steroid. DHEA is metabolized to androgens in peripheral tissues, but DHEAS requires desulfation to DHEA first. This sulfatase activity has been described but appears to be low in human beings, or at least the steady-state balance for the two opposing reactions far favors the sulfonated form.[77]

The co-substrate of the SULT2A1 reaction is phosphoadenine phosphosulfate (PAPS), the common sulfate donor of biochemical reactions. PAPS is synthesized from two molecules of adenosine triphosphate (ATP) and sulfate in two steps. In many species, ATP sulfurylase converts one molecule of both ATP and sulfate to adenine phosphosulfate (APS) and pyrophosphate, and APS kinase completes the synthesis of PAPS. In human beings, two isoforms of one enzyme, phosphoadenine phosphosulfate synthetase (PAPSS), catalyze both reactions. PAPSS2 is the major isoform in the adrenal gland and is responsible for PAPS generation for SULT2A1 in the adrenal cortex. Incomplete deficiency of PAPSS2 causes a form of premature adrenarche—the appearance of axillary and pubic hair—and childhood androgen excess,[78] because impaired DHEA sulfonation causes enhanced conversion of DHEA to androgens. Complete PAPSS2 deficiency has been described in kindred afflicted with dwarfism and skeletal dysplasia called spondyloepimetaphyseal dysplasia, Pakistani type, also called autosomal recessive brachyolmia. Patients with partial PAPSS2 deficiency have evidence of milder skeletal abnormalities.

STEROID DEGRADATION AND EXCRETION

In addition to interconversion via HSDs between weak and potent hormones, steroids undergo extensive hepatic metabolism, which leads to their permanent inactivation and excretion in urine. The 5α-reduction of T to DHT is an amplification reaction in prostate and genital skin,[79] but all Δ^4-steroids are substrates for the two 5α-reductase isoenzymes as well. In the liver, 5α-reductase type 1 converts cortisol, progesterone, and other hormones to their 5α-reduced dihydro (or *allo*-) derivatives. These intermediates are now substrates for the AKR1C enzymes, which then catalyze 3α-reduction to the *allo*-tetrahydrosteroids. Also in liver, AKR1D1, which is steroid 5β-reductase, performs the first step in conversion to tetrahydrosteroids, such as cortisol to tetrahydrocortisol. In general, the 5β-route of catabolism accounts for more steroid degradation than the 5α-route, with some interindividual variation.

The hydroxyl group at the 3-position in the (*allo*)-tetrahydrosteroids and Δ^5-steroids allows for not only sulfonation but also glucuronidation, similar to the "Phase II" conjugation reaction common in drug metabolism.[80] Several uridine diphosphate glucuronyltransferase (UGT) enzymes use hydroxysteroids as substrates, and this glucuronide moiety is a signal for excretion via anion transporters/solute carrier proteins in the kidney. A major fraction of the steroids synthesized in the endocrine organs is thus eliminated as the glucuronide and sulfate conjugates. Of the ~10 mg of cortisol synthesized daily, for example, only 0.1–0.3% occurs in the urine as free cortisol, while the remaining 99+% is glucuronides and sulfates of tetrahydrocortisols, tetrahydrocortisones, and other metabolites. The UGT enzymes are also polymorphic within the population, which in part accounts for some of the interindividual differences in urinary steroid excretion patterns.

Certain common alleles of UGT2B7 appear to be the major enzymes for glucuronylation of glucocorticoid and mineralocorticoid metabolites.[81] The UGT2B4, UGT2B7, UGT2B15, and UGT2B17 enzymes all catalyze the glucuronylation of androgens and their metabolites such as androsterone and etiocholanolone (the major androgen metabolites in urine), as well as the androstanediols.[82] Androgen glucuronylation has been studied in detail due to its relevance to prostate cancer and to androgen doping in sports. UGT2B17 is the nearly exclusive enzyme that catalyzes T glucuronylation at the 17β-position, whereas epitestosterone (epiT, the 17α-epimer of T), DHT, and other androgen metabolites are substrates for both UGT2B15 and UGT2B17.[83] An allele containing a ~150 kb deletion, lacking the entire *UGT2B17* gene but not affecting the *UGT2B15* gene, is commonly distributed in the population,[84] particularly in Asia, where roughly 70% of the population has no functional UGT2B17 enzyme. As a consequence, exogenous T administration manifests as a high T/epiT ratio in urine, except for homozygotes for the *UGT2B17* deletion allele, for whom little T-glucuronide appears in the urine. After administration of a 500 mg T-enanthate injection, only half of homozygotes for the *UGT2B17* deletion allele have a urinary T/epiT ratio >4 and are considered a positive screen for exogenous T use, while all individuals with one or two wild-type copies of the *UGT2B17* allele have positive screens.[85] Consequently, homozygotes for the *UGT2B17* deletion allele taking exogenous testosterone might not be identified using the urinary T/epiT ratio testing. Estrogens and catechol estrogens also undergo UGT2B7-catalyzed glucuronylation, and these 18-carbon steroids are also substrates for some of the UGT2A enzymes.

Additional hepatic metabolism of steroids contributes to their inactivation and also to extra-adrenal conversion to active steroids. Both CYP3A4 and CYP2C19 are progesterone 21-hydroxylases, which yields DOC as a minor product with other hydroxysteroids.[86] CYP3A4 catalyzes 6β-hydroxylation of progesterone, cortisol, and testosterone; this reaction accounts for a considerable amount of hormone inactivation, particularly when orally administered. This phenomenon is important, because patients taking CYP3A4 inducers and inhibitors on cortisol replacement might require dose adjustment. The most profound effect is observed with adrenocortical cancer patients receiving mitotane therapy. Mitotane potently induces CYP3A4 expression and leads to more than 10-fold increase in 6β-hydroxycortisol production,[87] which mandates hydrocortisone dose increases in these patients.

PATHWAYS

Composite diagrams of steroidogenic pathways, such as Figure 8.2, can be misleading, because no steroidogenic cell type contains all of these enzymes and pathways. This section will dissect the major pathways of the different zones of the adrenal cortex, the placenta, and the different cells of the testis and ovary. The simplest pathways are those of the corpus luteum and the placenta, which terminate at P4. Only two enzymes—CYP11A1 and 3βHSD—are required, and there are no branch points or side products. The placenta does not even use StAR for cholesterol mobilization. The 3βHSD isoenzymes are the type 1 in the placenta and the type 2 in the corpus luteum.

In progressing through the adrenal cortex, the major product of the outermost ZG is the mineralocorticoid aldosterone. Low serum potassium concentrations and angiotensin II stimulate steroidogenesis in this zone, which act to elevate intracellular calcium and activate enzyme expression via calmodulin.[88] This zone also contains CYP11A1 and 3βHSD2, as well as CYP21A2, which converts P4 to DOC. CYP11B2 is uniquely expressed in the ZG, and its three sequential 11β-hydroxylase, 18-hydroxylase, and 18-oxidase activities metabolize DOC to B, 18OHB, and aldosterone (Figure 8.5(A)). Because DOC is a substrate for CYP11B2 and P4 is not, the ZG also has a single major pathway with no branch points, but as mentioned earlier, a significant amount of the 18OHB intermediate is released into the circulation. Basal steroidogenesis is also very low in the absence of angiotensin II; otherwise, hypertension would result as in primary aldosteronism.

The adrenal ZF contains CYP11A1, 3βHSD2, and CYP21A2 like the ZG. Unlike the ZG, which expresses CYP11B2, the ZF contains CYP11B1 and CYP17A1 instead. ACTH binds to and activates the melanocortin type 2 receptor (MC2R), which is a G-protein coupled receptor. The resultant increase in cAMP activates StAR, maintains expression of the four P450 enzymes, and drives cortisol production. The presence of three steroid hydroxylases with somewhat broad substrate specificity downstream of 3βHSD2, however, leads to branch points, ambiguity, and potential for additional products (Figure 8.5(B)). CYP11B1 also has low 18-hydroxylase activity, leading to some 18OHB synthesis.[89] Cortisol synthesis is normally very efficient, with circulating concentrations of the trihydroxysteroid cortisol 10–1000 times higher than those of its intermediates. Only small amounts of side products such as the dihydroxysteroids B and 21-deoxycortisol (21dF) are normally produced; however, when one of the steroid hydroxylases is absent or inhibited, the precursors are diverted to these ordinarily minor products. In 17-, 21-, and 11β-hydroxylase deficiencies, impaired cortisol synthesis leads to accumulation of DOC and B,[90] 17OHP and 21dF,[91] or DOC and 11-deoxycortisol,[92] respectively. These products are predictable, based on the known activities of these enzymes and inspection of Figure 8.5(B). Additional minor pathways are also present but not shown in the figure.

The ZR also produces steroids under ACTH stimulation of MC2R, but its enzymatic machinery differs considerably from that of the ZG. Rather than three steroid hydroxylases downstream of pregnenolone, the ZR has only one, CYP17A1. In addition, the ZR expresses abundant CYB5A,[93] which activates the 17,20-lyase activity of CYP17A1 and allows 19-carbon DHEA synthesis, and the ZR is deficient in 3βHSD2, which limits steroids to the Δ^5-pathway. SULT2A1 is also highly expressed in the ZR; consequently, the majority of DHEA formed is sulfonated, using PAPSS2-derived PAPS, and exported as DHEAS (Figure 8.5(C)). The ZR makes small amounts of T relative to DHEAS, due to small amounts of 3βHSD2 and the presence of AKR1C3,[94] which has low 17βHSD activity to convert AD to T.

The Leydig cell of the testis is similar to the ZR in that it has high CYP17A1 and CYB5A expression but no other steroid hydroxylases, which funnels pregnenolone to 19-carbon steroids. Elevated cAMP also drives steroidogenesis in the Leydig cell, which occurs when LH binds to its G-protein coupled receptor, which is also the receptor for chorionic gonadotropin (LH/CG receptor). Unlike the ZR, however, the Leydig cells lack SULT2A1 and uniquely express 17βHSD3,[69] which efficiently reduces 19-carbon ketosteroids to the corresponding hydroxysteroids. In addition, the Leydig cells express 3βHSD2; consequently, the major product is T, although several routes are possible due to the branch points seen in Figure 8.6(A). Most likely, the majority of synthesis follows the pathway

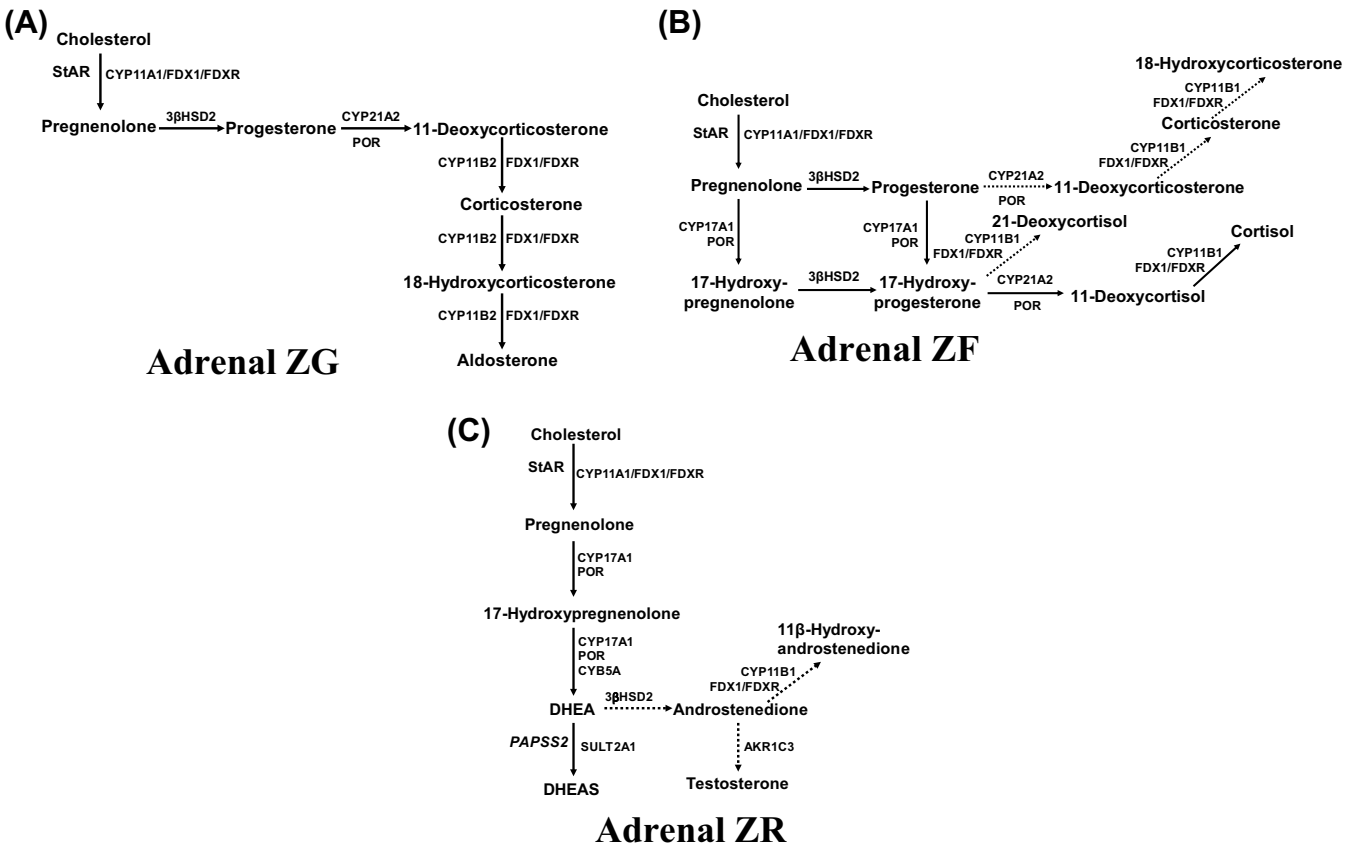

FIGURE 8.5 Steroidogenic pathways of the adrenal. (A) The zona glomerulosa makes aldosterone and few other products. (B) The zona fasciculata makes cortisol using three steroid hydroxylases. Minor products and pathways are shown with dotted lines, although these pathways become significant in disease states such as CAH. (C) The zona reticularis makes primarily DHEAS, yet a small amount of testosterone and other 19-carbon steroid are variably produced as well.

pregnenolone to DHEA via CYP17A1, 17βHSD3 reduction to androst-5-ene-3β,17β-diol, and finally 3βHSD2 oxidation to T.[36] This route employs the much higher 17,20-lyase activity of human CYP17A1 with 17Preg than with 17OHP, whereas the 3βHSD2 and 17βHSD3 activities are similar at each branch point.

The ovary uses a two-cell system to synthesize E2, the granulosa cells, and the theca cells. Follicle development and enzyme expression in the granulosa cells is primarily driven by follicle-stimulating hormone binding to its receptor, which increases intracellular cAMP. Elevated cAMP induces progesterone production and CYP19A1 (aromatase) expression. However, granulosa cells lack CYP17A1 and therefore cannot metabolize progesterone to C-19 steroids, which are substrates for aromatase. Theca cells, under LH stimulation, convert cholesterol to C-19 aromatase substrates.[95] Consequently, 19-carbon steroid synthesis proceeds to AD, but only a small amount is converted to T via AKR1C3. Instead, AD moves back to the granulosa cells, which surround the developing oocyte and contain both CYP19A1 and 17βHSD1 to complete the pathway AD to E1 to E2 (Figure 8.6(B)). Following ovulation, the granulosa cells undergo luteinization to the corpus luteum, which produces P4 via CYP11A1 and 3βHSD2 (Figure 8.6(C)).

The placenta has two disconnected steroidogenic pathways (Figure 8.6(D)). P4 synthesis is the same two-enzyme process as in the corpus luteum, and this process maintains the pregnancy after the luteo-placental shift at about six weeks of gestation. The placenta is also the site of estrogen synthesis during pregnancy, but CYP17A1 expression in the placenta is very low. Instead, the fetal adrenal is the source of 19-carbon steroid precursors to estrogen. DHEAS and 16α-hydroxyDHEAS from the fetus are desulfated by steroid sulfatase, oxidized to AD and 16α-hydroxyAD by 3βHSD1, aromatized to E1 and 16α-hydroxyE1 by CYP19A1, and reduced to E2 and estriol (E3) by 17βHSD1. The E2 and E3 are thus products of the fetoplacental unit rather than just the fetus or placenta.

The most recently described pathway is a route to DHT, which does not involve DHEA, AD, or T as intermediates and instead uses androsterone as the initial 19-carbon steroid, called the alternate or "backdoor pathway" to DHT.[96] Originally described in the neonatal tammar wallaby testis,[97] this pathway requires the

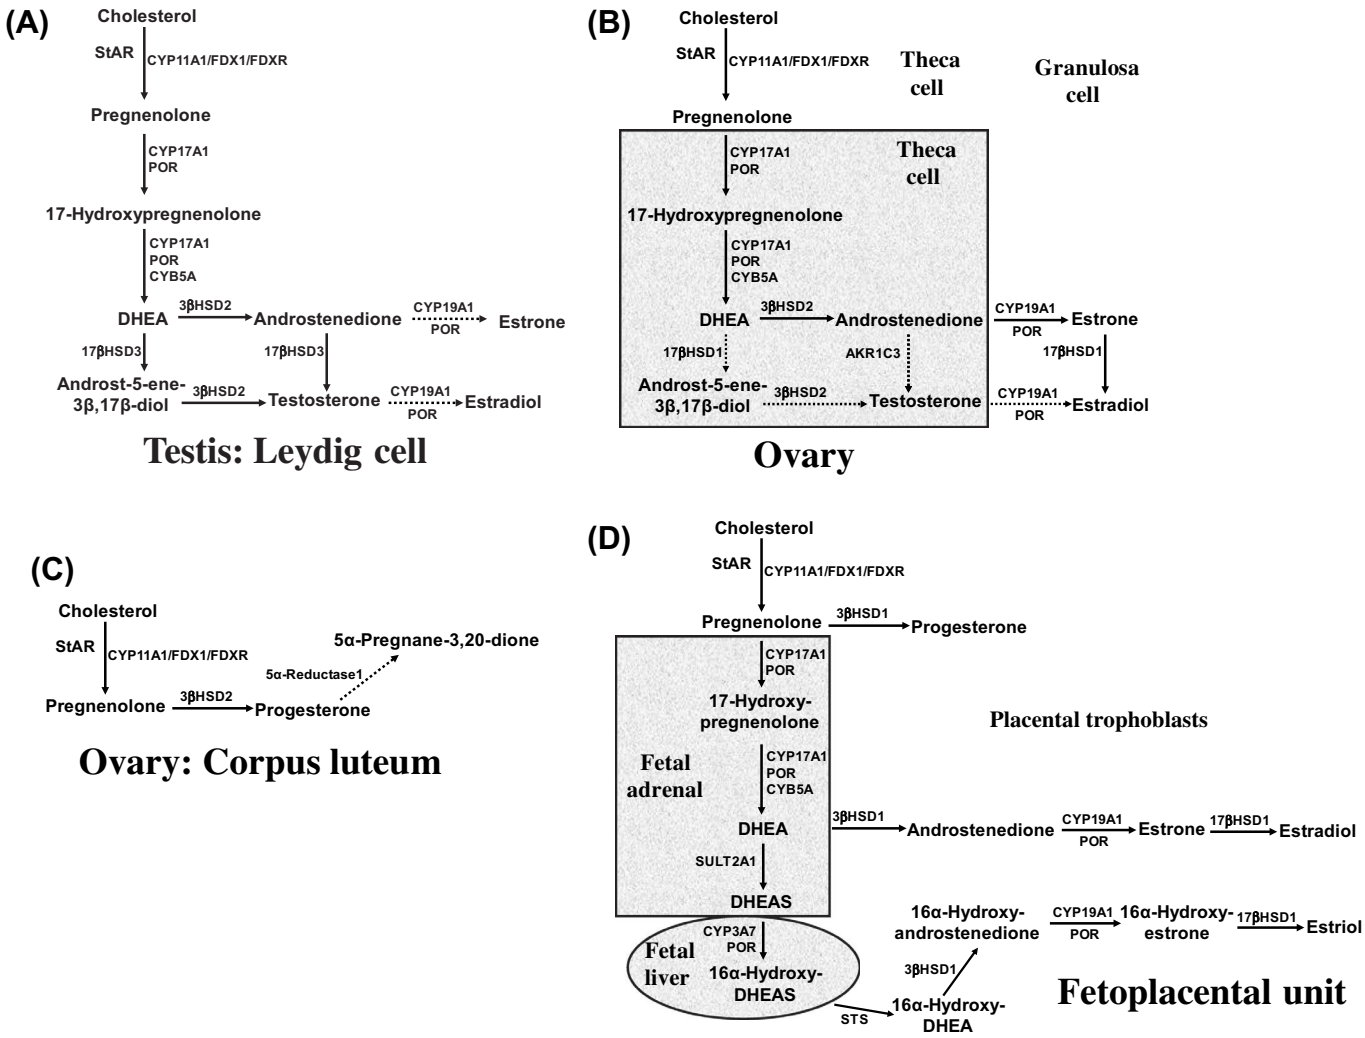

FIGURE 8.6 Steroidogenic pathways of the gonads and placenta. (A) Steroidogenesis in the testis (Leydig cell) yields T, although several sequences of intermediates are likely. (B) E2 production in the ovary uses two cell types. The granulosa cells generate pregnenolone and complete the conversion of androgens to estrogens (reactions in clear area outside box), while the theca cells convert pregnenolone to androstenedione (reactions inside textured box). Theca cells also convert cholesterol to pregnenolone (label in white area adjacent to this reaction). (C) In the corpus luteum, steroidogenesis proceeds only to P4 using two enzymes CYP11A1 and 3βHSD2, and because the corpus luteum also expresses 5α-reductase type 1, a significant amount of P4 is reduced to 5α-pregnane-3,20-dione. (D) Placental steroidogenesis has two pathways. P4 production in the placenta mimics that of the corpus luteum, except using 3βHSD1 (not type 2). E2 and E3 synthesis in the fetoplacental unit is a complex interplay of three compartments. The fetal adrenal (textured square) generates the required 19-carbon precursor DHEAS, some of which is 16α-hydroxylated in the fetal liver (textured oval) via CYP3A7 to 16α-hydroxyDHEAS. The placental steroid sulfatase (STS) and 3βHSD1 enzymes remove the sulfate and oxidize/isomerize the steroid to yield 16α-hydroxyandrostenedione; parallel reactions also occur with DHEAS to form AD (STS reaction not shown in figure to avoid clutter). These 19-carbon, Δ^4 steroids are substrates for aromatase (CYP19A1), and the products—16α-hydroxyestrone and estrone—are substrates for 17βHSD1, yielding the potent estrogens E3 and E2, respectively.

presence of 5α-reductase activity in the steroidogenic cell. In this pathway, P4 or more typically 17OHP is both 5α- and 3α-reduced, forming Pdiol, which is the substrate for the 17,20-lyase activity of CYP17A1 (Figure 8.7). Human CYP17A1 catalyzes the cleavage of Pdiol to androsterone even more efficiently than the conversion of 17Preg to DHEA, and the former reaction is about as rapid in the absence of CYB5A as the latter reaction in the presence of CYB5A.[31] The backdoor pathway contributes proportionately greater to androgen flux in pathologic states characterized by 17OHP accumulation, as first described in POR deficiency.[15,98] This route explains why 46,XX newborns with POR deficiency can be born partially virilized, when postnatal androgen synthesis is poor. Similarly, this pathway might be responsible for the severe virilization in 46,XX newborns with 21OHD and explain why, in contrast, those with 3βHSD2 deficiency—who produce even more DHEA than in 21OHD but cannot make 17OHP in the adrenal—are only slightly virilized late in gestation.[96] In addition, the description of two families with 46,XY DSD and combined deficiencies of AKR1C2

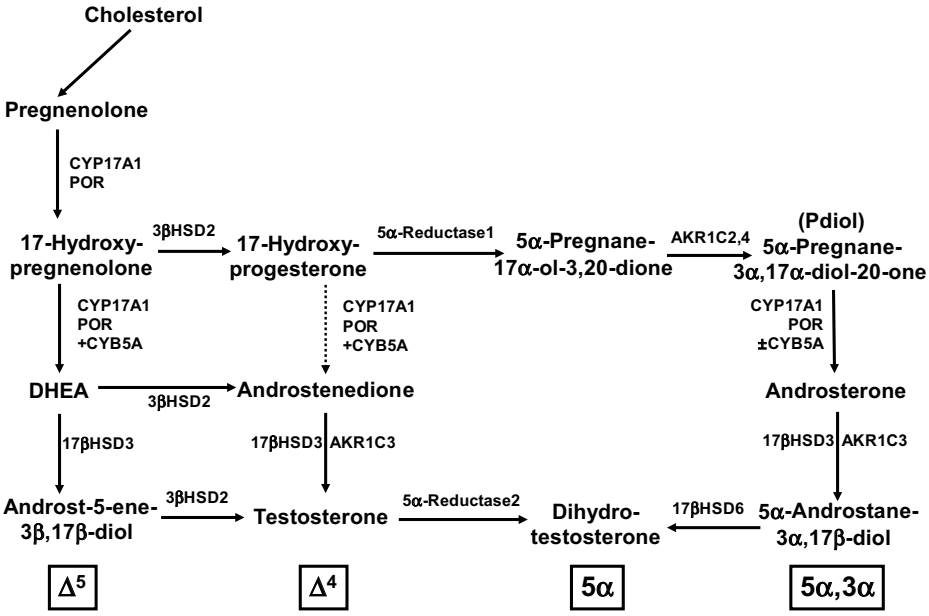

FIGURE 8.7 The alternate or "backdoor pathway" to DHT. This pathway requires that 5α-reductase activity is present and abundant 17OHP. The canonical pathways are also shown for comparison.

and AKR1C4,[70] which probably catalyze one or more steps of this pathway in human beings, suggests that the backdoor pathway might also be important for normal male development, at least for some individuals.

Variations in these canonical pathways occur frequently in disease states. Blocks in the normal pathways to cortisol in 21OHD cause accumulation of 17OHP and 21dF, but in addition, high 17OHP shunts steroids to androgens via the backdoor pathway in the first year of life[99] and possibly during fetal life. Unusual combinations of enzymes occur in tumors, such as prostate cancer cell lines, in which 3βHSD1 and 5α-reductase type 1 are the dominant isoforms unlike normal prostate or testis. These cells convert DHEA to DHT via that pathway DHEA→AD→5α-androstane-3,17-dione (5αdione)→DHT, entirely bypassing T.[100]

COMPARISON WITH OTHER SPECIES

Many of the enzymes, intermediates, and pathways found in human steroidogenesis are common to most other species, such as the cholesterol side-chain cleavage and the 3βHSD reactions as the earliest steps. For the latter steps and products, which diverge significantly among species, steroidogenesis in human beings is more similar to that of other large mammals such as cows and primates rather than rodents. For example, the major glucocorticoid product of the human adrenal cortex is cortisol, which bears hydroxyl groups at the 11β-, 17α-, and 21-positions, as is the case in monkeys, cows, and dogs. In contrast, rodent adrenals synthesize primarily corticosterone (11β- and 21-hydroxylated), because mouse and rat adrenals are deficient in CYP17A1 and thus lack significant 17-hydroxylase activity. For this same reason, the rodent adrenal makes little DHEA or DHEAS, and only the adrenals of large mammals make 19-carbon steroids.[101] The preferred pathway of the 17,20-lyase reaction is also variable, with the human and bovine CYP17A1 enzymes favoring the Δ^5-pathway,[35] the rodent enzymes favoring the Δ^4-pathway,[102,103] and the pig enzymes roughly equal for both pathways.[6] In some species of fish, two CYP17A1 isoenzymes exist, one with 17,20-lyase activity and the other without.[104]

The HSD reactions are also quite different amongst species. Human beings contain only two functional 3βHSD genes—*HSD3B1* and *HSD3B2*—whereas rodents express at least six 3βHSD isoenzymes from a gene cluster.[105] The differences in the 17βHSD isoenzymes are even more variable.[106] All mammals have an equivalent of "estrogenic" 17βHSD1 and "androgenic" 17βHSD3, although the numbering, which generally reflects order of cDNA cloning rather than any physiologic organization, might also vary amongst species.

The pathways and physiology of the fetoplacental unit and pregnancy is perhaps the aspect of steroidogenesis that is the most highly divergent amongst species. In the rabbit, the corpus luteum produces P4 throughout pregnancy without a shift to placental dominance, which is why a *CYP11A1* deletion rather than StAR mutations causes lipoid CAH in a strain of rabbits.[107] The contributions of the human fetal adrenal to steroidogenesis in pregnancy, by providing the 19-carbon steroid substrate, are rather unique among eutherian mammals. In sheep, the fetal adrenal produces cortisol but not DHEA derivatives late in gestation, which induces

CYP17A1 expression in the placenta, thus providing substrate for aromatase and estradiol synthesis toward term.[108] Withdrawal of P4 action is critical for parturition in many species, but the mechanism of this withdrawal varies from decreased production to increased catabolism to reduced sensitivity amongst various species (see Chapter 42).

CONCLUSION

Steroidogenesis in the adrenal, gonads, and placenta is a directional process designed to synthesize one or a few final steroid products unique to each cell type. The specific enzymes present in each cell type determine the major products of that cell. Regulation of steroidogenesis is complex and redundant, although the consequences of an enzyme deficiency or blockade are usually apparent from inspection of the general pathway scheme. Once one leaves these traditional steroidogenic glands, the pathways and enzymes are difficult to predict and can change depending on a variety of factors.

Strongly held beliefs and dogma about human steroid biosynthesis have been dashed many times in the last 50 years, and new enzymes, pathways, and diseases continue to be described. Among the remaining unsolved problems are the molecular details of StAR action; the structural features of the steroid hydroxylases, which convey their unique substrate selectivity and regiochemistries; the contributions of the various HSDs to peripheral androgen and estrogen synthesis; and the biochemistry of the H6PDH-11βHSD1 enzyme system. Steroidogenesis in the nontraditional tissues such as the brain and colon has been recognized for decades, but the contribution of de novo synthesis from cholesterol compared to conversion of circulating precursors remains unknown. Some steroids such as tetrahydrodeoxycorticosterone or allopregnanolone bind to and modulate the activities of ion channels, and these steroids also elicit behavioral or electrophysiological changes. The route of synthesis from circulating 21-carbon precursors is predictable from the principles discussed previously, via sequential 5α- and 3α-reduction of DOC or P4, respectively. The evidence supporting their synthesis from cholesterol in the brain, however, is controversial. A similar debate rages in prostate cancer, where the source of androgens driving its receptor in advanced disease is controversial. Although many of the genetic diseases of steroidogenesis are rare, disordered steroidogenesis occurs commonly in prevalent diseases such as polycystic ovarian syndrome and primary aldosteronism. A better understanding of milder defects such as these will enable major advances in the treatment of infertility and reproductive senescence.

CHAPTER

9

Gonadal Steroid Action

Neil J. McKenna

Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA

INTRODUCTION

Steroid hormones comprise a large class of bioactive cholesterol-derived compounds defined by a central four-carbon-ring system. They comprise the *sex steroids* or *gonadal steroids*, which encompass estrogens, progestins, and androgens (AR) (Figure 9.1), and the *adrenal steroids*, principally glucocorticoids and mineralocorticoids. While the adrenal steroids have certain functions that relate to reproduction, the scope of this chapter will be limited to the gonadal steroids. The mechanism of action of gonadal steroids is best characterized with regard to their interaction with members of the nuclear receptor (NR) superfamily of transcription factors, which, upon binding their cognate ligands, engage specific sequences in the regulatory regions of target genes to regulate their transcriptional output.[1] A heterogeneous class of molecules termed coregulators mediates many of the diverse mechanistic functions of the gonadal steroids and their receptors, and contributes to the integration of steroid signals with those of parallel cellular signaling pathways to effect tissue-selective patterns of transcriptional regulation.[2,3] In addition to their NR-dependent modes of action, gonadal steroids signal through membrane receptors to directly engage cellular kinase cascades, culminating in both transcriptional and nontranscriptional functional endpoints.[4] In the realm of mammalian reproductive physiology, gonadal steroids support numerous aspects of mammalian reproductive physiology, encompassing growth and differentiation of the uterus, ovary, mammary gland, prostate, and testis; the maintenance of pregnancy in the female and spermatogenesis in the male; and mediation of the development of secondary sexual characteristics in the musculoskeletal system and other organs. Moreover, these hormones have myriad effects on tissues of the central nervous system (CNS) that themselves exert profound effects on reproductive organs in both sexes.

The purpose of this chapter is not to provide a catalog of molecular pathways activated by each major class of steroids in the various reproductive tissues that are sensitive to these hormones, but rather to provide an overview of the types of molecular and transcriptional responses that steroid hormones utilize to effect their physiological actions. In this way, the reader will be introduced to a framework of general concepts regarding steroid hormone action that will serve as a point of departure to explore more select aspects of testosterone (T), estradiol (E2), and progesterone (P) actions as they relate to the physiology of reproduction. The chapter opens with a discussion of historical aspects of gonadal steroid action and goes on to emphasize mechanistic aspects of their cellular functions, both genomic, resulting in the direct regulation of target genes, and nongenomic, mediated through cytoplasmic effectors.

The Gonadal Steroids

Figure 9.1 shows the principal bioactive gonadal steroids, which have tissue-selective effects in most organs and cell types in the body, including the gonads themselves. In the female, the ovary is the site of synthesis of the three classes of gonadal steroids, namely, the C18 estrogens, the C19 androgens, and the C21 progestins, all of which are derived from the entry of cholesterol to the steroidogenic pathway. A detailed discussion of ovarian steroid synthesis is beyond the scope of this chapter and can be found elsewhere in this volume (see Chapter 8). In brief, ovarian steroids are synthesized in the granulosa (estrogens) and thecal (progestins and AR) cell layers of the ovarian follicle, and the corpus luteum (progestins). Ovarian steroid biosynthesis engages enzymes in the cytochrome P450 and oxidoreductase classes, genes encoding that are under transcriptional control by the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone. All three classes of

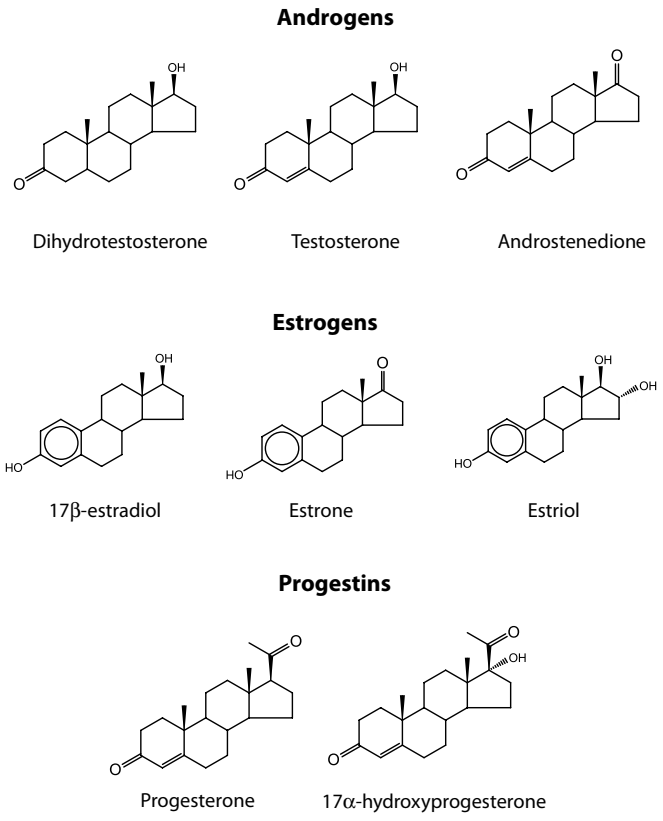

FIGURE 9.1 Gonadal steroids. 17β-estradiol (E2), progesterone (P), testosterone (T), and dihydrotestosterone (DHT).

ovarian steroids are converted in the ovary to metabolites of uncertain function. Testicular steroidogenesis initially involves the production of T from cholesterol by the interstitial Leydig cells of the testis. In brief again, this process is driven by one of two pathways: the Δ4 pathway in the rat and mouse, and the Δ5 pathway in humans and higher primates. T undergoes conversion in the Leydig cells, or in the prostate, by 5α-reductase to 5α-dihydrotestosterone (DHT), the most potent bioactive androgen. Genes encoding enzymes in androgen biosynthesis are under the control of LH.

Historical Perspectives

It has been nearly six decades since the influence of gonadal steroids on enzyme activity, and de novo protein synthesis was first characterized in the context of regulation of cellular metabolism. The rapid uptake of E2 in target tissues gave rise to the appreciation at a relatively early stage that the mode of action of steroid hormones, namely, diffusion across the cell plasma membrane, differed fundamentally from that of peptide hormones.[5] Steroid target tissues were defined by their ability to bind and retain hormone, giving rise to the concept of specific cellular receptors for these molecules that mediated their function, at least in part. By the mid-1970s, characterization of these receptors had defined their existence in specific multiprotein complexes that alternated between larger forms, of the order of 8S as estimated by sucrose density gradient centrifugation, to smaller 6S and 4S forms.[6,7] It became clear that the binding of hormone to the receptor had profound implications, including the induction of conformational changes in the complexes[8] and, in some cases, translocation to the nucleus.[9] The development of these early mechanistic models proceeded alongside seminal functional studies of steroid biology, such as those by Gordon Tomkins, who demonstrated specific inhibition in rat metabolic tissues of diphosphopyridine nucleotide dehydrogenase by P, E2, T, and other steroids.[10]

Experiments in the early 1960s demonstrating a stimulatory effect of E2 on the rate of RNA synthesis were the first to demonstrate a conceptual link between E2—and steroid hormones as a class—and the regulation of gene expression. The concept of a "nuclear acceptor", while initially nebulous, represented an appreciation that the nuclear effects of steroids could be ascribed at least in part to their engagement of specific nuclear entities to mediate their downstream functions. Subsequent experiments by Yamamoto and Alberts[7,11] germinated the concept of the existence of high-affinity DNA sequences (termed hormone response elements) to which the hormone–receptor complex bound, and these were paralleled by studies demonstrating E2-induced increases in the rate of ovalbumin mRNA synthesis in chick oviduct.[12,13] Subsequent to the purification of receptors for P, E2, glucocorticoids, and AR, a model emerged in the late 1970s and early 1980s in which hormone entered the target cell, bound to receptor, translocated to the nucleus, engaged chromatin-binding sites, and initiated the synthesis of specific mRNA and protein species.[14]

TRANSCRIPTIONAL ACTIONS OF GONADAL STEROIDS

Introduction

While this section will highlight mechanistic principles of classical steroid action, many of these principles apply also to members of the broader NR superfamily. NRs comprise a large superfamily of conserved transcription factors that are activated by their steroid hormone ligands and play essential roles in diverse biological processes. For example, the estrogen, P, and androgen receptors are important in reproduction; glucocorticoid receptors are important in glucose metabolism and stress; the thyroid hormone receptor is important in oxidative metabolism; and peroxisome proliferator-activated receptors (PPARs) are important in lipid and energy metabolism.[15] Coregulators are

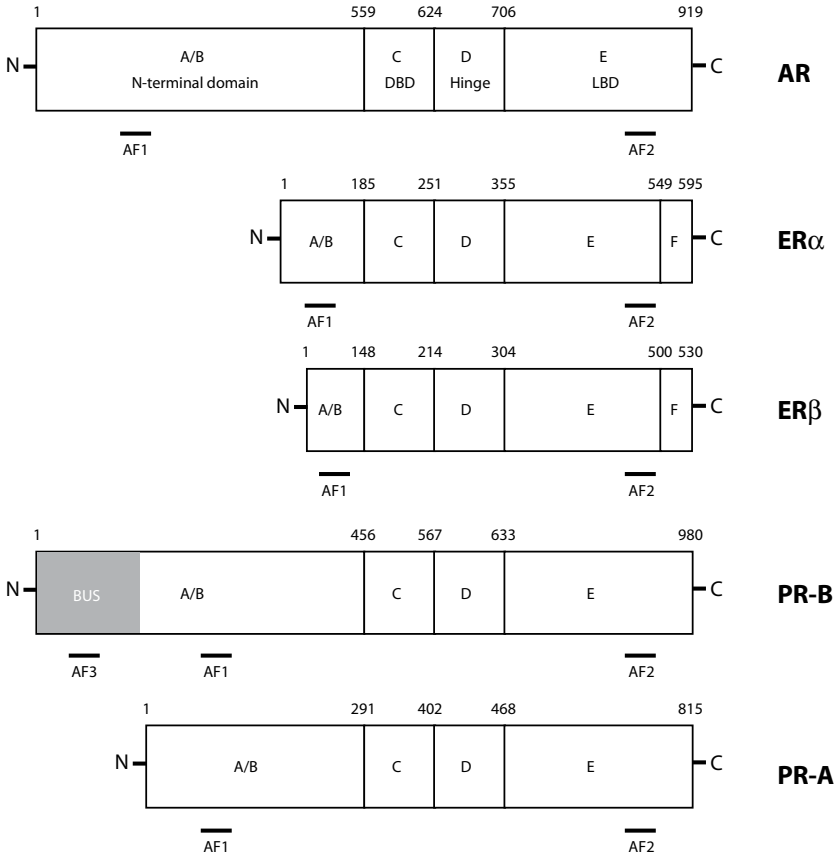

FIGURE 9.2 The gonadal steroid receptors. Androgen receptor (AR) and estrogen receptors α (ESR1) and β (ESR2) share a number of common domains, including an N-terminal A/B domain (containing activation function 1 (AF1)), a DNA-binding domain (DBD; C), a hinge domain (D), and a C-terminal ligand-binding domain (LBD; E) containing AF2. ESRs possess a C-terminal F domain, and PGR-B contains an N-terminal B-upstream segment (BUS) containing a third activation function, AF3.

molecules recruited by ligand-bound activated NRs (or other DNA-binding transcription factors) to effect enhanced (coactivators) or repressed (corepressors) gene expression. In contrast to NRs, which are structurally conserved, their coregulators are diverse, both structurally and in the way they regulate transcriptional process, namely, through a diverse array of enzymatic activities such as acetylation–deacetylation, methylation–demethylation, ubiquitination, and phosphorylation, or as chromatin remodelers.[2,16] Overall, through their opposing actions, a balance of the actions of coactivators and corepressors contributes to the remarkable spatiotemporal diversity of gonadal steroid action.

The early biochemical experiments discussed in the introductory section above were followed in the 1980s by a series of experiments that availed themselves of advances in recombinant DNA technology, and that resulted in the cloning of receptors for E2 (ESRs), P (PGR), and AR. These receptors collectively represent the classical gonadal steroid receptors, referred to here as SRs (reviewed in detail in Ref. 17). Based on significant amino acid sequence identity in various subdomains, SRs and other NRs were designated as a family of evolutionarily related transcription factors, the NR superfamily. These subdomains are now designated as defining structural features of members of this superfamily (Figure 9.2). On a general level, NRs are composed of an amino-terminal activation function (AF1) (A/B domain), the DNA-binding domain (DBD) (C), a hinge region (D), and a carboxy-terminal ligand-binding domain (LBD) (E). An F domain in the human ER is thought to exert a repressive effect on receptor dimerization in the presence of E2.[18] Mutational analysis of the E domain led to the designation of a second activation function, AF2, which is indispensable for proper ligand-dependent activation by NRs. Other functions have been ascribed to the E domain, including ligand binding, heat shock protein (HSP) interactions (6), and nuclear localization. These functional domains reflect an intricate, but well-characterized, ligand-mediated receptor activation pathway. This multistep process involves activation of receptor by binding of the cognate hormone, a change in receptor structure and dissociation of several HSPs,[19] nuclear translocation of the activated receptor, and dimerization and apposition of the transformed receptor to its DNA response elements. More recent years have seen the identification of a constellation of proteins that are important for the regulation of gene expression by NRs, the coregulators,[3] although the sequence of events by which activated, DNA-bound receptor achieves transcriptional regulation in a tissue-selective manner remains only vaguely characterized. Implicit

in this discussion is the fundamental role played by the specific engagement of ligand by the ligand-binding domain, coordinating nuclear translocation, DNA binding, and the recruitment of coregulators to direct an appropriate transcriptional response to the hormonal signal. I draw the reader's attention to the fact that in this chapter, I have chosen not to discuss steroid receptor coactivators and corepressors as distinct molecular entities, since abundant evidence has demonstrated that they have many overlapping and complementary roles and, in some cases, both functions exist within the same protein.[2] If there is one tenet that is taken away from this chapter, it is that steroid receptor regulation of gene expression is a highly contextual process and that principles gleaned from one experimental or physiological context might not necessarily find application in another—for example, due to distinct complements of coregulators in different cells.

Gonadal Steroid Receptors

Regulation of cell and nuclear function by T and DHT is mediated by the AR, which is remarkable for a long polyglutamine tract in its N-terminal region that has been implicated in Kennedy's disease due to its effect on ligand binding.[20] The classical effects of E2 on gene expression are mediated by ESR1 (ERα) and ESR2 (ERβ), which share 94% amino acid homology in the DBD and approximately 55% homology in the LBD, although significant sequence divergence exists in the N-terminal, hinge, and C-terminal regions of the ESRs.[21] Moreover, numerous variants of both isoforms have been reported in a number of different species, cell types, and physiological events. ESRs contain dual activation functions (AFs) that have been shown to interact with distinct groups of coactivators. The N-terminal activation function 1 (AF1) mediates ligand-independent activation of the ESR, whereas the conformation and activity of AF2, located in the LBD, are determined by ligand binding.[21] As might be anticipated from the relatively low sequence homology in the LBD, the ESRs differ in their affinity for physiological and synthetic ligands, and although they have many coregulators in common, some are specific to one or the other receptor subtype. In general, the effects of estrogen in a given tissue are a function of the expression ratio of the isoforms of ESR, the complement of coregulators expressed in the cell, the activity of parallel afferent signal transduction pathways, as well as patterns of epigenomic modification of the promoters of their cognate target genes. As with AR, these coregulatory molecules may influence the response in both a ligand- and promoter-dependent context, which in turn may be influenced by other signaling pathways.

The DBD of PGR is flanked by an upstream N-terminal region that contains the ligand-independent AF1 and a downstream hinge region and C-terminal LBD. Two PGR isoforms, PGR-A and PGR-B, differ in an additional 164 amino acids in the extreme N-terminal region of PGR-B known as the B-upstream segment (BUS; Figure 9.2),[17] which contains a third activation function, AF3. T47D human breast cancer cells have served as the workhorse for study of PGR signaling, and in these cells, synthesis of the PGR-A and PGR-B isoforms has been shown by Pierre Chambon's group to be driven by alternative transcriptional initiation from two distinct promoters[22] located at −711 to +31 and +464 to +1105 of the transcription start site, respectively. Several different transcripts encode PGR and, in addition to containing translational start sites for PGR-A and PGR-B, they also encode a minor N-terminally truncated receptor, PGR-C. In general, PGR-A and PGR-B are expressed at comparable levels in P target tissues, including the mammary gland and uterus, although their ratio is known to differ in breast tumors. The major factors that regulate PGR mRNA levels in a variety of cells and tissues are E2 or related estrogens (Figure 9.1) bound to ERs. PGRs are E2 regulated in the uterus, including the endometrium; in the pituitary and brain; in the mammary gland and breast; and in other tissues.[23]

Steroid Receptor Transcriptional Coregulators

A remarkable aspect of steroid signaling is the functional diversity of transcriptional coregulators with which steroid receptors, activated by either ligand binding or phosphorylation by kinase cascades (see the section Nontranscriptional Effectors of Gonadal Steroids), interact to effect transcriptional regulation (Figure 9.3). These include recruitment of histone acetyltransferase (HAT) and methylase activities in the form of nuclear coactivators (NCOAs) and protein methyltransferases (PRMTs), the kinase activities of the mitogen-activated protein kinase (MAPK) family of proteins, and two additional enzyme activities, adenosinetriphosphatase (ATPase) and glycosylation. This section focuses on factors associated with the transcriptional effects of gonadal steroids, followed by a discussion of the cross talk between NRs and other classes of DNA-binding transcription factors, and concludes with a summary of selected classical transcriptional targets of gonadal steroids.

Histone Acetylases and Deacetylases

The organization of eukaryotic chromosomes into nucleosomal subunits confers a thermodynamic barrier to the activation of gene expression. The DNA–histone salt interactions that maintain nucleosomal structure can be offset to some extent by the acetylation of key basic lysine moieties, a reaction catalyzed by cellular HATs. The overall loss of compact nucleosomal structure that

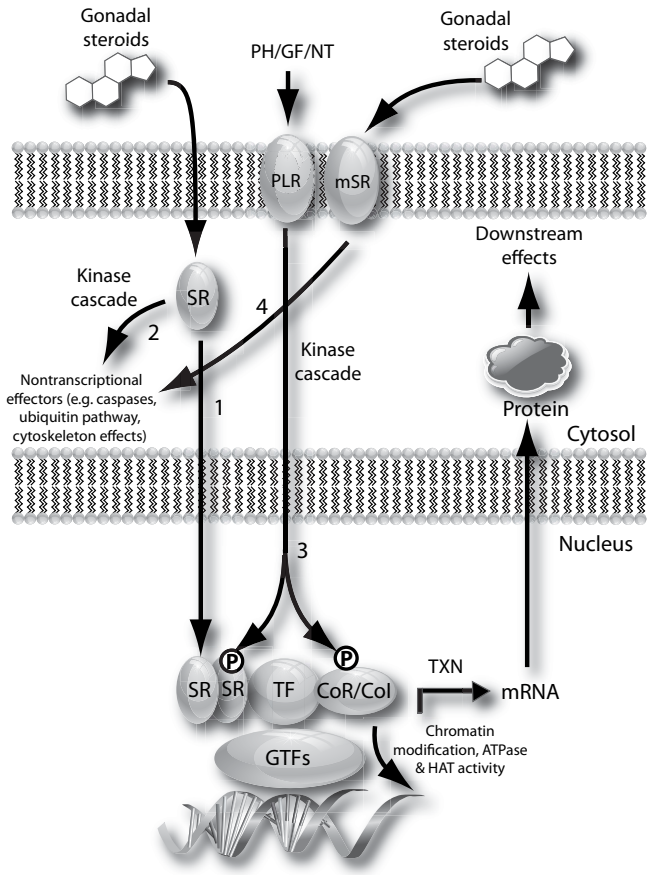

FIGURE 9.3 General models for signaling by gonadal steroids and SRs. (1) In the classical model of steroid-dependent, SR-dependent, genomic action, gonadal steroids bind directly to SRs in the cytoplasm, inducing the recruitment of nuclear coregulators (CoR) and cointegrators (CoI) and directly modulating expression of target genes (TXN), often in association with other classes of transcription factors (TFs). (2) In steroid-dependent, SR-dependent, nongenomic signaling, gonadal steroids have also been reported to elicit rapid cellular effects via cross talk of SRs with cellular kinase cascades. (3) In the steroid-independent, SR-dependent, genomic-signaling model, the binding of a variety of peptide hormones (PH), growth factors (GF) and neurotransmitters (NT) to their receptors (peptide ligand receptors (PLRs)) also touches off a variety of kinase cascades targeting steroid receptors (SRs) and coregulators (CoRs), which collectively modulate target gene expression via general transcription factors (GTFs), leading to de novo protein synthesis. (4) Finally, in the steroid-dependent, SR-independent signaling model, steroids are also thought to interact with nonclassical membrane steroid receptors (mSRs) with rapid functional endpoints in the cytoplasm and nucleus. Phosphorylation events are represented by an encircled P. *Source: Adapted from Ref. 24. Copyright 2012, The Endocrine Society.*

ensues from acetylation facilitates access of transcriptional mediators to the promoter template. Conversely, recruitment of histone deacetylases (HDACs) is thought to result in loss of the acetyl groups, reestablishing the coherence of the nucleosomal structure and restricting access of transcription factors to the promoter. Emerging evidence suggests that initial models casting acetylases as transcriptional coactivators and deacetylases as transcriptional corepressors are oversimplified and that the functions of these classes of transcriptional coregulators are context dependent,[3] and for this reason they will be discussed here in tandem.

Members of the (NCOA) family,[25] including NCOA1 (nuclear receptor coactivator 1), nuclear receptor coactivator 2 (NCOA2)/GRIP1, and nuclear receptor coactivator 3 (NCOA3)/p/CIP, which contain intrinsic histone acetyltransferase activity, act as general transcriptional coregulators for SRs. Members of this family also possess a basic helix–loop–helix (bHLH) domain, linking them to other members of this large family of transcription factors, and suggesting that although they do not bind DNA directly, they may have had that function at some point during their evolution. The possession by NCOA family members of Per–Arnt–Sim (PAS) domains also points to some commonality of function between them and the proteins originally shown to contain this motif (i.e., the period circadian protein, the aryl hydrocarbon receptor, and single-minded protein).[26] NCOA family members bind NRs directly through LXXLL motifs, or NR boxes, and stimulate their transcriptional AF in a hormone-dependent fashion as has been shown for AR,[27,28] ESRs,[29–31] and PGR.[32,33]

Active gene repression was originally thought to be a property of a subclass of nonsteroid NRs, which are tethered to their target gene promoters in the absence of ligand, and the discovery that gene silencing was also a property of SRs opened up an entirely new facet in gonadal steroid signaling. In addition to the well-documented interactions of SRs with proteins generally considered positive regulators of transcription, SR function also encompasses transcriptional corepressors that, analogous to the HAT activity of coactivators, possess intrinsic HDAC activity and recruit other HDACs to effect repression at target gene promoters. Nuclear receptor corepressor 1 (NCOR1) was originally shown to cooperate with unliganded retinoic acid receptor and thyroid hormone receptor to effect repression by bringing about conditions of chromatin condensation and inhibiting access to the target gene promoters of general transcription factors (see the section General Transcription Factors). As is the case with many other factors that regulate eukaryotic transcription, NCOR1 is a component of a ternary complex that includes other HDACs and negative nuclear factors such as SIN3A (SIN3 transcription regulator homolog A) and SIN3B (SIN3 transcription regulator homolog B), mammalian homologs of the yeast transcriptional repressor, Sin3p. Inhibition of activated SRs by NCOR1 has been demonstrated in the case of AR,[34] PGR,[35] and ESR,[36] pointing to a possible role for NCOR1 in negative-feedback regulation at SR-regulated promoters. Closely related to NCOR1 is NCOR2/SMRT, originally cloned as the silencing mediator of retinoid and thyroid receptors (SMRT), which is, like NCOR1, a conserved transcriptional repressor that

participates in silencing of eukaryotic gene promoters with a host of transcription factors.[37] As with NCOR1, SMRT has been shown to mediate the repression of gonadal steroid-regulated promoters.[5,38]

In addition to being shown to be members of the multiprotein complex recruited by NCOR1 and NCOR2, members of the HDAC–acuc–alpha family of proteins[39] act as AR corepressors in their own right, and like NCOR1 and NCOR2, may bridge between different transcription factors to integrate silencing by multiple transcription factors. HDAC1 interacts with retinoblastoma 1 (RB1), another characterized AR coregulator, to play the role of a key element in the regulation of cell proliferation and differentiation. Evidence indicates that AR, KAT5 (K(lysine) acetyltransferase 5)/TIP60 (a histone acetyltransferase), and HDAC1 participate as components of a trimeric complex to regulate expression of the promoter of the "gold-standard" androgen-regulated gene, prostate-specific antigen (PSA), suggesting that a finely controlled balance between acetylation and deacetylation is an important component of androgen regulation of gene expression.[40] Other lines of evidence indicate that principles of transcriptional regulation originally thought to be specific to non-SR members of the NR superfamily also extend to pathways that mediate gonadal steroid action. 5′TG3′ interacting factor (TGIF1)[41] is a member of the evolutionarily conserved three-amino-acid loop extension (TALE) class of homeodomain proteins that was originally shown to repress signaling by RXRalpha, a non-SR member of the NR superfamily, and which has been shown to function as a transcriptional silencer of the transcription factor SMAD2 (Sma- and Mad-related proteins (SMAD) family member 2). TGIF has been shown to interact with Sin3A and to repress AR-mediated transcription in an androgen-independent manner.[42]

In addition to acetylation and deacetylation, a host of other enzymes and proteins that effect specific posttranslational modifications have been shown to be important components of androgen action. The protein arginine N-methyltransferase (PRMT) family includes CARM1 (coactivator-associated arginine methyltransferase 1) and PRMT1, and posttranslational methylation of nuclear proteins by proteins in this family is known to play an important regulatory role in many biological processes through myriad transcription factors, including AR[43] and PGR.[44] Conversely, demethylation of histones in the vicinity of target gene promoters has also been tied to transcriptional regulation by gonadal steroids. The mouse mammary tumor virus (MMTV) promoter has been a model for induction of gene expression via signaling by P and other steroid hormones since the mid-1980s. Miguel Beato's group has recently detailed the intricate interplay between liganded PGR and members of the large transcriptional coregulatory complexes ASCOM (ASC2 complex) and NURF (nucleosome remodeling factor) in the regulation of this promoter.[45] Interactions between liganded PGR and several intrinsic and ancillary enzymatic components of this complex, including the H3K4 demethylase KDM5B (lysine (K)-specific demethylase 5B), effect displacement of histone H1 during the first minute of MMTV promoter activation.[45]

Transcriptional Cointegrators

See Figure 9.3. SRs have been shown to recruit a number of proteins referred to as transcriptional cointegrators, which are large, highly conserved multifunctional proteins that integrate the functions of different transcription factors and signaling pathways at target gene promoters (Figure 9.3). CREB-binding protein (CREBBP or CBP) was originally identified as protein localized in the nucleus that was recruited by cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB),[46] and has since been demonstrated to mediate important facets of cell growth in a wide variety of physiological settings, including reproduction. In addition to associating with CBP as a member of a multi-subunit nuclear complex, CBP has been shown to possess intrinsic histone acetyltransferase (HAT) activity to target the function of many nuclear proteins in addition to histones, and also acts as a scaffold to stabilize additional protein interactions with the transcription complex. CBP has been shown to be an important player in gonadal steroid action by functioning as a coactivator for AR[47] and ESR.[48]

Transcriptional interference between SRs and other transcription factors for limiting amounts of CBP in the cell is thought to be an important facet of the appropriate distribution of cellular signaling inputs between distinct afferent signaling conduits. Extensive regions of CBP, including the bromodomain, the cysteine-rich region, and the HAT domain, share significant regions of very high sequence similarity with EP300, the adenovirus E1A-associated cellular p300 transcriptional coactivator protein.[49] While often implied as synonyms for a single functional entity, these are distinct proteins with distinct functions, albeit with a considerable degree of functional redundancy. Similar to CBP, the HAT activity of EP300 participates in the regulation of transcription and chromatin remodeling by diverse transcription factors, including CREB and hypoxic-inducible factor 1 A (HIF1A), and is a critical player in the regulation of cell proliferation and differentiation. Given the close functional connections between CREBBP and EP300, the identification of the AR as a direct target of p300[50] and ESRs[51] is intuitive. Another group of highly conserved factors that have been shown to participate in classical genomic androgen signaling is the Mediator (MED) complex.[52] One of the critical steps in transcriptional regulation is at the nexus of regulatory factors and the

initiation of transcription by RNA polymerase II, and the MED complex is known to be a critical player at this interface. As with CBP and p300, members of this complex participate in signaling by many transcription factors, including specificity protein 1 (SP1). Chromatin immunoprecipitation (ChIP) assays have demonstrated that MED1 is recruited to the PSA promoter in ligand-stimulated LNCaP cells, indicating that the MED complex has a critical role in modulating signaling by AR,[53] and similar observations have been made in the case of ESR and E2.[36]

DNA and Chromatin Modification

Eukaryotic DNA is packaged into a naturally repressed three-dimensional network supported by numerous intricate, hierarchical protein–DNA interactions, and this default silenced state requires the mediation of large, energy-consuming protein complexes involved in DNA and chromatin modification (see Figure 9.3). These complexes carve out functional niches in the vicinity of target genes to effect access for transcriptional regulatory complexes. Members of the ATP-dependent chromatin remodeling complex SNF–SWI (sucrose nonfermentable and Switch), including SMARCAs (SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a), SMARCDs, and SMARCEs, are recruited by activated ESR[54–56] and PGR[57–59] to bring DNA helicase and ATPase activities to bear on local chromatin structure and facilitate transcriptional activation. TDG (thymine–DNA glycosylase),[60] a member of the TDG–mug DNA glycosylase family, strips thymine moieties from mismatched G–T pairings that occur during DNA replication and recombination. It achieves this through hydrolysis of the carbon–nitrogen bond in the backbone of the DNA double helix and the mispaired thymine, thereby playing an important role in mitigating against spontaneous deamination of 5-methylcytosine and cytosine.

Consistent with recent studies demonstrating the importance of DNA breakpoint repair in gonadal SR function,[61,62] two proteins representing important classes of DNA maintenance proteins have been implicated as coregulators of PGR action. High-mobility group (HMG) proteins[63] constitute members of the nonhistone chromosomal HMG protein family that are widely expressed and present in the nuclei of higher eukaryotic cells. By virtue of their ability to induce bending in DNA and the formation of DNA circles, as well as mediate breakpoint repair and ligation, HMG family members have been speculated to be involved in long-distance interactions between regulatory DNA elements, and transcription regulatory factors HMG1 and HMG2 have been demonstrated to increase the DNA-binding affinity of PGR and to stimulate the transcriptional activity of PGR in target cells.[64] It can be reasonably speculated that they endow PGR with the ability to activate or repress transcription over long genomic distances, conceivably through the de novo creation and repair of breakpoints, as has been shown in the case of AR.[62] Moreover, long-range looping interactions between the promoter and enhancer during prolactin and glucocorticoid regulation of the beta-casein promoter are inhibited by liganded PGR.[65] XRCC6 (X-ray repair complementing defective repair in Chinese hamster cells 6), also known as KU70, is a member of a nuclear DNA protein kinase-containing complex that functions as a DNA- and ATP-dependent helicase whose activity is required for double-strand break repair. The KU70 complex has been shown to interact with PGR in vitro,[66] suggesting a potential role for this holoenzyme in P regulation of gene expression.

RNA Helicases

RNA–protein interactions play central roles in the posttranscriptional regulation of gene expression, serving as the basis for feedback regulation of the mRNA output of a specific promoter by direct binding of an RNA-binding protein to its own RNA,[67] or for mediating the actions of microRNAs.[68] A major class of RNA-binding proteins is the RNA helicases, which represent the largest group of enzymes in RNA processing metabolism, and are critically required for all cellular processes relating to RNA. Members of the DEAD box subfamily proteins of ATP-dependent RNA helicases,[69] defined by the presence of the eponymous conserved Asp–Glu–Ala–Asp (DEAD) motif, have been linked to a variety of cellular processes involving modifications of RNA secondary structure, including transcript splicing, translation initiation, and the assembly of ribonucleoprotein complexes. Members of this family, DDX5 and DDX17, have been shown to coregulate ESR-dependent regulation of gene expression.[36] While the concept of regulation of mRNA levels has been a central component of the model of steroid hormone action since the early 1970s, it was only with the discovery of an interaction between members of the U2AF family of RNA-binding proteins and ESR[70] that the notion of qualitative regulation of promoter output gained credence. U2AF is a bi-subunit protein that is recruited to exon–intron boundaries in nascent mRNA transcripts, and also forms specific interactions with specific intronic polypyrimidine sequences during spliceosome assembly in a manner thought to stabilize its overall structure.[71]

General Transcription Factors

Initiation of transcription at RNA polymerase II-regulated genes is a complex process (Figure 9.3), requiring the mediation of over 60 distinct factors, arguably the most important of which is transcription factor IID (TFIID), a multi-subunit factor composed of the

TATA-binding protein (TBP) and an array of highly conserved proteins known as TBP-associated factors, or TAFs.[72] TFIID binds to core regions of gene promoters to serve as a platform to stabilize the construction of additional members of the transcriptional pre-initiation complex. In addition to the wealth of coregulators that participate in estrogen signaling, in part by recruitment of general transcription factors (GTFs) (Figure 9.3), the direct interaction of activated ESR with TFIID[73] suggests that it and possibly other SRs retain the intrinsic ability to directly contact basal transcription factors to coordinate the assembly of the protein complexes required to initiate transcription.

Transcription Factor Cross Talk

Genomic steroid signaling regulates cellular functions indirectly through modulating the expression of target genes via the classical gonadal SRs. As has been discussed here, this can occur by direct binding of the receptor homodimer to estrogen (EREs), P (PREs), or androgen response elements (AREs) in the vicinity of their target genes. A second mode of action, known as regulation in *trans*, is by tethering indirectly to other promoter sites through protein–protein interactions with members of other classes of transcription factors such as Sp1 and Fos–Jun (AP1), a phenomenon that presumably acts to integrate the multiple stimuli to which cells are subjected from endocrine, paracrine, and autocrine inputs. FOXA1 (forkhead box A1) and FOXO1 (forkhead box O1) are members of the forkhead class of DNA-binding proteins,[74] which are defined by possession of a unique forkhead domain, and they have been shown to play a role in tethering a variety of transcription factors to DNA promoters. Both have been shown to act as modulators of AR-[75,76] and ESR[77,78]-mediated transcription, suggesting that the interaction of activated SRs with their target genes may not exclusively rely upon interactions between the DBD and HREs for these receptors, as has historically been held to be the case.

The importance in estrogenic signaling of *trans* interactions between ESR and transcription factors engaged by other cellular signaling transduction pathways is becoming increasingly well understood, and has prompted a radical revision of our notion of what constitutes an ESR target gene. Building on earlier observations,[77,78] Myles Brown's laboratory has shown that FOXA1 is required for the majority of DNA-binding events in E2 stimulated MCF7 cells.[79,80] The interaction of ESR with hepatocyte nuclear factor 4 alpha,[81] a critical factor in the development of the hepatic, renal, and digestive systems, highlights the importance of the interactions of ESR, not only with other classes of transcription factors but also with other members of the NR superfamily. The overarching principles to emerge are that the requirement for interaction of activated ESR with EREs in its target genes is an obsolete notion, and that target genes are defined less by their physical properties and more by the specific signaling context and the complement of ancillary transcription factors expressed and appropriately activated in a given cell.

Inflammatory processes are fundamental to the regulation of cellular proliferation, and many proinflammatory stimuli, such as those initiated by cytokines and microbial products, are mediated by nuclear factor kappa beta (NFκB).[82] When released from a repressive complex in its activated form, this transcriptional regulator undergoes nuclear translocation and stimulates the expression of a large number of genes. Transcriptional interference between AR and RelA, one of the subunits of NFκB,[83] suggests that mutual antagonism between these transcription factors may be due to competition for a common coactivator such as CBP, and is an important mechanism for load balancing between these transcription factors.[83] The mammalian SMAD family of proteins is evolutionarily related to *Drosophila* "mothers against decapentaplegic" proteins (Mad) and function as signal transduction factors and modulators of gene expression for myriad signaling pathways.[84] A broad spectrum of biological responses is subject to regulation by SMAD proteins, including cell proliferation and death, cell–cell communication, morphogenesis, and immunological responses. The identification of functional interactions between androgen-activated AR and SMAD1,[85] SMAD3,[86] and SMAD4[87] suggests that cooperation between this family of proteins and AR, and conceivably generally across the NR superfamily, represents a broad thematic element in the regulation of eukaryotic gene expression.

Two other transcription factors shown to be recruited by ESR in its mediation of estrogenic signaling are SP1 and X-box binding protein 1 (XBP1). SP1 is a well-characterized bifunctional (activation and repression) zinc finger transcription factor implicated in multiple processes in cellular physiology, including cell growth and differentiation, apoptosis, DNA damage repair, and remodeling of chromatin.[88] SP1 has been identified, in addition to FOXOA1, as another important transinteracting factor that mediates ERE-independent interactions with target genes.[89] XBP1, another basic leucine zipper domain (bZIP) transcription factor, is thought to play a role in the processing of unfolded proteins in the endoplasmic reticulum, and has been shown to contribute to ligand-independent activation of ESR.[90]

The transcription factor BRCA1 plays a major role in the maintenance of genomic stability and has been exhaustively characterized as a tumor suppressor protein whose functional derangement contributes to the progression of a large percentage of hereditary breast cancers.[91] BRCA1 has been shown to be present in a large multi-subunit complex, referred to as BASC (BRCA1-associated genome surveillance complex),

which contains DNA damage sensors and other signal transducers and which is thought to be involved in DNA repair of double-stranded breaks and recombination. BRCA1 has been shown to cross talk with AR signaling,[92] an observation that echoes more recent work documenting the role of DNA breakage and repair in the long-range regulation of transcription by activated AR complexes.[62] The appearance of translocation breakpoints during SR-mediated transcriptional regulation has been attributed to the binding of liganded AR to specific intronic regions and the induction of DNA-modifying enzyme complexes,[62] phenomena that trigger the rapid intra- and interchromosomal interactions that are required for translocations.

While better characterized in the case of AR and the ESRs, the theme of transcription factor cross talk extends to PGR, and is reflected in its functional interactions with basic leucine zipper transcription factor 3 (BATF3),[93] Kruppel-like factor 9 (KLF9; aka BTEB1),[94] and BPTF.[45] BATF3 is a member of the basic leucine zipper transcription factor family, deficiency of which has been associated with deficits in the development of lymphocytes, antigen cross-presentation, and cytotoxic T lymphocyte responses to viral infection. BATF3, also known as JDP1, has been shown to bind to the PGR DBD in a hormone-independent manner, suggesting a possible mechanistic basis for the historically well-established role of P signaling in modulation of the immune system during pregnancy. The protein encoded by the KLF9 gene is a Kruppel-like transcription factor that interacts with GC box elements in the promoters of its target genes to alternately potentiate or repress mRNA expression. KLF9 has been shown to interact discriminately with the two major PGR isoforms, PGR-A and PGR-B, potentiating ligand-dependent PGR-B-mediated transactivation and augmenting PGR-A inhibition of PGR-B activity.[94] The ubiquitin ligase activity of BRCA1 has been shown to be involved in regulating the rate of PGR protein turnover,[95] thereby controlling the rate of PGR recruitment to target genes. Moreover, by mediating ubiquitination of histone H2A, BRCA1 modulates transcriptional repression of PGR-regulated genes. It has been speculated that mutations in BRCA1 would relieve the repression of PGR target gene expression and provide for an environment in which proliferation of the mammary gland epithelium—a risk factor for breast cancer—can proceed.

Steroid Transcriptional Targets

Activated SRs regulate the tissue-specific transcription of a large number of genes, the diversity of whose functions reiterate the crucial role that gonadal steroids play in coordinating physiological responses in a large number of tissues. This section discusses selected transcriptional targets of the three SRs to afford the reader an insight into some of the myriad cellular processes that are subject to regulation by gonadal steroids.

The *TMPRSS22* gene[96] encodes a protein with a number of different functional domains, including a type II transmembrane domain, a receptor class A domain, a scavenger receptor cysteine-rich domain, and a protease domain. TMPRSS2 has been shown to be robustly induced by AR[97,98] and is downregulated in androgen-independent prostate tumors, and a fusion of the TMPRSS2 gene with the erythroblast transformation-specific (ETS)-related gene, a member of the ETS family of transcription factors, is one of the best characterized genetic lesions in prostate cancer. Another strongly induced androgen-signaling target gene, *FKBP5* (FK506 binding protein 5),[99] encodes a *cis–trans* prolyl isomerase that is a member of the immunophilin family of proteins, whose members play critical functions in immunoregulation. Along with HSP90 and HSP23, FKBP5 has been shown to interact functionally with mature hetero-oligomeric PGR in the absence of their ligand, hinting at a role for mutual antagonism between AR and PGR in the regulation of their respective target gene networks. Moreover, the role of an AR-regulated gene in immune processes is redolent of empirical observations of a sex bias in autoimmune disease.[100] In terms of androgen repression of target gene expression, members of the ADAMTS (a disintegrin-like and metallopeptidase (reprolysin type) with thrombospondin type 1 motif) family,[101] including ADAMTS1 and ADAMTS15, are downregulated by AR.[97,98] Members of the ADAMTS family share several distinct protein modules, including propeptide, metalloproteinase, and disintegrin-like domains and a thrombospondin type 1 (TS) motif. Expression of ADAMTS15 has been shown to be predictive for survival in certain tumors, inviting speculation that downregulation of this gene by AR is an important component of their stimulation of prostate cancer growth.

Estrogen-regulated gene expression programs have been exhaustively studied in cancer cells in recent years using a combination of expression microarrays, RNA-Seq, and genome-wide location analysis (GWLA). Collectively, these studies have reported different numbers of E2/ESR-regulated genes in MCF7 (Michigan Cancer Foundation 7) breast cancer cells, ranging from ~500 to ~3000 genes, depending on the duration of ligand treatment and the techniques to quantify expression levels. These and previous studies (for references, please refer to the Transcriptomine database[97]) have defined a group of gold-standard E2-regulated genes, including trefoil factor 1 (*TFF1*), growth regulation by estrogen in breast cancer 1 (*GREB1*), *CCND1* (cyclin D1), insulin-like growth factor-binding protein 4 (*IGFBP4*), adenosine A1 receptor (*ADORA1*), and *MYC* (v-myc avian myelocytomatosis viral oncogene homolog). TFF1 is a member of the trefoil family of proteins, which contain one or

more copies of the trefoil motif, a 40-amino-acid residue domain that contains three conserved disulfide bonds. TFF1 has been shown to suppress transcription of the CDH1 gene to enhance cell migration and invasiveness.[102] GREB1 is a rapidly induced E2 target gene that has been shown by numerous studies[103,104] to stimulate cell growth and proliferation in E2 target tissues such as the mammary gland. CCND1 and MYC are key players in the regulation of the cell cycle, CCND1 being a cyclin whose function is required for the G1/S transition,[105] and the transcription factor oncoprotein MYC being a well-established regulator of multiple genes in cell cycle progression and cellular transformation.[106] In addition to primarily nuclear proteins, E2 also induces genes encoding proteins that participate in pro-proliferative cellular kinase cascades. ADORA1 is the adenosine A1 receptor,[107] a member of the G-protein coupled receptor (GPCR) superfamily of receptors, and IGFBP4 binds to and potentiates the function of insulin-like growth factors (IGFs), which are well-known signals for stimulation of cell growth. Collectively, the functions of these effectors of estrogenic signaling are reflective of the role of estrogen in enhancing cell growth, proliferation, motility, and survival.

Activation by P signaling of the IHH (Indian hedgehog), WNT (wingless-type MMTV integration site), and BMP (bone morphogenetic protein) pathways in the epithelial and stromal compartments of the uterus mediate embryo attachment and implantation, subsequent decidualization of the underlying stroma, as well as uterine glandular development (see Chapter 24). A variety of genes have been implicated as effectors of P-induced, PGR-dependent cellular proliferation, morphogenesis, and differentiation, including Wnt4, ID4 (DNA-binding protein inhibitor), receptor activator of nuclear factor kappa-B ligand (RANKL), IHH, and heart- and neural crest derivatives-expressed 2 (HAND2). Members of the Wnt protein family play widespread roles in the regulation of differentiation and cell fate. Wnt activity on target cells involves interaction with frizzled (Fz), a transmembrane receptor that sets off a series of intracellular events, culminating in the formation by β-catenin of complex with TCF, a transcription factor that mediates induction of proliferative downstream genes.[108] Expression of Wnt4 in the mammary epithelium increases during pregnancy to initiate ductal proliferation and morphogenesis through induction of cyclin D1 and p21. ID4 is a member of the basic helix–loop–helix (HLH) family of Id proteins, which function as corepressors of other bHLH transcription factors to inhibit differentiation.[109] ID4 is acutely induced by P4 in the mammary gland of ovariectomized adult mice and is induced during pregnancy in ESR+/PGR+ luminal epithelial cells, which increase dramatically and transiently during early pregnancy; this increase was restricted to ESR+/PGR+ luminal epithelial cells, indicating that ID4 may be involved in the early proliferative expansion phase of P signaling-dependent morphogenesis. RANKL, which is acutely induced by P in the mammary gland in a PGR-dependent manner, is a cytokine member of the tumor necrosis factor alpha (TNFα) superfamily that signals through a transmembrane receptor to activate signaling cascades and upregulate target genes, including the NFκB target gene cyclin D1. RANKL-null mutants are deficient in cellular proliferation and alveologenesis of the mammary gland during pregnancy. *Ihh*, a rapidly induced target gene, is a member of the hedgehog (Hh) signaling pathway that has been shown to be critical for development. Finally, induction of HAND2 by P mediates the inhibition of estrogen-induced epithelial proliferation in the uterus.[110]

NONTRANSCRIPTIONAL EFFECTORS OF GONADAL STEROIDS

Cell Kinase Cascades

In addition to the classical steroid-dependent, SR-dependent genomic model of SR action (Figure 9.3), substantial evidence exists for rapid actions of cytoplasmic SRs engaging effector proteins associated with cellular kinase cascades, in what is referred to as the steroid-dependent, SR-dependent nongenomic model of steroid action (Figure 9.3). Reciprocal functional interplay between cellular kinase pathways, in particular those regulated by growth factors, and estrogenic signaling was suggested as long ago as 1981 by Ferdinando Auricchio's group, who furnished biochemical evidence for its regulation by cytoplasmic phosphorylation and subsequent nuclear dephosphorylation.[111] Since that time, the discovery that an abundance of proteins that participate in these kinase cascades are in fact cytoplasmic SR effector proteins sketches a mechanistic basis for these pioneering discoveries.

The serine–threonine protein kinase encoded by the v-akt murine thymoma viral oncogene homolog 1 (*AKT1*) gene[112] has been shown to be activated by a pathway regulated by phosphatidylinositol 3-kinase and the platelet-derived growth factor, illustrating the cross talk that occurs through phosphorylation by cellular kinase pathways of AR and other SRs by cellular kinases.[113,114] AKT is an important regulatory factor in the developing nervous system, suggesting a potential role in regulation of androgen action in the CNS. AKT1 has also been shown to inactivate components of the apoptotic machinery by phosphorylation and has also been shown to downregulate androgen-induced apoptosis through phosphorylation and inhibition of the AR,[115] as well as integrating with ESR signaling.[116] The calmodulin 1 (CALM1) gene encodes a member of the EF-hand

calcium-binding protein family,[117] which has been demonstrated to interact with other members of this family as a multi-subunit, reversible phosphorylase–kinase complex, and is also known to recruit AR and modulate androgen signaling.[118] The regulation of intracellular calcium storage and release is a critical component of cellular signaling. The multifunctional calreticulin protein[119] is a major player in the binding and storage of Ca(2+) binding in the endoplasmic reticulum lumen. Interestingly, calreticulin has been shown to bind to the synthetic peptide sequence KLGFFKR, which bears a high degree of similarity to a peptide sequence in the DBD of members of the NR superfamily. Reflecting this, data indicate that calreticulin acts as a coregulator of the transcriptional AFs of modulator of AR and other SRs.[120]

Peptide ligand receptors (PLRs; Figure 9.3) are cell surface transmembrane glycoproteins that are activated by the binding of peptide ligands, which induce receptor dimerization and tyrosine autophosphorylation and activation of downstream kinase cascades targeting steroid receptors and coregulators. EGFR (epidermal growth factor receptor) is a member of the ErbB family of receptors, which includes HER2/neu, and whose members transduce signals that profoundly and rapidly stimulate cellular growth and proliferation and repress apoptosis.[121] Unsurprisingly, dysregulation of the function of these receptors has been consistently linked to myriad human cancers. ESR has been shown to be activated by EGFR phosphorylation[122] in a manner independent of its DNA-binding ability, indicating that the pro-proliferative and anti-apoptotic effects of this interaction may be attributable, at least in part, to tethering of ESR to other DNA-bound transcription factors.

A-kinase anchor proteins (AKAPs)[123] interact with and sequester the regulatory subunit of PKA (protein kinase A) to specific regions within the cell. One member of this family, AKAP13A, exists in a variety of splice variants containing a patchwork of functional motifs, including the dbl oncogene homology (DH) and pleckstrin homology (PH) domains. By effecting guanine nucleotide exchange activation of the Rho–Rac family of GTP-binding proteins, the DH domain drives conversion of the inactive GTPase to the active signal transduction-competent form. Evidence suggests that by interacting with components of different pathways, AKAP13A and other AKAPs serve as scaffolding proteins to coordinate flux through parallel afferent signaling pathways. Evidence casting AKAP13A as a physical and functional partner of ESR[124] invites conjecture that in doing so, it provides a nexus between ESR and cellular kinase pathways. Another growth factor receptor tyrosine kinase, IGF1R,[125] binds insulin-like growth factor to exert anti-apoptotic effects and is robustly overexpressed in a variety of malignant tissues, where it enhances cell survival. The binding of the ESR1, but not ESR2, isoform with IGF1R[126] demonstrates that ESR2 is required for full function of the IGF1R regulated signaling pathway. MAPKs, also referred to as extracellular signal-regulated kinases (ERKs), are intracellular kinases that act as molecular gates to integrate numerous afferent signaling inputs from the host of cell surface receptors amassed on the surface of eukaryotic cells.[127] Signals conveyed by kinase-activated MAP kinases ultimately regulate the activity of transcription factors in the nucleus to modulate cellular gene expression patterns, through which they impinge upon practically every known cellular function, including proliferation, differentiation, and apoptosis. Numerous studies have documented the phosphorylation and functional regulation of ESR by members of the MAPK family, including MAPK1,[128] MAPK3,[129] and MAPK14,[130] an observation that has also been made for PGR.[131]

Downstream of MAPKs are members of the MKNK (MAP kinase interacting serine–threonine kinase) family of proteins, which are activated through interactions with MAPKs.[132] In addition to conserved DLG (Asp–Leu–Gly) and ENIL (Glu–Asn–Ile–Leu) motifs, MKNK2 contains an amino-terminal region containing multiple basic amino acid residues. This motif engages importin A, a cytoplasmic–nuclear shuttle protein, and phosphorylates the translation factor scaffold factor eIF4G during the initiation of mRNA translation. A role for MKNK2 in protein processing is also hinted at based on its interaction with members of the CBC (VHL (Von Hippel–Lindau)) ubiquitin ligase E3 complex, including VHL, ring-box 1 (Rbx1), and cullin 2 (CUL2). The identification of MKNK2 as an ESR-interacting protein[133] reflects previous work identifying ubiquitin ligases as important coregulators of estrogenic signaling, and reiterating the importance of efficient processing of receptors for optimum signal transduction. Providing further evidence of the importance of receptor recycling in estrogen-mediated signal transduction, ESR has been shown to recruit COPS5 (COP9 complex homolog subunit 5)–Jab1, a member of the E3–ubiquitin ligase-associated COP9 signalosome, in an interaction that increases the rate of ligand-induced ESR degradation.[134]

Two proteins upstream of MAPKs that are involved in the regulation of cell growth and apoptosis, GADD45B and GNAI1, have been characterized as functional partners in signaling by ESR. GADD45B (growth arrest and DNA-damage-inducible, beta)[135] is induced in response to cellular stress, such as that which follows treatment with DNA damage agents, and in turn it activates MAP3K4 (mitogen-activated protein kinase kinase kinase 4, or MEKK4) an activator of the p38–JNK (Jun amino-terminal kinases) pathway. While GADD45B plays a variety of context-specific roles in the cell, it is, along with related proteins such as GADD45G (growth arrest and DNA-damage-inducible, gamma; also called

cytokine-responsive protein (CR6)), primarily a negative regulator of cell growth. It was identified as an interacting partner of ESR in a yeast two-hybrid screen, a method commonly used during the early characterization of ESR-interacting proteins.[136] While the yeast two-hybrid screen platform has generated a daunting amount of data, it should be borne in mind that there is a fundamental distinction between interactions of which a given protein is *capable* and those that are physiologically *meaningful*. In order to fully validate an interaction for a given protein, therefore—in this case, coregulation of ESR—comprehensive in vivo validation in terms of gain and loss of function must be demonstrated.

As is the case with androgen and E2 signaling, P-mediated signaling exhibits a high degree of codependency with cellular kinase cascades, and abundant evidence suggests multiple points of vertical integration of these signaling axes, exemplified by the identification of the tyrosine kinase SRC (v-src avian sarcoma (Schmidt-Ruppin A-2) viral oncogene homolog, not related to SRC1, the name by which NCOA1 was originally cloned) and FGFR2 (fibroblast growth factor receptor 2) as coactivators of PGR-dependent regulation of gene expression (see steroid-dependent, SR-independent nongenomic signaling; Figure 9.3). SRC bears a high degree of similarity to the protein encoded by the v-src gene of Rous sarcoma virus and has been implicated as a proto-oncoprotein with a role in the development of a variety of human tumors. Motifs within SRC, referred to as SRC homology 3, are found in a variety of cytoplasmic signaling molecules.[137] Work in the laboratory of Dean Edwards identified a polyproline motif in the amino terminus of the human PGR involved in the formation of P-dependent complexes between PGR and the SH3 domains of HCK (hemopoietic cell kinase), GRB2 (growth factor receptor-bound protein 2), and SRC itself. Mutational analysis showed that rapid P signaling was dependent on the integrity of this motif, implicated in the accelerated transduction of P-initiated membrane signaling to cytoplasmic and nuclear targets.[138] Upstream of SRC tyrosine kinases are membrane receptors for a variety of peptides and polypeptides that regulate the functions of eukaryotic cells. FGFR2 is a member of the conserved fibroblast growth factor receptor family, members of which comprise an extracellular region composed of three immunoglobulin-like domains, a hydrophobic membrane domain, and a cytoplasmic tyrosine kinase moiety. The interaction of the extracellular region of the protein with fibroblast growth factor 2 initiates a cascade of cytoplasmic phosphorylation event signals with nuclear and cytoplasmic endpoints in the regulation of cell growth, proliferation, and differentiation. A complex functional interaction between FGFR2, STAT5 (signal transducer and activator of transcription 5A), and PGR has been shown to potentiate PGR regulation of gene expression,[139] exemplifying the ability of PGR to tap into these diverse signaling pathways at the level of both the growth factor receptor and the transcription factors.

Cell Cycle Proteins

The interaction of SRs with a variety of factors with functions related to regulation of the cell cycle points to the profound effect of steroids on the proliferative capacity of their target tissues. Somewhat counterintuitively, given the role of AR and ESR1 in the progression of prostate cancer and breast cancer, respectively, several of these factors function as tumor suppressor proteins. RB1, for example, one of the first genes to be identified as a tumor suppressor gene,[140] is a negative regulator of the cell cycle and has been shown to mediate stabilization of cellular heterochromatin. RB1 has been shown to interact with and regulate the function of AR,[141] suggesting that it induces the transcriptional activation potential of AR in prostate cells, and postulating a link between negative regulation of growth and AR function, potentially as part of a feedback loop.

Several other cell cycle regulators are important modulators of SR function. Cyclin D1 and cyclin E1 belong to the highly conserved cyclin family, expression of which is subject to sensitive regulation during the cell cycle.[142] Cyclins are known to regulate the functions of a number of CDKs (cyclin-dependent kinases), members of the Ser–Thr protein kinase family that have been shown to function as part of large protein complexes, and whose activity is required for cell cycle G1/S transition. Coordinating of mitotic timing and regulation of mitotic checkpoints is thought to be a function in large part of the variable expression patterns of cyclins during distinct phases of the cell cycle. Cyclin D1[143] and cyclin E1[144] have been shown to interact with and regulate the function of AR, reflecting a close connection between the phosphorylation status of AR and regulation of the cell cycle. Moreover, a direct connection between CDKs and AR function has been demonstrated for CDK1,[145] CDK6,[146] CDK7,[147] and CDK9.[148] The numerous functional interactions between AR and cell cycle regulatory proteins provide a mechanistic window into the regulation by AR of a variety of "immediate early" genes involved in cell cycle regulation, including FOS (FBJ murine osteosarcoma viral oncogene homolog) and JUN (jun proto-oncogene) (for references, see the Transcriptomine database of NR-regulated genes[97]).

Ubiquitin Pathway

The spindle checkpoint assembly plays an important role in chromosomal surveillance and in ensuring appropriate chromosomal segregation. CUEDC2 (CUE domain

containing 2),[149] a ubiquitin-binding motif-containing protein, is a cell cycle regulator known to be involved in spindle checkpoint inactivation, and cellular depletion of this protein has been shown to cause a checkpoint delay in the metaphase–anaphase transition. CUEDC2 has been shown to act as a corepressor of PGR and to increase its rate of degradation by the ubiquitin proteasome system,[150] hinting at a functional link between P signaling and regulation of the cell cycle. Furthermore, expression of the *UBR5* gene, which encodes a member of the HECT (homology to E6-AP carboxyl terminus) family of E3 ubiquitin-protein ligases, is induced by P. UBR5 has been shown to interact with and potentiate the transcriptional activity of PGR,[151] hinting at a possible role for this protein in a feed-forward mechanism to potentiate cellular sensitivity to P signaling. While ubiquitination targets proteins for degradation, other posttranslational modifications act as molecular postcodes, directing target proteins to specific cellular destinations or to carry out specific spatiotemporal functions. SUMO1 (small ubiquitin-like modifier 1) is a member of the small ubiquitin-like modifier class of proteins, which stages target proteins for functions in processes as diverse as nuclear transport, regulation of gene expression, apoptosis, and the modulation of protein stability.[152] The characterization of PGR and the pan-coregulator NCOA1–SRC-1 as molecular targets of SUMO1, and the potentiation of PGR transcriptional activity that occurs pursuant to sumoylation, cast this protein as a critical modulator of PGR-dependent gene expression.

Members of the PIAS (protein inhibitor of activated STAT) family of transcriptional coregulators have been shown to function as modulators of androgen signaling.[153] PIAS3, for example, is a SUMO–E3 ligase that mediates the covalent attachment of a SUMOylated protein to specific target substrates. PIAS1, which contains a zinc-binding domain and a region rich in acidic amino acid residues, has been shown to inhibit transcriptional regulation by members of the STAT family of transcription factors, not only reiterating the importance of coregulators in integrating signaling across distinct SRs, but also encompassing multiple distinct classes of transcription factors.

The Cytoskeleton: Cell Trafficking, Motility, and Cell–Cell Communication

A large number of steroid receptor effector proteins tie into functions associated with the cellular skeleton, including cell–cell communication, cell motility, and subcellular trafficking. Two proteins with functional connections to the cytoskeleton and subcellular trafficking, major vault protein (MVP)[154] and integrin beta 3 binding protein (ITGB3BP),[155] have been demonstrated to function as ESR effector proteins. MVP[156] is a member of the vault complex, a series of large RNA–protein structures thought to be involved in transport between the nucleus and the cytoplasm, and has been shown to be the target of a variety of cellular kinase cascades, including phosphoinositide 3-kinase (PI3K)–Akt, Janus kinase (JAK)–STAT, and MAPK-mediated pathways. MVP has been shown by a variety of studies to be a potential prognostic marker in multiple distinct tumor types. The encoded protein may play a role in multiple cellular processes by regulating the MAPK, JAK–STAT, and signaling pathways. Integrins are cellular receptors that, as their name implies, are integrated into the plasma membrane of eukaryotic cells, which play an important role in cell–cell interactions. Integrin-binding proteins, such as ITGB3BP,[157] bind to the cytoplasmic domain of these receptors to mediate the transduction of signals to downstream effector proteins, thereby communicating the status of the extracellular environment to signaling pathways within the cell. ITGB3BP is also present in the centromere-specific histone H3 variant nucleosome associated complex (CENP-NAC), hinting at a possible role in the regulation of mitosis. As well as being shown as a coactivator for ESR and other members of the NR superfamily, including TRs and RXRs, ITGB3BP silences transcription by NFκB-regulated transcription factors. This Janus-faced functionality (i.e., a given protein acting as an activator or coactivator in one context and a repressor or corepressor in another) is a recurring theme in NR coregulator biology and, in addition to illustrating the remarkable economy of eukaryotic cellular physiology, reiterates the need to avoid classifying coregulator function solely on the basis of the strictly defined experimental conditions in which they were initially characterized. The *FHL2* gene encodes a member of the four-and-a-half-LIM-only protein family, containing two characteristic, highly conserved, tandemly arranged zinc finger domains in which four highly conserved cysteine residues chelate a zinc atom in each of the zinc fingers. FHL2,[158] a cardiac-specific protein, is thought to have a role in the assembly of extracellular membranes, and was identified in a yeast two-hybrid based screen for ESR-interacting proteins in a human heart cDNA library.[159]

The existence in the genome of high-affinity binding sites for SRs has been known since early biochemical experiments on steroid hormone biology, and the discovery of coregulators has shed additional light on these seminal observations. SAFB[160] is a DNA-binding protein with high specificity for scaffold or matrix attachment region DNA elements (S/MAR DNA), which are eukaryotic sequences where chromosomes anchor to the surrounding nuclear matrix. Members of the scaffold attachment factor family have been postulated to act as molecular foundations on which large transcriptional complexes of the type known to be involved in androgen signaling are assembled on target gene promoters.

SAFB, which has been implicated in the etiology of breast cancer, has been shown to function as an ESR corepressor,[161] although, as with other corepressors, this does not exclude the possibility that it can function as a coactivator in different physiological or signaling contexts. Another member of the SAF family, SAFB2, has also been shown to function as an ESR corepressor.[162] While SAFB1 is primarily localized to the nucleus, SAFB2 is also distributed in the cytoplasm and has been shown to interact with vinexin, a protein implicated in integrating cellular signaling with cytoskeleton components. Collectively, these results reinforce the importance of communication between ESR signaling and the cytoskeleton and shed additional light on the intimate connection between estrogenic signaling and cellular mobility.

In opposition to the tumor suppressors that regulate AR function is the oncoprotein and scaffolding factor CAV1 (caveolin 1), an important component of the caveolae membranes, which has been shown to play a role in cell–cell communication by mediating functional interactions between integrin subunits and the Ras–ERK pathway to promote progression through the cell cycle.[163] Using a mammalian two-hybrid assay system, it has been shown that AR interacts with the N-terminus of CAV1,[164] a protein that promotes cell survival and angiogenesis, thereby giving some insight into a mechanism for the role of AR as a tumor promoter, at least in the case of prostate cancer.[165]

ESR cell biology is closely linked to the regulation of cell division and cellular motility and, by extension, the cytoskeleton, and this is reflected in the involvement of several coregulators with the cytoskeleton. ESR has been shown to interact with catenin β, which is encoded by the *CTNNB1* gene,[166] and which was originally identified as a component of a complex of factors that form adherens junctions, which are required for the establishment and maintenance of mechanical attachments between epithelial cells. CTNNB1 has been shown to play an anchoring function in connection with actin components of the cytoskeleton, and a role for this protein has been intimated in transducing contact inhibitory signals that are involved in bringing a halt to cell division upon completion of the epithelial cell layer. A functional relationship between ESR and CTNNB1 was first demonstrated during cross talk between ESR and signaling by the Wnt family of proteins,[167] which are conserved signaling factors that coordinate cell–cell interactions.

Caspases

Members of the caspase family of proteins exist in inactive pro-enzymatic forms, which undergo processing via proteolysis at select, evolutionarily conserved aspartic residues to produce large and small subunits that undergo dimerization to generate the active enzymatic form of the protein and play a central role in cellular apoptosis.[168] Enzymes in the caspase family carry out proteolytic cleavage to activate the precursor form of interleukin 1 (IL1), a factor involved in a variety of processes related to cellular inflammation, and have been implicated in the etiology of neurodegenerative diseases. Several members of the CASP family, including CASP1, CASP3, CASP7, and CASP8,[169] have been shown to interact with and regulate the function of AR.

STEROID SIGNALING VIA MEMBRANE RECEPTORS

Genomic steroid signaling originates either via activation of SRs through interactions with their cognate ligands or by activation of SRs via phosphorylation in the cytoplasm, followed by nuclear translocation (Figure 9.3). In contrast, rapid (within minutes of hormone exposure) signaling of gonadal steroids through a variety of membrane receptors (mSRs) activates myriad kinase-driven signaling cascades (PI3K, phospholipase C, MAPK, ERK, PKA/C, etc.) that can affect cell function directly—for example, through phosphorylation of cytoplasmic and membrane proteins, or indirectly through modulation of gene expression by targeting transcription factors (Figure 9.3). The body of work on mSRs notwithstanding, the focus of this chapter is largely on signaling by classical steroid receptors, and for a discussion of mSRs the reader is referred to current reviews on the topic.[4]

Of the three classes of gonadal steroids, signaling via mSRs has been characterized most comprehensively in the case of the estrogens, including proteins such as ER-X, GPR30,[170] and Gq-mER, whose functions have been demonstrated to be important for rapid estrogenic signaling in the brain, particularly the hypothalamus and cortex. ER-X is a high-affinity estrogen receptor that bears sequence homology to classical ESRs, and that is associated with caveolar-like regions in neocortical neurons.[171] GPR30 is a GPCR, which also has high affinity for E2 and which is thought to mediate expedited actions of E2 in reproductive tissue through the ERK pathway. GPR30 is also expressed in the hypothalamus, with peaks of expression in the supplementary cortex, the piriform cortex, the supraoptic nucleus, the paraventricular nucleus of the thalamus, and other areas,[172] although its function in these regions is not fully understood. Gq-mER, another membrane E2 receptor classified as a GPCR, was originally characterized in the hypothalamus, and has been suggested to engage a number of rapid signaling pathways through PKC and interacting protein 3 (IP3).[173] While membrane PGRs have been claimed to exist in some species, better characterized is rapid signaling of P through

interactions of cytoplasmic PGR with elements of the SRC pathway (see the section Cell Kinase Cascades). Nonclassical signaling by AR during spermatogenesis has been shown to take place via a variety of methods, including rapid T-mediated calcium influx, activation of a (GPCR), and subsequent activation of the PLC pathway, and via the direct interaction of the classical AR with the SH3 domain of SRC, which culminates in activation of the MAPK cascade.[174]

COREGULATORS AND GONADAL STEROID PHYSIOLOGY

One of the interesting aspects of SR coregulators is the mechanistic basis they provide for historical observations of steroid physiology. For example, abundant historical evidence links estrogenic signaling in multiple facets of the immune system, including resistance to infection and the stimulation of the growth of important classes of immune cells.[175] LCK, a member of the Src family of protein tyrosine kinases (PTKs), was originally identified as an important factor in the thymocyte development in the immune system.[176] LCK appears to be subject to extensive posttranslational modification such as palmitoylation and myristylation, and also contains Src homology domains that govern interactions with phosphotyrosine- and proline-rich motifs, respectively. Given the recruitment by ESR of LCK,[177] possibly to functionally engage cell surface receptors such as CD4 and CD8, a role for LCK can be envisaged in communicating the signaling status of other immunoregulatory signal transduction pathways to the ESR and vice versa. ESR-regulated transcriptomes in the immune system are further expanded through its interactions with CEBPB, a bZIP transcription factor that, in addition to homodimerizing to regulate transcription of its target genes, forms heterodimers with other members of the CEBP family.[178] CEBPB has well-defined roles in the regulation of gene networks involved in the immune and inflammatory responses. E2-dependent repression by ESR of IL6, a gene involved in mediating bone resorption by stimulating the maturation of immature osteoclasts, has been shown to be mediated through its interaction with NFκB and CEBPB, and demonstrates a clear dichotomy between the mechanisms of ESR transactivation and transrepression.[179]

The beneficial effects of estrogen on lipid metabolism in humans have been well characterized in the literature.[180] Estrogen replacement therapy, for example, is known to have beneficial effects on the incidence of cardiovascular disease, an effect that has been attributed to maintenance of optimal serum concentrations of low-density lipoprotein (LDL) cholesterol concentrations. The identification of two key players in lipid metabolism, SREBF1 and PPARGC1, as ESR coregulators sheds some light on the mechanistic basis for this effect, and reiterates the importance of coregulators in integrating multiple afferent signaling inputs to maintain homeostatic control over multiple organ systems. SREBF1, a member of the basic helix–loop–helix–leucine zipper (bHLH-Zip) transcription factor family, has been shown to regulate the expression of the LDL receptor gene, in addition to a variety of genes involved in sterol biosynthesis. E2 has been shown to regulate the expression of the high-density lipoprotein receptor (HDLR) scavenger receptor class B type I (SRBI) gene[181] in part through direct interaction with SREBF1, identifying this transcription factor as a coregulator of ESR signaling. PPARGC1 was first identified as a cold-inducible coactivator of PPARG, a master regulator of adipose tissue and a fatty acid-activated orphan member of the NR superfamily. It has since been shown to mediate transcriptional regulation by other members of the NR superfamily, in addition to other transcription factors such as CREB and nuclear respiratory factors. PPARGC1 is now known to be a critical player in whole-body energy homeostasis, with functions as diverse as regulation of mitochondrial biogenesis, specification of muscle fiber–type determination, regulation of blood pressure, and coordination of cellular cholesterol homoeostasis. The characterization of PPARGC1 as an ESR coactivator[182] identifies a key convergence point between PPARG and ESR signaling in the regulation of fat metabolism.

Xenobiotics, including dioxin and polycyclic hydrocarbons such as bisphenol A, are environmental or industrial compounds that impact the physiology of living organisms, and, as such, organisms have evolved a variety of mechanisms to process and excrete these compounds. The activation of a battery of genes encoding enzymes that catalyze their catabolism is a common mechanism among mammals, and one of the primary transcription factors that orchestrates the expression of these genes is the aryl hydrocarbon (Ah) receptor (AhR).[183] In the absence of ligand, cytosolic Ah receptor is sequestered with HSP90, but upon binding of xenobiotic ligands, nuclear translocation of the ligand-binding subunit occurs, followed by interaction with xenobiotic response elements in the promoters of its target genes. A coregulator for AhR, ARNT, has also been identified as a coregulator for ESR[184] and has been postulated as a mechanistic basis for transrepression by ESR of AHR-dependent regulation of gene expression. Interestingly, ARNT is a subunit of a heterodimeric transcription factor, adding further complexity to an already intricate model for interactions between ESR and other classes of transcription factors. AHR, also known as CUL4B, has been linked to ESR signal transduction directly, its E3 ubiquitin ligase functionality having been shown

to target ESR and other gonadal steroid receptors for degradation.[185]

INFORMATIC APPROACHES AND TRANSCRIPTIONAL REGULATION BY GONADAL STEROIDS

The advent of global discovery-driven data acquisition, or "-omics", platforms, especially transcriptomic and GWLA, has afforded researchers the opportunity to shed light on aspects of gonadal steroid action that, while characterized on an empirical level, have lacked a molecular basis that would place the effects of these hormones in the context of the wider systemic physiology of their target tissues.

Global transcriptomic platforms such as microarrays and, more recently, RNA-Seq have demonstrated themselves to be of considerable use in opening novel vistas for gonadal steroid biology, by virtue of the fact that an a priori hypothesis relating to a specific gene or gene network is not required. While extrapolation of data points from a single cell culture model to all steroid target tissues must be exercised with caution, and tissue-specific epigenomic factors ultimately influence the complement of genes regulated in any one tissue, these studies do provide a starting point on which hypotheses for androgen action in other tissues can be based. The NR field has been extremely active in the production of transcriptomic data sets, which have documented the regulation by gonadal steroids of a variety of target genes in models representative of historically well-characterized steroid-regulated tissues, chiefly the LNCaP, MCF7, and T47D cell lines. Given that several public databases of steroid-regulated genes have existed in the past but have since been taken offline, there is a current dearth of web-based databases for mining gene expression data that are relevant to gonadal steroids, with the exception being the Nuclear Receptor Signaling Atlas (NURSA) Transcriptomine resource[97] at www.nursa.org/transcriptomine.

While expression microarrays provide a valuable global perspective on the collective transcriptional response to steroid hormones, they are not designed to distinguish between direct and indirect regulation of genes by SRs, or the contribution, if any, of ligand functions involving cytoplasmic effectors in a given tissue. The relatively new discipline of GWLA encompasses a group of chromatin immunoprecipitation-based techniques that provide data on the specific genomic locations of NRs and coregulators in specific signaling contexts, and that have demonstrated tissue-specific patterns of DNA binding by SRs.[186] The term "cistromics" coined by the laboratory of Myles Brown—recognized as the pioneer in the field—in the latter part of the last decade describes the complete set of *cis*-acting targets of a transacting factor across the genome. Early adopters of GWLA used affinity purification of protein–DNA mixtures (chromatin IP, or ChIP) coupled to solid-phase tiled arrays (ChIP–chip), but this technique has been largely supplanted by the advent of massively parallel sequencing platforms in the form of ChIP-seq. The GWLA waters are muddied to an extent by the fact that, as has been discussed, DNA-bound SRs can influence transcriptional events at promoters far distant from their sites of occupancy, both proximal and distal, such that tying transcription of a specific gene to a specific DNA-binding event can for now be done only tentatively. As has also been alluded to here, Brown's groundbreaking papers demonstrated unequivocally that cross talk on DNA of ERα with transcription factors such as FoxA1 was an early event in the regulation of ERα target genes in MCF7 cells.[80] A more recent variant on the GWLA theme is GRO-Seq (global run-on-Seq), a deep sequencing approach that acts as a measure of direct transcriptional output by mapping the location and orientation of RNA polymerase II.[187] In this study, Lee Kraus's laboratory applied the technique to E2 stimulation of MCF7 cells, opening up the possibility of defining the time course of regulation of transcripts directly regulated by E2.

In technical terms, the field of gonadal steroid action is very well positioned to accumulate the informatic raw data from which novel testable hypotheses can emerge. Transcriptomic surveys are increasingly being complemented by next-generation sequencing approaches, and advances in GWLA make possible the integration of data sets from different platforms to provide additional context and increase confidence in the functional relevance of the data provided by each. In addition, the subdiscipline of epigenomics profiles the myriad posttranslational modifications of chromatin-associated proteins such as histones that an increasing body of evidence is linking to tissue-specific regulation of gene expression. Proteomics technologies such as mass spectrometry add detail both upstream and downstream of transcriptional events regulated by steroid hormones. Upstream, they report on patterns of post-translational modifications of receptors and coregulators and provide insights into how these might dictate the elaboration of tissue- and ligand-specific transcriptomes.[24] Downstream, proteomic studies define the identity and function of de novo proteins and protein complexes that give effect to gonadal steroid actions in their target tissues. Finally, the relatively nascent (in the reproductive endocrinology field, at least) discipline of metabolomics reports on the impact in terms of target cell biochemistry, and of the exposure of a given target cell to a specific gonadal steroid. In combination with the use of conventional and conditional gene knockout and knockdown models, which have already shown

themselves to be powerful tools in discerning the contribution of gonadal steroid receptors and isoforms to their tissue-selective effects, the technologies that these disciplines encompass are poised to provide vast amounts of new data in addition to what have already been generated.

CONCLUSION

Gonadal steroid action encompasses the complex interplay of classical and nonclassical steroid signaling pathways in numerous target tissues, including the mammary gland, uterus, ovary, and CNS, with effects in many other physiological contexts that are beyond the scope of this chapter, but that nevertheless ultimately impact the reproductive homeostasis of both sexes. Common principles have emerged from the study of signaling by the individual gonadal steroids—arguably, the most important of which is the diverse constellation of functions that coregulators bring to bear in the regulation of gene expression by these hormones, and upon which this chapter has largely focused. Moreover, abundant evidence has demonstrated that the lines of demarcation between gonadal steroid receptors and other classes of transcription factors are arbitrary at best. The appreciation is growing that a full understanding of gonadal steroid biology requires a perspective on the numerous points of integration between gonadal steroid signaling axes and those under the control of peptide hormones, growth factors, cytokines, and neurotransmitters acting through their cognate receptors (Figure 9.3), among other signaling molecules.

In comparison to its prodigious generation of data, however, the discipline of reproductive endocrinology has been slow to embrace the importance of archiving raw data sets in specialist public repositories. It is only when data sets are archived, consistently annotated, integrated, and exposed for data mining for the entire reproductive endocrinology community that the full value of the financial and scientific investment in these data sets can be realized. In technical terms, our field is firmly in the twenty-first century but is served by a model of data dissemination that remains in the twentieth century and in many ways has still not shrugged the vestiges of the nineteenth. The discipline of reproductive endocrinology holds great promise for increasing our understanding of human physiology as well as for setting the stage for the development of novel therapeutics, but the speed at which it does this will be determined ultimately by the extent to which scientists and clinicians from diverse subdisciplines find common ground in the rich mine of data points that the field has produced and will continue to produce in the coming decades.

INTRODUCTION

Gonadotropin-releasing hormone (GnRH, also known as GnRH I or luteinizing hormone (LH)-releasing hormone) is synthesized and stored in neurons within the medial basal hypothalamus and the preoptic area of the brain. The human gene (*GNRH1*) is located on chromosome 8 and encodes a 92-amino-acid pre-prohormone. This is processed within GnRH neurons to produce the linear decapeptide that is secreted by regulated exocytosis from nerve terminals in the median eminence, and then passes via the hypothalamo–hypophyseal portal circulation to the anterior pituitary gland. In the context of gonadotrope cell function within the anterior pituitary gland, the hypogonadal (HPG) mouse provided genetic evidence of the required role of GnRH in the regulation of the reproductive axis. The HPG mouse harbors a single nucleotide insertion within the gene encoding GnRH, resulting in a loss-of-function mutation.[1] This mutation results in a loss of GnRH stimulation of gonadotropes, a critical step in the control of the synthesis and secretion of gonadotropins. Consistent with this finding, the HPG mouse reproductive phenotype could be rescued by exogenous administration of GnRH. Moreover, several labs carried out transplantation of hypothalamic neurons to rescue the hypogonadal phenotype.[2–4] Human mutations leading to abnormal migration of GnRH neurons from the olfactory bulb to the hypothalamus (Kallman's syndrome)[5–16] or within the GnRH receptors (GnRHRs)[17–19] were linked to hypogonadotropic hypogonadism, suggesting that normal migration of GnRH neurons to specific nuclei within the hypothalamus or appropriate expression of the GnRHR in the plasma membrane of gonadotropes was critical for the gonadotrope to convert a hypothalamic signal (GnRH) into a systemic response (the secretion of follicle-stimulating hormone (FSH) and LH) governing fertility. These mouse models and human disease conditions underscore the importance of the pituitary and its adjacency to the hypothalamus and infundibulum to establish effective neuroendocrine communication between the brain and pituitary within the reproductive axis.

GnRHRs are G-protein coupled receptors (GPCRs) that mediate the effects of GnRH on the synthesis and secretion of LH and FSH. These are heterodimeric glycoprotein hormones that share a common α-glycoprotein hormone subunit (αGSU) but have distinct β subunits (LHβ and FSHβ). LH stimulates testosterone production in males and ovulation as well as corpus luteum formation and function in females, whereas FSH stimulates spermatogenesis in males and ovarian follicle formation as well as estrogen secretion in females. The gonadal steroids (estrogen, progesterone, and testosterone) exert feedback effects, acting centrally to influence GnRH secretion and at the pituitary to influence gonadotrope responsiveness to GnRH. Thus, GnRH is a hypothalamic decapeptide that mediates central control of reproduction, but this simple statement rests on several decades of research[20–40] establishing, amongst other things, the nature of the interaction between the brain

and humoral regulation of reproduction and the identity of the hypothalamic releasing factor. This paved the way for detailed understanding of the physiological role of GnRH as well as its mechanism of action, all of which has informed the therapeutic targeting of its receptors in treatment of reproductive disorders and hormone-dependent cancers.

Milestones in the discipline of neuroendocrinology include the discoveries of "neurosecretion" in fish and insects and that the brain controls the endocrine system by regulated patterns of peptide hormone synthesis and release.[41–43] Several groups embarked on the purification of putative hypothalamic releasing factors, notably the two competing groups of Roger Guillemin and Andrew V. Schally who, given the low yields of existing techniques, were faced with the Herculean task of isolating peptides from millions of sheep and pig brains collected from the slaughterhouse. Both groups eventually isolated the GnRH decapeptide, identified its structure, and synthesized it.[26,44–50] The identical peptide was subsequently found in numerous species (including humans) and was shown to control secretion of both LH and FSH.[26] The importance of this work was recognized in 1977 when Guillemin and Schally (along with Rosalind Yalow) were awarded the Nobel Prize in Medicine for their "discoveries concerning the peptide hormones of the brain". Even before its chemical identity had been established, clinical studies with purified GnRH had demonstrated its ability to stimulate LH and FSH release in humans.[51–53] However, knowledge of the structure and the availability of synthetic GnRH led to more extensive work and to the development of GnRH analogs (with agonist or antagonist activity) that are now used extensively for assisted reproduction and for the treatment of hormone-dependent cancers and other hormone-dependent conditions such as endometriosis. The discoveries that GnRH secretion is pulsatile and that its effects on gonadotropes are dependent on stimulation paradigms have been pivotal for therapeutic manipulation of the system. Thus, Ernst Knobil and colleagues first noted pulses in levels of LH in rhesus monkey circulation[54] and demonstrated their importance by showing that hypothalamic lesions prevented menstrual cyclicity and LH pulses in monkeys, and that menstrual cycles could be restored by injection of GnRH at sufficient frequency.[55,56] When the frequency of LH pulses caused by GnRH injection was too low or too high, LH secretion was suppressed,[57,58] providing the rationale for therapeutic inhibition of gonadotropin secretion by GnRH agonists as well as antagonists. Pulsatile LH secretion has subsequently been shown in many species and is attributed to pulsatile electrical activity in brain regions containing GnRH neurons, driving pulsatile secretion of GnRH into the portal circulation. Notably, Knobil's group monitored multiunit activity (MUA) in the monkey mediobasal hypothalamus and found that LH pulses correspond to periodic MUA volleys in individual monkeys.[59–61] Moreover, Clarke's group was able to monitor pulses of GnRH within the portal circulation of ewes,[62] opening the way for "ultra-frequent" portal sampling and the increasing evidence that each LH pulse is driven by a pulse of GnRH in the portal circulation.[63,64] Recent studies have greatly advanced our understanding of the nature of the GnRH pulse generator and its regulation by gonadal steroids, by higher centers, and by other environmental inputs (such as photoperiod, nutritional status, and stress). These are dealt with elsewhere in this book, whereas mechanisms of GnRH action and GnRH pulse frequency decoding by its target cells are covered in the section Pituitary Actions and Mechanisms of Action of GnRH.

In addition to the in vivo approaches outlined in this section, GnRH action has been extensively explored in vitro. Pituitary explants and enzymatically dispersed pituitary cell cultures proved to be valuable models for studying GnRH signaling in vitro, but an obvious issue is that gonadotropes form only a small subset (typically, 5–15%) of the cells within the pituitary.[65,66] This can complicate experiments and necessitate monitoring of gonadotrope-specific experimental measures (e.g., gonadotropin secretion or GnRHR expression), single-cell measurements (e.g., Ca^{2+} concentration or electrophysiological study of identified gonadotropes), or gonadotrope purification. Nevertheless, the development of gonadotrope-lineage cell lines[67,68] provided an important advance facilitating the study of GnRH effects on gonadotropin expression and (perhaps most importantly) the cloning of mouse GnRHR.[69,70] This was rapidly followed by the cloning of GnRHRs from humans[71–73] and other species,[74–79] which enabled extensive work on heterologously expressed GnRHRs in academic and industry research labs. It also ushered in the current era where molecular and genetic techniques enable detailed exploration of specific receptors and effectors in health and disease, as well as more holistic approaches to understanding the molecular and cellular effects of GnRH and its role in reproductive endocrinology, at the systems level. This chapter is intended to provide a broad overview of GnRH and its target cells, starting with a brief coverage of gonadotropes and their development (see the section Gonadotropes) and leading into more detailed coverage of GnRH action. Emphasis is placed on effects of the hormone on pituitary gonadotropes (see the section Pituitary Actions and Mechanisms of Action of GnRH), although additional regulators of these cells and additional GnRH target cells are also briefly considered (see the section Autocrine and Paracrine Regulation of Gonadotropes). Similarly, emphasis is placed on molecular and cellular mechanisms, although physiological, therapeutic,

and pathophysiological relevance is also highlighted where appropriate. Given the breadth of the topic, a vast amount of important work is necessarily excluded. We hope to convey some of the excitement of recent developments in the field and apologize in advance to friends and colleagues whose work could not be incorporated.

GONADOTROPES

Early Insights into Pituitary Organogenesis, the Gonadotrope Lineage, and Fertility

H. Rathke first described the developmental origins of the pituitary gland in the 1830s. The developmental placode and invagination of the oral ectoderm that give rise to the adult anterior pituitary bear his name (Rathke's pouch) to the present day. A careful anatomical description of the pharyngeal end of Rathke's pouch was provided by E. Frazer in 1911,[80] outlining morphological changes within the developing embryo. These early studies provided clear anatomical evidence of the adjacency between the neural and oral ectoderm. Further, thickening of the placode suggested proliferation of cell populations leading to expansion of Rathke's pouch. In 1926, early ablation studies by P.E. Smith[81] demonstrated that removal of the pituitary gland in rats resulted in loss of ovarian function and in ovarian atrophy; this outcome could be reversed with replacement therapy in the form of pituitary transplantation, leading to insight into the role of the pituitary in producing "activities" that could regulate distal organs such as the gonads. Compelling work from F.L. Hisaw and his colleagues (S.L. Leonard and H.L. Fevold) in the early 1930s characterized two important activities from the adult pituitary gland in rabbits, labeling them follicular- and corpus luteum–stimulating activities[82,83] and providing initial evidence that two gonadotropic hormones (FSH and LH) were produced and released by the pituitary gland to control the development of ovarian follicles, ovulation, and thus fertility. These studies were later extended in elegant studies by R.O. Greep and colleagues of pituitary stalk transections in male and female rats leading to infertility[84,85]; however, the studies by Greep and colleagues speculated that the stalk transections resulted in a loss of blood flow to the anterior pituitary rather than loss of hypothalamic input. It was reported by Geoffrey Harris in a series of articles that helped to provide more definitive insight into the role of the hypothalamus in control of anterior pituitary function.[86–88] In these studies, surgical transection did indeed result in infertility, and recovery from transection via regeneration of the portal vasculature restored estrous cycles in rats. This restoration could be blocked effectively if transections were carried out with placement of a physical barrier (e.g., a small disk) between the transected stalk and the adenophypophysis, blocking regeneration of the portal vasculature. Thus, loss of hypothalamic signals to the pituitary gland through surgical transection resulted in hypogonadotropic hypogonadism in these animals, suggesting that control of pituitary gonadotropins was indeed governed by activities (releasing peptides) within the hypothalamus.

The anterior portion of the pituitary is characterized by five distinct endocrine cell types giving rise to six peptide hormones involved in the regulation of metabolism, growth, reproduction, lactation, and accommodation to stress. These cell lineages include the lactotrope (prolactin producing), the somatotrope (growth hormone (GH) producing), the thyrotrope (thyroid-stimulating hormone (TSH) producing), the adrenocorticotrope (adrenal corticotropic hormone (ACTH) producing) and the gonadotrope (FSH and LH producing). Loss of function of any of these cell lineages is linked to diseases ranging from altered long-bone growth and dwarfism to hypogonadotropic hypogonadism and infertility. Important genetic studies in early mouse models help to crystallize the role of a number of transcription factors and secreted molecules working in a paracrine manner to support pituitary development and cell lineage specification (extensively reviewed in Refs 89–97). Early characterization of the Snell and Ames dwarf mice[98–101] led to a remarkable understanding of the role of the pituitary gland in normal postnatal growth governed by GH. In both of these mutant mouse lines, deficiency of GH production was characteristic, and analyses of the genetic causes led to the discovery of causal mutations in homeobox containing transcription factors POU1F1 (POU domain, class 1, transcription factor 1; pituitary-specific transcription factor 1 (Pit1) and growth hormone factor 1 (GHF1) in the Snell dwarf) and Prophet of Pit1 (PROP1 in the Ames dwarf) underlying the GH deficiency. PROP1 induces transcriptional control of POU1F1 (Pit1), while POU1F1 binds to and transactivates the GH and prolactin gene promoters in somatotropes and lactotropes, respectively.[98,102–112] Thus, POU1F1 is thought of as a key transcription factor required for the terminal differentiation of cell lineages within the anterior pituitary, and this discovery set the stage for analyses of other transcription factors and secreted molecules that control pituitary organogenesis. More in-depth understanding of the so-called Pit1-dependent lineages (somatotropes, lactotropes, and thyrotropes) can be found in Chapter 12. Here, we focus broadly on lineage determination and specific mechanisms of gonadotrope differentiation during fetal development.

Inductive Model of Pituitary Organogenesis

Development of the pituitary gland requires important embryological tissue interactions via elaborate paracrine-signaling systems and an extensive transcription factor network that are critical for the pituitary anlagen to give rise to the diverse cell lineages within the anterior pituitary. This system is an excellent model of the study of organogenesis. In this section, we outline the key signaling systems and transcriptional mechanisms that underlie the ability of five distinct endocrine cell types to differentiate essentially side by side to control so many diverse physiological functions.

The anterior and intermediate lobes of the pituitary emerge initially from a thickening of oral ectoderm at the roof of the presumptive oral cavity (as early as E7.5 in the mouse) that eventually gives rise to the emergence and expansion of Rathke's pouch; the posterior portion of the pituitary gland is derived from neural ectoderm from the diencephalon overlying the oral ectoderm. Thus, two distinct embryological compartments give rise to the adult gland. The close physical proximity of the oral ectoderm and the neural ectoderm of the diencephalon is critical for the formation of the gland and essentially establishes a lifelong relationship between the anterior pituitary and the hypothalamus. Studies using coculture of these two embryological epithelia from rats provide important evidence that appropriate specification of cell lineages within Rathke's pouch (from oral ectoderm) results from secretion of diffusible factors from the diencephalon (neural ectoderm) functioning in a paracrine manner.[113–115] These secreted factors appear to control the differentiation of progenitor cells in the oral ectoderm into discrete cell lineages.

Much of what we understand currently about pituitary cell proliferation and specification is the result of perturbations of signaling molecules and transcriptional regulators in naturally occurring mouse models or from genetically modified mice. This section will largely focus on mouse model systems illustrating key points. Such notables as M.G. Rosenfeld, H. Westphal, J. Drouin, and S.A. Camper (and their remarkable trainees[89–97]) have contributed greatly to the field, and the reader is directed to this rather large body of important literature. Focusing on such model systems, Westphal and colleagues[116] describe the induction and formation of Rathke's pouch as a multistep process. In the mouse, the initial event in the inductive model is the formation of the rudimentary pouch at ~E8.5, which is characterized by a thickening of the oral ectoderm at the point where the oral and neural ectoderm come into close physical proximity.[117] This is followed over the next several days by an involution and expansion of Rathke's pouch toward the diencephalon.[118] The culmination of this event is the formation of a definitive pouch, with the diencephalon evaginating toward the oral ectoderm (Figure 10.1). The definitive pouch is formed by E12.5 and is marked by a complete detachment from the remaining oral ectoderm[119,120] and the appearance of hormone-secreting cell lineages defining the anterior lobe. Thus, tissue interactions between the oral and neural ectoderm via paracrine factors are essential for the induction and proliferation of Rathke's pouch. In addition, cell lineage determination within the anterior lobe requires the presence of important mesenchymal-expressed paracrine factors derived from the neural crest that surround the definitive pouch. Key paracrine factors from both the diencephalon and the surrounding mesenchyme are outlined throughout the rest of this section.

Paracrine Factors and Pituitary Development

Bone morphogenic protein (BMP4): The diencephalon is an important source of secreted signaling molecules governing pituitary development and cell lineage determination. As outlined in this chapter, the close physical proximity of the diencephalon and the oral ectoderm is central to the inductive model of pituitary organogenesis. At E8.5, BMP4 begins to be secreted from the diencephalon, reaching a peak at E9.5. By E11.5, BMP4 expression decreases to a nadir.[93,121] Several pieces of evidence underlie the importance of the window of BMP4 expression in the establishment of the placode within the oral ectoderm. Perhaps most compelling of these studies is the knockout of BMP4 in mice where the pouch placode within the oral ectoderm fails to form.[118] Consistent with this, misexpression of noggin (a BMP antagonist) using a Pitx1 promoter (directing expression in the oral ectoderm, as outlined in this chapter[118]) results in similar defects. Concurrent with the BMP4 expression domain in the diencephalon, sonic hedgehog (Shh) initially is uniformly expressed within the ventral diencephalon and oral ectoderm; however, Shh expression is specifically excluded from the region of the developing placode and invaginating Rathke's pouch, suggesting that the Shh expression domain (or lack thereof) defines the limits of the invaginating pouch. Repression of Shh expression within the oral ectoderm destined to become the pouch appears to be linked to BMP4 expression from the diencephalon.[93,95,122,123] Deletion of Shh or Gli family members (downstream targets of Shh signaling) in mice results in abnormal pituitary development (variable to complete absence of the gland).[121,124–127] Since the notochord is a primary source of Shh controlling or shaping midline structures in development, it is difficult to know definitively that the loss of Shh leading the disruption of pituitary development is direct or a function of more generalized abnormal midline development within embryos lacking Shh.

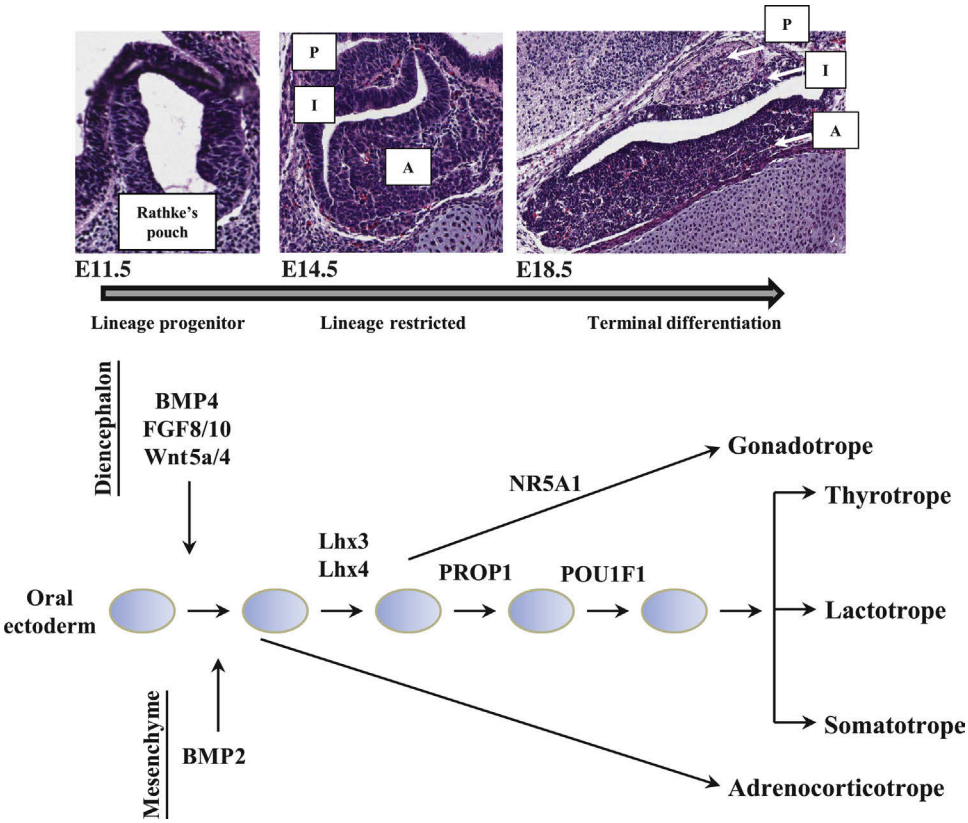

FIGURE 10.1 Pituitary development. This figure is reproduced in color in the color plate section. The pituitary gland emerges from important interactions between the oral and neural ectoderm (diencephalon). Early expansion of the oral ectoderm appears to be functionally related to paracrine signals (such as bone morphogenic proteins (BMPs) and fibroblast growth factors (FGFs)) originating from the neural ectoderm and affecting proliferation and early differentiation of the oral ectoderm. The resulting expansion of tissue forms Rathke's pouch, the anlagen of the presumptive lineage progenitors of the anterior and intermediate lobes of the gland. In addition to signals emerging from the diencephalon, the surrounding mesenchyme provides additional paracrine signaling from BMPs, further restricting lineage identity. Differentiation of the five endocrine cell types within the anterior lobe of the pituitary is controlled by concise expression of a series of transcription factors that serve to restrict cell identity and drive terminal differentiation of the anterior pituitary. For specification of the gonadotrope cell lineage, early expression of Lhx3 (controlled by FGF signaling) and later expression of NR5A1 are central. Interestingly, Lhx3 and NR5A1 play central roles in the regulation of the four gonadotrope signature genes that define gonadotrope function in the adult animal. Sagittal tissue sections shown are from the mouse (unpublished data from M.S. Roberson and A.M. Navratil; e11.5 represents embryonic age in days post conception; P: posterior; I: intermediate; A: anterior).

Fibroblast growth factor (FGF): In addition to BMP4, FGF8 and FGF10 are also expressed and secreted from the ventral diencephalon and appear to be critical in the expansion of Rathke's pouch. FGF10 or FGF receptor 2IIIb (FGFR2IIIb) knockout mice initially form Rathke's pouch; however, the pouch quickly undergoes marked cell death. As a result, FGF10$^{-/-}$ and FGFR2IIIb$^{-/-}$ animals display pituitary agenesis by E14.5,[128,129] suggesting that activation of FGFR2IIIb plays an important role in cell survival in the developing gland. FGF8 expression begins at E9.25, slightly later than BMP4. The FGF8$^{-/-}$ mouse dies at E8.5, prior to pituitary organogenesis[121,130]; as such, this precludes examining the direct role of FGF8 on the development of Rathke's pouch. Evidence for the importance of FGF8 comes from in vitro studies examining the impact of the ventral diencephalon and FGF8 on Rathke's pouch explants. Coculture of ventral diencephalon with Rathke's pouch explants leads to expression of the Lin11, Isl1 and Mec-3 (LIM) homeodomain transcription factor Lhx3 within the oral ectoderm.[121,130] Similar increases in Lhx3 occur when pouch explants are placed in proximity to FGF8-soaked beads, suggesting that the action of the ventral diencephalon on Lhx3 expression in the pouch is dependent on FGF8. Importantly (as outlined in this chapter), in Lhx3 null mice, Rathke's pouch forms but does not develop into a definitive gland.[118] These studies support the conclusion that FGF8 from the ventral diencephalon is required for upregulation of Lhx3. Lhx3 also plays a key role in the expression of a number of gonadotrope-specific genes in the adult animal (described in this chapter), supporting the conclusion that at least some of the transcription factors required for normal pituitary organogenesis retain a functional role in gonadotrope cell behavior following birth.

More definitive clues regarding the role of FGF8 and Lhx3 came from the knockout of Nkx2.1, another homeobox protein expressed in the diencephalon. The Nkx2.1$^{-/-}$ mouse is characterized by pituitary aplasia[131] and provides direct evidence that a transcription factor expressed exclusively within the diencephalon is required for development of the adjacent oral ectoderm. The expression domain of FGF8 in Nkx2.1$^{-/-}$ mice is essentially absent, while the BMP4 expression domain remains intact.[118,132] Thus, the Nkx2.1$^{-/-}$ model provided an opportunity to directly examine the role of FGF8 in vivo. The loss of FGF8 within the diencephalon in the Nkx2.1 null mouse resulted in a loss of Lhx3 expression within the developing pouch, providing important corroboration for in vitro studies demonstrating a requirement of FGF8 signaling for normal upregulation of Lhx3 within the developing pouch. Collectively, BMP4 expression within the diencephalon is required for rudimentary pouch formation, while FGF8 has a clear role in upregulation of Lhx3 and expansion of the rudimentary pouch into a definitive pouch through either induction of proliferation or increased anterior pituitary cell survival. The presence of FGF8 (and likely other FGFs) is proposed to create a dorsoventral polarization of the Lhx3 expression domain and provides a mechanism for continued proliferation of dorsal cell populations in closest proximity with the FGF signal source.

Wnts: Wnt5a and Wnt4 and presumably β-catenin signaling have been linked to the development of the pituitary gland. Wnt5a is expressed within the ventral diencephalon, while Wnt4 expression appears within Rathke's pouch.[133] The Wnt5a$^{-/-}$ mouse is characterized by abnormal pouch morphology and elevated numbers of adrenocorticotropes; however, this pituitary phenotype appears to be relatively mild. The Wnt4$^{-/-}$ mouse displays mild pituitary hypoplasia with reduced numbers of gonadotropes. The Wnt5a–Wnt4$^{-/-}$ double mutant shows both of these phenotypes, suggesting that signaling through Wnt5a and Wnt4 occurs independently in different cell lineages.[93]

BMP2: The paracrine effectors derived from the ventral diencephalon and the emerging pouch appear to play critical roles in establishing signaling centers and secreted factor gradients involved in the regulation of cell proliferation, cell survival, and differentiation. However, as the definitive pouch develops and detaches from the oral ectoderm, the developing gland is surrounded with mesenchyme derived largely from the neural crest. This mesenchymal compartment adds to the signaling complexity of the developing gland as a source of BMP2 beginning at E10.5. Expression of BMP2 appears to induce ventral markers of pituitary cell lineages, including the homeobox gene Isl1 and the α subunit of the glycoprotein hormones (αGSU). Isl1 is expressed within the oral ectoderm beginning at E9.5 and is later (E10.5) restricted to the ventral portion of the gland, coincident with increased BMP2 expression from the mesenchyme. Isl1$^{-/-}$ animals die in midgestation (E10) due to fetal abnormalities not linked to the pituitary; however, at E9.5, a hypoplastic pouch does form, suggesting that Isl1 may be involved in proliferation and/or survival of cells within the developing pouch.[118,121] αGSU is a common subunit to the glycoprotein hormone family, including LH, FSH, and TSH, and is expressed in the ventral portion of the pouch eventually associated with the thyrotrope and gonadotrope cell lineages.

Expression of BMP2 from the mesenchyme surrounding the ventral portion of the developing pouch provides a ventral signaling gradient in opposition to the more dorsal FGF8 gradient arising from the diencephalon and infundibulum.[93,121,134] These two signals clearly play differential roles in the induction of transcription factors involved in cell lineage determination. As outlined in this chapter, FGF8 is required for the expression of Lhx3, while BMP2 appears to be necessary for expression of Isl1. These opposing gradients regulate the emergence of cell lineages by E12.5, with corticotropes appearing initially and more closely aligned with the dorsal portion of the pouch, associated with FGF8 signaling, while thyrotropes, gonadotropes, and lactotropes reside initially in the more ventral portion of the developing gland. These observations support the hypothesis that opposing FGF8 and BMP2 signaling gradients create a spatially and temporally restricted pattern of lineage specification.[119,120] Perturbing these gradients can alter pituitary cell lineage specification. For example, ectopic expression of a dominant-negative form of the BMPR1A receptor in αGSU-expressing cells leads to retarded differentiation of lactotropes, thyrotropes, and somatotropes and a hypoplastic gland, suggesting that BMP2 expression from the mesenchyme regulates important differentiation mechanisms through BMPR1A. Conversely, shifting the signaling polarity with overexpression of FGF8 throughout the pouch appears to induce hyperplasia within the pouch and reduce cell differentiation within the anterior pituitary.[121] These studies suggest that FGF8 supports cell proliferation and/or cell survival while inhibiting some differentiation programs. The end result is the establishment of five endocrine cell identities, each defined by a set of signature genes that confers cell identity. For the gonadotrope, these signature genes include αGSU, the β subunits for LH and FSH, and expression of GnRHR to provide a mechanism for hypothalamic control of the synthesis and secretion of these gonadotropic hormones. For the pituitary in general and each cell lineage during development, specific sets of transcription factors regulate cell identity and are in large part regulated by the signaling network outlined in this chapter.

Also outlined in this chapter are the core transcription factors that contribute to early and late aspects of pituitary organogenesis.

Transcription Factor Network Regulating Pituitary Development

As discussed here, Nkx2.1 is a homeobox factor, and expression of Nkx2.1 is detectable at E8.5 within the ventral diencephalon and is not expressed within the oral ectoderm. Targeted deletion of Nkx2.1 in mice results in failed development of the anterior and intermediate lobes of the pituitary, products of the oral ectoderm.[135] Nkx2.1 appears to be required for expression of FGF8 within the diencephalon; FGF8 is necessary for the upregulation of Lhx3 (described here) within the developing pouch.

Both Pitx1 and Pitx2 play important roles in establishing the early pituitary primordia. Pitx1 is expressed at E9.5 uniformly in oral ectoderm and continues to be expressed within Rathke's pouch. Pitx1 and Shh have overlapping expression domains within the oral ectoderm. Coincident with increased BMP4 expression from the ventral diencephalon, Shh expression is extinguished within the rudimentary pouch; however, Pitx1 continues to be expressed. Pitx1$^{-/-}$ mice display a modest pituitary phenotype with decreased expression of the β subunits to the gonadotropins as well as TSH.[123] Pitx2 appears to play a more prominent role in pituitary-specific activity than Pitx1. Pitx2 gene deletion in mice results in apparently normal establishment of the definitive pouch; however, the pouch fails to proliferate and, based upon in vitro studies, this may be regulated by Wnt signaling (as described here). Pitx2$^{-/-}$ pituitaries are characterized by the presence of only the adrenocorticotrope lineage, the earliest lineage to emerge in development. Both Pitx1 and Pitx2 appear to play a regulatory role in the expression of Lhx3, and in somatotropes and lactotropes, Pitx2 is critical for expression of Pit1 (outlined in this chapter). Interestingly, Pitx1 and Pitx2 appear to bind to and transactivate the gene promoters of αGSU, the gonadotropin β subunits, TSHβ, GH, and prolactin, making the importance of this bicoid factor quite far-reaching in terms of pituitary function.[136]

The LIM homeodomain-containing transcription factors Isl1, Lhx3, and Lhx4 are also obligate early determinants of pituitary development. Isl1 expression is initiated within Rathke's pouch at E8.5 and appears throughout Rathke's pouch at E9.5. By E10.5, Isl1 expression is limited to the ventral portion of the pouch in proximity to the BMP2 gradient.[121] The effects of Isl1 appear to be most critical early in establishment of the primitive pouch. Isl1 null mice display a pouch epithelium characterized by hypoplasia, suggesting that Isl1 supports early progenitor proliferation.[118] Lhx3 is initially expressed at E9.5 within Rathke's pouch.[137] By E12.5, Lhx3 expression is more restricted to the dorsal portion of the pouch[121] and Lhx3 expression persists in the adult pituitary gland. In the Lhx3 null animal, the pouch forms initially but fails to proliferate, leading to inappropriate cell differentiation. Loss of Lhx3 has been linked to elevated levels of apoptosis within the early pouch, leading to hypoplasia.[138] This lesion results in a loss of nearly all differentiated cell lineages within the anterior pituitary with the exception of adrenocorticotropes producing ACTH,[96] a condition similar to human patients with genetic mutations within the LHX3 gene.[96,139,140] Lhx4 also has an important impact on the developing gland; however, this effect is less robust than that of Lhx3, and Lhx4 clearly cannot rescue the Lhx3 null phenotype. Lhx4 is expressed at E9.5 in an expression domain consistent with Lhx3; however, unlike Lhx3, the Lhx4 expression domain becomes restricted by E15.5. Lhx4$^{-/-}$ mutants display elevated cell death within the developing pituitary by E12.5 and E14.5[97,137,141]; by near term, the Lhx4 mutants have reduced numbers of somatotropes and lactotropes. The compound Lhx3–Lhx4 double null is embryonically lethal and fails to form a definitive pouch.

Transcription Factor Network and Lineage Specification within the Pituitary

The individual transcriptional activators outlined in this chapter play fundamental roles in organizing early events of pituitary organogenesis and shared functions to regulate specific cell lineage determination; however, definitive lineage specification requires additional transcription factors to fully define the gene program that delineates the function of a specific cell lineage. Perhaps the most clearly defined example of lineage specification within the anterior pituitary comes from regulation of PROP1 and POU1F1 (Pit1) ultimately giving rise to the so-called Pit1 lineages, somatotropes, lactotropes, and thyrotropes. PROP1 is initially expressed by E10.5, peaks at E12.5, and is largely extinguished by E14.5–15.5.[142] The naturally occurring Ames dwarf mouse is characterized by a missense point mutation (S83P) within PROP1, leading to reduced DNA-binding activity of PROP1 at target genes.[99,101] PROP1 expression appears to precede that of POU1F1, consistent with its name "Prophet of Pit1". In vitro and in-tissue chromatin immunoprecipitation studies support the conclusion that PROP1 can bind to and transactivate the POU1F1 gene promoter. Reconstituting the S83P mutation in vivo gives rise to animals with combined pituitary hormone deficiency (CPHD) with a loss of GH, prolactin, and TSH-producing cells. Interestingly, mutations in PROP1 also give rise to a reduction in gonadotrope cell populations; however, the mechanisms associated with this loss have not yet been elucidated.

The Snell and Jackson dwarf mouse lines are also characterized by a loss of the Pit1 cell lineages and CPHD. The Snell mouse has a point mutation within the DNA-binding domain (W261C) of POU1F1, leading to reduced DNA-binding affinity at target genes.[98,143,144] The Jackson dwarf also lacks POU1F1; however, this appears to be a consequence of a larger scale chromosomal rearrangement. Loss of POU1F1 in genetically engineered mouse models results in a similar CPHD phenotype. Consistent with a role in cell lineage specification, POU1F1 expression initiates later in development (E13.5) and appears just prior to the extinguished expression of PROP1. POU1F1 expression is restricted to the caudomedial portion of the developing gland and is a definitive marker for lactrotropes, somatotropes, and thyrotropes; these lineages are completely absent in POU1F1-deficient mice. Interestingly, the absence of POU1F1 also results in expanded corticotrope and gonadotrope populations, suggesting that one role of POU1F1 is potentially to repress these latter two lineages. Elegant molecular endocrinology and biochemical studies have demonstrated that POU1F1 directly binds to and transactivates the GH, prolactin, TSHβ, and GH-releasing hormone receptor genes, providing important key mechanistic information for how POU1F1 is capable of controlling these lineages via direct regulation of a cohort of signature genes that defines lactotropes, somatotropes, and to a certain extent thyrotropes.[93]

NR5A1 and Specification of the Gonadotrope Lineage

Cell lineage commitment reflects the genetic signature required to define the differentiated character of the specific cell type. The gonadotrope must be able to respond to hypothalamic stimuli via GnRH and produce gonadotropin hormones to control gonadal function. Thus, the gonadotrope cell lineage is defined by at least four signature genes: the gonadotropin subunits (αGSU, LHβ, and FSHβ) and GnRHR.[38] The gonadotrope is the last of the cell lineages to become fully differentiated during pituitary organogenesis; however, expression of αGSU (one of the earliest markers of pituitary development) is a requisite component of this lineage. At E10.5, αGSU expression appears coincident with expression of Lhx3, other ventral markers (Isl1), and the BMP2 expression from the mesenchyme surrounding Rathke's pouch. Due to the overlapping requirement of αGSU in the thyrotrope and gonadotrope cell lineage, true gonadotrope lineage commitment is often associated with the expression of the orphan nuclear receptor NR5A1 (nuclear receptor subfamily 5, group A, member 1 (also known as steroidogenic factor 1 or SF1) at E13.5. NR5A1$^{-/-}$ mice die perinatally (at p8) due to adrenocorticoid insufficiency.[145,146] The phenotype of this mouse is actually remarkable, demonstrating that NR5A1 expression in vivo is required for normal development of the ventromedial hypothalamus and the adrenals and gonads. Specific conditional deletion of NR5A1 in pituitary gonadotropes using the αGSU–Cre deleted strain revealed that loss of NR5A1 in gonadotropes and thyrotropes resulted in hypogonadotropic-hypogonadal infertility linked to deficiencies in the αGSU and β subunits to LH and FSH along with reduced or absent GnRHR expression.[147] This striking hypogonadal phenotype was effectively rescued by administration of exogenous gonadotropins and, interestingly, by GnRH administration. Thus, NR5A1 is absolutely required for the regulation of the four gonadotrope signature genes; however, the definitive role of NR5A1 on the regulation of GnRHRs may be only partial.

NR5A1 mouse models have provided important in vivo details regarding the role and requirement of this orphan nuclear receptor in the development and function of the hypothalamic–pituitary–gonadal axis and the specific importance of NR5A1 on gonadotrope lineage specification. Equally important have been observations of naturally occurring mutations of NR5A1 in human populations and their impact on fertility.[12,13,148–150] NR5A1 is a 461-amino-acid protein with several discrete and important domains, including activator function domains and DNA-binding domains (DBDs). DBD is characterized by the presence of two zinc fingers at the amino termini of the protein. A patient presenting with primary adrenal failure and XY sex reversal was characterized with a G35E substitution mutation in NR5A1. This mutation occurred within the P box of the first zinc finger in NR5A1, rendering the protein incapable of DNA binding and transactivation of target genes linked to steroidogenesis and, perhaps more relevant to this discussion, the β subunit to LH in the gonadotrope. This human phenotype was entirely consistent with observations made in mouse models and underscored the importance of NR5A1 on gonadotrope cell function (as well as steroidogenic tissues) in human patients.

The importance of NR5A1 is potentially far-reaching as a determinant of the gonadotrope lineage and gonadotrope cell biology since this orphan nuclear receptor has been shown to interact with a rather large number of chromatin-remodeling complexes that serve as coactivators, corepressors, and transcription factors.[150] It is perhaps not surprising that as an orphan steroid hormone receptor, protein–protein interactions and recruitment of chromatin-remodeling machinery to target genes are fundamental components of NR5A1 action in steroidogenic tissues. In the context of NR5A1-dependent promoters of steroidogenic enzymes (cytochrome P450 (CYP)11A1, CYP17, and CYP21), NR5A1 recruits coactivators such as cyclic adenosine monophosphate (cAMP)

response element-binding protein (CREB)-binding protein (CBP)/p300, p300/CBP associated factor (PCAF), and glutamate receptor interacting protein 1 (GRIP1) to these promoters, effectively modulating chromatin structure via histone acetylation.[151–153] Conversely, corepressor activity associated with C-terminal binding protein 1 (CtBP1), receptor-interacting protein 140 (RIP140), and the silencing mediator of retinoid and thyroid hormone receptors (SMRT) can also be recruited by NR5A1 complexes bound to CYP17 and CYP21 gene promoters to modulate steroidogenic activity via chromatin repression.[153–160] Interestingly, NR5A1 interactions with GRIP1 and SMRT depend upon the phosphorylation state of NR5A1 at S.[161] S[161] is a likely substrate for extracellular signal-regulated kinase (ERK) signaling (a key signaling system induced by GnRHR activation) and appears to be necessary for NR5A1 to assume an active confirmation in the absence of a ligand. This suggests that in some instances, the activation and phosphorylation state of NR5A1 controls protein–protein interactions and that higher order complexes controlling chromatin structure and gene transcription at NR5A1 target gene promoters may be critical for NR5A1 action in gonadotropes.

NR5A1 forming complexes with other transcriptional regulators appears to be critical to the specific regulation of gonadotropin subunit genes. As indicated here, NR5A1 plays a critical role in the regulation of the four gonadotrope signature genes during development, and the specific mechanisms of transcriptional activation of these gene promoters are addressed in other sections of this chapter. Here we simply point out the breadth of NR5A1 interactions with various factors to illustrate the diverse mechanisms of action of NR5A1, specifically in the gonadotrope. NR5A1 interacts directly with early growth response factor 1 (Egr1) and Pitx1 to regulate the activity of the rat LHβ subunit gene promoter.[162,163] Egr1 is an immediate early-response gene induced by GnRHR activation and is critical within the GnRH signaling network for LHβ subunit gene transcription.[164,165] Egr1$^{-/-}$ females are infertile due to a specific deficiency in LHβ subunit gene transcription via signaling through ERK1 and ERK2.[38,166] Pitx1 and Pitx2 were identified early in this chapter as key regulators of pituitary development and lineage determination. Both Pitx isoforms are bicoid-related homeodomain-containing transcription factors. Interaction between NR5A1 and Pitx1 results in a synergistic activation of the bovine LHβ gene promoter; overexpression of Egr1 or GnRH treatment enhances this activity further, suggesting that higher order complexes between these factors are critical for LHβ gene transcription. From a mechanistic perspective, interactions between the amino termini of NR5A1 and the carboxyl termini of Pitx1 appear to reconstitute full NR5A1 activity in the absence of a ligand-binding domain. These observations support speculation that interaction between NR5A1 and Pitx1 during gonadotrope development may occur without the need for a putative NR5A1 ligand.[162]

NR5A1 has also been shown to interact with androgen receptor (AR), leading to repression of the rat LHβ subunit gene promoter.[167] Androgens have important negative-feedback effects in the hypothalamic–pituitary–gonadal axis, and the direct interaction between androgens, AR, and NR5A1 has important implications regarding negative feedback directly at the level of the gonadotrope. Interestingly, association between NR5A1 and AR occurs through the ligand-binding domain of NR5A1 and the DNA-binding domain of the AR. Furthermore, the addition of Egr1 or Pitx1 to these binding complexes competes for NR5A1–AR interactions and, as such, relieves the androgen-mediated repression of the LHβ promoter. In other studies, the small nuclear RING finger (SNURF) protein also interacts with AR and as such serves as a putative coactivator at the LHβ subunit promoter.[168] The effects of SNURF are associated with direct interaction between SNURF and NR5A1, and this complex appears to blunt or reverse the repressive effects of androgens and ARs on the LHβ promoter.

Nuclear factor Y (NFY) and NR5A1 form a binding complex associated with regulation of the FSHβ subunit gene promoter.[169] Using a GST pulldown approach, NFYA (but not NFYB or NFYC) was shown to specifically interact with NR5A1. The importance of this interaction is presently not clear; however, the *cis* regulatory elements binding NFYA and NR5A1 within the FSHβ promoter do establish these transcription factors as critical for its full transcriptional expression in gonadotropes.[170]

Collectively, NR5A1 plays a central role in gonadotrope cell lineage determination largely via contributions to transcriptional activation to four gonadotrope signature genes. Importantly, NR5A1 can physically interact with a large number of chromatin-remodeling proteins identified in the context of steroidogenic enzyme gene promoter regulation, supporting speculation that similar complexes may be involved in the regulation of gonadotrope-specific genes. Moreover, a number of transcription factors have also been shown to interact with NR5A1 in the context of control of gonadotropin β subunit gene promoters or in conjunction with GnRH action. While not specifically examined within the pituitary anlagen during development, it seems highly plausible that NR5A1 interactions with some, if not all, of these transcription factors may contribute to gonadotrope lineage determination and coordination of gonadotrope-specific gene regulation during pituitary organogenesis. Clearly, NR5A1 plays a critical and continued role in the expression of cell-specific genes within the gonadotrope in the postnatal animal and into adulthood. Control of the gonadotrope signature genes also

includes regulation by a number of other transcription factors critical for development of the pituitary gland and, in particular, the gonadotrope. These include the Pitx family members and the LIM homeodomain factors such as Lhx3.

Changes in Biosynthesis of Gonadotropin Subunits and the GnRHR during the Estrous Cycle

A central outcome of an estrous cycle is the temporal coordination of sex behavior and timing of ovulation with uterine receptivity to establish successful implantation and pregnancy. This is accomplished through coordination of the ovarian and uterine cycles through GnRH and gonadotropin secretion regulating follicle and gamete maturation and ovulation and the production of gonadal steroid and peptide hormones. During the 4-day estrous cycle of the rodent, ovulation is preceded by a preovulatory surge of GnRH and LH that occurs on the evening of proestrus. GnRH-dependent FSH also surges at this time; however, elevated levels of FSH persist in circulation through the morning of estrus, and inhibin appears to regulate the latter portion of this biphasic FSH surge.[171–177]

The sensitivity of the gonadotrope leading up to the LH surge is regulated by increased expression of transcripts encoding the GnRHR. During the afternoon of proestrus, GnRHR mRNA is markedly increased, leading to increased numbers of GnRHRs within hours of the LH surge.[171,178] As preovulatory follicles undergo late-stage maturation, increased synthesis and secretion of estradiol are critical in coordinating increased expression of GnRHRs as well as sex behavior at estrus. Transcripts for the β subunit of LH increase coordinately with elevated GnRHR mRNA prior to the LH surge that is presumably associated with increased GnRH responsiveness of the gonadotrope and the need for high relative levels of LH biosynthesis in anticipation of the surge. FSHβ mRNA also increases during the proestrus period; however, this increase occurs later relative to LHβ and persists into the morning of estrus, consistent with FSH in circulation. Interestingly, transcripts for the α subunit to the glycoprotein hormones do not change appreciably during the proestrus period, suggesting that this common subunit to the gonadotropins is not rate limiting in gonadotropin biosynthesis leading up to the preovulatory surge. Collectively, it appears that estradiol-dependent increases in sensitivity to GnRH are coupled with increased GnRH-dependent increases in the β subunits to LH and FSH that are necessary for a preovulatory gonadotropin surge. In addition, factors such as inhibin (and likely activin) specifically modulate FSH biosynthesis following the surge.

Relationships involved in the gonadal control of negative-feedback mechanisms governing the regulation of GnRHR and gonadotrope subunit transcripts within the gonadotrope may be best demonstrated by examining the responses to removal of the gonad and the loss of gonadal steroid hormones and inhibin. Castration in both genders results in an increase in the secretion of both LH and FSH related to the removal of these gonadal steroid–linked negative-feedback mechanisms.[166,179] In female rats, replacement of estradiol following castration blunts the castration-induced rise in gonadotropin secretion and elevation in gonadotropin subunit mRNAs.[180] Interestingly, in estrogen receptor α (ESR1) null animals, gonadotropin subunit transcripts are elevated in gonadotropes without castration,[181] again providing important evidence that estradiol feedback via ESR1 is central to controlling gonadotrope cell function.

Response of the gonadotropin subunit mRNAs to castration varies with gender. In some recently published studies using quantitative polymerase chain reaction (PCR) to assess pituitary mRNA content 7 days following castration in male and female mice, αGSU, LHβ, and FSHβ mRNAs all increased in both genders. However, the relative increase in transcript abundance was greater in females relative to males of similar age,[166] although in these studies the stage of the estrous cycles in females was not standardized. Interestingly, in these mice, transcripts for the GnRHR in male and female mice were unaffected (males) or slightly diminished (females) with castration. This observation is in contrast to male and female rats where castration resulted in elevated GnRHR transcript abundance.[75,182] This may reflect differences in species or in the methodologies used to quantify transcript levels. The use of castration in many of these experiments focused on the response of the gonadotrope to a physiologically relevant elevation of GnRH pulse stimuli with the ablation of the gonad. The response of increased GnRH pulse frequency to regulate αGSU and LHβ subunit mRNAs was dependent upon intracellular signaling between the GnRHR and the ERK pathway. This pathway is dealt with in more detail in the section Mitogen-Activated Protein Kinases but it is important to note here that postcastration elevation in αGSU and LHβ subunit mRNAs was greatly blunted or abolished in male and female mice that harbored a conditional gonadotrope-specific deletion of ERK1 and ERK2. These were the first studies to demonstrate a specific requirement for GnRH-induced ERK signaling mediating the postcastration response of gonadotropin subunits.[166] Postcastration-induced LH secretion was also greatly blunted with the loss of ERK signaling in male and female mice, suggesting fidelity between transcription and biosynthesis; in contrast, the loss of ERK signaling failed to affect FSH secretion in either gender.

PITUITARY ACTIONS AND MECHANISMS OF ACTION OF GnRH

GnRH Receptors

Prior to their cloning, GnRHRs were extensively characterized as binding sites mediating potent GnRH effects, notably on synthesis and secretion of gonadotropins and on receptor regulation.[20–24] Early radioligand-binding studies revealed a single class of binding sites with classical receptor characteristics (high affinity and specificity as well as saturability) in pituitaries from several species.[183–185] The dissociation constant (K_d) for binding of GnRH to pituitary GnRHRs has been estimated (for several species) to be between 2 and 5 nM, whereas the K_d for the GnRH agonist (des-Gly^{10}-D-Ala^6)*N*-GnRH-*N*-ethylamide is between 0.2 and 1 nM.[183–189] Radioligand binding to GnRHRs in cell membranes varies markedly under different physiological conditions (during development and through puberty, the estrous cycle, pregnancy, and lactation), and this reflects changes in receptor number rather than affinity.[20,189–191] GnRHR number is also altered in primary cell cultures and in gonadotrope-derived cell lines by numerous treatments, including gonadal steroids and GnRH itself.[20,37,76,188–194] The number of rat or mouse GnRHRs has been estimated at 20,000–80,000 sites per cell in various models,[188,193,195] although calculating the number of receptors at the cell surface is complicated by the fact that the number of gonadotropes also varies under different conditions and because the enriched membrane preparations used for binding experiments likely contain membranes other than the plasma membrane. Nevertheless, the effects of GnRH are dependent upon the GnRHR number in many models, and the observed physiological changes in the number of pituitary GnRHRs immediately implies that GnRH expression and/or compartmentalization are regulated, as discussed in the section Desensitization and Receptor Internalization.

Cloning of GnRHRs revealed them to be members of the rhodopsin-like GPCR family (family A), and their identification as GPCRs is consistent with the fact that the GnRHRs of gonadotropes and gonadotrope-lineage cells act primarily via $G_{q/11}$ to activate phospholipase C (PLC). Consequently, they mediate elevation of cytoplasmic [Ca^{2+}] and activation of protein kinase C (PKC) isozymes, both of which are important for GnRHR-mediated effects on gonadotropin synthesis and secretion.[21,23–25,27,34–36,39,40,187,196] The cloned vertebrate GnRHRs can be broadly divided into three groups. All of the cloned mammalian GnRHRs are in groups I or II,[27,197] and the type I GnRHRs of humans, rats, mice, pigs, sheep, and horses have >80% amino acid sequence homology.[35] There are also multiple forms of GnRH peptide, although reptiles, birds, and mammals express only GnRH I and GnRH II (pGlu–His–Trp–Ser–His–Gly–Trp–Tyr–Pro–Gly–NH_2). The latter is widely distributed in the central nervous system (CNS),[198–200] where it may act as a neurotransmitter or neuromodulator, whereas GnRH I acting via pituitary type I GnRHRs is the essential cognate pairing for central control of mammalian reproduction. Type II GnRHRs are selectively activated by GnRH II and bind GnRH I poorly. In spite of the fact that GnRH II is ubiquitously expressed, the type II GnRHR is silenced in several species, including some primates. Thus, although marmosets express GnRH I and GnRH II as well as GnRHR I and GnRHR II, in humans there is a frameshift mutation and premature stop codon in the GnRHR II (pseudo)gene, so the two GnRH ligands likely act via a single type I GnRHR.[27,39,197,201] In addition to expression in the pituitary, GnRHRs are found (often along with GnRH) in many other tissues, including those of the brain and the reproductive system.[25,27,30,36,39,197,202] Most interest in extrapituitary GnRHRs stems from the discovery that they are expressed by numerous cancers, including those of the mammary, prostate, and ovary. In cells derived from such cancers GnRH analogs (or cytotoxic derivatives) often exert antiproliferative and/or pro-apoptotic effects,[30,39,40,161,202–236] raising the exciting possibility that such direct action may contribute to the therapeutic effects of GnRH analogs in cancer treatment.

Type I GnRHRs are proteins of 327 (or, in humans, 328) amino acids. Their crystal structure is unknown, so molecular models rely on predictions from the solved structure of rhodopsin or, more recently, those of other GPCRs, including the β1 and β2 adrenergic receptors.[25,27,31] This indicates that GnRHRs, like other GPCRs, have the characteristic seven transmembrane domains (TMDs) linked by three intracellular (IC1-3) and three extracellular (EC1-3) loops. There is a 35-amino-acid extracellular amino-terminal domain, and receptor structure is stabilized by disulfide bridges between EC1 and EC2 and between EC2 and the amino-terminal domain. There are also glycosylation sites within the N-terminal domain, at Asn18 in the human (h)GnRHR and Asn4 and Asn18 in the mouse (m)GnRHR. Mutation of these sites reduces cell surface GnRHR number (without altering receptor binding affinity), implying that glycosylation is important for GnRHR trafficking and/or stability, but not for conformation of the ligand-binding pocket.[25,27,31,39,237,238] Many point mutations have been introduced into GnRHRs, and functional analysis has yielded increasingly detailed maps of the predicted GnRHR tertiary structures annotated for amino acids involved in ligand binding and effector activation. This is reviewed elsewhere[25,27,30,31,34,35,238–240] and will not be considered in detail here, although type I GnRHRs have a number of atypical or unique structural features that certainly warrant mention. Firstly, there is a highly conserved Asp–Arg–Tyr sequence

toward the cytoplasmic end of TM3 in most GPCRs, which is replaced in GnRHRs by Asp–Arg–Ser, but this alteration is thought to have little or no effect on binding or signaling.[25,241] Secondly, there is an Asn at the position of a highly conserved Asp in TMD2 as the opposite change in 7TMD where the consensus Asn–Pro–XX–Tyr motif is Asp–Pro–XX–Tyr in GnRHRs. This interchange of conserved residues raised the possibility that they interact, as supported by the discovery that when Asn87 is replaced with Asp, there is no detectable binding, but when Asp318 is replaced with Asn (as well as replacement of Asn87 with Asp), binding is rescued. This recovery of high-affinity binding by reciprocal mutation (Asp87 and Asn318 GnRHR) supports the possibility that the two residues are adjacent to one another in space and helped confirm and refine models for structure of the TMD helix bundle.[25] A third, quite remarkable feature of GnRHR structure is that type I mammalian GnRHRs lack the intracellular carboxyl-terminal tail region (C-tail) found in all other GPCRs. The fact that this structure is present in all type II and III GnRHRs and in nonmammalian type I GnRHRs implies a period of rapidly accelerated molecular evolution with the advent of mammalian type I GnRHRs.[27,30,31,197,242,243] The C-tails of GPCRs have important roles in the regulation of receptor trafficking, desensitization, and signaling, and the functional relevance of their absence from mammalian type I GnRHRs is discussed here.

Although it was initially assumed that GPCRs function as monomers, it is increasingly evident that they can act as dimers or higher order multimers that may be homomeric or heteromeric.[244,245] For some GPCRs, oligomerization is thought to be associated with biogenesis in the endoplasmic reticulum (ER), whereas for others it can occur at the plasma membrane in association with ligand activation and/or ligand-induced internalization.[244–246] For GnRHRs, early studies using antibody to cross-link ligands suggested that small-scale receptor–receptor interaction (i.e., dimerization) was stimulatory; indeed, it is now thought that "microaggregation" of GnRHRs is a central and early event leading to productive calcium signaling and secretion of gonadotropins.[247,248] As more advanced biophysical techniques were developed, such as fluorescence resonance energy transfer (FRET) and fluorescence recovery after photobleaching (FRAP), greater details emerged regarding association of the GnRHR within the plasma membrane.[249,250] Such studies revealed that ligand occupancy of the GnRHR caused a marked reduction in the lateral diffusion kinetics of the receptor within the membrane as well as GnRH-dependent energy transfer between GnRHRs fused to different fluorophores, suggesting they indeed could self-associate within the plasma membrane of the gonadotrope. Importantly, administration of receptor antagonists (such as antide) in similar studies did not result in energy transfer between GnRHRs, suggesting that only GnRH agonists would promote the receptor oligomerization that is correlated with productive signaling. These experiments provided additional support to the microaggregration hypothesis and revealed the importance of receptor-associated membrane dynamics on GnRH action (sections Desensitization and Receptor Internalization and Lipid Rafts).

Heterotrimeric G-Proteins, Ca^{2+} Metabolism, and Acute Regulation of Gonadotropin Secretion

The endogenous GnRHRs of pituitary gonadotropes and gonadotrope-lineage cell lines signal primarily via the G_q and/or G_{11}. These are heterotrimeric G-proteins containing α, β, and γ subunits, of which the α subunits bind either guanosine-5′-triphosphate (GTP) or guanosine diphosphate (GDP).[251] Activated GPCRs are guanine nucleotide exchange factors for their cognate heterotrimeric G-proteins, stimulating the exchange of GDP for GTP. The GTP-bound α subunits separate from the βγ subunits (that remain bound to one another) and regulate enzyme or ion channel target proteins. In the case of G_q and G_{11}, the main target is phosphatidylinositol-specific phospholipase C (particularly PLC β1), which is activated primarily by the α subunits but also by βγ subunits. PLC cleaves membrane inositol phospholipids (particularly phosphatidylinositol-4,5-bisphosphate (PIP_2)) to generate inositol-1,4,5-trisphosphate (IP_3) and diacylyglycerol (DAG). IP_3 is a hydrophilic molecule that diffuses away from the membrane and acts via intracellular receptors that are ligand-gated Ca^{2+} channels on intracellular Ca^{2+} stores, mediating mobilization of Ca^{2+} and elevation of the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$). Diacyclglycerols are lipophilic molecules that stay in the membrane, where they can activate PKC isozymes.[251] The PKCs are serine–threonine protein kinases divided into three families with characteristic domain structures and activation mechanisms. Thus, the conventional forms (cPKCs: α, βI, βII, and γ) are acutely activated by Ca^{2+} and DAG, the novel forms (nPKCs: δ, ε, θ, and η) are activated by DAG but not Ca^{2+}, and the atypical forms (aPKCs: ζ and ι/λ) are not activated by DAG or Ca^{2+}. The cPKCs are largely cytoplasmic in unstimulated cells, but Ca^{2+} binding induces their translocation to the membrane where they can be activated by DAG.[251] Similar translocation occurs with the nPKCs but is slower because they lack the C2 Ca^{2+}-binding domain needed for this Ca^{2+}-dependent increase in affinity for membranes.

There is abundant evidence from numerous models that GnRHRs engage the classical bifurcating signaling pathway that is outlined here[21,23–25,37,76,187,252–257] and illustrated in Figure 10.2. This includes the demonstration that radioligand binding to GnRHRs is modulated

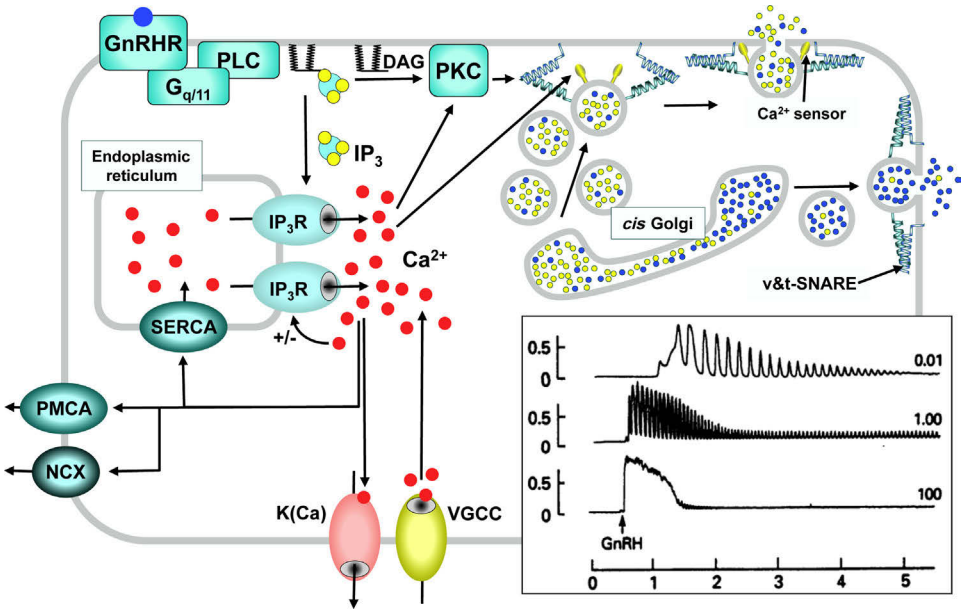

FIGURE 10.2 Acute effects of GnRH on Ca^{2+} and gonadotropin secretion. This figure is reproduced in color in the color plate section. GnRH acts via Gq/11 coupled GPCRs to activate PLC, with consequent IP_3-mediated Ca^{2+} mobilization and Ca^{2+}–DAG-mediated activation of PKC. The interplay of Ca^{2+} mobilization from intracellular stores and Ca^{2+} entry across the plasma membrane increases $[Ca^{2+}]_i$. This response may be oscillatory or more sustained, often with a spike–plateau-type profile. The response elicited by GnRH varies according to cell type and stimulus intensity but is also variable from cell to cell, even within isogenic cell populations. The GnRHR-mediated increase in $[Ca^{2+}]_i$ drives the secretion of LH and FSH by regulated exocytosis, a process likely involving interaction of a vSNARE (i.e., synaptobrevin) and a t-SNARE (i.e., syntaxin) as well as regulation by a Ca^{2+} sensor (i.e., synaptotagmin). PKC can also stimulate gonadotropin secretion, acting as a positive modulator of Ca^{2+}-driven exocytosis. In addition to regulated exocytosis, gonadotropins may be secreted via the constitutive pathway. The proportion of FSH (blue circles) secreted constitutively is higher than that of LH (yellow circles), and this could reflect sorting into distinct secretory vesicles formed at the Golgi. This principle is illustrated here by the presence of a Ca^{2+} sensor on LH-enriched vesicles but not on FSH-enriched vesicles. The inset shows μM $[Ca^{2+}]_i$ in individual cells stimulated with the indicated concentration of GnRH (plotted against time in min) and is adapted from Ref. 258.

by guanine nucleotides, which is indicative of G-protein binding,[259] as well as GnRH-induced downregulation of α_q and α_{11},[260] which is a characteristic consequence of their activation. PLC activation has been documented by showing GnRH-induced reduction in PIP_2 and associated increases in DAG and IP_3. Similarly, GnRH causes an increase in [^{3}H]inositol phosphate (IP) production in cells pretreated with [^{3}H]inositol (in order to label inositol phospholipids), an effect that can be prevented by inhibition of PLC.[252,261–264] PKC activation was initially documented with assays of enzymatic activity, showing that GnRH stimulates PKC translocation from the cytoplasm to the plasma membrane in vitro and in vivo.[265,266] In the latter case, the effect was inhibited by Ca^{2+} channel antagonists,[266] implying activation of one or more cPKC isozymes. Gonadotrope lineage αT3-1 and LβT2 cells express members of all three PKC families (α, β, δ, ε, θ, ι/λ, and ζ),[37,267–271] and translocation indicated activation of α, β, ε, and ζ isoforms by GnRH in αT3-1 cells.[37,267,270,271] In LβT2 cells, GnRH reduces levels of PKCδ, ε, and θ, which provides indirect evidence for their activation[272] and is consistent with the observation that PKCδ and PKCε can mediate GnRH-stimulated adenylyl cyclase activity in these cells.[273]

As expected for a $G_{q/11}$-coupled GPCR, activated GnRHRs mediate rapid increases in $[Ca^{2+}]_i$.[24,25,27,32,34,36–38,187,192,196,257,274–281] In some models, including gonadotrope lineage cell lines, high concentrations of GnRH cause a pronounced biphasic elevation of $[Ca^{2+}]_i$, with an initial spike followed by a more or less sustained plateau response, but in other models, including primary cultures of rodent gonadotropes, GnRH causes an oscillatory increase in the $[Ca^{2+}]_i$ or a spike response followed by $[Ca^{2+}]_i$ oscillations.[24,257,278–284] The spike phase of the response is attributed to IP_3-mediated Ca^{2+} mobilization from the ER, and its transience reflects the reduced $[Ca^{2+}]$ in the lumen of the ER as well as removal of Ca^{2+} from the cytoplasm by sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA) pumps, mitochondrial uptake, as well as Ca^{2+} ATPase pumps and Na^+–Ca^{2+} exchangers in the plasma membrane.[251]

To understand subsequent response phases, it is important to recognize that gonadotropes (like other endocrine anterior pituitary cells) are excitable cells in which electrically driven Ca^{2+} signals resemble those of neurons.[257,281] Gonadotropes show spontaneous electrical activity, in which gradually increasing membrane

potential reaches a threshold at which voltage-gated Ca^{2+} channels (VGCCs) are activated. This not only gives rise to the spiking depolarization but also drives voltage-gated Ca^{2+} influx. Where GnRH causes spike–plateau-type elevation of $[Ca^{2+}]_i$, the plateau response is rapidly reversed on transfer to Ca^{2+}-free medium, demonstrating dependence on ongoing entry across the plasma membrane, and this likely reflects depolarization and activation of voltage-gated Ca^{2+} influx and/or capacitative Ca^{2+} entry.[251,257,281,285] Where GnRH causes oscillatory increases in $[Ca^{2+}]_i$, these reflect the interplay of two oscillators. Here, key observations are that GnRH-induced $[Ca^{2+}]_i$ oscillations continue after the transfer of cells to Ca^{2+}-free medium and when membrane potential is clamped to prevent voltage gating, and the findings that oscillations can be caused by microinjection of metabolically stable IP_3 analogs or prevented by SERCA pump inhibition.[257,281,286–288] A mathematical model has been developed in which this oscillation is due to fast activation of IP_3 receptors (by Ca^{2+} and IP_3) and their slow inactivation (by Ca^{2+}). A fundamental feature of this model is the fast activation by Ca^{2+}, providing positive feedback for the upstroke of the oscillation, and the slow inactivation by Ca^{2+}, providing negative feedback for the downstroke.[257,281] This closed-cell oscillation model mirrors experimental observations but also predicts that a proportion of the Ca^{2+} mobilized in each oscillation will be pumped out of the cell. The driving force for IP_3 receptor–mediated Ca^{2+} mobilization is thereby reduced, so that oscillations will reduce in frequency and amplitude over time and will eventually terminate.[257] However, in an open system, influx of Ca^{2+} across the plasma membrane may prevent this run-down by enabling refilling of intracellular Ca^{2+} stores between pulses. The importance of this refilling is illustrated by experiments in which GnRH-stimulated Ca^{2+} oscillations run down in cells clamped at −60 mV to prevent Ca^{2+} entry via Ca_v, but increase as membrane potential is increased toward −20 mV to increase Ca^{2+} entry.[286,289] This demonstrates that oscillatory Ca_v-mediated Ca^{2+} entry is not needed for Ca^{2+} oscillations, but the bidirectional coupling of the ER and plasma membrane actually does provide coordinated ER and plasma membrane oscillations. Mobilization of Ca^{2+} from the ER leads to stimulation of Ca^{2+}-activated SK channels that contribute to hyperpolarization of the gonadotrope plasma membrane, and is followed by a burst of electrical oscillations. Each Ca^{2+} spike activates a Ca^{2+}-activated K^+ current that terminates or interrupts this electrical spiking. Thus, there are antiphasic oscillators, with membrane potential oscillations causing the Ca^{2+} entry needed for refilling of intracellular stores and Ca^{2+} oscillations that periodically interrupt the membrane oscillations and drive Ca^{2+}-dependent processes.

Ca^{2+} acts via sensors and effectors to influence a vast number of cellular activities, and in the case of GnRH, most emphasis has been placed on its role in mediation of exocytotic gonadotropin secretion as well as transcriptional regulation. Indeed, some of the earliest work on GnRH signaling revealed the importance of Ca^{2+},[23,24,183,190,192,290–293] showing not only that GnRH-stimulated gonadotropin secretion was markedly reduced in Ca^{2+}-free medium but also that the effect of GnRH on secretion could be mimicked by manipulations used to increase the $[Ca^{2+}]_i$ without GnRHR activation (Ca^{2+} ionophores, membrane depolarization, etc.). The spike–plateau phases of Ca^{2+} mobilization are mirrored by GnRH-stimulated gonadotropin secretion,[23,24,294] demonstrating the close relationship between $[Ca^{2+}]_i$ and exocytosis from gonadotropes. It is generally thought that global increases in $[Ca^{2+}]_i$ mediate GnRH-stimulated exocytosis, as opposed to the localized high concentrations of Ca^{2+} that mediate neurotransmitter secretion into the synapse,[281] and that the pattern of Ca^{2+} responses is not critical for secretion, as it can be evoked by either spike–plateau or oscillatory Ca^{2+} signals.[281,284] The Ca^{2+} effectors mediating GnRH-stimulated gonadotropin secretion have not been described in detail, although it has long been known that GnRH causes rapid translocation of the ubiquitous Ca^{2+} sensor calmodulin from the cytoplasm to the plasma membrane and that pharmacological inhibition of calmodulin can inhibit GnRH-stimulated gonadotropin secretion.[291,295–298] It is also well established that GnRHR-mediated PKC activation can be rapid (as revealed by rapid translocation to membranes) and that PKC activation can rapidly increase gonadotropin secretion. However, early PKC depletion experiments[274,299] revealed that the phorbol ester-sensitive PKC isozymes are not absolutely required for GnRH-stimulated gonadotropin secretion (whereas elevation of the $[Ca^{2+}]_i$ is required), implying that GnRH-stimulated gonadotropin secretion is Ca^{2+} mediated and PKC modulated.[192,274,299–301] This is in accord with data showing that PKC activation increases secretion from gonadotropes by increasing the sensitivity of the secretory machinery to Ca^{2+}(rather than by increasing the size of the releasable hormone pool) and that prior PKC activation can increase the potency of GnRH and Ca^{2+} ionophores at stimulation of gonadotropin secretion.[302,303] In other models, the small G-protein Rab3 tethers secretory vesicles to the plasma membrane, facilitating the NSF-primed assembly of vesicle membrane and target membrane proteins (i.e., syntaxin and synaptobrevin, complexed with synaptosomal-associated protein 25 (SNAP25)) that docks the granule to the membrane.[251] This docking machinery interacts with the Ca^{2+}-activated synaptotagmin that drives the fusion of docked vesicles with their target membranes. To our knowledge, the nature of this secretory machinery has

not been explored in detail in gonadotropes, although it is known that SNAP, soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE), and Rab3 family proteins are expressed in gonadotropes and that GnRH can increase SNAP25 mRNA expression in αT3-1 cells.[304] Here, it is also important to recognize that although Ca^{2+} mediates stimulation of regulated secretion, a significant proportion of gonadotropin secretion is via the constitutive pathway (Figure 10.2), such that pulses of GnRH-stimulated gonadotropin secretion are superimposed over significant levels of basal secretion.[34] Indeed, the proportion of FSH secreted constitutively exceeds that for LH,[34] and examination of hypophyseal and peripheral blood has revealed a high degree of synchrony between pulses of GnRH and LH, whereas FSH pulses are associated with only a small proportion of GnRH pulses.[305,306] Since LH and FSH are present in the same gonadotrope,[307,308] this requires sorting of the gonadotropins into distinct vesicles, and it is noteworthy that only vesicles containing LH are associated with the storage protein secretogranin II and that the amount of LH stored in the pituitary can be 10–50 times higher than that of FSH.[34,309,310] Thus, GnRH-stimulated Ca^{2+} transients drive regulated exocytotic release of storage vesicles containing LH, but have a less pronounced effect on FSH secretion because it is less abundant in these vesicles and is, instead, directed largely for constitutive secretion.[34]

Although GnRHRs characteristically mediate activation of G_q and/or G_{11}, there is good evidence for activation of other heterotrimeric G-proteins and for G-protein-independent GnRHR signaling. Early work with pituitary cells revealed that GnRH can stimulate an increase in cAMP levels,[311] although this does not necessarily reflect activation of G_s in gonadotropes. Moreover, GnRHRs have been shown not to increase cAMP or to do so by mechanisms other than G_s activation in various models.[273,312,313] Nevertheless, Arora et al. (1998) showed that GnRHRs expressed in COS cells mediate cAMP elevation and identified amino acids in IC1 required for the cAMP response but not for stimulation of [^{3}H]IP accumulation, uncoupling that argues against the cAMP response occurring downstream of PLC.[314] GnRH can also increase cAMP accumulation in LβT2 gonadotropes,[273,315] an effect that has been attributed to sequential activation of G_q and adenylyl cyclase (i.e., PKC-mediated activation of adenylyl cyclases 5 and 7[273]) or to direct activation of G_s.[315] In the latter case, GTP loading provided direct evidence for G_s activation. As noted here, GnRHRs are expressed in a number of nonpituitary sites, and the most compelling evidence for activation of multiple G-proteins by endogenous GnRHRs comes from work with immortalized GnRH-producing neurons.[316,317] In these cells, GnRH causes activation of G_s, G_i, and G_q as revealed by agonist-induced release of activated G-protein subunits from membranes and associated functional responses. Temporal differences were observed in G-protein activation, and a molecular switch was described with G_s being activated at lower GnRH concentrations than G_i and G_q.[316,317] There is also considerable evidence for GnRHR-mediated activation of G_i in cancer cell lines as, for example, in JEG-3 human choriocarcinoma cells, and in the human benign prostate hyperplasia (BPH) epithelial cell line (BPH1),[318] where GnRH inhibits forskolin-stimulated cAMP accumulation, and this effect is blocked by pertussis toxin, implying mediation by G_i. Moreover, in several models pertussis toxin has been shown to prevent antiproliferative effects of GnRHR ligands, again suggesting action via G_i.[318] In general, it appears that G_i is an important mediator of the antiproliferative effects of extrapituitary GnRHRs, whereas G_q is the primary mediator of pituitary GnRHR effects on gonadotropin synthesis and secretion.[39] Together, these studies demonstrate the potential for GnRH to activate distinct heterotrimeric G-proteins and to do so in a manner that is dependent upon cell context.

Multiple Lipid-Derived Messengers

Membrane phospholipids are a major source of signaling molecules generated in response to receptors activating distinct phospholipases that differ in terms of their preferred substrates and the phospholipid bonds that they hydrolyze. The phosphoinositide-specific PLCs are divided into five main groups: PLCβ, γ, δ, ε, and ζ. They have distinct domain structures and activation mechanisms but all have PIP_2 as the preferred substrate, and they cleave this to generate IP_3 and DAG.[251] There are two forms of phospholipases D (PLD); PLD1, which is associated with vesicles of the endosomal–lysosomal pathway, and PLD2, which is mainly located at the plasma membrane. Both act mainly on phosphatidylcholine to produce phosphatidic acid (PA) and polar alcohol. At least 20 phospholipase A2 (PLA2) enzymes have been cloned in mammals, all of which release long-chain unsaturated fatty acids, including arachidonic acid (AA), oleic acid, and linoleic acid, from the sn-2 position of membrane phospholipids.[37,319] They are divided into the small secretory forms ($sPLA_2$) that are activated by mM Ca^{2+}, the cytosolic forms ($cPLA_2$) that are activated by serine phosphorylation and by μM Ca^{2+}, and the calcium-independent group ($iPLA_2$). The AA produced by PLA_2 can directly regulate target proteins, can be converted to prostaglandins (PGs) and thromboxanes via cycloxygenase 1 (COX1) or COX2 and PG synthase, or via lipoxygenases can be converted to lipid mediators, including leukotrienes.[37] GnRHRs characteristically mediate rapid (within 5–30 s) activation of PLCβ, which may be followed (after approx. 5–15 min) by activation

of PLD and PLA_2. The PA produced by PLD can be converted to DAG, so its delayed activation may mediate a second, more sustained wave of PKC activation.[37] Conversely, GnRHRs have been shown to cause a c-Src-mediated activation of diacylglycerol kinase (DGK)-ζ, an enzyme that phosphorylates DAG to produce PA. PA is itself able to alter activity of PAK1 and RasGAP as well as DNA synthesis and actin polymerization,[320] so PLD and DGK-ζ may both promote PA-mediated signaling.

Lipoxygenase products of AA metabolism are implicated in control of GnRH secretion and synthesis,[37] and its PG products have been shown to selectively inhibit GnRH-stimulated LH secretion.[37] Whereas GnRHR-mediated PLCβ stimulation involves direct activation by subunits of $G_{q/11}$, activation of PLA_2 and PLD is less direct. Many GPCRs activate PLD via the small G-protein ARF and RhoA, and this effect appears dependent on the presence of an Asn–Pro–XX–Tyr motif in TMD7 (and, as noted above, this is Asp–Pro–XX–Tyr in GnRHRs). Consequently, they do not cause ARF-mediated PLD activation, but they do so if the Asp is replaced by Asn.[321,322] Instead, it is thought that PLD activation occurs downstream of PLC and PKC, as it is reduced by inhibition of PLC and by depletion of PKC or inhibition of Ca^{2+} entry via VGCCs.[24,323,324] Whilst considering the hierarchical activation of phospholipases, it is also important to recognize that GnRHRs cause a PKC-mediated activation of epidermal growth factor (EGF) receptors in some models (see the section Mitogen-Activated Protein Kinases) and might therefore be expected to activate PLCγ, a well-established effector for EGF receptors. Moreover, since all of the PI-specific PLCs (β, γ, δ, and ε) are Ca^{2+} sensitive,[251] the potential exists for their activation as a consequence of GnRHR-mediated Ca^{2+} mobilization. PLA_2 activation by GnRH has not been explored extensively, although a recent study showed that LβT2 cells express $cPLA_2$ and $iPLA_2$ transcripts and (rather surprisingly) that GnRH caused AA release by activation of the Ca^{2+}-insensitive $iPLA_2$.[319]

Although much work on GnRH signaling focuses on PIP_2 as a source of signaling intermediates, PIP_2 is itself an extremely important signaling molecule that directly regulates effectors, including transient receptor potential channels (TRPV1 and TRPM7), K^+ channels (ATP-sensitive, HERG, and KCNQ K^+ channels), and PLD,[251] although the potential relevance of such effects for GnRH signaling has not, to our knowledge, been explored. Moreover, enzymes of the PI3-kinase (PI3K) family phosphorylate PIP_2 to generate $PI3,4,5P_3$, the main second messenger in the PI3K signaling pathway that influences a wide range of cellular processes, including glycogen metabolism, gene transcription, and cell growth and apoptosis.[251] Tyrosine kinase receptors can feed into this pathway by p85-mediated activation of class 1A PI3K, whereas GPCRs can do so by βγ subunit–mediated activation of class 1B PI3K.[251] Both phosphorylate PIP_2 to generate $PI3,4,5P_3$, which directly activates several important target proteins, including PLCγ and PKCs δ and ζ, as well as the serine–threonine protein kinase Akt–protein kinase B (PKB) that has important effects on cell fate and monomeric G-proteins (Rac, Rho, and Cdc42) that regulate cytoskeletal architecture.[251] Roles of the PI3K signaling pathway in GnRH signaling have not been extensively explored, although GnRH has been shown to activate PI3K via transactivation of EGF receptors in GT1-7 cells (immortalized GnRH-expressing neurons),[325] whereas it inhibits IGF-I-stimulated activation of Akt–PKB in αT3-1 cells[326] and PI3K has been identified as a negative regulator of FSHβ and LHβ gene expression in LβT2 cells.[327]

Mitogen-Activated Protein Kinases

Mitogen-activated protein kinases (MAPKs) are Ser–Thr protein kinases with pivotal roles in control of many cellular activities, including proliferation, survival, differentiation, growth, and apoptosis. The MAPK modules contain three protein kinases—an MAPK kinase kinase (MAPKKK), an MAPK kinase (MAPKK), and MAPK—that phosphorylate and activate one another in sequence, as well as numerous upstream regulators and downstream effectors[251,328–330] (Figure 10.3). The four major mammalian cascades are designated according to their MAPKs, which are ERK1 and ERK2 in the ERK cascade, c-Jun N-terminal kinases 1–3 (JNK1–3) in the JNK cascade, p38α–δ in the p38–stress-activated protein kinase, and big MAPK (BMK) in the ERK5 cascade.[251] The best characterized of these is the ERK cascade (where the term ERK is used to mean ERK1 and/or ERK2), in which a Raf protein kinase (i.e., the MAPKKKs Raf1, A-Raf, and B-Raf) phosphorylates and activates MEK (i.e., the MAPKKs MEK1 and MEK2). Activated MEK then phosphorylates ERK on Thr and Tyr residues of a TEY activation loop. ERK is a Ser–Thr kinase that phosphorylates substrates in a consensus Pro-X-Ser/Thr–Pro sequence. It has numerous substrates, including cytoplasmic proteins such as cPLA2, B-Raf, and SOS (Son of Sevenless), and transcription factors such as c-Fos, c-Jun, Elk1, STAT1, CREB, and Egr1.[251] ERK is mostly cytoplasmic in unstimulated cells, but activation causes its translocation to the nucleus, facilitating access to transcription-regulating substrates and thereby mediating effects on cell fate.[331–335] ERK does not contain nuclear localization or export signals, and it therefore relies on association with other proteins for appropriate cellular compartmentalization.[336] Thus, cytoplasmic and nuclear binding proteins influence ERK distribution by altering the proportion of ERK available for movement to or from the nucleus. Notably, MEK is a major cytoplasmic scaffold of ERK. When MEK phosphorylates

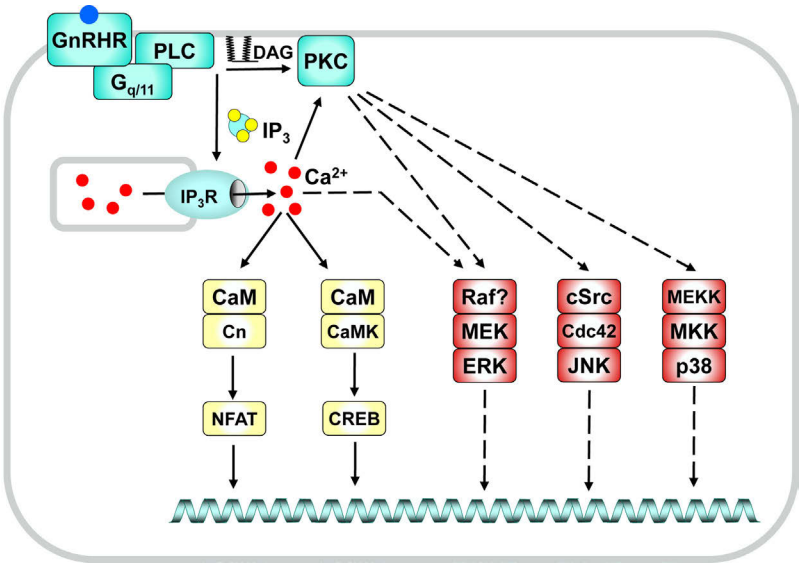

FIGURE 10.3 GnRH signaling from the plasma membrane to the nucleus. This figure illustrates pathways by which GnRHR can mediate effects on gene expression. One of the key Ca^{2+} targets implicated in GnRH action is calmodulin (CaM), which has the potential to activate the Ca^{2+}-sensitive transcription factor NFAT by activation of the protein phosphatase calcineurin (Cn), and to activate the transcription factor CREB by activation of calmodulin-dependent protein kinase (CaMK). The other key Ca^{2+} target illustrated is PKC, which acts (by numerous mechanisms) as a positive regulator of ERK, JNK, and p38 MAPK cascades, each of which influences gene expression by phosphorylation of targets, including transcription factors. This illustrates only a small proportion of the known mechanisms. For the sake of simplicity, we focus solely on chronic responses following the acute effects shown in Figure 10.2 and have not included cross-talk, convergence, compartmentalization, or kinetics.

ERK, this causes its liberation from MEK and facilitates its interaction with other proteins, including those of the nuclear pore complex. Consequently, MEK activation characteristically increases the proportion of ERK in the nucleus, and this effect is dependent upon the TEY motif but not on catalytic activity of ERK.[337–344] Other proteins that can cause cytoplasmic retention of ERK include PEA15, dual-specificity phosphatase 6 (DUSP6), β-arrestins, and Sef.[335,345–350] In contrast, expression of nuclear DUSPs 2, 4, and 5 can mediate dephosphorylation and nuclear anchoring of ERK.[351–354]

ERK binds to a large number of proteins (>400, including substrates, scaffolds, and phosphatases) in a dynamic and highly specific manner,[336] and this is dependent upon docking domains. The common docking (CD) motif in ERK binds to Lys- and Arg-rich sequences called D (docking) domains in its binding partners.[355] Another docking site in ERK protein partners is termed the DEF (docking site for ERK: F/Y-X-F/Y-P) motif, and this binds to a DEF-binding pocket (DBP) in ERK.[356,357] ERK protein partners can contain D and/or DEF domains,[356,358–360] and release of ERK from MEK exposes these docking sites for interaction with other binding partners during stimulation.

The classic mechanism for ERK activation involves stimulation of tyrosine kinase receptors that dimerize to facilitate autophosphorylation on tyrosines and consequent recruitment of transducers. Thus, for example, EGF-activated ErbB1 receptors recruit an adapter protein (Grb2) via its SH2 domains, and Grb2 binds SOS via the SH3 proline-rich domain. SOS is a guanine nucleotide exchange factor for the monomeric G-protein Ras, and the active (GTP-bound) form of Ras activates the MAPKKK Raf.[251] However, many other stimuli activate ERK by a range of mechanisms that may or may not involve transactivation of tyrosine kinase receptors. GnRH has been shown to activate ERK in many systems, and the mechanisms appear to be dependent upon cell context. The endogenous GnRHRs of rat pituitary cells and gonadotrope lineage αT3-1 or LβT2 cells mediate ERK activation that is dependent upon PKC and on Ca^{2+} influx via VGCCs,[37,38,361–366] which is in accord with evidence showing that PKC can feed into activation of Raf and that ERK activation is often Ca^{2+} dependent.[251] However, the absolute role of Raf in ERK activation by GnRH is not completely clear since conditional deletion of c-Raf kinase in mouse gonadotropes did not cause a reproductive phenotype.[367] GnRH-mediated ERK activation was also shown to be dependent upon c-Src and Ras in αT3-1 cells and upon c-Src in LβT2 cells, supporting a model in which PKC causes a c-Src-mediated activation of Ras.[37,361,362] As an alternative mechanism, the endogenous GnRHRs of GT1-7 cells cause PKC-mediated transactivation of EGF receptors and consequent activation of ERK. EGF receptor transactivation could reflect c-Src-mediated phosphorylation of the EGF receptor, or the shedding of soluble EGF receptor ligands such as heparin-binding EGF.[368] In the

latter case, matrix metalloproteinases (MMPs) release the soluble ligand to activate EGF receptors and feed into the canonical activation pathway. In GT1-7 cells, GnRH causes a PKC-mediated activation of MMPs and an EGF receptor–mediated activation of ERK,[368] whereas GnRHR-mediated ERK activation has been reported to be independent of EGF receptors in αT3-1 and LβT2 cells[361,362] or to be dependent on MMP2 and MMP9 and EGF receptor transactivation in αT3-1 cells.[369]

In addition to activation of ERK, GnRH can activate the JNK, p38, and ERK5 cascades in various cell models with variable kinetics (Figure 10.3). The canonical JNK cascade is activated in response to osmotic stress and redox stress that activate monomeric G-proteins (Rac, Cdc42, and Rho), which activate MAPKKKs, including MEKK1, MLK1, TAK1, ASK1, and TPL2. These phosphorylate and activate the MAPKKs MEK4 and MEK7, which, in turn, phosphorylate and activate JNKs 1–3.[251] The JNKs influence cell fate (particularly cell division and apoptosis) by phosphorylation of effectors, including c-Jun, Jun-B, Jun-D, ATF2, and Elk1. GnRH causes JNK activation that has been reported to be dependent upon PKC, c-Src, CDC42–Rac1, and MEKK1 in αT3-1 cells,[370] whereas others have reported dependence on Ca^{2+} but not PKC in these cells,[371] or independence from PKC and Ca^{2+} in LβT2 cells.[365] The canonical p38 cascade is activated under osmotic stress and by Fas ligand, which cause receptor-mediated activation of the MAPKKK TAK1, and by some cytokines that cause Rac- and Cdc42-mediated activation of TAK1. TAK1 then phosphorylates and activates the MAPKK MEK3, which in turn activates and phosphorylates the p38α–δ MAPKs.[251] The p38 MAPKs mediate effects on cell function (notably apoptosis, cytokine release, and cell cycle arrest) by phosphorylation of cytoplasmic targets, including MNK, MSK, MK3, and MK5, and nuclear targets, including ATF2, Ets, SAP1, and CHOP. GnRH activates p38 MAPK in αT3-1 and LβT2 cells, an effect that is mimicked by a PKC-activating phorbol ester and prevented by PKC depletion, implying mediation by PKC.[269,362] Finally, several mitogens and cell stress activate the ERK5 cascade via an upstream transducer (LAD1) that activates the MAPKKKs MEKK2 and MEKK3. These then activate the MAPKK MEK5, which phosphorylates and activates ERK5. ERK5 activates a number of transcription factors, including MEF2, SAP1, and Fra1. These mediate ERK5 effects on cell proliferation and stress responses,[37] and recently, GnRH was shown to activate ERK5 in LβT2 cells.[372]

In contrast to the information available on activation mechanisms, much less is known about inactivation of MAPKs after GnRH stimulation, an issue that is particularly germane with physiologically relevant pulsatile stimulation (see the section Extrapituitary GnRHRs and Context-Dependent GnRHR Signaling and Ligand Bias). This is a complex area as the human genome has many phosphatases involved in signal transduction, including 23 Ser–Thr phosphatases and a protein tyrosine phosphatase (PTP) family with 106 members.[373–375] The PTPs can be divided into four subfamilies on the basis of amino acid sequence in the catalytic domains, and the first of these (type I Cys-based PTPs) is further divided into the classical PTPs and the dual-specificity phosphatases (DUSPs). MAPKs can be dephosphorylated and inactivated by multiple Ser–Thr phosphatases and PTPs,[374] so the number of enzymes that inactivate MAPKs by dephosphorylating one or both of the phosphosites in their activation loops is much greater than the number of activating kinases.[373,374] In the case of GnRH signaling, most work has focused on the DUSPs, enzymes characterized by their ability to dephosphorylate both the Tyr and the Ser–Thr residue within the same substrate. The catalytic pocket of DUSPs is shallower than that of other PTPs, and it is thought that this enables them to simultaneously accommodate both phosphosites in the substrate.[374] Two major groups of DUSPs are the MAPK phosphatases (MKPs) and the closely related atypical DUSPs.[374] The three groups of MKPs acting directly on MAPKs are (1) the nuclear-inducible MKPs (DUSP1–MKP1, DUSP2–PAC1, DUSP4–MKP2, and DUSP5–VH3), which all dephosphorylate ERK and (with the exception of DUSP5) also dephosphorylate JNK and/or p38; (2) the cytoplasmic ERK MKPs (DUSP6–MKP3, DUSP7–PYST2, and DUSP9–MKP4), which preferentially target ERK; and (3) the JNK–p38 MKPs (DUSP8–VH5, DUSP10–MKP5, and DUSP16–MKP7), which preferentially target JNK–p38.[353,354,373–378] In addition, the atypical DUSPs lack obvious MAPK-targeting motifs and dephosphorylate a broad group of substrates. However, some members of this group are known to act directly on MAPKs.

Many stimuli cause an ERK-mediated increase in expression of nuclear-inducible MKPs that can influence the amplitude, duration, and cellular compartmentalization of MAPK activation. Indeed, early studies showed that GnRH increases the expression of two nuclear-inducible MKPs (DUSP1 and DUSP4) in αT3-1 cells.[379–381] In this model, the increased expression of MKPs caused by sustained stimulation with GnRH exerted negative feedback on JNK but had little or no effect on the ERK response. Subsequent work in a GnRHR-transfected HeLa cell model again revealed induction of DUSP1 and DUSP4 (as well as DUSP2) by GnRH.[382] In this model, endogenous ERKs were knocked down with small interfering RNA (siRNA), and recombinant adenoviruses were used to add back an ERK2–GFP reporter at a concentration similar to that of the endogenous kinase in normal cells.[353,354,382] This approach enables mutant constructs to be used, and it was found that GnRH has a greater effect on ERK activation when a D319N mutation is introduced into ERK2 in order to prevent

D-domain-dependent association with binding partners, including DUSPs.[382] Similar amplification of responses was seen when protein neosynthesis was prevented with cycloheximide,[382] and a siRNA screen targeting all of the expressed DUSPs revealed effects of GnRH to be influenced by knockdown of DUSP from each MKP class (DUSPs 3, 5, 9, 10, and 16). Nevertheless, knockdown of DUSPs 1, 2, and 4 (alone or in combination) did not alter GnRHR effects. Thus, GnRH-mediated ERK responses are modulated by DUSPs and are dependent on both protein neosynthesis and D-domain binding, but the nuclear-inducible DUSPs appear not to shape ERK signaling in this model,[382] as has been reported for DUSP1 and DUSP4 in αT3-1 cells.

This section has been intended primarily to describe the fundamental pathways and mechanisms of MAPK activation by GnRHRs. However, much work focuses on the role of these pathways in mediating GnRH effect on gene expression, and this is dealt with in the section Regulation of Gene Expression. Similarly, more recent work on the compartmentalization of signaling, the spatial and temporal aspects of ERK activation, and the roles of MAPKs in mediation of pulsatile GnRHR signaling are dealt with in the sections Lipid Rafts and Extrapituitary GnRHRs, Context-Dependent GnRHR Signaling, and Ligand Bias.

Regulation of Gene Expression

The GnRH-Induced Gene Network: A Genomewide Perspective

The Sealfon group has been instrumental in examining the genomewide impact of GnRH on models of the pituitary gonadotrope.[383–387] These studies were carried out in the LβT2 gonadotrope-derived cell line examining changes in transcript abundance at 1 and 6 h following application of GnRH. Custom cDNA microarrays containing 956 clones of transcripts identified via literature search or from input from collaborating laboratories were used. These studies were some of the initial efforts to describe genomewide responses to GnRH, and they identified a relatively large group of transcripts that helped to identify the immediate early gene repertoire, including a group of transcription factors and modulators of cell signaling.[383] Based upon the cDNA microarray, transcript abundance for transcription factors such as c-Fos, Egr1, and ATF3 was markedly upregulated from 1.3- to 30-fold and formed the foundation for later analyses of regulation of the gonadotrope signature genes. For example, the activator protein 1 (AP1) heterodimer (a c-Fos–c-Jun heterodimer) plays an important role in the regulation of FSHβ and αGSU promoters,[170,388] Egr1 plays an essential role in the regulation of the LHβ gene promoter,[164,389] and ATF3 was linked to expression of the human αGSU gene promoter.[388,390] The signaling and transcriptional networks induced by GnRH in this cell model are reviewed extensively in Refs 391,392. These types of genomewide analyses have not yet been reported in vivo using mouse models to confirm the important findings of the LβT2 cell model.

The genomewide micro-RNA (miRNA) transcriptome was also investigated by the Sealfon group in LβT2 cells using microarrays to examine the possibility that miRNAs may play an important role in modulating responses to GnRH in gonadotropes.[393] Several hundred miRNAs were detected in this cell model, were validated beyond the microarray using quantitative PCR (qPCR), and were largely present independent of GnRH action. Two miRNAs (miR-132 and miR-212) were regulated by GnRH, but these miRNAs did not respond to specific changes in GnRH pulse frequency. Follow-up experiments by the Webster group[394] demonstrated that miR-132 and miR-212 targeted p250 Rho GAP, a GTPase-activating protein. Using knockdown strategies, p250 Rho GAP appears to play an important role in the GnRH-induced modification of LβT2 cell morphology. Loss of p250 Rho GAP resulted in increased activity of the small GTPase Rac, leading to increased formation of neurite-like cellular processes and a marked increase in cell motility in vitro. Collectively, these studies suggest important genomewide alterations in the RNA and miRNA transcriptomes in LβT2 cells, setting the stage for these types of analyses of these potential changes induced by GnRH and potentially GnRH pulse frequency in vivo.

Transcriptional Regulation of the Gonadotrope Signature Genes

This chapter has outlined mechanisms associated with the development of pituitary cell lineages during organogenesis. This complex process is critically dependent upon specific transcriptional regulators such as Lhx3, NR5A1, and Pitx family members. Cell differentiation largely reflects the ability of specific transcriptional regulators to control cell-specific gene expression networks. This scenario is not necessarily specific to developmental programs and can often reflect mechanisms that persist into the adulthood of a living animal. For example, NR5A1 and Pitx family members contribute to the regulation of GnRHR, αGSU, LHβ, and FSHβ subunit gene promoters, while Lhx3 appears to regulate GnRHR, αGSU, and FSHβ subunit gene promoters. Furthermore, expression of the four gonadotrope signature genes during the estrous cycle and following castration reflects physiologically relevant input by factors such as gonadal steroids and GnRH pulsatility directly on the gonadotrope that modulates "inducible" gene regulation appropriate to physiological needs, such as during the transition from the prepubertal to sexually mature state and during portions of the estrous cycle leading up to the preovulatory surge of LH and ovulation. The

following section explores the transcription factors and signaling systems that contribute to the regulation of the GnRHR, αGSU, LHβ, and FSHβ subunit gene promoters (Figure 10.4). Where relevant, we explore mouse gene knockout models that provide critical in vivo evidence for these relationships.

Regulation of the GnRHR Gene Promoter

In the context of the mammalian estrous cycle, changes in GnRHR gene transcription lead to crucial changes in receptor numbers at the plasma membrane of the gonadotrope. Increased receptor numbers alter the sensitivity and responsiveness of the gonadotrope during physiologically relevant situations such as changes leading to the preovulatory surge of LH and ovulation. GnRH and estradiol are thought to be key regulators of GnRHR gene expression.[395–400] Moreover, the GnRHR gene promoter is also a target of activin signaling in the gonadotrope.[401–407] In some instances, GnRH and activin may function together to regulate GnRHR transcription. Alternatively, regulation of GnRHR transcript abundance is likely to be independent of gene transcription and can be regulated at the translational level.[408] Here, we focus primarily on discussions of regulatory mechanisms of the murine GnRHR since much of what we know of the gene regulation of the GnRHR comes from this species, from both murine clonal cell lines and gene knockout models. The reader should bear in mind that important species similarities and differences exist; due to space constraints, these species differences are not covered to any great extent here.

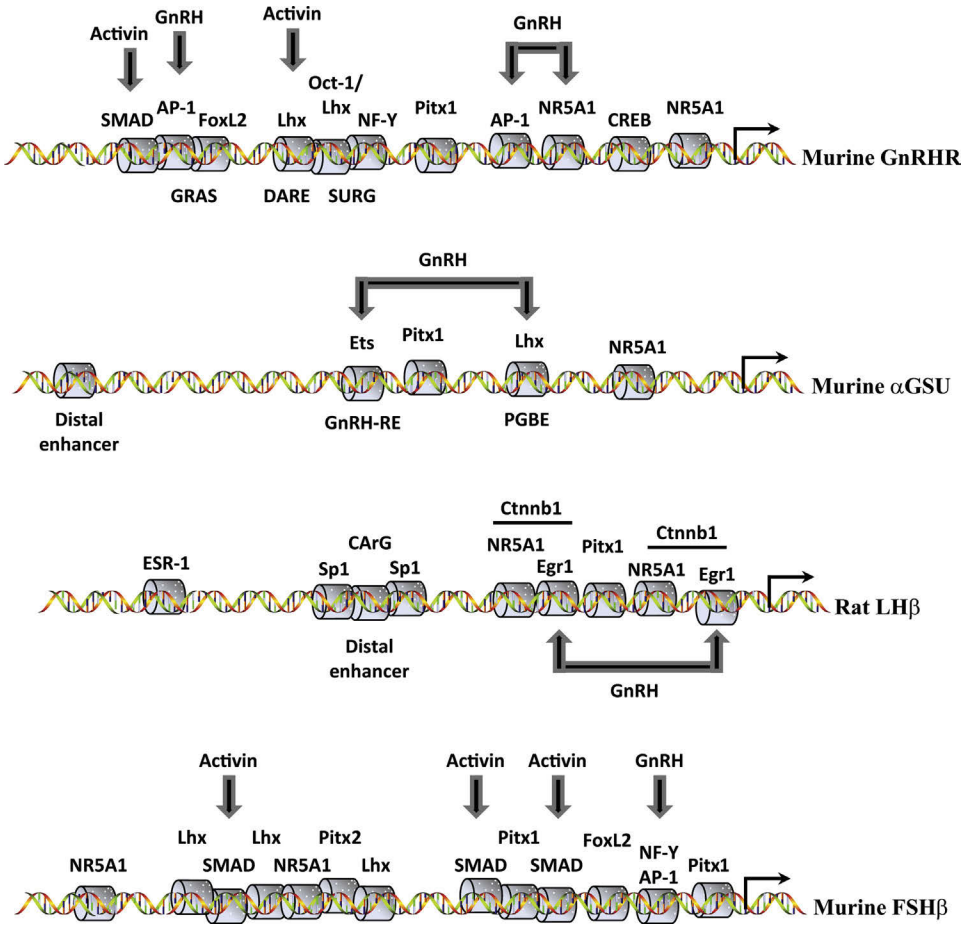

FIGURE 10.4 Transcriptional control of the gonadotrope signature gene promoters. The diagram depicts the 5′ flanking sequences from the four signature genes that define the gonadotrope cell lineage; the murine GnRHR, the murine glycoprotein hormone α subunit (αGSU), the rat LHβ subunit, and the murine FSHβ subunit. Individual *cis* regulatory elements and associated transcription factors are depicted within the promoter upstream of the transcription start site (depicted by the black arrow). Spatial organization of these elements is not drawn to scale but reflects the relative placement of these elements within the promoter. Single and combinations of elements involved in regulation by GnRH and activin are identified by the gray and black arrows. In some instances, single or combinatorial elements are identified: GRAS: GnRHR-activating sequence; DARE: downstream activin regulatory element; SURG: sequence underlying responsiveness to GnRH; GnRH-RE: GnRH responsive element; PGBE: pituitary glycoprotein hormone basal element.

In the mouse, basal and GnRH-regulated control of the GnRHR promoter requires 1.2–1.9 kb of the 5′ flanking sequence. Gonadotrope-specific expression and induction by GnRH were seen in transgenic mice harboring reporters controlled by either of two GnRHR promoter fragments.[397,409,410] Similar observations were made using clonal gonadotropic and heterologous cell lines. Within this region of the murine GnRHR gene promoter, a number of *cis* regulatory elements have been identified, including the GnRHR activating sequence (GRAS),[411,412] sequences underlying responsiveness to GnRH (SURG),[397,413] the downstream activin regulatory element (DARE),[414] an AP1 site, a NR5A1-binding site,[412] and a Pitx1-binding site.[415,416] The GRAS element is a complex combination of an SMAD, AP1, and forkhead factor–binding sites; mutations within GRAS, the AP1 site, and the NR5A1 element each have a marked impact on basal regulation of the murine GnRHR promoter; and mutations in all three of these elements essentially abolish promoter activity. The engagement of the AP1 and NR5A1 elements appears to be critical for basal and GnRH-stimulated activity of this promoter, and these data provide corroborative evidence for the importance of NR5A1 on GnRHR regulation, consistent with the NR5A1 null mouse described in this chapter.[146,147] However, since gonadotropin secretion can be partially rescued by exogenous GnRH treatment in the NR5A1$^{-/-}$ mouse, it seems likely that the role of NR5A1 in gonadotropes is in combinatorial context with other important regulators of GnRHR promoter activity. The role of the AP1 site is clearly central to GnRH regulation of the GnRHR, and this finding helps to substantiate findings that GnRH action to activate the c-Jun N-terminal pathway and Fos–Jun family members is required with this role.[400] Interestingly, gonadotrope-specific conditional deletion of ERK1 and ERK2 does not appear to have a strong impact on GnRHR transcript levels in the mouse gonadotrope in vivo,[38,166] suggesting that GnRH-induced JNK activity is central to this AP1 site.

Activins play an important role in the regulation of both the GnRHR and FSHβ subunit (described further in this chapter) gene promoters in gonadotropes. Activins are TGFβ family members composed of inhibin βA and βB dimers.[170,417] Originally identified along with inhibin from gonadal extracts, activin is now known to be synthesized and secreted by gonadotropes to function in an autocrine and/or paracrine manner. Given the fact that activin has important effects of GnRHR gene transcription, the overall impact of activin action on gonadotropes likely goes well beyond regulation of FSH synthesis and secretion. In the context of the GnRHR promoter, the GRAS binding site along with the DARE element appears to be critical for activin regulation; and GRAS together with the AP1 site facilitates synergistic activation by GnRH and activin.[411] The SMAD binding site within GRAS is central to activin action. Activin induces recruitment of SMAD3 and SMAD4 to the SMAD-binding site in GRAS; SMAD association with this complex is required for the recruitment of SMAD3.[411] Administration of activin alone in αT3-1 cells does not affect GnRHR promoter activity; however, in combination with GnRH, activin induces a synergistic transcriptional response. A direct effect of activin on the murine GnRHR was better defined by culturing gonadotrope cells in the presence of follistatin, a known inhibitor of FSH secretion through inhibition of activin action.[170,414] These studies suggested that follistatin effectively interferes with endogenous activin produced by gonadotropes and with activin inhibition, GnRHR promoter activity was induced. Using this strategy, these authors were able to more critically define the *cis*-acting regulatory elements necessary for activin action. This included identification of the DARE element consisting of a binding site for a putative homeobox protein likely in the Lhx family; Lhx2 or Lhx3 are likely candidates; however, this has not been confirmed.[414] Thus, activin action on the murine GnRHR required GRAS and DARE and the combined actions of GRAS, DARE and the AP1/NR5A1 sites working as an enhanceosome facilitate synergist activation of the GnRHR by activin and GnRH.

The third component to bind to the GRAS element is the forkhead factor, FoxL2.[411,418] Interaction between FoxL2 and the proximal end of the GRAS element was demonstrated using standard DNA binding assays along with definitive interactions shown using a yeast two-hybrid system. Interestingly, FoxL2 was also shown to physically interact with both AP1 and SMAD4 and optimally with a SMAD3/4 dimer. FoxL2 is first expressed in the anterior pituitary coincident with αGSU during development, and expression persists in gonadotropes and thyrotropes into adulthood.[418] Interestingly, disruption of FoxL2 by mutation in human patients or by knockout in mice results in sterility due to gonadal dysgenesis reminiscent of premature ovarian failure.[419,420] Thus, the impact of FoxL2 is clear at multiple levels of the hypothalamic–pituitary–gonadal axis.

The SURG element within the murine GnRHR promoter lies in close proximity to the GRAS element, and together with the AP1 site, the SURG element facilitates basal and GnRH-stimulated GnRHR promoter activity.[396,397] Like the GRAS element, SURG is a composite element consisting of binding sites for Oct1 and NF-Y; mutations in these elements reduce basal expression of the promoter, and combined SURG and AP1 site mutations abolish GnRH action on the GnRHR promoter. Also important to this mechanism is Pitx1 binding to the proximal murine GnRHR promoter.[416] Pitx1 in combination with the SURG element and the AP1 site, and in particular specific interactions between c-Jun and Pitx1, facilitate GnRH-induced GnRHR promoter activation.

Given the importance of estradiol in GnRHR regulation during the estrous cycle, the presence of an estradiol responsive element within the GnRHR gene promoter would not be surprising; however, this is not the case. The effects of estradiol on GnRHR are directly at the level of the gonadotrope[421–423] based on studies using primary culture of pituitary cells in the absence of hypothalamic input. Original predictions included the possibility that since estrogen receptor α (ESR1) and Fos–Jun family members could functionally interact in complexes associated with chromatin-remodeling enzymes, the effects of estradiol via ESR1 were through the AP1 site within the GnRHR promoter.[424] More recently, using ovine pituitary cells, Nett and colleagues[398] demonstrated that estradiol action on the ovine GnRHR was robust and could be recapitulated with estradiol–bovine serum albumen (BSA) conjugates, suggesting that the effects of estradiol were not through direct genomic actions but were indirect through membrane-associated ESR1. Defining this unique pathway will likely provide important clues for how estradiol functions as a critical regulator of GnRHR gene transcription during the mammalian estrous cycle.

Transcriptional regulation of GnRHRs within gonadotropes is critical in facilitating changes in gonadotrope sensitivity to GnRH during the mammalian estrous cycle. However, not all changes in GnRHR levels are via gene expression, and key mechanisms may include modulation of GnRHR protein levels by modulating translation efficiency of the GnRHR transcripts.[408] Using αT3-1 cells as a model system, chronic exposure to high relative levels of GnRH resulted in a depletion of ~75% of cell surface receptors by 24 h. Interestingly, GnRHR transcript levels were unchanged in the paradigm. Isolation of the transcripts and subsequent injection into *Xenopus* oocytes revealed that these GnRHR transcripts were greatly compromised in their ability to generate cell surface GnRHRs capable of mediating membrane-associated electrical currents. Translational inhibition appeared to be attributed to compromised translational efficiency on polyribosomes. Thus, chronic exposure to GnRH pharmacologically or potentially during the preovulatory GnRH–LH surge downregulates GnRHRs without apparent changes in GnRH-induced gene transcription but altered translational efficiency.[408]

Regulation of the Glycoprotein Hormone α Subunit Gene Promoter

The glycoprotein hormones (LH, FSH, TSH, and chorionic gonadotropins in primates and equines) are heterodimers consisting of a common αGSU and a hormone-specific β subunit. The β subunits of LH and FSH appear to be rate limiting in the formation of these heterodimeric hormones and confer individual hormone specificity.[425] Conversely, the αGSU is common to all of these hormones within a species and does not appear rate limiting in the assembly of the gonadotropins. A great deal of research has focused on the cell type–specific regulation of the gonadotropin subunit gene promoters due to their central importance to the regulation of gonadal function and fertility.[38] Moreover, analysis of the αGSU has represented an important model system for cell-specific transcriptional regulation since this same gene is regulated differently in gonadotropes, thyrotropes, and placental trophoblasts.[426–432] This includes a rather complex analysis of the contributions of combinations of *cis* regulatory elements in a so-called combinatorial code that control cell-specific regulation.[428]

In the mouse, ~0.5 kb of a 5′ flanking sequence is required for basal gonadotrope-specific expression of the αGSU promoter; in humans, a 0.88 kb fragment has been central to these studies. In mouse models in vivo, ~4.3 kb of the mouse promoter has been used to direct Cre recombinase expression to gonadotropes and thyrotropes.[166,433] The central regulator of αGSU gene transcription appears to be GnRH, where loss of hypothalamic GnRH stimuli results in a marked reduction of αGSU transcript abundance[4,434–436]; GnRH replacement in these models rescues this phenotype. These studies are complicated by the fact that αGSU is also expressed in thyrotropes, which contributes to the overall measurement of these transcripts. In addition to GnRH, androgens have been implicated as a modulator of negative feedback on αGSU gene transcription specifically at the level of the gonadotrope.

Basal regulation of the αGSU is regulated through the actions of three elements within the mouse promoter; the pituitary glycoprotein hormone basal element (PGBE), a Pitx1, and NR5A1-binding sites. The PGBE was originally identified in a mutagenesis screen of the promoter where mutations in this site dramatically reduced basal expression and, to a lesser extent, interfered with GnRH-induced expression of αGSU.[426,427,437] Expression cloning of a λGT11 library using a multimer of the PGBE yielded the complete open reading frame of a LIM class homeobox-containing protein, Lhx2.[437] Lhx2 was shown to be expressed abundantly in αT3-1 cells and in cell lines derived from the thyrotrope lineage.[438] Despite this in vitro evidence, Lhx2 expression does not appear within the developing anterior portion of the pituitary gland, and identification of Lhx2 appeared to identify an important class (LIM domain containing) of transcription factors but likely not the factor specific to αGSU.[89] Subsequent to these experiments, Lhx3 and Lhx4 were identified as key regulators of pituitary organogenesis (as outlined in detail in this chapter), and Lhx3 is a more likely candidate as the binding factor regulating the effects of the PGBE in mature gonadotropes.[93,137,140] The PGBE is conserved in the human αGSU promoter, where it likely plays a similar role in maintenance of

basal promoter activity.[439–441] The Pitx1-binding site also supports basal activity of the mouse αGSU promoter.[123,442] Interestingly, Lhx3 and Pitx1 appear to cooperate in the regulation of αGSU, and Pitx1 may indeed lie upstream of Lhx3 since disruption of Pitx1 results in a reduction in both Lhx3 and αGSU transcript expression in gonadotropes. The NR5A1-binding site is also critical for gonadotrope-specific regulation.[443] As indicated here, NR5A1 orchestrates the expression of a large cohort of steroidogenic enzymes, and it is critical to the development of the hypothalamic–pituitary–gonadal axis.[145,147] Conditional deletion of NR5A1 results in a marked reduction in αGSU expression, supporting the conclusion that NR5A1 plays a key role in gonadotrope gene regulatory mechanisms associated with αGSU.

GnRH induction of αGSU gene expression in αT3-1 cells is mediated by both the PGBE and a putative Ets factor–binding site termed the GnRH–responsive element (RE[426,427,444]). Multimers of the GnRH–RE were not sufficient to support basal transcription; however, these multimers were responsive to GnRH and phorbol esters used to activate PKC isozymes in transfection studies. In contrast, PGBE multimers supported basal transcription but were unresponsive to GnRH. Reconstituting the GnRH–RE and PGBE into the same reporter construct restored basal expression and augmented GnRH inducibility of this reporter. These studies suggested that the combined actions of the cell type–specific Lhx factor were permissive in conferring hormone responsiveness to the promoter via Ets factors whose expression was likely ubiquitous. Ets factors represent a large family of transcriptional regulators characterized by a conserved Ets domain, a DNA-binding domain favoring a 5′-GGAA central core binding motif.[444] Family members include Ets1 and Ets2 along with Elk1, an Ets-related factor associated with a serum response element shown to be critical for cellular responses to growth factors via receptor tyrosine kinases mediating ERK and JNK signaling. The GnRH–RE was identified using a mutagenesis screen where the mutation overlapped a motif consistent with an Ets factor–binding site. The DNA-binding domain of Ets2 was sufficient to specifically bind the GnRH–RE, and overexpression of a dominant-negative form of Ets2 could block GnRH induction of the αGSU reporter. These data suggested that an Ets family member is likely to be involved; however, the specific family member expressed in gonadotropes has not yet been determined. The possibility that GnRH signaling to the αGSU functions through a target of ERK signaling is supported by observations that gonadotrope conditional deletion of both ERK isoforms results in a marked reduction in basal and GnRH-stimulated accumulation of αGSU in vivo. This was corroborated by a sharp reduction in LH in serum in female double ERK knockouts.[166] A definitive mechanism coupling GnRH, αGSU, and putative Ets factors in vivo has yet to be elucidated.

The human αGSU gene promoter contains several elements conserved in the mouse promoter (the PGBE-, Pitx1-, and NR5A1-binding sites). In addition, other specific elements have been characterized in the human promoter, including two basal elements termed αBE1 and αBE2 and a cluster of elements (the trophoblast specific element (TSE), an α activating sequence (αACT), two consensus cAMP response elements (CREs), a junctional regulatory element, and a cytidine–cytidine–adenosine–adenosine–thymidine (CCAAT) box). Based upon mutational analysis, αBE1 and αBE 2[431] appear to be important regulatory sequences controlling basal expression of the human αGSU promoter in gonadotropes but not trophoblasts; however, little is known regarding the transacting factors that occupy these elements. The TSE, αACT, and the dual CREs play important regulatory roles in gonadotropes as well as trophoblast cells based upon scanning mutations. Of these, the dual CREs are likely the most prominent in the context of GnRH-induced expression of the αGSU.[388] Transcript profiling of immediate genes induced by GnRH reveals marked upregulation of activator protein 3 (ATF3). ATF3 has been identified as an immediate early response gene in genomewide studies of GnRH action. Expression of the human αGSU in αT3-1 cells is enhanced markedly by administration of GnRH. This induction could be abolished by pharmacological blockade of GnRH-induced ERK and JNK signaling and required the dual CREs. ATF3 upregulation could also be abolished using ERK and JNK pharmacological inhibitors, and overexpression of ATF3 in gonadotropes mimicked the effects of GnRH on this promoter. These studies supported the hypothesis that GnRH-induced ATF3 mediated increased human αGSU expression via ATF3 at the dual CREs. A similar mechanism was also reported for GnRH-induced secretogranin II promoter activity via consensus CREs.[390] Secretogranin II is a member of the chromogranin family of proteins found in secretory vesicles along with LH in gonadotropes. Finally, androgens have been demonstrated to repress human αGSU via the dual CREs and sequences comprising the αBEs.[445] The ability of androgens to function as negative-feedback inhibitors directly at the gonadotrope was associated with physical interactions between the ligand-bound androgen receptor and c-Jun–ATF2 heterodimers at the CREs. Again, these studies focused attention on the important role of the dual CREs of the human αGSU on both upregulation by GnRH and repression by androgens.

Regulation of the LHβ Subunit Gene Promoter

As indicated here, the β subunit to LH confers biological activity to the LH heterodimer.[425] Much of what we know regarding the transcriptional regulation of

the LHβ gene promoter comes from work done in the rat with confirmation from important knockout mouse models. Like αGSU, the LHβ gene promoter is sensitive to stimulation by GnRH and negative-feedback mechanisms associated with androgens and estradiol. In the rat, *cis* regulatory elements within ~0.5 kb of the transcription start site are sufficient to confer basal and GnRH-regulated expression on this gene in gonadotrope cell lines such as LβT2 cells. These elements include two specificity protein 1 (Sp1) sites, a CArg box, two NR5A1-binding sites, two Egr1 sites, and a Pitx1-binding site.

Responsiveness of the rat LHβ promoter to estradiol requires sequences further upstream within the promoter.[446] SP1 sites and the CArG box reflect an enhancer that lies more distal to the transcription start site of the promoter, and these sites appear to support basal regulation as well as control by the androgen receptor.[447] Importantly, the NR5A1, Egr1, and Pitx1 elements are highly conserved in the rat, bovine, equine, and human, suggesting an evolutionary importance to these elements in the control of LHβ in gonadotropes. The conservation of these sites is completely consistent with the role and requirement for these same transcription factors in coordinating promoters regulating the GnRHR, αGSU, LHβ, and FSHβ (detailed in this chapter).

Mutations in the NR5A1, Egr1, and Pitx1 sites all reduce basal expression of the LHβ gene promoter.[448–452] These three elements and their cognate-binding proteins form complex interactions leading to transcriptional activity of the LHβ promoter. For example, NR5A1 and Egr1 *cis* elements functionally interact in the regulation of LHβ,[163,448,451,453] and this interaction appears to facilitate synergistic activation of this promoter when stimulated by GnRH. Recently, GnRH-induced β-catenin (Ctnnb1) was shown to also participate in the interaction between NR5A1 and Egr1.[454] In those studies, association between Ctnnb1 and NR5A1 was required to facilitate the NR5A1–Egr1 interaction at the LHβ promoter. Knockdown of Ctnnb1 blunted GnRH-induced LHβ promoter activity in LβT2 cells. Ctnnb1 is thought to serve as a coactivator to NR5A1 activity at this promoter; however, this effect appears to be independent of glycogen synthase kinase 3, a critical regulator of Ctnnb1 activity since GnRH receptor activation results in inactivation of this kinase.[455–457] NR5A1, Egr1, and Pitx1 have also been shown to form a tripartite complex mediating GnRH-stimulated LHβ transcription.[162,163] The more distal Sp1 sites also appear to contribute to GnRH responsiveness since mutations within these elements blunt GnRH-induced activation of this promoter in vitro. Moreover, mutations within the Sp1 elements along with disruption of NR5A1 and Egr1 elements essentially abolish GnRH response of LHβ in in vitro cell models.[389,458]

Perhaps the most compelling evidence for the role of NR5A1 and Egr1 in LHβ subunit gene regulation comes from genetically modified mouse models. As discussed here, conditional deletion of NR5A1 in the pituitary results in the specific loss of LHβ subunit transcripts, providing important evidence that NR5A1 is required for the regulation of this gene in vivo.[147] The caveat here is that NR5A1 is also required for normal GnRHR expression, suggesting that both direct and indirect effects of NR5A1 and GnRH are plausible. Equally compelling is the role of Egr1 on LHβ transcript abundance in mouse knockout models.[164] Egr1 is an immediate early response gene induced by GnRH in both in vitro and in vivo model systems.[38,166,383,391] The regulation of the Egr1 gene is primarily mediated by the serum response element and Elk1 binding within the 5′ flanking sequences on the Egr1 gene promoter and appears to be the target of signaling from a wide variety of receptor systems, including GnRH.[459–465] Given the diversity of conditions shown to upregulate Egr1 as an immediate early gene via the serum response element, it was somewhat surprising that the Egr1 knockout mouse was born at expected frequencies and one of the primary lesions of this mouse model was female-specific infertility due to the specific loss of LHβ subunit gene regulation in the gonadotrope.[164] Ovariectomy in this mouse model resulted in the specific inhibition of castration-induced upregulation of LHβ without having a significant impact on the regulation of FSHβ subunit transcript abundance. Indeed, GnRH-induced Egr1 is absolutely required for LHβ gene expression. Further, Egr1 regulation by GnRH requires signaling through the ERK pathway, and specific conditional deletion of both ERK1 and ERK2 from gonadotropes results in a loss of Egr1 upregulation coincident with a loss of LHβ transcripts.[166] Collectively, these studies underscore the importance of Egr1 in the regulation of LHβ by GnRH–ERK signaling in gonadotropes in vivo.

The specific regulation of Egr1 is complicated by a well-characterized intracellular feedback loop involving Egr1-binding partners Ngfi-A-binding proteins 1 and 2 (NAB1 and NAB2).[453,466–470] In vitro, GnRH clearly induces NAB1 and NAB2 with kinetics slightly delayed compared to Egr1.[467] NAB1 and Egr1 physically interact, and this interaction results in inhibition of Egr1 action on target genes; however, this observation is controversial when, in specific situations, NAB1 and NAB2 have been observed to enhance Egr1 action or have little effect.[467–474] In the context of GnRH effects on LHβ in LβT2 cells, NAB1 and NAB2 appear to serve as GnRH-inducible repressors of Egr1 action, establishing an important intracellular negative-feedback system within the gonadotrope.[467,468] However, in rats examined in vivo and rat pituitary cells in primary culture, GnRH pulses did not affect NAB1 accumulation, suggesting that species and or in vitro model systems may vary in the role of NABs in the regulation of LHβ.[468]

Steroid hormones have been shown to impact LHβ subunit promoter activity. Androgens have a negative effect on LHβ promoter activity; however, the specific *cis* regulatory elements involved in this action are not entirely clear.[167,475] Inhibition by androgens is likely to involve interaction of the AR with components of the NR5A1 and Egr1 sites within the proximal LHβ promoter. AR can interact with both NR5A1 and Egr1, and these observations support speculation that this interaction blunts responsiveness of the promoter, particularly to GnRH stimulation in gonadotropes. AR suppression of LHβ has also been linked to suppression of NR5A1 activity on the LHβ promoter along the more distal Sp1 sites.[167] Given the central role of the NR5A1-, Egr1-, and Pitx1-linked enhancer, it seems plausible that ligand-bound AR forms a critical interface with this tripartite enhancer to modulate LHβ promoter activity.

Estradiol also has an indirect effect on mouse LHβ gene expression within gonadotropes. Initial studies examining the impact of estradiol on rat LHβ promoter activity identified an estrogen-responsive element that lies considerably upstream of the NR5A1, Egr1, and Pitx1 sites. Using an in vitro heterologous system (GH3 cells of lactotrope origin) known to be estradiol responsive, estradiol administration increased LHβ promoter activity several-fold.[476] In later studies using LβT2 cells (of gonadotrope origin), the direct effects of estradiol on the mouse LHβ promoter were only observed to augment GnRH action through increased levels of Egr1 following combined administration of estrogen and GnRH.[477] Given the novel role of estradiol action at the plasma membrane of pituitary gonadotropes described in the context of the GnRHR promoter,[398] it is presently difficult to parse out genomic versus nonclassical ESR action on the LHβ promoter.

Regulation of the FSHβ Subunit Gene Promoter

Regulatory mechanisms governing the control of the FSHβ subunit promoter arguably are the most complex of the gonadotropin subunits and perhaps the least understood. This is based on the complexity of the GnRH pulse parameters and variations in GnRH pulsatility controlling the FSH and LHβ subunit promoters, together with additional control of FSHβ by activin–inhibin and follistatin. In addition, a relative paucity of cell lines derived from the gonadotrope lineage that endogenously express FSHβ with fidelity to the in vivo situation contributes to this problem. Moreover, marked species differences appear to exist in the transcriptional control of FSHβ, and in some cases it is difficult to reconcile in vitro approaches in clonal cell lines and in vivo evidence just beginning to emerge from mouse model systems. The details of these mechanisms have been reviewed recently in very comprehensive fashion by Bernard.[170] Due to space constraints, the reader is directed to this[170] and other reviews[478,479] for a more detailed examination of FSHβ gene regulation.

Consistent with other gonadotrope signature genes, FSHβ promoter activity is regulated by *cis* regulatory elements binding NR5A1, Lhx3, and Pitx family members. In addition, binding sites for SMAD proteins are central to regulation by activin. Approximately 4 kb of the human FSHβ subunit gene promoter is sufficient to convey cell type–specific regulation in the transgenic mouse[480]; in the sheep, ~5.5 kb of a 5′ flanking sequence was sufficient for gonadotrope-specific expression in vivo.[481,482] The *cis* regulatory elements described here all are found within ~0.5 kb of the transcription start site, and their importance has been identified primarily using luciferase reporter constructs in the LβT2 cell line; these genomic promoter fragments are considerably smaller than those examined in transgenic mice.

The role of NR5A1 on FSHβ subunit regulation is best exemplified by the gonadotrope-specific conditional knockout of NR5A1 in mice[147]; these animals display markedly reduced levels of FSH immunoreactivity in the anterior pituitary. However, these studies are confounded by a loss of the GnRHR, with conditional deletion of NR5A1 making a clear interpretation of the specific role of NR5A1 on FSHβ expression somewhat difficult to determine.[170] Consistent with this notion, the direct effects of NR5A1 alone on FSHβ transcription appear to be relatively modest and likely dependent upon binding partners central to basal regulation.[169] For example, NR5A1 and NFY can physically and functionally interact in the context of the two NR5A1 and single NFY *cis* elements in the mouse FSHβ promoter in the LβT2 cell line. Mutations in at least one of the NR5A1 sites combined with an NFY binding site mutation was required to blunt basal expression of the promoter. Furthermore, this combination of elements and transcription factors also confers gonadotrope-specific expression. NR5A1 and NFY each have been shown to interact with and recruit chromatin-remodeling complexes to gene promoters,[151–153,483,484] supporting the possibility that higher order complexes incorporating histone acetyl transferases and potentially deacetylases may function to control gonadotrope-specific expression.

Development of the anterior pituitary is dependent upon Lhx3 in the mouse.[97,116,137] Human patients presenting with CPHDs have also been shown to have genetic loss-of-function mutations in Lhx3 correlated with CPHD, including deficiency in FSH production and secretion. While these reports do not provide a direct link to loss of Lhx3 function at the FSHβ gene promoter, they do underscore the importance of Lhx3 as a critical regulator of pituitary cell function and potentially as a transcriptional activator of the human FSHβ subunit promoter.[485–488] Multiple Lhx3-binding sites have been identified on the human FSHβ promoter, and

overexpression studies suggest that Lhx3 is sufficient to transactivate this promoter.[485] The porcine FSHβ promoter has also been characterized with multiple Lhx3-binding sites, several of which appear to be conserved with the human promoter.[485] The potential role of Lhx3 in FSHβ promoter activity is consistent with the required role of Lhx3 in the regulation of the αGSU and a presumed role in the regulation of the GnRHR gene promoters in the fully differentiated gonadotrope.

Pitx1 and Pitx2 also play functional roles in the regulation of the rodent and human FSHβ subunit promoter in LβT2 cells.[489,490] Using mutational analyses and DNA-binding studies, the effects of Pitx family members occur via a conserved *cis* element to support FSHβ transactivation. Using Pitx dominant-negative overexpression and knockdown approaches, studies support the conclusion that Pitx1 and Pitx2 are required for basal and activin-stimulated FSHβ (described in this chapter).[490] As indicated, Pitx proteins form complexes with a number of transcriptional regulators, including the association between Pitx, NR5A1, and Egr1,[162,163] supporting speculation that similar types of protein–protein interactions may support basal and GnRH- or activin-stimulated expression of the FSHβ gene; however, this has not been characterized.

The hypogonadal mouse with a loss of GnRH signaling provides definitive evidence for the role of GnRH in the regulation of FSHβ in rodents.[2–4,434] This conclusion is also supported by studies of hypothalamic-pituitary disconnection studies in sheep resulting in a hypogonadotropic-hypogonadal phenotype.[435,436,491] In both instances, exogenous administration of GnRH rescues gonadotropin subunit mRNA levels, including FSHβ, in these animal models. Despite the profound effects of GnRH on FSH biosynthesis, relatively little is known regarding molecular mechanisms involved in this regulation. In rat and human FSHβ promoters, half sites for AP1 appear to mediate the effects of GnRH in some instances.[492,493] For example, using mutational analysis of an AP1 half-site and overexpression studies of dominant-negative forms of AP1 in the mouse FSHβ promoter, loss of this site or interference by the dominant-negative AP1 resulted in a blunted response of the promoter to GnRH in LβT2 cells. The presence of the AP1 site predicts a role for GnRH-induced ERK activation governing this mechanism; indeed, pharmacological disruption of the ERK and the p38 MAPK pathways blocked the stimulatory effects of GnRH in the human promoter in LβT2 cells. These in vitro studies are difficult to reconcile with recent studies of a conditional gonadotrope-specific knockout of ERK1 and ERK2 in the mouse.[166] While loss of ERK signaling in gonadotropes in vivo resulted in female-specific infertility, this deficiency was attributable to a loss of GnRH-induced αGSU and, in particular, LHβ subunit expression. This genetic ERK lesion had very little effect on GnRH induction of FSHβ, circulating levels of FSH, or the distribution of ovarian follicles in the ERK conditional double knockout. Thus, while the AP1 site is likely to play a key role in GnRH induction of FSHβ, the signaling pathways leading to AP1-mediated transactivation are likely to include novel mechanisms potentially independent of GnRH-induced ERK signaling.

The effects of AP1 on the rat and mouse FSHβ promoters may also include physical interaction with the adjacent NF-Y binding site.[493] The close proximity of the NF-Y and AP1 site along with the observation that NF-Y-A can physically interact with c-Jun in the context of an AP1 complex support this idea. An overlapping E-box that binds basic helix–loop–helix proteins in the upstream stimulatory factor family is also likely to be involved since mutations within this site blunt GnRH-induced FSHβ subunit transcription in vitro.[494] Alternatively, and perhaps not surprisingly, the AP1 site in the rat FSHβ promoter can also bind CREB.[495] Using LβT2 cells, these studies provide important evidence that the AP1 site can indeed bind CREB, and the use of a dominant-negative CREB (but not dominant-negative AP1) and CREB knockdown suggests that it is CREB rather than AP1 heterodimers that mediates GnRH action on the FSHβ promoter. Moreover, the ability of the FSHβ promoter to discriminate differential GnRH pulse frequency may depend upon competition between CREB and inducible cAMP early repressor (ICER) binding at this site. FSHβ transcription is favored by slow relative GnRH pulsatility, while rapid GnRH pulsing favors LHβ and αGSU transcription.[496,497] Rapid pulsing also favors ICER accumulation that can directly compete for CREB binding at the AP1 site and blunt transactivation by GnRH. The potential involvement of CREB rather than AP1 may also be consistent with GnRH-induced signaling to the mouse FSHβ promoter independent of the ERK pathway.

Along with GnRH action, FSHβ gene transcription is also controlled by activin signaling. Activins, along with inhibin and follistatin, are members of the transforming growth factor β (TGFβ) family and have been described thus far in the context of control of SMAD activity at the GnRHR gene promoter. Administration of activin to gonadotrope cells results in a marked upregulation of FSHβ transcript abundance,[498–502] while inhibin and follistatin inhibit this action through interference between activin and the activin receptor or by sequestering activin away from the receptor by direct binding.[502] The actions of activin are largely mediated via the activin receptor ACVR2[405,503]; this knockout mouse model provides strong support for the role of activin signaling in the gonadotrope directing expression of FSHβ and the GnRHR. Activin and follistatin are both expressed in gonadotropes; follistatin is also expressed in other pituitary cell lineages, including

folliculostellate cells,[504] and their actions to control activin signaling to FSHβ are thought to be autocrine and/or paracrine within the anterior pituitary.

Activin signaling via ACVR2 (the type II receptor) occurs in collaboration with the type I receptors ALK4 and/or ALK7 in gonadotropes[505–508]; however, it appears that ALK4 may have higher importance in activin signaling based upon pharmacological studies in LβT2 cells and the ALK7 knockout mouse.[170] Activin engagement of the activin receptor complex results in rapid phosphorylation of SMAD2 and SMAD3, followed by nuclear localization of SMAD2/3 and SMAD4 complexes in LβT2 cells.[509] SMAD complexes engage the FSHβ gene promoter via multiple SMAD-binding sites in the mouse promoter; however, the presence of consensus SMAD-binding sites is not conserved across species.[170] Mutations that interfere with SMAD binding to these elements blunt activin-induced FSHβ gene transcription in LβT2 cells. Interestingly, mutations that interfere with Pitx1 and Pitx2 binding to the mouse FSHβ promoter blunt the responsiveness of the promoter to activin or expression of SMAD2/3/4.[490] Furthermore, SMAD3 can physically interact with Pitx1 and Pitx2, suggesting that activin-induced FSHβ promoter activity requires association between at least SMAD3 and Pitx family members.

The forkhead factor FoxL2 appears to play a key role in the regulation of FSHβ promoter activity.[510] Developmentally, loss of FoxL2 does not appear to impact the development of the gonadotrope lineage; however, FoxL2-deficient gonadotropes have marked reduction in FSHβ transcript expression. The role of FoxL2 in governing FSHβ appears to be linked to the interaction between FoxL2 and activin signaling.[511–514] In the human and mouse FSHβ subunit promoter, FoxL2 appears to interact with the promoter and FoxL2 is required for FSHβ responsiveness to activin; however, the FoxL2-binding sites alone are not sufficient to confer activin responsiveness.[511,514] In other studies of the mouse FSHβ promoter, a specific FoxL2-binding site was demonstrated, and the actions of FoxL2 and SMADs were shown to induce a synergistic transcriptional response.[513] Thus, the regulation of FSHβ in the mouse by activin includes the activation of SMAD2/3 coupled with SMAD4. Interactions between FoxL2 and SMAD complexes in this gene promoter initiate high-level promoter activity within the gonadotrope. The caveat here is that there is clear evidence of species variation in the context of FSHβ regulation by activin and the role of FoxL2 in this process.[170]

Activin signaling at the gonadotrope through local production and secretion of activin also contributes to how the gonadotrope responds to a GnRH stimulus in the context of FSHβ promoter activity. For example, activin plays an important role in the regulation of the GnRHR, creating the opportunity for activin to contribute to the sensitivity of the gonadotrope to a GnRH stimulus. Furthermore, the action of GnRH along with activin appears to induce a synergistic activation of the mouse and rat FSHβ gene promoter in LβT2 cells independent of GnRH-induced ERK pathway activation but was observed to depend upon GnRH-induced p38 MAPK activity.[515,516] A similar transcriptional synergy between activin and GnRH signaling occurs on the human FSHβ promoter.[492] In these studies, GnRH-induced activity of AP1 via ERK and p38 MAPK activation and blockade of these pathways or the use of a dominant-negative Fos protein or mutation of AP1 sites within the human promoter provided strong support for this mechanism. Thus, across multiple mammalian species, response of the FSHβ promoter to GnRH pulses is greatly affected by activin levels within the local pituitary milieu. The ability to specifically titrate FSHβ gene regulatory mechanisms in the apparent absence of LHβ regulation provides important clues to how these two gonadotropin subunit genes are regulated in complex physiological situations such as during the estrous cycle.

Androgens and glucocorticoids have been shown to stimulate FSHβ transcript abundance and FSH secretion in primary cultures of pituitary cells obtained from male rats.[517] Furthermore, glucocorticoid or androgen treatment augmented the effects of activin in these studies. Interestingly, these steroids have diverse effects on follistatin production from the same culture. For example, androgens suppressed follistatin mRNA levels, while dexamethasone enhanced follistatin transcript levels; the addition of activin to dexamethasone-treated pituitary cell cultures further augmented upregulation of follistatin. These experiments suggest that control of FSHβ by androgens and glucocorticoids may occur by diverse mechanisms, including a direct effect of androgens and an indirect effect of glucocorticoids via changes in follistatin abundance. The combined effects of glucocorticoids and activin on FSHβ were also recapitulated in the LβT2 cell model, where the combined actions of both agonists resulted in synergistic activation of the mouse FSHβ promoter.[518] This synergistic transcriptional response was promoter specific in LβT2 cells, was inhibitable by the addition of follistatin, and required SMAD2/3 binding to this promoter. Collectively, these studies reflect the importance of local activin signaling on the responsiveness of the gonadotrope to GnRH and gonadal and adrenal steroid hormones. This illustrates the importance of the local pituitary milieu with regard to activin and follistatin on regulation of the FSHβ subunit gene promoter.

Desensitization and Receptor Internalization

As noted here, pulsatile release of GnRH is crucial for gonadotropin biosynthesis and secretion in vivo.[55,56] Pulses of GnRH can raise circulating gonadotropin and

gonadal steroid levels, and this is exploited in assisted reproduction and in treatment of hypogonadotropic hypogonadism, whereas with sustained and/or high doses of agonists (particularly metabolically stable agonist analogs of GnRH), the initial secretory response is followed by reduced levels of gonadotropins and gonadal steroids. This is exploited with subcutaneous depot formulations of GnRH agonists that are used to treat central precocious puberty, uterine fibroids, endometriosis, and gonadal steroid-sensitive cancers, including those of the breast and prostate.[22,26,519] This can be viewed in light of the fact that all cells adapt to their environments in order to be able to function under a wide range of environmental conditions. Very often, cells adapt to low-level stimulation (by hormones, neurotransmitters, growth factors, etc.) by increasing sensitivity to the stimulus (sensitization), and they adapt to intense stimulation by reducing sensitivity to the stimulus (desensitization).[251] Such adaptation may be homologous (where exposure to a stimulus alters responsiveness to the same stimulus) or heterologous (where exposure to a stimulus alters responsiveness to another stimulus). Intense stimulation of gonadotropes with GnRH causes pronounced desensitization of GnRH-stimulated gonadotropin secretion, whereas brief GnRH stimulation can actually increase responsiveness to a later stimulus in a process known as "self-priming" that is thought important for generation of the preovulatory gonadotropin surge.[520–522] Moreover, gonadal steroids can also act directly on gonadotropes or gonadotrope-derived cell lines to increase or reduce responsiveness to GnRH, so these cells show sensitization and desensitization that may be homologous or heterologous.

Since therapeutic applications of GnRH agonists revolve around exploitation or avoidance of desensitization, most work in this area has inevitably focused on homologous desensitization. Here, it is important to recognize that intense stimulation typically causes desensitization of 7TM-mediated responses, and that changes in receptor coupling provide the rapidest and best described cause of such desensitization.[523,524] Activation of 7TM receptors is typically followed by their desensitization and internalization. These processes involve receptor phosphorylation that is stimulated by agonist binding, is typically rapid (occurring in seconds to minutes), and may be mediated by specific G-protein receptor kinases (GRKs), by second messenger-regulated kinases (e.g., PKC or PKA), or by casein kinases.[525–527] This phosphorylation may facilitate association with arrestins 2 or 3, which block G-protein binding and thereby prevent effector activation.[523,524] Since this effect is seen within seconds to minutes and is specific to the activated receptor, it is termed rapid homologous receptor desensitization. Arrestins also act as adapters, binding to proteins such as AP2 and clathrin and thereby targeting desensitized 7TM receptors for internalization.[523,524,527–529] These receptors are internalized from the cell surface by endocytosis, most often via clathrin-coated vesicles. The formation of these vesicles is typically controlled by a dynamin collar, which separates the nascent endosome from the plasma membrane.[530,531] After internalization, the receptors are either recycled to the cell surface (promoting resensitization) or targeted to lysosomes for degradation (promoting receptor downregulation).[532] In addition, it is now well established that arrestins can act as scaffolds for assembly of complexes containing 7TM receptors and effectors. These can include Src, MAPKKKs, and MAPKs, and arrestins can mediate G-protein-independent activation of these effectors.[347,348,524,533–537] Consequently, mechanisms previously thought of in terms of switching receptor signaling off may actually be switching between two distinct modes of receptor signaling (from G-protein mediated to arrestin dependent).

It is well established that sustained exposure to GnRH causes desensitization of GnRH-stimulated gonadotropin secretion and that this is associated with GnRHR downregulation and internalization of GnRHRs via coated pits,[274,538,539] so it could have been anticipated that GnRHRs would follow the model outlined here. However, the amino acids phosphorylated to facilitate arrestin binding are most often located within the C-terminal tails of 7TM receptors, and this raised the possibility that the absence of C-tails in type I mammalian GnRHRs might cause resistance to rapid desensitization. Indeed, this was demonstrated in early functional studies using GnRH-stimulated [^{3}H]IP accumulation (in cells prelabeled with [^{3}H]inositol and stimulated in the presence of LiCl) as a readout for GnRHR-mediated PLC activation of αT3-1 cells.[540] In this study, the initial rate of [^{3}H]IP accumulation was maintained for at least 90 min, and, since this is typically not maintained beyond 1 min with desensitizing receptors, it clearly implied that the endogenous mouse GnRHRs of these cells do not rapidly desensitize. These data have been confirmed and extended in numerous studies showing that mammalian GnRHRs without C-tails do not undergo rapid homologous desensitization or agonist-induced phosphorylation and do not bind arrestins.[194,541–554] They do undergo agonist-induced internalization, but this is relatively slow and is neither arrestin dependent nor associated with arrestin translocation to the plasma membrane or to endosomes containing internalized GnRHRs. Here, it is important to recognize that although type I mammalian GnRHRs lack C-tails, nonmammalian GnRHRs do have such tails with potential sites for phosphorylation and arrestin binding. This has facilitated comparative studies with wild-type or chimeric receptors, and several groups have shown that activation of nonmammalian GnRHRs with C-tails does cause their rapid

homologous desensitization and internalization, and that these processes are associated with and dependent upon agonist-induced receptor phosphorylation and arrestin binding. Moreover, studies with truncated nonmammalian GnRHRs (i.e., catfish GnRHRs with C-tail deletions), chimeric GnRHRs (i.e., type I rat, human, or sheep GnRHRs with added *Xenopus laevis* or catfish C-tails), or nonmammalian GnRHRs with potential C-tail phosphorylation sites removed support the idea that phosphorylation within the C-tails causes arrestin-mediated desensitization and rapid homologous desensitization of GnRHRs that have C-tails.[543,545–550,553]

The data outlined here are consistent with the suggestion[540] that absence of C-tails in type I GnRHRs underlies their atypical resistance to desensitization. However, GnRHR-mediated gonadotropin secretion certainly does desensitize, so other mechanisms must be involved. Indeed, gonadotropes may well provide a unique opportunity for investigation of downstream adaptive responses to 7TM receptor activation, in the absence of receptor desensitization. In exploring this, we have found that sustained stimulation of αT3-1 cells with GnRH causes a pronounced desensitization of Ca^{2+} responses,[194,541] an effect that was associated with and apparently dependent upon a GnRH-stimulated reduction in the IP_3 receptor number.[552] Sustained activation of several PLC-activating GPCRs has been shown to cause IP_3 receptor downregulation, an effect attributed to the ligand-stimulated ubiquitinylation and consequent proteolysis of the activated IP_3 receptors.[555–557] However, this effect is typically slow and modest as compared to the pronounced and rapid effect of GnRH (80% reduction within 20–30 min). Thus it appears that this receptor, which is atypically resistant to desensitization, is unusually efficient at provoking this form of postreceptor desensitization.[552] It is important to recognize, however, that the relevance of this effect to desensitization of gonadotropin secretion has not been established. Other effects, such as depletion of releasable gonadotropin pools,[558,559] downregulation of GnRHRs, upregulation of RGS proteins, desensitization of VGCCs,[560] and reduced gonadotropin synthesis (section Regulation of Gene Expression), may well prove to be more important for long-term desensitization of gonadotropin secretion in vivo.

Heterotrimeric G-Protein-Independent Signaling

As noted here, arrestins can act as scaffolds, facilitating the interaction of phosphorylated 7TM receptors with other regulatory proteins. The arrestin-mediated coupling of GPCRs to clathrin, AP2, and NSF directs GPCRs for internalization via clathrin-coated vesicles (CCVs), and the binding to kinases such as JNK3, ASK1, Src, ERK, and Raf can mediate MAPK signaling in a heterotrimeric G-protein-independent manner.[347,348,529,533–537] One of the earliest indications of a signaling role for receptor-associated arrestins was the demonstration that β2 adrenergic receptor stimulation not only activated the tyrosine kinase c-Src but also caused it to bind to the receptor-associated arrestin 2. The arrestin-associated c-Src could then phosphorylate and activate dynamin 1, causing dynamin-dependent receptor internalization. This raised the possibility that a similar paradigm would be applicable to GnRHRs; that is, arrestin binding to the C-tail of nonmammalian GnRHRs would target them for Src and dynamin-dependent internalization. In accord with this, internalization of a *X. laevis* (X)GnRHR is dynamin sensitive (inhibited by expression of the GTPase-deficient, dominant-negative, K44A dynamin 1), whereas internalization of the hGnRHR is not.[548,551,554] Moreover, addition of the XGnRHR C-tail to the C-terminus of the hGnRHR, either alone or in addition to exchange of the third intracellular loop regions, directed the receptor for arrestin and dynamin-dependent internalization.[554] Although these chimeric receptors have comparable affinity and ligand specificity to the wild-type hGnRHRs, the dual chimera did not signal (as judged by the lack of effect on Ca^{2+} or cAMP), and inhibition of Src had no effect on internalization of any of these constructs. These data suggest that arrestin mediates signaling of C-tailed GnRHRs to dynamin, but the β2 adrenergic receptor paradigm is not entirely applicable because internalization is independent of Src (and apparently does not require receptor activation). As an alternative, we considered the possibility that arrestin scaffolding might mediate ERK activation by C-tailed GnRHRs and found that hGnRHR and XGnRHR mediated ERK activation with similar kinetics (rapid and transient increases in ppERK to maxima at 5–15 min) in HeLa cells.[366,561] These responses were not sensitive to blockade of dynamin-dependent receptor internalization or to coexpression of arrestins or a dominant-negative truncated arrestin. The increase in ppERK mediated by both receptors was not attenuated by inhibition of EGF receptor transactivation, PI3K, or Src, but was dependent on PKC. We therefore reassessed the arrestin dependence of GnRHR-mediated ERK activation in the presence of a PKC inhibitor and found that the XGnRHR-mediated increase in ppERK was indeed blocked by the dominant-negative arrestin, whereas the hGnRHR-mediated effect was not.[366,561] In addition, the chimeric receptor (the full-length hGnRHR with the added XGnRHR C-tail) mediated ERK activation, and introduction of an A261K mutation within the third intracellular loop prevented G-protein activation by this construct without completely blocking ERK activation.[40] Accordingly, these data provide the first direct demonstration of arrestin-mediated (heterotrimeric G-protein-independent) GnRHR signaling and raise the intriguing possibility that the evolution of GnRHRs has restricted

their signaling repertoire. The modulation and mediation of signaling by arrestins may be characteristic of GnRHRs with C-tails, and the absence of such effects for type I mammalian GnRHRs may enable them to faithfully transduce GnRH signal into intracellular G-protein activation. This could have adaptive advantages in situations such as the preovulatory gonadotropin surge, where there is an increase in GnRH pulse frequency or a sustained increase in GnRH[63,562–564] and where a corresponding surge in downstream signaling might otherwise be prevented by receptor desensitization.

Further evidence for GnRHR-mediated and heterotrimeric G-protein-independent activation of ERK has been obtained with GnRHR-transfected HEK293 cells in which GnRHRs mediate cytoskeletal reorganization and GnRHR-mediated ERK activation is prevented by cytoskeletal disruption.[565] Indeed, GnRHRs mediate ultrastructural changes in several models, including the HEK293 cell model in which they cause the formation of numerous spinelike plasma membrane protrusions.[320,565] These contain focal adhesions, and GnRHR activation causes rapid activation and translocation of Pyk2 to these processes.[320,565] Pyk2 is a proline-rich protein tyrosine kinase member of the focal adhesion kinase (FAK) family that mediates ERK activation by 7TM receptors. In GnRHR-expressing HEK293 cells, GnRH-stimulated ERK activation was not Pyk2 mediated[566] but was dependent upon assembly of an ERK–FAK–c-Src signaling complex within focal adhesions and was resistant to blockade by inhibitors of phospholipase C or PKC.[565] It was, however, dependent upon Rac and was therefore attributed to a novel monomeric G-protein-dependent pathway and not to the classical heterotrimeric G-protein–phospholipase C pathway.[565] However, these mechanisms are controversial as others have reported that PKC inhibition prevents GnRHR-mediated ERK activation in GnRHR-expressing HEK293 cells.[566] Moreover, calmodulin mediates GnRH-stimulated ERK activation in αT3-1 cells,[567] and GnRHR-mediated Pyk2 activation does contribute to GnRH-stimulated ERK activation in the αT3-1 model.[567]

Intracellular GnRHRs

Another fundamental feature of GnRHRs related to the C-tail is that a large proportion of these receptors are actually intracellular.[195,539,568–576] This was highlighted by work on hGnRHR mutants that cause infertility and were found to be nonfunctional because of impaired trafficking (as opposed to deficient signaling).[568,569,572,575,576] It then became clear that even wild-type hGnRHRs are relatively poorly expressed at the cell surface. This can be viewed in light of the fact that at least 50% of newly synthesized protein fails to meet quality control criteria for ER exit. Instead, proteins may enter the ER-associated protein degradation (ERAD) system in which misfolded proteins traffic to the cytoplasm and are polyubiquitinated, targeting them to proteasomes for degradation.[577,578] This certainly applies to 7TM receptors,[579–582] as, for example, less than 40% of delta opioid receptors exit the ER after appropriate glycosylation and folding.[581,582] Although the features controlling ER exit for 7TM receptors are not well known, they certainly include glycosylation because only 7TM receptors with mature glycosylation patterns typically traffic to the cell surface. For hGnRHRs, the presence of a primate-specific Lys191, the absence of a second N-terminal glycosylation site, and the absence of a C-tail are all implicated in poor cell surface expression.[195,237,568,570,572,573,575,576,583] Indeed, when we quantified HA-tagged GnRHRs at the cell surface and within cells,[195,570,571,573] we found that at least 95% of hGnRHRs were intracellular after heterologous expression in hormone-dependent cancer cells (MCF7, T47D, PC3, and LnCAP cells). In MCF7 cells, less than 1% of hGnRHRs were at the cell surface, and this remarkably small proportion was increased as much as 10–50-fold for hGnRHRs with C-tails (in comparisons of a *X. laevis* GnRHR with the human GnRHR and of a chimeric type I mammalian GnRHR with added XGnRHR C-tail). The proportion of hGnRHRs at the cell surface was also approximately fivefold higher in gonadotrope-derived cell lines (LβT2 and αT4) than in hormone-dependent cancer cells, demonstrating that GnRHR compartmentalization is dependent upon the cellular context.[570,573] Cell permeant GnRHR ligands are being developed as potential orally active GnRHR antagonists[584] and we found that the proportion of hGnRHRs at the cell surface was also increased (10–20-fold) by a nonpeptide indole GnRHR antagonists (IN3). This compound had been shown elsewhere to rescue signaling by the trafficking-impaired hGnRHR mutants noted here.[568,569,572,575] It is thought to act as a pharmacological chaperone, aiding the folding of ER-resident GnRHRs into a conformation needed to meet ER exit quality control criteria, and thereby increasing GnRHR trafficking to the cell surface. In the absence of reliable antibodies to hGnRHRs, these studies have been performed primarily with tagged receptors. It is therefore important to recognize that the chaperone effects on hGnRHR trafficking are paralleled by effects on receptor function (i.e., rescue of signaling via trafficking-deficient mutants and enhanced signaling via wild-type hGnRHRs) and that these effects can also be seen with epitope tag-free GnRHRs.[195,568–573,575,576] The caveat remains, however, that the number and proportion of native receptors at the cell surface have not been defined for hGnRHRs in pituitary or extrapituitary sites. Moreover, although a great deal is known about control of GnRHR expression and internalization, we know of no work addressing the possibility that the proportion of hGnRHRs failing ER

exit quality control criteria is regulated to meet physiological demand.

The idea that intracellular GnRHRs are primarily located in the ER is supported by imaging studies[195,568–573,575,576,585] and by work showing that proteins involved in ER exit quality control also influence the number of GnRHRs at the cell surface.[586–588] However, not all intracellular GnRHRs are ER residents; they are also presumably located in transport vesicles of the exocytotic, endocytotic, and lysosomal degradation pathways. Moreover, binding studies have revealed GnRHRs in nuclear fractions of several cell types,[589–592] and this has been confirmed recently by immunohistochemical work showing that epitope-tagged hGnRHRs are located in the nuclear envelope[585] as well as the ER. In contrast, an XGnRHR was more effectively expressed at the cell surface and was not found in the nuclear envelope. This is not surprising given the fact that the ER and nuclear envelope are contiguous, but it was also shown that GnRH could stimulate the acetylation and phosphorylation of histone 3 in purified nuclei.[585] An obvious question is how or whether such receptors could be ligand activated, and it was speculated that they could be subject to intracrine regulation in cells producing both GnRH and GnRHRs.[585] Accordingly, GnRHRs are among a small number of 7TM receptors known to exist in the nuclear envelope, and a functional role in this location may well be specific for type I mammalian GnRHRs.

Lipid Rafts

In addition to trafficking to and from the cell surface, it is well established that compartmentalization within the plasma membrane influences the activity of many receptors and effectors. Early work focused on the aggregation (patching and capping) of GnRHRs at the cell surface that precedes agonist-induced GnRHR internalization[548,554,593,594] and on the possible relevance of mobility within the plasma membrane for formation of GnRHR multimers. This section examines the ability of the GnRHRs to aggregate and associate within discrete membrane compartments and how this membrane localization may affect productive signaling within the gonadotrope. Early studies by Naor and Catt[595] made use of rhodamine-derivatized agonists of GnRH to track ligand–receptor complexes on the surface of gonadotropes. Despite the observation that rhodamine-derivatized GnRH displayed reduced receptor affinity and ability to induce LH secretion, these studies revealed that upon ligand binding, the GnRHR transitions from diffuse distribution across the membrane to points of focal aggregation followed by internalization. Microaggregation of the GnRHR appears to be a central and early event leading to productive calcium signaling and secretion of gonadotropins.[247,248]

From the early 1970s to the early 1990s, plasma membrane dynamics was characterized by the fluid mosaic model of lipids and proteins within a uniform bilayer.[596,597] This early view supported the notion that the multiplicity of lipids within the plasma membrane simply played a passive role that formed the structure of the membrane; membrane-associated proteins were essentially adrift within the bilayer. Association of proteins within the lipid bilayer could occur via membrane-spanning domains such as with 7TM receptors or via lipid modifications (e.g., myristoylation) of proteins effectively linking them to the plasma membrane.[598] Since that time, a great deal has been learned regarding the lipid and protein composition and dynamics of the plasma membrane and how the biophysical properties of the membrane may provide a unique contribution to the organization of receptors and signaling systems within the membrane. Here we focus on the membrane raft hypothesis, which posits that various lipids and sterols present within the plasma membrane have variable affinities for each other as well as for specific integral membrane and membrane-associated proteins. The high-affinity association between lipids and proteins is able to form (transiently) stable and biochemically distinct domains within the membrane nucleating foci (or rafts) where signaling intermediates can concentrate[598–604] (Figure 10.5).

Biochemically distinct domains within the membrane appear to be dependent upon the lipid composition within these domains. For example, GPI-anchored proteins were recoverable from plasma membrane in sucrose density gradients if these preparations were made in the presence of low levels of nonionic detergents such as Triton X-100 at low temperatures.[605] The lipid composition of these detergent-resistant membranes was enriched in cholesterol and sphingolipids and gave rise to a so-called liquid-ordered domain due to the tight packing of cholesterol and sphingolipids within the domain or raft relative to the more liquid-disordered state of the surrounding plasma membrane.[598,604] The unique composition of the sphingolipid–cholesterol-enriched raft is thought to include (or exclude) specific proteins in this compartment, effectively assembling (for example) receptor populations with intracellular signaling intermediates to form platforms or complexes to facilitate cell signaling.[38,606] The importance of these rafts is to facilitate rapid response kinetics by preassembling signaling complexes that could respond quickly upon receptor activation. While this is an attractive hypothesis, the fact that these detergent-resistant membranes required isolation at low temperatures raised significant controversy as to whether these membrane compartments existed in normal cell membranes at physiological temperatures or were simply artifacts of the conditions necessary to recover the rafts.[598,604,607] Visualization of these dynamic

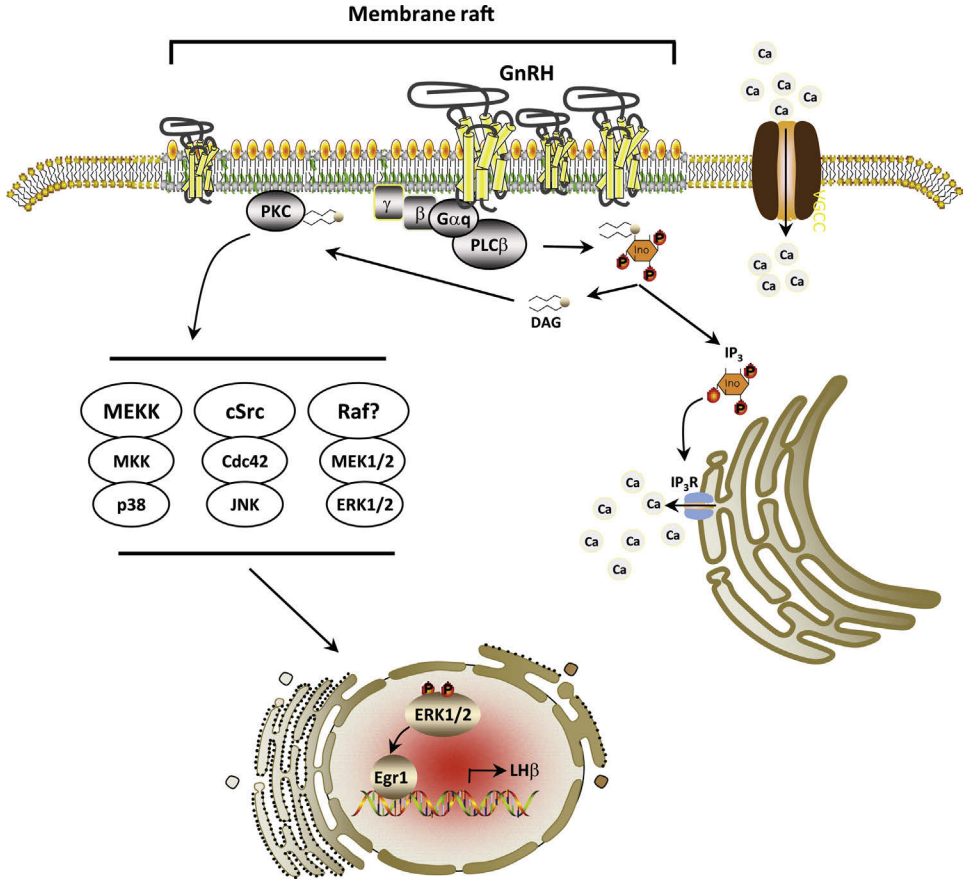

FIGURE 10.5 Membrane rafts as GnRHR signaling platforms. Proposed model for membrane raft-associated GnRHR facilitates signaling to the mitogen-activated protein kinase (MAPK) pathways in gonadotropes. The G-protein coupled GnRHR initiates signaling via Gαq (and associate β and γ subunits) and activation of PLCβ. The GnRHR is a constitutive and exclusive occupant of a detergent-resistant, low-buoyant-density membrane compartment, the membrane raft. Gαq also resides within the raft but can be isolated from nonraft membrane fractions. Activation of PLCβ results in the elaboration of two second important messengers, DAG and IP_3. DAG (along with cell calcium) induces activation of PKC isozymes, while IP_3 promotes mobilization of intracellular calcium via interaction with IP_3 receptors (IP_3R) within the endoplasmic reticulum. Membrane depolarization also induces an important source of intracellular calcium via an influx of extracellular calcium through VGCCs within the membrane. VGCCs are not specifically associated with the membrane raft compartment. Activation of PKC isozymes appears to be critical for activation of multiple MAPK pathways, particularly activation of the ERK cascade. ERKs are co-localized with the GnRHR within rafts, and phosphorylated (activated) ERKs are raft localized following GnRH treatment in αT3-1 cells, suggesting that this compartment may serve as an activating platform for GnRH signaling. Once activated, ERKs nuclear translocate to phosphorylate transcription factors in the nucleus and can affect gene transcription such as the activation of the LHβ gene promoter by Egr1. Interestingly, while Raf kinase appears to be a canonical activator of MAPK–ERK kinases (MEKs) and is localized to membrane rafts along with the GnRHR, recent evidence suggests that at least c-Raf kinase is not required for GnRH-induced ERK activation.[367] A detailed understanding of the role of p38 MAPK and JNK pathway signaling via rafts awaits analyses. *Source: Adapted from Ref. 38.*

compartments in living cells has been elusive; however, recent advances in high-resolution fluorescent imaging have begun to provide convincing evidence of the existence of membrane rafts as small (20–200 nm), highly dynamic, sterol- and sphingolipid-enriched domains capable of facilitating protein–lipid and protein–protein interactions to form signaling platforms.[608] Importantly, the size of membrane rafts and the time scale in which they coalesce and dissociate are thought to be extremely small and rapid, giving rise to a remarkably dynamic system that can be affected by and have great impact on the inclusion or exclusion of receptors and intracellular signaling systems in the membrane compartments.

As indicated earlier, microaggregation of GnRHRs following ligand binding was an early observation suggesting that receptor compartmentalization within the plasma membrane may be important in the context of hormone action.[249,250] Compartmentalization of intracellular signaling from the murine GnRHR may be equally important. This possibility is underscored from studies examining the roles and requirement for specific calcium signaling in GnRH-induced activation of specific MAPK pathways.[363,371] In those studies, GnRH activation of the ERK and JNK pathways was clearly separable based on inhibition of two different Ca^{2+} pools, both induced by GnRH: intracellular calcium release induced by IP_3

and influx of extracellular calcium through VGCCs. Disruption of VGCC activity using dihydropyridine receptor antagonists (like nifedipine) resulted in the specific inhibition of GnRH-induced ERK (but not JNK) activation. These studies supported speculation that local or compartmentalized calcium signaling may play an important role in signaling between the GnRHR, VGCC calcium, and the ERK pathway. Furthermore, this was consistent with the notion that the local signaling environment associated with GnRHR microaggregation may be necessary if calcium influx via VGCCs is maintained in microdomains adjacent to the plasma membrane.[363]

The microaggregation hypothesis was further substantiated by the observation that the murine GnRHR was a constitutive and exclusive occupant in membrane rafts within gonadotropes.[38,606,609–611] Solubilization of αT3-1 cells in nonionic detergent at 4 °C, and their subsequent fractionation in discontinuous sucrose gradients, resulted in enrichment of the GnRHR in detergent-resistant membrane fractions with low buoyant density. In addition to these biochemical characteristics, raft compartments within the plasma membrane have also been defined by specific marker proteins. For example, caveolae are a form of rafts characterized by invaginations within the membrane to form flasklike deflection marked by the presence of caveolins 1–3.[598,612,613] Importantly, caveolins interact directly with cholesterol-enriched membranes, forming scaffolds that structurally support rafts and the signaling intermediates within them.[614,615] While specific cell types are critical in the formation of raft compartments, caveolin isoforms are not expressed within gonadotropes (in αT3-1 cells or in murine pituitary cells) and thus do not appear to play a role in raft compartments harboring the GnRHR.[606,609,616] Flotillins 1 and 2 appear to be ubiquitously expressed and also mark raft compartments; however, unlike caveolae, enrichment of flotillins forms rafts that do not change membrane topology. Both isoforms of flotillin are expressed within gonadotropes and mark raft compartments specifically associated with the murine GnRHR.[38,606,609–611]

Enrichment of cholesterol, sphingolipids, and the ganglioside GM1 in the membrane raft has been useful in our understanding of how the GnRHR functions within these liquid-ordered domains. Binding of fluorescently labeled cholera toxin B, which selectively binds to GM1 in living cells, has been used to mark raft compartments within the plasma membrane and colocalize with the GnRHR in the plasma membrane of gonadotropes.[609,611] GnRHR–GM1 colocalization studies using confocal microscopy have helped to corroborate the biochemical fraction studies described here. Manipulating plasma membrane cholesterol content has been used to examine the requirement of the raft domain on signaling via the GnRHR. Depleting cholesterol from the plasma membrane using methyl β-cyclodextrin results in an uncoupling of the GnRHR to activation of the ERK pathway; repletion of cholesterol in cholesterol-depleted plasma membrane effectively rescues this signaling phenotype.[38,611] These studies provide important evidence that raft occupancy by the GnRHR is essential for hormone action, likely by virtue of the receptor's proximity to signaling complexes also residing within the raft. This hypothesis is supported by the additional observations that a number of signaling intermediates also are present within flotillin-positive rafts. These include Gαq, c-Raf kinase, MEK, ERK1 and ERK2, calmodulin, and 14-3-3 adapter protein isoforms. Furthermore, it appears that ERK protein levels are stabilized within the raft upon GnRH administration to gonadotropes, and GnRH-induced ERK phosphorylation and activation occur rapidly within the raft compartment.[38,606,609,611,617] Based on these colocalization and functional studies, it is entirely plausible that since all of the intermediates leading to ERK activation by GnRH reside within the raft, disrupting the raft by cholesterol depletion would lead to uncoupling the ability of the GnRHR to activate the ERK pathway. While these studies provided compelling evidence for a requirement for intact raft compartments for GnRHR signaling, cholesterol depletion–repletion studies require very careful interpretation since loss of cholesterol within the plasma membrane can be damaging in general to cellular homeostasis. The repletion of cholesterol to depleted membranes to recouple GnRH-induced ERK signaling helps to obviate this important concern. Overall, these studies suggest that the constitutive occupancy of the GnRHR in flotillin-marked membrane rafts in gonadotropes is critical to GnRHR signaling.

An important feature of GnRHR and membrane raft association is the defining characteristics or domains within the receptor and raft that facilitate constitutive occupancy within the membrane compartment. Unfortunately, very little is known regarding the biochemical basis for how this receptor partitions into rafts constitutively and engages the ERK pathway. As described in this chapter, a unique feature of the type I GnRHR is an apparent lack of a C-tail. Fusing the C-tail of the nonraft associated LH receptor onto the GnRHR results in a repartitioning of the hybrid GnRHR into nonraft domains within the plasma membrane.[610] These hybrid GnRHRs could bind GnRH and productively signal for ERK activation. Repartitioning of GnRHRs into nonraft compartments was dependent upon the specific C-tail used in the chimeras, providing evidence that the C-tail alone does not dictate raft localization. Another important possibility for raft targeting of the GnRHR is the glycosylation state of the receptor. As presented earlier, mutations at Asn4 and Asn18 reduce trafficking of the murine GnRHR to the plasma membrane.[27] Although speculative, it is entirely plausible that the glycosylation

state at either or both of these residues may facilitate partitioning of the GnRHR into membrane rafts. Additional studies will be necessary to determine if such a mechanism may exist.

Decoding GnRH Pulse Frequency

GnRH effects on its target cells depend upon pulse frequency, as illustrated by early studies showing that constant GnRH suppresses LH and FSH secretion, whereas restoration of GnRH pulses restores gonadotropin secretion.[55–58] Changing GnRH pulse frequency is also the primary means by which the body alters its reproductive status during development, with an increase in GnRH frequency driving the increased gametogenesis and gonadal steroid production at puberty,[29] and stimulation paradigm is crucial for therapeutic manipulation of this system.

In a signal transduction cascade, upstream responses may have rapid onset and decay and therefore track pulsatile inputs closely. In contrast, downstream responses with slower onset and/or offset may not have returned to baseline before repeat stimulation. This is illustrated in Figure 10.6(A), where sequential activation of three effector proteins is considered (i.e., three tiers in a signal transduction cascade), and where high pulse frequency and/or slow response kinetics generates cumulative sawtooth-type responses (lower right panel of Figure 10.6(A)). In essence, this generates a curvilinear relationship between pulse frequency and system output (as measured by the area under the curve for the response traces) that is dependent upon activation and inactivation kinetics for the output measured and can yield near-maximal responses at submaximal pulse frequency (Figure 10.6(B)). This can provide an extremely efficient means of signaling, and such efficiency may be particularly pertinent for central control of reproduction, as it is mediated by the GnRH secreted by a remarkably small number (hundreds) of hypothalamic neurons. Another important consequence of these relationships is that

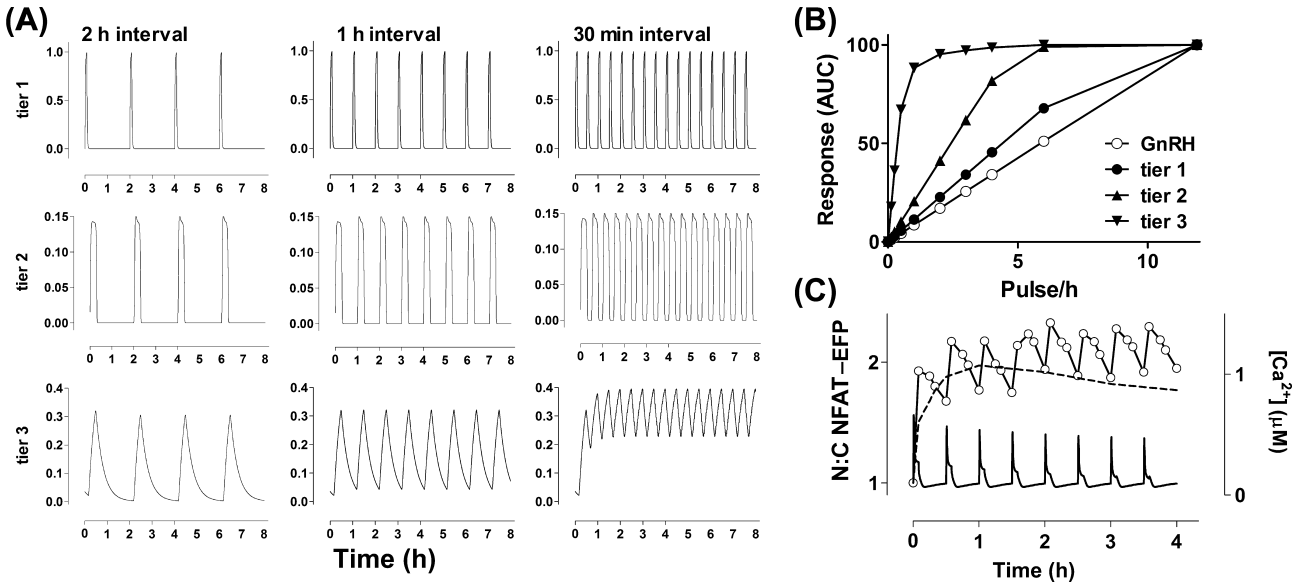

FIGURE 10.6 GnRH pulse frequency dependence. Panel (A) illustrates possible responses to 5 min GnRH at 2 h, 1 h, or 30 min pulse intervals, considering the sequential activation of three effector proteins (a three-tier signaling pathway). With pulsatile stimulation, upstream responses may have rapid onset and offset, following the input closely (tiers 1 and 2), but downstream responses with slower activation and/or inactivation may not have returned to baseline values before repeat stimulation. This can cause cumulative sawtooth responses that do not return to basal levels between pulses when pulse frequency is sufficiently high (tier 3). This can increase the efficiency of signaling, and the different kinetics for activation and inactivation at each tier can yield differences in frequency dependence. This is shown in panel (B), where the relationship between pulse frequency and response is estimated using the area under the curve for the input signal (GnRH) or responses at three sequential tiers of a signaling pathway (tiers 1–3), again using 5 min stimuli. Note that maximal activation at tier 1 requires continuous stimulation (12 pulses/h), whereas near-maximal activation occurs at 1 pulse/h in tier 3. Note also that the outputs are all increasing monotonic relationships, so these processes do not explain the bell-shaped frequency–response relationships seen for GnRH effects on gonadotropin subunit and GnRHR expression. Such maximal activation at submaximal pulse frequency is thought to require positive or negative feedback or feedforward loops or cooperative convergent signaling, as shown in Figure 10.7. Panel (C) shows wet-lab data for the effect of pulsatile GnRH (5 min pulses of 1 nM at 30 min intervals) on the nuclear–cytoplasmic ratio of NFAT–EFP (open circles), a Ca^{2+}-dependent transcription factor used as a downstream readout for Ca^{2+} mobilization. Also shown are the mathematically modeled transient increases in $[Ca^{2+}]_i$ that drive the NFAT translocation (lower solid trace) and the NFAT–EFP ratio in cells receiving constant stimulation with 1 nM GnRH (dotted trace). Note that the NFAT translocation response is slower in onset and offset than the $[Ca^{2+}]_i$ input, yielding a cumulative sawtooth increase in N:C ratio, and that the area under the curve for the response to pulsatile GnRH is comparable to that for constant GnRH, demonstrating the efficiency increase with pulsatile stimulation. *Source: Figure adapted from Refs 618,619.*

they can provide output specificity, as a given pulse frequency could drive a low, intermediate, or near-maximal response for different biological outputs, dependent on the output-specific time delays in activation and inactivation (Figure 10.6(B)). These principles are illustrated by work with fluorescent reporters for activation of the Ras–MEK–ERK and Ca^{2+}–calmodulin pathways.[620,621] Here, GnRHR-expressing HeLa cells were stimulated with GnRH pulses, and live cell imaging was used to monitor cytoplasmic-to-nuclear translocation of ERK2–GFP (reflecting ERK activation) and NFAT–EFP (reflecting Ca^{2+}–calmodulin–calcineurin-dependent activation of the Ca^{2+}-dependent transcription factor, NFAT). Five-minute pulses of GnRH cause rapid, transient, and reproducible translocation of ERK2–GFP and NFAT–EFP from the cytoplasm to the nucleus, but the latter responses were slower in onset and decay so that at high pulse frequency (2 pulses/hour), sawtooth responses were seen for the NFAT–EFP response but not for the ERK2–GFP response (Figure 10.7(A)). Indeed, the integrated NFAT–EFP translocation response was comparable for sustained GnRH and pulsatile GnRH (Figure 10.6(C)), whereas this is not the case for the ERK2–GFP translocation response, illustrating the additional economy and specificity provided by pulsatile GnRH in this system.

The other obvious reason for use of GnRH pulses in biological systems is that the pulses convey specific information. Theoretically, pulse height, width, shape, and frequency and interpulse GnRH concentration could all encode information, but research emphasis has been on pulse frequency and the mechanisms by which it is decoded by gonadotropes. Here, it is important to recognize that, for the data in Figure 10.6, the outputs all increase to a maximum at maximal pulse frequency (or constant stimulation), whereas for some effects of GnRH this is not the case. It is now well established that transcriptional effects of GnRH are dependent upon pulse frequency[35,36,75,182,495,496,622–633] and that GnRH pulse frequency–response relationships are dependent upon the endpoint measured. This is seen in work with luciferase reporters for gonadotrope signature genes, where it was shown[622] that optimal GnRH pulse frequencies for expression of LHβ, FSHβ, αGSU, and GnRHR reporters differed, with 20 h transcriptional responses of LβT2 cells being maximal with constant stimulation or with pulses of 2, 0.5, and 1 h intervals, respectively.[622] In essence, GnRH can elicit bell-shaped pulse frequency–response relationships (i.e., maximal responses at submaximal pulse frequency), and this has been described as genuine frequency decoding (as opposed to the simple frequency dependence shown in Figure 10.6). It is thought to require more complex signal architecture involving feedback or feedforward loops[634] and is exemplified by the bell-shaped frequency–response relationships seen for effects of GnRH on transcription reporters containing LHβ, FSHβ, or GnRHR promoters.[622] However, the nature of these loops is unclear, and three distinct possibilities are highlighted in the literature. The first is that rapid (transcription-independent) negative feedback reduces information transfer from the cytoplasm to the nucleus at high GnRH pulse frequency (shown schematically as black feedback loops in Figure 10.7(C)). Rapid homologous receptor desensitization can be excluded as a potential mechanism because type I mammalian GnRHRs do not show this behavior (see the section Desensitization and Receptor Internalization). GnRH does, however, cause downregulation of cell surface GnRHRs (see the section Desensitization and Receptor Internalization again), and a recent mathematical model of GnRH signaling predicts pulse frequency–dependent desensitization of upstream signals as a consequence of GnRHR downregulation.[635] The second possibility is that frequency decoding reflects the interplay of transcription factors, as exemplified by work on Egr1 and a co-regulator (Nab-2) at the LHβ promoter. In this model, low pulse frequency causes transient Egr1 expression, driving expression of Nab2, which then inhibits LHβ expression, whereas at high pulse frequency more sustained increases in Egr1 quench Nab2 and increase LHβ transcription.[467] For the FSHβ promoter, a similar interplay between c-Fos and the co-regulator TGIF has been proposed to underlie preferential activation at low GnRH pulse frequency. CREB and ICER may be involved as high pulse frequencies preferentially induce ICER, causing transcriptional repression by competing for a CRE site in the FSHβ promoter.[495,636] The third possibility is that transcription-dependent negative feedback on upstream pathways occurs at high GnRH pulse frequency (red feedback loops in Figure 10.7(C)). This could include GnRHR-mediated induction of the regulator of G-protein signaling 2 (RGS2), which has the potential to inhibit all responses downstream of $G_{q/11}$,[391,392] or induction of MAPK phosphatases (MKPs) with the potential to modulate GnRHR-mediated MAPK signaling.[372,637] The live cell imaging experiments described here provide some insight, as the ERK2–GFP and NFAT–EFP translocation responses were both reproducible with repeated GnRH pulses (Figure 10.7(A)). This lack of desensitization argues against upstream negative feedback attenuating the signals passing from the cytoplasm to the nucleus. Moreover, Egr1-responsive and NFAT-responsive luciferase reporters were also used as transcriptional readouts for ERK and NFAT activation in these experiments, and both showed maximal responses at maximal GnRH pulse frequency.[620,621] Importantly, luciferase reporters for LHβ and FSHβ showed maximal responses at submaximal pulse frequency in the HeLa cell model used, demonstrating that genuine frequency-decoding behavior is not restricted to gonadotropes.[620,621]

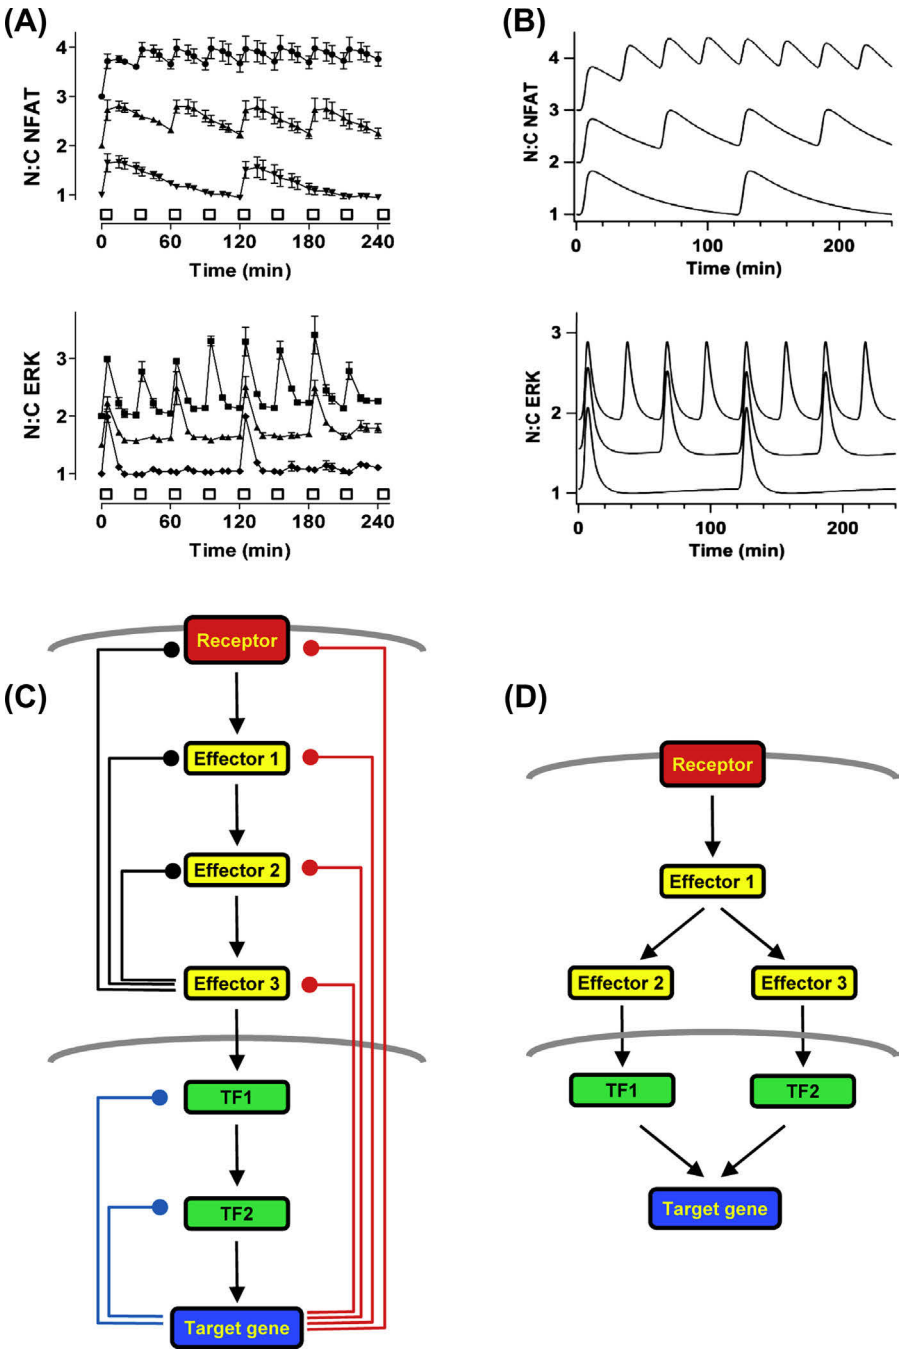

FIGURE 10.7 GnRH pulse frequency decoding, part I. This figure is reproduced in color in the color plate section. Panel (A) shows the effects of pulsatile GnRH (1 nM pulses of 5 min duration and varied intervals) on the nuclear:cytoplasmic ratio (N:C) of NFAT2–EFP (upper chart) or ERK2–GFP (lower chart). In each case, the data are normalized to the prestimulation value and are offset on the vertical axis for clarity. Note that neither of the responses shows desensitization from pulse to pulse and that NFAT–EFP shows a cumulative sawtoothed response at the highest pulse frequency, whereas the ERK2–GFP response is not sawtoothed at any frequency (because it is rapidly reversed on removal of GnRH). Panel (B) shows data from an ordinary differential equation–based mathematical model that mirrors the empirical data for NFAT–EFP and ERK2–GFP translocation. Panel (C) shows a schematic signal transduction cascade in which a receptor in the plasma membrane causes sequential activation of three cytoplasmic proteins (effectors 1–3), and the last of these drives sequential activation of two transcription factors (TF1 and TF2) within the nucleus, which are upstream of a target gene. Also illustrated are multiple negative-feedback loops that could be restricted to the cytoplasm (black) or could involve transcription-dependent feedback to cytoplasmic proteins (red) or nuclear proteins (blue). Panel (D) shows a schematic network in which the receptor activates a bifurcating signal transduction pathway involving three cytoplasmic effectors and two nuclear transcription factors and where these transcription factors converge on the target gene. The empirical and modeled data in panels (A) and (B) suggest that the signal passing from the cytoplasm to the nucleus does not desensitize with pulsatile GnRH, arguing against the upstream negative-feedback pathways shown in black or red in panel (C). *Source: The data in panels (A) and (B) are adapted from Refs 618,620,621.*

A more recent study used mathematical modeling to explore possible frequency-decoding mechanisms. A dynamical model was generated that differs from other GnRH-signaling models[372,635,638] in that it incorporates the Ca^{2+}–calmodulin–calcineurin–NFAT and Raf–MEK–ERK pathways, includes nuclear and cytoplasmic compartments, and lacks negative feedback. The model predictions accurately mirrored empirical data for effects of GnRH pulses on translocation of NFAT–EFP and ERK2–GFP (compare Figure 10.7(A) and (B)), so these could be used as inputs to the transcriptome (shown schematically in Figures 10.7(D) and 10.8(B)). In doing so, it was assumed that two transcription factors (TF1 and TF2) act at distinct sites on a common gene promoter (using NFAT as TF1 and an undefined ERK-dependent TF as TF2). Three distinct logic gates were considered: an "and-gate" where the TF effects are additive, an "or-gate" where only one TF is needed, and a "cooperative gate" where the two TFs act synergistically. This model predicted that bell-shaped frequency–response curves could be achieved when the two TFs are activated with different kinetics and when the two TFs

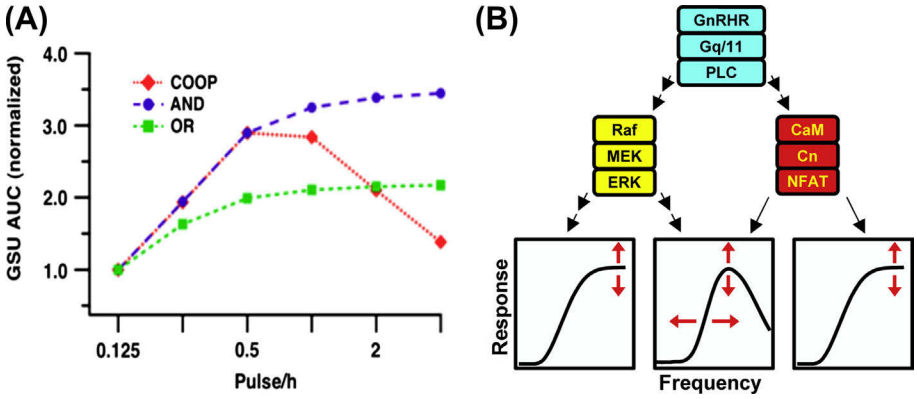

FIGURE 10.8 GnRH pulse frequency decoding, part II. For panel (A), the modeled data in Figure 10.7(B) were used as inputs to the transcriptome, assuming convergent signaling via an "and-gate", an "or-gate," or a "cooperative gate" and activation of an undefined target (termed GSU for gonadotropin subunit). Modeling outputs (area under the curve for GSU expression over time) under different stimulation conditions predicted increasing monotonic relationships for pulse frequency–dependent gene expression with the and-gate and the or-gate but a nonmonotonic relationship with the cooperative gate. Further work predicted that altering the amount of key model parameters (i.e., a concentration of effectors such as ERK or NFAT) would influence response amplitude with the and-gate or the or-gate, but with the cooperative gate could also influence the pulse frequency at which maximal outputs are obtained (panel (B)).

act cooperatively.[618,639] The characteristic feature of maximal response at submaximal frequency was never seen with the and-gate or with the or-gate (Figure 10.8(A)). The kernel of the model is the assumption of Michaelis–Menten kinetics driving the association of two distinct TFs with their target DNA and (in the cooperative scenario) the association of these TF–DNA complexes with one another.[618,639] Accordingly, the cooperative gate differs from conventional computational logic gates but may well have widespread relevance for biological systems, such as transcription regulation by assembly of multimeric protein–DNA complexes potentially like those described for the regulation of the gonadotrope signature gene promoters (see the section Regulation of Gene Expression).

This modeling assumed a simple network with a GnRHR–G_q–PLC module upstream of Raf–MEK–ERK and Ca^{2+}–calmodulin–calcineurin–NFAT modules (Figure 10.8(B)), both of which drive transcription. This is clearly a vast oversimplification of transcriptional regulation by GnRH, as it excludes many known upstream pathways and interactions. It also excludes the real complexity of the combinatorial signals mediating transcriptional effects of GnRH (also in the section Regulation of Gene Expression) and only considers regulation of a generic gene target (termed GSU and not equated to any specific β or α subunit). Nevertheless, the model does illustrate the potential for the ERK and NFAT pathways to decode frequency when acting on a shared target. Since LHβ and FSHβ promoters are both responsive to NFAT and ERK, it predicts that genuine GnRH frequency decoding will be absent for an ERK-responsive reporter or an NFAT-responsive reporter but may occur with FSHβ and LHβ, and this is supported by the work with luciferase reporters outlined here. However, the real value of the model is that it shows how a simple network could yield relatively complex input–output behaviors. The model predicts bell-shaped frequency–response relationships as a likely consequence of the activation of two effectors, as long as they have different kinetics and converge in a cooperative manner on a common target (Figures 10.7(D) and 10.8(B)). This architecture is abundant in signaling pathways, so the implication is that genuine frequency decoding is a likely emergent feature of signaling networks rather than just a function of specific proteins or modules within the network. In the case of GnRH, it illustrates the possibility that such behavior could be generated without negative feedback (note the absence of feedback in Figure 10.7(D)). Indeed, we suggest that pulsatile GnRH secretion and the resistance of type I mammalian GnRHRs to desensitization both serve to minimize negative feedback and thereby place increasing reliance on such downstream combinatorial mechanisms.

Another important aspect of the mathematical modeling approach is that manipulation of model parameters suggests a surprising degree of plasticity.[618,639] Thus, the model outlined here predicts not only that cooperative convergence of the Raf–MEK–ERK and Ca^{2+}–calmodulin–calcineurin–NFAT pathways could cause maximal transcription responses at submaximal GnRH pulse frequency, but also that the optimal pulse frequency may be dependent on model parameters such as the concentrations of ERK and NFAT as well as the kinetics of their activation and inactivation (Figure 10.8(B); McArdle and Tsaneva-Atanasova, unpublished data). To our knowledge, the control of these parameters has not been explored, except in the case of ERK-signaling

kinetics. Comparison of hGnRHR and XGnRHR signaling suggests that receptor desensitization and internalization (which differ markedly for these receptors without and with C-tails) are not important determinants of the kinetics or magnitude of whole-cell ERK phosphorylation.[561] However, ERK responses are modulated by many ERK-interacting proteins, including dual-specificity phosphatases (DUSPs) induced by GnRH, some of which can both scaffold and inactivate ERKs. Using siRNA to target DUSPs, we found that 12 of the 16 DUSPs expressed in HeLa cells influenced ERK responses to sustained stimulation with GnRH or a PKC activator.[353,354,640,641] Moreover, GnRH can increase expression of nuclear-inducible MKP family DUSPs,[353,366,382,640] and a recent computational model illustrated the potential for pulse frequency decoding by MAPK pathways and inducible phosphatases.[372] To our knowledge, the possibility that optimal GnRH pulse frequencies (i.e., for regulation of LHβ and FSHβ expression) vary under different physiological conditions or as a function of ERK inactivation kinetics have not been explored experimentally. Nevertheless, the possible occurrence of coordinated regulation of GnRH pulse frequency and frequency–response relationships is certainly intriguing.

Extrapituitary GnRHRs, Context-Dependent GnRHR Signaling, and Ligand Bias
