Pituitary GnRHRs are targeted with agonists and antagonists to cause the medical castration that underlies their efficacy against steroid hormone-dependent neoplasms,[26,519] but GnRHR expression is not restricted to the pituitary. Indeed, GnRHRs are found (often along with GnRH) in many cancers of reproductive tissues.[30] These extrapituitary GnRHRs are of particular interest in light of the fact that GnRH analogs, or cytotoxic derivatives of such analogs, can inhibit proliferation, stimulate apoptosis, and inhibit migration in cell lines derived from such cancers.[30,39,40,161,202–236] Investigation of these systems has revealed major functional differences between GnRHRs in pituitary and extrapituitary sites. In radioligand binding studies,[208] pituitary GnRHRs have high affinity for ligands such as Buserelin (nM K_d values), whereas much of the work on extrapituitary GnRHRs reveals low affinity binding (μM K_d values). In the pituitary, GnRHRs couple via $G_{q/11}$ to PLC, causing an IP_3-mediated mobilization of Ca^{2+} and a PKC-mediated activation of MAPKs (see the section Mitogen-Activated Protein Kinases), but there is little evidence for PLC activation by native extrapituitary GnRHRs. Instead, G_i-mediated activation of protein phosphatases and inhibition of MAPK activity may underlie at least some of the antiproliferative effects mediated by GnRHRs in these cancer cells.[208,209,211,215,216,219,236] A further distinction is that ligands acting as competitive antagonists of pituitary GnRHRs can sometimes mimic the effects of agonists in cancer cells, implying that the agonist–antagonist dichotomy established for pituitary GnRHRs may not be applicable to extrapituitary GnRHRs.[208,216,219,220] The simplest explanation for differing pharmacology with pituitary and extrapituitary GnRHRs would be that they are mediated by distinct receptors, but the type I hGnRHR transcripts expressed in pituitary and extrapituitary sites are identical.[642] The cloning of type II GnRHRs in primates[79] and the demonstration that GnRH II has potent antiproliferative and/or apoptotic effects[217,221,224,225,228,234] raised the possibility that the functional differences reflected mediation by type I and type II receptors. However, humans express a type II GnRHR pseudogene that does not encode functional GnRHRs.[27,39,197,201] Moreover, effects of GnRH I and GnRH II can both be prevented by depletion of type I GnRHRs,[234] confirming action via a single GnRHR. Consequently, it is generally thought that both GnRH I and II effects are mediated by type I GnRHRs in humans.[31,201]

The second obvious possibility is that type I hGnRHR function is dependent upon the cell type in which it is expressed. Identical receptors could presumably signal differently in different cellular environments because of differences in access to effectors, either because whole-cell expression levels of receptors and/or effectors differ or because the proteins are differentially insulated from one another (in space or time). To explore this, we made use of the fact that subclones of hormone-dependent cancer cell lines often differ from one another. Thus, the endogenous GnRHRs of breast cancer (MCF7) and prostate cancer (PC3) cells can mediate direct antiproliferative effects of GnRHR ligands, but in our hands these cells did not express measurable GnRHRs, as judged by binding and functional assays.[213,218,223] However, when recombinant adenovirus was used to express type I GnRHRs in these cells (at levels similar to those found in gonadotropes), the heterologously expressed receptors were very similar (in terms of binding affinity, ligand specificity, and $G_{q/11}$ coupling) to those of the native GnRHRs in gonadotropes. Moreover, activation of these receptors did reduce proliferation, with effects apparently mediated by G_q rather than G_i.[213,218,223] Such experiments with heterologous GnRHRs are clearly consistent, with a role for GnRHR in the mediation of direct effects on cell fate. Nevertheless, it remains unclear why the native type I GnRHR of GnRHR-positive breast and prostate cancer cells should mediate proliferation inhibition by a distinct mechanism to the type I GnRHR expressed heterologously in GnRHR-negative versions of the same cells.

With the protocols used here, it was possible to vary GnRHR number (by varying the adenoviral titer) and to express modified GnRHRs (i.e., chimeric type I GnRHRs with an added type II GnRHR C-tail), and this revealed

the importance of receptor number and function as determinants of efficacy for proliferation inhibition.[223] The data implied that the resistance of type I GnRHRs to desensitization might enable them to effectively mediate proliferation inhibition and that manipulations increasing GnRHR expression might increase the direct antiproliferative effect. In this regard, it is also important that a large proportion of hGnRHRs are intracellular, whereas GnRHRs from other species can be expressed more effectively at the cell surface (see the section Intracellular GnRHRs). Indeed, when fluorescence microscopy was used to explore this,[195,570] it was found that <1% of HA-tagged hGnRHRs were at the cell surface in two hormone-dependent cancer cell lines (MCF7 and DU145). This was increased 7–18-fold by treatment with a small-molecule GnRHR antagonist (the pharmacological chaperone IN3) that was actually able to increase GnRHR-mediated antiproliferative and pro-apoptotic effects. Interestingly, the proportion of hGnRHRs at the surface was at least fivefold higher in gonadotrope-lineage LβT2 cells than in the hormone-dependent cancer cell lines, and the pharmacological chaperone caused a more modest 1.5–3-fold increase in the proportion of receptors at the cell surface.[223,570] This provides a clear demonstration of a cell context-dependent GnRHR function. It also raises the possibility that compartmentalization may underlie some of the reported functional differences between pituitary and extrapituitary GnRHRs. Thus, binding studies with crude plasma membrane preparations (that were developed largely for work with rodent tissues and cells) may be inappropriate for detection of hGnRHRs that are predominantly intracellular in cancer cells. Similarly, rapid responses such as Ca^{2+} mobilization and [^{3}H] IP accumulation may be more readily detected when a large proportion of GnRHRs are located in the plasma membrane (as is the case for rodent GnRHRs in gonadotropes), whereas chronic effects on proliferation may provide time for intracellular receptors to traffic to the surface for signaling (favoring the detection of responses mediated by hGnRHRs in cancer cells).

Until recently, it was generally thought that any given 7TM receptor would have one active conformation and couple to one G-protein (e.g., G_s or G_q) with one effector (i.e., adenylyl cyclase or PLC), but it is now evident that some 7TM receptors act via multiple G-proteins to control multiple effectors.[643–645] Such divergent signaling can reflect the existence of multiple active conformations preferentially coupled to distinct effectors, in which case specific ligands may preferentially stabilize different active conformations and bias signaling to distinct effectors.[643–645] Accordingly, a third possibility is that cell context-dependent effects of GnRH analogs reflect ligand bias,[40] which is also known as functional selectivity, biased receptor signaling, pluridimensional efficacy, biased agonism, or ligand-induced selective signaling.

Ligand bias requires the existence of at least two distinct active receptor conformations that are preferentially stabilized by different agonists and preferentially coupled to different effectors. In reality, however, the system is much more complex, with numerous different tertiary structures predominantly occurring in related groups of preferred conformations known as receptor ensembles.[643–645] Ligands are then thought to alter the thermodynamics of receptor ensemble formations, and the distinct conformations within them have the potential to differentially activate distinct effectors. In this way, ligand efficacy reflects stabilization of ensembles of receptor conformations and is specific for the effectors activated by such ensembles. It is unlikely that any two ligands would produce identical receptor ensembles or that different receptor ensembles would activate effectors identically,[645] so ligand bias is now seen as a likely (possible inevitable) feature of 7TM receptor function. For type I mammalian GnRHRs, the absence of agonist-induced receptor phosphorylation and arrestin-mediated signaling may limit the number of GnRHR conformations and the effector repertoire, but even with these receptors there is good evidence for multiple active receptor conformations and ligand bias for upstream signaling pathways (i.e., G_q versus G_s), global downstream readouts (i.e., inhibition of proliferation), as well as receptor trafficking (to and from the plasma membrane).

It is important to recognize that the cell context-dependent effects of GnRHR ligands may largely be due to differences in effector abundance and signal architecture, rather than ligand bias. Indeed, the fact that GnRHRs mediate activation of G_s in LβT2 cells[315] and of G_i in some hormone-dependent cancer cells,[219,220,232,318] but apparently have neither effect in αT3-1 cells,[312,313] does not necessarily reflect stabilization of different active GnRHR conformations (or conformation ensembles). Similarly, the cell context-dependent mechanisms underlying GnRHR-mediated ERK activation[646] do not require activation of different GnRHR conformations. However, other differences cannot be easily explained without invoking distinct types of GnRHR or distinct active conformations of a single type of GnRHR. Thus, it is well known that the peptide "antagonist" cetrorelix is a pure antagonist of GnRH effects on [^{3}H]IP accumulation and gonadotropin secretion in pituitary cells, but it actually mimics antiproliferative effects of GnRH in some models.[214,225,318] Similarly, GnRH I is more potent than GnRH II at stimulation of IP accumulation by type I GnRHRs in pituitary cells, which is the reverse of the situation for inhibition of proliferation in some models.[30,39,221,225,232,548] Since this reversal of potency or efficacy appears not to reflect action via different receptors (as discussed here), ligand bias remains the most likely explanation for much data showing differences in ligand specificity when native GnRHR-mediated effects have been compared in different cell types.[40]

More direct evidence for ligand bias comes from work with different ligands and non-native GnRHRs. For example, we found that XGnRHRs expressed in HeLa cells had higher affinity for GnRH II than for Buserelin (a type I mammalian GnRHR-selective agonist) and that PKC activation increased the affinity of the XGnRHRs for GnRH II but not for Buserelin.[647] This was paralleled by an increase in Ca^{2+} mobilization by GnRH II (but not Buserelin), and, interestingly, the C-tail was shown to be crucial for this effect as chimeric receptors (type I sheep or hGnRHRs with an added XGnRHR C-tail) showed the same PKC-mediated increase in binding to GnRH II but not Buserelin. These data demonstrate a novel form of "inside-out signaling" and the existence of distinct active conformations of GnRHRs,[647] which is an essential prerequisite for ligand bias at these receptors. Further evidence for ligand bias comes from work comparing the effects of GnRH analogs on different type I mammalian GnRHR-mediated responses. It was found[318] that a series of GnRHR ligands all inhibited proliferation in JEG-3 cells and BPH1 cells (both with native hGnRHRs) and in SCL60 cells (which have exogenous rat GnRHRs). They all apparently activated G_i and caused Gi-dependent (PTX-sensitive) inhibition of proliferation.[318] Marked ligand bias was observed because GnRH I stimulated [^{3}H]IP accumulation; activated ERK, p38, and JNK; and inhibited proliferation, whereas a GnRH analog (135-25) mimicked all other GnRH I effects but failed to increase [^{3}H]IP accumulation.[318] In the SCL60 cells, GnRH I is more potent at stimulation of [^{3}H]IP accumulation (EC_{50} < 1 nM) than for inhibition of proliferation (EC_{50} approximately 100 nM), whereas GnRH II has comparable potency for both experimental endpoints (EC_{50} values 10–100 nM). There are only three amino acid differences between GnRH I and II, and subsequent work revealed that Tyr^8 of GnRH II is the main determinant of its bias toward proliferation inhibition. Here, the idea is that interaction of Arg^8 of GnRH I with Asp^{303} of the GnRHR stabilizes a conformation that preferentially activates G_q, whereas no such interaction occurs with ligands containing Tyr.[8] Instead the Tyr^8 of GnRH II faces away from Asp,[303] and the ligand stabilizes a different receptor conformation that preferentially activates G_i.[648] More recently, domain swapping (human–catfish and human–chicken GnRHR chimeras) was used to demonstrate the importance of extracellular domains as determinants of ligand specificity, and provided further evidence that GnRH I and GnRH II stabilize distinct active GnRHR conformations.[649]

Ligand bias at GnRHRs is also evident in work on GnRHR localization and trafficking. As noted in the section Intracellular GnRHRs, nonpeptide pharmacological chaperones can increase GnRHR trafficking to the cell surface, providing an additional endpoint for consideration of ligand bias. Indeed, the work with such chaperones provides a marked example of ligand pluridimensional efficacy as nonpeptide ligands can act as antagonists in terms of cell surface GnRHR signaling, but as agonists in terms of anterograde trafficking. This raises the intriguing possibility that ligands could be developed that are selective for these effects. Indeed, when we compared three nonpeptide antagonists (IN3, NBI42902, and NBI54048), we found marked differences in potency for inhibition of cell surface GnRHR signaling but not for effects on cell surface expression (C. McArdle, unpublished data), implying that these effects may be selectively manipulated. These data also indicate that the cell surface and intracellular GnRHRs have different conformations, which is not unexpected as most GnRHRs within the cell have apparently failed quality control criteria for ER exit, whereas those at the cell surface evidently have not.

In assessing the effects of pharmacological chaperones on GnRHR expression, control experiments were performed with two peptide antagonists (antide and cetrorelix). These membrane-impermeant GnRH ligands would not be expected to access intracellular GnRHRs and, as expected, had no effect on the proportion of hGnRHRs at the cell surface in MCF7 cells.[570] However, when the XGnRHR C-tail was added to the hGnRHR in order to increase cell surface expression, it was noted that the peptide antagonists further increased cell surface expression of h.XGnRHRs. Although the effect was modest, it raised the possibility that the peptides might act at the surface to increase GnRHR number by slowing internalization, and subsequent work showed that this is indeed the case.[573] Indeed, a pronounced synergism can occur when a nonpeptide chaperone is used to increase GnRHR trafficking to the cell surface and a peptide antagonist (cetrorelix) is used to slow internalization from the cell surface. This effect was seen with hGnRHRs and mGnRHRs and in gonadotrope-lineage LβT2 cells, as well as in HeLa cells. Cetrorelix is not known to stimulate signaling in these models, and similar data were obtained using the signal-defective A261K mutant of the hGnRHR.[573] Thus, although the mechanisms are not known, this work clearly demonstrates that the cetrorelix-occupied hGnRHR is functionally distinct from the unoccupied receptor and that cetrorelix can be a pure antagonist for GnRH I-stimulated [^{3}H]IP accumulation and Ca^{2+} signaling, and an inverse agonist for GnRHR internalization. Importantly, this form of ligand bias was seen with a compound that is used clinically and in gonadotropes, the only proven targets for GnRHR-directed therapy.

Ligand bias has a number of implications for understanding and manipulating GnRHR signaling. It provides a likely explanation for early studies showing reversal of potency or efficacy when comparing the effects of GnRHR ligands in different cell types. It may

also prove crucial for understanding the physiological relevance of the two GnRH ligands acting via a single type of GnRHR in humans. Moreover, it highlights the need to qualify classical pharmacological descriptors; for example, cetrorelix is well established as a full antagonist of GnRHR-mediated gonadotropin secretion from pituitary cells but is an inverse agonist for downregulation of cell surface GnRHRs in others (as discussed here). Similarly, nonpeptide ligands that are pure antagonists for GnRHR-mediated IP accumulation and Ca^{2+} signaling are also full agonists for GnRHR trafficking to the cell surface, providing complex pharmacological profiles dependent upon relative potency for the two effects and receptor location before ligand exposure. Most importantly, however, it raises the exciting possibility of developing ligands that more selectively engage therapeutically beneficial effectors and responses. Here, an obvious strategy would be to develop GnRHR ligands that are antagonists for G_q-mediated stimulation of gonadotropin secretion from the pituitary and agonists for direct G_i-mediated antiproliferative effects on hormone-dependent cancers. However, this remains highly speculative, and a major challenge is now to understand the pharmacological relevance of biased GnRHR signaling in vivo.

AUTOCRINE AND PARACRINE REGULATION OF GONADOTROPES

The vast majority of work on gonadotrope cell signaling focuses inevitably on molecular mechanisms of GnRH action. However, these cells sense and respond to numerous additional extracellular stimuli, including the gonadal steroids 17β estradiol, progesterone, and testosterone, each of which can act centrally to influence GnRH secretion but can also act directly at the pituitary to modulate GnRH effects on gonadotropes. They are also targets for numerous local regulators for which physiological roles are largely unknown. The earliest evidence for such local regulation is anatomical. Thus, in 1970, Nakane[650] showed that GH, prolactin, and ACTH were stored in different cell types, whereas many gonadotropes were immunoreactive for both LH and FSH, and also noted that the cells were not randomly distributed; somatotropes were often closely associated with corticotropes, just as lactotropes were often associated with gonadotropes. In fact, gonadotropes are often found in clusters that may be tightly juxtaposed to blood vessels and/or with lactotropes or folliculostellate cells.[651] The field was advanced with the development of techniques for partial purification of the different cell types from mixed-cell populations of dispersed anterior pituitaries. It was found, for example, that when enriched gonadotropes were stimulated with GnRH, they released surprisingly high amounts of FSH, implying that the microenvironment of gonadotropes within mixed-cell populations restricts FSH secretion.[651,652] When gonadotrope-enriched cell populations were remixed with gonadotrope-poor populations (prolactin-positive cells), this again influenced the FSH:LH ratio secreted.[651,653] It has since become clear that gonadotropes are influenced by many local regulatory factors that mediate communication between gonadotropes and between different cell types, particularly between gonadotropes, lactotropes, and folliculostellate cells, in the anterior pituitary.[651] More recently, sophisticated 3D imaging techniques have revealed that cells thought to be dispersed throughout the gland actually form extensive networks that coordinate cell population responses to stimulation and remodel under different physiological conditions.[654–657] Such studies highlight the question of how such homotypic or heterotypic communication is mediated. The autocrine and paracrine regulation of gonadotropes has been thoroughly reviewed by Carl Denef, who lists over 100 extracellular signaling molecules that have been identified in the anterior pituitary.[651] Some of the paracrine regulators of pituitary organogenesis are described in see the section Paracrine Factors and Pituitary Development. Here we highlight a few additional systems, selected to illustrate different signaling paradigms.

Activins, Inhibin, and Follistatin

Activin and inhibin are members of the TGF-β family. They were first characterized as proteins that activate and inhibit FSH expression (respectively), but this has led to a broader understanding of the roles played by several family members (including BMPs and TGFs) in the control of pituitary development (in the section Paracrine Factors and Pituitary Development) as well as the differential control of gonadotrope signature gene expression (see the section Regulation of Gene Expression). Inhibins were first characterized as gonadal feedback regulators of FSH secretion, and analysis of side fractions from inhibin purification led to the discovery of activins and the realization that they were members of the TGF-β family. Inhibins have an α subunit combined with one of two β subunits (A or B) to produce inhibin βA or βB. Activins are dimers containing only the β subunits (i.e., activin A is a dimer of βA subunits, activin B is a dimer of βB subunits, and activin A/B is a dimer of βA and βB subunits). These proteins play important roles in the hypothalamo–pituitary–gonadal axis, with gonadotropes being a site of synthesis of α and β inhibins, as well as the main site of activin synthesis in the mammalian pituitary.[478,479,651,658,659] Activin is an important local regulator of FSH synthesis, and this action is one of the fundamental reasons why GnRH has selective effects on

LH and FSH secretion under different physiological conditions. It is thought that gonadotrope-derived activin B exerts a tonic stimulatory effect on FSH synthesis that can be prevented by inhibin.[660] Evidence for such a role has been obtained with immunoneutralization experiments showing that activin can mediate the rise in FSH seen after ovariectomy in the rat. In physiological settings, activins are thought to mediate the increased expression of FSH in estrus (i.e., the secondary rise occurring after the GnRH-driven preovulatory gonadotropin surge) and also contribute to the juvenile FSH surge occurring as the gonadotrope cell population expands in 1–2-week-old female rats.[651]

TGF-β family ligands act via cell surface receptors with intrinsic serine–threonine kinase (RSK) activity. They are divided into two groups, type I receptors (collectively termed ALKs for activin receptor-like kinases) and type II receptors, each of which functions as a heteromeric protein complex.[478,479,658,659] Complexity is added by the fact that ligands characteristically bind more than one type of receptor and that their receptors signal cooperatively. Activins act via two of the five mammalian type II receptors (ActRII and ActRIIB) and one of the seven type I receptors (ActR1B–ALK4). In the female rat, ActRII is expressed in many anterior pituitary cell types, whereas ActRIIB is apparently only expressed by gonadotropes.[661,662] A current activation model is that ligand binding brings type I and type II receptors together so that the constitutively active type II receptor can phosphorylate specific residues in the type I receptor. The phosphorylated type I receptors then recruit and activate SMADs. These are transcription factors with an N-terminal MH1 domain containing DNA binding and nuclear localization sequences, and a C-terminal MH2 domain needed for transactivation.[479] The situation is a little more complex with inhibins because their signaling requires expression of a betaglycan termed TβRIII (originally characterized as a TGF-β2 co-receptor). Here, the idea is that binding of inhibin to TβRIII promotes high-affinity binding of the ligand to type II receptors (ActRII, ActRIIB, and BMPRII). The TβRIII–inhibin–type II receptor complex does not lead to type I receptor recruitment and importantly sequesters type II receptors, so that inhibin not only fails to activate the cells but also prevents activin from doing so. This explains why activin and inhibin typically behave as functional antagonists and why the inhibitory effect of inhibin is only seen in cells expressing the TβRIII proteoglycan.[479]

Effects of activins can also be opposed by follistatins, cystein-rich monomeric proteins that bind and neutralize activins at a molar follistatin–activin ratio of 2:1. Inhibition is achieved because the two follistatin molecules bind activins with high affinity, occluding the type I and type II receptor–binding sites.[478,479,651] Follistatins are often coexpressed with the ligands with which they bind, and many of their effects are attributed to autocrine or paracrine neutralization. In the pituitary, follistatins are thought to be produced by both gonadotropes and folliculostellate cells.[651] Fluctuations in pituitary follistatin levels through the estrous cycle are generally suggestive of a role in control of FSH expression, and its production is influenced by GnRH and gonadal steroids, providing a mechanism for hormonal modulation of locally produced activin B.[651]

Pituitary Adenylyl Cyclase-Activating Polypeptide

In addition to GnRH, gonadotropes are targets for a large number of 7TM receptor-activating ligands.[651] These include oxytocin, endothelin-1, galanin, β-endorphin, neuropeptide Y, nucleotides (discussed further here), and pituitary adenylyl cyclase-activating polypeptide (PACAP), a highly conserved member of the vasoactive peptide (VIP)–secretin–glucagon peptide superfamily. PACAP is widely distributed in the nervous, immune, gastrointestinal, cardiac, and endocrine systems but was originally isolated from hypothalamic extracts based on its ability to stimulate cAMP production by primary cultures of rat pituitary cells.[663,664] The major forms are a 38-amino-acid peptide (PACAP38) and a C-terminally truncated 27-amino-acid form (PACAP27) that is less prevalent in most tissues.[651,663–666] It acts via three distinct types of 7TM receptors: $VPAC_1$ and $VPAC_2$, which have similar affinity for VIP and PACAP, and PAC_1, which is highly selective for PACAP.[665–668] PAC_1 receptors have the potential to couple directly to both G_s and $G_{q/11}$ and exist as splice variants differing in the presence or absence of sequences termed "hip" and "hop" in the third intracellular loop (i.e., one, two, or neither of these sequences is present).[651,666,668–670] Early work showed that (for most PAC_1 variants) PACAP38 and PACAP27 had comparable potency for stimulation of cAMP production, whereas PACAP38 was much more potent than PACAP27 for stimulation of [^{3}H]IP accumulation.[671] This is of particular interest in terms of ligand bias (see the section Decoding GnRH Pulse Frequency), as it provides an early example of receptor function that could not be explained by existing models; these functional features immediately suggested that the two ligands activated different conformations of the same receptor and that these conformations activated effectors differentially.

The major secretory cells and folliculostellate cells of the anterior pituitary all express at least one form of PACAP receptor.[651] Notably, PACAP activates PAC_1, causing a G_s-mediated stimulation of cAMP production and a $G_{q/11}$-mediated increase $[Ca^{2+}]_i$ in gonadotropes and gonadotrope cell lines.[277,313,651,665,668,672–675] Moreover, there is increasing evidence that PACAP is an important regulator of both gonadotropin secretion and

expression of signature genes in gonadotropes, acting either alone or by virtue of its ability to modulate GnRH effects.[651,665,668,674,676–681] Since PACAP was initially purified from hypothalami and PACAP concentration is higher in the portal circulation than in the periphery,[651] PACAP is seen as a hypothalamo-hyophysiotropic hormone that uniquely appears to target both gonadotropes and folliculostellate cells.[651] However, there is also evidence for a local role within the anterior pituitary. Notably, PACAP has been detected in rat and human pituitaries (by immunoassay) and in rat gonadotropes (by immunohistochemistry), whereas PACAP mRNA has been detected in folliculostellate cells.[651,682–686] Interestingly, it has been shown that PACAP increases follistatin expression by gonadotropes and folliculostellate cells,[675,687,688] raising the possibility that it modulates activin signaling in the pituitary.[665] Finally, when considering the possible effects of GnRH on cAMP signaling in gonadotropes, it is worth bearing in mind that maximal activation of PAC_1 receptors on gonadotrope-derived cell lines causes much greater elevation of cAMP than GnRH does,[313,668,673] and that GnRH actually causes a PKC-mediated inhibition of PAC_1-mediated cAMP elevation.[313] Accordingly, if gonadotropes are exposed to stimulatory concentrations of (local or hormonal) PACAP in vivo, GnRH pulses could actually inhibit rather than stimulate cAMP production.[313]

Extracellular Nucleotides

The purines adenosine, ADP, and ATP, and the pyrimidines UDP and UTP (uridine 5′ diphosphate and uridine 5′ triphosphate, respectively), can all act as extracellular signaling molecules. Many cells release them in a regulated manner, to act on target cells via specific cell surface purinergic receptors.[651,689] ATP is well established as an extracellular signaling molecule for skeletal muscle and adrenal chromaffin cells, as well as fibroblasts and endothelial cells. It also acts as a neurotransmitter, co-transmitter, or neuromodulator in the central and peripheral nervous systems.[689] Extracellular ATP is rapidly metabolized to ADP, and then via adenosine monophosphate to adenosine.[651,689] Extracellular ATP can activate G-protein coupled P2Y receptors (P2YRs) or ion-conducting P2X receptors (P2XRs), whereas ADP activates P2YRs (but not P2XRs), and adenosine activates G-protein coupled adenosine receptors (ARs) but not P2XRs or P2YRs. UTP and UDP are also native agonists for P2YRs. Anterior pituitary cells express at least six of the seven cloned P2XRs, two of the eight cloned P2YRs, and all four cloned ARs.[281,651,667,689] At least four of the mammalian P2YRs ($P2Y_1$, $P2Y_2$, $P2Y_4$, and $P2Y_6$) act via $G_{q/11}$.[281,667] The P2XRs are ATP-gated ion channels, with each subunit having two transmembrane domains, and three subunits forming the functional receptor. They gate Na^+, K^+, and Ca^{2+} primarily, and activation characteristically increases Ca^{2+} entry across the plasma membrane either directly or secondary to depolarization by P2XR-mediated ion currents.[281,667,689]

Pituitary cells store ATP in secretory granules and co-secrete it with hormones during agonist-stimulated exocytosis.[651,689–692] Pituitary ATP receptors were first characterized in gonadotropes and in gonadotrope-derived cell lines.[690,693,694] These were identified as P2YRs that were activated by ATP and UTP and caused a $G_{q/11}$-mediated activation of PLC with consequent mobilization of Ca^{2+} from intracellular stores and activation of PKC.[690,693,694] However, cell enrichment protocols have shown that Ca^{2+}-mobilizing P2YRs are located predominantly in lactotropes and not gonadotropes.[689] The reason for this discrepancy is unknown but may relate to the use of different rat strains (Wistar versus Sprague–Dawley, as discussed in Ref. 689). The cell enrichment study also indicated that P2XR is expressed by all of the anterior pituitary secretory cell types.[689] Multiple P2XR transcripts are expressed by pituitary cells, but functional profiling revealed the presence of P2X2R in gonadotropes (and somatotropes), as opposed to P2X3R, P2X4R, and P2X7R in lactotropes. GnRH can stimulate ATP release from dispersed pituitary cell cultures,[690,691] and ATP can stimulate LH secretion and amplify GnRHR-mediated gonadotropin secretion.[651,689–694] Consequently, although physiological roles are not established, it seems likely that ATP of autocrine or paracrine origin acts via P2XRs and/or P2YRs on gonadotropes to amplify the GnRH effects on Ca^{2+} signaling, as well as the downstream consequences of such signaling.

Natruiretic Peptides, Nitric Oxide, and Guanylyl Cyclases

The major mammalian natriuretic peptides are atrial-, B-type, and C-type natriuretic peptide (ANP, BNP, and CNP, respectively). They act via cell surface receptors with intrinsic guanylyl cyclase activity termed NPR1 (GC-A) and NPR2 (GC-B).[667] These enzymes, also known as particulate guanylyl cyclases, have a single transmembrane domain but are thought to act as homodimers.[667,695] NPR1 is selectively activated by ANP and BNP, whereas NPR2 is selective for CNP, and all mediate elevation of cGMP levels in their target cells. ANP and BNP are well-characterized regulators of cardiac and renal function, but the physiological roles of CNP are less clear. Transgenic deletion of the mouse CNP gene (*Nppc*) causes dwarfism and skeletal abnormalities, revealing a critical role in endochondral ossification.[342] Female mice with this deletion are also infertile, as are mice in which the gene encoding GC-B (*Npr2*) is deleted, and this is consistent with evidence supporting a role for CNP in the hypothalamo–pituitary–gonadal

axis.[695–701] Thus, the anterior pituitary contains the highest tissue concentration of CNP, and immunostaining revealed particularly strong expression in gonadotropes,[702] where it is found within secretory vesicles.[700] Moreover, CNP causes marked increases in cGMP levels in GnRH-expressing neurons, primary cultures of pituitary cells, gonadotrope cell lines, as well as endocrine cells of the testis, ovary, placenta, and uterus.[703–710] The fact that gonadotropes produce and respond to CNP is suggestive of an autocrine function,[702,711] although other anterior pituitary cell types are also CNP responsive, suggesting a possible paracrine role for gonadotrope-derived CNP.[651,700,701] Although CNP does not stimulate LH secretion or modulate GnRH-stimulated LH secretion,[695,698,700] work with gonadotrope-derived cell lines reveals that it can stimulate the human αGSU promoter[700] and that GnRH may stimulate CNP expression (transcriptional regulation of the proximal *Nppc* gene).[700] Nevertheless, the physiological relevance of pituitary CNP–NPR2 signaling in the pituitary remains unknown, largely because so little is known about physiologically relevant cGMP targets in this tissue.

Nitric oxide (NO) is a gaseous signaling molecule that plays important roles in the immune, cardiovascular, and neuronal systems. It is produced from L-arginine by nitric oxide synthase (NOS) and exerts physiological effects by activation of soluble guanylyl cyclases to generate cGMP. There are three forms of NOS; neuronal (nNOS) and endothelial (eNOS), which are expressed constitutively and are activated by Ca^{2+}–calmodulin, and inducible (iNOS), which is Ca^{2+} independent.[251,651] nNOS is expressed in the anterior pituitary, where it is located primarily in gonadotropes and folliculostellate cells. In male rats nNOS is located predominantly in folliculostellate cells, whereas in female rats it is predominantly found in gonadotropes.[651] nNOS expression is also controlled by GnRH, as agonists can increase nNOS expression in gonadotropes.[712,713] Moreover, gonadotrope nNOS expression increases during the afternoon of proestrus and can be increased by gonadectomy, and both of these effects are prevented by GnRH antagonists.[712,713] Such effects may reflect the presence of the AF2 transactivation domain of NR5A1 (SF1) in the nNOS promoter[714] as a likely target for GnRH. In addition to effects on expression, GnRH would be predicted to acutely increase nNOS activity by activation of Ca^{2+}–calmodulin. In accord with this, GnRH has been shown to acutely increase cGMP concentrations in pituitary cells in vitro, and this effect was blocked by NOS inhibition.[712]

In vitro studies have shown that NO can stimulate basal LH and FSH secretion and inhibit GnRH-stimulated LH and FSH secretion.[715–717] Thus, GnRH-stimulated gonadotropin secretion can be inhibited with an NO donor and enhanced with an nNOS inhibitor. Similarly, in vivo treatment with an NOS inhibitor has been shown to reduce LH and FSH responses to GnRH in humans.[718] However, effects of NO on gonadotropin secretion remain rather controversial (see Denef 2008 for a discussion of stimulatory and inhibitory effects[651]), and as with the natriuretic peptide studies discussed here, understanding the physiological role of nNOS in this system is hampered by a lack of information on NO–cGMP targets in pituitary cells. Here, it is important to recognize that NO activates a number of target proteins, including cycloxygenase enzymes and ion channels as well as the soluble guanylyl cyclases. At physiological concentrations its effects are largely mediated by soluble guanylyl cyclases, but at higher concentrations it also has pronounced cytotoxic effects, reacting for example with superoxide to produce peroxynitrite that further decomposes to generate cytotoxic oxygen radicals. Such effects presumably underlie the ability of NO donors to stimulate LH and FSH secretion, as these responses were shown to be cGMP independent,[716] and no such effect is seen when cGMP is elevated with CNP (as discussed here).

The fact that gonadotropes appear to use regulators of multiple guanylyl cyclases for autocrine or paracrine regulation raises the obvious question of whether the source of cGMP (i.e., generation by particulate or soluble guanylyl cyclases) is relevant for function. GnRH-stimulated gonadotropin secretion is modulated by NO donors or NOS inhibitors (in a cGMP-dependent manner) but not by CNP (as discussed here), which implies that effects of soluble and particulate guanylyl cyclases are not identical. In terms of potential cross-talk, it is intriguing that GnRH causes a rapid PKC-mediated inhibition of CNP-stimulated cGMP accumulation[711] and a Ca^{2+}–calmodulin -mediated activation of nNOS, so it has the potential to rapidly shift the balance of signaling from particulate to soluble guanylyl cyclases. Further potential for cross-talk arises as activation of cGMP-dependent phosphodiesterase activity provides the potential for CNP to modulate the effects of NO or PACAP (on cGMP and cAMP, respectively), whereas PACAP has been shown to increase nNOS expression and potentiate the GnRH-stimulated increase in cGMP in gonadotropes.[719]

CONCLUSION

The past few decades have seen massive advances in our understanding of gonadotropes, with increasingly detailed models published for gonadotrope development, the GnRHR signaling network, the transcriptional regulation of gonadotrope signature genes, and the local control of gonadotrope function. In spite of the increasingly complex nature of such models, they can all be assumed to be vast oversimplifications, not least because most have little or no information on kinetics and compartmentalization. The importance of kinetics is self-evident in a system where the CNS provides a frequency-encoded

signal to gonadotropes, yet surprisingly little is known about mechanisms of GnRH pulse frequency decoding. We know a great deal about how different Ca^{2+} responses are created and are beginning to understand how MAPK responses are shaped, but we know very little about how they are interpreted by gonadotropes. Similarly, we are just beginning to understand the dynamic nature of the transcriptome, but we know remarkably little about the dynamics of autocrine or paracrine regulatory systems. Compartmentalization of signaling proteins is equally important, as highlighted by recent work showing that the majority of hGnRHRs are actually intracellular and that GnRHR signaling is dependent upon its location within the plane of the plasma membrane. Here, we know very little about what controls the proportion of GnRHRs reaching the cell surface and how the membrane raft partitioning of GnRHRs and their effectors are controlled. Accordingly, we believe that a major challenge for future work is to overlay space and time on existing schemas for gonadotrope biological control mechanisms. Adding spatiotemporal features to already complex biological models will inevitably challenge existing approaches, so it is likely that mathematically rigorous system approaches will be increasingly important, irrespective of whether the system studied is the GnRHR conformation ensemble, the gonadotrope signature gene transcriptome, the GnRHR signaling network, the anterior pituitary, or the individual. Here, an obvious caveat is that mathematical modeling can predict likely regulatory mechanisms extremely efficiently, but their biological relevance can only be established by testing in biological systems with increased use of genetically tractable systems such as mouse models. Mathematical modeling can also enable system simplification by highlighting parameters likely to have little influence on system behavior. However, an alternative approach to simplification would be to focus on parameters known to influence gonadotrope function in vivo. Here, it is telling that only a handful of gonadotrope proteins are known to be essential for normal reproductive function in vivo (GnRHR, αGSU, LHβ, FSHβ, and ERKs) and that pharmacological manipulation of gonadotrope function still directly targets only GnRHRs. Perhaps the greatest challenge for the future lies in translating the large amount of mechanistic information available from cell lines and mouse models into genuine therapeutic benefits to control pituitary-dependent reproductive outcomes.

CHAPTER

11

Physiology of the Adult Gonadotropin-Releasing Hormone Neuronal Network

Allan E. Herbison

Center for Neuroendocrinology and Department of Physiology, Otago School of Medical Sciences, Dunedin, New Zealand

INTRODUCTION

This chapter aims to provide an overview of knowledge regarding the properties and operating features of the gonadotropin-releasing hormone (GnRH) neuronal network as it exists in the normal adult mammal. The GnRH neuronal network is defined as the GnRH neurons and their associated assembly of neuronal and glial cells responsible for controlling GnRH secretion into the pituitary portal circulation. Multiple internal homeostatic and external factors influence the activity of GnRH neurons to achieve levels of fertility appropriate for the animal. This chapter does not extend to a review of the mechanisms through which stress, aging, lactation, seasonality, or adverse metabolism impact upon GnRH neurons. These are all topics of separate chapters in this volume. The fascinating developmental biology of GnRH neurons has been reviewed recently[1,2] and is not touched on here. In addition, the mechanisms underlying the activation of GnRH neurons at puberty in rodent, sheep, and primates can be found in separate chapters of this volume, alongside species-specific chapters on the ovarian cycles of mammals.

The last version of this chapter devoted considerable attention to other forms of the GnRH decapeptide, in particular GnRH-II.[3] Due to the limited evidence for a role of GnRH-II in reproductive control, and the relatively few advances made in this area over recent times, the reader is referred to the 2006 chapter[3] and a recent review[4] for information on this subject.

For this review, "GnRH-I" is represented as "GnRH". It is pertinent to note that the 10–amino acid peptide was originally named "luteinizing hormone-releasing hormone" (LHRH), being isolated and established as a potent stimulator of luteinizing hormone (LH) secretion in the early 1970s by the Schally and Guillemin laboratories.[5,6] Although LHRH was recognized to stimulate the secretion of both LH and FSH, the possibility that a selective FSH-releasing factor may exist[7] resulted in the persistence of the LHRH nomenclature for many years. Today, LHRH is almost invariably termed GnRH.

Since writing the 2006 chapter, it is readily apparent that the last few years have been dominated by kisspeptin. The discovery of a role for kisspeptin in fertility control has sparked huge renewed enthusiasm in investigating the neurobiology of the GnRH neuron and been an incredible boon for scientists in the field in many ways. The author is embarrassed to note that kisspeptin got "just another neuropeptide" coverage in the last version of this chapter. This is now corrected. While undoubtedly representing the most important neuropeptidergic input to GnRH neurons presently known, it remains that the network requires more than just kisspeptin and GnRH neurons to function. Importantly, other fields of enquiry have continued to make important discoveries.

As noted in 2004, progress in the field of GnRH neurobiology is almost totally dependent upon technological advances in neuroscience, and these continuously revise our understanding of the GnRH neuron. For example, the 1990s were the years of the GT1 cell and GnRH mRNA in situ hybridization, and while observations from those studies were no doubt correct, their impact as techniques upon our current understanding of GnRH neuron physiology has lessened. The past decade has been dominated technically by the use of transgenic and knockout mouse models allowing a plethora of brain slice electrophysiological and in vivo reproductive

profiling studies to be undertaken. As new neuroscience techniques are brought to the GnRH neuron field, it will be fascinating to observe how results from the current mouse models will stand the test of time.

THE GnRH NEURON

Neuroanatomy

Julien Barry and colleagues working in Lille, France, were the first to generate antisera directed against GnRH that could be used for immunocytochemistry.[8] During the 1970s this group dominated the neuroanatomical mapping of GnRH neuron cell bodies and fibers in the brains of a wide variety of vertebrate species including humans (for review see Ref. 9). These studies were complemented in the late 1970s by neuroanatomical investigations by Ann-Judith Silverman[10] and Gloria Hoffman[11] in the USA and Bela Flerko[12] in Hungary. After this there was a worldwide explosion of interest in mapping GnRH immunoreactivity in multiple species at different developmental time points and in relation to varying endocrine states. Major landmarks in GnRH neuron neuroanatomy have also come from ultrastructural studies undertaken by the Silverman, Witkin, Jennes, Beauvillian, Liposits, and Lehman laboratories (for review see Ref. 13) in addition to experiments identifying the hypophysiotropic population of GnRH neurons that project to the median eminence.[14–16] Functionally, the discovery by Hoffman and colleagues that the immediate early gene cFos could be used to indicate activity patterns of GnRH neurons, at least in relation to the GnRH surge,[17,18] has had an enduring influence on experimental GnRH neurobiology.

Distribution of GnRH Neuron Cell Bodies

As a consequence of the unique developmental origins of GnRH neurons within the nose, the GnRH cell bodies come to reside as a scattered "continuum" along their migratory pathway within the mammalian forebrain (Figure 11.1). The GnRH neuron cell bodies can be found to reside anywhere along an axis extending from the olfactory bulbs to the medial septal nuclei and preoptic area through to the ventral aspects of the anterior hypothalamic area (AHA) and mediobasal hypothalamus (MBH). This distribution is sometimes referred to as the "inverted Y" pattern with the rostral-most midline GnRH somata in the medial septum (MS) splitting at the beginning of the third ventricle within the rostral preoptic area (rPOA) to form the two arms of the inverted "Y" that extend back into the ventral AHA and MBH (Figure 11.1). Although this continuum can be found in all mammals, there are species differences as to where the majority of GnRH neurons come to reside along this pathway.[13] In the sheep, rat, and mouse the great majority of GnRH somata are located near the junction of the inverted "Y" in and around the rPOA. Whereas small numbers of GnRH neurons do exist further caudal in the sheep and mouse, it is debatable whether any GnRH perikarya exist in the MBH of the rat. In contrast, a more even distribution of GnRH cell bodies throughout this rostro-caudal continuum is evident in guinea pigs, monkeys, and humans.[19–23]

Whereas the olfactory-to-hypothalamic continuum accounts for nearly all GnRH neurons in mammals, individual cell bodies can occasionally be found outside this distribution in regions such as the bed nucleus of the stria terminalis, subfornical organ, and even the corpus callosum and cingulate cortex.[15,24] The locations of these "aberrant" GnRH neurons may result from individual cells encountering abnormal migratory cues during development.[25]

It is worth noting that GnRH is also expressed in multiple extrahypothalamic cell populations during development in mice and primates.[26,27] The expression of GnRH mRNA and GnRH peptide within these other cell types declines soon after birth in the mouse.[26] This may not be the case in the primate where widespread GnRH-1 mRNA-expressing cells remain evident in the adult human.[28] However, whether these cells utilize GnRH-1 as a neuropeptide is doubtful as these extrahypothalamic neurons appear to express only fragments of the decapeptide such as GnRH$^{1\text{-}5}$.[29]

GnRH Neuron Morphology

Studies undertaken over the last decade have substantially modified how we view the GnRH neuron. In particular, the ability to fill individual living GnRH neurons in situ with small molecular weight dyes has enabled the whole of the GnRH neuron to be visualized rather than just those parts of the cell that contained GnRH peptide.[30] This has revealed the full extent of the GnRH neuron dendrite and revolutionized our understanding of how GnRH neurons must function.

In most species, the GnRH neuron is comprised of a cell body and two simple dendrites giving it a bipolar morphology (Figure 11.2(A) and (B)). The orientation of the bipolar GnRH neuron depends upon its location in the brain; the rostral GnRH neurons in the MS exhibit a vertical orientation and this changes gradually along the continuum to a near horizontal orientation for the caudal-most GnRH neurons in the MBH. This changing orientation may reflect the pathway of GnRH neurons as they migrate through the brain to reside in these different locations (Figure 11.1). However, it should be noted that not all GnRH neurons exhibit this simple bipolar morphology. In sheep, for example, some GnRH neurons can display complex multipolar morphologies

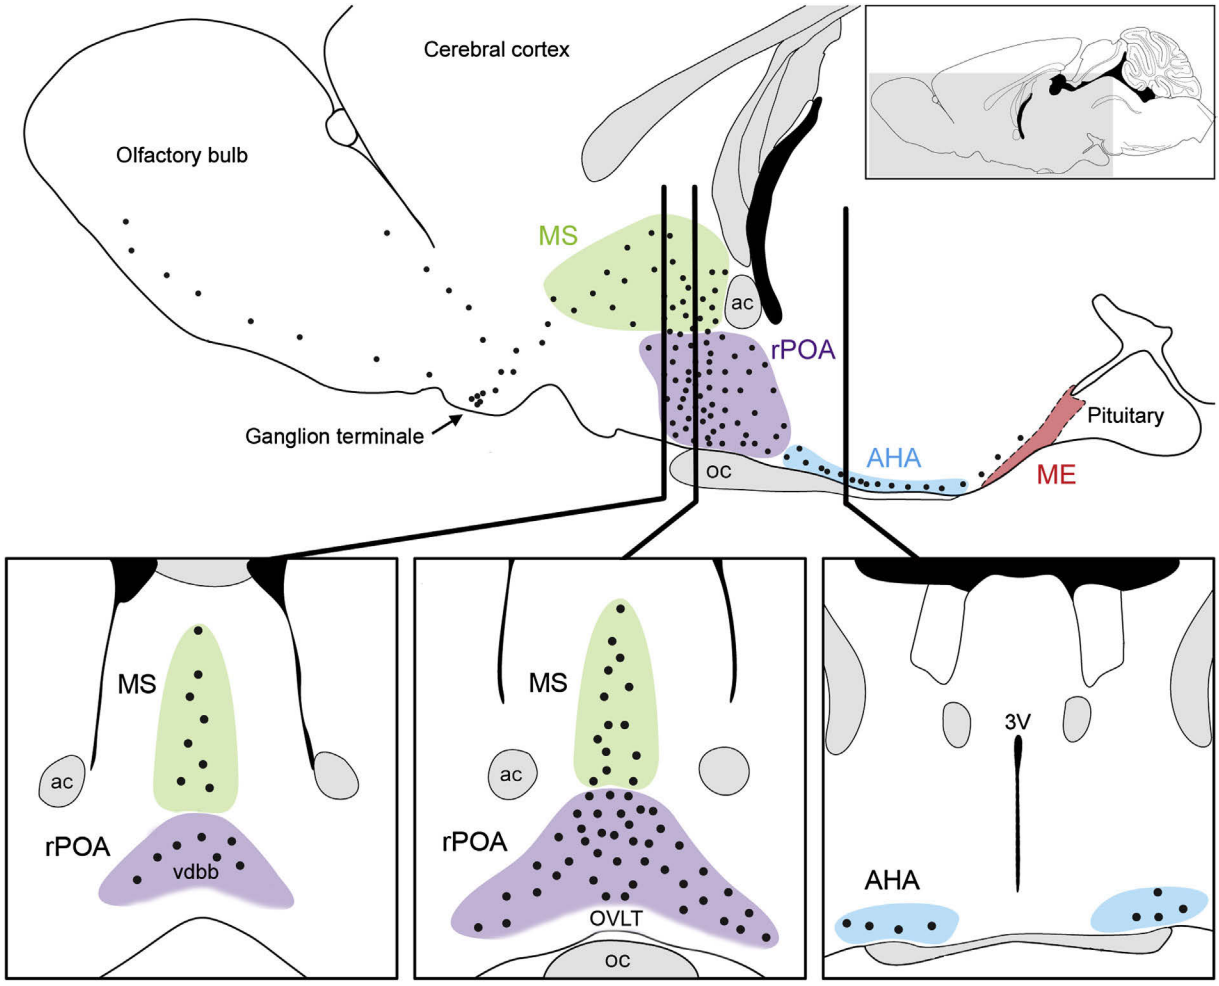

FIGURE 11.1 Distribution of GnRH neurons in the mouse brain. Schematic diagrams showing the distribution of GnRH neurons (black dots) in the sagittal (top) and coronal (bottom) planes. The GnRH neuron continuum extends from the olfactory bulb through to the median eminence (ME), with the great majority of GnRH neurons residing within three arbitrarily defined anatomical brain regions: the medial septal (MS) population, the rostral preoptic area (rPOA) population, and the caudal-most anterior hypothalamic area (AHA) neurons. Note the projection zone for GnRH neurons in the median eminence. Coronal views at the three locations indicated on the sagittal plane are shown below where the concept of the "inverted Y" distribution is more clearly observed. Abbreviations: ac, anterior commissure; oc, optic chiasm; vdbb, vertical limb of the diagonal band of Broca; OVLT, organum vasculosum of the lamina terminals; 3V, third ventricle. *Source: Diagram courtesy of Dr Michel Herde.*

(Figure 11.2(C))[31] as can GnRH neurons located near the organum vasculosum of the lamina terminalis (OVLT) in mice.[32] There is also growing appreciation that the dendritic morphology of a GnRH neuron is modifiable; a notable rearrangement of dendritic structure occurs in the mouse around the time of puberty,[33,34] and seasonal differences have also been observed in the sheep.[35]

Cell filling experiments in transgenic GnRH-green fluorescent protein (GFP) mice have revealed that GnRH neurons exhibit remarkably long dendrites that can extend for over 2000 μm[36] (Figure 11.2(D)). These dendrites are usually oriented parallel to each other and, remarkably, can bundle together being held in direct contact by specialized zona adherens.[37] Shared synapses, where one input synapses on two adjacent GnRH neuron dendrites, are found at these bundling sites, providing one possible location for synchronized control of GnRH neurons by afferent inputs.[37] In addition to vertical dendritic bundling, a small number of GnRH neurons extend dendrites in a manner perpendicular to the vertical GnRH neuron dendrite streams.[37] These new observations have emphasized that, despite the scattered distribution of their somata, the GnRH neurons may form a connected syncytium through their dendritic projections. However, beyond these shared synapses, and rare cytoplasmic bridges,[38] precisely how these dendritic alignments might help synchronize the GnRH neuron population remains unknown.

Another major observation originating from cell filling experiments has been that GnRH neurons in the mouse exhibit numerous spines on their somata and dendrites.[34,36] Prior to this, electron microscopic

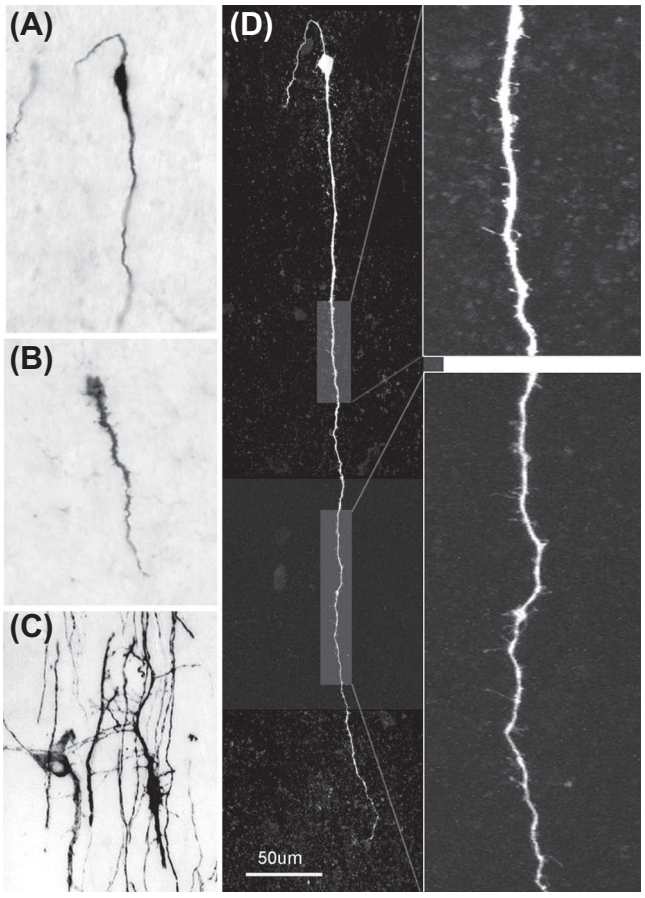

FIGURE 11.2 GnRH neuron morphology in the mouse and sheep. The typical morphology of GnRH neurons in the mouse is shown by the cells in (A) and (B), with (B) exhibiting a clear "spiny" morphology following GnRH immunocytochemistry. The two cells in (C) exhibit the more complex and variable morphology of GnRH cell bodies in the sheep. (D), a montage showing the soma and dendritic structure of an adult mouse GnRH neuron filled with biocytin in situ. Note the length of the primary dendrite (over 500 μm) and the high density of spines throughout the length of the dendrite (two highlighted insets).

investigations had found very little evidence for synapses on GnRH neuron somata[39–42] and, thus, generated the once widely held concept that GnRH neurons receive few synaptic inputs. The observation of numerous spines decorating the long GnRH neuron dendrites (Figure 11.2(D)) provided clear evidence that GnRH neurons receive substantial synaptic input.[36] Thus, while it may be true that synapse density on GnRH neuron somata is relatively low compared with neighboring unidentified cells, this is more than compensated for by the numbers of spines and synaptic inputs along the considerable length of the GnRH neuron dendrites. Although almost all GnRH neurons exhibit numerous dendritic spines, there is heterogeneity in the numbers of spines[36] and this correlates with early work reporting the presence of "spiny" and "smooth" contour GnRH neurons using GnRH immunocytochemistry (Figure 11.2(A) and (B)).[39,42–44] The neurochemical identities of inputs to spines on GnRH neurons are not yet established. However, spine density has been shown to be plastic with alterations observed during pubertal development[34,45] and following changes in circulating gonadal steroid concentrations in the adult.[46–48] Remarkably, it is only the cFos-activated GnRH neurons of the rPOA that exhibit spine changes leading up to the GnRH surge.[46] Studies are just beginning to understand the intracellular mechanisms regulating spine density in GnRH neurons in vivo.[49]

A notable feature of GnRH neurons at the ultrastructural level has been that of substantial glial cell contact or "wrapping" of the cell body.[42,50,51] In the monkey and sheep, a wide range (0–90%) of glial ensheathment of individual GnRH neurons has been observed,[50,51] and recent studies have also reported astrocytic interactions with GnRH neuron cell bodies in humans.[52] Interestingly, glial cell invaginations can be seen to separate presynaptic terminals from postsynaptic densities on the GnRH neuron in rats and sheep.[42,50] Such observations emphasize the potential importance of glia in modulating the efficiency of afferent inputs to GnRH neurons.

GnRH Neuron Projections to the Median Eminence (the Dendron)

The principal projection site of the GnRH neuron is the external zone of the median eminence where GnRH is released into the pituitary portal circulation. Retrograde tracing studies have revealed that between 50% and 70% of all GnRH neurons project to the median eminence.[14,16,23] In the rat, mouse, and sheep, the somata of the GnRH neurons innervating the median eminence are scattered throughout the GnRH continuum.[14,16,53,54] A similar situation exists in the monkey, although the percentage of GnRH neurons projecting to the median eminence is highest within the preoptic area and MBH, with none of the rostral-most GnRH neurons in the MS and diagonal band of Broca being hypophysiotropic.[23]

One of the more remarkable recent findings in the GnRH neuron field has been that the great majority of GnRH neurons do not have axons but send atypical dendritic projections to the median eminence.[55] Using mouse brain slices that maintain GnRH neuron projections to the median eminence, coupled with cell filling and electrophysiology, it was discovered that the GnRH neuron projection to the median eminence is actually a dendrite that receives synaptic inputs along its complete length while also propagating action potentials.[55] This blend of both dendritic and axonal properties has led to the process being termed the "dendron".[55] Once arriving at the median eminence, the GnRH neuron dendron splits into many individual axon-like processes that project to blood vessels and ramify widely throughout the median eminence. Detailed reconstructions of GnRH

neurons also show that the dorsal-orientated dendrite, which initially projects away from the median eminence, often does a hairpin loop turn and itself also eventually projects to the median eminence. Alongside evidence for the initiation of action potentials in the proximal dendron,[56,57] this morphology marks the GnRH neuron as being unique within the central nervous system.

In essence, the GnRH neuron could now be looked upon as one very long information processing cable with three key specializations: (1) a cell body that is responsible for biosynthetic regulation and patterning of electrical activity;[58] (2) an action potential initiation zone in the proximal part of the most ventral dendron[57] (see following); and (3) terminal modifications of the dendron into axon-like nerve terminals for secretion of GnRH into the portal circulation.[55] This new morphology of the GnRH neuron may provide an explanation for curious past experimental results, not the least being the initial puzzling over why GnRH neurons should have such long dendrites. It also predicts important features of GnRH neuron activity and regulation. First, synaptic inputs along the full length of the dendron will have a role in regulating its activity at the median eminence. Those near the spike initiation site will be especially important in determining the overall level of cell excitability, those at the cell body for regulating gene expression, and those at the distal dendron should be able to modulate directly GnRH secretion within the median eminence. The past practice of examining synaptic inputs/appositions on the GnRH neuron cell body alone may be of little relevance in terms of understanding the regulation of GnRH secretion. The presence of synaptic inputs on the distal dendron just before it splits into axons in the median eminence may account for the curious but long-standing lack of evidence for presynaptic synapses on GnRH nerve terminals themselves.[59,60] Equally, neurotransmitter inputs to the distal dendron may explain why so many neurotransmitters and neuropeptides were able to modulate GnRH secretion from "median eminence" preparations in vitro that had no GnRH neuron cell bodies.

Within the median eminence itself, GnRH axons form close associations with tanycytes, the specialized ependymal cells of the third ventricle, so that GnRH neurovascular terminals are often encapsulated by tanycytic endfeet.[61–63] In addition, the GnRH terminals do not sit directly adjacent to the endothelial basal lamina ready to release GnRH into the pericapillary space of the portal system.[50,64–66] Instead, the tanycyte-encapsulated GnRH terminals are located several microns from the basal lamina,[64] and astrocytic processes may exist as a further barrier between the terminal and portal vasculature.[60] This arrangement suggests that access of the decapeptide to the portal system upon release from the GnRH terminal is not straightforward and that ultrastructural variations may represent an additional mechanism for regulating portal GnRH profiles.[61,65,67] Several molecules derived from nonneuronal cells in the median eminence may regulate this process in a steroid-dependent manner (see the section Glial Elements of the GnRH Network).

GnRH Neuron Projections Elsewhere in the Brain

There are abundant GnRH neuron projections in the brain outside the median eminence. For example, in the rat, GnRH-immunoreactive fibers are found in all of the circumventricular organs, medial and cortical amygdaloid complex, stria terminalis, habenula, hippocampus, interpeduncular nucleus, neocortex, and periaqueductal gray.[24,68] There is also a significant number of GnRH neurons located in olfactory brain regions that may provide GnRH neuron inputs into these networks (for review see Ref. 13). Whether GnRH neurons project axons or dendrites to these extrahypothalamic sites remains unclear. Although the great majority of GnRH neurons only have dendrites,[55] a small number have been found to elaborate an axon in addition to their dendrites (Herde and Herbison, unpublished).

One surprising recent observation has been that many of the GnRH neurons in the medial aspects of the rPOA extend one of their dendrites into the OVLT.[32] Such dendrites begin as a normal projection from the cell body, but once they get within approximately 100 μm of the OVLT they begin to branch substantially and ramify throughout the OVLT. As assessed by the presence of spines and electrophysiological responses to excitatory neurotransmitters such as glutamate and kisspeptin, these processes maintain dendritic properties within the OVLT although, ultrastructurally, both axonal and dendritic GnRH-immunoreactive profiles were observed in the mouse OVLT.[32] As these dendrites, and indeed GnRH neuron somata located within 100 μm of the OVLT, are outside the blood–brain barrier, they are well placed to monitor blood-borne molecules. Approximately 85% of GnRH neurons with dendritic projections in the OVLT are thought to be involved in the GnRH surge mechanism,[32] and it is speculated that this ability to sample blood constituents beyond the blood–brain barrier may be of particular importance in regulating the preovulatory surge. However, it remains that the function of the dense OVLT GnRH-immunoreactive fiber innervation has been debated for many years without any clear resolution.[69]

It is likely that most GnRH neuron projections to extrahypothalamic brain regions represent locations where GnRH is released to act as a neuropeptide transmitter. These non-hypophysiotropic GnRH neurons are rarely investigated despite the likelihood that they comprise up to 30% of all GnRH neurons.[16] One experimental difficulty in characterizing this subpopulation is the present inability to actually identify which GnRH neurons

are hypophysiotropic in brain slice preparations. This no doubt contributes to the frequently encountered issue of GnRH neuron heterogeneity. Indeed, despite substantial evidence showing neuromodulatory effects of GnRH throughout the brain,[70,71] the physiological roles of GnRH in these brain areas are essentially unknown. One exception has been the GnRH neuron projections to the midbrain periaqueductal gray that are believed to be involved in regulating female reproductive behavior.[72,73] A role for GnRH in sexual behavior raises the possibility that a mechanism may exist to coordinate the release of GnRH at the median eminence and the midbrain periaqueductal gray on proestrus. One possibility would be for GnRH neurons with dendrons projecting to the median eminence to also send axons to the periaqueductal gray. Another, for which there is initial evidence, is that GnRH overflows into the cerebrospinal fluid from the arcuate-median eminence complex at the time of the surge to coordinate the activity of distant reproductive neural networks such as the periaqueductal gray.[69,74] Interestingly, another likely site of action for GnRH in the cerebrospinal fluid is the hippocampus where it may modulate spine density in a cyclic manner.[75] At present, very little is known about the functions of non-hypophysiotropic GnRH neurons. One recent interesting speculation is that GnRH may mediate antiaging effects throughout the brain.[76]

GnRH Neuron Electrophysiology

GnRH Neuron Firing Patterns

Direct electrical recordings of adult GnRH neurons were first achieved in acute brain slices obtained from guinea pigs,[77] followed by mice,[78–80] and, subsequently, rats.[81] Whereas the initial studies were extremely laborious, requiring post hoc identification of GnRH neurons,[77,82] the development of three transgenic GnRH-GFP mouse lines[78,79,83] and a GnRH-GFP rat[84] has greatly facilitated investigations into the electrical properties of adult GnRH neurons (for recent review see Ref. 85).

To date, GnRH neurons have been recorded in the acute brain slice preparation using three different modes of electrophysiology: (1) on-cell recordings in which an electrode is placed against the cell membrane to measure action potential firing; (2) whole-cell recordings in which the patch electrode "breaks into" the cell to measure ionic currents and subthreshold membrane potential changes; and (3) perforated-patch recordings in which a patch electrode is placed on the outside of the cell but where molecules within the electrode "drill" small holes in the membrane to enable sufficient electrical communication to measure ion channels and membrane potential. Unlike whole-cell recordings, the latter method has the advantage of leaving the internal milieu of the GnRH neuron relatively undisturbed. The choice of recording mode depends upon the question asked and the expertise available.

While acute brain slices from GnRH-GFP mice have been critical in making GnRH neurons accessible for electrophysiological experiments, it is important to be aware of the caveats of this approach. Foremost, it is an in vitro experimental preparation in which both the GnRH neurons and their afferent inputs are damaged. The extent of this deafferentation is difficult to assess, but, considering results from other neuronal cell types,[86,87] there is almost certainly a reduction in synaptic input to GnRH neurons compared with in vivo. For example, magnocellular vasopressin neurons behave quite differently in the brain slice compared to in vivo.[88] Equally, damage to the long GnRH neuron dendrites is unavoidable during the brain slicing procedure and can have a significant impact upon the observations of electrophysiological experiments.[89] Some of these concerns have, indeed, been recently highlighted by the first report of GnRH neuron firing patterns in vivo in the anesthetized mouse.[90] While this study showed that, as in the brain slice, GnRH neurons exhibit heterogenous firing patterns, the patterns of firing in vivo were different to those found in vitro. For example, whereas ~65% of GnRH neurons in vitro exhibit burst firing, only ~15% of GnRH neurons in vivo exhibit this behavior, with the great majority showing relatively high levels of unpatterned firing.[90]

Experimenters have employed different slice preparations to try to alleviate some of these issues, including conventional coronal and sagittal slices, although, in the end, these have had rather little impact on the properties or firing characteristics of GnRH neurons recorded.[89,91] Unconventional slicing procedures have, nevertheless, been able to preserve specific inputs to GnRH neurons such as that from neurons in the rostral periventricular region of the third ventricle (RP3V) using a precisely angled, horizontal brain slice preparation.[92] More recently, a thick hypothalamic "chunk" preparation has been developed in which AHA GnRH neurons and their projections to the median eminence are preserved.[89]

Investigators have found individual adult GnRH neurons in the rat and mouse to exhibit a range of different spontaneous firing patterns. Although seldom detailed fully in papers, this includes GnRH neurons that are silent, continuously active, or irregularly active, including what are commonly called bursting cells (Figure 11.3). As this variability in firing behavior also exists in vivo,[90] it likely represents true heterogeneity within the GnRH neuron population. In this regard, it is interesting to note that cultured (i.e., undamaged) embryonic GnRH neurons also exhibit marked heterogeneity in their firing characteristics,[93,94] as do adult GnRH neurons stripped of their dendrites.[95] Disappointingly, no GnRH neuron electrophysiological "finger-print" has emerged, and it

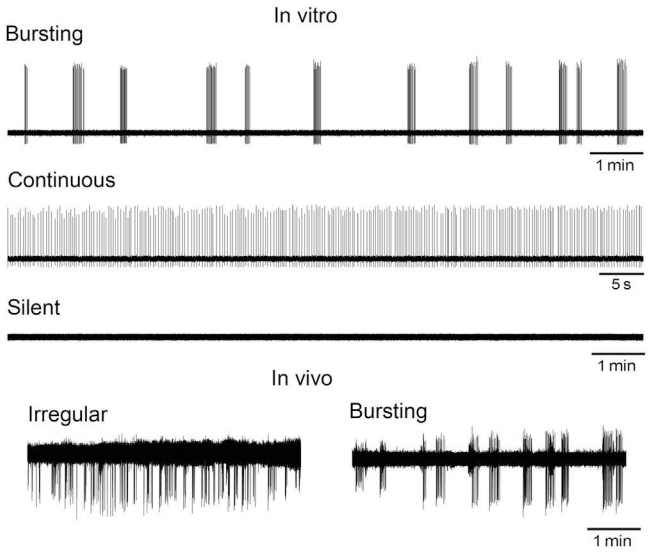

FIGURE 11.3 Typical firing patterns of adult rodent GnRH neurons in vitro (top) and in vivo (bottom). The three top traces show the typical bursting, continuous, and silent types of firing exhibited by adult GnRH neurons in the acute brain slice preparation using cell-attached recording mode. The bottom two recordings show cell-attached firing patterns from GnRH neurons in vivo in the anesthetized adult mouse. Each deflection up or down represents a single action potential.

has turned out to be extremely difficult to correlate these heterogenous firing patterns with suspected pulsatile or surge patterns of GnRH/LH secretion.[96–98]

The heterogeneity in firing, alongside the different methods of recording, characterizing, and documenting GnRH neuron activity by the various laboratories, makes it challenging to be conclusive about what "on average" a GnRH neuron population looks like in terms of its spontaneous electrical firing. Nevertheless, guided by data from minimally invasive cell-attached recordings,[58,89,96,97,99,100] it seems reasonable to state that the majority of adult GnRH neurons in the acute brain slice exhibit burst firing, while another population is silent, and a further smaller group exhibits continuous activity (Figure 11.3). These patterns are observed in gonadectomized as well as intact male and female mice throughout the estrous cycle. Studies from the Herbison laboratory indicate this split to be ~65% bursting, ~30% silent, and ~5% continuously firing GnRH neurons in various brain slice preparations made from male and female mice.[58,89] In contrast, in vivo recordings of GnRH neurons show this split to be ~15% bursting, ~15% silent, with the remainder exhibiting ongoing irregular-continuous firing[90] (Figure 11.3).

GnRH Neuron Burst Firing

Much attention has focused upon burst firing in GnRH neurons on the supposition that, if similar to magnocellular oxytocin and vasopressin neurons,[101] this represents that most effective release pattern for generating pulses of secretion from neuroendocrine nerve terminals. It is important to note that this supposition has not yet been tested for GnRH neurons, and whether burst firing is especially important for pulsatile GnRH secretion is unknown.[102] Nevertheless, it is very likely to be useful to establish the mechanisms underlying burst firing even if only for the fact that it occurs in the majority of GnRH neurons in vitro and may represent a "default" pattern of firing for a denervated GnRH neuron in vivo. Information from several studies of adult and embryonic GnRH neurons indicates that most burst firing in GnRH neurons can be characterized as consisting of 2–5 action potentials occurring over ~2 s, with intraburst frequencies of up to 10 Hz and the interburst interval being either every ~20 s or longer.[58,85,89,93,94,96]

To understand the etiology of burst firing, the first challenge has been to establish whether it represents an intrinsic property of a GnRH neuron or if it requires extrinsic inputs. This issue has still not been resolved satisfactorily. One early piece of evidence for a completely intrinsic "burst generator" has come from the observation that acutely disassociated adult GnRH neurons are still able to exhibit episodic firing.[95] However, the very erratic firing exhibited by those individual disassociated cells is not typical of the relatively evenly spaced burst firing observed in individual GnRH neurons in the slice preparation (Figure 11.3).[85] Further, those cells did not have dendrites, and it is now established that most action potentials are initiated in the GnRH neuron dendrite.[56,57]

Another piece of evidence widely used to support the presence of an intrinsic burst generator in GnRH neurons is the observation that the immortalized GnRH-secreting GT1 cell lines exhibit episodic calcium events, burst firing, and pulsatile GnRH secretion.[103,104] However, it is becoming increasing apparent that GT1 cells are not an appropriate model of adult GnRH neurons in vivo. For example, episodic activity in GT1 cells depends upon complex calcium signaling and gap junctional intercommunication, and yet no evidence has been found for gap junctional coupling between adult GnRH neurons in situ.[105] Furthermore, GT1 cells utilize calcium differently than native GnRH neurons.[106]

Although the case for an intrinsic pulse generator underlying burst firing is not strong, it remains that evidence for an important role of extrinsic inputs is similarly weak. For example, a study has recently demonstrated that GnRH neuron burst firing is independent of all fast ionotropic GABA and glutamate signaling.[107] Thus, the impact and balance of intrinsic versus extrinsic influences upon GnRH neuron burst firing remains unresolved. Recent progress in deciphering some of the ionic mechanisms operating within a GnRH neuron to control burst firing dynamics (see following) indicates that GnRH neurons are, at least, able to modulate their patterns of bursting. However, the key unresolved

issue is whether each burst is triggered by an intrinsic or extrinsic mechanism or, indeed, by both processes. Depressingly, studies in magnocelluar neurons have highlighted that the mechanisms underlying burst firing in vitro are likely to be different from those encountered in vivo.[88]

Ion Channels Expressed by GnRH Neurons

Investigations over recent years have described several distinct ion channels and conductances in adult rodent GnRH neurons (Table 11.1). These studies show that GnRH neurons use typical combinations of voltage-dependent sodium channels and A-type potassium, large-conductance calcium-activated potassium (BK) channels, as well as delayed-rectifier potassium channels to generate action potentials[79,82,109,110] (Table 11.1). Following the action potential, however, a relatively unusual cluster of ion channels is used by GnRH neurons to generate the after depolarization potential (ADP) and after hyperpolarization potential (AHP) that summate to determine post-spike excitability (Figure 11.4(A)).

TABLE 11.1 Ion Channels Expressed by Adult GnRH Neurons in the Rat and Mouse

Channel	Role in GnRH Neurons	References
Volatge-gated Na^+	Action potential initiation	79
Slow TTX-sensitive Na^+	After-depolarizing potential (ADP), burst firing dynamics	108
Delayed rectifyer K^+	Repolarization of membrane after action potential	82,109,110

The ADP in GnRH neurons is activated ~200 ms after the action potential and can be rather slow, lasting for up to 1–2 s.[108,120] An unusual TTX-sensitive sodium current, possibly located within the soma of the GnRH neuron, underlies this ADP.[108] As the ADP elevates membrane potential soon after the action potential, it provides a depolarized plateau facilitating repetitive firing that would contribute to a burst (Figure 11.4(A)).

The AHP acts in the opposite manner to the ADP by generating a period of hyperpolarization following the action potential (Figure 11.4(A)). The AHP in GnRH neurons is driven predominantly by calcium-activated potassium conductances; the small-conductance calcium-activated potassium channels (SK) and "UCL-sensitive channels".[58,111–113] Although encoded by the normal SK1-3 transcripts, the SK channel is unique in GnRH neurons in that, once activated, its current lasts for several seconds, compared with ~200 ms in other neurons (Figure 11.4(A)). As a hyperpolarizing influence on the cell, the SK current counteracts the ADP and suppresses firing immediately after the first action potential. Thus, the SK channel plays a role in terminating burst firing by controlling the duration of the burst and the spacing of action potentials within it. In terms of burst patterning, activated and spontaneous bursts in GnRH neurons often exhibit spike frequency adaptation whereby the interval between individual spikes in the burst becomes progressively longer; this phenomenon is attributed to the SK channel in GnRH neurons.[58,112]

The other channel contributing to the AHP in GnRH neurons is an unusual, molecularly uncharacterized, calcium-activated potassium channel that is antagonized by UCL2077 (Figure 11.4). This "UCL channel" (named after University College London where the antagonist was discovered) is extremely slow, activating over ~10 s and lasting for a further ~20 s. Being active outside the time of the ~2 s burst itself, the channel does not impact on intraburst dynamics but, rather, has a role in determining the interburst interval in GnRH neurons.[58]

Intracellular calcium within the GnRH neuron soma acts to coordinate several of the ion channels involved in bursting.[58] Although it had been appreciated for some time that embryonic GnRH neurons exhibit spontaneous increments in intracellular calcium concentration,[121,122] it was only recently that this was also found to occur in adult GnRH neurons[123] (Figure 11.4(B)). Subsequent studies in adult GnRH neurons have shown that these ~10 s long calcium transients are generated by small amounts of calcium entering through voltage-gated L-type calcium channels that evoke massive calcium-induced calcium release from inositol-1,4,5-trisphosphate receptor-dependent stores.[58] Once generated, one of the roles of the calcium transient is to coordinately

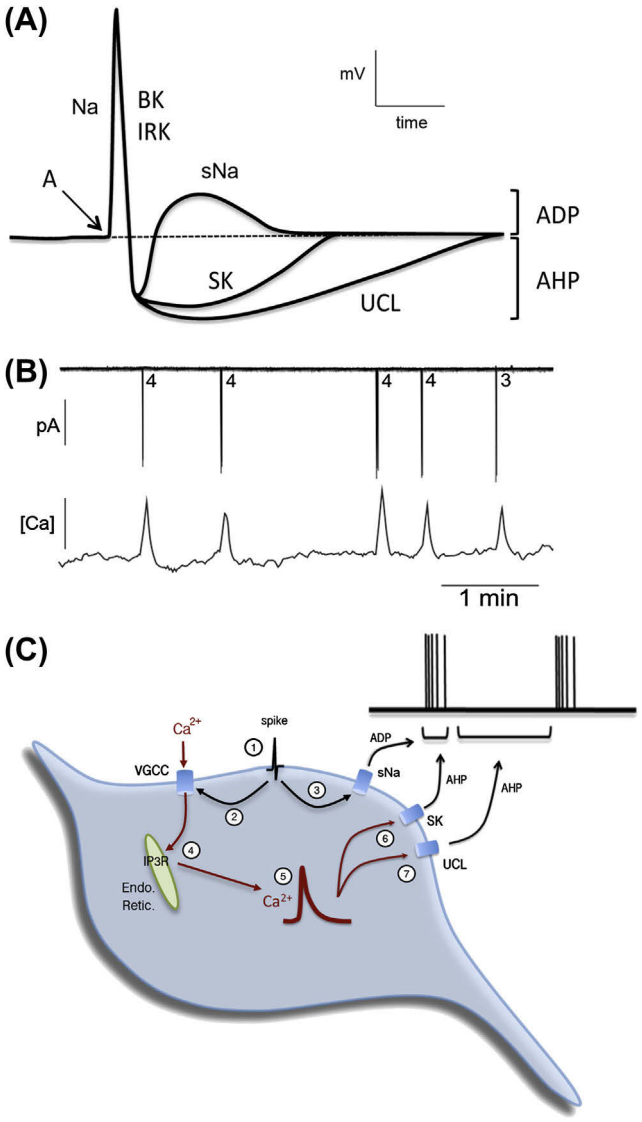

FIGURE 11.4 Electrical properties of adult rodent GnRH neurons. (A) Schematic (not to scale) diagram of the action potential and after potentials in GnRH neurons and the underlying currents. The action potential is generated in the normal manner by activation of voltage-gated sodium channels (Na) with repolarization occurring through inward rectifier (IRK) and large-conductance calcium-activated potassium (BK) channels. The A-type potassium current (A) is indicated to suppress the initiation of the action potential. Following the action potential, several different voltage- and calcium-dependent channels are activated to create the after depolarization potential (ADP) and after hyperpolarization potential (AHP). These include the activation of a slow voltage-gated sodium channel (sNa) to generate the ADP and a slow small-conductance calcium-activated potassium channel (SK) and even slower calcium-activated potassium channel (UCL) that generates the AHP. (B) Experimental trace showing simultaneous recording of bursts of action potentials (top, each number shows the number of action potentials in the burst) and intracellular calcium transients (bottom) occurring in adult GnRH neurons. (C) Schematic diagram indicating known channels involved in generating burst firing in GnRH neurons. The sequence starts with a spike (1) that (2) initiates calcium entry through voltage-gated calcium channels (VGCC) and (3) activates the slow sodium channel (sNa) that, in turn, drives the ADP promoting burst firing. The small calcium influx through VGCC is then amplified (4) through an IP3 receptor-dependent mechanism at the endoplasmic reticulum calcium stores to generate the ~10 s calcium transient (5). The transient activates SK channels (6) to generate an AHP that acts to suppress burst firing and also a slower calcium-dependent UCL channel (7) that prolongs the AHP and to help time when the next burst may occur.

activate the SK and UCL channels to control burst firing dynamics (Figure 11.4(C)). While calcium does not appear to directly regulate the sodium channel underlying the ADP, it does modulate its magnitude by controlling the AHP.[108,112] Blocking or modifying calcium dynamics at different points in this cascade alters burst firing in GnRH neurons.[58,118]

Together these studies suggest that a simple "core model" for burst firing in GnRH neurons could result from: (1) initiation of an action potential; (2) activation of the ADP to start the burst; (3) activation of the SK component of the AHP to terminate the burst; and (4) activation of the UCL component of the AHP to determine when the next burst will occur (Figure 11.4(C)). Indeed mathematical simulations with these basic elements are sufficient to generate GnRH neuron bursting behavior.[58,124] The mechanism underlying the initiation of the first action potential is unknown and forms the center of the debate regarding the intrinsic versus extrinsic origin of burst firing in GnRH neurons.

Although controversial,[116,117] two channels associated with pacemaking activity elsewhere in the brain can be found in some GnRH neurons and can evoke rebound depolarization and spiking. These are the fast-acting (~20 ms) T-type calcium channel and slower (~100 ms) hyperpolarization-activated cyclic nucleotide-gated (HCN) channel.[115–117] If either or both channels were activated by the slow AHP in GnRH neurons, they would provide a range of depolarizing sources that might then contribute to the ongoing burst or initiation of the first action potential required for the next burst. Although undoubtedly simplistic, each of (2–4) in the model outlined above are likely to be regulated by extrinsic inputs and, as such, would give the spectrum of firing observed in GnRH neurons. For example, upregulated SK channel activation, via altered intracellular calcium dynamics, would enhance the AHP and abolish burst firing, while downregulated UCL channels, through neurotransmitter modulation, would increase interburst frequency.

GnRH Neuron Dendrite Electrophysiology

As noted before, the discovery of the blended axon and dendrite (termed the *dendron*) requires a considerable revision of how the GnRH neuron functions to generate secretion in the median eminence. Unfortunately, recording the electrical activity and characteristics of

the GnRH neuron dendron is technically demanding.[56] Nevertheless, using cell-attached recordings and both sodium and calcium imaging, it has been possible to show that the great majority of action potentials are initiated from a spike initiation zone located 100–150 μm from the cell body down the dendron.[57] This has been further verified through visualization of the location of Ankyrin G, the scaffolding protein clustering together the channels required for spike initiation, at the same proximal dendritic location in GnRH neurons.[55]

Thus action potentials are generated in the proximal dendron and propagate to reach the median eminence to initiate GnRH secretion. Although action potentials traveling down the dendron can initiate calcium transients, these dendronic calcium events are very different from the long-duration calcium transients observed in the GnRH neuron cell body[57] and would not be sufficient to pattern the required calcium-activated potassium channels (Figure 11.4(C)). This, alongside evidence for key "burst firing channels" being located in the GnRH neuron soma (see previous discussion), indicates that the actual patterning of GnRH neuron firing probably occurs at the GnRH neuron soma. In this scenario, the spike initiated in the dendron would reach the soma to activate "burst channels" to (Figure 11.4(C)) generate subthreshold potentials that quickly propagate back to the spike initiation zone to generate the patterned firing of the cell.

The identity and roles of synaptic inputs along the GnRH neuron dendron are not established. This information is difficult to attain but, nevertheless, there is emerging evidence for both gradients and microdomains of $GABA_A$ and $GABA_B$ receptors on the GnRH neuron dendron.[89,118] How these and other neurotransmitter inputs function to control excitability, action potential conduction down the dendron, and subthreshold potentials in the GnRH nerve terminals within the median eminence, remains to be established.

GnRH Biosynthesis

GnRH-1 Gene

The *GnRH-1* gene was cloned in the human and rat by the Seeburg laboratory in the mid-1980s.[125,126] The *GnRH-1* coding sequence is found on chromosome 8 in the human and chromosome 14 in the mouse.[127] The gene is comprised of four short exons and three long introns spanning approximately 4.5 kb (Figure 11.5). The GnRH decapeptide is ultimately derived from exon 2, whereas GnRH-associated peptide (GAP) is transcribed from exons 2, 3, and 4 (Figure 11.5).[125,126] Transcription of the *GnRH* gene begins at multiple sites; for example, in the human, transcription starts at +1 for GnRH neurons and upstream at −579 for reproductive tissues such as the placenta (Figure 11.5).[128,129]

Much work has been undertaken examining the proximal promoter and enhancer elements within the *GnRH* gene 5′ sequence responsible for the regulation and neuron-specific expression of GnRH (for recent review see Ref. 130). The rat *GnRH* gene has received the most attention with the identification of a minimal 173 bp promoter (−173/+1) and three critical enhancer regions conferring neuron-specific *GnRH* expression located at −1863/−1571, −3135/−2631 and −4199/−3895[131–133] (Figure 11.5). Transgenic mice in which reporter constructs comprised of the 173 bp promoter and first 300 bp enhancer target the majority of GnRH neurons in vivo.[134] Substantial progress has been made in defining many of the transcription factors and their binding sites within the *GnRH* gene promoter and enhancers. These include POU (Oct1 and Brn2) and other homeodomain proteins (Msx, Dlx, Six6), as well as Otx2 and GATA transcription factors, that bind to motifs located throughout the *GnRH* promoter and enhancers.[135–139] In addition, important coactivators (Prep1/Pbx1) and corepressors (Goucho-related-gene proteins) active at the Oct1 binding site have been identified.[140,141] A recent study has shown that there are also elements within intronic regions of the *GnRH* gene that contribute to its regulation.[142] As the individual regulatory elements become apparent, an important challenge for this field will be to understand the mechanisms coordinating the expression of the various transcription factors to regulate *GnRH* gene expression during development and in the adult. For example, it is proposed that protein kinase C (PKC) phosphorylates or modulates no less than five different transcription factors to suppress *GnRH* gene expression.[130]

Less is known about the cell-specific and critical enhancer regions of the human GnRH gene. Initial studies using fragments of human *GnRH* 5′ sequence in murine GT1 cells indicated that important *GnRH* neuron-specific elements were located in the first 500 bp.[143] However, subsequent investigations using human *GnRH* sequences as transgenes in mice revealed that elements between −795 bp and −992 bp were critical for hypothalamic expression in vivo.[144] This is a similar region to that shown to be important for enhancing transcription at the upstream/placental transcription start site of the human *GnRH* gene.[128] Although caution is required when interpreting results obtained using human sequence in a mouse transcriptional environment, these data suggest that different regions of the rat and human GnRH promoter are used to confer GnRH neuron specificity (Figure 11.5). Interestingly, a CpG-rich island has recently been identified in the distal 5′ (−2126 to −1863) region of the rhesus monkey *GnRH* gene and this was found to be demethylated with GnRH neuron maturation in culture.[145] While the relationship of this demethylation to GnRH

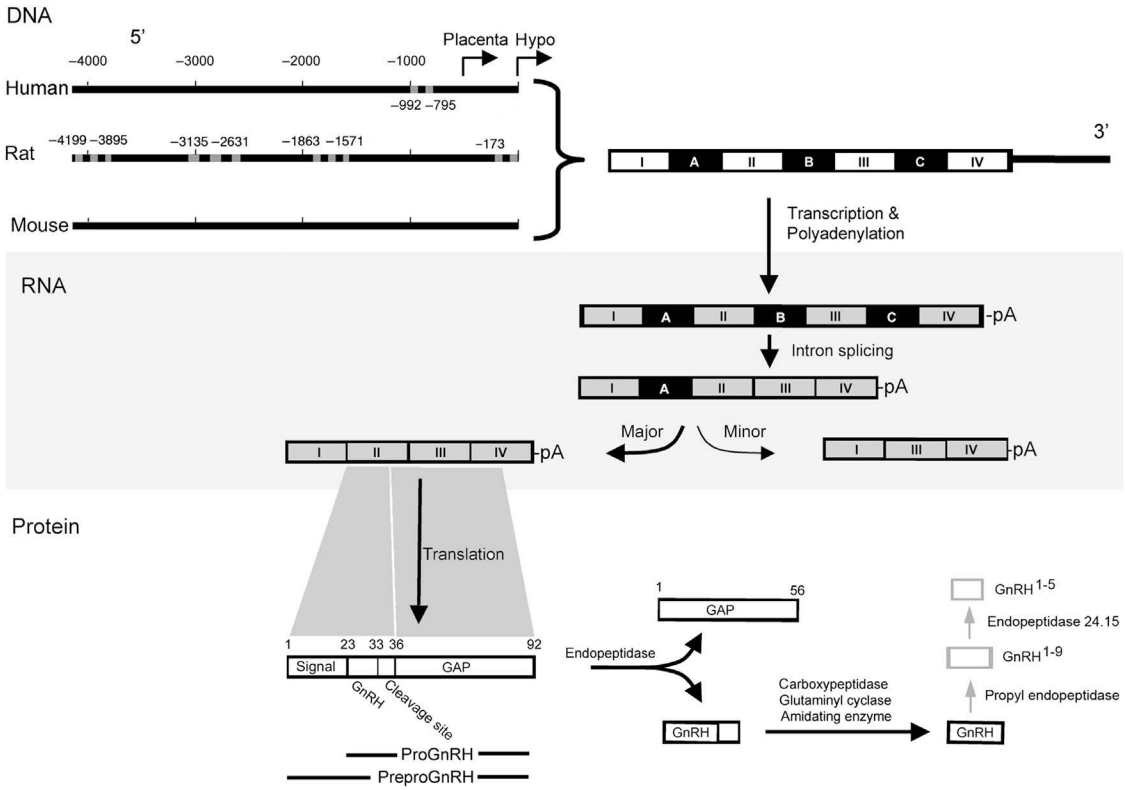

FIGURE 11.5 **Biosynthesis of GnRH and GAP.** Top panel depicts the structure of the GnRH gene with the 5′ regulatory sequence of human, rat, and mouse overlaid and specific regions of known function highlighted (see text). Middle panel depicts GnRH RNA and various splicing and processing intermediates. Bottom panel shows translation and posttranslational modifications that result in the final GnRH decapeptide.

biosynthesis is not yet clear, this study demonstrates that the *GnRH* gene may be subject to epigenetic remodeling.

The functional organization of the mouse *GnRH* gene has been examined in vivo utilizing transgenic approaches in mice. Transgenes comprised of different parts of mouse *GnRH* sequence coupled to the *lacZ* reporter have demonstrated that nearly all GnRH neurons are targeted using 5.2–3.5 kb of 5′ flanking sequence and that transgene expression levels in GnRH neurons decrease with shorter elements of 5′ flanking sequence.[146–148] These studies have not yet defined the role of any smaller regions of flanking sequence and the importance of the relatively conserved rat-mouse 173 bp promoter and first 300 bp enhancer of the rat.[130,149] Studies in the mouse have, however, provided some insight into the importance of 3′ flanking sequence as, although the first 3.5 kb of 3′ flanking sequence does not contribute substantially to the targeting of expression to the GnRH neurons, it does appear to contain sequences that suppress GnRH expression in non-GnRH neurons.[146]

Interestingly, there is evidence that GnRH gene transcription occurs in a fluctuating manner in GT1-7 cells. This is regulated by calcium and involves Oct1 transcriptional actions within the first enhancer site of the rat *GnRH* gene.[150,151] This spontaneous oscillation of GnRH transcription has recently been confirmed in vivo in transgenic mice where it exhibits a 10 h periodicity.[152] Whereas studies in cell lines have indicated that many different hormones and peptides can alter *GnRH* gene transcription in vitro (for recent review see Ref. 130), alterations in *GnRH* gene transcription in vivo have seldom been examined. Perhaps the best-characterized example of regulated *GnRH* gene transcription in vivo is that associated with estrogen positive feedback in the rat where a ~40% increase in GnRH gene transcription has been demonstrated 2–4 h prior to the onset of the GnRH surge.[153,154] Whether this increase is required for the generation of new peptide that will be released a few hours later, or whether it may be used to replenish stores for the next GnRH surge four days away, remains unknown. Changes in GnRH gene transcription rates have now also been detected in relation to estrogen negative feedback in the male mouse.[147]

GnRH-1 mRNA

Transcription of the *GnRH* gene produces a polyadenylated primary transcript of ~4200 bases that is processed by splicing to a mature transcript of 560 bases[125] (Figure 11.5). Maurer and Wray[155] estimated that single GnRH neurons contain >1000 GnRH mRNAs, making

them a high copy number transcript with levels comparable to that of housekeeping genes. One unusual feature of the GnRH neuron is that 30–40% of all GnRH transcripts are located in the nucleus at any one time,[156,157] and it has been suggested that this acts as a large steady-state pool of mRNA available for translocation into the cytoplasm when required.[158]

The processing of the primary transcript appears to be rapid, with a half-life in the order of 18 min for the primary transcript and 10 min for the mature transcript.[156,159] Studies in the rat and mouse indicate that intron B is rapidly excised from the primary transcript followed by intron C, with intron A being spliced out more slowly.[157,160] The removal of intron A is critical to enable efficient translation of the mature GnRH mRNA.[161] Whereas introns B and C contain appropriate consensus splice sites, intron A exhibits a suboptimal 3′ splice site that does not allow efficient splicing by the spliceosome complex.[160] Intron A can only be spliced out following the formation of a splice enhancer complex comprised of the serine/arginine-rich RNA-binding protein Tra2a and associated interacting proteins.[162] This complex must interact with exon splicing enhancers located in exons 3 and 4 to achieve the splicing of intron A.[162] Thus, it is postulated that introns B and C are removed in the normal manner, thereby bringing exons 3 and 4 physically closer to intron A to allow the recruitment of the splice enhancer complex that facilitates splicing of the suboptimal 3′ splice site in intron A.[161] The relative difficulty in excision of intron A explains why intron A-containing transcripts are found alongside the mature mRNA in the brain[157] and also provides an explanation for the presence of low levels of a further GnRH RNA splice variant missing exon 2 (Figure 11.5).[160,163] In this case, it is likely that splicing occurs between the normal 5′ splice site of intron A and the 3′ site of intron B, thus excising the whole of exon 2.[161]

The functional relevance of intron A splicing was revealed by demonstrating that the translation of intron A-containing transcripts is very poor compared with the mature RNA.[164] These observations regarding intron A provide a nice explanation for the failure of the *hpg* mouse to produce GnRH decapeptide.[165] The *hpg* mouse is infertile as a result of a spontaneous ~30 kb deletion in chromosome 14 that involves exons 3 and 4 of the GnRH gene.[165] It was unclear why RNA transcribed from exon 2, that is present in these mice and encodes GnRH, did not produce GnRH peptide. It now seems likely that the absence of exons 3 and 4 in these mice results in truncated RNAs unable to recruit the splice enhancer complex required to splice out intron A and thus results in the presence of an intron A-containing RNA that cannot be translated efficiently.[166] Together, these studies indicate that pre-RNA processing and the excision of intron A, in particular, is critical for the biosynthesis of GnRH decapeptide.

The mechanisms underlying the degradation of cytoplasmic GnRH mRNA are not established, but the half-life of transcript decay in primary cultured neurons has an initial rapid phase of 5–13 min followed by a much slower phase lasting around 30 h.[159] A primary role of poly(A+) tail shortening in transcript decay is suspected,[158] and the 3′ UTR of the mature mRNA is known to exhibit two highly conserved motifs that may bind factors regulating degradation.[159] As GnRH mRNA content has been shown to change in the presence of unaltered primary transcript during puberty,[167] and in response to neurotransmitters like NMDA,[168] the regulation of GnRH mRNA degradation or stability appears to be a major form of biosynthetic regulation in vivo.

GnRH-1 Peptide

Translation of the mature GnRH transcript results in the production of a preprohormone consisting of 92 amino acids (Figure 11.5). The first 23 N-terminal amino acids comprise a signal sequence with the remainder representing the prohormone in which GnRH is located at the N-terminal end and separated from GAP by a three–amino acid cleavage site (Figure 11.5). As PKC activation results in a significant decrease in the numbers of ribosomes associated with GnRH mRNA,[169] it is possible that the translation of preproGnRH is itself regulated. At least four different enzymatic steps are involved in the processing of the prohormone.[170] The initial step involves cleavage of the prohormone to create a GnRH intermediate and mature GAP (Figure 11.5). This is achieved by one or more endopeptidases and both prohormone convertase 1/3 and 2 are implicated in this process.[171–173] The GnRH intermediate then undergoes cleavage of its C-terminal basic residues by carboxypeptidase E.[170,171] The final steps in generating the biologically active decapeptide require the conversion of the N-terminal glutamine (Gln^1-GnRH) to pyroglutamate ($pGlu^1$-GnRH) by glutaminyl cyclase and the amidation of the C-terminal glycine by peptidylglycine alpha-amidating monooxygenase.[174] Immunocytochemical studies suggest that the processing of the GnRH prohormone occurs within vesicles during its transport down the dendron and within the nerve terminals.[175–177] It remains unclear whether the enzymatic processing of GnRH represents an opportunity for regulating GnRH biosynthesis in a physiological context.

One further posttranslational modification of GnRH is that of hydroxylation of the proline residue to create hydroxyproline (Hyp^9) GnRH. Gautron and colleagues have shown that as much as 10% of GnRH-like peptide in the hypothalamus exists as (Hyp^9) GnRH in adult rats.[178] The physiological significance of (Hyp^9) GnRH remains unknown.

Multiple enzymes appear to be involved in the degradation of the GnRH decapeptide with the most

important being zinc metalloendopeptidase EC 3.4.24.15 (EP24.15) and propyl endopeptidase (PEP). It is thought that PEP cleaves the carboxy-terminal glycine to generate $GnRH^{1–9}$ that is then processed by EP24.15 at the Tyr^5-Gly^6 bond to create the $GnRH^{1–5}$ and $GnRH^{6–9}$ fragments (Figure 11.5) (for recent review see Ref. 179). Studies examining the distribution of EP24.15 have shown that it is located in the perivascular space around the GnRH nerve terminals in the median eminence and that it can be secreted into the portal circulation.[180] Investigations have further shown that a selective antagonist of EP24.15 reduces GnRH degradation and enhances LH secretion in vivo.[180–182] Thus, it seems likely that endopeptidases represent a further factor capable of determining the profile or amounts of GnRH reaching the gonadotrophs. The degradation of GnRH may also be regulated physiologically as a small reduction in PEP levels was observed at the time of the LH surge in the sheep, suggesting that a decrease in peptidase activity may contribute to enhanced GnRH release at that time.[183] In contrast, levels of EP24.15 were not found to fluctuate over the estrous cycle of rats[180] or in sheep.[183] It is intriguing to note that $GnRH,^{1–5}$ the product of EP24.15, may itself be biologically active and not simply a degradation product.[179] The $GnRH^{1–5}$ fragment has been shown to function as an NMDA receptor antagonist and also modulate female reproductive behaviour.[184]

GnRH-Associated Peptide

The 56-amino acid GAP is generated from the propeptide following endopeptidase processing (Figure 11.5) and is present in GnRH nerve terminals and released into the portal system.[185,186] Soon after cloning the GnRH/GAP gene, it was reported that human recombinant GAP stimulated LH and FSH release in a GnRH receptor–independent manner and also inhibited prolactin secretion from rat pituitary cultures.[187,188] This sparked substantial investigation into the role of GAP in the regulation of prolactin and gonadotropin secretion in the late 1980s. In essence, the effects of GAP on prolactin secretion were not found to be repeatable by other laboratories or, at best, only very weak, and a similar fate awaited the role of GAP in the regulation of LH and FSH secretion (for review see Ref. 3). Activity in this field died in the early 1990s, and, perhaps surprisingly, the functional significance of GAP remains unknown.

Regulation of Biosynthesis

It is clear from the previous description that, in addition to the electrical activity of a GnRH neuron, multiple biosynthetic and catabolic processes are responsible for determining the final levels of GnRH entering the portal circulation. Whereas the various biosynthetic steps must be operational to enable GnRH secretion from the nerve terminal, the physiological impact of regulating their efficiency at any one point is much less clear. For example, a variety of different stimuli have been shown to alter GnRH mRNA levels by 20–30%[158,189] indicating that transcription and mRNA processing can be regulated. However, it remains to be resolved whether these relatively modest changes in mRNA levels have any functional impact upon the long-term functioning of a cell type that maintains "housekeeping gene" levels of GnRH mRNA content.

As GnRH neurons maintain a very high level of GnRH decapeptide (approximately 1 pg or 10^9 molecules/cell)[155] it might be argued that a high constitutive level of GnRH biosynthesis is sufficient without the need for complex regulation. If biosynthesis were to be regulated, however, it would seem sensible to have biosynthesis coupled to secretion in a neuroendocrine neuron. Whereas evidence for this exists prior to the GnRH surge in the rat,[154,158,190] it is not typically the case. During development in vitro, GnRH mRNA expression lags significantly behind GnRH secretion in the monkey,[145] and large increases in GnRH secretion can even occur in the face of decreasing GnRH mRNA expression.[158,191,192] Thus, it would appear that a tight relationship does not necessarily exist between secretion and biosynthesis in GnRH neurons, with the level of coupling likely to depend more upon the precise location (soma versus dendron) and type of stimulus presented to the GnRH neuron.

Neurotransmitters Co-Expressed by GnRH Neurons

Electron microscopic investigations have identified the presence of both dense core and clear synaptic vesicles within GnRH neurons.[42,50] Many dense core vesicles in GnRH neurons label for GnRH as well as GAP, demonstrating that, as expected, they contain the peptides encoded by *GnRH*. However, the clear vesicles in GnRH neurons, along with some dense core vesicles, are not labeled by GnRH,[42] suggesting that other neurotransmitters may be synthesized and released by GnRH neurons.

Over the years many neuropeptides have been reported to be expressed in GnRH neurons including pro-opiomelanocortin-related peptides,[193,194] delta sleep-inducing peptide,[195] galanin[196,197] cholecystokinin,[198] neurotensin,[198] and orphanin FQ.[199] In most cases these observations of co-expression have come from a laboratory working in a single species and their generalization to all mammalian GnRH neurons is unclear. The exception is galanin that has been well documented to be co-expressed by subpopulations of GnRH neurons in multiple species, although its role remains unknown. In relation to the clear vesicles identified in GnRH neurons, it is interesting to note evidence that GnRH neurons may use glutamate as a neurotransmitter (see following).

Galanin

The neuropeptide galanin was first identified to be expressed by GnRH neurons in the rat.[196,197] Subsequent studies showed that galanin was synthesized in a highly sexually dimorphic manner being present in ~70% of GnRH neuron soma and terminals in the adult female but only around 20% in the male rat.[200,201] Whereas a similar pattern of sexual dimorphic expression is seen in the mouse,[202] this does not exist in the sheep where all GnRH neurons express galanin regardless of sex.[203] In contrast, no galanin was reported in GnRH neurons of the macaque monkey.[204] Although the GnRH neurons expressing galanin are found throughout the GnRH neuron continuum, there is a slight overrepresentation of co-localization in the preoptic subpopulation activated at the time of the GnRH/LH surge.[205]

The biosynthesis of galanin in GnRH neurons is regulated in a gonadal steroid- and/or activity-dependent manner with galanin gene expression in GnRH neurons peaking at the time of the GnRH/LH surge.[206–208] With evidence that galanin facilitates GnRH-stimulated LH secretion directly from gonadotrophs,[196,209,210] as well as GnRH release from the median eminence,[197,211] it is proposed that co-released galanin aids the generation of the LH surge by acting at both brain and pituitary sites.[212] As some GnRH neurons express galanin receptor mRNA,[213,214] it is conceivable that galanin acts directly back upon its own co-secreting nerve terminal in the median eminence to facilitate GnRH secretion.

Galanin is likely to be used as a signaling molecule by multiple elements within the GnRH neuronal network, and it is important to distinguish between roles of galanin secreted by GnRH neurons and galanin released by many other neurons within the network. For example, GnRH neurons are themselves excited directly by galanin.[215] Unfortunately, it is usually impossible to distinguish between these two origins of galanin release in physiological experiments. Furthermore, as noted by Shine[216] remarking on the similarities between galanin and a politician "It (galanin) has not been found to be primarily responsible for any important activity, but rather to modulate many and thus take credit for a wide range of outcomes". This may be the situation for galanin within the GnRH neuronal network. Whereas a plausible modulatory role can be suggested, evidence for a critical role of co-expressed galanin in GnRH neurons is lacking. The galanin knockout mouse is fertile and exhibits no reproductive phenotype attributable to abnormal GnRH function.[217,218] Equally, mice with a functional deletion of the GalR1 gene are reported to breed normally.[219] Nevertheless, the LH surge can be abolished by i.c.v. galantide, the galanin receptor antagonist in the rat.[211] Whether galantide is acting to block effects of galanin secreted by GnRH neurons, galanin on GnRH neurons, or galanin released by other cells within the network is unknown. Nevertheless, it seems reasonable to suggest that galanin co-released from GnRH neurons plays a role in facilitating GnRH and LH secretion, particularly at the time of the surge.

Glutamate

The first indication that glutamate may be synthesized by GnRH neurons for use as a neurotransmitter came from the observation that essentially all GnRH neurons in the male rat expressed vesicular glutamate transporter 2 (VGlut2) mRNA.[220] Although not in agreement with previous and subsequent studies that found no evidence for vGlut2 protein in GnRH neurons,[35,221] another investigation found that a vGlut2 promoter construct directed expression to a subpopulation of GnRH neurons located in the medial septum of the mouse.[222] These interesting observations suggested that GnRH neurons may release glutamate from their nerve terminals in the median eminence. However, roles for glutamate at the pituitary in regulating gonadotropin secretion are unclear. It turns out that almost all hypophysiotropic neuroendocrine cells express VGlut2 mRNA,[223] so it is difficult to envisage how any specificity might be achieved between the various neuroendocrine axes all secreting glutamate into the pituitary portal system.

There is, nevertheless, evidence for recurrent-collateral innervation of GnRH neurons,[224,225] so it remains possible that glutamate might be involved in some form of auto-excitation. Repetitive depolarization of a GnRH neuron can decrease the frequency of GABAergic synaptic events at its cell body. As this phenomenon is blocked by metabotropic glutamate receptor (mGluR) antagonists, it is possible that "self" release of glutamate may activate mGluR on GABA inputs to GnRH neurons to control their excitability.[226] At present, the functional significance of VGlut2 mRNA expression by rat GnRH neurons, and the role of glutamate in auto-feedback regulation of the GnRH neuron, require further exploration. Notably, recent studies have failed to detect VGlut2 within the GnRH nerve terminals of mice or humans.[227]

COMPONENTS OF THE GnRH NEURONAL NETWORK

The GnRH neuronal network is defined here as the GnRH neurons and the associated assembly of brain cells responsible for controlling GnRH release into the pituitary portal circulation. Broadly these "brain cells" can be defined as either neurons or glial cells and will be dealt with separately. For clarity with regard to GnRH neuron dendritic processes, the word *dendron* will only be used in reference to a dendritic projection that innervates the median eminence. In all other cases the

structure will be referred to as a *dendrite* even though the investigated process may well end up innervating the median eminence and, in fact, be a dendron.

Neuronal Elements

If one were to make a conservative assumption that an individual GnRH neuron received inputs from 1000 cells[36] and that each of these interneurons, in turn, received ~5000 inputs,[228] the activity of any one GnRH neuron would be influenced directly or indirectly by approximately 5 million first- and second-order neurons. If third-order neuronal connections were considered, then the numbers of potential neurons involved becomes substantial. As the 5 million primary and secondary afferent inputs to a single GnRH neuron are likely to utilize a wide range of different neurotransmitters, it is not surprising to find that essentially any neurochemical administered into the ventricular system of an animal alters LH secretion (Tables 11.2 and 11.3). As such, it would seem that the challenge is not to catalog every possible neurotransmitter involved in the network but rather to define the functional hierarchy of these inputs.

The definition of those neural inputs that represent the primary afferents to the GnRH neurons will be of most interest, as these should have the greatest influence upon the behavior of the GnRH neuron. Ideally, the definition of a neurotransmitter used by a functionally significant primary afferent within this network would require: (1) evidence that it alters LH and/or FSH secretion when administered into the brain in vivo; (2) demonstration that it can alter GnRH secretion either in vivo or in vitro; (3) anatomical evidence for direct neuronal inputs to GnRH neurons, particularly if this was corroborated with evidence for the expression of an appropriate receptor by the GnRH neurons; and (4) electrophysiological evidence for a direct effect of the particular neurotransmitter on the electrical excitability of a GnRH neuron. A review of the existing literature using these criteria (Tables 11.2 and 11.3) shows that there are several neurotransmitter candidates that have fulfilled many of the criteria listed herein.

Having defined these "primary afferent neurotransmitters" on this basis it is critical to establish the location of their cell bodies, their physiological roles, and relative contribution to the final output of the GnRH neuron. Some primary inputs to GnRH neurons might be expected to have only subtle modulatory or permissive effects, whereas others would represent powerful, tonically active drivers of their excitability. This is a formidable challenge and partial sets of data exist for only a small number of neurotransmitters. The following review focuses on the amino acid transmitters GABA and glutamate, the classical neurotransmitter norepinephrine (NE), and several neuropeptides including GnRH, kisspeptin, neurokinin B (NKB), neuropeptide Y (NPY), and RFamide-related peptide-3 (RFRP-3).

The definition of a neurotransmitter that is used by a primary afferent input to the GnRH neurons requires six criteria to be filled. This includes evidence that the neurotransmitter (1) alters gonadotropin secretion when injected intracerebrally (IC) or intracerebroventricularly (ICV), (2) can alter GnRH secretion, (3) is present in fibers observed by immunocytochemistry (ICC) to be in the vicinity of the GnRH cell bodies, dendrites, or terminals, (4) is present in terminals observed by electron microscopy (EM) to synapse upon GnRH neurons, (5) has cognate receptor protein or mRNA expressed by GnRH neurons, and (6) evokes direct actions upon GnRH neurons to alter their electrical excitability. The prefix indicates the species in which the evidence exists (**r** = rat, **m** = mouse, **s** = sheep, **p** = primate, **gp** = guinea pig), and the appropriate reference is given in superscript.

The definition of a functionally relevant neuropeptide that is used by a primary afferent input to the GnRH neurons requires six criteria to be filled. This includes evidence that the neuropeptide (1) alters gonadotropin secretion when injected intracerebrally (IC) or intracerebroventricularly (ICV), (2) can alter GnRH secretion, (3) is present in fibers observed by immunocytochemistry (ICC) to be in the vicinity of the GnRH cell bodies or terminals, (4) is present in terminals observed by electron microscopy (EM) to synapse upon GnRH neurons, (5) has cognate receptor protein or mRNA expressed by GnRH neurons, and (6) evokes direct actions upon GnRH neurons to alter their electrical excitability. The prefix indicates the species in which the evidence exists (**r** = rat, **m** = mouse, **s** = sheep, **p** = primate, **gp** = guinea pig, **hmst** = hamster), and the appropriate reference is given in superscript.

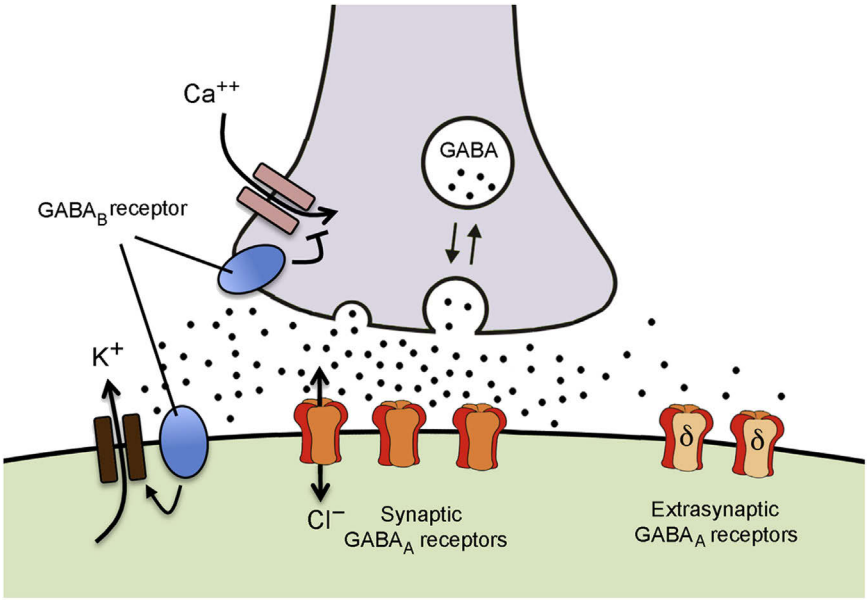

FIGURE 11.6 Modes of GABA action upon GnRH neurons. Presynaptic GABA terminals from the RP3V and other brain sites release GABA into the synaptic space where it activates $GABA_A$ receptors to initiate phasic transmission and $GABA_B$ receptors to suppress excitability. GABA spilling outside of the synapse activates extrasynaptic $GABA_A$ receptors, comprised of delta $GABA_A$ receptor subunits that generate a tonic membrane hyperpolarization. GABA diffusing back to the nerve terminal can activate presynaptic $GABA_B$ receptors that act to inhibit calcium entry into the terminal and suppress presynaptic vesicular release.

GABA

There is little doubt that GABA directly regulates the activity of all GnRH neurons in mammalian species. The most comprehensive assessment of GABA actions to date has been undertaken in the rodent where electrophysiological and gene-profiling studies show that all GnRH neurons express postsynaptic ionotropic $GABA_A$ receptors (for review see Ref. 365) and the vast majority (~90%) are influenced by pre- or postsynaptic metabotropic $GABA_B$ receptors[89,366,367] (Figure 11.6). Electrophysiological studies have also found that almost all GnRH-GFP neurons in the acute brain slice preparation are under a constant barrage of GABA release recorded as fast postsynaptic currents (PSCs) resulting from activation of $GABA_A$ receptors on the membrane of GnRH neurons.[80,368] In the acute brain slice, GABA release on GnRH neurons is far greater than that of glutamate as the rate of $GABA_A$-mediated events is typically 5- to 10-fold greater than glutamate events.[91,369–372]

The sources of GABA inputs to GnRH neurons remain poorly defined. Recent electrophysiological studies have indicated that GABA neurons located in the anteroventral periventricular area (AVPV),[92] lateral preoptic area,[373] and, possibly, the suprachiasmatic nucleus (SCN)[91] provide direct GABAergic inputs to GnRH neurons. These inputs are likely to co-express a variety of other neuropeptides, and a recent investigation has demonstrated the frequency-dependent coding of GABA versus neuropeptide release from such afferents to GnRH neurons.[92]

It seems likely that GABA neurons target the GnRH neuron cell body as well as its dendrites and dendrons projecting to the ME. Electron microscopic studies provided initial evidence that rat GnRH neuron cell bodies receive GABAergic inputs,[374,375] and this was extended by immunohistochemistry experiments showing that GABAergic terminals are apposed to the GnRH neuron cell body as well as the proximal 50 µm of dendrite in mice[34] and sheep.[35] More recent electrophysiological studies have shown that functional $GABA_A$ receptors exist at least up to 200 µm along the proximal dendrite[118] as well as on the dendron as it enters the ME.[55] It is possible that $GABA_A$ receptor

density is highest in the very proximal dendrite and then falls at the level of the cell body as well as more distally along the GnRH neuron dendron in mice. Investigations in human males have also shown the presence of GABA appositions on the cell body and proximal dendrites of GnRH neurons although, in this species, the cell body appears to have the highest density.[227]

The $GABA_A$ receptor on GnRH neurons signals in two different ways, termed *phasic* and *tonic*. Phasic refers to the normal fast activation of $GABA_A$ receptors within the synapse generating the PSCs. Tonic represents the activation of extrasynaptic $GABA_A$ receptors by low ambient concentrations of GABA in the extracellular space[376] and generates a persistent current that helps determine resting membrane potential. Whereas phasic $GABA_A$ receptor signaling has long been recognized in GnRH neurons, it is only recently that tonic $GABA_A$ signaling has been identified in these neurons.[373,377] Mediated by δ subunit-containing $GABA_A$ receptors and partly dependent upon the activity of glial and neuronal GABA transporters, tonic $GABA_A$ receptor signaling was found to hyperpolarize the membrane by ~5 mV in mouse GnRH neurons.[377] Whether this tonic inhibitory current can be modulated is presently unknown, but it may represent an important means for determining the excitability of GnRH neurons.

Another characteristic of $GABA_A$ receptor signaling in GnRH neurons is that, in the acute brain slice preparation, PSCs are not dependent to any large extent upon electrical activity in the presynaptic GABA neurons.[91,378,379] This type of activity-independent or "spontaneous" GABA release is also observed when recording from other neurons, and it remains unclear whether this simply reflects chaotic vesicular release at the presynaptic terminal membrane or is a regulated, purposeful form of neurotransmission.[380] Nevertheless, investigators have suggested that rates of spontaneous $GABA_A$ PSCs may reflect the degree of GABAergic input to a cell[381] and be involved in multiple functions including stabilizing synaptic networks.[380,382] Certainly, the frequency of $GABA_A$ receptor PSCs has been found to change in response to a variety of different experimental manipulations (for review see Ref. 85), and these may reflect changes in the density of GABA inputs to GnRH neuron cell bodies. Finally, with respect to the characteristics of $GABA_A$ receptor signaling in GnRH neurons, it is worth noting that all recordings to date have been made from GnRH neurons in vitro that will have had most of their inputs severed in the brain slicing. Recordings from other neuronal cell types in vivo have revealed that levels of synaptic activity are up to 50-times higher in vivo compared with the acute brain slice preparation and that this has important consequences for the behavior of those cells.[383,384] Establishing the actual rate and pattern of GnRH neuron $GABA_A$ PSCs in a more intact preparation will be an important future goal.

For the majority of neurons in the mammalian forebrain, GABA acts through $GABA_A$ receptors to stimulate their excitability during development, before switching to its well-established inhibitory role in the adult nervous system.[385,386] While there is agreement that $GABA_A$ receptor activation can exert an excitatory influence upon rodent GnRH neurons up until the time of puberty, its role in the adult has been controversial (for review see Ref. 365). Much of this controversy arose from initial studies reporting either inhibitory[387] or excitatory[388] effects of exogenous $GABA_A$ receptor activation upon GnRH neuron firing. Although there is now a consensus that exogenous $GABA_A$ receptor activation is at least transiently excitatory in adult GnRH neurons,[89,365,389] it remains that the role and direction of endogenous $GABA_A$ receptor activation is unclear. Investigations in the acute brain slice preparation have demonstrated inhibitory, excitatory, or, indeed, no effects of a range of different $GABA_A$ receptor antagonists on GnRH neuron firing.[83,92,99,390,391] Although only small numbers of GnRH neurons have been tested as yet in vivo, there is a consistent suppressive action of $GABA_A$ receptor antagonists on GnRH neurons firing.[90] This indicates that, in vivo, $GABA_A$ receptor signaling is essential for GnRH neurons to exhibit their normal firing patterns.

The membrane chloride ion gradient is the principal determinant of whether $GABA_A$ receptors depolarize or hyperpolarize a cell. As such, an understanding of the regulation of transporters and channels responsible for determining chloride ion equilibrium within GnRH neurons remains critical. The potassium-chloride co-transporter 2 (KCC2) is thought to be the key protein maintaining a low intracellular chloride concentration compatible with hyperpolarizing effects of GABA in adult neurons.[392] Although KCC2 mRNA was initially not detected in adult GnRH neurons,[388] a subsequent study has demonstrated KCC2 immunoreactivity in approximately one-third of adult mouse GnRH neurons.[393]

Given that all neurons express $GABA_A$ receptors, it has not been surprising to find evidence for roles of GABA in multiple aspects of reproduction including puberty onset gonadal steroid modulation of LH secretion (see following), seasonality and the metabolic control of reproduction (see other chapters in this volume). However, the physiological roles of GABAergic inputs to GnRH neurons themselves have not yet been established with certainty. Although striking correlations can be found between the frequency of $GABA_A$ receptor events in GnRH neurons and a wide range of physiological and pathophysiological scenarios (for review see Ref. 85), this does not necessarily mean that they are causally related. Furthermore, these events are almost always action potential–independent, and the real patterns of $GABA_A$

receptor activation are likely to be substantially different in vivo. A further difficulty in ascribing an important role to $GABA_A$ receptor activation comes from a recent study in genetically manipulated mice reporting that a selective 70–90% knockdown of $GABA_A$ receptor signaling at the GnRH neuron itself had no major impact upon LH secretion or fertility.[394] This indicates that either GnRH neurons can maintain normal function with only minimal $GABA_A$ receptor signaling or that there is sufficient network compensation to overcome the loss of this receptor. It is also notable that acute $GABA_A$ receptor inhibition does not alter burst firing in GnRH neurons,[390] although, again, this may be an artifact of the brain slice preparation.[88]

Thus, despite the seemingly large amount of data, it is difficult to pin down a specific physiological role for $GABA_A$ receptor–mediated events at the GnRH neuron in regulating their activity. For this, we may still have to fall back on in vivo whole-animal investigations that have shown that $GABA_A$ receptor signaling in the vicinity of the GnRH cell bodies in the preoptic area is necessary for both pulsatile and surge modes of LH secretion to occur normally.[395–398] Whether those effects arise from the direct modulation of $GABA_A$ receptor signaling at the GnRH neuron or indirect actions on neuronal afferents to GnRH neurons, remains unknown.

As first recognized in guinea pigs,[77] the great majority of GnRH neurons are also regulated by $GABA_B$ receptors (Figure 11.6). Receptor profiling studies have since shown the presence of both $GABA_B$-R1 and $GABA_B$-R2 subunits in most mouse and sheep GnRH neurons,[367,399] and electrophysiological experiments have demonstrated that 80–90% of mouse GnRH neurons express functional $GABA_B$ receptors.[366,367] There is agreement that both exogenous and endogenous $GABA_B$ receptor activation inhibits the electrical excitability of GnRH neurons most likely through activation of an outward potassium current.[77,89,366,367] There is initial evidence that $GABA_A$ receptor signaling may predominate at the GnRH neuron soma while $GABA_B$ signaling dominates at the dendrite.[89] Studies have also shown that $GABA_B$ receptors act presynaptically to suppress the activity of GABA and glutamate inputs to GnRH neurons.[366]

The emerging importance of $GABA_B$ receptors in modulating GnRH neuron excitability is paralleled by studies in vivo where $GABA_B$ receptor activation has been found to suppress LH secretion in rats and sheep.[400–405] Furthermore, alongside several other defects, GnRH secretion and fertility are abnormal in global $GABA_B$ receptor knockout mice.[406,407]

While much attention has focused upon GABA actions at the GnRH neuron cell body, it is important to bear in mind that GABA is also likely to modulate distal elements of the GnRH neuron near the median eminence. Both $GABA_A$ and $GABA_B$ receptor activation have been shown to alter GnRH secretion at this level,[408,409] and the GnRH neuron dendron receives GABAergic inputs that signal through the $GABA_A$ receptor.[55]

Glutamate

Substantial evidence implicates glutamatergic neurons as being an important class of primary afferents to the GnRH neurons in mammalian species (for recent review see Ref. 410). Adult GnRH neurons in the mouse respond to exogenous glutamate, AMPA, NMDA, and kainite,[79,95,389,411] and the activation of glutamatergic inputs from the AVPV to GnRH neurons has revealed the presence of substantial endogenous AMPA and NMDA receptor–mediated transmission in these cells.[92] Whereas AMPA and NMDA receptor activation both occur quickly, the AMPA current is short lived compared with the longer-duration NMDA current.[92] Although only able to examine low frequency (~0.1 Hz) action potential–independent release, the majority of GnRH neurons in the acute brain slice exhibit ongoing AMPA-mediated transmission with lesser amounts of NMDA-mediated synaptic activity.[370] Overall, these electrophysiological studies have shown that most (80–100%) GnRH neurons exhibit functional AMPA receptors, whereas only a small subpopulation (~20%) have detectable NMDA receptors.

In general, the previous functional observations fit with the many immunohistochemical and in situ hybridization studies that have been undertaken over past years examining the expression of NR1, 2A and 2B (NMDA), GluR1-4 (AMPA), GluK1 and 5 (kainate) receptor subunits in rodent GnRH neurons (for review see Ref. 410). Also, electron microscopic evidence for glutamatergic synapses on GnRH neuron cell bodies has been found in both the rat and monkey.[221,412]

Less attention has been paid to the presence and role of mGluRs on GnRH neurons. Nevertheless, there is evidence for mGluR subunit mRNAs in GnRH neurons,[214] and a subgroup of GnRH neurons in the MS are excited by Group I mGluR agonists.[222] There is also evidence that Group II/III agonists are indirectly active by modulating GABA inputs to GnRH neurons.[226]

Data also suggest a potential role for glutamate actions at the level of the GnRH nerve terminal to regulate secretion. In vitro preparations of GnRH nerve terminals that are devoid of GnRH cell bodies but maintain the GnRH neuron dendron have been found to release GnRH in response to glutamatergic agonists.[409,413] Whether this represents a direct effect of glutamate upon the GnRH nerve terminal or dendron is not known, but immunocytochemical evidence exists for the expression of both NMDA and kainate receptors by GnRH nerve terminals,[59] and the distal dendron responds to glutamate.[55] Remarkably, the NMDA receptor has been localized to the dense core vesicles actually containing GnRH.[414] There are abundant glutamatergic fibers within the

median eminence and some lie directly adjacent to the GnRH nerve fibers, but, as is the case generally, there have been no demonstrations of conventional glutamatergic synapses upon GnRH nerve terminals.[59,412]

Although it is very likely that GnRH neurons receive glutamatergic inputs from many different brain regions, at present, the only documented input is from the AVPV.[92] This lack of detail underscores the difficulty in ascribing a role of primary afferent glutamatergic inputs to GnRH neurons and is further compounded by the genetic deletion of GluR2 or all NMDA receptors from GnRH neurons having no fertility phenotype.[415] This suggests that NMDA and GluR2-containing AMPA receptors on GnRH neurons are either not essential for fertility or can be compensated for in the mutant mouse. Nevertheless, multiple acute antagonist studies in vivo have documented the necessity of AMPA/kainate and NMDA signaling for enabling both pulsatile and surge modes of LH secretion.[416–419]

GnRH

Electron microscopic studies show that GnRH-immunoreactive terminals comprise up to 10% of all synapses detected on GnRH cell bodies in the rat[225,420,421] and monkey.[282] Further, investigations in the mouse have shown that GnRH neurons express GnRH-1 receptor (GnRH-R1) transcripts[214,422,423] and that their electrical activity is regulated directly by GnRH.[424] Together these data demonstrate that GnRH neurons receive direct inputs from GnRH neurons. Whether this represents recurrent collateral innervation or connections between different GnRH neurons is unknown.

The precise effects of GnRH on the electrical excitability of GnRH neurons are contentious. In the immortalized GT1 cells, GnRH-R1 signals through at least three different G-proteins (Gs, Gq, and Gi) in a concentration-dependent manner. Whereas nM GnRH activates a Gs-cAMP pathway, μM GnRH activates an opposing Gi-cAMP cascade while μM or nM GnRH stimulates the Gq-$[Ca^{2+}]$i pathway. Evidence that a dose-dependent G-protein cascade may also exist in adult GnRH neurons was presented by Xu and coworkers[422] who showed that 20 nM GnRH decreased the firing rate of GnRH neurons from gonadectomized male mice, whereas 200 nM and 2 μM increased firing rate. However, these same responses were not identified in a subsequent study examining the effects of GnRH on GnRH neurons in intact male and female mice where the predominant response was one of modest depolarization of ~50% of GnRH neurons that was independent of GnRH concentration.[424] Also, GnRH was found to activate GnRH neurons in embryonic rats.[425] It is possible that the initial nM inhibitory effects arose from indirect actions[371] or are a property of gonadectomized mice. The subcellular mechanisms involved in GnRH-R1 signaling in adult GnRH neurons are not fully established. One study has shown that GnRH decreases intracellular calcium levels in GnRH neurons,[424] while another has implicated the M-current in GnRH actions.[423]

The GnRH modulation of GnRH neurons provides an example of a neurotransmitter or neuropeptide where its direct actions on GnRH neuron electrical excitability do not fit well with its reported effects on LH secretion in vivo. Numerous studies in vivo with nonprimate species have shown that i.v. or i.c.v. GnRH inhibits portal GnRH or plasma LH secretion[426–429] suggesting a potential short-loop negative feedback role for GnRH within the GnRH neuronal network. This has also been observed in vitro where GnRH decreases, and GnRH antagonists increase, the frequency of GnRH pulses from adult hypothalamic cell cultures.[430] Thus, the suppressive influence of GnRH administered into the brain upon GnRH/LH secretion is not mirrored by its stimulatory effects on GnRH neuron excitability. One explanation may lie in the observation that GnRH inhibits GnRH release from tissue fragments containing only GnRH axons and terminals,[428,431,432] whereas it stimulates LH secretion when applied directly to the region of the GnRH cell bodies in the preoptic area.[433] Thus, as for other neurotransmitters, it is possible that when given i.c.v., GnRH acts at more than one site to regulate GnRH secretion with possible inhibitory actions at the terminals and stimulatory effects at the cell bodies. At present, the mechanisms of GnRH action upon the GnRH terminals are unknown.

What might be the function of a stimulatory GnRH ultrashort-loop feedback at the level of the GnRH soma? This depends very much on whether the GnRH inputs to GnRH neurons are from the same cell (recurrent collateral autofeedback) or from other GnRH neurons. One possibility, related to the latter scenario, would be that GnRH neuron–GnRH neuron signalling enables the coordination of the anatomically dispersed GnRH cell bodies. For example, the LH surge is abolished following intracerebral GnRH-R1 antisense treatment,[434] and it is possible that even a modest depolarizing influence of GnRH could build to a generalized activation of the 50% of preoptic GnRH neurons recruited at the time of the GnRH surge.[18] Intriguingly, however, when this hypothesis was tested in brain slices, it was found that some GnRH neurons switched from being depolarized to hyperpolarized by GnRH specifically during the proestrous phase of the estrous cycle.[424] While some recent progress has been made in defining the effects of GnRH on GnRH neuron excitability, it remains that the physiological role of GnRH-R1 signaling within the adult GnRH neuron is unclear.

Kisspeptin

The kisspeptin projections to GnRH neurons represent an important "high hierarchy" component

of the neuronal network that plays a critical role in many facets of GnRH neuron functioning. This section outlines the neuroanatomy of the kisspeptin system in rodents, sheep, and primates and then briefly considers the roles of kisspeptin neurons in regulating GnRH neurons in rodents. Readers are referred to the species-specific chapters in this volume on reproductive control for detailed reviews of kisspeptin action in sheep and primates. Kisspeptin also features strongly in other chapters on puberty and metabolic control.

ANATOMY

In virtually every mammalian species examined to date, neurons synthesizing kisspeptin are clustered in two brain regions: the preoptic area and mediobasal hypothalamus (Figure 11.7). Within the rat and mouse, the preoptic area kisspeptin neurons lie very close to the third ventricle located within the AVPV and periventricular nucleus of the preoptic area (PVpo)[435,439–441] (Figure 11.7). This distribution lies within the RP3V, a brain region previously defined to contain the estrogen receptor–expressing neurons that innervate GnRH neurons in the mouse.[442] The RP3V kisspeptin neurons in the mouse elaborate a relatively simple multipolar dendritic tree that runs parallel with the surface of the third ventricle.[443] Within the MBH of the rodent, a large population of kisspeptin neurons is found throughout the rostro-caudal extent of the arcuate nucleus (ARN)[439,440] (Figure 11.7). Due to the dense kisspeptin fiber innervation within the ARN that essentially outlines the borders of the nucleus, the identification of ARN kisspeptin cell bodies by immunocytochemistry has often been challenging in both rodent species.[435,444,445] In addition to these two major populations of kisspeptin neurons, small numbers of cells synthesizing authentic Kiss1 mRNA and/or kisspeptin are also found in the dorsosmedial

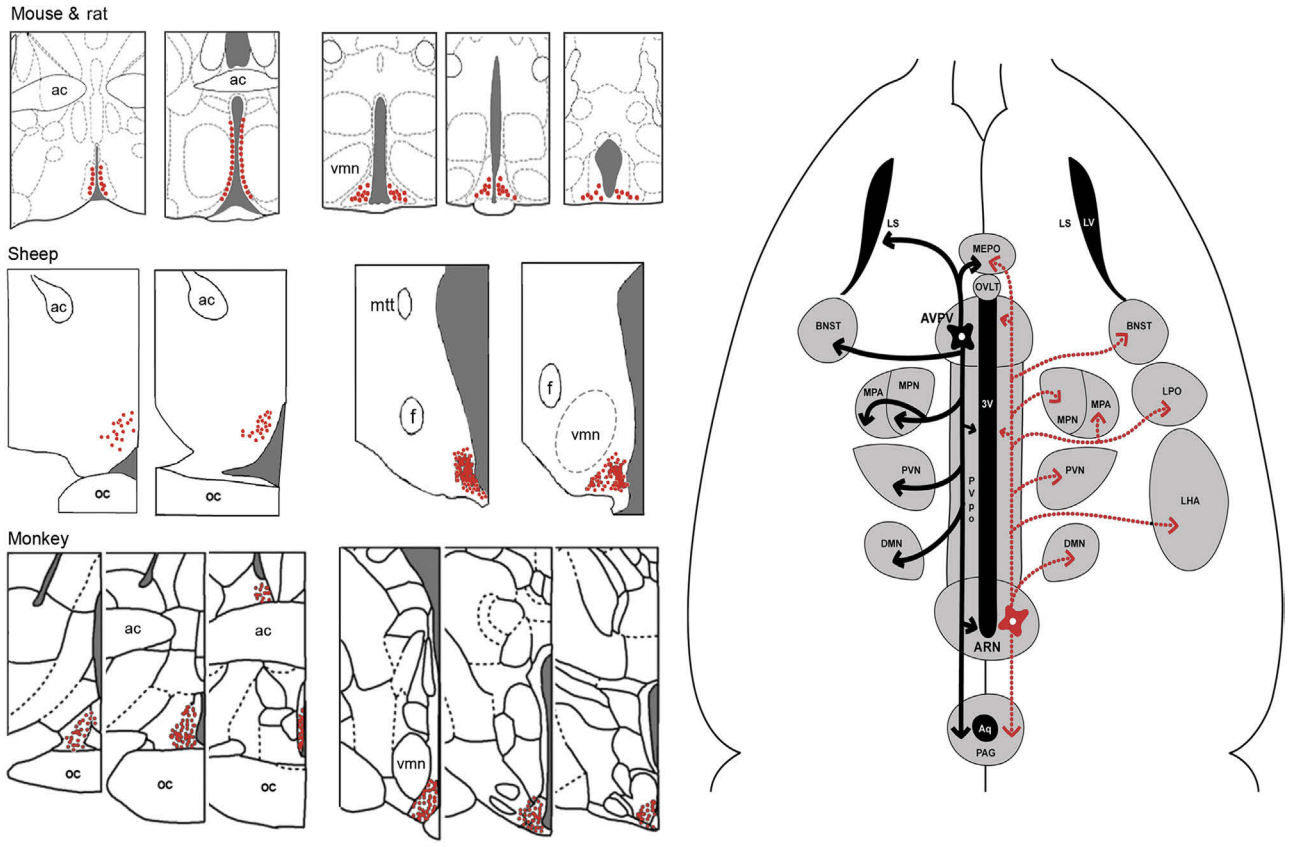

FIGURE 11.7 Sites of kisspeptin neurons in the hypothalamus and their projections in the mouse brain. Left: The locations of kisspeptin cells bodies (dots) in the hypothalamus of the rodent, sheep, and monkey are shown. *Source: These schematic diagrams are based on data reported in Ref. 435–437.* Right: the projections of AVPV (solid lines) and ARN (dotted lines) kisspeptin neurons are shown on a schematized horizontal flat-map of the mouse brain. Abbreviations: Aq, cerebral aqueduct; ARN, arcuate nucleus; AVPV, anteroventral periventricular nucleus; ac, anterior commissure; BNST, bed nucleus of the stria terminalis; DMN, dorsomedial nucleus; LS, lateral septum; LHA, lateral hypothalamic area; LPO, lateral preoptic area; LV, lateral ventricle; MEPO, median preoptic nucleus; MPA, medial preoptic area; MPN, medial preoptic nucleus; mtt, mammilothalamic tract; oc, optic chiasm; OVLT, organum vasculosum of the lamina terminalis; PAG, periaqueductal gray; PVN, paraventricular nucleus; PVPO, periventricular nucleus; vmn, ventromedial nucleus. *Source: Published with permission from Yeo and Herbison[438].*

hypothalamus[435] and amygdala[446] of normal adult rodents.

The distribution of kisspeptin cells in the sheep is very similar to that of the rodent with the exception that the relatively small number of preoptic cells do not reside close to the wall of the third ventricle and are scattered more medially within the preoptic area[436,447,448] (Figure 11.7). The ARN population is again found throughout the rostro-caudal aspects of the ARN.[436,447,448] Mapping studies have also shown the existence of the two major kisspeptin populations in higher primates.[437,449,450] The monkey exhibits a preoptic kisspeptin population that is scattered within the preoptic area and also located in periventricular nuclei[437] (Figure 11.7). The other population of kisspeptin cells is found in the infundibular nucleus, analogous to the ARN in other species (Figure 11.7). A further population of kisspeptin neurons is observed in the anterior division of the bed nucleus of the stria terminalis of the monkey;[437] this has not yet been observed in other species.

It is evident from the wide distribution of kisspeptin fibers within the hypothalamus and other limbic brain regions that the preoptic and ARN kisspeptin neurons project to many different brain nuclei.[435,445] Tract tracing studies have been undertaken in rodents to characterize the kisspeptin neuron projections from the preoptic area and ARN;[438,451,452] this information is summarized in part in Figure 11.7. In essence, both populations are found to innervate many different hypothalamic brain areas with, in general, the preoptic population projecting to more medially located nuclei compared with ARN projections (Figure 11.7). These observations serve to reinforce the notion that the kisspeptin neurons are involved in regulating a wide range of limbic brain functions in addition to the control of gonadotropin secretion.

One interesting feature of kisspeptin neurons is that they co-express numerous classical and neuropeptidergic neurotransmitters. Studies in rodents have shown that subpopulations of RP3V kisspeptin neurons also synthesize GABA, dopamine, met-enkephalin, and galanin. It is reported that ~70% of RP3V kisspeptin neurons express glutamic acid decarboxylase-1 mRNA[453] and that 50% and 80% synthesize tyrosine hydroxylase protein and mRNA, respectively, in adult mice.[241,454] Interestingly, this differs from rats where <20% of RP3V kisspeptin neurons express TH mRNA.[440] In terms of neuropeptides, ~30% of RP3V kisspeptin neurons have recently been found to co-express met-enkephalin and up to 80% express galanin.[455,456] To date, no similar studies have been reported for the preoptic kisspeptin neurons of other species.

Within the ARN, a high degree of neuropeptide co-expression is found between kisspeptin, NKB, and dynorphin, and this has led to these cells being termed the KNDy (Kisspeptin, NKB, Dynorphin) neurons.[457] Initially discovered in the sheep,[458] this pattern of co-expression has now been identified in rodents, primates, and several other species.[457] However, the degree of co-expression between these three neuropeptides appears to vary according to sex, gonadal steroid status, and species. For example, only approximately 50% of NKB neurons in the ARN of the male mouse express kisspeptin,[459] and a recent study did not find high levels of co-expression between any of the three neuropeptides in the infundibular nucleus of human males.[460] In addition to NKB and dynorphin, galanin has also been detected in ARN kisspeptin neurons in the adult mouse.[455,456] Similar to the RP3V, there is evidence that some ARN kisspeptin neurons synthesize classical amino acid transmitters GABA and glutamate.[453,461]

PHYSIOLOGY

In keeping with the early evidence that kisspeptin was an extremely potent activator of LH secretion in several species,[449,462,463] it has been no surprise to find that kisspeptin is the most potent activator of GnRH neuron excitability yet discovered.[464] Different technical approaches all indicate that the great majority (~85%) of GnRH neurons express the kisspeptin receptor (GPR54 or KISS1R) in adult rodents.[464–466] Furthermore, GnRH neurons are likely to synthesize GPR54 before birth[466] and may even do so from early in embryonic development.[467,468] While there is abundant evidence for potent direct actions of kisspeptin on GnRH neurons, there may also be indirect pathways through which kisspeptin can modulate the activity of GnRH neurons. Kisspeptin is reported to stimulate nitric oxide (NO) release around the OVLT[469] and also modulate amino acid transmission to GnRH neurons.[470]

It is becoming increasingly evident that kisspeptin inputs to GnRH neurons are critical for these cells to exhibit their normal patterns of activity in response to a variety of stimuli. For example, GPR54 knockout mice are unable to exhibit high frequency, high amplitude LH secretion following gonadectomy,[471] and neurotransmitters known to stimulate LH secretion are barely effective in the GPR54 knockout mice.[472] While often interpreted as demonstrating a serial relationship (i.e., neurotransmitter X acts on kisspeptin neurons to activate GnRH neurons), it is much more likely this reflects a "dependent parallel" relationship whereby neurotransmitter X is no longer able to activate GnRH neurons if the kisspeptin input is not present. The opposite is not true, however, as many mouse models and experiments that result in suppressed reproductive function or hormone secretion are "rescued" by kisspeptin treatment. Again, these studies are sometimes wrongly interpreted as showing that the defect is in kisspeptin; it is more likely that kisspeptin is such a potent activator of GnRH neurons that it can overcome many different insults to these cells.

Several laboratories[222,470,473,474] have investigated the intracellular signaling mechanisms underlying the remarkably potent actions of kisspeptin on native GnRH neurons. Overall, there is good agreement that GPR54 activation results in the modulation of at least two different ion channels: closure of a tonically active inward rectifying potassium channel and opening of a nonselective cation channel, very likely to be a member of the transient receptor potential-like channel family. Precisely how activation of the Gq-coupled GPR54 receptor modulates these channels is unclear as, although phospholipase C is involved, the roles of the expected downstream signaling molecules such as diacylglycerol, inositol trisphosphate, and intracellular calcium remain contentious.[473,474] Another interesting, but as yet unexplained,[473] feature of kisspeptin action is the mechanism that enables brief kisspeptin exposure to generate very prolonged activation of the GnRH neurons in vitro.

RP3V KISSPEPTIN NEURONS

The RP3V kisspeptin neurons are thought to have a key role in activating GnRH neurons to generate the preovulatory GnRH/LH surge in female rodents. This population of cells exhibits all of the key features expected for a neuronal input to GnRH neurons to be involved in the surge mechanism. The kisspeptin neurons: (1) are located in the RP3V, the key brain region involved in the generation of the GnRH/LH surge in rodents;[442] (2) sexually dimorphic, with 10- to 20-fold more kisspeptin neurons in the RP3V of females compared with males;[440,475] (3) express ER alpha,[476] the key receptor isoform involved in the surge mechanism;[477] (4) exhibit estradiol-regulated ion channels and electrical activity;[478,479] (5) are activated coincidentally with GnRH neurons at the time of the surge, as assessed by cFos immunohistochemistry;[480,481] (6) project to and directly activate GnRH neurons;[92] and finally (7) are essential alongside GPR54 for the generation of the GnRH/LH surge in mice and rats.[441,481,482] There is also evidence that circadian inputs may impact upon RP3V kisspeptin neurons to time the onset of the GnRH surge in rodents.[483–485] Although sexually dimorphic populations of kisspeptin neurons are also located in the preoptic area of the sheep[486] and primate,[450] their role in the GnRH surge mechanism is unknown. Recent studies have, however, shown that sheep preoptic kisspeptin neurons express cFos at the time of the surge in this species.[436,487] It remains unknown whether all the kisspeptin neurons in the RP3V are involved in the surge mechanism or whether there may be functional subpopulations. Certainly, the surge mechanism can occur with less than 50% of the normal number of RP3V kisspeptin neurons.[488]

Studies also indicate that the RP3V kisspeptin neurons are involved in puberty onset in female rodents. Intriguingly, RP3V kisspeptin-immunoreactive cell bodies and kisspeptin fibers around GnRH neurons appear just at the time of puberty onset in male and female rodents.[475,489] As this increase in kisspeptin biosynthesis is dependent upon estradiol, it is likely that the RP3V kisspeptin neurons represent a population of neurons brought into play in late puberty to enable the final development of the positive feedback mechanism in female rodents.[490] Mice in which ERα is deleted from all kisspeptin neurons showed markedly disordered puberty.[482] The role of the small RP3V kisspeptin population in male puberty onset is unclear despite having the same gonadal steroid-dependent pattern of postnatal expression.[491]

ARCUATE KISSPEPTIN NEURONS

The arcuate kisspeptin neurons have been suggested to have roles in the estrogen negative feedback mechanism, puberty onset, and GnRH pulse generation. Unlike the RP3V population, these neurons are found to express kisspeptin from mid-embryogenesis with a peak in expression in both sexes just before birth.[492] It remains controversial whether sex differences exist in the numbers of arcuate neurons that synthesize kisspeptin in rodents.[440,489,493]

Surprisingly, the pathway(s) through which arcuate kisspeptin neurons regulate GnRH neurons are not yet established. Although arcuate kisspeptin neurons send projections to the preoptic area,[438] there is presently little evidence for direct innervation of the GnRH neuron cell bodies.[451,455] Furthermore, it seems unlikely that kisspeptin fibers directly innervate GnRH nerve terminals in the external zone of the median eminence as: (1) very few kisspeptin fibers are found in this area;[435] (2) no ultrastructural evidence has been found for direct presynaptic kisspeptin inputs on GnRH nerve terminals;[494] and (3) kisspeptin neurons do not take up Fluorogold injected peripherally in rats or mice.[438,494] Thus, the anatomical connection between arcuate kisspeptin neurons and GnRH neurons remains unknown and is an important point that requires clarification.

One intriguing property of arcuate kisspeptin neurons is that the biosynthesis of kisspeptin is regulated by estradiol in a manner opposite to that of the RP3V kisspeptin cells. Thus, gonadectomy enhances, and estradiol suppresses, Kiss1 mRNA and protein levels in the ARN. This has led to the hypothesis that estradiol reduces a stimulatory kisspeptin input to GnRH neurons to suppress GnRH secretion and thereby bring about estrogen negative feedback. This hypothesis was supported by investigations showing that the postovariectomy increase in LH secretion was blunted in GPR54 knockout mice[471] as well as in rats with arcuate nucleus-specific, saporin-deleted, kisspeptin neurons.[495] However, these studies could also be interpreted as showing that arcuate kisspeptin neurons are simply required for GnRH neurons to drive pulsatile LH secretion without any role

in mediating estradiol actions. Recent electrophysiological studies examining arcuate kisspeptin neuron firing in acute brain slices have also questioned the estrogen negative feedback model as gonadectomy resulted in even lower firing rates than the already low levels found in intact mice—a result opposite to that predicted by the model.[496] Thus, the estrogen negative feedback role for arcuate kisspeptin neurons in the rodent presently rests on biosynthesis data with definitive functional evidence yet to be presented.

Arcuate kisspeptin neurons may also have a role in puberty onset. Some investigators have observed transient or sustained increases in arcuate kisspeptin levels across postnatal development.[489,493,497] Furthermore, genetic deletion of ER alpha from kisspeptin neurons results in the early onset of puberty in female mice, and this may be attributable to the arcuate kisspeptin population.[482] As for the negative feedback theory, the case for arcuate kisspeptin neurons being involved in puberty onset requires further support.

Studies with GPR54 antagonists demonstrate that kisspeptin-GPR54 signaling is required for normal pulsatile GnRH and LH secretion in a range of experimental animals.[498] Whether this function derives from the RP3V and/or arcuate kisspeptin neuron populations is unclear at present. Mice with ARN diphtheria toxin–deleted kisspeptin neurons fail to exhibit regular estrous cycles,[499] suggesting a possible role of arcuate cells in pulse generation. Also, infusion of GPR54 antagonists directly into the ARN is found to suppress pulsatile LH secretion,[500] indicating an important role for kisspeptin-GPR54 signaling within this area for pulse generation. Most importantly, like NE and NPY, the release of kisspeptin occurs in an episodic manner within the MBH of the monkey, and this coincides with pulsatile GnRH release.[501] Another influential push for a role of arcuate kisspeptin neurons in pulse generation comes from a theoretical pulse generator model involving interconnected KNDy neurons within the ARN.[457] Morphological and electrophysiological studies have provided evidence that kisspeptin neurons may be reciprocally connected as NKB can excite kisspeptin neurons in the mouse.[459] The model proposes that different dynamics of dynorphin and NKB signaling within this pathway would generate oscillatory activity in the arcuate kisspeptin neurons that would then entrain GnRH neurons to generate pulses. Much has yet to be done to explore this interesting model, and further evidence for a role of arcuate kisspeptin neurons in pulse generation remains to be gathered.

Neurokinin B

Neurons expressing NKB are located throughout the brain with several populations found within the hypothalamus including the ARN, ventromedial nucleus, lateral hypothalamic area, and extending into the zona incerta.[502,503] Studies in the early 1990s by the Rance laboratory initiated interest in NKB by showing an increase in tachykinin family gene expression in the infundibular nucleus of postmenopausal women.[504] This was followed by studies suggesting a role for arcuate NKB neurons in the control of GnRH neurons in the rat[505] and experiments in the sheep showing that almost all arcuate NKB neurons expressed estrogen receptors and were sexually dimorphic.[506,507] The recent identification of infertility in humans with *NKB* (known as *TAC3* in humans and *Tac2* in rodents) and the NKB receptor *NK3R* (known as *TAC3R/Tacr3*) mutations[508] has sparked substantial new interest in this neuropeptide. As noted before in the Kisspeptin section, the observation that a subpopulation of NKB neurons in the ARN express kisspeptin in rodents,[451,459,509] sheep,[458] goats,[510] and primates[460,511] has further focused investigators' attention on NKB.

A substantial number of recent studies have examined the effects of ICV NKB upon LH secretion in several species. In general, investigations in rodents have not provided any clear consensus of NKB action, with NKB being reported to inhibit, stimulate, or have no effect upon LH secretion.[512–516] If anything, the very familiar "neuropeptide pattern" of: (a) LH inhibition in gonadectomized rodents; versus (b) LH stimulation in intact or steroid-supplemented gonadectomized rodents appears to exist for NKB, as it does for many other neuropeptides administered ICV.[272] Given the existence of several distinct NKB cell populations projecting throughout the brain[451,452,503] and the widespread activation of neurons following ICV NKB,[516] it is perhaps not surprising that little consensus has been achieved with this approach. Studies in the sheep have shown that ICV NKB stimulates LH secretion in the follicular phase but has no effect in luteal ewes.[517] An investigation in agonadal prepubertal male monkeys revealed a stimulatory effect of intravenous NKB on LH secretion, suggesting that NKB may even act outside the blood–brain barrier to achieve its actions.[511]

At present, relatively little is known about how any of the NKB populations in the brain interact with GnRH neurons to modulate fertility. Studies in the female mouse and rat have indicated that GnRH neurons express mRNA and protein for NK3R,[215,518] although others have failed to detect the receptor in GnRH neurons in the male mouse and ewe.[459,519] The relative absence of NKB fibers around GnRH neuron cell bodies in the rodent,[451,455,518] and lack of any effect of NKB on GnRH neuron excitability in the mouse[459] indicate that the GnRH soma and proximal dendron may not express the appropriate receptors for NKB. In contrast, early immunohistochemical studies reported that NK3R was present on GnRH nerve terminals in the median eminence[518] and abundant NKB fibers have been detected

in nearby GnRH neuron elements within and around the median eminence in all species examined.[451,460,511,518] Thus, it has been proposed that direct effects of NKB on GnRH neurons may occur at the level of the median eminence,[505] presumably on the GnRH neuron dendron. This would be consistent with intravenous NKB being able to modulate LH secretion.[511] As there is substantial, but not complete, co-expression of kisspeptin with NKB fibers in the median eminence,[451,452] it is thought that the relevant NKB population regulating GnRH neurons is that located in the ARN.

The precise roles of NKB within the GnRH neuronal network remain to be established. As NKB is expressed in arcuate KNDy neurons, it shares many of the putative roles of that cell population. For example, as NKB stimulates the electrical activity of arcuate kisspeptin neurons, it has been proposed to be part of the KNDy pulse generator mechanism.[459] However, in general, when examined in the same assays or protocols, the effects of NKB are overshadowed greatly by kisspeptin. For example, in contrast to the complete infertility of kisspeptin and GPR54 knockout mice, NK3R knockout mice are only subfertile.[520] Whereas the effects of kisspeptin on the reproductive axis are very consistent across the sexes, reproductive states, and animal species, this is not the case for NKB,[505] where, in addition, complex interactions exist with other neurotransmitter systems.[521] Furthermore, recent studies have examined the potential for NKB to be involved in puberty onset. Again unlike kisspeptin, there is no evidence for a significant role of NKB in puberty with, if anything, only a modest modulatory influence observed.[502,522]

Similar to kisspeptin biosynthesis, NKB mRNA in the rodent arcuate nucleus is suppressed by estradiol in an ERα-dependent manner,[512,523,524] and this has led to the suggestion that the coordinated suppression of both kisspeptin and NKB in KNDy neurons may be involved in the estrogen negative feedback mechanism.[459] Also, NKB and kisspeptin expression is increased, and dynorphin reduced, in the infundibular neurons of postmenopausal women.[505] While these studies clearly show that NKB gene expression is modulated potently by gonadal steroids, a role for arcuate NKB neurons in mediating estrogen negative feedback has yet to be established.

Neuropeptide Y

Neuroanatomical investigations in several species indicated the likelihood that NPY neurons located in both the arcuate nucleus and brainstem provide direct inputs to GnRH neuron cells.[3] Over recent years, the major advance in understanding NPY actions in relation to fertility has come from electrophysiological studies examining the effects of NPY on GnRH neuron excitability. In the ovariectomized (OVX) rat, NPY was found to directly hyperpolarize GnRH neurons through the NPY Y5 receptor.[525] In adult female mice, the same direct hyperpolarizing action of NPY was identified, although it occurred through the Y1 receptor.[270] Unexpectedly, direct stimulatory actions of NPY were also observed acting through the Y4 receptor that has low affinity for NPY and is likely to be the natural receptor for pancreatic polypeptide.[270] Finally, studies in embryonic GnRH neurons also found a likely direct inhibitory action of NPY acting through Y1 receptors.[526] Thus, it would appear that NPY exerts a predominant direct inhibitory influence upon GnRH neuron excitability and that this is mediated by Y5 receptors in rats and Y1 receptors in embryonic and adult intact female mice. Whether a true species difference exists for the NPY receptor subtype expressed by GnRH neurons remains unclear. Receptor labeling studies in the rat have indicated that GnRH nerve terminals exhibit Y1 receptor immunoreactivity, while GnRH cell soma are immunoreactive for the Y5 receptor.[527,528]

It is difficult at present to reconcile these direct inhibitory actions of NPY on the GnRH neuron excitability with the reported effects of NPY on rodent LH secretion in vivo. This is most probably due to NPY acting at multiple levels within the GnRH neuron network and pituitary gland to control gonadotropin secretion. For example, there is an array of different NPY receptors reported to be involved in the activation of GnRH secretion within the median eminence,[529,530] in addition to direct Y1 receptor-mediated facilitatory effects upon the gonadotroph itself.[531–535] Thus, ICV NPY is likely to act at multiple different sites to modulate LH secretion and, indeed, exhibits the typical "neuropeptide pattern" of inhibiting LH in gonadectomized animals and stimulating LH in intact or estradiol-treated rats.[272] Studies in NPY knockout mice have not advanced the understanding of NPY to any great extent, as LH levels in OVX and OVX estradiol-replaced mice are normal, although the magnitude of the LH surge is halved in mutant mice compared with wild-type mice.[533,536] Thus, at present, it would seem that the GnRH neuron can be modulated by NPY directly and indirectly at multiple locations, including the cell body and terminals, with none of these actions being essential for their normal behavior, at least in mice.

It is possible that NPY plays a more influential, or at least easily decipherable, role in regulating GnRH neuron secretion in the monkey. In this species, the infusion of NPY into the median eminence of females stimulates GnRH secretion irrespective of its gonadal status.[537–539] Furthermore, NPY levels fluctuate in synchrony with GnRH release within the monkey median eminence, and pharmacological reductions of NPY activity suppress GnRH pulsatility.[540,541] It is interesting to note that NPY release fluctuates in the same manner as NE within the median eminence of the monkey,[542] suggesting that it

may be the brainstem neurons co-expressing NPY and NE that provide this input. Together, these observations indicate that NPY acting in the vicinity of the MBH may have an important physiological role in enabling pulsatile GnRH release in the female monkey and that NPY is most likely to act at the level of the GnRH dendron and nerve terminals to achieve this regulation.[543] In contrast, NPY may exert very different actions in the male primate as i.c.v. NPY inhibits pulsatile LH secretion in gonadectomized male monkeys.[544]

Brought together, it seems likely that NPY is used by a variety of different inputs to GnRH neurons subserving different roles. One of these may be to facilitate GnRH neuron pulse generation at the level of the GnRH dendron/nerve terminals, but other functions related to nutrition and metabolism, for example, almost certainly exist.[545] Establishing the roles of each specific NPY input to GnRH neurons will be a very significant challenge. Aside from the likely different physiological roles of ARN and brainstem NPY inputs to the GnRH neurons, there remains the issue of establishing the significance of co-released agouti-related peptide (Agrp), GABA and NE. Looking at NPY actions independently of Agrp, GABA and NE may be misleading when investigating a neuropeptide that is an established neuromodulator of other neurotransmitter actions.[546]

Norepinephrine

Relatively little new information has accrued on NE since the last chapter published in 2006.[3] A series of experiments in the mouse have, nevertheless, demonstrated that A2 and A6 NE inputs to GnRH neurons exert a direct suppressive influence on GnRH neuron excitability.[249,547] Prior studies on this topic had relied upon confocal appositions[548] or tract-tracing studies that could not be certain whether the labeled NE cell bodies innervated GnRH neurons or other cells in the neighborhood.[549–553] Using conditional pseudorabies virus in GnRH-Cre mice, it was possible to undertake GnRH neuron-specific retrograde tracing, and this showed that NE neurons located in the brainstem A2 and A6 cell groups innervated GnRH neurons directly.[249] Subsequent electrophysiological studies using GnRH-GFP transgenic mice showed that NE acts through both α1 and β-adrenergic receptors to exert direct hyperpolarizing actions on the great majority (80–90%) of adult GnRH neurons.[547] These studies agreed well with prior GnRH neuron gene-profiling work demonstrating the presence of α1 and β-adrenergic receptors transcripts in mouse GnRH neurons.[215] Thus, it would appear that direct NE inputs from the A2 and A6 cell groups act to suppress GnRH neuron excitability in the mouse.

In relation to the new neuroanatomical information, it is interesting to note that species differences appear to exist in the location of ascending NE inputs to GnRH neurons. Although not established with the same confidence allowed in the mouse, it seems that A1, A2, and A6 cells are important in the rat[549,550,554] while only A1 and A6 cells are involved in the network in sheep.[552] Furthermore, it is possible that NE inputs also influence GnRH secretion indirectly within the median eminence[554–557] and an input to the AVPV has also been reported.[558]

A case has been made for a role of NE in the generation of pulsatile GnRH/LH secretion.[559] Experiments in the monkey have shown the importance of α-adrenergic receptors in enabling pulsatile LH secretion[560] and revealed a striking correlation between NE levels in the MBH and pulsatile LH secretion.[542] Early studies in rats also showed that NE inputs near GnRH neurons are critical for pulsatile LH secretion; infusions of *either* adrenergic agonists or antagonists into the vicinity of the GnRH cell bodies in rats and monkeys were found to have the *same* effect of reducing pulsatile GnRH and LH secretion.[542,561–564] These results suggested that NE exerts a permissive influence within the GnRH neuronal network by enabling network function rather than driving it in any particular direction.[559] This idea is further supported by evidence for the reemergence of pulsatile LH release several weeks after complete destruction of the ascending NE pathways.[565,566] Elsewhere in the brain, and particularly in sensory neural networks, NE is well established to act as a permissive neuromodulator that does not carry any specific information but modulates the responses of target neurons to their inputs.[567] This can occur through NE altering signal-to-noise ratios and/or altering the threshold for activation of neurons to specific stimuli; for example, NE reduces the "noisy" spontaneous firing of thalamic neurons to make them more receptive to the effects of key afferent inputs.[568]

Perhaps the clearest indicator of NE's permissive role within the GnRH neuronal network is in relation to the preovulatory GnRH/LH surge. There is evidence for the activation of brainstem NE neurons at this time,[558,569] and studies in rats have shown that preoptic NE concentrations in the vicinity of the GnRH neuron cell bodies begin to increase on the morning of the surge.[558,570–572] This activation of NE neurons on the morning of proestrus appears to depend upon the rising levels of estradiol at this time.[573] As NE levels are elevated hours before the abrupt activation of GnRH neurons on proestrous afternoon, this suggests that they are facilitators rather than the trigger. A similar conclusion has been reached in the sheep,[574] and brainstem NE neurons have also been implicated in the mechanism underlying induced-ovulation in the rabbit.[575–577] Interestingly, the progressive failure of the LH surge mechanism in older rats is associated with reduced or absent increases in preoptic area NE levels.[571]

Precisely how NE acts within the network to promote the presumed high-output state of GnRH neurons

required for individual pulses or the surge is unknown. The recent electrophysiological studies clearly show that NE exerts a potent suppressive influence upon the spontaneous firing of about 50% of GnRH neurons on proestrus.[547] One possibility is that, as in other brain areas,[567] NE reduces spontaneous firing to make the effects of specific inputs more apparent; in this case spontaneous firing could be reduced to increase the overall impact of potentially time-locked RP3V inputs that initiate GnRH neuron activation.

Together, these studies indicate an important permissive role for NE within the GnRH neuronal network. Whether this permissive influence occurs through primary NE afferents to GnRH soma or terminals, or involves parallel, indirect actions of brainstem NE neurons is unknown. Equally, the influence of co-released molecules such as NPY and, possibly ATP,[578] on NE actions remain to be established.

RFRP-3

In 2000 a family of novel peptides with a C-terminal LPXRFamide (X = L or Q) motif was discovered and termed the RFamide-related peptides (RFRPs).[579] Remarkably, an avian homolog of RFRP was found to inhibit gonadotropin secretion directly at the pituitary gland in the quail,[580] raising the possibility that a gonadotropin release-inhibiting hormone had been found. As such, this quail RFRP was termed gonadotropin-inhibitory hormone (GnIH).[580] Subsequent studies in many different bird species have shown that the GnIH peptide is synthesized predominantly by hypophysiotropic parvocellular neurons located in the paraventricular nucleus.[580,581] Receptors for GnIH are present in the avian pituitary,[582,583] and GnIH inhibits both the synthesis and release of LH in all avian species examined to date (for review see Ref. 584). In addition to an action at the pituitary, avian GnRH neurons express Gpr147, the receptor for GnIH,[585] and GnIH-immunoreactive fibers exist close to the cell bodies of GnRH neurons in birds.[585,586] Hence, avian GnIH neurons exert a dual influence upon gonadotropin secretion by directly regulating both pituitary gonadotrophs and GnRH neurons. The widespread distribution of GnIH and its receptor within the avian brain and periphery suggest that there may also be indirect actions of GnIH on the reproductive axis, in addition to roles for GnIH in a range of other systems.[584]

The GnIH peptide itself does not exist in mammals with the mammalian gene orthologous to avian GnIH encoding an precursor that produces two similar LPXRFamide neuropeptides termed RFRP-1 and RFRP-3.[579,587] In situ hybridization and immunocytochemistry studies have shown that cell bodies expressing RFRP precursor mRNA or RFRP-1 and -3 protein are located within and around the dorsomedial hypothalamus of rodents and that these RFRP neurons project widely within the brain.[588–592] Sheep and monkeys have their RFRP neurons located primarily within the dorsomedial and paraventricular nuclei of the hypothalamus.[437,593,594]

The functional role of RFRPs in regulating reproduction in mammals has been more difficult to ascertain and appears to be species, and possibly even sex, dependent. Whereas there is evidence for a direct, albeit modest, role of RFRP-3 in regulating pituitary gonadotropin release in vivo in the sheep,[595,596] this is much less certain in other species. RFRP-immunoreactive fibers have been detected within the median eminence of hamsters, but not primates, although Gpr147 is expressed by gonadotrophs of both species.[437,593,597,598] Studies examining the effects of peripheral RFRP-3 administration on LH secretion have been inconclusive, with inhibitory, stimulatory, or no effects observed.[591,597,599] The hamster is one species where effects of RFRP-1 have also been detected on LH secretion.[591] In the case of the rat, no evidence has been found that RFRP neurons project to the median eminence,[600] and peripheral RFRP-3 has been found to have highly variable inhibitory or no effects upon LH secretion in vivo or in vitro.[589,600–603]

If RFRP does act directly at the pituitary in mammals it remains unclear how this might occur. A recent portal bleeding study in the sheep found that, while detectable in portal blood, RFRP does not fluctuate in relationship to LH pulses.[596] This demonstrates that RFRP is unlikely to have a role in generating or shaping pulsatile GnRH and LH secretion, although it remains possible that it may have more general actions on gonadotroph activity during different seasons in the ewe.[596]

Although the evidence for RFRP being a true hypophysiotropic releasing factor in mammals is slim, it remains that intracerebral administration of RFRP-3 can modulate LH secretion in rats, sheep, and hamsters. This most likely reflects central actions of RFRP within the GnRH neuronal network itself. There is evidence for RFRP fibers around GnRH neuron cell bodies in all mammalian species examined to date[437,589,594,597,598,604] and subpopulations of GnRH neurons express Gpr147.[591,592,604] Most importantly, RFRP-3 is found to exert direct, predominantly suppressive, actions upon the excitability of a subpopulation of GnRH neurons in the mouse.[605,606] Also, administration of RFRP-3 can suppress the cFos activation of GnRH neurons at the time of the LH surge in the rat.[603]

Together, these data demonstrate that, as in birds,[584] the GnRH neuronal network includes a direct RFRP neuron projection from the dorsomedial/paraventricular nucleus to a subpopulation of GnRH neurons in mammals. The physiological role of this projection is uncertain with studies suggesting possible roles in mediating the effects of season[591,594,596,599,607] and stress[608,609] upon the reproductive axis. Given the widespread projections of RFRP neurons throughout the brain, it has not been surprising to find that this neuropeptide is also implicated

in regulating the release of multiple pituitary hormones, as well as a variety of other central functions.[584,610]

Glial Elements of the GnRH Network

As noted in the neuroanatomy section of this chapter, there is substantial evidence for a close physical relationship between glial cells and GnRH neurons at the level of their cell bodies as well as their terminals in the median eminence. Led by the Prevot and Ojeda laboratories, much recent work has been undertaken examining astrocyte-GnRH soma/dendrite interactions and the complex endothelial-tanycyte-GnRH nerve terminal dynamics within the median eminence (for reviews see Ref. 611,612). Together, these studies indicate potent roles for glial cells within the GnRH neuronal network.

Neuronal-glial Interactions at the GnRH Neuron Soma

Astrocytes modulate the activity of GnRH neurons through both direct physical means as well as through signaling molecules. In relation to the former, individual GnRH neurons have up to 90% of their cell soma in direct apposition to glial cell elements depending on the gonadal steroid environment.[51] Specifically, fine protrusions from glial cells can be seen to interdigitate between presynaptic terminals and the postsynaptic membrane of the GnRH neuron.[42,50] Thus, it seems possible that plasticity in glial cell wrapping could modulate the afferent input to a GnRH neuron. Firm evidence for this is lacking, however. A consistent correlation does not exist between levels of glial cell ensheathment and the predicted activity levels of GnRH neurons.[278,613] To date, there is no information on glial cell wrapping of the GnRH neuron dendrites and dendrons.

It is now evident that astrocytes in the vicinity of the GnRH neuron cell bodies secrete prostaglandins, specifically PGE2, to modulate the electrical excitability of GnRH neurons.[614,615] The secretion of PGE2 from astrocytes is regulated by activation of the ErbB receptor family that, in turn, can be controlled by other glial factors such as transforming growth factor alpha (TGFα) and neuregulin[616] as well as neuronal inputs involving activation of glutamatergic metabotropic and ionotropic receptors.[617] All GnRH neurons are reported to be activated by PGE2 and, remarkably, in the acute brain slice, show dependency on tonic PGE2 release to maintain their normal levels of electrical activity.[615] These investigations indicate a powerful role for local glial cells in determining GnRH neuron excitability; further studies are now needed to identify precisely which aspects of GnRH neuron physiology are modulated by this pathway. One study has shown that preoptic levels of ErbB receptors are maximal at the time of the GnRH surge and that knockdown of erbB signaling in this area results in acyclicity.[618] In addition, it seems likely that other glial-derived signaling factors such as TGFβ may be involved.[619] As the tools are developed, this area of GnRH neuron biology will likely become increasingly complex.

Endothelial-Tanycyte-GnRH Nerve Terminal Interactions

Electron- and light-microscopic studies have shown that the GnRH nerve terminals within the median eminence are typically enveloped by tanycytic end-feet and sit away from the basal lamina of the endothelial cell wall.[61,63,67,620] Remarkably, at the time of the preovulatory GnRH surge, substantial structural remodeling occurs involving tanycytic end-feet retraction, sprouting of GnRH nerve terminals to reach the hypophysial blood vessels, and increased permeability of the blood vessels themselves.[64,65,621] These changes, although allowing only approximately 10% of GnRH nerve terminals to be abutting portal vessels,[65] are thought to play a role in enhancing GnRH secretion into the portal system at the time of the surge.[611] How critical this process is to successful fertility is not yet established.

Some progress has been made in understanding the mechanisms underlying the dynamic changes in tanycyte morphology at proestrus. Again, this has been found to involve the erbB receptor family and PGE2; in this case, TGFα released by tanycytes acts back on erbB receptors to promote PGE2 synthesis by tanycytes that, in turn, secretes TGFβ to retract tanycyte processes.[622] Some clarity was brought to understanding how this pathway works by showing that estradiol upregulates the TGFα converting enzyme within the median eminence,[623] indicating that the proestrous rise in estradiol would facilitate tanycyte retraction by promoting TGFα secretion.

Prevot and colleagues have also addressed the important question of whether the vascular endothelial cell is itself involved in this tanycyte retraction mechanism. It is proposed that the endothelial cells produce NO in response to the elevated levels of estradiol on proestrus and that this has two major effects; first, it directly activates GnRH secretion from the nerve terminal, and second, NO activates both soluble guanylyl cyclase (to enhance cGMP levels) and cyclooxygenase (to generate PGE2 secretion) to facilitate tanycyte end-feet retraction.[624–626] Together with the TGF studies outlined before, it would seem that there is a very sophisticated, multidimensional mechanism for regulating tanycytic morphology within the median eminence.

SYNCHRONIZATION AND PULSATILITY

Generation of a GnRH Pulse

Portal bleeding and microdialysis approaches in a variety of species have documented the pulsatile nature of GnRH release and its typically tight correlation with

pulsatile LH secretion.[542,627–636] The intervals between GnRH pulses in vivo range from 40 to 60 min in the gonadectomized monkey, sheep, and rat, with longer intervals reported in intact animals.[542,632–634,637–640] Although GnRH secretion has not been measured in the mouse in vivo, inference from pulsatile LH measurements suggests that GnRH pulses also occur approximately every 60 min in gonadectomized female mice[641,642] and every 3 h in intact males.[643] Detailed analysis of the dynamics of a GnRH pulse has been undertaken in the sheep and revealed that each pulse begins abruptly, plateaus for ~5 min, and then falls precipitously.[631,637] As a general concept, Goodman and Karsch coined the term *hypothalamic pulse generator* in 1981 to describe the neural mechanism responsible for this pulsatility.[644] However, 30 years later the question of what makes up the pulse generator, and how the dispersed GnRH neurons generate a sharp ~5 min pulse of GnRH into the portal system every hour, remains one of the most important unanswered questions in GnRH neurobiology.

While it is self-evident that GnRH neurons ultimately have a role in pulse generation, precisely which GnRH neurons are involved in generating a GnRH pulse remains unknown. Studies involving the transplantation of GnRH neurons into the ventricular system of the *hpg* mouse (that have a genetic mutation resulting in no GnRH peptide expression) indicate that as few as 20 GnRH neurons are sufficient to generate pulsatile LH secretion.[645] Further, a mouse line with only ~80 GnRH neurons can support normal reproductive activity in males, implying their ability to release LH in a pulsatile manner.[646] Thus, under pathological conditions, it would appear that <10% of GnRH neurons are sufficient for pulsatile GnRH secretion to occur. Exactly which of the ~1000 GnRH neurons are involved in generating pulses is unclear. Are they located in a specific area or intermingled with other GnRH neurons? Do the same GnRH neurons generate each pulse, or are they the same GnRH neurons as those generating the surge? The answers to these important questions remain to be determined. There is, however, some evidence that the caudal-most GnRH neurons may be specifically involved in pulse generation. Studies using cFos have reported that a small number of ~100 GnRH neurons located in the MBH of the sheep are activated prior to an LH pulse.[647] Similarly, the most caudal GnRH neurons in the rat express cFos following naloxone treatment that evokes a pulse of LH.[648]

Another pressing question is that of defining whether the GnRH neurons act independently or together with other neurons and glial cells within the network to generate GnRH pulses. It was expected that the ability to make electrical recordings from adult GnRH neurons in situ would be of considerable benefit in answering this question. Based on the observations from GnRH portal bleeding investigations and evidence that 10 Hz activation of GnRH terminals is required to release GnRH in the median eminence,[649] there was great expectation that at least some GnRH neurons would exhibit ~10 Hz firing for 5 min periods once every hour in gonadectomized rodents. As noted in the section GnRH Neuron Electrophysiology, electrical recordings from individual adult GnRH neurons in the rodent brain slice have not found such a correlate or resolved the issue of GnRH pulse generation. Although most GnRH neurons in vitro fire in a bursting mode, this occurs as ~2 s bursts most often every 20 s, whole orders of magnitude out of phase with 5 min LH pulses that occur once every hour. Furthermore, on rare occasions where it has been possible to record the burst firing of multiple GnRH neurons in the same slice preparation, there has been no evidence found for the synchronization of bursting between cells.[650] This complete failure to provide any temporal correlation between episodic GnRH neuron firing patterns and pulsatile GnRH secretion suggests that either: (1) GnRH neuron burst firing measured at the cell body is not driving the patterning of secretion at the median eminence, or (2) that the acute brain slice procedure is inappropriate for examining this issue. The recent demonstration that only ~15% of GnRH neurons exhibit burst firing in vivo[90] may support the second possibility.

The inability to detect GnRH neurons displaying the expected "electrophysiological pulse profile" has greatly hindered progress in identifying how GnRH pulses occur. As the importance of GnRH neuron burst firing to pulsatile LH secretion remains dubious, whether or not burst firing originates from intrinsic and/or extrinsic mechanisms within the GnRH neuron (see the section GnRH Neuron Electrophysiology) is not especially helpful in deciphering the mechanism generating LH pulses. Arguably, most progress in understanding this mechanism has come from experiments involving embryonic GnRH neurons. After two to three weeks in culture, embryonic nasal explant cultures begin to exhibit pulsatile GnRH release with a frequency of ~50 min in the monkey[651] and sheep,[652] ~30 min in the rat,[653] and ~25 min in the mouse.[654]

Terasawa and colleagues have examined the cellular mechanisms behind this pulsatile GnRH secretion in the monkey olfactory placode and shown that GnRH neurons exhibit calcium oscillations with intervals of ~8 min and that these become synchronized every 50 min.[121,655] A similar scenario was reported by the Wray laboratory for GnRH neurons from the mouse olfactory placode where calcium peaks synchronized every ~20 min and that, when >30% of GnRH neurons were involved in a synchronized event, this was associated with a GnRH pulse.[122,654] As in adult GnRH neurons,[58] the calcium peaks in cultured embryonic cells reflect episodes of bursting electrical activity.[656] As such, these data suggest

that synchronization mechanisms exist between embryonic GnRH neurons that are important for generating pulsatile GnRH secretion. Although enriched in GnRH neurons, these preparations also contain other neuronal and nonneuronal cell types, and it remains to be determined whether GnRH neurons interact with these other cells to generate a pulsatile pattern of release.[657]

Another experimental model that has been used to examine GnRH pulsatility has been the GnRH-secreting GT1 cell line. As these cultures contain only GnRH-secreting cells, their ability to generate pulsatile GnRH secretion with an interpulse interval of 20–40 min[103] has been taken to infer that GnRH neurons can generate pulses on their own. However, the relevance of GT1 cells to adult GnRH neurons in vivo has increasingly been questioned. With regard to pulsatility, episodic GnRH secretion from GT1 cells is known to depend upon extensive gap junctional coupling.[658,659] However, adult GnRH neurons in vivo do not utilize gap junctions for communication.[105] Thus, while it remains interesting that cultured GT1 cells can organize themselves into an episodic secretory population, the mechanism being used does not resemble that employed by GnRH neurons in vivo.

Other avenues of investigation into the nature of GnRH pulsatility have focused upon the roles of cAMP and circadian clock genes in GnRH neurons. In terms of the former, using a rat transgenic strategy, Weiner and colleagues reported that the depletion of cAMP levels within GnRH neurons reduces pulsatile LH secretion in vivo.[660] Whether this depletion in cAMP acts specifically on the pulse-generating mechanism or more generally to alter electrical excitability of GnRH neurons is not known. The appeal of circadian genes as modulators of episodic activity in GnRH neurons has been substantial[661] despite the difficulty of aligning a 24 h process with the 30–60 min pulsatility required for GnRH neurons. Nevertheless, molecular clocks with periodicity as low as 2 h have been reported,[662] and, overall, their importance in pulse generation remains to be determined.

GnRH Neuron Synchronization

At least a subpopulation of GnRH neurons must be synchronized to achieve episodic GnRH secretion at the median eminence. How this occurs remains unknown and leaves room for speculation about the possible mechanisms. Two possible models for GnRH neuron synchronization are noted below (Figure 11.8).

Intrinsic Pulse Generation

This model is centered around GnRH neurons themselves having sufficient interconnectedness to achieve a synchronous output (Figure 11.8). This is termed *intrinsic* in that it involves only GnRH neurons. Precisely how individual GnRH neurons may communicate with one another to achieve this synchronization is unclear. Classical neurotransmission between GnRH neurons using GnRH or one of its co-expressed transmitters is one possibility. Studies indicate that GnRH has modest stimulatory effects on the excitability of about 50% of GnRH neurons (see the section Neuronal Elements). Alternatively, as some GnRH neurons may co-express glutamate (see the section Neurotransmitters Co-expressed by GnRH Neurons), this may provide a more potent synchronizing stimulus. To date, however, limited numbers of dual recordings from GnRH neurons in the brain slice have failed to show any classical form of reciprocal neurotransmission.[105] Humoral forms of intercommunication between GnRH neurons have also been proposed. Intriguingly, acutely disassociated adult hypothalami secrete GnRH in a pulsatile manner that is not different to that of intact hypothalami maintained in vitro.[430,663] These data suggest that diffusible molecules may be involved in the synchronization of GnRH release in vitro. Roles for NO,[469,664] endocannabinoids[268,614] and ATP[655] have been suggested, although, in these cases, the source of synchronizing influence would not be "intrinsic".

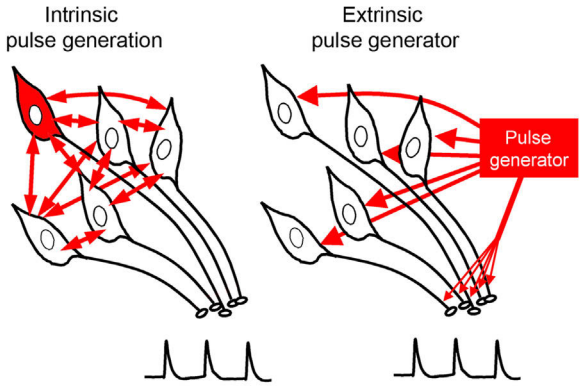

FIGURE 11.8 GnRH neuron synchronization. Schematic diagram showing two potential models for GnRH neuron synchronization. In the Intrinsic Model, the GnRH neurons alone are able to form reciprocal communication with one another thus allowing a buildup of network excitability. The episodic nature of this activity might be driven by one subset of GnRH neurons (shaded) that determine the pace of the interconnectedness. In the Extrinsic Model, the synchronization of the GnRH neurons is generated and controlled by a remote set of neurons with pulse-generating properties.

If the GnRH neurons are able to influence each other's activity, the source of the periodicity needs to be ascertained. It may be that a small subset of GnRH neurons has pulse generator capabilities and is able to drive the activity of all the others. This possibility takes inference from investigations in magnocellular oxytocin neurons where prior to the beginning of each oxytocin burst, "leader" oxytocin neurons become activated and then drive or recruit the activity of the rest of the oxytocin neurons

to generate a period of synchronous high frequency firing.[665] Based on cFos expression studies, "surge GnRH neurons" do not all suddenly fire together at the onset of the surge but, rather, appear to be progressively recruited over the ascending phase of the surge.[666] Interestingly, a very small number of burst-firing GnRH neurons (~1%) exhibit large "spontaneous" membrane oscillations that might represent a strong driving force within the GnRH neuron population.[100] It may, of course, also be the case that there is no "leader" group of cells and that excitability gradually gains momentum both spatially and temporally within the appropriate GnRH neuron population until it reaches a level upon which coordinated bursting activity of large numbers of GnRH neurons occurs.

Extrinsic Pulse Generation

This model is based around the possibility that GnRH neurons have no powerful direct interactions with one another and that the synchronizing influence is generated by an entirely separate group of neurons within the GnRH neuronal network (Figure 11.8). There are, in fact, several blends of this model that extend from GnRH neurons being complete slaves to an extrinsic pulse generator, through to them having a modest degree of episodic activity that is enabled or further entrained by network interactions. For example, in the deafferentated acute brain slice, the short 2 s burst behavior of GnRH neurons may represent something akin to an idling engine awaiting extrinsic acceleration.

Where the extrinsic pulse generator(s) may reside is difficult to assess and controversial. Studies in the rat have suggested that neurons located in the MBH may comprise a critical element of the pulse-generating network. Deafferentation experiments in which the preoptic area is disconnected from the MBH were found to be compatible with pulsatile LH secretion.[667–669] However, as there is an almost complete absence of GnRH neuron cell bodies in the MBH of the rat, it is difficult to understand how the dendron or terminals alone could maintain GnRH secretion for anything more than a few hours. Importantly, subchiasmatic projections from preoptic GnRH neurons to the median eminence were discovered, and it is possible that these were left intact in these deafferentation studies.[670] Those investigations may have revealed, instead, that a small number of preoptic GnRH neurons using a subchiasmatic axonal pathway are sufficient to enable pulsatile GnRH secretion.[670] Nevertheless, Weick and colleagues[668] found that, when combined with anterior hypothalamic deafferentation, highly localized lesions of the rostral-most pole of the ARN completely abolished pulsatile LH release. A similar effect was found when deafferentation procedures involved the rostral ARN[671] suggesting that a group of cells in this area, or fibers passing through it, were critical for pulsatile LH release. Interestingly, electrolytic or chemical lesions of the main body of the ARN itself have no effect upon pulsatile LH secretion with or without anterior hypothalamic deafferentation,[668,672] suggesting that it may be cells or fibers passing through the rostral pole of the arcuate nucleus that are critical.

As monkeys and sheep have GnRH neuron cell bodies spread throughout the preoptic area and MBH, similar types of lesion studies may not be as revealing in terms of defining the location of neurons involved in the pulse generator. Nevertheless, in both species, anterior hypothalamic deafferentation studies indicate that GnRH neurons within the MBH are sufficient to maintain pulsatile GnRH secretion,[673–675] although they do not exclude a similar role for preoptic GnRH neurons under normal circumstances. However, relatively selective lesions of the ARN in two monkeys were shown to suppress LH secretion, indicating a clear role for this brain region in the regulation of LH secretion.[676] Electrical multiunit recording studies have further shown an excellent correlation between the occurrence of action potential volleys in the MBH and pulsatile LH secretion in several species.[677–680] However, despite speculation that it may be the kisspeptin neurons,[510] the identity of the cell types generating these multiunit recordings has not been determined to date.

A pulse generator may regulate the GnRH neuron cell bodies, dendrons, and/or terminals to synchronize and drive episodic activity (Figure 11.8). A recent study found that the long dendrites of GnRH neurons often bundle together and receive shared synapses where one axon innervates two adjacent bundling dendrites.[37] Although the identity of the axons participating in the shared synapses is not known, this observation provides key information that synchronization may occur through afferent input to the dendrite/dendron. Indeed, the clustering of GnRH neuron dendrons and terminals in the vicinity of the median eminence makes them very attractive targets for any external synchronizing influence. Curiously, episodic GnRH release is reported to continue for several hours in vitro in the absence of the GnRH cell bodies[409,681,682] suggesting that some degree of synchronization exists at the GnRH neuron distal dendron and terminal. The nature of this synchronizing influence is unknown and may derive from synaptic inputs from a pulse generator located in the adjacent ARN, for example, or as a humoral form of communication, for example, by NO.[626,683]

As noted, these models are speculative and represent theoretical models for experimental testing. It seems most likely to the author that GnRH pulse generation occurs from a blend of intrinsic interconnectedness coupled with an external pulse generator.

Generation of a GnRH Surge

It is well established that the preovulatory LH surge in mammalian females is generated by a relatively

abrupt and prolonged increase in GnRH release within the portal vasculature[631,632,634,638,684–692] (Figure 11.9). Detailed analyses of portal GnRH secretion in the ewe have shown that GnRH release changes from a strictly episodic pattern to one of significant nonepisodic GnRH release intermingled with high-frequency pulsatile GnRH secretion prior to the surge.[690,693,694] Ultimately, the GnRH surge itself appears to be composed of high-frequency pulsatile events superimposed upon a high constant level of GnRH outpouring (Figure 11.9). This massive increase in GnRH secretion continues for a period of >24 h, considerably beyond the duration of the LH surge it induces, before returning to a strictly episodic pattern of release.[684,689]

The profile of the GnRH surge is thought to be similar in other species although, because of technical constraints, less detailed information is available. In the monkey, both median eminence and third ventricular monitoring of GnRH concentrations have shown that a marked increase in GnRH release occurs at the time of the LH surge.[687,688] The precise profile of GnRH release has not been studied on a minute-by-minute basis but seems likely to be comprised of pulsatile events superimposed upon high basal outpourings of GnRH.[687] Like the sheep, the GnRH surge in the monkey long outlasts the LH surge.[687] Investigations of this kind in the rat have used push–pull or microdialysis approaches to sample GnRH in the median eminence. Hampered by a lack of good temporal resolution, these studies have, nevertheless, reported a clear increase in GnRH secretion correlated with the LH surge.[630,685,686] The dynamics of the GnRH surge in the rat appears to take the form of a marked increase in GnRH pulse amplitude with more minor variations in GnRH pulse frequency and interpulse secretion.[630,639,695,696] Whether the proestrous increase in GnRH secretion in the rat persists for several hours after the end of the LH surge, as it does in the sheep and monkey, is not clear.

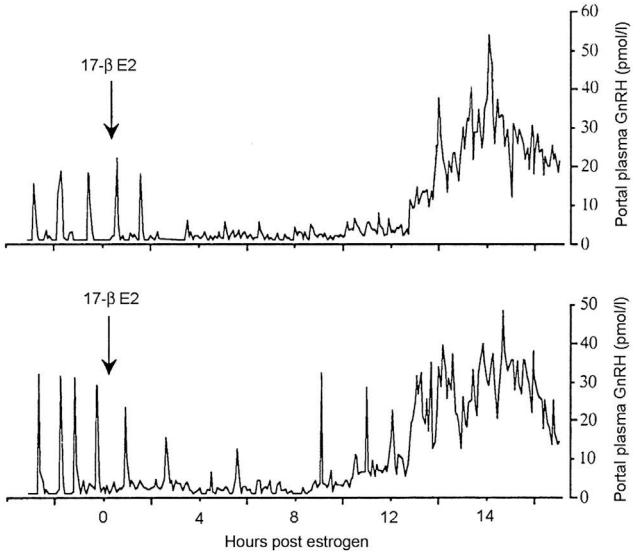

FIGURE 11.9 Effects of estradiol on GnRH secretion in vivo. Portal plasma GnRH concentrations in two OVX ewes showing their response to parenteral 17β-estradiol administration. Note that GnRH secretion is clearly pulsatile with sharp episodes of GnRH secretion. Following estradiol there is a relatively rapid phase of negative feedback with reduced amplitude and frequency of GnRH pulses, which is then followed approximately 12 h later by an increase in pulsatile and baseline GnRH resulting in the GnRH surge. *Source: Adapted with permission from Caraty et al. (1989).*[632]

It seems highly likely that the GnRH neurons responsible for the generation of the LH surge represent a specific subpopulation. It is clear in the rat that ~50% of preoptic area GnRH neurons clustered around the OVLT express cFos at time of the surge,[17] and it seems reasonable to assume that these cells are activated to release GnRH at this time.[18] A similar situation exists in the mouse where ~50% of GnRH neurons around the OVLT and extending back into the AHA express cFos at the time of the surge.[89,477] Interestingly, the surge-activated GnRH neurons preferentially co-express galanin[205] and exhibit highly selective changes in spine density at the time of the surge.[46] Whereas similar studies in the sheep have also found that only a subpopulation of GnRH neurons express cFos at the time of the surge, no preferential topography of the cFos-expressing GnRH neurons was detected.[697] Intriguingly, no increase in the numbers of GnRH neurons expressing cFos was detected at the time of the surge in the monkey.[698]

Given that around half of GnRH neurons in the preoptic area are involved in the GnRH surge mechanism, it seemed likely that targeted electrical recordings of GnRH neurons in the acute brain slice would provide important information about their patterns of electrical activity at the time of the surge. Profiling of the surge in sheep indicated hugely elevated basal and episodic GnRH secretion into the portal vasculature (Figure 11.9). However, to date, only one group has reported any positive data on this subject. Using a model in which ovariectomized, estradiol-treated mice exhibit daily LH surges, mean GnRH neuron firing rates were found to be elevated by ~2-fold on the afternoon of the surge compared with ovariectomized, vehicle-treated mice.[98] The pattern of GnRH neurons firing was highly episodic in both surging and ovariectomized mice with no difference in instantaneous firing frequency. This was a surprisingly modest change in GnRH neuron firing considering the presumed substantial change in GnRH secretion that occurs ate this time in vivo.

As for the GnRH pulse, this lack of a substantial correlation between GnRH neuron firing in the brain slice and the GnRH/LH surge may arise as a consequence of the brain slicing or, indeed, represent the true situation at the level of the cell body. As noted in the section Glial Elements of the GnRH Network, there is substantial

morphological rearrangement of GnRH nerve terminals in relation to their proximity to the vasculature at the time of the surge, although this is unlikely on its own to drive sufficient GnRH secretion to account for the surge. Equally, it is possible that the surge is generated by alterations in synchronization at the level of the distal dendron. How this issue will be resolved remains uncertain, but it may, ultimately, require in vivo recordings of multiple GnRH neurons at the time of the surge.

HETEROGENEITY WITHIN THE GnRH NEURONAL PHENOTYPE

Aside from intrinsic properties common to all neurons, it would appear that the only features shared by all GnRH neurons are that of GnRH biosynthesis and the presence of functional GABA and glutamatergic inputs. Virtually everything else that has been described so far in GnRH neurons has been detected in only subgroups of these cells. As highlighted throughout the chapter, this heterogeneity exists across multiple parameters including GnRH neuron projection patterns, light and electron microscopic appearance, co-expression of neuropeptides, firing patterns, rates of GnRH biosynthesis, as well as ion channel and neurotransmitter receptor expression. Of these parameters, only two have functional correlates as yet. The first is whether GnRH neurons project to the median eminence or not—those that do being hypophysiotropic GnRH neurons and those that don't being involved in other ill-defined actions of GnRH within the brain. The second is their classification as to whether or not they express cFos at the time of the GnRH surge, where it is presumed that those that do are involved in GnRH surge generation.

The relationship of the various heterogenous features to each other has been difficult to ascertain. The one exception has been with regard to the GnRH neurons that express c-Fos at the time of the surge. This subpopulation of GnRH neurons is more likely to project outside the blood–brain barrier;[699] receive more galanin,[309] glutamate,[700] and vasoactive intestinal polypeptide (VIP)[701] inputs than other GnRH neurons; exhibit spine plasticity at the time of the surge;[46] be more transcriptionally active in terms of GnRH mRNA;[702] and are more likely to co-express galanin.[205] In the rat and mouse, these cFos-expressing GnRH neurons are found predominantly, but not exclusively, in the vicinity of the OVLT,[17,481] where gonadal steroids exert their most profound effects upon GnRH biosynthesis.[703–705] Together, these observations suggest that a functionally distinct subpopulation within the GnRH population is located preferentially around the OVLT and is involved in the generation of the GnRH surge.

Another potential functional subpopulation, but with much less supporting evidence, concerns GnRH neurons located in the MBH in appropriate species. Lesion studies in the monkey[673] and guinea pig[19] have indicated that GnRH neurons located in the mediobasal hypothalamus may be of particular relevance to episodic gonadotropin secretion in those species. Also, a study in the sheep indicated that MBH GnRH neurons expressed cFos preferentially in relation to LH pulses.[647] This subpopulation of GnRH neurons may also have a different pattern of innervation compared with GnRH neurons in the preoptic area in monkeys.[51]

Other heterogenous properties of GnRH neurons can also be distributed in a topographic manner. For example, the rostral-most GnRH neurons in the MS of the monkey do not project to the median eminence,[23] while only MS GnRH neurons in the rodent express the GalR1 receptor[213] as well as specific $GABA_A$ receptor subunit mRNAs.[706] However, not all MS GnRH neurons are alike as distinct populations of kisspeptin or metabotropic glutamate receptor-sensitive GnRH neurons are found in the mouse MS.[222] Viewed from a different neuroanatomical perspective, it has also been reported that the GnRH neurons located closest to the third ventricle express NMDA receptors whereas those placed more laterally do not.[707] Nevertheless, as noted before, many of the heterogenous characteristics of GnRH neurons occur in a manner independent of the location of the cell body. This is perhaps best highlighted by the observation that the hypophysiotropic GnRH neurons are scattered throughout the GnRH neuron continuum of rodents and sheep[14,16,53] and the preoptic area and MBH of monkeys.[23]

What is clear is that it is not appropriate to consider the GnRH neuron population as a homogeneous group of cells with a unitary function. A major challenge for future research will be to establish the functional significance of this extensive level of heterogeneity within the GnRH neuron population. With new techniques allowing better cellular and molecular definition of the GnRH neurons, it will likely become increasingly important to refine investigations to particular subsets of GnRH neurons.

ESTROUS CYCLE PLASTICITY

Whereas pulsatile GnRH secretion occurs in a regular and continuous manner in males, spontaneously ovulating females exhibit cycles of episodic GnRH secretion over the course of the ovarian cycle. This section concentrates upon the mechanisms responsible for this remarkable plasticity in the GnRH neuronal network of females. While taking insight from the sheep and monkey, the section focuses upon rodent studies. Readers are also

referred to other chapters in this book devoted to control of the ovarian cycle in the sheep and monkey. While dedicated to the understanding of GnRH neurons, it is appreciated that significant feedback actions also occur at the pituitary gonadotrope to help shape gonadotropin secretion (see Chapters 10,26,27,28 and 33 for a detailed review of this subject).

In female rodents there are clear interactions between a circadian signal and the fluctuating gonadal steroid concentrations that drive GnRH neuron network plasticity.[708–710] It is most convenient, therefore, to consider circadian and then estradiol and progesterone mechanisms separately before providing an integrated model for estrous cyclicity.

Circadian Inputs

In rodents, lesions involving the SCN result in a complete abolition of the preovulatory LH surge, indicating the critical role of this structure in generating a circadian signal within the GnRH network of these species.[711–715] Mutations of the core circadian clock gene *clock* also result in failed cyclicity and surges.[716] How the SCN relays this information to the GnRH neurons is under investigation with both direct and indirect pathways likely. The involvement of diffusible molecules originating from the SCN, as has been found for wheel-running rhythms,[717] seems unlikely to be relevant for GnRH neuron activation.[712,718]

Anterograde tracing studies have shown that SCN neurons project directly to the GnRH neurons in rodents[719,720] and that this principally involves VIP inputs from the ventrolateral SCN.[361,719] Experiments in the rat have shown that ~40% of GnRH neurons express the VIP receptor VPAC2[362] and that ~30% of GnRH neurons in the mouse are surrounded by VIP-immunoreactive fibers.[721] Furthermore, VIP inputs selectively target GnRH neurons that express cFos at the time of the surge.[701] Importantly, electrophysiological studies have recently shown that VIP exerts a time-of-day- and estradiol-dependent excitatory action upon a subpopulation of GnRH neurons; VIP increases the mean firing rates of approximately half of GnRH neurons from ovariectomized, estradiol-treated female mice but only when recorded between 1400 and 1600 h.[364]

In addition to direct projections to GnRH neurons, SCN inputs also innervate the AVPV where they likely regulate ER-expressing cells.[720,722] A circadian rhythm in cAMP levels exists within cells of the AVPV of the rat.[723] Recent studies have demonstrated that kisspeptin neurons in the AVPV exhibit circadian patterns of cFos, circadian transcription factors, and *Kiss1* gene expression, and that this likely originates from a dorsomedial SCN vasopressin input.[483–485,724,725] Interestingly, neonatal cocultures of the SCN and preoptic area that enable a circadian pattern of GnRH release to occur correlate better with vasopressin secretion rather than that of VIP.[653] Furthermore, the inability of *clock* mutant mice to exhibit an LH surge can be reversed to some extent by treatment with vasopressin acting through the vasopressin 1a receptor.[716] However, the precise effects of vasopressin on AVPV neurons are not as yet known.

Thus, the SCN appears to be able to deliver a circadian input to the GnRH neuronal network through at least two different pathways: one involving a direct likely VIP input to the GnRH neurons and another indirect vasopressin input to the AVPV neurons that then relay the signal to the GnRH neurons.[484] There is evidence that the effectiveness of both inputs is critically dependent upon the prevailing estradiol concentrations.[364,485] Similarly, circadian differences in GABA and glutamate inputs to GnRH neurons are only present in the presence of estradiol.[91,726] While there is a clear anatomical substrate for the interaction between vasopressin and estradiol within the ER-expressing cells of the AVPV, it is less certain how estradiol may modulate the direct VIP input to GnRH neurons.

Although the SCN undoubtedly provides circadian information to the GnRH neuronal network, exactly when this occurs is unclear. Classic studies using pentobarbital to anesthetize rats for 1–2 h identified a "critical period" of 5–7 h prior to "lights off," during which neural activity was essential for the LH surge to occur.[709] A similar time point of ~5 h prior to "lights off" has been demonstrated in the mouse.[726] It is possible that this critical period represents a time at which a key circadian signal is delivered to the network, although the importance of other neural processes mediating estradiol actions at this time cannot be excluded. Interestingly, a mouse model that clamps estradiol levels to examine circadian influences finds differences between GnRH neuron firing rates in the morning and afternoon in vitro,[98] suggesting that the circadian signal is "embedded" in the local circuitry even after brain slicing.

Estradiol Inputs to GnRH Neurons

In spontaneously ovulating species, the rising plasma estradiol levels of the mid-to-late follicular phase of the cycle evoke a positive feedback action upon the GnRH network to induce the gonadotropin surge. At other times of the cycle estradiol is responsible for exerting a suppressive negative feedback effect upon gonadotropin secretion. At least three fundamentally different modes of estradiol action work together to influence the output of the GnRH neuronal network, and these will be reviewed briefly before considering the negative and positive feedback mechanisms.

Direct Estradiol Actions on GnRH Neurons

Although initially controversial,[727] it is now well accepted that GnRH neurons express only the ERβ isoform of the ER in all mammalian species examined to date, including mice,[728] rats,[729–731] sheep,[732] and humans.[733] However, the classical transcriptional or other roles for ERβ in GnRH neurons remain unclear. The receptor is not required for the regulation of GnRH mRNA expression by estradiol[734] but may possibly have a role in steroid regulation of galanin synthesis in GnRH neurons.[735] There is also evidence that ERβ in GnRH neurons may mediate rapid effects of estradiol on GnRH neurons (see following).

One of the principal difficulties in assigning a physiological role for ERβ in GnRH neurons has been the highly variable reproductive phenotype of the different ERβKO mouse lines. The initial mouse line[736] was reported to have only modestly impaired fertility as female knockout mice had fewer litters and fewer pups. The next ERβKO line to be produced exhibited a more variable reproductive phenotype with female mice displaying normal fertility through to infertility.[737] As some of this variation may have resulted from the presence of ERβ splice variants missing exon 3, a complete ERβKO null mouse was generated in which ERβ and all of its known splice variants were deleted.[738] These mutant male and female mice were uniformly infertile with females displaying disordered estrous cyclicity. While much of the reproductive phenotype of these mice is attributed to abnormalities in the gonads,[737,739] it remains possible that some of the phenotype derives from ERβ expressed by GnRH neurons.

There has been substantial interest over the last decade in the possibility that estradiol may exert direct, nonclassical actions upon adult GnRH neurons (for recent reviews see Refs 740–742). This idea was spawned by an early electrophysiological study demonstrating a rapid hyperpolarizing influence of estradiol upon GnRH neurons in the guinea pig.[77] Subsequent investigations have shown that estradiol rapidly phosphorylates cAMP response element binding protein (CREB),[743] modulates potassium-ATP channels,[744] elevates intracellular calcium concentrations,[745] and also alters the firing rate[745–747] of adult mouse GnRH neurons. Estradiol has also been found to rapidly modulate calcium levels in embryonic GnRH neurons from the mouse and monkey.[748,749]

In relation to the acute effects of estradiol on GnRH neuron firing rate in adult mice, there has been little consensus between laboratories with inhibitory or excitatory effects reported to depend upon the dose of estradiol tested[746] or the basal level of GnRH neuron activity prior to testing with estradiol.[747] Some of this inconsistency may come from the use of the sudden bath application of widely varying low pM to high nM concentrations of estradiol in the face of almost no understanding of the actual profile and levels of estradiol a GnRH neuron would normally be exposed to during the estrous cycle.[741] Furthermore, the precise identity and location of the receptors mediating these variable rapid effects of estradiol on adult GnRH neurons are only poorly defined, with little evidence that they are, in fact, direct actions on GnRH neurons. Indeed, the only consistent finding from adult studies so far has been that low pM, presumably physiological, concentrations of estradiol act indirectly via ERα to modulate GABA inputs to GnRH neurons.[745,746] To date, CREB phosphorylation is the only rapid effect of estradiol on adult GnRH neurons that has been proven to depend upon ERβ expressed by these cells.[750] Whereas the rapid effects of estradiol on calcium peaks in embryonic GnRH neurons are also dependent upon ERβ in the mouse,[749] the receptors mediating these actions in the monkey are, curiously, different with both an STX-sensitive receptor and GPR30 implicated.[751]

In summary, while there is good evidence for the expression of ERβ in GnRH neurons, and therefore direct actions of estradiol on these cells, the transcriptional targets of ERβ remain unknown. Similarly, while there are now a plethora of nonclassical rapid effects of estradiol reported for GnRH neurons, deciphering which, if any, of these actions are physiologically relevant remains an important goal.

Indirect Transsynaptic Pathways of Estradiol Action

Given the predominant role of ERα in mediating estrogen feedback actions upon GnRH neurons (see following) and absence of ERα in GnRH neurons,[727] it is apparent that estradiol must exert significant indirect actions on GnRH neurons. In this light, it has been a major challenge to ascertain the locations of estrogen-receptive afferent inputs to GnRH neurons. This is no trivial matter and has been frustrated by conventional tract-tracing methodologies not being able to generate any definitive description of the identity and locations of ER-expressing neurons that project to the GnRH neurons. For example, it has been possible to define the locations of ER-expressing neurons that project to the general vicinity of the GnRH cell bodies,[550] but it has not been possible to confirm that these cells make direct synaptic contacts with GnRH neurons.

The combination of transgenic strategies with viral tract tracing has recently made it possible to undertake GnRH neuron-specific retrograde tract tracing in the mouse brain.[752] Using this approach, the primary afferents to preoptic GnRH neurons have now been determined in the mouse.[249,477,753] Dual labeling for ERα in these experiments demonstrated that the estrogen-receptive primary afferents to GnRH neurons are highly

concentrated within three contiguous hypothalamic nuclei: the AVPV, PVpo, and median preoptic nucleus, subsequently defined as the RP3V.[442] A smaller number of ERα-expressing afferents were also found within the arcuate nucleus.[477] While these brain areas were not entirely unexpected, this tracing strategy provided the essential neuroanatomical framework for understanding the direct transsynaptic regulation of GnRH neurons by estradiol.

Key questions remain as to what the neurochemical phenotypes of these ER-expressing cells may be. Likely cell types within the RP3V include neurons utilizing GABA,[754,755] glutamate,[756] or both amino acid transmitters,[757] as well as neuropeptides such as neurotensin[758] and kisspeptin.[441,480,481] The development of a new angled brain slice preparation has enabled the functional effects of AVPV afferents to GnRH neurons to be examined in situ. This approach has provided functional evidence that AVPV neurons expressing GABA, glutamate, and kisspeptin all project to and regulate the excitability of GnRH neurons.[92]

Indirect Non-Neuronal Sites of Estradiol Action

As noted in the section Glial Elements of the GnRH Network, glial cells form close structural and signaling relationships with GnRH neuron cell bodies, dendrites, and terminals. As astrocytes and ependymal cells express both classical and membrane ERs,[759–761] they may serve as indirect targets for estradiol to alter the activity of GnRH neurons. Importantly, estradiol-dependent alterations in glial cell morphology are not necessarily slow, and significant changes may be observed within 5 h in vitro.[762]

In terms of direct structural modifications, an ultrastructural study in the monkey reported that ovariectomy resulted in a significant increase in the apposition of glial processes to the GnRH neuron soma, with a concomitant decrease in synaptic input, and that this was partly reversed by estradiol treatment.[51] This effect was not observed in the female rat[763] but, nevertheless, suggests the possibility that glial cell "wrapping" of GnRH neurons may be regulated by estradiol and that this may impact on the amount of synaptic innervation a cell receives.

In contrast to the cell body, there is more substantial evidence that the GnRH nerve terminals are subjected to estradiol-dependent glial cell wrapping. In this case, estradiol modifies the tanycyte envelopment of the GnRH nerve terminals so that, at the time of proestrus, the tanycytic end-feet are retracted, allowing increased numbers of GnRH terminals within the pericapillary space.[64,65,764] Recent investigations have identified that the high levels of estradiol on proestrus act through at least two mechanisms to retract the tanycytic end-feet: one involving the promotion of TGFα levels within the median eminence and the other enhancing NO release from endothelial cells[623,625] (see the section Glial Elements of the GnRH Network).

The other potential mechanism through which glial cells could contribute to the plasticity of the network would be through the estradiol-dependent secretion of molecules that regulate the activity of GnRH neurons. For example, an important role for prostaglandins secreted by astrocytes neighboring GnRH neurons was recently revealed in controlling the electrical excitability of GnRH neurons.[615] However, it remains unclear whether this signaling pathway is modulated by gonadal steroids. Although estradiol is reported to increase PGE2 receptor expression in GnRH neurons,[765] the impact of PGE2 on GnRH neuron excitability was found to be equivalent throughout the estrous cycle.[615] Other molecules secreted by glial cells, such as TGFβ,[766] are known to be estradiol sensitive, but their role in driving estrous cycle plasticity in vivo remains unclear at this time.[767]

Estrogen Positive Feedback

It is first important to define what the positive feedback effects of estradiol are on GnRH neurons. In terms of GnRH secretion, some of the most useful data have come from portal bleeding experiments in sheep.[632,640,693,694,768] Those studies demonstrate that the first change from the strictly episodic negative feedback pattern of GnRH secretion begins about 4 h before the onset of the GnRH surge when significant interpulse GnRH secretion is observed. This is followed by an increase in GnRH pulse frequency and amplitude and further enhanced by elevated interpulse secretion over the next 2–4 h immediately prior to the abrupt onset of the GnRH surge comprised of a massive, continuous release of GnRH with superimposed pulses. Hence, in the ewe, estradiol's positive feedback effects are to evoke a gradual increase in episodic GnRH secretion alongside the initiation of a continuous pattern of release that ultimately "explodes" into the prolonged GnRH surge (Figure 11.9). Portal bleeding studies have not been possible in the rat, but there is, nevertheless, evidence of increased irregular GnRH secretion prior to the surge in this species as well.[696] The activation of preoptic GnRH neurons, as evidenced by cFos expression, suggests that while the first cells are activated rather abruptly, the remaining "surge" neurons are progressively recruited as the GnRH/LH surge advances.[666]

How does estradiol, in association with a circadian input in rodents, bring about these changes in GnRH neuron secretion? One clue lies in the dynamics of the estradiol signal that are interpreted by the GnRH network to evoke the surge. In all mammalian species, the LH/GnRH surge is only induced by an estradiol signal of sufficiently high or increasing levels that lasts for several hours.[632,687,689,708,769–772] Attempts to refine the

exact period of estradiol exposure required in the ewe have suggested that a 7–14 h period is the absolute minimum.[773] Critically, as found earlier for the LH surge in the rat,[708] studies in the sheep also reported that estradiol did not need to be present at the actual time of surge initiation for a normal GnRH surge to occur.[773] Together, these observations indicate that the GnRH network "reads" a prolonged, high circulating estradiol concentration as the appropriate signal to initiate positive feedback. The length of the estradiol exposure and the fact that estradiol need not be present at the time of surge onset itself is compatible with the idea that estradiol acts in a classical genomic manner to alter gene expression profiles within the network to induce the surge. This concept has been supported by a study showing that mice expressing a mutated ERα unable to bind to DNA estrogen response elements are unable to generate positive feedback.[774]

Which cell types within the network might be regulated by estradiol in this manner to induce the changing patterns of GnRH release at the time of the surge? Several lines of evidence strongly suggest that estradiol uses an ERα-expressing RP3V transsynaptic input to drive positive feedback in rodents (for review, see Ref. 442) (Figure 11.10).

Lesion, Implant and Neurochemical Studies

The great majority of lesioning and estradiol implant studies addressing the sites of action of estradiol in regulating LH secretion have been undertaken in the rat. Lesions of both of the principal RP3V nuclei, the AVPV and PVpo, were found to result in persistent estrous and the abolition of the estradiol- or estradiol-plus-progesterone-induced LH surge.[711,775,776] Furthermore, estradiol placed in the medial preoptic area was able to generate an LH surge in the rat,[777,778] while similarly positioned implants of antiestrogens inhibited the estradiol-induced LH surge.[779,780] In contrast, implants of estradiol into the MBH do not elicit a surge-like alteration in LH secretion in the rat.[777,778]

There is abundant ERα and ERβ expression within neurons of the RP3V,[758,781,782] and a subpopulation of ERα-expressing neurons in this region provides direct inputs to GnRH neurons in the mouse.[477] This, coupled with cFos evidence for the activation of RP3V neurons at the time of the LH surge in rats and mice,[481,783] strongly suggests that estradiol regulates the activity of RP3V neurons to activate GnRH neurons.

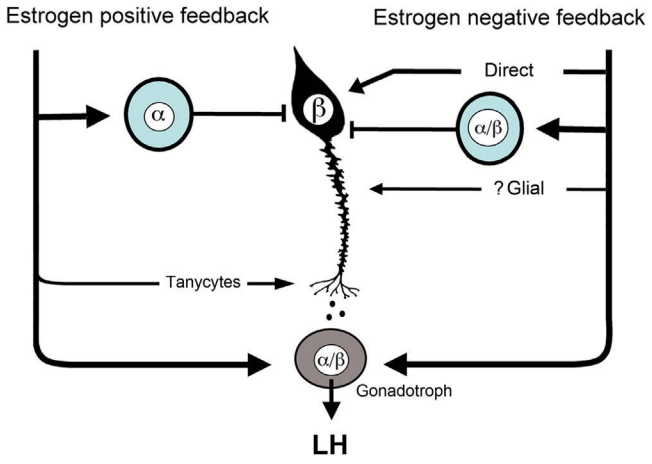

FIGURE 11.10 Model of estradiol feedback actions. Schematic diagram showing proposed modes of estradiol action within the GnRH neuron network for positive and negative feedback. α and β indicate location of ERα and ERβ, respectively.

Transgenic and Mutant Mouse Studies

The generation of mouse models with ER deletions and mutations has been important in determining the ER isoform involved in positive feedback. The global ERαKO mouse lines are infertile with severely abnormal gonadotropin hormone levels whereas, as noted above, ERβKO mutants show a milder hormonal phenotype and varying degrees of infertility.[734,736,737,739,784] Investigations employing global ERαKO and ERβKO mice have shown that the LH surge is absent in ERαKO mice but present in ERβKO.[477] Furthermore, studies with ERα- and ERβ-selective agonists demonstrate that only ERα activation can evoke the LH surge in wild-type mice.[477] Using cell-specific transgenic strategies, it was also shown that it is neurons expressing ERα rather than other cell types that are essential for the LH surge in mice.[477] Together, these studies identified that ERα-expressing neurons are both necessary and sufficient for the estrogen positive feedback mechanism in mice. This does not mean that ERβ or nonneuronal ERα-expressing cells are not involved in the surge mechanism, rather that they play a replaceable or modulatory function within the network. For example, the infusion of an ERβ antisense oligonucleotide into the third ventricle of rats prolongs estrous cycle duration but does not stop it.[782]

GnRH Neuron Electrophysiology Studies

Using a daily surge mouse model, investigators have shown that mean GnRH neuron firing rates are elevated at the time of the surge compared with recordings made earlier in the morning.[98] As this model clamps estradiol at a constant high level, it is unclear what the impact of estradiol is other than enabling a strong circadian imprint on the network. Nevertheless, this important facilitatory role of estradiol is known to be dependent upon classical ERα signaling[785] and correlated with changes in $GABA_A$ receptor signaling.[91] Other studies using standard ovariectomized, estradiol-treated mouse models have indicated that the rising levels of estradiol required to generate the LH surge are correlated

with increased expression and function of T-type calcium channels in GnRH neurons.[116] These channels are involved in rebound excitation and have been suggested to contribute to increased excitability of GnRH neurons on proestrus.[116]

Specific ERα–RP3V Afferents to GnRH Neurons

The previous studies provide good evidence that an ERα-expressing population of cells located in the RP3V relays the estrogen positive feedback signal to GnRH neurons in rodents. A variety of classical neurotransmitters and neuropeptides are synthesized by RP3V neurons, and several of these are known to express ERα including glutamate,[756] GABA,[755] dynorphin,[786] enkephalin,[786,787] galanin,[788] substance P,[789] calcitonin gene-related peptide,[790] kisspeptin,[441,480,481] and neurotensin.[758] At present, a case for the involvement of RP3V glutamate, GABA, and kisspeptin neurons can be made in the positive feedback mechanism, with a role for neurotensin recently being excluded in the mouse.[331]

Glutamate. Glutamatergic neurons in the AVPV provide direct inputs to GnRH neurons and act to enhance GnRH neuron excitability.[92] Furthermore, "surge GnRH neurons" exhibit a substantial increase in dendritic spine density at the time of the surge, and it is possible that spine density reflects glutamatergic input to these cells.[46] Glutamate levels are reported to increase within the vicinity of the GnRH neuron cell bodies at the time of the surge in the rat,[791,792] although it is not certain whether this glutamate arises only from RP3V afferents. Recordings of glutamate-mediated postsynaptic events in adult GnRH neurons in the brain slice have failed, however, to detect any change at the time of positive feedback, although it needs to be borne in mind that this study was only able to measure action potential–independent glutamate activity.[370] Finally, although not addressing the role of RP3V glutamatergic cells specifically, antagonists of glutamatergic receptors administered into the ventricular system of rats block the occurrence of the LH surge.[417,418,793]

GABA. There is a consistent set of data across species showing that GABA levels within the vicinity of the GnRH cell bodies rise in the morning and then fall precipitously in the afternoon just before the onset of the LH surge.[791,794–797] Pharmacological studies with $GABA_A$ receptor antagonists have further indicated that this fall in GABA release is necessary for the GnRH surge to proceed.[397,798,799] Whether this fluctuation in GABA levels results from changes in circulating estradiol concentrations and/or circadian influences remains unclear.[573,796] The origin of GABAergic inputs to GnRH neurons is unclear as, in addition to a substantial input from the RP3V,[92] GABA neurons in the lateral preoptic area,[373] as well as many other possible locations, innervate GnRH cells.

Perhaps more problematic is determining what effects these changes in GABA levels may have on GnRH neuron excitability. A study examining $GABA_A$ receptor–mediated synaptic events on GnRH neurons in the brain slice found that their frequency and amplitude increases in about one-third of GnRH neurons at the predicted time of the onset of the GnRH surge.[91] This temporal profile of changing $GABA_A$ receptor activity does not, however, fit with the in vivo microdialysis and push–pull analyses noted previously, and indicates that either: (1) the GABA release data are not an appropriate representation of GABA concentrations at the $GABA_A$ receptors expressed by GnRH neurons; or (2) that the brain slice is not providing a true reflection of GABA inputs in vivo. It is very likely that both of these possibilities are in play. Although the great majority of in vivo i.c.v. experiments indicate that $GABA_A$ receptor activation is inhibitory to LH secretion,[3] it needs to be borne in mind that i.c.v. drug administration is a very blunt tool for probing neuronal circuitry in the brain. Equally, the GnRH neuron in the brain slice suffers from substantial deafferentation, with all distant GABAergic inputs to GnRH neurons being absent. The final solution to this issue seems likely to require better experimental models of the GnRH neuronal network. For example, the use of thick hypothalamic "chunk" rather than a thin brain slice has shown that the effects of GABA on GnRH neurons are dependent upon how much of the GnRH neuron soma and dendron exist in the preparation.[89] Ultimately, however, this issue may only be resolved in vivo. Interestingly, a mouse model in which 70–90% of $GABA_A$ receptor signaling was deleted selectively from GnRH neurons exhibited normal positive feedback.[394]

The GnRH neurons also express $GABA_B$ receptors,[366,367] and GABA release activated from the RP3V can, at higher stimulation frequencies, inhibit GnRH neuron activity through the $GABA_B$ receptor.[92] Thus, there may be a fine balance between the amount of GABA released and whether it activates stimulatory $GABA_A$ receptors and/or inhibitory $GABA_B$ receptors. In addition, it is now recognized that $GABA_B$ receptors exert a potent inhibitory presynaptic influence on RP3V terminals synapsing on GnRH neurons.[366] Intriguingly, the potency of these $GABA_B$ receptors declines substantially at proestrus, thereby maximizing the influence of RP3V inputs on GnRH neurons at this time.[366]

Kisspeptin. The RP3V kisspeptin neurons have all the characteristics required of a neuronal phenotype involved in the positive feedback mechanism. These cells project to GnRH neurons and, when activated at >5 Hz stimulation frequencies, release kisspeptin to initiate prolonged GnRH neuron firing.[92] The RP3V kisspeptin neurons are highly sexually dimorphic, being 20-fold more plentiful in females,[440,475] express ERα,[441,480,481] and exhibit estradiol-regulated currents determining their intrinsic

excitability.[478] On the basis of cFos expression, RP3V kisspeptin neurons are activated at the time of surge onset in parallel with that of the GnRH neurons.[441,480,481] It is noteworthy, however, that recent electrophysiological studies of RP3V kisspeptin neurons did not find a significant change in kisspeptin neuron firing rate at the time of the surge in the acute brain slice.[496] Again, this may be due to the deafferentation of the kisspeptin neurons in that preparation. Finally, although not selective for the RP3V, mice with global mutations of kisspeptin or GPR54 fail to exhibit positive feedback,[481] as do mice with ERα deleted from all kisspeptin neurons.[482]

In summary, a variety of investigations now provide solid evidence that estrogen positive feedback in rodents originates primarily from classic transcriptional activity of ERα within RP3V neurons. While an important role for kisspeptin neurons has been delineated in transmitting this excitatory stimulus to GnRH neurons, it is likely that other transsynaptic inputs are also involved. As yet, there is a relatively poor correlation between the firing rates of GnRH neurons measured in the acute brain slice with the presumed massive increase in GnRH secretion within the median eminence of the mouse. The ERα-expressing cells of the RP3V provide a convenient locus for the integration of estradiol and circadian stimuli within the network, but precisely how this may occur remains a mystery. Outside of direct transsynaptic modes of action for positive feedback, there is also compelling evidence for estradiol-dependent morphological rearrangements involving the GnRH nerve terminals, although their relative importance to the generation of the GnRH surge remains to be established.

Estrogen Negative Feedback

Compared with the positive feedback mechanism, where there has been significant progress over the last decade, the mechanisms underlying estrogen negative feedback remain unclear. Indeed, the potent negative feedback actions of estradiol at the pituitary gland have made it difficult to establish whether there is a significant role for the GnRH neurons in this mechanism. Nevertheless, by measuring GnRH secretion directly in a variety of species, it has been possible to show that bolus estradiol administration to gonadectomized animals results in a relatively rapid (1–2 h) suppression of GnRH secretion[632,770,800] (Figure 11.9). These changes principally involve a decrease in GnRH pulse amplitude although changes in frequency have also been observed.[637,800,801] In rats, the opposite strategy of examining the effects of gonadectomy on GnRH secretion has also been assessed. The results of these studies indicate that the time following gonadectomy is critical as male rats gonadectomized for over 1 month showed no difference in GnRH secretion[630] whereas rats gonadectomized for 1 or 4 days exhibited significant increases in GnRH pulse frequency and/or amplitude.[633,802]

Brain Sites and ER Isoform Studies

The brain sites at which estrogen negative feedback occur have been difficult to elucidate. In rats, estradiol implants within the vicinity of the GnRH cell bodies in the preoptic area[803] as well as within the MBH[804–806] have been shown to suppress LH secretion. Although some of the MBH results may have been confounded by diffusion of estradiol to the pituitary,[807] the suppressive effects of estradiol within the preoptic area do not agree with observations that antiestrogen implants or lesions of this area do not prevent negative feedback.[711,776,779,780] Thus, it remains unclear where within the brain estradiol acts to suppress GnRH release in rodents.

Investigations employing mouse genetic models have been used to determine the ER isoform involved in estrogen negative feedback in the mouse. As for positive feedback, ERα appears to be the major receptor involved. Basal LH levels in intact ERαKO mice are similar to those of OVX wild-type mice and do not suppress following estradiol treatment.[739,808] This clearly suggests a major role for ERα in negative feedback somewhere within the pituitary and/or GnRH network. Both the pituitary- and neuron-specific ERαKO mouse lines can exhibit normal basal LH levels, indicating that one system may compensate for the deletion of the other.[477,809] The modest suppressive influence of gonadal steroids upon GnRH mRNA expression is also absent in ERαKO mice,[734] indicating that ERα-dependent elements are also involved in the suppression of GnRH biosynthesis.

Importantly, it appears that ERα acts in both a classical and nonclassical manner to suppress LH secretion. The generation of a mouse line in which ERα is no longer able to bind to consensus DNA estradiol response elements revealed that approximately 50% of estradiol-induced LH suppression resulted from classical ER signaling while the other half utilized a different mechanism.[774] In contrast to ERα, the ERβKO mouse exhibits normal[739] or only modestly impaired[734] LH levels and normal GnRH mRNA negative feedback.[734] Thus, at present, the role of ERβ, and ERβ expressed by GnRH neurons, in estrogen negative feedback cannot be excluded, but appears to be relatively minor compared with ERα.[810]

GnRH Neuron Electrophysiological Studies

Several GnRH neuron electrophysiological studies have been undertaken by the Moenter group examining the firing rates of GnRH neurons at the time of negative feedback. Initially this group examined GnRH neurons in a standard ovariectomized, estradiol-treated mouse model where recordings were undertaken in the afternoon 7 days after ovariectomy and estradiol/oil replacement. Although finding that overall mean GnRH

neuron firing rates were not different between ovariectomized and estrogen negative feedback mice, a significant difference was detected in the patterning of firing with estradiol-treated mice having longer and more frequent silent periods.[99] A further study in this model revealed that estradiol regulated the expression of two different potassium channels, although in such a way that it would contribute to increased, rather than decreased, GnRH neuron excitability at a time of negative feedback.[109] It has later been suggested by the authors that the timing of this model may in fact reflect estrogen positive feedback mechanisms.[98]

Subsequent studies by the Moenter laboratory have used an estradiol-treated, ovariectomized mouse model that uses constant high estradiol levels to generate an LH surge every day. Caution needs to be taken in interpreting the results of these investigations as circadian factors are the key determinant of dissimilarities between morning and afternoon recordings, rather than the normal differences in circulating estradiol levels found across the 4–5 day estrous cycle. Under these circumstances, "morning recordings" show GnRH neurons to have a significantly lower mean firing rate than "afternoon recordings," and this is dependent upon amino acid transmission and classical ERα signaling.[98,726,785] However, comparisons between mean firing rates in the morning from ovariectomized oil- and estradiol-treated animals revealed no significant differences, indicating little correlation between GnRH neuron firing and the known high and low LH levels at these times.[98] Interestingly, despite having similar mean firing rates, the frequency of ionotropic glutamate receptor-mediated events in GnRH neurons was markedly reduced in morning recordings of estradiol-treated mice compared with ovariectomized controls.[370] This suggests that glutamatergic inputs are modulated by estradiol-dependent circadian factors in this mouse model.

Direct GnRH Neuron and Rapid Estradiol Actions

The mechanisms through which estradiol restrains GnRH pulse frequency and amplitude to help achieve negative feedback may well incorporate all three modes of estradiol action: direct, indirect transsynaptic, and indirect nonneuronal. In relation to direct actions of estradiol, the genes regulated by ERβ in GnRH neurons are unidentified and, as such, the direct classical actions of estradiol on these cells are unknown. The only mechanism established to date to occur directly at the GnRH neuron involves the ERβ-dependent phosphorylation of CREB.[49,743,750] A series of studies have shown that estradiol acts through ERK1/2 and other upstream kinases to increase CREB phosphorylation within 15 min in GnRH neurons in vitro and in vivo.[750] This effect was abolished in both the GnRH neuron-specific ERβKO mouse in vivo and by synaptic transmission blockers in vitro, indicating that estradiol may act through two dependent parallel pathways involving ERα/ERβ synaptic input as well as ERβ in GnRH neurons to phosphorylate CREB.[750] It was recently reported that intact GnRH neuron-specific CREB knockout mice exhibit normal basal levels of LH alongside moderately disordered estrous cycles and an inability of estradiol to acutely suppress LH secretion in OVX animals.[49] This suggests that direct estradiol-dependent CREB phosphorylation in GnRH neurons may be involved in aspects of negative feedback that underlie the acute suppression of LH secretion following bolus administration of estradiol. This rapid, nonclassical mechanism of estradiol action may, nevertheless, occur persistently throughout the estrous cycle.[743,750]

Other rapid actions of estradiol on GnRH neurons have been reported, but it remains unknown whether they are direct actions and/or what their role may be in the nonclassical[774] aspects of estrogen negative feedback. Acute treatment with physiological low pM concentrations of estradiol was not found to have any effects on the intrinsic properties of GnRH neurons but did impact upon GABA and glutamate signaling to these cells in an ERα- and ERβ-dependent manner.[746] Another study demonstrated that high nM estradiol concentrations activated an atypical membrane ER that utilized PKC and PKA signaling to ultimately enhance potassium ATP channel activity in GnRH neurons.[744] A further report has shown that low nM estradiol modulates L-type and R-type voltage-gated calcium channels in GnRH neurons through unknown mechanisms involving ERβ and GPR30, respectively.[117]

Several reports from embryonic GnRH neurons demonstrate that estradiol enhances the frequency of calcium transients, suggesting that acute estradiol enhances GnRH neuron burst firing in these preparations.[748,749] It is unclear how this might correlate with estrogen negative feedback. Recent studies have also found that acute estradiol can also enhance calcium transients in GnRH neurons from adult mice.[745] However, in this case, it is interesting to find that the acute effects of estradiol in adult GnRH neurons were state-dependent such that silent cells were activated and spontaneously active neurons were inhibited.[747] This indicated an overall tendency for acute estradiol to "even out" activity patterns within the GnRH neuron population. What these different GnRH neuron populations may represent functionally is unknown.

Finally, it is important to note that other signaling cascades may also be involved in the acute negative feedback network action. P21-activated kinase in the preoptic area is rapidly phosphorylated by estradiol in a nonclassical mechanism, and acute estradiol suppression of LH is blocked by a p21-activated kinase antagonist given ICV.[811]

Indirect Transsynaptic Actions

Evidence that negative feedback can be initiated remote to the GnRH neurons and is dependent upon ERα suggests the presence of indirect transsynaptic modes of estrogen action. As noted, the ERα-expressing primary

afferent inputs to GnRH neurons are located predominantly in the RP3V and arcuate nucleus while those for ERβ are unknown. The absence of a marker (like cFos for positive feedback) indicating those neuronal populations that have altered activity at the time of negative feedback has greatly hindered progress in identifying the relevant neuronal populations within the network. Over the years, many different neurotransmitter systems have been implicated in the negative feedback mechanism.[229] Nevertheless, two neurochemical phenotypes have more evidence than most as being potentially important: preoptic GABAergic neurons and arcuate kisspeptin cells.

The GABAergic neurons of the rodent preoptic area are sensitive to fluctuations in circulating estradiol levels,[755] and GABA neurons in the RP3V and lateral preoptic area project directly to GnRH neurons.[92,373] Preoptic GABAergic neurons express ERα, and estradiol has been shown to increase GABA release, GABA reuptake mechanisms, and $GABA_A$ receptor subunit expression in the preoptic area (for review, see Ref. 755). Thus, in the presence of estradiol, GABAergic neurotransmission within the preoptic area is increased, and, accordingly, it has been hypothesized that estradiol acts to enhance the activity of GABAergic primary afferents to the GnRH neurons to suppress their electrical firing. This concept is supported by: (1) evidence for an inverse correlation between endogenous GABA levels within the vicinity of the GnRH cell bodies and circulating LH levels;[812–814] (2) activation of preoptic $GABA_A$ receptors resulting in the suppression pulsatile LH secretion in OVX animals;[395,396,398] and (3) the pharmacological blockade of $GABA_A$ receptors elevating LH levels in OVX estradiol-treated rats.[815] However, mouse electrophysiological studies have found that $GABA_A$ receptor activation exerts predominant excitatory, and not inhibitory, actions on GnRH neurons.[365] This discord between "inhibitory rat in vivo" and "excitatory mouse in vitro" might be explained, in part, by GABA actions at $GABA_B$ receptors, in addition to the likelihood that excessive $GABA_A$ receptor activation in vivo may well depolarize GnRH neurons into a state where they are unable to fire action potentials and thus become inhibited.[365]

One curious result has come from mice in which 70–90% of $GABA_A$ receptor signaling was deleted selectively from GnRH neurons. These animals show normal fertility but have a markedly enhanced rise in LH following ovariectomy and increased sensitivity to acute estradiol negative feedback.[394] How this apparent increase in estrogen negative feedback sensitivity comes about is not known. It does, however, suggest that the network may compensate for the $GABA_A$ receptor loss by generating a different type of negative feedback mechanism. While such observations provide evidence that a $GABA_A$ input to GnRH neurons is probably involved in the normal negative feedback mechanism in mice, precisely what these GABA afferents do is unknown.

There is presently substantial enthusiasm for the possibility that kisspeptin neurons in the rodent ARN are a site of estrogen negative feedback. Ovariectomy increases arcuate Kiss1 mRNA expression, and estradiol treatment returns transcript levels to normal in mice and rats.[476,480] As such, it was hypothesized that estradiol suppresses an excitatory arcuate kisspeptin drive to the GnRH neurons.[816] In other words, ovariectomy allows the emergence of the arcuate kisspeptin cells to drive GnRH neurons to generate high LH secretion. It is established that almost all arcuate kisspeptin neurons express ERα and that estradiol utilizes ERα in a nonclassical manner to regulate Kiss1 mRNA levels in these cells.[476,817] This hypothesis has received support from studies showing that the postovariectomy increase in LH secretion was reduced in GPR54 knockout mice[471] as well as in rats with arcuate nucleus-specific, saporin-deleted, kisspeptin neurons.[495] However, as noted in the Kisspeptin section Neuronal Elements, estradiol was still able to suppress LH secretion in both of these experimental models. This may indicate that arcuate kisspeptin neurons are more important for GnRH neurons to exhibit the pattern of activity required to drive the high amplitude, high frequency LH secretion of ovariectomy. Recent electrophysiological studies examining arcuate kisspeptin neuron firing in the acute brain slice have also questioned the kisspeptin estrogen negative feedback hypothesis as gonadectomy resulted in even lower firing rates than the already low levels found in intact mice—a result opposite to that predicted by the model.[496] Thus, at present, the estrogen negative feedback role for arcuate kisspeptin neurons in the rodent requires further evidence.

In summary, investigations to date have emphasized the role of ERα in the estrogen negative feedback mechanism, but the brain sites and neurochemical identity of the cells involved in this process remain obscure. It seems likely that negative feedback is multimodal in nature with estradiol exerting both classical and nonclassical actions over different temporal time frames to directly and indirectly suppress GnRH pulse frequency and amplitude. There is evidence for a modest rearrangement of GnRH neuron firing pattern, rather than firing rate, associated with negative feedback, although better mouse models need to be developed to address this further. Whereas some rapid, nonclassical estradiol actions may occur directly at the GnRH neuron and be partly responsible for acute estradiol suppression, the physiological significance of most remain unclear. It seems highly likely that ERα-expressing transsynaptic inputs are involved in sensing and transmitting information on circulating estradiol levels to GnRH neurons, although there is actually rather little compelling evidence supporting a role for any specific neuronal phenotype in negative feedback. Finally, glial cell structural rearrangements involving GnRH neurons could be envisaged to

provide a relatively stable form of negative feedback, but, again, evidence for this remains to be gathered.

Progesterone

Progesterone exerts an important regulatory influence on the activity of GnRH neurons at several different time points. Foremost, the elevated levels of circulating progesterone during the luteal phase exhibit a potent suppressive influence upon GnRH and LH secretion in spontaneously ovulating species including humans.[818–820] The principal role of this luteal-phase increase in progesterone may be to prevent GnRH surges on the days subsequent to ovulation.[821] In addition to this inhibitory action, it is also evident that progesterone can enhance the time of onset and amplitude of the GnRH/LH surge in rodent and primate species.[822–824] There has, however, been some debate as to precisely when circulating progesterone levels increase in relation to the onset of the LH surge.[825–827] It has been argued that this positive feedback effect of progesterone may, instead, originate from production by astrocytes within the brain.[828]

Modes of Progesterone Action

Recent discoveries have greatly expanded the potential modes of progesterone action on cells. Classic genomic regulation, as well as rapid effects, arise through the progesterone receptor (PR) isoforms PR_A and PR_B, while rapid actions of progesterone can also occur through at least two different classes of progesterone-binding receptors: progestin/adipoQ (PAQR) receptors (sometimes called *membrane PRs*) and progesterone receptor membrane component 1 (PgRMC1).[829] In addition to these receptors, progesterone is also rapidly metabolized in the brain to neuroactive steroids that allosterically modulate the activity of a variety of neurotransmitter receptors.[830,831]

In terms of direct actions on GnRH neurons, it seems that these cells do not express appreciable amounts of the classic PRs. Immunocytochemistry studies have failed to detect PR in the sheep[832] and monkey,[833] although a small population of medially located GnRH neurons were observed to express PR immunoreactivity in the guinea pig.[834] A recent study of cultured nasal placode GnRH neurons has, however, demonstrated that all embryonic GnRH neurons express mRNA and protein for PgRMC1 but not PR or PAQRs.[835] That study also showed that a subpopulation of adult GnRH neurons in the mouse expressed PgRMC1 immunoreactivity.[835] In terms of neurosteroids, the 5α-pregnan-3α-ol-20-one (allopregnanolone) metabolite is known to directly modulate the activity of $GABA_A$ receptors expressed by GnRH neurons,[836,837] implicating a role for glial cell neurosteroid synthesis in transmitting progesterone feedback to GnRH neurons.

In addition to direct actions, it seems likely that progesterone modulates GnRH neuron activity through transsynaptic inputs. Progesterone receptors have been detected in many hypothalamic populations including glutamatergic,[838] GABAergic,[833,838,839] dopaminergic,[840,841] and neuropeptidergic[842–844] cells, as well as brainstem NE neurons.[845,846] However, as yet, the PR-expressing neurons that project directly to the GnRH neurons are not known.

Progesterone Negative Feedback

Evidence to date suggests that progesterone utilizes a combination of genomic and rapid actions to suppress LH pulsatility during the luteal phase. Investigations by Skinner and colleagues in the ewe have shown that progesterone can act relatively quickly (~50 min) to suppress GnRH pulse frequency and that this requires the presence of estradiol-induced PRs.[847] Investigations in the mouse suggest a mixture of modes of progesterone action as intact PR knockout mice exhibit elevated LH levels despite maintaining rapid suppressive effects of progesterone.[848,849] The evidence for PgRMC1 in adult GnRH neurons and demonstration that 10 nM progesterone rapidly suppresses calcium peaks in about 50% of embryonic GnRH neurons[835] provides one mechanism for rapid, direct suppression of GnRH neuron activity. It is of note, however, that high 1 μM concentrations of progesterone were not reported to alter the excitability of adult mouse GnRH neurons.[836]

Classic PR signaling may suppress GnRH pulse frequency through any one of a number of different transsynaptic inputs. Investigators have shown a role for endogenous opioid peptides in progesterone negative feedback,[637,850–852] and work in the sheep has also highlighted the potential importance of PR-expressing dynorphin (i.e., KNDy) neurons within the arcuate nucleus within the GnRH network in this species.[281,842,853] There is also evidence to suggest that opioid peptides are involved in the progesterone-induced suppression of LH secretion in humans.[854]

The direct and rapid modulation of GnRH neurons by progesterone metabolites derived from nearby glial cells may also play a role in suppressing pulsatile LH secretion during the luteal phase of the cycle. Allopregnanolone has been reported to suppress GnRH secretion,[855] LH release,[856] and ovulation[857] in the rat, but has no effects on LH in the mouse[849] or sheep.[847] Further confusion about the precise roles of allopregnanolone comes from the observation that the rapid allosteric modulation of $GABA_A$ receptors would be expected to enhance, rather than suppress, GnRH neuron excitability in the mouse.[365]

Thus, as for estrogen negative feedback, progesterone negative feedback during the luteal phase seems likely to result from a combination of direct and indirect

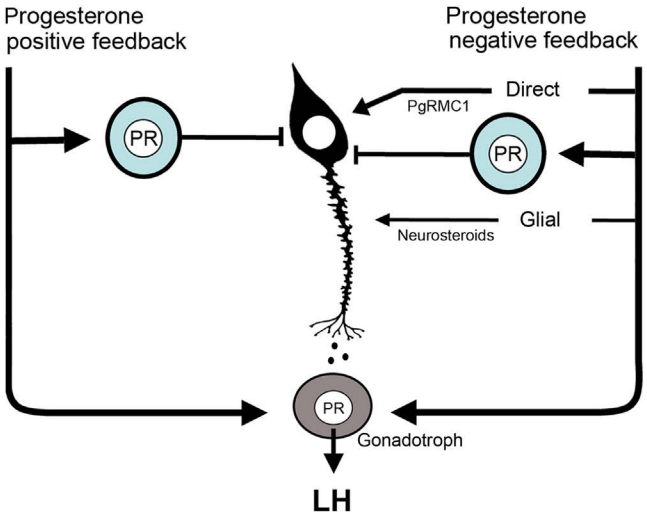

FIGURE 11.11 Model of progesterone feedback actions. Schematic diagram showing proposed modes of progesterone action within the GnRH neuron network for positive and negative feedback. Abbreviations: PR, progesterone receptor; PgRMC1, progesterone receptor membrane component 1.

transsynaptic and glial mechanisms involving both classical transcriptional and nonclassical modes of action (Figure 11.11).

Progesterone Positive Feedback

Progesterone can advance the time of onset of the GnRH/LH surge and also greatly magnify its amplitude in rodents and primates.[822–824,858] Both of these effects have a critical requirement for estradiol-induced PRs[848,859–861] suggesting that classical mechanisms of estradiol-dependent gene transcription are involved. Further, PR antagonists given before the onset of the proestrous or estradiol-induced LH surge result in its marked attenuation.[860,862,863] While the previous evidence indicates a predominant classical PR mode for progesterone positive feedback, it is noteworthy that progesterone can exert rapid stimulatory effects on GnRH secretion,[864] and the direct allopregnanolone actions on GnRH neurons may be excitatory (see previous discussion).

However, a major difficulty in understanding the physiological significance of these stimulatory effects of progesterone has revolved around the lack of evidence for significant circulating progesterone secretion before the onset of the endogenous GnRH/LH surge.[272,825–827] Two solutions to this issue have been proposed. The first involves the proposition that follicular-phase estradiol acts in a nonclassical manner to induce astrocytes to secrete progesterone de novo within the brain (astrocrine hypothesis) and thereby provides sufficient presurge progesterone exposure within the GnRH network in the absence of significant circulating levels of progesterone.[828,865] The second solution hypothesizes that ligand-independent PR activation may underlie the stimulatory roles of PRs in the surge generation.[696] In that model, the rise in follicular-phase estrogens initiates or enhances PR expression in RP3V cells that then enables them to be transactivated by stimuli other than progesterone to help initiate the surge.

The neurochemical identity of neurons within the GnRH neuron network involved directly in the transsynaptic activation of the GnRH neurons by progesterone is not clear. Again, however, endogenous opioid peptides have been favored as having a key role. There is abundant evidence that progesterone can facilitate the estradiol/circadian-induced decline in both β-endorphin levels and opioid receptor expression prior to the onset of the LH surge in the rat, thereby enhancing the disinhibition of the GnRH neurons.[866–873] It has also been suggested that the role of progesterone to suppress the occurrence of daily LH surges after ovulation results from the activation of opioid peptide signaling within the GnRH network.[858] One difficulty with this proposed pathway is that GnRH neurons in the rat do not express the appropriate opioid receptors[874] and rarely respond directly to β-endorphin or μ opiate receptor agonists in mice.[270]

Another progesterone-modulated transsynaptic input that has received recent attention is the NE input from the locus coeruleus.[558] In a recent study, both the preovulatory LH surge and rise in preoptic NE concentrations were greatly enhanced by progesterone treatment, and this was shown to originate from the locus coeruleus NE cells known to express PR.[558,846] Also, it is evident that the RP3V kisspeptin neurons implicated in estrogen positive feedback mechanism express PRs.[481] This indicates that progesterone facilitation of the GnRH/LH surge may well occur through the same kisspeptin pathway driving estrogen positive feedback.

Together, these investigations indicate the importance of classical estradiol-induced progesterone actions in the facilitation of the GnRH/LH surge. The source of progesterone and its targets within the GnRH neuronal network are currently being established. However, it is possible that progesterone simply utilizes the existing ERα positive feedback pathway to enhance activation of the GnRH neurons at the time of the surge.

An Integrated Model of Estrous Cycle Plasticity

Figure 11.12 provides an overview of a model bringing together estradiol, progesterone, and circadian influences within the network to generate estrous cycle plasticity in GnRH secretion.

It is apparent that the potent circadian input within the network occurs through at least two transsynaptic mechanisms: one direct to the GnRH neurons and one indirect pathway that regulates steroid-receptive inputs to GnRH neurons. The relative importance of these two

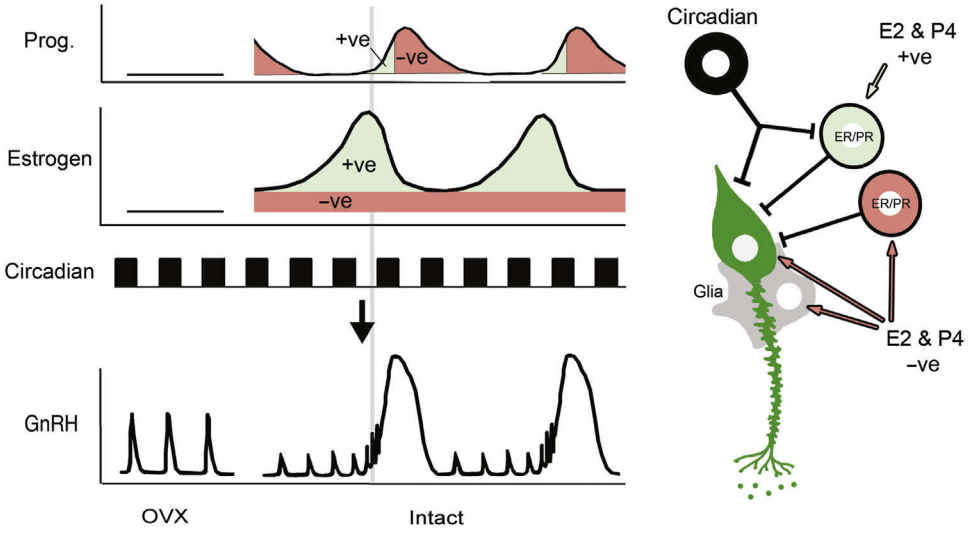

FIGURE 11.12 Model of integrated circadian, estradiol, and progesterone influences within the GnRH neuronal network. Left: Schematized profiles of circulating progesterone (prog.), estradiol, and the daily circadian signal are given above the profile of GnRH secretion in ovariectomized (OVX) and intact rats. In OVX rats, the secretion of estradiol and progesterone is minimal, and this reveals "free-running" high amplitude, high frequency GnRH pulsatility that is not strongly entrained by the circadian input in adults. In intact female rats, significant progesterone secretion is only observed coincident with the onset of the GnRH surge (light gray vertical line). Whereas the initial period of progesterone secretion exerts a stimulatory feedback effect (marked as +ve), further boosting estrogen positive feedback, the subsequent progesterone secretion exerts negative feedback actions (marked as –ve). Estradiol feedback is proposed to exist as two separate feedback mechanisms that run simultaneously; the positive feedback pathway is entrained by the rising estradiol levels of the follicular phase and "breaks through" the relatively constant negative feedback pathway (marked as –ve) once every cycle to generate the GnRH surge. The precise timing of the surge is entrained by circadian inputs (black boxes) to the positive feedback pathway. Right: Schematized model showing the nature of the different pathways within the GnRH neuronal network. Circadian inputs regulate GnRH neurons through direct and indirect pathways. Both estradiol (E2) and progesterone (P4) positive feedback act primarily through an ERα/PR-expressing transsynaptic mode. In contrast, the negative feedback actions of both estradiol and progesterone appear to be multimodal utilizing direct, transsynaptic and glial cell modalities to suppress the activity of GnRH neurons.

pathways is not yet clear. However, there is abundant evidence that circadian influences within the network are only clearly observed in the presence of estradiol, suggesting that the indirect pathway is prominent.

Estradiol is the principal driver of plasticity across the cycle, and it is proposed that the negative and positive feedback actions of estrogens are driven by separate neuronal/glial ensembles. Not only are the temporal dynamics of negative and positive feedback different but there is evidence that one can occur without the presence of the other.[875–877] Thus estradiol is not modeled as a negative–positive feedback "switch," as is commonly assumed, but as two separate pathways that are active in parallel. In essence, estrogen negative feedback is always present and relatively constant in impact, while the strength of the estrogen positive feedback pathway is totally dependent upon the threshold level of circulating estradiol. This means that the efficacy of positive feedback is directly related to circulating estradiol levels and, as such, it "breaks through" the negative feedback influence once every cycle driven by high estradiol levels of the late follicular phase. Thus, the ultimate impact on the GnRH neuron is the sum of the two pathways. There is abundant evidence that estrogen positive feedback represents a classical concentration-dependent, transcriptional mode of action, and that this likely resides within RP3V cells projecting to GnRH neurons.

The estrogen negative feedback pathway is proposed here to result from direct, transsynaptic, and glial cell modes of action. The multimodal nature of this pathway likely underlies the present difficulty in deciphering its components and precise characteristics. With several components using multiple different modes of communication and mechanisms of estradiol action, it may also explain the robustness of negative feedback from a physiological perspective. While positive feedback can be perturbed rather easily, defects in the suppressive influence of estradiol on LH secretion are rarely encountered.

Present evidence indicates that the mechanism and mode of progesterone positive feedback within the network looks much like that of estrogen positive feedback. In many ways it makes sense that progesterone should "piggyback" on the estrogen positive feedback transsynaptic pathway as, during the first few hours of the surge, it is required to generate the same stimulatory action on GnRH secretion. A subpopulation of the ERα-expressing neuronal afferents to GnRH neurons will likely be the same cells expressing estradiol-dependent PRs. Again, similar to estradiol, the negative feedback pathways appear to be complex

and involve multiple different signaling mechanisms and cell types. Whether there is actually any overlap between the estradiol and progesterone negative feedback pathways is unclear, but given the different temporal domains that they are working within, this may be less likely.

Brought together, this simplistic model of circadian, estradiol, and progesterone mechanics can relatively easily explain the marked plasticity of the network across the cycle. Studies over the coming years will no doubt substantiate or invalidate parts of the model.

CONCLUSION

This review has documented the very substantial progress that has been made in the field of GnRH neurobiology over the last decade and how this has built upon our existing knowledge. With respect to the GnRH neurons themselves, the ability to now examine the electrophysiological properties of native cells with relative ease in vitro has provided a whole new dimension of detailed information as to what makes the GnRH neuron active. Perhaps surprisingly given the decades of prior research, the morphology of the GnRH neuron has also evolved further in recent years, again made possible by developing new ways of looking at these cells. In contrast, our understanding of the biosynthesis of GnRH is relatively mature and has not advanced to the same extent in recent times.

While there is every reason to be optimistic about making substantial future advances in understanding the GnRH neuronal phenotype, the larger and more daunting challenge will be to make headway in deciphering the functioning of the GnRH neuronal network, in particular, how the network functions together to generate a pulse of GnRH and how the gonadal steroid negative feedback mechanism works. It is likely that little further will be gained by measuring changes in LH following third ventricular administration of yet another neuropeptide or transmitter. Rather, the challenge is to develop technologies that can interrogate different components of the GnRH neuronal network in a selective manner. This will mean developing new techniques tailored to address the actual key questions rather than simply reusing old, familiar approaches to generate data. The neuroendocrine field has an excellent pedigree in driving technical innovation, and new methodologies may come from within the community or by adapting advances elsewhere in neuroscience. The considerable resources, risks, and creativity required to develop these new approaches will likely require collaborative efforts between the various GnRH neurobiology laboratories to facilitate any rapid progress.

Acknowledgments

The author is very much indebted to past and present members of the Herbison laboratory for many stimulating discussions and arguments that underlie much of the theoretical work proposed in this review. I wish to thank Simon de Croft, Pauline Campos, Xinhuai Liu, Jenny Clarkson, Karl Iremonger, Richard Piet, Rebecca Campbell, and Greg Anderson for reading and commenting upon parts or all of this chapter. The Herbison laboratory is indebted to the New Zealand Health Research Council for financial support.

CHAPTER

12

Hypothalamic Control of Prolactin Secretion, and the Multiple Reproductive Functions of Prolactin

David R. Grattan

INTRODUCTION

Prolactin is an anterior pituitary hormone that is essential for the process of lactation, and it is this function from which its name is derived. In addition to this critical role in reproduction, however, prolactin is also known to have many other actions in the body. A seminal review from Charles Nicoll published in 1974[1] listed 85 different actions of prolactin; this list was updated and expanded by Paul Kelly and colleagues in 1998,[2] and no doubt could be expanded further. It has now become almost a cliché to describe prolactin as having over 300 distinct biological actions. The breadth of potential functions is conceptually difficult to comprehend. In both the original and updated lists of prolactin actions, the various functions were subdivided into a number of different categories, of which reproduction was but one. Other functions included water and electrolyte balance, growth and development, endocrinology and metabolism, brain and behavior, and immunoregulation. The experimental evidence for each action is quite clear, but, when examined in isolation, many of the reported actions of prolactin do not appear to be essential. Hence, prolactin has been thought of as a pleiotropic adaptive hormone, having multiple distinct roles in the homeostatic regulation of many different processes, but not essential or irreplaceable for any of them (apart from lactation).

For the purposes of this chapter, we have taken a different approach. Rather than look at reproduction as one category out of many prolactin-responsive functions, we have considered how the multiple different actions of prolactin might, in fact, contribute to the one primary outcome of successful reproduction. In essence, rather than contemplate over 300 different actions of prolactin, we have asked the question "What are 300 things that need to change in a mammal to enable pregnancy and lactation?" When faced with a novel action of prolactin, for example in bone or the pancreas, we tried to think about why this tissue might need to change its function during pregnancy or lactation. In this context, an action on bone might be necessary to mobilize calcium for milk production, and metabolic effects of prolactin might balance glucose supply for support of fetal growth and maternal survival or conditions for lactation. While this might not completely account for all of the known actions of prolactin, it provides a useful contextual framework to think about the roles of prolactin in the physiology of reproduction. An important concept in considering the roles of prolactin in reproduction is that these functions are in fact mediated by multiple ligands (pituitary prolactin and the placental lactogens), acting through a common receptor.

The breadth of prolactin's functions likely originates from the evolutionary history of this molecule. While

in mammals prolactin provides the critical signal that induces mammary gland development and milk production, the hormone predates mammals in evolutionary time. Thus, prolactin is present in fish, reptiles, amphibia, and birds, where it clearly has functions unrelated to lactation. It appears to have arisen as a duplication of an ancestral gene in early vertebrates, resulting in the formation of the prolactin and growth hormone genes.[3] These two paralogs have subsequently evolved quite distinct functions in modern vertebrates. In non-mammalian vertebrates, prolactin is involved in osmoregulation and fluid balance, regulating ion and water flux across epithelial layers in a variety of tissues.[4] It is also involved in regulation of the skin and integument. At least some of these actions are targeted toward the reproductive process. For example, in some birds, prolactin induces a nutritious secretion from the epithelial cells of the crop sac, adding components to food that is then regurgitated to feed their offspring. This is highly analogous to lactation, where mammals provide nutrition to their offspring through secretions from epithelial glands located in the skin. Prolactin also influences a number of reproduction-related behaviors, including migration in amphibia and nest building in birds. In mammals, the roles of prolactin appear to have specialized further, but may have a similar basis. Lactation generates a demand on fluid balance and a demand on metabolic processes for energy, and it requires behavioral changes in the mothers. It seems logical that the same signal that was co-opted by evolution to stimulate milk secretion would also be used to induce modifications in other processes to facilitate this key reproductive process.

In this chapter, we have focused on the broader role of prolactin in reproductive physiology. We have reviewed the hypothalamic control of prolactin secretion and its regulation at the level of the anterior pituitary gland. The different patterns of prolactin secretion are discussed, including the important role that placental lactogenic hormones play during pregnancy and the overall role of prolactin in reproduction. We have then reviewed the major reproductive functions of prolactin, both its actions in peripheral tissues and its actions in the brain to influence important reproductive behaviors. Within this section, there is a focus on the distribution of prolactin receptors, and identification of the cell types responding to prolactin. Finally, we have looked at emerging evidence for the involvement of prolactin in a range of reproductive disorders, ranging from infertility to neurological and mood conditions and a number of reproductive cancers. Because we have taken quite a different approach, we consider that the present chapter complements, rather than replaces, the authoritative chapters published in earlier editions of this book (e.g., Refs 5–7).

THE PROLACTIN RECEPTOR AND SIGNAL TRANSDUCTION

The prolactin receptor is a member of the cytokine family of receptors,[2] and its expression is widespread in the body, consistent with the pleiotropic roles of prolactin in reproduction and other functions. Before discussing the ligands in detail, we think it is useful to have a basic understanding of the signal transduction properties of this receptor. Later in this chapter, we will discuss tissue-specific receptor distribution when describing functions of prolactin. In this section, however, we will examine prolactin signal transduction pathways (with a summary diagram illustrating the major pathways shown in Figure 12.1).

The prolactin receptor is a single transmembrane-spanning protein without an intrinsic kinase domain, and signaling occurs via activation of receptor dimers. A number of different receptor isoforms has been identified, and each is formed by posttranscriptional processing of the prolactin receptor transcript.[8–11] Although multiple promoters and first exons have been reported,[12,13] the extracellular domain (coding sequence begins at exon 3) is common to all receptor subtypes and is well conserved among species.[14] The different first exons and associated promoter regions are involved in the tissue-specific expression of the receptor, enabling differential control of receptor expression in different tissues.[15] The transmembrane domain is also shared by all subtypes, apart from circulating "soluble receptors" that may be formed by alternative splicing of the primary transcript[11,16] or by proteolytic cleavage of the extracellular domain.[17] The transmembrane domain may be critical in the formation of ligand-free receptor dimers,[14] and this is potentially important in signal transduction mechanisms (discussed further in this chapter). There are multiple different intracellular domains that are formed by alternative splicing of the primary transcript.[8–11] Full signal transduction requires the "long form" of the receptor,[2] while a number of short forms have been described in different species, typically involving replacement of exon 10 of the gene with an alternative and different last exon. These short forms lack the tyrosine phosphorylation sites that form docking sites for Src homology 2 (SH2) proteins (discussed in this section), and therefore cannot activate many of the signaling pathways that are activated by the long form of the receptor. However, the short forms do retain some signal transduction capacity, and specific functions are beginning to be ascribed to these isoforms. There is some evidence that the short forms may act as regulatory molecules by forming heterodimers with the long form of the receptor and thereby blocking signal transduction,[18–21] but recent studies looking specifically at

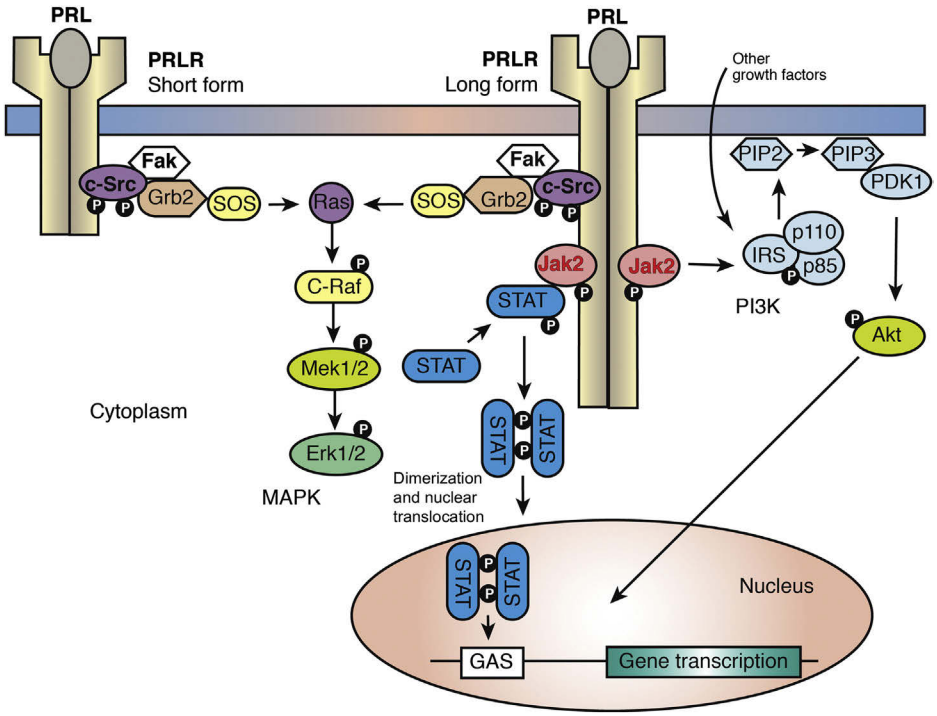

FIGURE 12.1 Diagrammatic representation of the multiple signal transduction pathways mediating prolactin action in different tissues (see the text for definitions of abbreviations). The major pathway mediating prolactin action is the JAK–STAT pathway, which is activated by the long form of the prolactin receptor. The short form of the receptor has a truncated intracellular domain that lacks the STAT binding residues but can activate the MAPK pathway in a manner that can be independent of JAK2. The long form may also activate the PI3K pathway or at least amplify responses through this pathway that are induced by other growth factors, such as insulin, IGF, and leptin.

the functions of the short forms have begun to identify roles for these isoforms that are distinct from those of the long form.[22–24]

Prolactin binds to two prolactin receptor molecules to form an active heterotrimeric receptor–ligand–receptor complex. Brooks recently reviewed the evidence suggesting that this complex is formed by a ligand-induced dimerization of two receptor molecules.[14] His group has demonstrated that binding sites on the prolactin molecule interact in sequence, with a receptor binding at "site 1" on the ligand inducing a conformational change that allows binding of a second receptor molecule to "site 2" on the ligand,[25] followed by a dimerization of the receptor molecules through interface of the two extracellular S2 subdomains.[14] An alternative view is that the receptors are present in the membrane as ligand-independent dimers.[26] Sequential binding of one receptor to site 1 and then the second receptor to site 2 induces a conformation change resulting in activation of the complex.[27] Regardless of whether the initial hormone binding is to monomers or dimers of the receptor, it is clear that binding must occur in this sequence[28,29] and that activation of signaling requires the full heterotrimer of one ligand plus two receptors[a]. Ligand binding induces a conformation change in the hormone-binding site that is communicated via allosteric interactions through the transmembrane domain to induce structural changes in the internal domain,[29] allowing autophosphorylation and activation of the receptor-associated Janus kinase 2 (Jak2). Jak2 phosphorylates the receptor, establishing docking sites of SH2 domain proteins (Figure 12.1). The major substrates for these sites are the signal transducer and activator of transcription (Stat) molecules, Stat5a and Stat5b.[2] Upon binding to the receptor, Stat5 is phosphorylated by Jak2, triggering the formation of transcriptionally active Stat dimers. Either homodimers or heterodimers of Stat5a/b then translocate to the nucleus, binding to specific sequences of the DNA to activate the transcription of target genes. Other SH2 domain–containing signaling proteins, such as Src, Fyn, and Tec, may also bind to this Jak2-activated site and participate in prolactin signaling. There are 10 tyrosine residues on the long form of the prolactin receptor, and the unique amino acid composition of these 10 sites within the

[a] Modeling of the ligand-induced structural changes underlying prolactin receptor signaling has informed the design of prolactin antagonists[30,31] and provided insight into the mechanisms underlying how some variants can act as both antagonist and agonist.[32] Such antagonists could be used as therapy for conditions such as breast or prostate cancer by counteracting the effects of activating mutations of the prolactin receptor or competing with locally produced prolactin (which is unresponsive to classic prolactin-lowering drugs such as bromocriptine).[33,34] Animal studies with these antagonists have been limited by their short half-life in vivo, but transgenic models with ubiquitous antagonist expression have been developed to demonstrate their ability to prevent prolactin-induced tumorigenesis.[35]

prolactin receptor will likely result in a unique subset of the 110-member SH2 domain family of proteins[36] to be activated in a particular pattern, generating the specific functional consequence of prolactin signal transduction in a cell.[14]

While extensive evidence demonstrates that Jak2 is critical to many of the functions of prolactin, particularly those involving activation of Stat signaling, prolactin has also been shown to activate multiple other signaling pathways, both dependent on and independent of Jak2 activation (Figure 12.1). For example, prolactin acting through Jak2 can induce phosphorylation of insulin receptor substrate 1 and 2 (IRS1 and IRS2, respectively),[37,38] providing docking sites for the p85 subunit of phosphatidylinositol-3-kinase (PI3K), resulting in activation of PI3K and its downstream biological effects. More recently, it was suggested that Jak2 does not initiate activation of Akt (a downstream target of PI3K) but greatly intensifies this through signaling cross-talk with other growth factor receptors.[39] Prolactin also activates the mitogen-activated protein kinases (MAPK) such as extracellular-regulated kinase (ERK) 1 and 2,[40,41] and this can occur in cells lacking functional Jak2,[39] possibly through activation of c-Src kinase independently of Jak2.[39,42] Thus, prolactin-induced signal transduction is complex, and different combinations of signal transduction pathways may be activated in different cell types. Future studies will be required to characterize the unique complex of downstream mediators activated in each tissue of interest.

Signaling through the JAK–STAT pathway is attenuated by members of a family of cytokine-inducible suppressors of cytokine signaling (SOCS) proteins.[43–45] These proteins are activated by cytokines, including prolactin, and then act as intracellular feedback inhibitors of signaling.[46,47] There are eight members of the SOCS family (Cis and SOCS1–7), and each has a different mechanism of action to suppress JAK–STAT signaling. For example, SOCS1 binds directly to Jak2 and inhibits its catalytic activity, while SOCS3 binds to specific regions in the intracellular domain of the cytokine receptor, preventing STAT binding.[48] The analysis of transgenic mice lacking SOCS genes has begun to shed light on their in vivo roles. Although *Socs1*$^{-/-}$ mice die perinatally due to immune dysregulation, the *Socs1*$^{-/-}$ mice can be rescued if bred on an interferon γ–deficient background.[49] These mice displayed enhanced mammary lobuloaveolar development during pregnancy and increased milk production. Moreover, deletion of a single copy of *Socs1* rescued lactational defects in mice that were heterozygous for a knockout of the prolactin receptor.[49] These data suggest an important physiological role for SOCS1 in limiting prolactin signaling. SOCS2 also functions as a physiological inhibitor of prolactin signaling. It is transcriptionally regulated by prolactin, and deletion of *Socs2* within the mammary gland rescues lactation in heterozygous prolactin receptor knockout mice.[50] SOCS3 is closely related to SOCS1 and is upregulated by prolactin in some tissues, but it appears to preferentially target STAT3 and hence may not be a major regulator of prolactin signaling.[48] In addition to the SOCS molecules, a number of other regulators of the JAK–STAT pathway have been identified, including the protein inhibitors of activated STATs (PIAS) and SH2-containing phosphatases.[51] While the full extent of the physiological roles of these proteins in prolactin signaling remains to be determined, it is clear that endogenous regulation of the JAK–STAT pathway is an important controlling mechanism that is likely to play a significant role in the reproductive functions of prolactin.

NEUROENDOCRINE CONTROL OF PROLACTIN SECRETION

Prolactin Secretion is Inhibited by Dopamine from the Hypothalamus

Unique among pituitary hormones, prolactin is predominantly inhibited by the hypothalamus and will be spontaneously secreted at high levels should hypothalamic inhibition be interrupted or if pituitary cells are grown in culture.[52,53] This was originally demonstrated when Everett observed that the rat pituitary could maintain the corpus luteum even after the pituitary stalk had been severed or after the transplantation of a pituitary gland under the kidney capsule.[54] As prolactin was known to be a luteotrophic hormone in rodents (as discussed here), these observations suggested the spontaneous secretion of prolactin from lactotroph cells of the pituitary gland without a requirement for input from the hypothalamus. Subsequently, it was shown that ectopic pituitary grafts could maintain lactation, again suggesting high levels of prolactin secretion without hypothalamic stimulation.[55] Repeating the classic experiments of Geoffrey Harris and Dora Jacobsohn that first proved humoral regulation of the pituitary gland by the hypothalamus,[56] Nikitovitch-Winer and Everett conducted a series of experiments in hypophysectomized rats, transplanting a pituitary gland either under the kidney capsule or back under the median eminence of the hypothalamus. They showed that while pituitaries located away from the hypothalamus would induce pseudopregnancy, a marker of elevated prolactin secretion in rodents (also discussed here), normal cycles would result when pituitaries were revascularized by portal vessels under the median eminence.[57] The use of ectopic pituitary glands, relieved of the hypothalamic inhibition of prolactin secretion, subsequently became a standard model of hyperprolactinemia.[58] With the

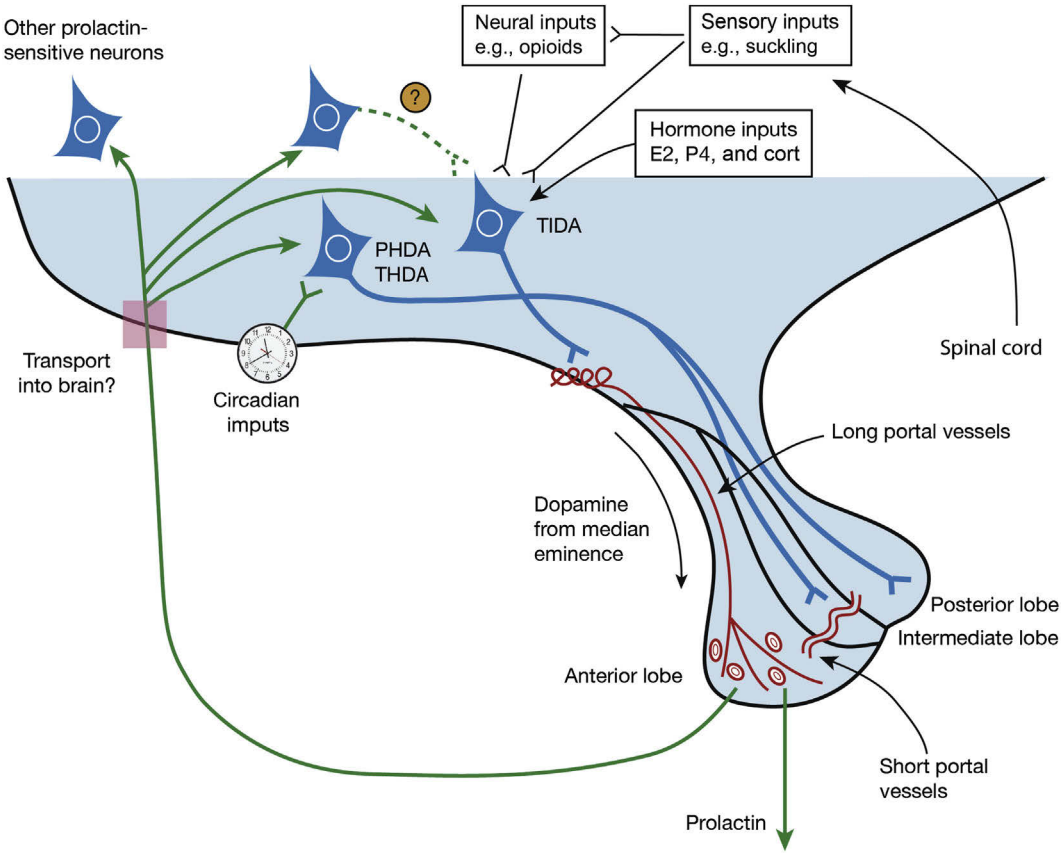

FIGURE 12.2 Neuroendocrine dopamine (NEDA) neurons in the hypothalamus, consisting of the tuberoinfundibular dopamine (TIDA) neurons projecting to the median eminence, and the tuberohypophyseal (THDA) and periventricular hypophyseal (PHDA) dopamine neurons projecting to the posterior lobe and intermediate lobe, respectively. These neurons regulate prolactin secretion, with dopamine reaching the anterior pituitary from the TIDA neurons via the long portal vessels, and from the THDA and PHDA neurons via the short portal vessels. Prolactin directly stimulates these three populations of neurons, resulting in short-loop negative-feedback regulation of its own secretion, as well as activating a number of other prolactin-responsive neurons in the brain. Multiple factors regulate prolactin secretion indirectly through altering activity of the NEDA neurons, including circadian, sensory, and neural inputs, as well as other hormones such as estradiol (E2), progesterone (P4), and corticosterone–cortisol (Cort).

development of prolactin radioimmunoassays in the early 1970s, it was confirmed that median eminence lesions[59] or severing the pituitary stalk[60] resulted in elevated prolactin secretion, consistent with the concept of a prolactin-inhibitory factor coming from the hypothalamus (Figure 12.2).

Two groups independently demonstrated that the hypothalamus released a prolactin-inhibitory factor that could prevent prolactin secretion from anterior pituitary cells in vitro.[61,62] The identification of this prolactin-inhibitory factor as dopamine, a catecholamine neurotransmitter, was controversial because all other hypothalamic hormones identified had been peptide hormones. Observations that drugs such as reserpine, which depletes endogenous dopamine, induced pseudopregnancy in rats[63] had provided the first clue, but it was assumed that the catecholamines were working as neurotransmitters in the brain by altering the release of a hypothalamic hormone.[64] However, about this time, Fuxe identified high levels of dopaminergic nerve terminals in the median eminence[65] consistent with the possibility of neurosecretion into the portal blood. MacLeod championed the view that dopamine was, in fact, a hypothalamic hormone, demonstrating that dopamine inhibited prolactin secretion from isolated pituitary glands and that dopaminergic agonists were also effective at suppressing prolactin secretion in vivo.[66] Dopamine was subsequently identified in the pituitary portal blood,[67] and an elegant series of studies showed that changing levels of dopamine in the portal blood could account for much of the variation in prolactin secretion from the anterior pituitary gland.[68–71] Dopamine receptors have subsequently been identified on lactotroph cells in the pituitary, with inhibition of prolactin mediated through the dopamine 2 (D2) receptor (D2R) subtype[72] (see the section Dopamine Inhibition of Lactotroph Function and Proliferation via the D2 Receptor on pituitary regulation). Mice lacking D2R are hyperprolactinemic.[73,74]

In the original studies of hypothalamic neurosecretion of dopamine, there was some suggestion that levels of dopamine detected in the portal blood were insufficient to account for the full inhibition of prolactin secretion. These studies involved depleting endogenous catecholamines with an inhibitor of tyrosine hydroxylase (TH, the rate-limiting enzyme involved in dopamine synthesis) and then infusing exogenous dopamine at the concentrations detected in the portal blood. Prolactin was suppressed by only about 60% with these "physiological" levels of dopamine, suggesting that there might be other prolactin-inhibitory factors.[71,75] However, it is now clear that these early experiments did not take into account an important additional source of dopamine reaching the anterior pituitary from the posterior pituitary gland by means of short portal vessels.[76] Evidence now suggests that prolactin secretion is regulated by three populations of neuroendocrine dopaminergic neurons[77]: the tuberoinfundibular (TIDA), tuberohypophyseal (THDA), and periventricular hypophyseal (PHDA) dopaminergic neurons. TIDA neurons arise from the dorsomedial arcuate nucleus and project to the external zone of the median eminence[78] (Figure 12.2). Dopamine diffuses into the capillaries of the pituitary portal blood vessels and is transported to the anterior pituitary. THDA neurons originate in the rostral arcuate nucleus and project in the hypothalamo-hypophyseal tract to the intermediate and neural lobes of the pituitary gland.[79,80] PHDA neurons arise more rostrally in the periventricular nucleus, with axons terminating solely in the intermediate lobe of the pituitary gland.[81] Dopamine from THDA and PHDA neurons contributes to basal regulation of prolactin secretion after transport to the anterior pituitary gland through short portal vessels from the neurohypophysis.[76] Together, these hypothalamic sources of dopamine are sufficient to account for all of the inhibition of prolactin from the pituitary gland. While they are anatomically distinct populations, most evidence suggests that they are functionally similar in terms of their regulation and pattern of dopamine release. Moreover, there is considerable overlap in their dendritic fields.[82] Hence, we support using the terminology introduced by Freeman et al.[83] to refer to these neurons involved in prolactin secretion collectively as the neuroendocrine dopamine (NEDA) neurons (Figure 12.2).

Characteristics of Neuroendocrine Dopamine Neurons

The NEDA neurons are typically described as being small parvocellular neurons approximately 20 μm in diameter, and they have 3–5 primary dendrites generating a relatively large dendritic field extending several hundreds of microns from the cell bodies.[82,84] Dendrites can be identified in both the coronal and sagittal planes, with more rostral and dorsal dendrites typically arranged in a dorsoventral orientation, while the more ventral dendrites tend to be oriented in parallel with the rostrocaudal plane. The axon principally originates off one of the main dendritic shafts and projects ventrally toward the median eminence, although some axons projecting elsewhere have also been described.[84] Within the median eminence, there are many large TH-immunoreactive nerve terminals (approximately 1 μm in diameter) in the vicinity of the primary capillary plexus of the portal blood system.[82] Recent electrophysiological studies of TIDA neurons, either in rats with post hoc identification[85] or in transgenic mice expressing green fluorescent protein (GFP) under the control of the TH promoter (TH–GFP)[86] (see Figure 12.3), have offered the opportunity to fill cells with a marker dye, revealing the full extent of the dendritic arborization. The dendrites can be seen to branch throughout the arcuate nucleus, with spiny processes visible that are indicative of extensive innervation, in contrast to the fine axonal processes arising off the primary dendrite and projecting ventrally to the median eminence.

Because of the scattered nature and mixed phenotype of hypothalamic neurons, electrophysiological studies of NEDA neurons have been difficult to conduct. There have been a few studies of unidentified cells in the arcuate nucleus that have been interpreted as "putative" TIDA neurons based on a variety of characteristics.[87–89] A more specific approach is to label the cells being recorded and then identify them by immunohistochemistry post hoc (e.g., Ref. 90). This is an accurate method, but it can be extremely time-consuming as many cells need to be examined and only a relatively small proportion will be the cells of interest. A recent study using this approach in prepubertal rats was able to identify a particular pattern of electrical oscillations that was unique to the TIDA neurons in the dorsomedial arcuate nucleus, allowing a thorough investigation of electrophysiological properties of these neurons.[85] This study described TIDA neurons exhibiting a robust oscillation between hyperpolarized and depolarized states, with periodicity of about 20 s and a spontaneous firing rate of approximately 4 Hz during the depolarized "upstate". Remarkably, the TIDA neurons were found to show a synchronous pattern of firing suggestive of an interconnected network, dependent on the functional expression of gap junctions.[85] It was proposed that this synchronous firing might provide optimal population output from the neurons to generate sufficient dopamine to inhibit prolactin secretion at the level of the lactotroph. An alternative approach to study TIDA neurons in mice has been to take advantage of transgenic technologies to label these neurons with a fluorescent marker. For example, TH–GFP mice[91] or mice expressing yellow fluorescent protein in dopamine transporter (DAT)-positive

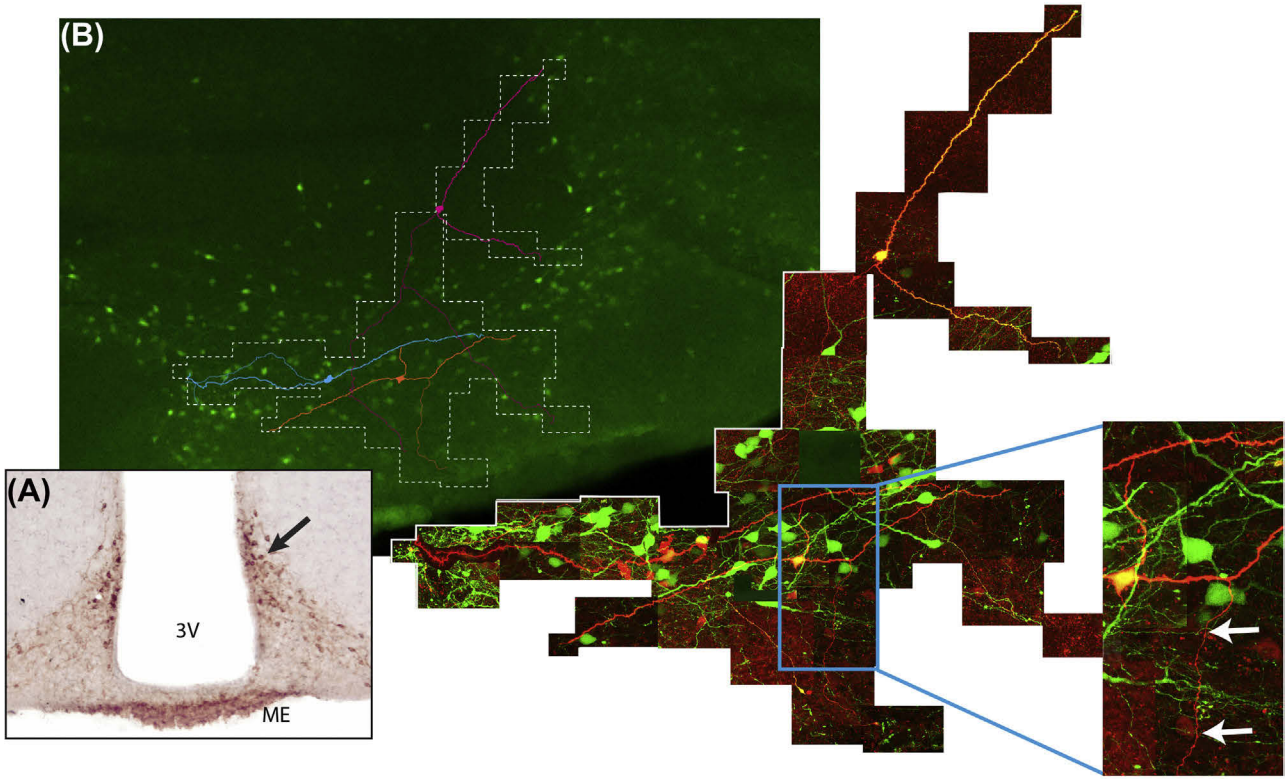

FIGURE 12.3 Neuroanatomy of the TIDA neurons. This figure is reproduced in color in the color plate section. Panel A shows a coronal section through the mouse hypothalamus, with TIDA neurons identified by tyrosine hydroxylase (TH) immunoreactivity (3V: third ventricle; ME: median eminence). Note the cell bodies in the dorsomedial arcuate nucleus (arrow), as well as strong staining in the nerve terminals in the external zone of the median eminence. Panel B shows a low-power sagittal view of the hypothalamus from a mouse in which green fluorescent protein is expressed under the control of the TH promoter (green). These neurons were visualized in a brain slice, and then three individual TH-positive neurons were filled with neurobiotin (red; but pseudocolored pink, blue and orange in the low power view), allowing visualization of the full extent of the nerve processes. The montage (right) is constructed from multiple high-power views obtained using a laser confocal microscope, illustrating the dentritic tree of three filled cells extending a long distance throughout the nucleus. In the enlargement (right), note the major dendrites coming off the cell body, identified by a wide diameter and multiple spiny processes. The thin, smooth axon (arrow) arises off a primary dendrite and projects down toward the median eminence in the base of the hypothalamus. *Source: Images provided by Drs Michel Herde and Allan Herbison, based on work published in Ref. 86.*

neurons[92] allow identification of NEDA neurons in a brain slice, and the firing patterns can be monitored in these models. The DAT model is potentially more specific as TH is expressed in all catecholamine neurons, whereas DAT is specific to dopaminergic neurons. In the arcuate nucleus, however, the only cells labeled in each case are dopaminergic neurons, the majority of which are NEDA.[84] In practice, studies using these approaches in mice have observed a similar pattern of firing to that seen in the rat, although only a small proportion of TIDA neurons showed the phasic oscillations in this model. It is possible that this approach allowed identification of additional NEDA neurons not detected in the rat study, whereas the oscillating cells are only a subset. Nevertheless, a major additional finding from the mouse work was the demonstration that patterns of firing of an individual TIDA neuron were reflected in the pattern of dopamine release from the population, as measured using in vivo amperometry in the median eminence (measuring dopamine by electrochemical detection of its oxidation induced at a specific voltage via a carbon fiber electrode).[92] These data support the concept postulated by Broberger and colleagues[85] that the neurons act as a synchronous network to release dopamine in a pulsatile or phasic fashion.

Short-Loop Negative Feedback

Concurrent with studies establishing the role of dopamine as a physiological prolactin-inhibiting factor, it was found that prolactin stimulated hypothalamic dopamine synthesis[93] and turnover,[94,95] increased metabolism in the median eminence,[96] and promoted dopamine secretion into the pituitary portal blood.[97] These observations identified the afferent limb of a classic negative-feedback mechanism regulating prolactin secretion (see Figure 12.2). Multiple studies in the subsequent two decades have confirmed the reciprocal relationship between prolactin and hypothalamic dopamine secretion. By comparison with other pituitary hormones that act on endocrine

tissue in the body, and for which feedback is provided through the secretions of those endocrine organs (e.g., gonadal steroids for gonadotropic hormones, or glucocorticoids for adrenocorticotrophic hormone), this has been termed "short-loop" feedback, because the pituitary hormone itself provides the feedback signal.

Prolactin acts directly on NEDA neurons, which express prolactin receptors.[98–100] Prolactin stimulates gene expression of TH in NEDA neurons[101] and also modulates the phosphorylation of TH, resulting in increased dopamine synthesis.[102] Dopamine synthesis and release are increased in response to acute or chronic increases in prolactin levels in blood,[103,104] while hyperprolactinemia results in suppression of dopamine secretion,[101] thus fulfilling the criteria to be a homeostatic regulatory system. Activation of NEDA neurons by prolactin requires activation of the JAK2–STAT5b signal transduction pathway.[105–110] As only the long form of the prolactin receptor can activate the JAK–STAT pathway, involvement of STAT5b in the prolactin regulation of NEDA neurons strongly implicates this isoform as the critical protein-mediating prolactin action, and this isoform has been specifically identified on TIDA neurons.[100] In addition to activating STAT5b, prolactin activates a range of other signaling pathways in TIDA neurons, including MAPK, and these pathways are also involved in regulation of dopamine synthesis through modulating the phosphorylation of TH, resulting in increased activity of this enzyme.[102] While the short form of the receptor cannot activate the JAK–STAT pathway, it can mediate some actions of prolactin through MAPK pathways.[111] The short form of the receptor is expressed in the arcuate nucleus of the hypothalamus[112,113] and could possibly influence TH phosphorylation. As described in this chapter, the short form of the receptor may act as a competitive inhibitor of prolactin action by forming inactive heterodimer receptor complexes with the long form,[18–21] thereby preventing activation of the JAK–STAT pathway. Interestingly, short-form mRNA levels in the arcuate nucleus increase during late pregnancy and lactation,[114] raising the possibility that an increasing ratio of short- to long-form prolactin receptors may contribute to a change in the responsiveness of NEDA neurons to prolactin at this time (see the section Prolactin Secretion during Pregnancy in Rodents on pregnancy and lactation).

Using biochemical indices of activity of TIDA neurons, a complex time course of prolactin action has been described, with a "rapid" component of increased activity observed 2–4 h after prolactin treatment[115] and a delayed component seen approximately 12 h after prolactin treatment.[104,116] The former component likely involves rapid, prolactin-induced serine phosphorylation of TH,[102] resulting in increased enzyme activity. These effects of prolactin are presumably mediated acutely by a range of other signaling pathways, including protein kinase C and MAP kinase.[102] The latter component requires protein synthesis,[117] consistent with a role for transcriptional signaling through the JAK–STAT5 pathway. Recent data from three groups have demonstrated very rapid actions of prolactin on the electrical activity of TIDA neurons in transgenic mice expressing fluorescent markers in dopamine neurons[90,91] or in prepubertal male rats, where TIDA neurons were identified by their characteristic phasic firing pattern.[118] These studies show that prolactin induced a fourfold increase in the firing rate within minutes of application, reversibly changing the firing pattern from a basal phasic pattern to a tonically active pattern. The prolactin-induced increase in firing was directly associated with an increased release of dopamine from the median eminence, measured by in vivo amperometry.[92] It seems unlikely that these rapid actions involve the JAK–STAT pathway, as this pathway is involved in transcriptional regulation (see Figure 12.1). Hence this indicates a physiological role for other pathways in mediating prolactin action in these cells. The rapid action of prolactin appears to involve two components: a low-voltage component from transient receptor potential (TRP)-like currents and a high-voltage component from inhibition of Ca^{2+}-dependent, BK-type K^+ currents. These components are mediated through distinct pathways, with the high-voltage component being wortmannin sensitive, suggesting an involvement of the PI3K pathway, whereas the low-voltage component is not.[118]

Interestingly, prolactin action through TRP channels has been previously reported to increase excitability in trigeminal sensory neurons[119] (specifically through TRP-V1 receptors). Prolactin-induced hyperalgesia may be mediated through local production of prolactin in response to tissue inflammation,[120] but this raises an interesting question about whether there might be a role for circulating prolactin in regulating sensory nociception during lactation.

Combined with earlier data on prolactin feedback, it is now apparent that multiple levels of signaling occur in the NEDA neurons (see Figure 12.4). It seems likely that the JAK–STAT pathway mediates transcriptional responses to prolactin, including an increase in mRNA expression for TH.[101,102] In addition to this transcriptional regulation, however, prolactin also increases the phosphorylation of TH through a pathway involving intracellular protein kinases,[102,121] leading to enhanced activity of the enzyme[122] and increased synthesis of dopamine. The data on electrical activity provide evidence for a third level of control in that prolactin also rapidly increases the firing rate of these neurons, resulting in increased dopamine secretion into the portal blood. Thus,

it would appear that TIDA neurons are regulated by prolactin through rapid and transient changes in electrical activity, slower but more prolonged changes in protein phosphorylation, and transcriptional events maintaining changes in gene transcription to regulate neuronal function over a much longer time course.

The complex, multilevel regulation of TIDA neurons by prolactin likely reflects the importance of maintaining tight control over the function of these cells. In terms of the transcriptional response, the TIDA neuronal population is highly sensitive to prolactin, such that a high proportion of neurons show phosphorylated STAT in their nucleus, when exposed to only basal levels of serum prolactin.[123] This is consistent with observations from neurochemistry studies showing that these neurons are tonically activated by basal levels of prolactin, with bromocriptine-induced suppression of prolactin leading to decreased activity.[101] Despite the fact that low levels of basal prolactin are sufficient to maintain a transcriptional response in TIDA neurons, the neurons remain responsive and are still able to show an acute change in firing rate following exposure to additional prolactin. The ability to rapidly respond to changes in prolactin levels and remain responsive throughout a range of prolactin concentrations may be critical to allow TIDA neurons to tightly regulate prolactin secretion through negative feedback.

Effect of Prolactin on Development of the TIDA Neuronal System

Prolactin plays a critical role in the development of the NEDA neurons. Mice that exhibit mutations of the transcription factors *Prop1* or *Pou1f1* (e.g., Ames dwarf or Snell dwarf mice, respectively) lack prolactin (along with growth hormone and thyroid-stimulating hormone (TSH)) and have markedly fewer NEDA neurons in their hypothalamus, as measured by TH immunoreactivity.[124,125] This deficiency develops postnatally, as the number of NEDA neurons present soon after birth is normal.[126] Treatment of these mice with prolactin during the neonatal period and up to puberty,[127] but not in adulthood,[128] rescues the NEDA neurons. NEDA neurons are present with functional connections from immediately after birth,[129] and thus these data suggest that prolactin or growth hormone is required to maintain NEDA neurons postnatally, and that without exposure to prolactin these neurons are lost. Interestingly, transgenic mice that specifically lack prolactin do not exhibit the same loss of NEDA neurons,[130] although they do show a loss of dopamine production,[131] suggesting that some sort of compensation during development is able to make up for the lack of prolactin. It is likely that the presence of growth hormone in these models can account for this compensation during development.[132] While treatment with prolactin in the adult was initially reported as ineffective at rescuing the NEDA neurons, subsequent studies using

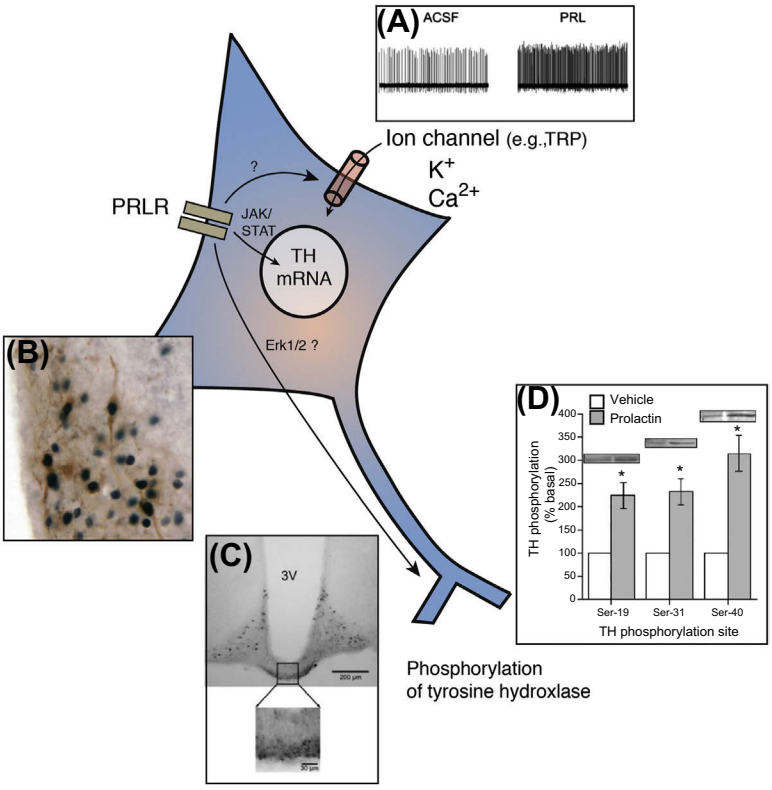

FIGURE 12.4 Diagrammatic representation of the multiple levels of prolactin feedback on NEDA neurons. This figure is reproduced in color in the color plate section. Prolactin binds to prolactin receptors on NEDA neurons and then acutely (within 5 min) increases the firing rate of those neurons. Inset (A) shows prolactin-induced increase in the firing rate of a TIDA neuron.[92] Prolactin also increases the phosphorylation of STAT5 in TIDA neurons (approximately 15–20 min), inducing a transcriptional response. Inset (B) shows prolactin-induced STAT5 immunoreactivity (black) co-localized with immunoreactivity for tyrosine hydroxylase (TH) (brown), demonstrating direct prolactin action in these cells.[91] Finally, prolactin induces the phosphorylation of TH (approximately 15–30 min) both within the cell body and, more particularly, in the nerve terminals within the median eminence. Inset (C) shows prolactin-induced serine 40 phospho-TH immunoreactivity in the arcuate nucleus and median eminence (unpublished data); inset (D) shows prolactin-induced phosphorylation of TH at serines 19, 31, and 40 in mediobasal hypothalamic cultures.[102] ? indicates an uncertain mechanism; $^*P < 0.05$.

homologous hormone from pituitary grafts and longer periods of prolactin exposure in the adult were able to increase the numbers of NEDA neurons present in the hypothalamus.[133] This observation suggests that plasticity is possible in the mature hypothalamus, possibly involving transdifferentiation of other neuronal phenotypes into dopamine cells with sufficient stimulation.

Transport of Prolactin across the Blood–Brain Barrier

The clear role for prolactin as a feedback regulator of hypothalamic dopamine neurons suggests that there must be a mechanism for prolactin to enter the brain. Being a relatively large polypeptide hormone (197–199 amino acids, 21 kDa), prolactin would be expected to be excluded from nervous tissue by the specialized tight junctions between vascular endothelial cells in the brain that form the so-called blood–brain barrier".[134] While it is possible that some prolactin-responsive regions, such as the arcuate nucleus–median eminence region, may have an incomplete blood–brain barrier such that hormones may have more direct access to neurons in this area,[135,136] many prolactin-responsive neurons are found well away from such regions. There is clear evidence, however, that systemic prolactin gains access to the cerebrospinal fluid (CSF). Prolactin levels in the CSF parallel changes in prolactin in the peripheral circulation.[137–139] Moreover, circulating prolactin was found to enter the brain through a saturable, carrier-mediated transport system.[140] By administering radiolabeled prolactin in rodents, high levels of binding were observed in the choroid plexus.[141,142] Consistent with these observations, the choroid plexus contains the highest level of prolactin receptor mRNA and protein of anywhere in the brain,[113,114,143] and levels of both the short and long forms increase in response to estrogen,[144] during pregnancy and lactation,[114,145] and in response to stress.[146] It has been widely assumed that the prolactin receptor might mediate prolactin entry into the CSF, but evidence for this is only circumstantial. Because the ependymal cells lining the cerebral ventricles lack tight junctions and do not limit diffusion into the neural parenchyma, prolactin entering the CSF would have ready access to neurons. Neurons expressing prolactin receptors in the brain are concentrated in periventricular regions, particularly in the hypothalamus.[143,147] Using prolactin-induced phosphorylation of STAT5 as a marker, it can be shown that peripheral administration of prolactin rapidly (within 30 min) activates these receptors in the brain.[123,147] This pattern of activation is essentially identical to that achieved by administration directly into the cerebral ventricles. Taken together, these data are all consistent with the concept that the choroid plexus–CSF route is the principal mechanism by which prolactin enters the brain, and it is possible that prolactin receptors in the choroid plexus may mediate this transport.

Interestingly, the short form of the prolactin receptor is highly expressed in the choroid plexus of the rat,[113] and this pattern of expression is homologous with another cytokine-type receptor, the leptin receptor. Like prolactin, leptin is synthesized and secreted in the periphery, and is transported into the brain. While there is evidence for leptin transport in the cerebral microvessels of the blood–brain barrier,[148,149] it is also clear that this hormone is transported into the CSF at the choroid plexus. The nonsignaling, short form of the leptin receptor is highly expressed in the choroid plexus[150] and is widely thought to act as a transporter.[151] By analogy, it has also been assumed that the short form of the prolactin receptor may be the key transport molecule for prolactin entry into the brain.[152] This assumption has not been tested, and the precise mechanism that translocates prolactin across this epithelial layer into the CSF remains to be determined. Prolactin and prolactin receptor internalization is well documented,[153] although this is typically associated with receptor degradation.[154] Receptor-mediated transport across an epithelial layer remains to be proven.

Regulation of NEDA Neurons

Many of the factors that regulate prolactin secretion do so by influencing the activity of the NEDA neurons in the hypothalamus. There is a vast literature on the range of different factors that can influence NEDA neurons, and this is well reviewed by Freeman and colleagues.[52] For the purposes of this chapter, we will focus on a few key factors that influence the reproductive functions of prolactin through an action mediated by changes in the activity of NEDA neurons: circadian rhythms, gonadal steroids, and opioid peptides.

Circadian rhythms: There is considerable evidence that dopamine secretion from the hypothalamus varies across the light–dark cycle,[89,155–157] and this is a major contributor to the circadian pattern of prolactin secretion in different states, including the preovulatory surge of prolactin[158] and the daily surges of prolactin[155,159] that are critical for the establishment of pregnancy in rodents. The daily rhythm of activity has been identified through neurochemical measures of dopamine synthesis,[160,161] expression of immediate early genes in the NEDA neurons,[162] and changes in the electrophysiological activity of presumed TIDA neurons (dopamine-inhibited neurons in the dorsomedial arcuate nucleus).[89] The dopaminergic tone is reduced at certain times during the day, such that prolactin secretion tends to be linked to specific times of day. For example, the proestrous prolactin surge in the rat peaks around the time of lights out, while

there are twice-daily surges of prolactin at specific times in the late afternoon and early morning during early pregnancy, which are associated with decreases in dopamine secretion from the median eminence. Superimposed on the inhibitory tone provided by hypothalamic NEDA neurons, there may also be a stimulatory tone that becomes apparent only when dopamine secretion is lowered.[163,164] Such circadian rhythms are typically coordinated by the suprachiasmatic nucleus, and lesions of the suprachiasmatic nucleus abolish rhythms in NEDA function.[156] It seems likely that vasoactive-intestinal peptide from the suprachiasmatic nucleus regulates the activity of NEDA neurons, entraining their activity to the circadian clock.[165] It is also clear, however, that specific clock genes are expressed within NEDA neurons, and expression of these genes shows a circadian rhythm.[166] Thus, these neurons maintain an independent oscillator, allowing a "free-running" rhythm, even in constant light or in the absence of inputs from the suprachiasmatic nucleus. Transient inhibition of clock genes by antisense oligonucleotides did not alter patterns of prolactin secretion,[166] however, making it difficult to interpret their physiological role.

Gonadal steroid hormones: Gonadal steroid hormones exert a marked influence on prolactin secretion, and this is particularly important to integrate the reproductive functions of prolactin with other parts of the hypothalamic–pituitary–gonadal axis. Gonadal steroids influence NEDA function in both males and females.[167–171] The NEDA neurons express receptors for both estrogen (estrogen receptor alpha (ERα)) and progesterone,[172–176] although they may not express androgen receptor.[177] Estradiol appears to render the NEDA neurons less sensitive to the stimulatory effects of prolactin.[178,179] The mechanism of this effect is not clear, as estradiol increases prolactin receptor expression on NEDA neurons,[98] and hence it is possible that chronic estradiol may affect prolactin responses downstream of the receptor through upregulating endogenous inhibitors of the JAK–STAT pathway, such as the SOCS proteins.[180] The effect of estradiol on NEDA neurons is further complicated by the fact that it activates prolactin synthesis and secretion from the anterior pituitary gland (see the section Lactotroph Function on pituitary). Thus, acute increases in estradiol are associated with activation of TIDA neurons, mediated by the estrogen-induced increase in prolactin from the pituitary.[181] In contrast, the predominant direct action of estradiol on NEDA neurons is one of inhibition,[171,178,179,182] suppressing TH expression[183,184] and activity[185] and reducing secretion of dopamine into the portal blood,[186] thereby facilitating prolactin secretion. Testosterone action in NEDA neurons in males appears to be similar to that of estradiol in females, decreasing the activity of TIDA neurons to facilitate prolactin secretion,[170,187] but it does not alter their responses to prolactin.[170]

The effects of progesterone on NEDA activity are equally complex. Progesterone treatment acutely decreases TH activity in these neurons,[188,189] but chronic elevations in progesterone result in increased TH activity[171,190] and increased secretion of dopamine into the portal blood.[191] Progesterone can also antagonize the inhibitory effects of estradiol on TH mRNA levels.[168] The acute inhibitory actions appear to involve a rapid decrease in the phosphorylation of TH, inactivating the enzyme and reducing dopamine synthesis,[189,192] and hence do not seem to involve the classical steroid hormone action via gene transcription. Effects of progesterone on NEDA neurons are dependent on the presence of estradiol,[184,189,193] likely because expression of the progesterone receptor in the brain is dependent on estradiol.[194–197] Hence, it is difficult to evaluate the effects of progesterone on NEDA neurons in isolation from the effects of estradiol.

Endogenous changes in ovarian steroids and the consequent changes in activity of NEDA neurons play a physiological role in the control of prolactin secretion during reproduction (see the section Patterns of Prolactin Secretion). For example, the endogenous circadian rhythm of NEDA neurons is dependent on ovarian steroids.[157] The estradiol-induced proestrous prolactin surge is associated with a steroid-dependent decline in TIDA activity,[188,192,198,199] with a prominent role for progesterone suppressing dopamine release during the plateau phase of the surge.[169,193] Similarly, ovarian steroids play a critical role in controlling the twice-daily prolactin surges required to sustain pregnancy in rodents.[200,201] During late pregnancy, a stimulatory role of progesterone predominates to maintain NEDA activity at high levels and suppress pituitary prolactin secretion. Progesterone withdrawal following luteolysis leads to the suppression of dopamine secretion and the induction of prolactin secretion.[202]

Opioid peptides: Endogenous opioid peptides have a critical role in regulating activity of TIDA neurons, thereby affecting pituitary prolactin secretion in several reproductive states. Opioids inhibit TIDA neurons, contributing to the suppression of dopamine secretion during the prolactin surges of early pregnancy[203,204] and during the antepartum period,[204] as well as during the prolactin secretory response to suckling.[205–209] These effects may be mediated by dynorphin neurons within the arcuate nucleus, as dynorphin terminals are found in close proximity to TIDA neurons.[210] Similarly, β-endorphin neurons have been observed to contact TIDA neurons,[211] but these make up a relatively small proportion of opioid inputs to these neurons. In addition, the TIDA neurons themselves express met-enkephalin,[212] and levels of enkephalin expression increase markedly during late pregnancy and lactation.[212,213] It is possible that increased local release of enkephalin might

contribute to the suppression of dopamine synthesis and release during these times, acting in an autocrine fashion on the TIDA neurons. Pharmacological targeting using subtype-specific receptor antagonists suggests that mu and kappa receptor subtypes, but not the delta receptor, are critical to endogenous opioid peptide regulation of prolactin secretion during these times.[204,208,214,215] These observations are consistent with the possible effect of dynorphin and endorphins, which act predominantly at the kappa and mu receptor subtypes, respectively.[216] Enkephalins are most potent at the delta receptor, which does not appear to be involved in the control of prolactin secretion, but they could also act via mu receptors to suppress dopamine secretion.[216] The opioid-like receptor (ORL1), which does not bind any opioid peptide with high affinity,[217] and the selective ligand orphanin FQ (OFQ) may also regulate prolactin secretion. Intracerebroventricular (ICV) injections of OFQ significantly increased prolactin secretion in males and females.[218,219] Like other opioid peptides, OFQ effects on prolactin seem to be mediated by an action on TIDA neuronal activity. ORL1 expression is found in the arcuate nucleus,[220,221] and OFQ treatment rapidly decreased activity of TIDA neurons, preceding the rise in prolactin secretion.[219]

Interest in the arcuate nucleus dynorphin neurons has recently been elevated by the observation that these neurons also express kisspeptin.[222] This peptide was discovered 10 years ago as being essential for fertility and reproduction,[223,224] and kisspeptin neurons have emerged as critical afferent connections in the neuronal circuit regulating gonadotropin-releasing hormone (GnRH) neurons.[225] The arcuate nucleus population of kisspeptin-producing neurons has recently been found to coexpress dynorphin and neurokinin-B[222,226] and may project widely in the hypothalamus[227] (the extent of these projections appears to have marked species differences[228]), and thus may have a range of functions other than simply stimulation of GnRH neurons. Such functions include appetite and food intake[229] and temperature regulation.[230] The original description of a dynorphin input to TIDA neurons[210] has recently been complemented by the description of kisspeptin–neurokinin B innervation of these neurons.[231,232] Kisspeptin injection into the lateral ventricle stimulates prolactin secretion,[233] consistent with the hypothesis that these neurons have a complex role in the regulation of TIDA neurons, potentially involving multiple bioactive peptides.

Prolactin-Releasing Factors

From the time of discovery of the hypothalamic hormones, it has been assumed that all pituitary hormones would be controlled by a hypophysiotrophic prolactin-releasing factor. The evidence outlined in this chapter, showing that prolactin was predominantly inhibited by the hypothalamus, did not detract from the search for a prolactin-releasing factor to complement dopaminergic inhibition.[234–236] In particular, there was evidence that removal of dopaminergic inhibition was not sufficient to account for the secretion of prolactin induced by stress[237] or suckling.[75] Early studies identified thyrotrophin-releasing hormone (TRH) as a potent stimulator of prolactin secretion, but TRH release from the median eminence did not increase in response to suckling[238,239] and there is no concurrent suckling-induced release of TSH,[240,241] suggesting that it is unlikely that TRH is a physiological regulator of prolactin secretion during suckling. Similarly, both positive and negative evidence exists for vasopressin[242] and oxytocin[243,244] as prolactin-releasing factors. To date, the evidence for a prolactin-releasing factor remains inconclusive, and no one factor convincingly meets the criteria originally assigned by Harris for a hypothalamic hypophysiotrophic factor (these criteria are as follows: (1) present in the median eminence, (2) present in the portal blood at concentrations greater than in the general circulation, and (3) levels fluctuate in the portal blood with electrical or reflex stimulation of the hypothalamus, and this correlates with pituitary hormone secretion).[245] Hence, interest remains high in the identification of hypophysiotropic prolactin regulatory factors, and some high-profile reports have produced a number of false dawns! For example, a novel prolactin-inhibitory factor was discovered within the precursor protein of GnRH,[246] but a physiological role for this "GnRH-associated peptide" in regulating prolactin secretion has not been forthcoming. Ben-Jonathan and colleagues identified a prolactin-releasing activity in the neurointermediate lobe,[247] but despite many subsequent studies, the identity and physiological role of this factor remain elusive. There was much excitement in the field when a novel neuropeptide was identified and named "prolactin releasing peptide", based on in vitro actions.[248] Unfortunately, based on a range of subsequent anatomical and physiological studies, this peptide is almost certainly not a physiological prolactin-releasing factor.[249,250] One interesting new observation is that the dopamine derivative salsolinol may act as a prolactin-releasing factor.[251] This metabolite would essentially originate from the NEDA neurons, particularly the PHDA and THDA populations terminating in the neurointermediate lobe, but exert an opposite effect to that of dopamine, consistent with the concept of a switch from negative to positive feedback. There is some evidence that salsolinol may be involved in both stress- and suckling-induced prolactin secretion,[252] but again, the physiological importance of these observations remains to be confirmed. At this stage, the jury is still out as to whether one or more prolactin-releasing factors are involved in the stimulation of prolactin release, and if so, their identity and function remain to be determined.

LACTOTROPH FUNCTION

The anterior pituitary gland is the main source of circulating prolactin, which is secreted from lactotrophs, one of the five specialized endocrine cell types in this organ. The gland develops from a region of oral ectoderm that forms Rathke's pouch around embryonic day 9 (E9.0) in the mouse.[253] The cells of Rathke's pouch proliferate to generate undifferentiated progenitors that initiate commitment to the various specialized hormonal cell types after exit from the cell cycle[254,255] and terminally differentiate as a result of expression of a cascade of transcription factors and signaling molecules.[253] The full repertoire of transcriptional activators and repressors that specify lactotrophs has not yet been defined, but the cells derive from the pituitary lineage expressing the transcription factor *Pou1f1* (also known as *Pit1*), as do somatotrophs and thyrotrophs, cells secreting growth hormone and TSH, respectively. Loss of functional POU1F1 protein in mice and humans leads to a hypoplastic pituitary gland and a failure of normal lactotroph specification and proliferation, with an absence of postnatal pituitary prolactin gene expression.[253] Recently, late-embryonic pituitary prolactin in the absence of POU1F1 has been described in mice with altered pituitary development,[256] possibly analogous with the *Pou1f1*-independent thyrotroph population that is found in the embryonic pituitary.[257]

Prolactin gene expression is first detected in the embryonic pituitary at E17.5 in the mouse, but only a few cells are detectable by immunohistochemistry before birth.[258] After birth, there is a rapid expansion of the number of lactotroph cells, which in mice increase exponentially from birth to 5 weeks of age but then remain static from 8 weeks of age in the absence of physiological change or tumors.[259] In rodents, the number of lactotrophs in adult females is higher than in males, a sexual dimorphism that begins around puberty and continues until adulthood, when the proportion of lactotrophs is approximately 35% of all pituitary cells in females but 20% in males.[260] The limited studies in humans suggest that there is no sexual dimorphism in lactotroph cell number in men compared with nulliparous women, although there is an increase in multiparous women.[261] Lactotrophs may not be a homogeneous population of cells, as subpopulations have been identified, based on morphology,[262] response to stimulation,[263] or spontaneous secretory activity.[264]

Stimulation of Lactotroph Proliferation

The factors controlling postnatal proliferation of lactotrophs have been only partially characterized, and it is apparent that a complex interaction of peripheral, hypothalamic, and intrapituitary signals determines the control of this cell population. There is an increase in lactotroph cell number in adult $Prl^{-/-}$ and $Prlr^{-/-}$ mice, indicating that there is a homeostatic regulation of the cell population under normal conditions.[265,266] A role for insulin-like growth factor 1 (IGF1) in the early postnatal expansion of lactotrophs has been shown in studies of IGF1 knockout mice, where there is a reduced number of pituitary lactotrophs by postnatal day 20.[267] This study also demonstrated the ability of estradiol and epidermal growth factor to cause lactotroph hyperplasia in mice before puberty, but it suggested that IGF1 may be permissive for these actions. In the adult, interaction of estradiol with growth factors modulates lactotroph proliferation, which is higher in females than males. The transient estradiol-induced increase in lactotroph mitotic activity on the afternoon of estrus[268] is likely mediated by ERα, since loss of this receptor leads to lactotroph hypoplasia.[269] A direct effect on lactotrophs has been suggested by in vitro studies where antagonists of this steroid receptor reduce lactotroph proliferation,[270] an effect that is dependent on antagonist-mediated degradation of the estrogen receptor.[271] Other studies, however, have suggested that in vivo the effects of estradiol may be indirect, since the increased lactotroph proliferation at estrus is blocked by anesthesia on the afternoon of proestrus, indicating that hypothalamic factors mediate at least some of the actions of estradiol.[272] The proliferative response of lactotrophs to estradiol is only transient,[273] and recently it has been shown that it also has a role in apoptosis of lactotrophs (reviewed in Ref. 274), demonstrating an important role for the steroid in maintaining tissue homeostasis.

A wide range of other factors has been described as causing proliferation of lactotrophs, several of which are paracrine factors released by other pituitary cell types or autocrine factors released by the lactotrophs themselves (reviewed in Ref. 275). The most convincing evidence for a role of these factors in driving lactotroph proliferation is from transgenic and knockout mouse studies, with hyperplasia in older adult females resulting from transgene overproduction of pituitary galanin,[276] nerve growth factor,[277] and transforming growth factor alpha,[278] whilst loss of galanin leads to a reduction in lactotroph proliferation in response to estradiol.[279] It has been suggested that prolactin itself may have a role in lactotroph proliferation, since prolactin receptors have been found in the pituitary and the rate of induction of pituitary tumors in mice correlates with the level of prolactin secretion.[74] Studies of both $Prlr^{-/-}$ and $Prl^{-/-}$ mice, however, suggest that this is unlikely, since the absence of prolactin signaling leads to even more dramatic lactotroph hyperplasia than that found in $D2r^{-/-}$ mice (see the section Dopamine Inhibition of Lactotroph Function and Proliferation via the D2 Receptor).[265,280]

Dopamine Inhibition of Lactotroph Function and Proliferation via the D2 Receptor

Unlike other pituitary hormone cell types, and indeed most other endocrine cells, lactotrophs secrete prolactin spontaneously in the absence of dopamine inhibition (as discussed in this chapter). Lactotrophs display spontaneous electrical activity, and Ca^{2+} influx through voltage-gated Ca^{2+}channels (VGCCs) leads to prolactin secretion (described in more detail in Ref. 6). Inhibition of calcium influx by dopamine results in reduced prolactin secretion from storage granules by altering the activity of VGCCs[281] and membrane hyperpolarization.[282,283] Of the five dopamine receptors, the two members of the D2-like receptor family, D2R and D4R, are found in the pituitary gland,[284,285] and it is through these D2-like receptors, which are coupled to a pertussis toxin–sensitive G protein ($G_{i/o}$),[286–288] that dopamine acts to inhibit lactotroph cell function and proliferation.[53,72] The importance of the role of D2R specifically in lactotroph regulation is apparent from the hyperprolactinemia observed in knockout mice with a loss of this receptor subtype.[73,74] Although there have been reports of dopamine stimulation of prolactin secretion at low concentrations,[289,290] this may be a rebound effect of dopamine removal,[291] which has been shown in perfused pituitary slice culture.[292] In addition to its effect on secretion, dopamine-induced suppression of adenylate cyclase leads to a reduction in prolactin gene expression,[293–295] which may also involve activation of protein kinase C[296] and ERK1/2[297] signaling pathways. The transcription factor POU1F1 has been shown to have a role in mediating the effects of dopamine on prolactin gene expression. This occurs at two levels, since POU1F1 has been shown to directly mediate dopaminergic effects on the prolactin promoter,[298] and the expression of POU1F1 is also downregulated by reduced adenylate cyclase activity,[293] leading to reduced prolactin gene expression.

It is well established that dopamine inhibits lactotroph proliferation, as this effect has been demonstrated in cultures of pituitary cells[295] as well as in vivo by suppression of estradiol-induced proliferation.[299] The effects of loss of D2R,[73,74] leading to abrogation of dopamine inhibition of the lactotroph, and of loss of the DAT,[300] leading to reduced reuptake of dopamine in median eminence nerve terminals with a consequent increase in dopamine reaching the pituitary, best define the in vivo role of dopamine in regulating lactotroph proliferation. In young adult animals, loss of dopamine inhibition has only a mild effect[74] or no effect[73] on lactotroph cell number, but with increasing age, there is a dramatic lactotroph hyperplasia, leading to prolactinoma formation in females and much later in males.[74,301] Increased dopamine from loss of DAT leads to a severe postnatal reduction in lactotroph proliferation, which leads to a dramatic reduction in the number of lactotrophs by 8 weeks of age.[300] The similarity of phenotypes between D2R knockout mice and those with a specific reduction of hypothalamic dopamine[302] suggests that D4R, while present in the pituitary, has a minor role in control of lactotroph proliferation. Interestingly, mice with a loss of prolactin receptor and D2R have a more advanced and severe hyperplasia and tumor formation than those with loss of either receptor alone,[280] demonstrating that dopamine inhibition is not the sole regulator of lactotroph proliferation and the existence of other homeostatic mechanisms controlling their cell number. Taken together, these models suggest that early lactotroph proliferation is principally regulated by nondopaminergic mechanisms, although cells remain responsive to high levels of dopamine from birth. The factors regulating this are undefined but may include IGF1. In adult animals, there is a complex interaction between dopamine and a number of other factors in the regulation of lactotroph proliferation, with a role for nondopaminergic factors that respond to a loss of prolactin signaling. In older animals, there is a physiological change that permits increased lactotroph hyperplasia despite hyperprolactinemia, suggesting a breakdown of regulatory homeostatic mechanisms, which can lead to tumor formation.

Of note in all of the models of lactotroph hyperplasia and tumorigenesis, both those resulting from overexpression of growth factors and those with reduced dopamine inhibition, is a dramatic effect of sex. A bias toward lactotroph hyperplasia and more rapid generation of pituitary tumors in females could be expected from the actions of estradiol, but this may not be the sole factor leading to the increased female hyperplasia. In *D2r*$^{-/-}$ mice with hyperplasia resulting from loss of dopamine inhibition, it was noted that males and females had similar serum estradiol levels.[74] The role of sex steroids in lactotroph hyperplasia in *D2r*$^{-/-}$ mice was further characterized by Low and colleagues, who found that gonadectomy reduced the lactotroph hyperplasia and tumor formation but that this could not be fully rescued by estradiol replacement, suggesting that ovarian factors other than estrogen are required for the proliferation of lactotrophs.[266]

Other Factors Regulating Prolactin Secretion in the Pituitary

In addition to dopamine, a number of other factors have been described as regulating secretion of prolactin from the lactotroph, although the physiological significance of these is not yet established. Hypothalamic somatostatin inhibits prolactin secretion through both cyclic adenosine monophosphate (cAMP)-dependent and -independent mechanisms,[303] and calcitonin, which may be of hypothalamic origin, has also been shown

to inhibit secretion.[304] In addition, local production of endothelin-1 and transforming growth factor beta may be autocrine or paracrine inhibitors of prolactin secretion.[305,306] Whilst estradiol is a major stimulator of prolactin secretion in mammals, this is principally through increased prolactin gene expression,[307] by increasing the number of lactotrophs (as discussed in this chapter), and by modifying lactotroph responsiveness to other regulators,[308–310] although a rapid nongenomic action of estradiol-stimulating prolactin secretion has been described.[263] A large number of other factors have been suggested as directly stimulating prolactin secretion, although a clear physiological role for many of these has not yet been demonstrated (reviewed in Ref. 52). These include the following:

- *Vasointestinal peptide (VIP)*: This is produced in the hypothalamus[311] and in lactotrophs themselves.[312] As well as in vitro and in vivo demonstrations of effects on prolactin secretion, passive immunization against VIP leads to reduced prolactin secretion.[313] It is possible that VIP was the ancestral regulator of prolactin secretion, since it is the primary prolactin-releasing factor in nonmammalian vertebrates.[314,315]
- *TRH*: This is released from the hypothalamus, is a regulator of thyrotrophs, and stimulates prolactin synthesis and secretion from lactotrophs,[316] which express TRH receptors.[317] However, no effect on prolactin secretion was found after stimulation of cultures of mouse pituitary slices,[292] and nonpregnant TRH-deficient mice have normal pituitary and serum prolactin,[318] although this could suggest species-specific effects of TRH. However, pituitary and serum prolactin were reduced in lactating TRH-deficient animals, even after thyrotrophin replacement, suggesting a role for TRH in stimulation of prolactin gene expression in lactating mice. The role of TRH may be further complicated by interaction with other regulatory factors, since an interaction between estradiol and TRH in stimulation of prolactin secretion has been described.[319]
- *Oxytocin*: This can reach the anterior pituitary from both peripheral circulation and short portal vessels linking the posterior and anterior lobes of the pituitary. Treatment of mouse pituitary slices with oxytocin stimulates prolactin release,[292] and antagonism of oxytocin leads to reduced prolactin secretion.[244,320] Oxytocin may have a complex interaction with dopamine in the control of prolactin secretion.[321]
- *Galanin*: Galanin is synthesized in both the hypothalamus and pituitary, has been shown to stimulate lactotroph function, and may be one factor mediating the effects of estradiol on lactotrophs.[276,279,322]

A number of other autocrine and paracrine factors have been shown to have prolactin-releasing activity (reviewed in Ref. 52).

Changes in Pituitary Function during Pregnancy and Lactation

Studies in rats and humans have shown an increase in lactotroph cell numbers in lactation, which in humans (but not rats) begins early in pregnancy,[323,324] with rapid regression back to prepregnant numbers after cessation of lactation.[325] Lactotroph hyperplasia was not found in lactating mice,[326,327] although this does not preclude increased lactotroph turnover resulting in altered function. This does suggest, however, that there may be species-specific differences in meeting the increased physiological demand for prolactin during lactation. There are several mechanisms that may lead to changes in the number of lactotrophs during pregnancy and lactation, including proliferation of lactotrophs, transdifferentiation between hormone cell types, apoptosis, and proliferation and differentiation of progenitor or stem cells:

Lactotroph proliferation: The sexual dimorphism in cell numbers in rodents is accompanied by a difference in the mitotic rate of lactotrophs, which is lower in males than females and begins to decline before puberty, whereas in females the mitotic index of lactotrophs peaks at 60 days of age.[268] Increased mitosis of lactotrophs has been found in late-pregnant rats[328] and in pregnant women.[323,329] There is a transient increase in lactotroph mitotic activity on the afternoon of estrus, which is dependent on estradiol.[268]

Transdifferentiation: The presence of some bihormonal GH–prolactin cells, known as mammosomatotrophs, in the pituitary, together with the timing of hormone expression and shared transcription factor requirements, have led to the suggestion that lactotrophs develop by transdifferentiation from somatotrophs. This was proposed to account for increased lactotrophs in pregnancy and lactation in rats[324] as well as in humans.[329] Studies using lineage tracing in mice, however, have suggested that, at least in this species, only a small proportion of lactotrophs is derived from somatotrophs.[330] The proportion of mammosomatotrophs in mice is much lower than in rats,[326] so it is possible that the proportion of lactotrophs arising from transdifferentiation may be higher in rats, the species where this has been studied in the most detail. Lineage studies have also demonstrated that lactotrophs do not transdifferentiate into any other pituitary cell type.[326]

Apoptosis: The increased lactotroph mitosis that occurs at estrus is accompanied by an increase in apoptosis

at the subsequent proestrus when pregnancy does not occur,[331] as well as at the end of lactation.[332] An interaction of estrogen and dopamine has been implicated in regulating this apoptosis.[333–335]

Progenitor cells: Recently, a population of cells in the pituitary with the characteristics of stem cells has been described.[336–338] These cells are potentially capable of differentiation into all pituitary hormone cell types. In the absence of lineage-tracing tools, the contribution of these cells to the lactotroph population in the normal pituitary is unclear; however, cell ablation studies suggest that they contribute to regeneration of lactotrophs in adult mice.[339]

Thus, a combination of processes results in altered function during pregnancy and lactation, optimizing prolactin production for lactation. The precise mechanism of these changes is not known and seems likely to involve some or all of the above processes, but the relative importance of each process may be different in different species.

Organization of Lactotrophs into a Network Affects Function

In recent years, the importance of cell organization in the function of pituitary cells has become apparent (reviewed in Ref. 340). An indication that lactotroph function is affected by contact between cells is suggested by in vitro studies showing that increasing the density of dispersed lactotrophs in culture augmented the inhibitory effects of dopamine.[341] The organization of lactotrophs in the female mouse pituitary has been studied using multiphoton imaging of pituitary slices with lactotrophs identified by the transgenic expression of DsRed fluorescent protein.[292] Lactotrophs are distributed throughout the anterior pituitary, with a higher density in the ventral region, and are organized into honeycomb-like structures.[327] This organization is distinct from that described for other pituitary cell types, for example somatotrophs,[342] suggesting that the pattern of organization may be related to the different secretory patterns of the hormones. In lactation, lactotroph organization is modified so that the honeycomb structure becomes more apparent and there is an increase in contacts between lactotrophs (see Figure 12.5) This increased structural organization is a response to the high demand for prolactin in lactation, rather than simply the result of physiological changes associated with pregnancy, because restricting prolactin demand by reducing the number of suckled pups reduces the extent of augmented network organization.[327] The change in organization of lactotrophs is accompanied by an increase in the synchronization of lactotroph secretory activity, monitored by calcium imaging, and is mediated by gap junctions. This suggests that the network is important for the increased secretory output of lactotrophs in lactation by coordinating the activity of subpopulations of cells. Surprisingly, after weaning, the augmented organization of lactotrophs persists, even after 3 months, and leads to a change in coordinated cell behavior and a further increase in prolactin output, showing that lactotrophs demonstrate experience-related structural and functional plasticity.[327]

PATTERNS OF PROLACTIN SECRETION

The pattern of prolactin secretion varies between species in a manner that is specific to the reproductive strategy of that species. Common to all mammals is the prolactin stimulus provided by suckling of the nipple by the young, which produces a signal in afferent somatosensory neuronal pathways that is relayed to the hypothalamus and then the pituitary, inducing prolactin secretion. This is a classical neuroendocrine reflex, where the amount of prolactin released depends on the intensity and duration

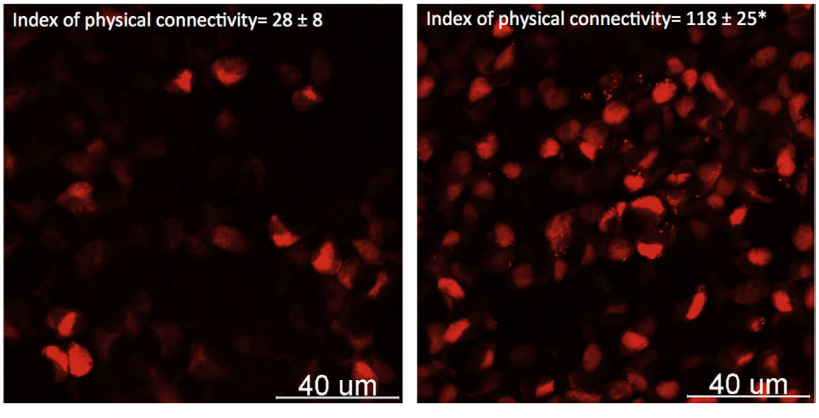

FIGURE 12.5 Biphoton imaging of pituitaries from virgin (left panel) and lactating (right panel) mice with transgenic expression of DsRedExpress fluorescent protein identifying lactotroph cells. This figure is reproduced in color in the color plate section. In the virgin pituitary, lactotrophs are organized into a network of honeycomb-like structures. In the lactating pituitary, these honeycomb structures become more pronounced, and there is an overall increase in the proportion of lactotrophs with homotypic contacts. The "index of physical connectivity" is generated by three-dimensional reconstructions of the fluorescent label and reflects the degree of structural connections of lactotrophs with other lactotrophs. *P <0.05. *Source: Image courtesy of Chrystel Lafont, Taoufik El Yandouzi, and Patrice Mollard, Montpellier, France, based on work published in Refs 327,340.*

of suckling.[5] Apart from suckling, the most physiologically relevant stimulus to prolactin secretion is estradiol, which stimulates prolactin secretion both through actions on the pituitary gland and through hypothalamic mechanisms. This action is particularly important during the reproductive cycle and during pregnancy. Interestingly, unlike the suckling-induced release of prolactin that is tightly linked to the stimulus itself, estradiol-induced prolactin secretion tends to be a global change in secretion that is superimposed on patterns generated by other factors, such as the light–dark cycle.[158] For example, estradiol induces a single afternoon prolactin surge observed during the afternoon of proestrus,[343] or in ovariectomized animals, chronic elevation in estradiol induces a daily afternoon prolactin surge.[344] During late pregnancy, there is another estrogen-dependent surge of prolactin secretion, again timed to the light–dark cycle.[180,345,346]

Another interesting prolactin stimulus is stress, which induces an acute increase in prolactin secretion in many species.[347] Stress-induced prolactin secretion is thought to be involved in modulation of the immune system, or as a counterregulatory mechanism to limit the hypothalamic–pituitary–adrenal axis response to stress. Prolactin can also act in the brain[348] to prevent the stress-induced formation of gastric ulcers.[349,350] This effect is associated with increased prolactin receptor expression in the choroid plexus[146] and in the paraventricular nucleus (PVN) of the hypothalamus.[348] Antisense-induced inhibition of prolactin receptor expression in the PVN prevents the ability of prolactin to block stress-induced changes in plasma calcium and gastric ulceration.[351] Thus, stress-induced changes in prolactin secretion might have protective actions in the body as well as reducing anxiety associated with the stressor. While some have argued that this release of prolactin is unlikely to have a major reproductive function,[352] the influence on the stress axis has been raised as potentially important in birds for maintaining reproductive function in the face of stress.[353] This latter context may be similar to a role of elevated prolactin in suppressing the stress response in mothers during pregnancy and lactation in mammals (discussed further in this chapter). For the purposes of this chapter, we will describe the patterns of prolactin secretion during the full reproductive cycle in rodents (as key experimental species) and contrast this with what is known about humans.

Prolactin Secretion during Pregnancy in Rodents

Prolactin secretion is relatively low during the estrous cycle in rats, resulting in concentrations in blood of <20 ng/ml, except for an estradiol-induced surge (peaking around 200–300 ng/ml) during the afternoon of proestrus,[354] which is largely coincident with the preovulatory luteinizing hormone (LH) surge (Figure 12.6). Some labs report a secondary surge during the afternoon of estrus,[355] which is likely dependent on how long estradiol levels stay elevated. The vaginocervical stimulation that female rats experience during mating provides the afferent input of a unique neuroendocrine reflex, resulting in the initiation of twice-daily surges of prolactin that are of similar magnitude to the proestrous surge.[200,356] These surges are not typical of a normal neuroendocrine reflex, as the stimulus does not need to be repeated for another surge to occur. Instead, the prolactin surges are timed by the light–dark cycle, with daily diurnal and nocturnal prolactin surges, the first in the afternoon at approximately the same time as the proestrous surge, and the second peaking approximately 2 h before the end of the dark phase. These surges provide luteotropic support for corpus luteum production of progesterone[343,357] and thus are critical for the maintenance of pregnancy. Prolactin surges persist for about 10 days in pregnant rats. A similar pattern of secretion has been reported in mice.[358,359]

The timing of the prolactin surges may be generated by the characteristics of the feedback mechanisms controlling prolactin secretion (Figure 12.6). Hence, estrogen- or mating-induced increases in prolactin activate hypothalamic dopamine neurons by short-loop feedback. Notwithstanding the rapid feedback effects described in this chapter, there is a 4–8 h delay in the overall neurochemical activation of the NEDA neurons,[104,116] likely involving changes in gene expression and new protein synthesis, before tonic dopamine secretion rises sufficiently to bring prolactin back to presurge levels. Falling prolactin then relieves the stimulatory drive to NEDA neurons, and dopamine release falls, potentially allowing a further prolactin surge to occur. Thus, NEDA neurons also exhibit a semicircadian pattern of activity during early pregnancy, with reduced dopamine release observed during the prolactin surges and elevated release between surges.[155,159,201] It is hypothesized that once initiated by the mating stimulus, the mating-induced prolactin surges are driven by a reciprocal interaction of an endogenous rhythm of oxytocin neurons stimulating prolactin release, followed by an inhibitory dopamine response with an intrinsic delay. This reciprocal fluctuation is entrained to the light–dark cycles by innervation of oxytocin neurons by vasoactive-intestinal peptide projections from the suprachiasmatic nucleus.[165,360,361]

The prolactin surges of early pregnancy are terminated in response to the increased secretion of placental lactogens from the developing conceptus.[362,363] The placental lactogens are structurally similar to prolactin and act in an identical manner, crossing into the brain and activating prolactin receptors on NEDA neurons to cause a sustained increase in dopamine release[159] and thereby inhibit the secretion of prolactin from the maternal pituitary.[362,364,365] Two forms of placental lactogen have been

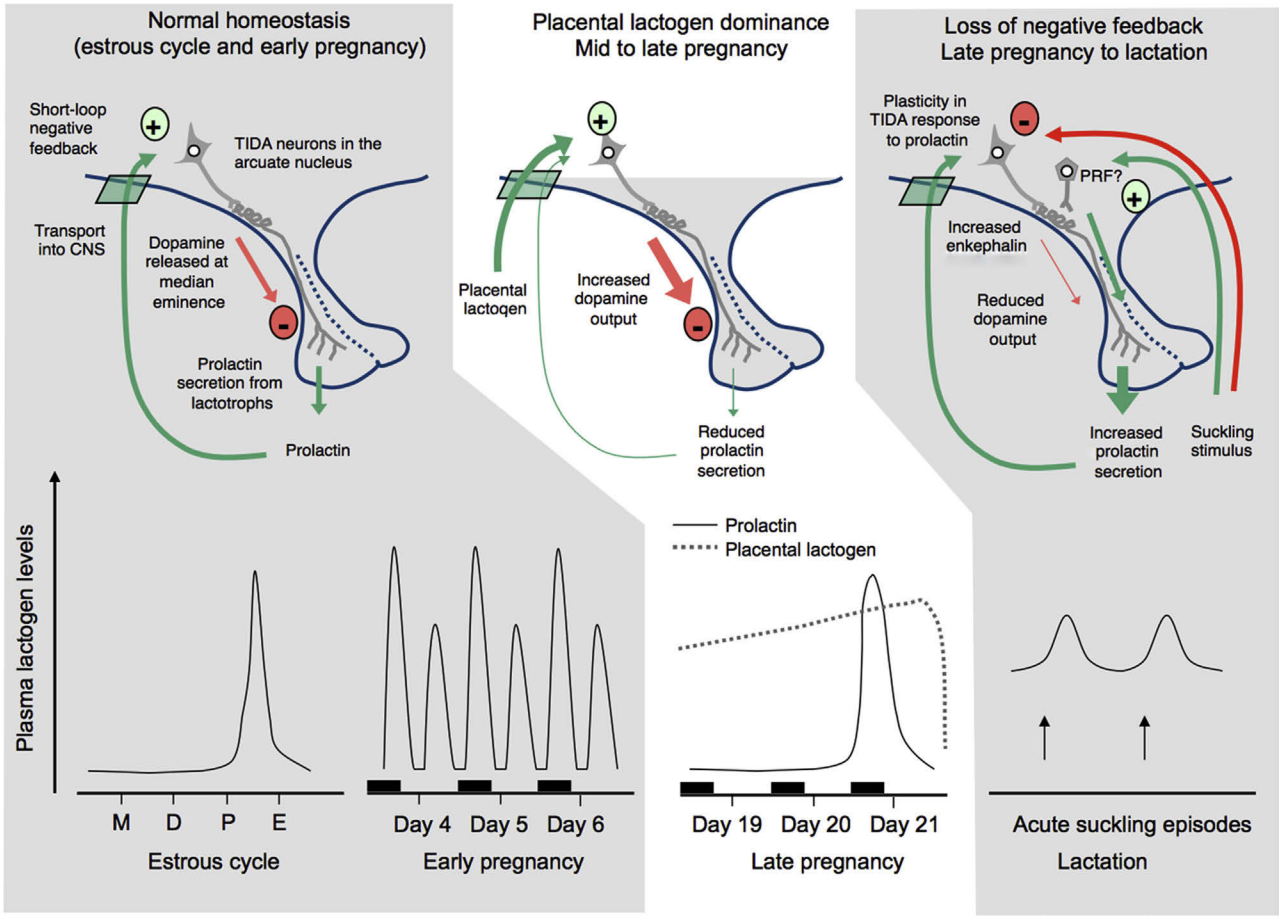

FIGURE 12.6 Diagrammatic representation of the major patterns of lactogen secretion in the rodent (prolactin: solid line; placental lactogen: dotted line), together with a cartoon depicting the changes in the hypothalamic control of prolactin secretion in the different physiological states. See the text for details. ? indicates an uncertain mechanism; *P <0.05.

identified in rats, placental lactogen-I (rPL-I) and -II (rPL-II).[366] rPL-I is present from day 8 of pregnancy and peaks in the circulation around day 13,[367] while rPL-II is first detected around day 10 of pregnancy, peaking near parturition.[368] Both variants bind to the prolactin receptor[367] and thus activate the short-loop feedback system inhibiting prolactin secretion.[364] As rPL-I is present earlier, it is most likely the signal that terminates early-pregnancy prolactin surges,[369] while rPL-II maintains this inhibition of prolactin secretion during the remainder of pregnancy. Thus, from the time of cessation of the prolactin surges until very near term, NEDA neuronal activity is high and maternal prolactin secretion is suppressed.[345] Because placental hormone secretion is not under the inhibitory control of the hypothalamus, this placental lactogen secretion essentially bypasses the maternal regulatory feedback pathways to provide high levels of prolactin receptor activation throughout the second half of pregnancy. Thus, at day 10 of pregnancy, there is a change in the pattern of prolactin receptor activation, from a phasic pattern of activation provided by twice-daily prolactin surges during early pregnancy to the chronic stimulation induced by placental lactogen (Figure 12.6). This chronic secretion of placental lactogen continues until term.

There is a distinct change in the mechanisms regulating prolactin secretion from late pregnancy and into lactation.[370] Up until this time, feedback regulation of prolactin secretion dominates. Despite the continued presence of placental lactogens, however, there is a decrease in NEDA neuronal activity during late pregnancy[345] associated with a nocturnal surge in pituitary prolactin secretion (300–500 ng/ml) immediately before parturition.[346,371] The timing of this event appears to be controlled by the changes in ovarian steroid hormones associated with this time, in that prolonging pregnancy with progesterone treatment delays the prolactin surge, while the surge can be advanced by estradiol treatment following progesterone withdrawal.[346] NEDA neurons no longer release dopamine in response to prolactin or placental lactogen at this time, rendering the short-loop negative-feedback system functionally inactive.[371] This adaptation persists into lactation, and NEDA neuronal activity remains low even during periods of elevated prolactin secretion.[68,372] Furthermore, treatment with

prolactin during late pregnancy[373,374] or lactation[372,375] does not affect NEDA activity, such that the high levels of pituitary prolactin secretion that are required for lactation and maternal behavior can be maintained throughout late pregnancy and lactation unencumbered by an inhibitory feedback system. There is no evidence that this loss of sensitivity is mediated by a downregulation of prolactin receptors on the TIDA neurons,[100] and indeed, recent evidence suggests that the rapid increase in electrical activity seen in response to prolactin persists in lactation.[92] Downstream of the prolactin receptor, however, there is a change in the cellular response. TH phosphorylation (serine 40) in the median eminence is decreased, and because phosphorylation of TH at this site is required for enzyme activity,[376] this means that the activity of TH is reduced, and the neurons no longer release dopamine in response to a change in firing rate.[92] Prolactin-induced activation of the transcription factor, STAT5b, which is essential for prolactin-mediated stimulation of dopamine synthesis and release,[106] is suppressed (but not abolished) during lactation, likely mediated by an upregulation of a family of endogenous inhibitors of STAT signaling, the SOCS proteins.[108,109,180] There is an increase in enkephalin expression in the NEDA neurons,[212,377,378] and it seems likely that elevated prolactin drives this enkephalin expression.[379] The function of enkephalin expression in NEDA neurons is not clear, but as described here, extensive data show that opioids inhibit the activity of NEDA neurons. It is therefore possible that prolactin-induced enkephalin release from these neurons will contribute to the suppression of dopamine secretion, effectively changing the short-loop feedback from a negative-feedback to a positive-feedback system, facilitating prolactin secretion (Figure 12.6).

After parturition, when placental lactogen is lost, prolactin secretion from the maternal pituitary again becomes the major source of lactogenic hormones in the maternal circulation. Prolactin secretion is now closely linked to the suckling stimulus from the young, which directly induces maternal prolactin release and thus ensures continued production of milk. Essentially, the production of prolactin during a feeding bout stimulates milk production to replace what was consumed, and the longer the suckling bout, the longer prolactin is elevated, matching milk production to demand. This highly coordinated release of prolactin is caused by a suckling-induced decrease of activity of TIDA neurons,[372,380,381] resulting in profound suppression of TH mRNA levels,[382] dephosphorylation of TH protein in the median eminence,[383] and reduced secretion of dopamine into the portal blood.[68] The specific pathway mediating the suckling-induced suppression of NEDA neurons is not clear. A direct neuronal pathway is involved, transmitting the somatosensory afferent information from the nipple via the spinal cord to the hypothalamus.[384] Recent evidence suggests that there is a direct pathway from the subparafascicular nucleus–posterior thalamus to the ventrolateral arcuate nucleus, possibly connecting with the dynorphin neurons located in this region.[385] Neurons in this pathway express the tuberoinfundibular peptide of 39 residues (TIP39), and this peptide may be a critical regulator of prolactin secretion in response to suckling,[386,387] acting through the parathyroid hormone 2 receptor[388] to suppress activity of NEDA neurons.

There is much debate about whether disinhibition per se is sufficient to account for the full suckling-induced release of prolactin. Certainly, administration of a dopamine D2R antagonist can result in a release of prolactin of similar magnitude to that seen during suckling.[389] However, whether such a total withdrawal of dopamine ever occurs in vivo is unlikely.[390] Where measured, the fall in portal blood dopamine may not account for the full release of prolactin.[75] Hence, there have been many attempts to identify prolactin-releasing factors that might be involved in stimulating prolactin secretion, particularly in response to suckling. Lesions of the PVN markedly impair the suckling-induced release of prolactin,[391,392] suggesting that this nucleus plays a key role in stimulating prolactin secretion. Similarly, removal of the posterior lobe of the pituitary blocks the suckling-induced release of prolactin.[247] A range of putative candidates from the PVN and/or posterior pituitary has now been examined, but the evidence for a physiological prolactin-releasing factor remains inconclusive (as discussed in this chapter).

Patterns of Prolactin Secretion in Pregnant and Lactating Women

Unlike rodents, in women no clear rise in prolactin secretion during the menstrual cycle has been documented that is associated with ovulation (reviewed in Ref. 393). Some studies show no change in prolactin at this time,[394] while others report a small rise.[395] In an excellent overview of multiple studies looking at hormonal changes during the menstrual cycle, Rubinow and colleagues concluded that there likely was a transient surge in prolactin associated with ovulation, but that many studies have missed this due to timing of sampling or suboptimal experimental conditions.[396] Even if this is correct, it is clearly not as prevalent as that seen in other species. It is possible that this is due to the relative lack of sensitivity of the human prolactin promoter to estradiol,[397] resulting in pituitary prolactin secretion being much less sensitive to changing levels of estradiol than is seen in rodents.[393]

While many studies have measured prolactin levels during pregnancy in women, they have been the focus of systematic investigation in relatively few. Both prolactin[398,399] and human placental lactogen (hPL; also known as chorionic somatomammotropin)[400] are present in the blood during pregnancy, in increasing amounts

with advancing gestation. There is also growth of the pituitary gland (reviewed in Ref. 401), with increased lactotroph size and number,[329] as discussed in this chapter. The concurrent rises in both prolactin and placental lactogen suggest that placental lactogen is ineffective at activating the short-loop feedback system to suppress prolactin secretion. This is interesting because unlike rodent placental lactogens, which are closely related to prolactin, hPL is in fact much more similar to human growth hormone (sharing an 85% homology, as opposed to a 22% homology with prolactin).[14] As growth hormone can activate the human prolactin receptor and is therefore considered lactogenic[b], the closely related placental lactogen can also activate the prolactin receptor. However, each ligand will bind to the receptor in a unique manner, potentially generating subtly different responses. It is possible that, as happens in late pregnancy in rodents, the NEDA neurons alter their response to prolactin (and placental lactogen), but that this happens relatively early in human gestation to allow the concurrent rise in prolactin and placental lactogen, although this has not been studied. As in other species, suckling induces a rapid increase in plasma prolactin, which is proportional to the duration and intensity of the suckling episode.[403]

Thus, in humans and other mammalian species, there are at least three adaptations to ensure high levels of lactogenic hormone activity during pregnancy and lactation. Firstly, the production of placental lactogen bypasses the inhibitory regulation of the maternal pituitary gland, providing constantly elevated levels of lactogenic hormones throughout pregnancy. Secondly, the maternal NEDA neurons change the manner in which they respond to prolactin (or placental lactogen) and cease to release dopamine, causing dopamine to remain low during late pregnancy and lactation despite elevated prolactin. Finally, maternal behavior and the introduction of the suckling stimulus provide the most powerful stimulus to prolactin secretion that is known in mammals. While these elevated levels of lactogenic hormones are clearly required for development of the mammary gland during pregnancy and for milk production during lactation, prolactin and placental lactogen are also able to act in a wide variety of other tissues in the body to facilitate the adaptive responses that are required for successful transition through these different reproductive states.

Extrapituitary Prolactin

The patterns of prolactin secretion described in this chapter all originate from secretion from the anterior pituitary gland, where the prolactin gene is expressed under the control of the pituitary-specific *Pou1f1* promoter. In humans and other primates, however, the prolactin gene is also expressed at extrapituitary sites, including immune tissues, adipose tissue, skin, and decidualized endometrium.[393] This extrapituitary expression is driven by an alternative promoter located 5.8 kb upstream of the pituitary transcription start site within a primate-specific long terminal repeat transposable element[c]. Of the various sites of extrapituitary prolactin production, decidual prolactin would appear to have an important function in reproduction. Decidual prolactin is identical to human pituitary prolactin and is present in amniotic fluid by week 9 of pregnancy, increasing to peak levels around midgestation. While decidual prolactin does not get into the maternal circulation in significant concentrations,[405] and hence its contribution to lactogenic effects in the mother is minimal, it is dramatically upregulated during pregnancy,[406] and its presence at the maternal–fetal interface is thought to have important paracrine roles in implantation,[407] controlling endometrial growth, as well as the volume and composition of amniotic fluid.[408] Local production of prolactin from adipocytes in the mammary gland may also play an important role in lactation[409] and certainly influences mammary carcinoma[410] (see the section Prolactin and Reproductive Disorders).

As rodents do not have this "primate-specific" distal promoter, extrapituitary prolactin would not be expected.[393] Nevertheless, numerous examples of extrapituitary

[b] The lactogenic activity of growth hormone was largely responsible for the delay in the discovery of human prolactin until the early 1970s. Prior to that time, many endocrinologists doubted that human prolactin existed. Although extracts of human pituitary glands could be shown to have prolactin-like effects, attempts to purify it identified only growth hormone.[402]

[c] The human prolactin gene locus is markedly different from that of the rodent prolactin gene. In humans, there is a single prolactin gene on the short arm of chromosome 6, surrounded by approximately a megabase of noncoding DNA. By contrast, the rodent prolactin gene exists as a large family of up to 26 closely related paralogs arising from multiple gene duplication events.[3] These genes are clustered on chromosomes 13 and 17 in the mouse and rat, respectively. It has been proposed that the use of an alternative promoter to drive human prolactin secretion in extrapituitary sites is an alternative strategy to compensate for the lack of expansion of the prolactin gene in primates.[404] No mutations of human prolactin have been described, and one interpretation of this is that such mutations might be lethal due to the lack of redundancy in the human prolactin gene. Another observation is that primates have evolved an expansion of the closely related growth hormone locus, with five different growth hormone–related genes providing the plasticity to produce pregnancy-related ligands, such as human chorionic somatomammotropin (human placental lactogen) and placental growth hormone variant, while rodents have a single growth hormone gene. The common theme is that many members of these gene families are expressed at the maternal–fetal interface, either in the decidual tissue or in the trophoblast cells of the placenta, suggesting an important role in pregnancy.

expression have been reported in rats and mice. For example, autocrine prolactin from mammary gland appears to be required for lactation initiation in mice.[411] "Pituitary" prolactin (as well as multiple prolactin-related genes) is also expressed in decidual tissue in rats[412] and mice.[413] The prolactin receptor is also expressed in these reproductive tissues in rats[414] and mice,[415] providing the substrate for autocrine mechanisms controlling cellular function. A potential explanation for this extrapituitary prolactin in rodents has recently been provided by the identification of a novel alternative promoter region distinct from that observed in humans.[416] These authors found that decidual prolactin is not a characteristic of all placental mammals, but has evolved at least three separate times in humans, rodents, and elephants, each with a different distal promoter. The regulation of expression is unlikely to be conserved, but the convergent evolution of prolactin expression at the maternal–fetal interface must convey an evolutionary advantage to these species. A Pouf1 variant has also recently been described in mice, potentially driving prolactin expression in mouse germ cells.[417]

REPRODUCTIVE FUNCTIONS OF PROLACTIN

Prolactin was identified and named for its critical role in the physiology of lactation, and this remains its best characterized reproductive function. As outlined in the introduction, however, in this chapter we have taken the approach of considering whether many of the multiple other pleiotrophic functions of prolactin are also functioning to prepare the mother for lactation. Thus, prolactin could be promoting adaptive responses in the mother, throughout pregnancy and lactation, to optimize her system for the metabolic and emotional demands of the lactating state. In this section, therefore, we will examine direct reproductive functions of prolactin in mammary gland, ovary, and brain, and then review a range of actions of prolactin in different tissues and examine how prolactin actions in these tissues might contribute to preparation for or support of lactation. In addition, however, it has to be acknowledged that some actions of prolactin do not fit clearly within this hypothesis. For example, approximately 25% of the male pituitary gland consists of lactotrophs, suggesting prolactin also has some function in males! Thus, we will also examine other reproductive roles of prolactin that may be unrelated to pregnancy or lactation. Importantly, while many of the functions of prolactin have been elucidated by the generation of prolactin[418] and prolactin receptor[419] knockout mice, it must be recognized that reproduction is controlled differently in different species, and some reported functions of prolactin may not be modeled well in mice. In addition, it is also important to recognize that if a particular function is not altered in a prolactin ($Prl^{-/-}$) or prolactin receptor ($Prlr^{-/-}$) knockout mouse, this is not absolute evidence that prolactin is not normally involved in that function. Developmental plasticity can sometimes compensate for deficient signaling pathways to maintain critical functions[d]. Hence, while we have drawn heavily on the transgenic mouse literature for the following sections, we have also tried to draw attention to key studies in other species, even when those observations are not necessarily present in the mouse.

Mammary Gland (See Also Chapter 46)

Hormones are not required for the embryonic and prepubertal development of the mammary gland, and the elongation of the ductal network that occurs during puberty is dependent on estrogen and growth hormone, but not prolactin.[422] Although both long and short forms of prolactin receptor are expressed in the fetal and neonatal mammary gland,[423] prolactin has not been shown to be critical for the early development of the mammary gland (mammogenesis). Indeed, $Prlr^{-/-}$ mice have normal embryonic postnatal development before puberty, showing that prolactin signaling is not required at these stages.[424] However, prolactin has a role in all of the processes of mammary development in the adult, including those leading to lactation and its maintenance[425]:

1. *Ductal side branching and formation of alveolar buds*: At puberty, ductal side branches and alveolar buds develop and increase in density at each subsequent estrous cycle, and both of these morphological changes fail to occur in both $Prl^{-/-}$ and $Prlr^{-/-}$ mice. By replacing progesterone in $Prlr^{-/-}$ animals, the effect of prolactin on ductal branching has been shown to be indirect, through its stimulation of progesterone synthesis.[426] Alveolar buds failed to develop after progesterone replacement, however, demonstrating a direct requirement for prolactin at this stage of mammary development.
2. *Lobuloaveolar development*: In pregnancy, there are dramatic changes in the structure and function of the mammary gland, with alveolar buds developing into lobuloalveoli that are capable of milk production (lactogenesis). The role of prolactin

[d] A classic "neuroendocrine" example is the oxytocin knockout mouse, which has a deficit in milk ejection but is able to give birth relatively normally.[420] This does not disprove the wealth of data showing that oxytocin is involved in parturition, but rather demonstrates that there are other processes that can compensate for this essential function in the absence of oxytocin.[421]

and its receptor in these processes has been dissected by transplantation of mammary epithelial cells from *Prlr*$^{-/-}$ animals into the cleared mammary glands of wild-type animals. Despite a completely normal endocrine environment in the host animals, lobuloalveolar development fails to occur in the transplanted tissue, demonstrating the absolute requirement for prolactin or placental lactogen in this process.[426] This role for prolactin signaling in lobuloalveolar development is confirmed by overexpression of a dominant negative form of the receptor in mammary epithelium[427] and is consistent with the impaired lobuloalveolar development and lactational failure seen in pregnant mice that are heterozygotes for the prolactin receptor deletion (*Prlr*$^{+/-}$).[428] Prolactin also plays a key role in polarization of the mammary epithelium and establishment of tight junctions during lactogenesis, establishing the cytological structure within the gland to enable milk secretion.[425]

3. *Lactation*: Prolactin is also required for the maintenance of lactation (galactopoiesis), although the specific requirements for prolactin vary across species (reviewed in Refs 425,429). Prolactin affects the production of milk by increasing the production of its constituents, in particular β-casein, whey acidic protein, and α-lactalbumin, lactose, and lipids.[430] A role for prolactin in increasing the production of β-casein and whey acidic protein is confirmed by their reduced expression in mice with targeted expression of dominant negative prolactin receptor to mammary epithelial cells.[427] Prolactin may also act as a lactating mammary cell survival factor by inhibiting the apoptosis and remodeling associated with involution.[431]

The mechanisms of prolactin's actions on the mammary gland are complex, with potential interactions with other hormones and their receptors, as well as paracrine factors that may mediate and modify prolactin signaling. In particular, the gonadal steroids estradiol and progesterone are critical co-regulators, as are glucocorticoids and insulin.[425] Whilst both long and short forms of the receptor are found in the gland from embryonic development to adulthood, there is considerable variation in total receptor expression as well as the relative abundance of different isoforms and heterogeneous distribution within the gland.[423] In lactating rats, there is a dramatic increase in expression of the long form of the prolactin receptor, with a less significant change in the expression of the short form, compared with either virgin or multiparous animals, although interestingly this is not reflected at the protein level.[432] The dynamics of prolactin receptor expression and distribution suggest differential actions of prolactin at different stages of gland development and function. Effects of prolactin appear to be mediated predominantly by the long form of the prolactin receptor, through activation of Stat5a, as there is an absence of ductal branching in mice lacking this transcription factor.[433] A role for the short form of the receptor at critical stages of gland development, however, is indicated by the rescue of lactation in *Prlr*$^{+/-}$ mice overexpressing this specific isoform.[434] Although the prolactin receptor is expressed in both epithelial and stromal compartments of the gland, the epithelial expression is sufficient for lobuloalveolar development, as demonstrated by transplant of stromal *Prlr*$^{-/-}$ cells and wild-type epithelium into cleared mammary fat pads, resulting in normal gland development.[426] A large number of factors downstream of prolactin receptor signaling in the mammary gland have been identified, including members of the Wnt pathway, epidermal growth factor receptor ligands, the TNF family member receptor activator of nuclear factor κB ligand (RANKL), and IGF2 (reviewed in Ref. 422). The complexity of prolactin signaling in the gland is further complicated by the emerging evidence for cross-talk between the prolactin and progesterone receptors.[435]

Ovary

One of the major roles of prolactin in nonprimate mammals is the maintenance of pregnancy, demonstrated by the infertility of both *Prl*$^{-/-}$ and *Prlr*$^{-/-}$ mice[418,419] and caused by a failure in the maintenance of the corpus luteum. The midcycle LH surge drives ovulation and initiates luteinization of the postovulatory follicle into a corpus luteum. Unlike primates, which have a long luteal phase allowing progesterone secretion to support a fertilized embryo for a sufficient period to allow implantation and initiation of chorionic gonadotropin secretion to enable maternal recognition of pregnancy (see also Chapters 23 and 28), rodents have a particularly short luteal phase. The mating stimulus is required to rescue the corpus luteum and maintain progesterone secretion[e] to allow implantation and the

[e] Because the prolactin surges of early pregnancy are induced by the physical vaginocervical stimulation provided by the act of mating, they do not depend on a fertile mating and can be induced by mating with a sterile male or by an appropriate artificial stimulation.[436] The prolactin surges induced in the absence of fertilized ova result in a state called pseudopregnancy, with hormonal changes that are essentially identical to those of early pregnancy.[356] The surges persist for approximately 12 days without further reinforcement, and their termination is thought to involve an inhibitory factor from the uterus.[437] The prolonged prolactin secretion maintains progesterone production, resulting in a sequence of diestrous-like vaginal smears. This characteristic of prolactin-induced acyclicity was used as a biomarker for hyperprolactinemia in early studies characterizing the control of prolactin secretion,[57] and it continues to be a useful marker in present biomedical experiments.

establishment of pregnancy, and in the absence of mating, the corpus luteum regresses within hours of ovulation. The twice-daily surges of prolactin resulting from cervical stimulation (as discussed here) are responsible for the increased life span of the corpus luteum and its secretion of progesterone early in pregnancy. In concert with the prolactin surges, there is an LH-driven upregulation of ovarian prolactin receptor expression, with short-form expression increased relatively more than the long form.[438] Maintenance of the corpus luteum is achieved through two actions of prolactin: increased corpus luteum expression of the luteinizing hormone receptor,[439,440] leading to increased expression of the steroidogenic enzymes required for progesterone synthesis,[441] and repression of 20α-hydroxysteroid dehydrogenase,[442] the enzyme responsible for progesterone metabolism in the ovary.[443] Prolactin also has an important role in corpus luteum estradiol biosynthesis via increased expression and activity of aromatase P450 and 17 beta-hydroxysteroid dehydrogenase (17βHSD) (reviewed in Ref. 444). Interestingly, part of this stimulation may occur specifically through interaction of 17βHSD with the short form of the prolactin receptor.[445] In addition to increasing estradiol synthesis, prolactin increases the signaling of this steroid as estrogen receptor expression in the corpus luteum is stimulated by prolactin, through Stat5 response elements present within the promoters of both ERα and ERβ.[444]

Differential effects of the two isoforms of prolactin receptor in ovarian function have been described in studies with animals in which one of the short forms of the prolactin receptor (PRLR-S1) is overexpressed in *Prlr*$^{+/-}$ mice. These studies have confirmed an essential role for the long isoform of the receptor in maintenance of the corpus luteum, because the short form could not rescue the corpus luteum following ovulation,[446] but they have also identified specific roles for the short form. Mice overexpressing PRLR-S1 show premature follicular development, followed by follicular atresia, such that by 5 months of age the ovarian follicles are completely depleted.[446] There were also a number of changes in the expression of specific transcription factors and gene targets.[23] Prolactin action through PRLR-S1 resulted in inhibition of MAPK signaling through activation of a MAPK-specific phosphatase identified as deoxyuridine diphosphate 1.[22] As MAPK signaling is critical to normal follicular function,[447] this inhibitory effect likely mediates the detrimental consequence of overexpression of PRLR-S1.

Clearly, the luteotrophic function of prolactin fits the hypothesis of a role in the maternal adaptation to pregnancy. However, in addition to this role in the maintenance and function of the corpus luteum, there is also evidence in rats that prolactin may exert a luteolytic action, with the preovulatory prolactin surge contributing to the regression of the corpus luteum from the previous ovulation.[448,449] Luteolysis fails to occur normally if the proestrous surge of prolactin is blocked.[450] Several studies have suggested that this action of prolactin may not be a direct action on cells of the corpus luteum but rather via stimulation of macrophage and lymphocyte cells of the immune system.[451,452] It is also possible that prolactin has a direct effect on the corpus luteum in mediating this immune cell–mediated luteolysis, since intercellular adhesion molecule-1, which plays a role in facilitating recruitment and binding of macrophages, is upregulated by prolactin in regressing corpora lutea.[453]

The rodent pattern of secretion and function of prolactin in ovarian function is not conserved in humans or other primates (see Ref. 393 for a review). While there is no dramatic change in prolactin secretion during the menstrual cycle (discussed in this chapter), it is possible that ovarian production of prolactin[454,455] may mediate some of the roles that are fulfilled by pituitary prolactin in rodents. Importantly, prolactin is not required for corpus luteum maintenance in humans. LH promotes the original development of the corpus luteum, and then human chorionic gonadotropin fulfills the role of rescue of the corpus luteum and the establishment of pregnancy.[456] However, the prolactin receptor is expressed in luteinized human granulosa cells,[454,457] and prolactin acts as a survival factor in human granulosa cells in vitro,[458] suggesting that it is possible that local or circulating prolactin may have a physiological function in this tissue.

Reproductive Tract

In addition to expression in the ovary, there is good evidence for expression of the prolactin receptor in the female reproductive tract. In mice, prolactin receptors are present in the uterus[415] and fallopian tube,[459] and levels of receptor expression are regulated by ovarian steroids. Similarly, in women, prolactin receptors are found in both the nonpregnant[460,461] and pregnant[406] uterus, as well as the fallopian tube.[459] Deletion of the prolactin receptor in *Prlr*$^{-/-}$ mice causes the uteri to be refractory to implantation,[462] suggesting that prolactin may be involved in the establishment and maintenance of pregnancy.

Fetal Development

Prolactin receptors are present in the preimplantation embryo[463] and are widely expressed during embryogenesis in both rodents[464–467] and humans,[468] particularly in bone and cartilage, brain, and pituitary. In rodents, much of fetal development occurs during the second half of pregnancy, when prolactin secretion is low, and while prolactin mRNA can be detected in the fetal pituitary at approximately embryonic day 15.5[469] or 17.5,[470]

prolactin protein is not present until much later in gestation,[258] and prolactin is not detectable in the serum until soon after birth.[471] Hence, the placental lactogens are likely to be the major ligands for fetal prolactin receptors during gestation. PL-II is present in fetal serum during the latter half of gestation[472] and presumably acts on prolactin receptors present at this time. Prolactin is also present in amniotic fluid in women, and this may also influence fetal prolactin receptors.[405,473] Disruption of the prolactin receptor does not result in fetal lethality but does induce a range of developmental defects.[419] This observation is supported by recent work using a zebrafish model, where temporary disruption of prolactin production during embryonic development caused multiple morphological defects, consistent with a role for prolactin in organogenesis.[474]

The observation that prolactin receptors were particularly abundant in the olfactory system in the fetus, and in the olfactory bulb specifically,[475] was very interesting because there is little or no expression detected in this region in the adult.[10] As well as being expressed in the olfactory epithelium and sensory neurons of the olfactory bulb, prolactin receptors are found in the fetal trigeminal ganglion, tongue, whisker follicles, and facial musculature. These organs are essential for odor detection, facial sensation, taste, and the neonatal suckling reflex. One tantalizing possibility is that since prolactin is secreted into milk[476] and can be absorbed intact across the neonatal intestine,[477,478] prolactin from the mother might access the offspring's olfactory system during suckling, providing a novel mechanism to signal from the mother to her infant, fostering appropriate behavioral interactions.

Reproductive Behaviors

Lordosis and female reproductive behavior: Because of the increase in prolactin associated with ovulation and the onset of estrous behavior, there has been some interest in a possible role for prolactin in regulating reproductive behavior, particularly in the female. The data, however, do not provide a clear picture. High levels of prolactin can inhibit lordosis in female rats,[479] although this may be due to its antigonatorophic effect (discussed further in this chapter). In contrast, bromocriptine-induced inhibition of prolactin secretion during the proestrous prolactin surge inhibits female receptivity,[480] and acute administration of prolactin directly into the midbrain stimulates lordosis,[481] consistent with a stimulatory role for prolactin in female reproductive behavior. In women, while the evidence of a preovulatory surge of prolactin is marginal (described in this chapter), there is a coitus-induced release of prolactin associated with orgasm.[482] This increase following orgasm is also seen in men[483,484] and has been proposed to be involved in the feedback suppression of sexual drive[485] contributing to the latency period following orgasm. More recently, it has been proposed that the long-lasting elevation of prolactin in women following coitus may be involved in the initiation of pregnancy, facilitating decidualization and implantation.[482]

Maternal care: The behavior of female rodents toward pups (either their own or those of another animal) changes dramatically at parturition, and new mothers display a range of pup-directed behaviors that include nursing, licking, and grooming as well as retrieval of the pups to a nest site.[486] This maternal care can be induced in virgin female rats with repeated exposure to pups, albeit with a latency period of several days.[487] There is a strong body of findings that support a role for prolactin in the central stimulation of the onset of maternal behavior. The initial observations utilized a rat preparation in which gonadectomized virgin rats were treated sequentially with a systemically administered steroid regimen that consisted of 10 days of progesterone exposure followed by exposure to estradiol. This steroid treatment elevated circulating prolactin concentrations[488] and stimulated a rapid onset of maternal care toward foster young.[489] Moreover, when steroid-treated females were concurrently treated with bromocriptine to suppress endogenous prolactin secretion, the onset of maternal behavior toward foster young was delayed.[488] These behavioral effects of prolactin can be mimicked by placental lactogen.[490] Prolactin actions on maternal behavior are mediated in the central nervous system, demonstrated by the observation that ICV infusion of prolactin or placental lactogen will induce maternal behavior, whereas the same dose administered systemically has no effect.[490,491] The medial preoptic area has previously been identified as an important region for maternal care.[492–494] Using localized injections into this region, Bridges and colleagues have identified the medial preoptic area as a critical site for prolactin action to stimulate maternal behavior.[491] Prolactin receptors are expressed throughout this region,[112,143,495,496] and levels are increased during lactation.[496,497]

Earlier work in mice has also implicated the hypothalamus as a possible site of prolactin action in stimulating maternal behavior and nest building in this species.[498] The critical role of prolactin in maternal care was confirmed in the prolactin receptor knockout model, with a deficiency in pup-induced maternal care in both virgin and primiparous $Prlr^{+/-}$ mice, and an even more severe deficit in virgin $Prlr^{-/-}$ animals[499] (full knockouts are infertile, precluding the study of maternal behavior in parous animals). Interestingly, $Prl^{-/-}$ animals exhibit some maternal behavior,[418] possibly as a result of embryonic or neonatal exposure to prolactin or placental lactogen or of the actions of other ligands on the prolactin receptor.[500] Prolactin actions on maternal behavior in

mice are not limited to the medial preoptic area. Prolactin-induced neurogenesis in the subventricular zone (SVZ) during early pregnancy[501] is also critical for the normal expression of maternal behavior postpartum.[359,502]

PROLACTIN-INDUCED ADAPTIVE RESPONSES CONTRIBUTING TO SUCCESSFUL REPRODUCTION

In addition to the direct roles of prolactin in reproductive tissues and on reproductive behaviors, as described in this chapter, prolactin has a wide range of other functions in the body. While at first look, a number of these seem quite unrelated to reproduction, we consider that many of these actions result in adaptive functional changes that will assist the mother in coping with the physiological, metabolic, and behavioral challenges of pregnancy and lactation. This is particularly true of the multiple actions of prolactin exerted in the brain. In this section, we will review a variety of prolactin actions from this context: adaptive changes in physiology to meet the novel demands of the transition through pregnancy and into lactation.

Metabolic Effects

There are numerous studies linking prolactin to the regulation of metabolism, and prolactin seems to be acting both in the central nervous system and in peripheral tissues to mediate these effects. While many of these studies show effects in males and nonpregnant females, prolactin is likely to be high in such individuals only under pathological conditions. From a physiological perspective, many of these metabolic effects of prolactin make more sense if considered as part of the metabolic adaptation to pregnancy and lactation.[503] During these states, there is a dramatic increase in maternal metabolic demand to support fetal growth, parturition, and milk production.[504] To meet this increased demand, a number of physiological changes occur in mothers, including a reduction in energy expenditure, increased food intake, and an increase in nutrient absorption from the gut. There is also a change in energy partitioning to ensure adequate nutrient supply for fetal growth, as well as increased white adipose tissue mass during pregnancy and subsequent mobilization of these fat stores in lactation. Here we will examine a wide range of metabolic responses to prolactin, and consider how this might contribute to the metabolic adaptations of pregnancy and lactation:

1. *Nutrient uptake*: Prolactin receptors are expressed in the digestive tract,[505,506] and prolactin has been reported to affect ion and nutrient absorption, epithelial cell proliferation, and gastrointestinal motility. Elevated prolactin alters the expression of a number of genes related to fluid and electrolyte homeostasis, especially for Ca^{2+} (which may be critical for adaptive changes in bone metabolism during pregnancy, as discussed in the section Bone and Calcium Homeostasis), Na^+, K^+, and Cl^- transport[507] and cell proliferation in the duodenum.[508] These data suggest that prolactin contributes to the hyperplasia of the intestinal epithelium and the increased expression of transporters that occurs during pregnancy and lactation.[509,510] Prolactin also upregulates hepatic bile salt transporters in rats, which may increase the absorption of lipids and fat-soluble vitamins.[511] In addition, administration of exogenous prolactin to cycling female rats results in the downregulation of liver enzymes that control amino acid oxidation and urea synthesis,[512] consistent with the hypothesis that prolactin may contribute to the alterations in protein metabolism seen in pregnant and lactating rats.
2. *Energy partitioning*: The prolactin receptor is expressed in adipose tissue in mice,[513] rats,[514] and humans,[515] and recent evidence indicates a role in adipogenesis and in the regulation of leptin secretion from adipocytes. *Prlr*$^{-/-}$ mice show a reduced adipose tissue weight, without overall reduction in body weight or food intake.[516] The effects on leptin secretion are complex, with prolactin apparently exerting negative effects on leptin secretion by adipose cells from mice[517] and rats[514] in vitro, but circulating leptin levels are elevated in hyperprolactinemia in vivo.[518] In contrast, chronic hyperprolactinemia results in hypoglycemia and decreased adiposity in mice.[513,519] An increase in brown-like adipocytes in white fat depots occurs in *Prlr*$^{-/-}$ mice,[520] promoting energy expenditure. The increased adiposity resulting from overexpression of the long form of prolactin receptor in the absence of the short form suggests that a balance in receptor signaling might be important for the regulation of adipose tissue.[521] Again, these effects or the mechanisms underlying them may be species specific, exemplified by different effects of prolactin on adipose tissue lipolysis in rats and mice.[522] Taken together, these data from nonpregnant animals are consistent with a role for prolactin in regulating energy partitioning at the level of the adipose tissue. Prolactin appears to predominantly promote adipogenesis and

energy storage. In the context of pregnancy, the rising levels of prolactin are therefore likely to favor energy storage, contributing to the anabolic state that characterizes early pregnancy. Prolactin may also exert other effects on metabolism through actions in the liver. High levels of prolactin receptors are expressed in the liver, and this is an interesting organ because it is one of the few where the short form of the receptor is predominant.[523] There are dramatic increases in liver expression of the long form of the receptor during pregnancy in mice, which revert to virgin levels in lactation.[524] In rats, there are significant changes in the ratio of isoforms expressed in the liver during lactation.[432] The specific function of prolactin receptors in the liver, however, is unknown.

3. *Body weight*: Hyperprolactinemia is associated with weight gain in a number of species, although these effects may be species specific. Chronic elevation of prolactin in humans is frequently associated with increased weight gain, which is reduced after normalization of prolactin,[525–527] and a similar effect is found in rats.[528–530] Evidence from genetically modified mice, however, is less clear, with either excess or loss of prolactin having little effect on weight gain.[513,522] Loss of prolactin receptors in knockout mouse studies has also produced inconsistent data,[531,532] although there may be a small effect of reduced body weight in female animals. Effects on body weight represent the composite of food intake and nutrient absorption, together with energy expenditure, and provide a crude insight into the potential metabolic functions of prolactin. Data on acute effects of prolactin on appetite are more consistent and are reviewed next.
4. *Appetite regulation*: Systemic prolactin administration increases food intake in a variety of species.[528,533–535] In rats, this treatment not only increases food intake but also causes a suppression of cyclic estradiol release and increases in plasma progesterone concentrations, effectively inducing a pseudopregnancy.[534,536] The anorectic effects of estrogens are well established.[537,538] Estradiol suppresses food intake, specifically reducing meal size[539,540] and increasing energy utilization.[541] Thus, low estradiol during pregnancy might enhance food intake and suppress leptin responsiveness.[542] Conversely, progesterone treatment stimulates weight gain and fat deposition as well as food intake.[543,544] The increase in food intake in female rats following prolactin treatment, therefore, could be mediated through effects on gonadal steroids. ICV administration of prolactin increases food intake without influencing estrous cyclicity, however, whether given by bidaily injections or via chronic infusions using an osmotic minipump.[534,545,546] Moreover, ICV administration of prolactin also increases food intake in ovariectomized rats.[546] Together, these data argue for the ability of central prolactin receptor activation to increase food intake independent of steroid hormone levels. Thus, the phasic prolactin secretion of early pregnancy is likely to contribute to the rapid increase in food intake seen in pregnant rodents,[547–549] both indirectly (by promoting progesterone secretion) and directly (through actions in the hypothalamus). Prolactin receptors are found in many of the nuclei involved in the homeostatic regulation of food intake, including the arcuate, ventromedial, and paraventricular nuclei,[143,147,495] and hence these nuclei form likely targets for prolactin action during pregnancy and lactation. However, prolactin receptors do not appear to be expressed in the arcuate neuropeptide Y (NPY) and proopiomelanocortin (POMC) neurons[100,550,551] that regulate appetite. Hence, it seems likely that prolactin acts downstream of the arcuate neurons, such as at the PVN. Consistent with this hypothesis, localized injections of prolactin directly into the PVN stimulate food intake in a dose-dependent manner in female rats.[552] Pregnancy is an interesting state with respect to leptin action, in that the hyperphagia in pregnancy persists despite the increase in serum leptin resulting from the increased fat mass.[553,554] These data have been interpreted to indicate a condition of leptin resistance during pregnancy. Whilst it is possible that the available leptin in the brain is blunted as a result of increased leptin-binding protein,[555,556] saturation of a transporter mechanism,[557] or reduced transporter expression,[558] there is a reduced response to leptin infusion directly into the brain in pregnancy,[548,559] suggesting that hypothalamic leptin resistance is an important factor in the continued hyperphagia throughout pregnancy (reviewed in Refs 560–563). To test the hypothesis that elevated prolactin mediates the pregnancy-induced leptin resistance, two groups have examined leptin responses in hyperprolactinemic animals. Woodside and colleagues used chronic ICV infusion of prolactin in nonpregnant female rats, and found that elevated prolactin prevented the reduction in body weight or food intake normally seen in response to a central injection of leptin.[545] This prolactin-induced leptin resistance occurs whether the leptin is administered to satiated rats or after a 24h fast.[545] The lack of a behavioral response to leptin was accompanied by a reduction in the ability of leptin to induce Fos expression and phosphorylation of STAT3 in both the paraventricular and ventromedial hypothalamic nuclei.[545] Consistent with these data, Augustine and colleagues have shown that ICV prolactin infusions induce leptin resistance in pseudopregnant rats.[564]

Interestingly, the pseudopregnant rats, which are hyperphagic in response to early-pregnancy-like changes in prolactin, estrogen, and progesterone, remain fully responsive to leptin. It was only after chronic prolactin infusion, mimicking the chronic elevation in placental lactogen secretion that is characteristic of midpregnancy, that they became leptin resistant like pregnant animals. Taken together, these data suggest that the prolactin surges during early pregnancy stimulate an initial orexigenic response, and the resultant hyperphagia is then maintained, in the face of rising leptin levels and a positive energy balance, by placental lactogen-induced leptin resistance. The mechanism of prolactin action on leptin responses is not clear. Prolactin receptors are widespread in the hypothalamus,[143,147,495,565] including the major nuclei involved in body weight regulation: the arcuate, ventromedial hypothalamic, and paraventricular nuclei (discussed in this chapter). In neurons, prolactin activates STAT5,[105,107,566] and in particular STAT5b,[106,110] whereas leptin predominantly acts though STAT3.[567] As both hormones are acting through the JAK–STAT pathway, there is potential for the endogenous regulatory proteins, such as SOCS proteins, to cross-talk between the two signaling pathways. In ovariectomized rats, prolactin induces SOCS1, SOCS3, and CIS but not SOCS2 within the arcuate nucleus.[108] This suggests that, as in response to other cytokines, these proteins are induced as a part of the prolactin signal transduction response. During late pregnancy and lactation, levels of SOCS1, SOCS3, and CIS mRNA were all markedly elevated in the arcuate nucleus,[108] and it seems likely that these proteins mediate the loss of prolactin-induced activation of STAT5b in TIDA neurons during lactation.[108,109,180,370] Conceivably, prolactin-induced SOCS proteins might also impact other cytokine signal transduction pathways, such as leptin. While the prolactin and leptin receptor are localized in the same nuclei, however, there is little evidence of co-localization.[563] As discussed in this section, leptin receptors are expressed on POMC and NPY neurons in the arcuate nucleus. Prolactin receptors are strongly expressed in the arcuate nucleus, but these are predominantly on dopamine neurons[100] and not on POMC or NPY neurons.[100,550,551] Similarly, in the ventromedial hypothalamic nucleus, leptin receptors are predominantly in the dorsomedial aspect of that nucleus, whereas prolactin receptors are exclusively in the ventrolateral part. Furthermore, even when expressed in the same cell type, the two pathways may not inhibit each other.[568] Hence, it seems unlikely that prolactin might act directly on the first-order leptin-responsive neurons to cause leptin resistance, and if prolactin is mediating the pregnancy-induced changes in these nuclei, it must be through an indirect pathway. At least part of the resistance to leptin during pregnancy, however, is caused by a downstream loss of responsiveness to αMSH,[569] presumably in the PVN.[570] Oxytocin neurons may function as a major downstream target of αMSH from leptin-responsive POMC neurons, and αMSH stimulates oxytocin release that then has anorectic actions.[571,572] These neurons also express leptin receptors,[573] and hence form a potential site for integration of reproductive and metabolic signals to regulate food intake. Prolactin receptors are expressed on oxytocin neurons in the PVN,[574] and prolactin acutely reduces the firing rate of oxytocin neurons. Hence, these data suggest that elevated prolactin during pregnancy might act to functionally antagonize αMSH action in the PVN, resulting in secondary leptin resistance, and are consistent with the hypothesis presented here that prolactin might act to stimulate appetite in these downstream pathways.[552] There is also evidence that prolactin, acting on central prolactin receptors in the hypothalamus, contributes to the hyperphagia of lactation (reviewed in Refs 575,576). Prolactin has been implicated in stimulating changes in NPY expression in lactating rats,[551] with prolactin receptors identified on NPY neurons in the dorsomedial hypothalamus (but not arcuate nucleus) during lactation.[550] Prolactin-induced stimulation of NPY in the dorsomedial hypothalamus[551] may augment the orexigenic effects of other NPY inputs to the PVN. As described in this chapter, prolactin is the major lactogenic hormone in the rat, and thus investigations of appetite and food intake by manipulating prolactin levels in postpartum females can be confounded by effects on milk production, since the energetic demands of milk production may cause a change in appetite, independent of any direct effects of prolactin. To distinguish the energetic demands of milk production from the sensory and hormonal responses to the suckling stimulus, elegant experiments have been completed in lactating rats following transection of the galactophores (the tube that delivers milk from the mammary gland to the nipple). In these animals, maternal behavior and suckling are normal, but the inability to deliver milk leads to rapid involution of the mammary gland and the consequent loss of the metabolic energy demands of milk production. These studies have shown that the increased food intake induced by suckling is maintained even in the absence of milk production.[577] Because galactophore-cut postpartum rats have similar hormonal profiles to those of intact lactating rats, it has been possible to use this model to study the specific contributions of

suckling-induced prolactin to hyperphagia. When prolactin levels are suppressed in galactophore-cut rats using the dopamine D2 agonist bromocriptine, food intake and body weight are decreased. Replacement of prolactin by chronic ICV infusion restores food intake, suggesting that the orexigenic effects of prolactin acting on prolactin receptors within the brain make a major contribution to the hyperphagia of galactophore-cut, suckling rats.[575,578]

5. *Glucose homeostasis*: Prolactin receptors are expressed in pancreatic β-cells.[579,580] Exposure of cultures of human, mouse, and rat β-cells to prolactin or placental lactogens in vitro leads to increased insulin secretion, upregulation of glucose-stimulated insulin secretion, increased insulin expression, and β-cell proliferation.[581–583] Prolactin also stimulates expression of glucose transporter 2[584] and promotes glucose entry into the β-cells, and as a consequence it enhances the activity of glucose-sensitive enzymes such as glucokinase.[585] Rats with chronically high prolactin have enhanced insulin secretion,[586] and targeted overexpression of placental lactogens in pancreatic β-cells increases β-cell mass and insulin production.[587] Conversely, mice deficient in prolactin receptors show reduced β-cell mass as early as 3 weeks of age, reduced insulin expression, and glucose-stimulated insulin secretion.[588] These data suggest that prolactin may play an important role in development of the β-cells, and in particular may promote the surge of maternal β-cell replication that occurs in the perinatal period. Consistent with the overall hypothesis in this chapter, much recent work has focused on the role of prolactin and placental lactogen in stimulating β-cell function during pregnancy.[589] As described here, there are marked changes in maternal energy balance during pregnancy, from anabolic conditions in early pregnancy leading to accumulation of fat stores to a catabolic state later in pregnancy promoting mobilization of energy stores and increased partitioning of nutrients to the conceptus to meet the high demand resulting from rapid fetal growth. Maternal tissues develop insulin resistance to meet the very high demands of the fetal–placental unit for glucose, which can consume 50% of total maternal glucose utilized by late pregnancy,[590] leading to an increased demand for maternal insulin secretion. A failure of pancreatic islets to meet this demand leads to gestational diabetes, affecting 135,000 pregnancies annually in the United States[591] and leading to a 70% increase in the risk of developing type 2 diabetes.[592] The pancreatic islet adapts to this altered demand by increasing β-cell mass, principally by increased cell proliferation,[593] enhanced insulin synthesis,[594] a decreased glucose-stimulated insulin threshold,[595] enhanced glucose and cAMP metabolism,[596] and increased gap junction coupling between β-cells.[597] There is good evidence that these changes in β-cell biology are a result of the chronic increase in prolactin and placental lactogen acting on the prolactin receptor.[598] As described in this chapter, pregnancy is associated with high levels of prolactin signaling, both due to prolactin itself and due to high levels of placental lactogen. There is a dramatic increase in prolactin receptor levels in the pancreas during pregnancy,[580,589] and hence many of the documented effects of prolactin on islet function, including expansion of β-cell fraction, enhanced insulin expression, and increased sensitivity to glucose-stimulated insulin secretion, are most physiologically relevant at this time. In $Prlr^{+/-}$ mice that have a 50% reduction in β-cell expression of prolactin receptors, there are reduced β-cell mass and proliferation, decreased glucose-stimulated insulin release, and impaired glucose tolerance during pregnancy.[599] These data demonstrate that prolactin and placental lactogen play a key role in the adaptations of the β-cells during pregnancy. The mechanism by which prolactin and placental lactogen increase the proliferation of β-cells has been studied extensively in recent years, as a result of the interest in increasing β-cell proliferation for therapeutic purposes in diabetes. The main pathway activated by prolactin in β-cells is STAT5,[583,600,601] although prolactin induction of insulin expression may be independent of that pathway.[602] Prolactin can also activate the PI3K and MAPK pathways in β-cells,[38] and reduce expression of the transcription factor FoxO1,[601,603] an inhibitor of β-cell proliferation.[604] The D cyclins have been shown to be essential for β-cell proliferation,[605] and transcription of cyclin D2 has been shown to be induced in β-cells by prolactin-induced activation of STAT5, leading to increased proliferation.[606] A role for menin, previously characterized as an endocrine tumor suppressor, in the regulation of the cell cycle inhibitors in β-cell has been described, as menin and its associated cell cycle inhibitors are downregulated in islet cells in pregnancy.[607] This response was also dependent on Stat5,[607] implicating signaling from the prolactin receptor, and has also been shown to involve induction of the transcription factor FoxM.[608] Recent studies have implicated pancreatic serotonin as an important factor that is induced by placental lactogens in islet cells of mice and can increase β-cell proliferation.[609,610] The serotonin-synthesizing enzymes Tph1 and Tph2 are induced by placental lactogen in primary pancreatic cultures

from nonpregnant animals, and their expression is increased in islets of pregnant mice, peaking at the 12th day of gestation, when there is also an increase in islet serotonin. It is possible that there is also an increase in serotonin receptor expression in islets in pregnancy, and loss of the 5HTr2b serotonin receptor was found to lead to a reduction in β-cell proliferation in pregnancy.[610] There is evidence for this important role for placental lactogen in β-cell adaption in humans, although given its pattern of secretion, prolactin may also have a role. Patients with prolactinomas have increased insulin secretion in response to glucose and decreased glucose tolerance similar to that found in pregnancy,[586,611,612] and the increased insulin is reduced after bromocriptine treatment to normalize prolactin secretion.[613] hPL has been found to increase β-cell survival and increase insulin secretion in vitro,[614] and prolactin has been shown to protect human β-cells from apoptosis.[615] The protective effects of prolactin and placental lactogen have been suggested to be of importance in countering the effects of a number of factors in pregnancy that have detrimental effects on β-cell survival and function, such as high glucocorticoids.[598,616]

Bone and Calcium Homeostasis

Prolactin receptors have been identified in multiple sites involved in calcium metabolism, including gastrointestinal tract, kidney, and bone, implicating a direct effect in these areas.[505,523,617–619] The *Prlr*$^{-/-}$ mouse is characterized by delayed bone formation, despite no apparent reduction in the number of osteoclasts.[618] Long- and short-form prolactin receptors have been localized specifically to chondrocytes[620] and osteoblasts,[618,621] but not osteoclasts.[618] Studies predominantly involving cultured cells have begun investigating direct prolactin-stimulated effects on bone at both basal and high prolactin levels.[622,623] Prolactin has been implicated in affecting osteoblast function rather than differentiation as it can decrease alkaline phosphatase activity and osteocalcin mRNA expression, two markers of osteoblast activity.[624] Furthermore, prolactin can alter the ratio of osteoblast-derived factors, RANKL and its decoy receptor osteoprotegerin (OPG), in a dose- and age-dependent manner.[624,625] In adult rats, prolactin stimulates an increase in RANKL expression and a simultaneous decrease in OPG levels, resulting in elevated bone resorption.[625] Pathological hyperprolactinemia leads to osteopenia and osteoporosis,[626,627] although this might also be secondary to the prolactin-induced decrease in estradiol levels (discussed further here).

Consistent with the overall hypothesis of this chapter, it seems likely that prolactin actions on bone and calcium homeostasis relate to the marked changes that occur during pregnancy and lactation. During pregnancy, women lose approximately 200–300 mg/day of calcium in the third trimester for mineralization of the developing fetal skeleton. This increases to 300–1000 mg/day for lactogenesis.[628] Consequently, adaptations in calcium metabolism are necessary during these reproductive states to safeguard the maternal skeleton against increased demand for calcium and other minerals from the growing fetus or neonate. Prolactin, which is elevated during pregnancy and lactation, has been described as the principal calcitropic hormone,[510] in terms of its action both on calcium absorption, described here, and on regulating bone turnover. During pregnancy, there is a net gain in bone density,[621] but during lactation, bone resorption is a major source of calcium for milk production.[628] The bone resorption occurring during lactation is dependent on prolactin,[621] but cannot solely be explained by a shift in the RANKL:OPG ratio.[625] In addition, prolactin has been shown to induce mRNA of other osteoblast-derived factors involved in osteoclastogenesis.[623] These include monocyte chemoattractant protein (MCP1), cyclooxygenase 2 (Cox2) at a prolactin concentration of 300 ng/ml, and tumor necrosis factor alpha (TNFα) and interleukin 1 (IL1) at a prolactin concentration of 500 ng/ml.[624] This indicates that increasing prolactin levels during pregnancy and especially lactation may act to switch on certain genes in a time-dependent manner. Furthermore, although prolactin has the ability to directly affect osteoblast function, it also acts as an indirect modulator of osteoclast production and activity.

The direct effects of prolactin on bone metabolism are well established, but it is possible that prolactin also acts indirectly to influence calcium homeostasis via the central nervous system. It is known that the hypothalamus exerts a regulatory control of peripheral calcium homeostasis.[629] Recent evidence has identified a role for the brain in mediating the actions of leptin on bone function[630,631] via the sympathetic nervous system. While there is no evidence as to whether prolactin might influence bone in the same manner, the stimulation of prolactin receptors in the hypothalamic PVN of the rat has been shown to be protective against stress-induced hypocalcemia,[348] and knockdown of prolactin receptor expression in this nucleus influenced circulating plasma calcium levels in nonstressed and stressed states,[351] thereby implicating a central prolactin mechanism in regulating circulating calcium levels.[351] It seems possible that such a mechanism could also play a role in the adaptive changes in calcium homeostasis during pregnancy and lactation.

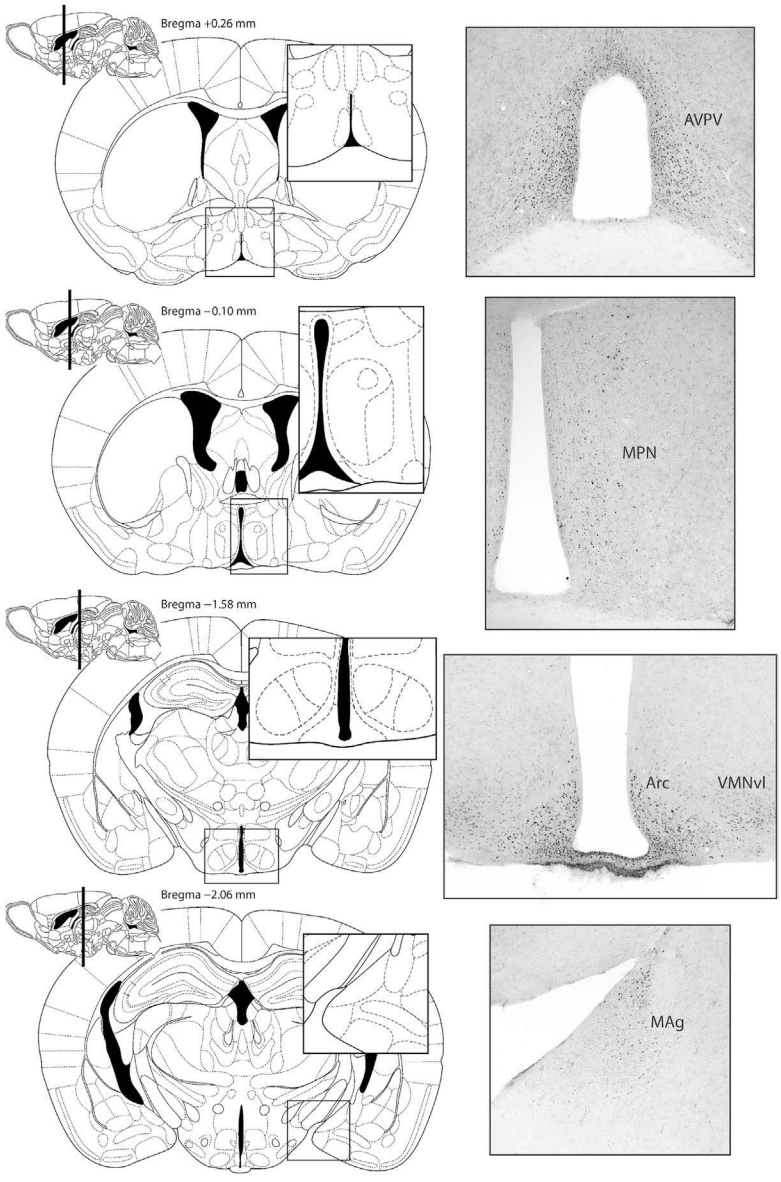

FIGURE 12.7 Map of prolactin-responsive neurons in the mouse brain (based on Refs 147,638). Diagrams on the left show the major structures of the mouse brain *(Source: Adapted from the Paxinos and Franklin brain atlas[639].)*. Micrographs on the right show prolactin-induced pSTAT5 (black dots represent nuclear staining of individual neurons) in different brain regions at that particular level. Major areas showing positive labeling of prolactin-responsive neurons are labeled (AVPV, anteroventral periventricular nucleus; MPN, medial preoptic nucleus; Arc, arcuate nucleus; VMNvl, ventromedial hypothalamic nucleus, ventrolateral subdivision; MAg, medial amygdala; MCG, midbrain central gray matter; AP, area postrema; NTS, nucleus of the solitary tract).

Brain Actions of Prolactin

In addition to the specific effects on reproductive behaviors, the central effects on appetite and metabolism, and the effects on NEDA neurons to influence its own secretion by short-loop negative feedback, outlined in this chapter, prolactin also exerts many other actions in the brain[632] that can be seen as facilitating reproductive processes.

Expression of prolactin receptors in the brain: Prolactin receptors have been identified in the brain, particularly in the rat, using in vitro binding assays and autoradiography,[633–636] immunohistochemistry,[143,496,637] and in situ hybridization.[112,495,565] More recently, prolactin-induced phosphorylation of STAT5 has been used to investigate prolactin-responsive neurons in the mouse brain.[147,638] All of these studies have provided a consistent picture of the distribution of prolactin receptors in the brain (see Figure 12.7). Expression is widespread, particularly in medial hypothalamic nuclei from the preoptic region to the caudal arcuate nucleus, but also in a number of extrahypothalamic regions. There are also

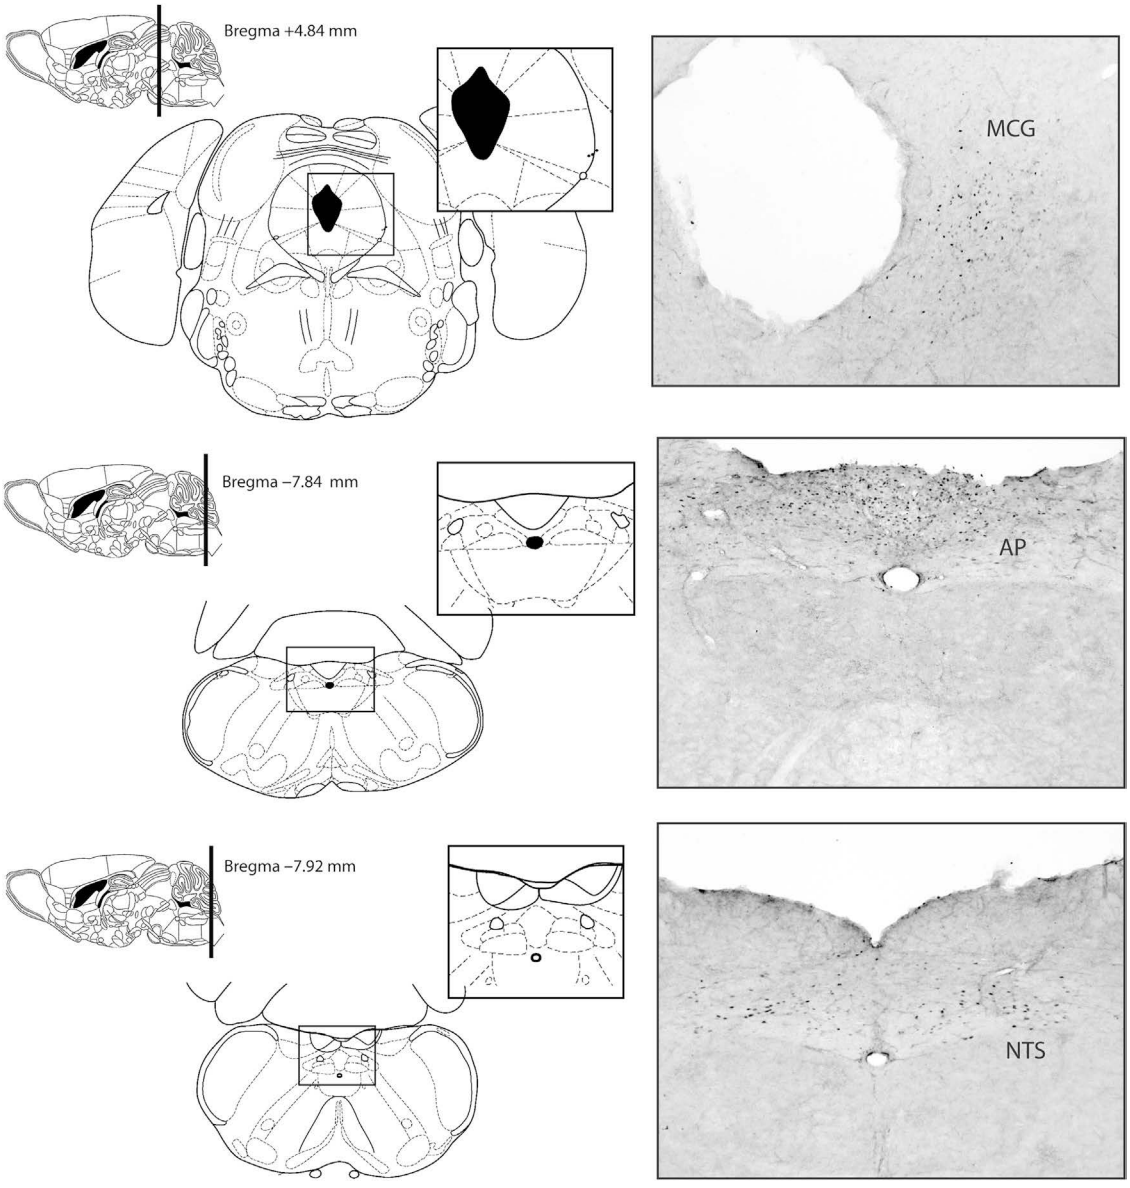

FIGURE 12.7 Cont'd

exceptionally high levels in the choroid plexus, and it has recently been reported that multiple variants of exon 1 of the prolactin receptor drive expression in this tissue.[640] Using the mouse as a model species, prolactin responsive neurons are observed to be particularly dense around the organum vasculosum of the lamina terminalis and rostral part of the third ventricle, in the anteroventral periventricular nucleus, periventricular preoptic nucleus, and median preoptic nucleus. At this level of the brain, there is also extensive prolactin receptor expression throughout the bed nucleus of the stria terminalis. Moving caudally, prolactin receptors are highly expressed in the medial preoptic nucleus, the supraoptic nucleus, and both the magnocellular and parvicellular subdivisions of the PVN. In the mediobasal hypothalamus, prolactin receptors are expressed in the arcuate nucleus and the ventrolateral subdivision of the ventromedial nucleus. Prolactin receptor expression is also seen in the medial amygdala at this level of the brain. In the midbrain, prolactin receptors are expressed in the parafascicular nucleus and central gray matter, and then in the hindbrain, area postrema, and nucleus of the solitary tract. Thus, there is considerable potential for prolactin to influence brain function.

The overall distribution of prolactin receptor–containing neurons strongly resembles the distribution of ERα in the mammalian brain.[641] There is significant evidence that prolactin receptor expression is directly influenced by estradiol[98,635,642,643] and progesterone,[644] and some of

the biological actions of prolactin in the brain are dependent on estradiol.[645] Prolactin receptor expression in the brain is also regulated during pregnancy[114,495,497,646] and lactation.[496,497,647–649] The mechanisms mediating increased expression of prolactin receptors in the brain of pregnant and/or lactating rats are not known. Prolactin itself may mediate an upregulation of its receptors,[650,651] as occurs in some other tissues. It is probable that hormonal changes of pregnancy, such as the high progesterone levels, prolonged elevations of placental and then pituitary lactogens, and the increasing estrogen–progesterone ratio prior to parturition, all play a role in stimulating the expression of prolactin receptors during pregnancy and lactation. The elevated prolactin receptor expression during lactation appears to result from the combined stimulatory effects of suckling-induced hyperprolactinemia, and the neural input from the suckling stimulus per se.[652]

The neurochemical phenotype of prolactin-responsive neurons in various regions is gradually being described. As well as being expressed on TIDA neurons in the arcuate nucleus,[98,100] prolactin receptors are also expressed in enkephalin neurons,[653] kisspeptin neurons,[654] as well as some as yet unidentified neurons in this nucleus. Despite evidence that prolactin might regulate β-endorphin production,[655–657] only a few POMC neurons express the long form of the prolactin receptor.[100] In the supraoptic and paraventricular nuclei, oxytocin neurons express the long form of the prolactin receptor.[574] In contrast, vasopressin neurons do not express the long form of the prolactin receptor but may express the short form of the receptor, as prolactin receptor-like immunoreactivity has been identified on these cells.[658] Prolactin has been reported to activate MAPK in corticotrophin-releasing hormone neurons in the PVN,[659] although this could be direct or indirect. In the dorsomedial hypothalamic nucleus, but not the arcuate nucleus, prolactin receptors are expressed on NPY-containing neurons.[550] In the ventromedial hypothalamic nucleus, prolactin receptors are localized on enkephalin neurons.[653] In the anteroventral periventricular nucleus, most kisspeptin neurons express the prolactin receptor, as well as many GABAergic neurons,[654] while very few GnRH neurons express prolactin receptors.[660] Hence, consistent with the pleiotropic role of prolactin, there are a wide variety of prolactin-sensitive neurons in the hypothalamus.

Adult neurogenesis: The changes in behavior associated with motherhood, as described in this chapter, are associated with neuronal plasticity leading to remodeling of neural circuits (reviewed in Ref. 661), some of which may be mediated by adult-born neurons in the hippocampus and olfactory bulb that are associated with learning.[662] Although recent reports have suggested a role for prolactin in neural stem cell proliferation[663] and increased hippocampal neurogenesis in both virgin female and male mice,[664] there is no evidence for either increased hippocampal neurogenesis in early or late gestation in rodents[359,501,665] or decreased postpartum proliferation during lactation.[666–669] There is increasing evidence, however, for increased neurogenesis in the SVZ of the forebrain during mate choice, early pregnancy, and lactation in rodents,[359,501,670–672] although the timing of this may differ between species.[665] A direct role for prolactin in this generation of new neurons has been shown by a similar increase in SVZ neurogenesis after infusion of prolactin either peripherally or intracerebroventrically in ovariectomized mice,[501] and reduced SVZ neurogenesis either in pregnant $PRLR^{+/-}$ mice[501] or after a suppression of prolactin in early pregnancy.[359] The newly generated neurons migrate to the olfactory bulb, where they are likely to have a role in the learning of novel odorants,[673] which is required for offspring recognition.[674] Prolactin has also been shown to have a role in the proliferation of both astrocyte[675] and oligodendrocyte[676] populations, which potentially leads to recovery of the brain after injury.[677] Intriguingly, this may be a mechanism underlying the remyelination of neurons associated with the remission of multiple sclerosis in the third trimester of pregnancy.[678] Taken together, these data indicate a key role for prolactin in promoting plasticity within the central nervous system, a function that is likely to be particularly prominent during pregnancy and lactation when prolactin levels are high. More work is required to determine the physiological relevance of these processes, although impaired maternal behavior has been observed when prolactin-induced neurogenesis is blocked during pregnancy in mice.[359,502]

Anxiety and stress responses: In pregnancy and lactation, there is a marked attenuation of anxiety as well as the hypothalamic–pituitary–adrenal axis response to stress[679–681] (see also Chapter 44). This is thought to help protect the fetus from adverse programming effects of elevated glucocorticoids during early development. Prolactin acts as an endogenous anxiolytic agent, able to induce dose-dependent suppression of anxiety behaviors[682] as well as the acute stress response.[683,684] Both of these effects could be prevented by central administration of antisense oligonucleotides directed against the prolactin receptor.[351,684] Chronic prolactin treatment blocked the stress-induced increase in corticotrophin-releasing hormone mRNA in the PVN, and reduced neuronal activation in response to stress, as measured by *c-Fos* mRNA.[682] In addition, stress-induced prolactin secretion has been associated with increased prolactin levels detected in the PVN.[685] Thus, it seems possible that prolactin may have a role in the suppression of the stress response

during pregnancy.[686] As with induction of maternal care, prolactin may have acute anxiolytic effects during late pregnancy or lactation, but it can also influence postpartum anxiety through its effect on neurogenesis early in pregnancy.[359]

Regulation of oxytocin neurons: Oxytocin neurons play a critical role in parturition, milk ejection, and maternal behavior. Prolactin receptors are expressed in oxytocin neurons,[574] and prolactin increases phosphorylation of STAT5,[687] induces expression of the transcription factor Egr1,[688] and acutely suppresses the firing rate of these neurons in nonpregnant females.[574,689,690] In contrast, prolactin appears to increase the secretion of oxytocin in males[691] and ovariectomized females,[692] likely through activation of neuronal nitric oxide synthesis.[691] As discussed here for TIDA neurons, it seems unlikely that the JAK–STAT response is mediating the acute effects on electrical activity; it is more likely to be inducing a change in gene transcription in these neurons. It has been proposed that the acute inhibitory effect on firing might reflect a feedback role,[693] regulating a putative prolactin-releasing role of oxytocin.[321,694] In lactating animals, prolactin stimulates oxytocin secretion[695,696] and expression of oxytocin mRNA,[697,698] likely involving the JAK–STAT pathway to activate gene transcription. Moreover, ICV administration of a prolactin receptor antagonist impairs parturition,[699] consistent with a role for prolactin in stimulating the normal firing pattern of oxytocin neurons at this time. Hence, prolactin has a complex role in the regulation of oxytocin neurons, and specific effects may be dependent on the physiological state of these neurons.

Suppression of fertility: Hyperprolactinemia is an established cause of infertility. Prolactin suppresses both the frequency and amplitude of LH pulses[700–702] and reduces GnRH secretion into the portal blood.[703–705] Prolactin can also act in the pituitary gland to suppress LH secretion.[706–708] In humans, pulsatile GnRH replacement can reverse the infertility induced by hyperprolactinemia,[709–711] suggesting that a prolactin-induced suppression of GnRH release is the primary cause of infertility. Such an effect might be mediated directly on GnRH neurons,[712] but since the majority of GnRH neurons do not express the prolactin receptor,[660] it is more likely that prolactin acts indirectly through prolactin-sensitive afferent neurons, such as kisspeptin or GABA neurons.[654]

During pregnancy and lactation, suppression of fertility may be a physiological function of hyperprolactinemia. Lactation is associated with a period of physiological suppression of fertility in most mammalian females, including women.[713] This is an important adaptive response, allowing the mother to focus her energy on feeding her new offspring before investing resources in a further pregnancy.[714] In humans, this function has served as a critical regulator of population growth, spacing the timing of births to allow the mother to ration her metabolic investment in reproduction across sequential pregnancies.[715] Other species, such as rodents, have evolved mechanisms to bypass this limit on fecundity, with postpartum ovulation and mating immediately after birth allowing a condition of concurrent pregnancy and lactation—despite anovulation throughout the duration of the lactation.[716] Even here, a delayed implantation ensures that the new litter is not born until the appropriate time of weaning of the original pups.[717,718] Despite the extensive impact on mammalian reproductive physiology, our understanding of the mechanisms mediating lactational infertility remains incomplete.[713,714] It is clear that the suckling stimulus is the critical inhibitory signal,[719] and the proximal cause of infertility is an almost-complete suppression of GnRH secretion from the hypothalamus and the consequent loss of pituitary gonadotropin secretion.[720] It seems likely that prolactin might be involved in the lactation-induced suppression of pulsatile secretion of GnRH, but earlier studies looking at this have been equivocal. Bromocriptine-induced suppression of prolactin secretion was not sufficient to fully reverse the effects of lactation in the presence of an ongoing suckling stimulus in rats,[719,721–724] although suppression of prolactin by itself was sufficient to increase pulse generator function in a subset of lactating monkeys.[725] The timing of these experiments might be important, as some studies have revealed changes in the relative roles of prolactin and/or suckling across the duration of pregnancy.[719] Studies have recently shown a loss of kisspeptin expression during lactation,[726–729] and given the prolactin receptor on these neurons,[654] this is again consistent with a possible role for prolactin in the lactation-induced suppression of GnRH.

Brain prolactin: While there is extensive evidence of systemic prolactin being transported into the brain, the possibility that central prolactin receptors are influenced by prolactin of brain origin should also be considered. The role of brain prolactin remains controversial, however, despite numerous reports of both the protein and its mRNA in brain tissue. As discussed in this chapter, it seems unlikely that the pituitary-specific promoter would drive prolactin expression in the brain in the rodent, but it remains possible that a novel promoter could induce expression in nervous system cells. The original observation of immunoreactive prolactin in the hypothalamus of rats[730] has been independently replicated by several groups,[731–736] although one study showed cross-reactivity of prolactin antiserum with POMC.[737] Importantly, prolactin-like immunoreactivity was not depleted by hypophysectomy, suggesting that it was unlikely to

be of pituitary origin. Moreover, de novo prolactin synthesis and prolactin release could be detected from hypothalamic fragments in vitro,[733,738,739] suggesting local production of prolactin in neurons or glial cells. Subsequently, prolactin mRNA was detected in brain tissue by real-time polymerase chain reaction[738,740,741] and by in situ hybridization in fetal sheep brains.[742] Prolactin expression in the brain has been colocalized with estrogen receptors[731,736] and appears to be stimulated by gonadal steroids.[731,738,740,743,744] Prolactin mRNA in the brain is also increased by stress and during lactation,[685,745] although there have not yet been any studies demonstrating prolactin mRNA in the adult brain by in situ hybridization. Although there is not universal agreement, most studies report prolactin or its mRNA in the medial preoptic, paraventricular, periventricular, and arcuate nuclei, where there are high levels of prolactin receptor, and thus it seems possible that some actions of prolactin in the brain might be mediated by prolactin acting as a neuropeptide as well as a neuroendocrine hormone.[746] It is not clear what levels of prolactin might be released into the central nervous system, relative to levels entering the brain from the systemic circulation. When pituitary prolactin is blocked by bromocriptine treatment, however, there is a complete absence of phosphorylated STAT5 in the brain,[147] suggesting that if brain prolactin is present, levels are insufficient to activate this pathway under basal conditions in the adult. It remains possible, though, that brain prolactin may play a role under specific conditions, such as during brain development[664] or in response to brain injury.[4,327,376,677]

REPRODUCTIVE ACTIONS OF PROLACTIN IN THE MALE

While our focus in this chapter has been on the broad roles of prolactin in helping the mother adapt to pregnancy and lactation, it is important to recognize that prolactin also has reproductive functions in the male. These functions have not been as widely studied as in the female, probably because the *complete* infertility found in knockout models is restricted to that sex.[418,419] Nevertheless, prolactin exerts physiologically significant functions in the male reproductive system, and we will summarize available data here.

Fertility

The male infertility and loss of libido associated with acute hyperprolactinemia[747] are most likely the results of inhibition of GnRH secretion (as discussed in this chapter). However, prolactin may also influence the male reproductive system directly. Prior to the generation of prolactin and prolactin receptor knockout models, roles for prolactin in testis function had been suggested by the observation that prolactin receptors are expressed in the testis,[748] and studies showing the effects of prolactin on Leydig cell response to LH[749,750] and on the Sertoli cell response to FSH.[751] The physiological importance of these roles was questioned, however, by reports that male *Prlr*$^{-/-}$ and *Prl*$^{-/-}$ mice were able to reproduce and have normal plasma testosterone concentrations, indicating normal testicular response to LH.[131,752] This has led to widespread assumption that prolactin is not involved in the normal regulation of fertility in the male. As discussed here, however, it is important to recognize that compensation is common in knockout models. The lack of overt phenotype in *Prlr*$^{-/-}$ mice does not necessary rule out a physiological function of prolactin in male fertility. In fact, the original description of *Prlr*$^{-/-}$ male mice reported reduced fertility in 33% of animals, and a further 20% were completely infertile,[419] which was confirmed in one subsequent study[753] but not another using the same model.[752] In *Prl*$^{-/-}$ mice, there was no reduced male fertility,[131] but these mice would have some prolactin and placental lactogen exposure from the mother and placenta. The lack of an infertility phenotype in *Prl*$^{-/-}$ males, as well as the inconsistent findings with *Prlr*$^{-/-}$ mice (which may be a result of different genetic background),[752] would be consistent with compensation by other factors or pathways. In studies of *Prlr*$^{-/-}$ mice where reduced fertility was found, mating behavior, intromission, ejaculation, testes weight, and spermatogenesis were all normal, and the cause of the infertility is unclear. Interestingly, in one study reporting *Prlr*$^{-/-}$ male mice with reduced fertility, those animals that were fertile had a prolonged latency to the first pregnancy, but subsequent mating with the same female was normal (postpartum mating).[753] These data implied that an abnormal male ejaculate–female reproductive tract interaction may be responsible for the reduced fertility in *Prlr*$^{-/-}$ mice. A role for the female immune response to semen has been suggested in preeclampsia, with tolerance in subsequent pregnancies with the same father.[754]

There are significant quantities of prolactin in human seminal plasma[755] and even higher concentrations in epididymal fluid,[756] and studies have suggested possible roles in sperm capacitation.[757,758] Prolactin receptors are strongly expressed in the midregions of human spermatozoa,[756] and prolactin acts as a pro-survival factor for these cells by suppressing entry into a programmed cell death pathway. While there is clear evidence for this pro-survival pathway, it is likely a redundant mechanism, with a number of other growth factors able to exert the same function.

Prostate Gland (See Also Chapter 18)

The prolactin receptor is expressed in the prostate gland,[759,760] and prolactin acts as a survival factor for

prostate cells in culture.[761] As seen in the testis, knockout of prolactin or its receptor did not reveal a key role for prolactin signaling in mouse prostate physiology,[752] but there is plenty of evidence for prolactin regulation of normal prostate function.[762] Analysis of changes in prostate gene expression resulting from loss of prolactin receptors implicates prolactin in the regulation of genes with roles in sperm–oocyte interaction, copulatory plug formation, and protection of sperm from female immune response.[753]

Paternal Behavior

The role and extent that the mammalian father plays in parental care of offspring vary amongst species, principally being dependent on ecological conditions that provide an advantage from biparental care for reproductive success.[763,764] Whilst numerous studies in a range of species, including humans,[765,766] have found an association between prolactin and paternal care,[767] the role that prolactin plays in the induction of paternal behavior is unclear and controversial, even in rodents.[768,769] This is, in part, a result of the differences in paternal behaviors between species. Nevertheless, paternal recognition of offspring to prevent infanticide and attacks on adult sons and daughters is consistent amongst most species. Pup contact by male rats can lead to some forms of parental care behavior, and this is associated with an increase in serum prolactin, as well as increased expression of the long form of the prolactin receptor.[770] Further evidence for a direct role for prolactin in paternal recognition of offspring has been shown by studies of *Prlr*$^{-/-}$ fathers, who fail to distinguish adult offspring from nonoffpring, possibly as a result of failure of prolactin-induced neurogenesis in the SVZ and the dentate gyrus.[771]

PROLACTIN AND REPRODUCTIVE DISORDERS

While the focus of this chapter has been on the role of prolactin in the physiology of reproduction, it is important to acknowledge that inappropriate prolactin levels, either too little or too much, are associated with a range of pathological conditions. As might be expected from its primary roles, prolactin is principally associated with disorders of the reproductive system, with the major pathologies being fertility disorders and cancers of the breast and prostate. However, in accordance with its potential roles in a modulation of a wide range of physiological systems, prolactin has been implicated in diseases as diverse as autoimmune disorders,[772] endometrial carcinoma,[773] peripartum cardiomyopathy,[774] chronic renal failure, hepatic insufficiency, and polycystic ovarian syndrome.[775]

Hyperprolactinemia

In addition to the high levels of prolactin secretion associated with a variety of normal physiological states, hyperprolactinemia can result from a number of pathological conditions and pharmacological treatments. Hyperprolactinemia is the most common endocrine disorder,[776] occurring in 1% of women,[777] and is recognized as a major cause of reproductive dysfunction. Delayed puberty is observed in both males and females.[778] Women with chronic hyperprolactinemia present with infertility, galactorrhea, amenorrhea, reduced libido, and even habitual abortion. Up to 40% of women presenting with secondary amenorrhea have increased serum prolactin levels.[779,780] Men may similarly present with infertility and galactorrhea, in addition to decreased libido. In men, hyperprolactinemia is present in approximately 16% of patients with erectile dysfunction and 11% of men with oligospermia.[747] Hyperprolactinemia is also a serious side effect of neuroleptic drugs, resulting in infertility and loss of libido in up to 70% of patients, representing one of the major causes of noncompliance with antipsychotic medication.[780] Most of the symptoms can be accounted for by an altered pattern of GnRH secretion, with a marked reduction in both the frequency and amplitude of LH pulses[709] (a direct result of GnRH pulses), and the suppression of LH pulsatility can be reversed by reducing serum prolactin concentrations to normal.[781] Pulsatile GnRH replacement can reverse the infertility induced by hyperprolactinemia,[709,710] suggesting that a prolactin-induced suppression of GnRH release is the primary cause of infertility.

The two principal pathologies leading to hyperprolactinemia are prolactin-secreting tumors known as prolactinomas (discussed in this section) and other sellar and parasellar lesions that lead to a functional disconnection of the normal dopaminergic control of lactotrophs. A functional disconnection of dopaminergic control can also occur after traumatic brain injury (TBI), which can result in pituitary stalk damage or posttraumatic deficits of dopamine. Hyperprolactinemia has been described in 52% of individuals during the acute period post TBI, with levels correlating with the severity of injury.[782] Pharmacological treatments that antagonize dopamine D2R or lead to reduced dopamine secretion are also a major cause of hyperproactinemia.

Prolactinomas: Whilst asymptomatic pituitary tumors are found in 14–22% of individuals at autopsy, symptomatic tumors are much rarer, occurring with a frequency of 1:1000 to 1:1300 in the general population.[783] These tumors are generally benign, and metastases occur in less than 0.5% of symptomatic pituitary tumors.[784] Prolactinomas are the most common, accounting for 30–35% of pituitary tumors, and are classified according to their size as microprolactinomas (<10 mm) or macroprolactinomas

(>10 mm). Prolactinomas have been reported to occur more frequently in females than males, most commonly between 20 and 50 years of age, although the more obvious symptoms in females may account for part of the apparent higher frequency. Prolactinomas are commonly successfully treated with dopamine agonists, such as cabergoline, which result in normalization of prolactin levels and reduction in tumor size.[785] Prolactinomas have a variable response to dopamine agonists, however, and in some tumors there is a complete resistance to these drugs.[786] There are multiple potential mechanisms underlying this dopamine agonist resistance (reviewed in Ref. 787), including reduced receptor density, disruptions of autocrine growth factor–signaling pathways, and potential alterations in dopamine receptor isoform expression.

The molecular alterations leading to prolactinoma formation are unclear, but the monoclonal origin of the tumors indicates a mutation occurring in a single cell that confers a growth advantage from activation of a proto-oncogene or inactivation of a tumor suppressor gene.[788] Mutations leading to the reduced dopamine sensitivity of lactotrophs are excellent candidates, as demonstrated by the tumor occurrence in D2R-deficient and dopamine-deficient mice.[302] However, it is likely that there are several different mechanisms underlying prolactinoma formation, with the low incidence of progression from microprolactinoma to macroadenoma, which occurs in only 4–7% of cases, suggesting that the two types of tumor have distinct origins.[789]

Breast Cancer

Both prolactin and its receptor have been shown by immunohistochemistry to be expressed in human breast carcinoma,[790] and the role that the hormone plays in normal breast development and function suggests that it is likely to have a role in mammary tumorigenesis, although this remains controversial.[791,792] Epidemiological data linking prolactin with the development of breast tumors are limited,[793] but an increasing number of studies are demonstrating a correlation between high circulating prolactin concentration and risk of subsequent development of breast cancer in women with a range of ethnic and genetic origins (e.g., Refs 794,795). There are potential complicating factors in demonstrating a link between high prolactin and risk of breast cancer. For example, patients with prolactinomas and extremely high levels of circulating prolactin frequently have hypogonadism,[796] and the resulting reduced estradiol may influence tumor development or even be protective if the breast tumor is estrogen dependent.[792] Both in vitro analyses of human breast cancer cell lines and in vivo studies of animal models have provided strong evidence for a role of prolactin in the etiology of breast cancer (reviewed in Refs 34,792). The effects of antibody and antagonist treatment indicate that local production of prolactin by breast tissue itself may have a role in mammary tumorigenesis[34,410] and it is possible that mammary gland prolactin may have a different effect than pituitary prolactin on the tissue, either from post-translational modification or by intracrine actions.[797] More recent studies have shown that the microvasculature of human breast tumors expresses the prolactin receptor and that prolactin may have a direct effect on endothelial cell migration,[798] suggesting a potential key role for the hormone in tumor angiogenesis.

Prolactin receptor signaling may also be an important variable in the development of breast cancer, with studies showing increased receptor concentration in malignant tissue[799] as well as differences in expression of different isoforms.[800] More recently, activating mutations in the prolactin receptor have been described that are associated with the development of breast fibroadenomas.[801] Prolactin effects on mammary carcinogenesis are likely to be mediated by Stat5 signaling, since reduced Stat5 decreases the incidence of mouse mammary tumors.[802] Other prolactin receptor–signaling pathways may have a role, however, for example the recent description of nuclear prolactin receptor signaling leading to increased ERα and progesterone receptor expression in breast cancer cell lines.[803]

A role for prolactin in mammary tumorigenesis has also been demonstrated in vivo in animal models with increased or decreased exposure of mammary tissue to prolactin. Transgenic mice with ubiquitous overexpression of rat prolactin have a 100% incidence of mammary carcinomas by 11–15 months of age,[804] whilst those with expression restricted to mammary epithelial cells have an increased incidence of mammary tumors from 5% to 65–80% in mice older than 19 months.[805] Conversely, loss of prolactin[806] or the prolactin receptor[807] leads to a retardation of mammary tumor formation in mice.

Prostate Cancer (See Also Chapter 18)

Although prostate and breast cancer have very different apparent pathologies, an association between these cancers is suggested by several similarities such as their biochemistry, hormone dependence, incidence, and risk factors.[808] Although in the case of prostate cancer there is no evidence for an increased risk from high circulating prolactin,[809] there is increasing evidence for a role of locally produced prolactin acting on prolactin receptors within the tissue in the etiology of these tumors.[760] Prolactin activation of the Jak2–Stat5a/b pathway has been demonstrated in ex vivo cultures of human prostate cancers, and there is a correlation between activated Stat5 and the histological grade of tumors.[810] As with in vitro studies

of breast cancer cell lines, blocking prolactin signaling with a receptor antagonist leads to decreased cell viability through induction of apoptosis,[811] whilst prolactin acts as a mitogen in primary cultures of rat prostate cells and in vivo.[761,812] Animal studies also implicate prolactin in the etiology of prostate cancer, with transgenic overexpression of prolactin in mice causing enlargement of the prostate gland[813,814] and a reduction in tumor incidence in prolactin receptor knockout mice[753] or following prostate-specific overexpression of a prolactin receptor antagonist.[35]

CONCLUSION

The textbook definitions of prolactin action focus on its essential role in stimulating milk production in lactation. It is presented as a simple hormone with a single function. While this function is important, arguably, it is not irreplaceable (at least in humans), and diseases of prolactin signaling are typically not life threatening. Moreover, when issues with prolactin secretion do arise, such as a pituitary adenoma causing hyperprolactinemia, these can be treated in the clinic using dopaminergic drugs such as bromocriptine or carbergoline. Hence, it can be tempting to consider that we know all we need to know about this hormone. However, we do not think this is the case! In this chapter, we have attempted to expand the definition of prolactin function by acknowledging the fact that prolactin influences numerous cell and tissue systems, and by emphasizing how this breadth of function might maximize the reproductive success of an individual. While knockout animals are viable and have failed to display major deficits consistent with all of the hormone's "300 biological actions", this does not mean that prolactin functions are not important. They might not be critical to the individual, but they may have a more general role in optimizing the survival of a species. As the hormone responsible for lactation, prolactin has clearly played a critical role in the evolution of mammals, as this function defines this class of animals. In this context, distinct roles for the hormone in different species, as well as in genetically distinct groups within the same species, and diverse mechanisms resulting in analogous functions are not unexpected.

There remains much for us to understand about the direct and indirect roles of prolactin in reproduction. This issue is complicated by the interaction of prolactin with many other biological systems, and by the many other neural and endocrine inputs that influence those same biological systems. Looking forward, it is likely that the specific roles of any one hormone within this complex milieu will be clarified by new research tools, such as the use of genetically modified mice with alterations of prolactin signaling in specific tissues and cell types, and at specific times during development. The mechanisms underlying the plasticity of the neuroendocrine control of prolactin during pregnancy and lactation also remain important questions to be answered. Similarly, the potential of prolactin in fetal programming and transgenerational modification of function is another potentially important question, supported by the broad range of adaptive changes promoted in the mother during pregnancy, the high levels of prolactin present during development, and the high levels of prolactin receptor expression in the fetus. Again, it seems likely that a mixture of genetic and epigenetic analyses and new technologies will be required to fully understand these questions. In addition, there is increasing evidence for local prolactin production altering tissue function, and this may be a more important factor than circulating prolactin, particularly when looking at prolactin-related diseases such as cancers. This has been largely overlooked until recently and will continue to be a fruitful area for research, as will the development of antagonists as potential therapies for a range of disorders and cancers.

It is without question that elevated prolactin is present in all mammals during pregnancy and lactation. The hypothalamic control of prolactin secretion exhibits profound plasticity during these states, changing from a predominantly inhibitory feedback system to one that facilitates a state of physiological hyperprolactinemia. The elevated prolactin is clearly essential for synthesizing and secreting milk from the mammary gland. Mammalian reproduction is far more complex than this relatively simple function of milk secretion, however, and we have highlighted how prolactin regulates and facilitates multiple parts of the full complex process of reproduction, culminating in lactation (see Figure 12.8). Thus, we have described how prolactin is important in the reproductive cycle of the female and enhances the fertility of the male. After conception, prolactin is involved in implantation and the establishment and maintenance of pregnancy. It acts on a wide variety of tissues, such as bone, pancreas, gut, liver, adipose tissue, and brain, to induce maternal systems to change their function to adapt to the new reproductive state. And it contributes to the behavioral changes that are an essential part of enabling milk delivery to the offspring. Disorders of prolactin function within these processes, by themselves, may not irretrievably compromise reproduction. Nevertheless, it would seem that understanding prolactin function within these processes will help us optimize reproductive events and help us intervene appropriately when these processes are impaired in individuals.

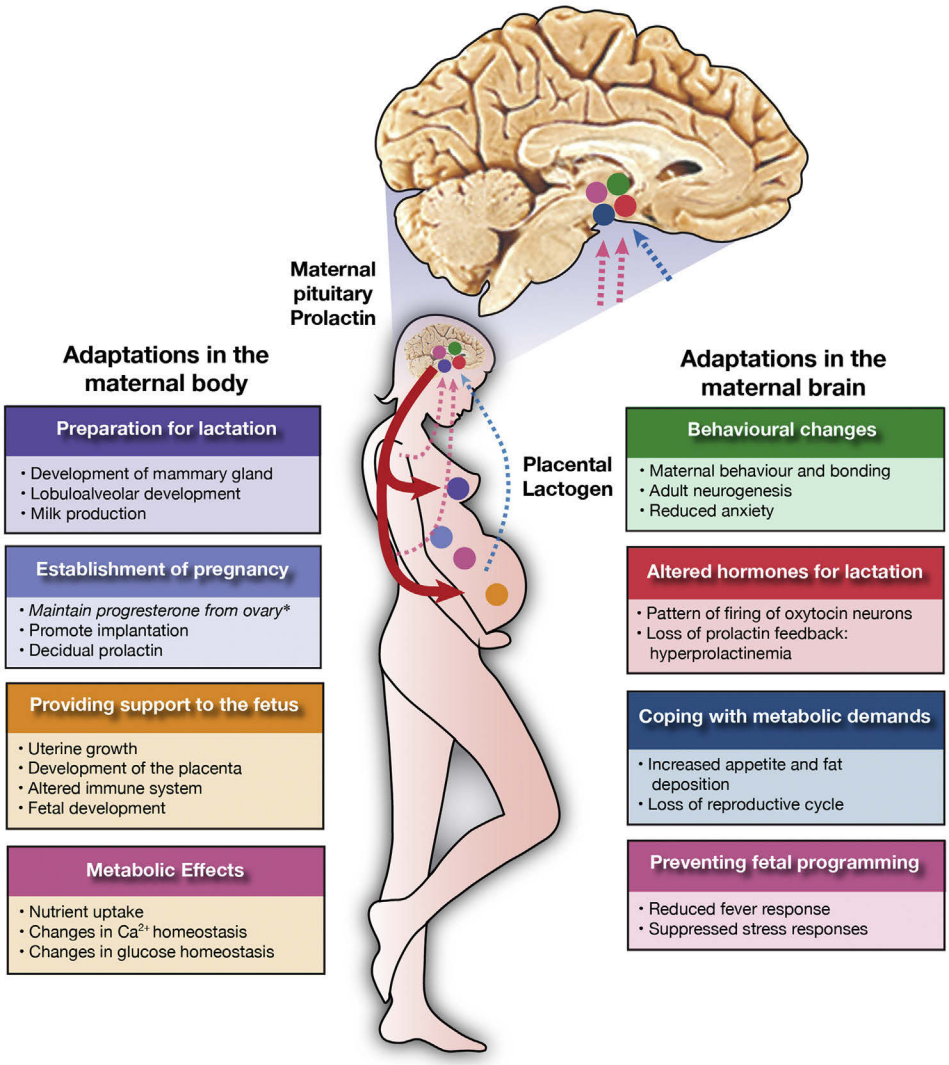

FIGURE 12.8 Summary of adaptive responses in the pregnant female that may be induced or regulated by prolactin and/or placental lactogen. This figure is reproduced in color in the color plate section. Note that while this figure shows a human pregnancy, most of the data are based on experimental data from laboratory animals, and some have not yet been confirmed in women. *Those shown in italics are known to occur only in rodents.

CHAPTER

13

Central Nervous System Control of Oxytocin Secretion during Lactation

William E. Armstrong

Department of Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN, USA

INTRODUCTION

For mammals, providing milk during lactation is critical to infant growth and survival. Successful lactation depends on many factors, but critically on sufficient milk production, instigated largely by the circulating adenohypophysial hormone prolactin, on the morphological development of mammary glands for milk storage and ejection, and on the secretion of the hormone oxytocin (OT) in order to expel the milk from alveolar storage to mammary ducts (or cisterns, or sinuses) for its retrieval by the nursing young. This chapter is concerned with this latter aspect, specifically focusing on OT neurons of the hypothalamus and their axonal projection to the neural lobe of the neurohypophysis: how their electrical activity relates to hormone release and milk ejection, how this activity is formed through intrinsic and synaptic properties, and how critical events during pregnancy may shape this system for optimal neuronal activity, and thus efficient secretion, during parturition (where OT promotes labor by uterine contractions) and lactation (where it contracts the myoepithelium surrounding alveoli to eject milk).

Although it is over a century since posterior lobe (a.k.a. neural lobe, or pars nervosa) extracts were first demonstrated to have powerful pressor, antidiuretic, uterotonic, and galactagogic activity[1–3] and now several decades since the neuronal character of OT neurons was established fully, historically there was slow acceptance that neural lobe secretions had a neuronal origin. Many investigators suggested an anatomical relationship between the neurohypophysis (which consists of the median eminence, pituitary stalk, and the neural lobe) and the hypothalamus based on a variety of methods. From the monograph of Geoffrey Harris summarizing this literature,[4] we know that histologists as early as 1860 had described an innervation of the neurohypophysis—Cajal[5] himself described unmyelinated fibers connecting the supraoptic nucleus (SON; his tangential nucleus in rat) to this region, but considered that the pituitary was a sensory organ, communicating afferent stimuli to the hypothalamus. In later studies the efferent nature of connections from hypothalamus, especially from the SON, was surmised from axonal degeneration after hypothalamic lesions and from the retrograde atrophy of hypothalamic neurons following tract section or hypophysectomy.[6–8] But it was not until the definitive histological work of Ernst Scharrer, Wolfgang Bargmann, and Bargmann's student Walter Hild that the origin of the active posterior lobe principles was shown to be hypothalamic neurons.[9] In mammals, fish, and amphibians, the Gomori-positive (i.e., cysteine-rich material stained with chrome-alum hematoxylin) axons with associated varicosities observed in the neurohypophysis could be traced from the gland back to large cells in the hypothalamus in the SON and paraventricular nucleus (PVN; or their homologs in lower vertebrates). Experimentally, the accumulation of transported material in proximal axons after pituitary stalk section, and its subsequent disappearance in the neurohypophysis, was consistent with the notion of anterograde axonal transport demonstrated in peripheral nerve.[10] Soon the physiologically active extracts from the posterior lobe of mammals were purified and their amino acid composition and sequence characterized as the closely related nonapeptides OT[11] and vasopressin (VP).[12]

In spite of what today seems the obvious force of the histological arguments, a continued hurdle lay in relating how the hypothalamus exerted this control. Electrical stimulation of the pituitary or the supraoptico-neurohypophysial tract had been known since the late 1940s to produce pressor, antidiuretic, and oxytocic actions, demonstrated in a classic series of experiments by Harris in rabbits.[4] Cross and Harris[13] even directly

observed the ejection of milk from a cannulated rabbit's teat when stimulating this tract. Other studies showing that damage to this tract often led to pronounced diuresis from the loss of VP[6] and a disruption of milk ejection[14] reinforced the primacy of hypothalamic control over the pituitary. Roughly coincident with Harris's 1951 monograph,[4] for example, was the aforementioned article by Bargmann and Scharrer[9] summarizing years of work using Gomori-positive stains and crystallizing the concept of neurosecretion. While believing, and in large part himself demonstrating, that hypothalamic electrical activity controlled neurohypophysial and adenohypophysial secretions, Harris[4] nevertheless espoused a view common at the time about the source of the hormone, writing: "the active substance present in the posterior extracts is formed in the tissues of the neurohypophysis, though the particular cells involved are unknown." However many histologists even outside the German school had commented on the fact that the cellular components of the neural lobe were not Gomori-positive, or at least, not richly so like hypothalamic neurons or the secretory cells of the anterior lobe and pancreas.[8] In 1958, Harris[15] acknowledged the now accepted view that it was the SON and PVN neurons that also synthesized the active pituitary principles, transporting them to the neural lobe for secretion from axon terminals.

Once it was established that the PVN and SON were the source of the active posterior lobe principles, and given that it had been known for many years that these hormones could be released by electrical stimulation either of the lobe itself, the hypothalamo-neurohypophysial tract, or from within the hypothalamus, it remained to be determined whether OT (or VP) cells were fully neuronal, that is, capable of firing regenerative action potentials, receiving synaptic input, etc. It's easy to understand why these functions were not intuitively assumed. The Gomori-positive axons were decorated with large swellings (Herring bodies) ending near capillaries (and not making synapses with neurons) in the neural lobe, and with the exception of their elongated axon (dendrites not extensively visible), their appearance was not unlike other gland cells, such as those in the adenohypophysis. This issue was directly addressed by Kandel's[16] landmark study of goldfish neurosecretory neurons in the magnocellular preoptic nucleus. These neurons make hormones related to VP and OT, isotocin or vasotocin, which are also secreted from the posterior lobe. Kandel[16] found that these neurons fired action potentials either spontaneously, or antidromically from pituitary stimulation, and also showed synaptic potentials in response to olfactory tract stimulation. Although osmotically responsive extracellular action potentials had been recorded from in or near the SON of rabbits[17] and cats,[18] it was not until antidromic identification was applied that it became certain that rodent neurosecretory neurons were similar to their lower vertebrate counterparts, verified first in the SON by Yagi et al.[19] The technique was later applied to the PVN of rabbits,[20,21] and similar studies were accomplished in the SON or PVN of cats,[22,23] dogs,[24] and monkeys.[25] Most studies found a relatively slow estimated conduction velocity (<1 m/s) consistent with the histological evidence of small diameter, unmyelinated axons in the neural stalk and lobe. Together with the anatomical work discussed earlier, and the classic experiments on stimulus-secretion coupling in the neurohypophysis from Douglas and Poisner,[26] these seminal electrophysiological forays form the scaffold for this chapter's exploration of how the central nervous system (CNS) controls OT release during lactation. Although there has been substantial work on the release of OT in many mammalian species, particularly cats, rabbits, pigs, primates, and guinea pigs, it is primarily in rat (but see below) that the behavior of OT neurons has been directly observed during secretion, and for which an overwhelming amount of experimental work on the neural control of OT neurons exists. In focusing on these neural aspects, it should be mentioned that there are many species differences in milk storage and ejection, and in mammary gland morphology, that have received excellent and extensive treatment in prior reviews and need not be revisited here.[27]

Long before the firm establishment of the hypothalamo-neurohypophysial system as described earlier, it was commonly thought that the brain influenced OT release. But this was not based initially on what later become known as the "suckling reflex"—where sensory information from the suckled nipples reached the brain to initiate milk ejection—it appears rather to be largely anecdotal evidence. Schäfer[28] commented in his classic text that while it is a "common experience that the quantity and quality of the milk is in women materially influenced by the condition of the nervous system," the results from animal experiments were "either entirely negative, or at most of a somewhat conflicting nature." The anecdotal "experience" is the knowledge that emotional factors influenced the ability of women to lactate—both positively (e.g., hearing a baby cry) and negatively (stress). That these experiences would be more apt to signal nervous system involvement than the response to suckling itself is not difficult to understand; suckling was often viewed as a way to locally remove milk, but not necessarily viewed as something needing the CNS. Thus it is the stimulation from other sensations, including emotional distress, that would be assumed to engage the nervous system at many levels. Initially, knowledge that cattle could be conditioned to increase milk let down by stimuli accompanying milking, as well as frightened or given adrenaline to "hold up" their milk,[29] prompted investigation of the autonomic nervous system. Early experiments led Bacq[30] to conclude that denervation of most sympathetic nerves

had little effect on lactation in rats; a similar conclusion was reached by Ely and Petersen[29] in cattle. The interest that adrenaline's ability to inhibit milk ejection might be the basis for emotional interference did not wane however,[31] and eventually it was determined that adrenaline can exert direct inhibitory effects on mammary tissue,[31,32] most likely due to an action on the myoepithelial cells mediated by β-adrenergic receptors.[33] Adrenaline's local actions on the pituitary could not account for all inhibition of milk ejection to stressful or even distracting visual, olfactory, and auditory stimuli, as peripheral OT injections could often overcome this stress-induced inhibition.[34,35] The brain-mediated stress-induced inhibition was convincingly, if by today's standards grotesquely, shown by Taleisnik and Deis,[36] who found that inhibition of OT release to leg fracture in rats was completely abolished during cortical spreading depression. This study not only suggested that cortical processing of painful stimuli was involved in this suppression but importantly suggested that cortical activity in rats is somehow permissive, and that sensory activation of the cortex is *not necessary* for suckling-induced OT release, a point that will be made again later in this chapter. The ability of electrical stimulation of the cortex to inhibit lactation was later confirmed by Ausebrook and Holland,[37] a finding confirming Cross's[32] original notion that the hypothalamus possessed inhibitory as well as excitatory pituitary influences.

The known ability of some anesthetics/analgesics to either block milk ejection outright, like ketamine or neuroleptics, or others to block or severely delay lactation at higher doses, *without* interfering with OT's ability to eject milk after intravenous injection, is further indication of central nervous involvement in the reflex.[38,39] Interestingly, experimentally and in the rat, especially, anesthetics are necessary for prolonged examination of the reflex even if they may delay its onset after the young attach, because the dam is easily distracted by environmental stimuli and will stop nursing.[38] In this regard even as our best animal model in terms of experimental access and an overwhelming history of reference, the rat is somewhat unusual among mammals in that cortical slow-wave sleep always accompanies lactation.[40,41] Not only is slow-wave sleep *not* a requirement among other experimental mammals studied,[42,43] many animals appear vigilant when nursing,[39] whereas suckling is soporific in conscious rats.[41]

MILK EJECTION IN RESPONSE TO SUCKLING IS AN ATYPICAL NEURONAL REFLEX

There is great variety in the nursing patterns of mammals, which for those studied experimentally, ranges from the once-a-day, short feedings of rabbits, to the prolonged nursing bouts of rats.[39] While in all mammals suckling stimulates OT release from the neural lobe, which in turn contracts the alveolar myoepithelium of the gland to force milk into ducts (or analogous chambers) where the young can access it, ruminants represent a specialized case since milk ejection at nursing, while present, is not immediately required due to the storage capacity of udders. In addition, the reflexive release is variable within and across animals: the start of the OT secretion can be relatively immediate, or delayed for minutes. This is especially true in animals under anesthesia, as indicated previously.

The best early suggestion of a centrally, neuronally mediated, reflexive release of OT in response to the sensory stimulus of suckling was probably provided by Ingelbrecht,[44] who found that in rats receiving lower spinal cord section (between last thoracic and first lumbar segments), thus removing ascending somatosensory pathways from the posterior teats, pups given only posterior teats to suckle died, whereas those given only anterior teats survived. Importantly, when pups together suckled the anterior teats *and* posterior teats in this preparation, *all suckling pups survived!* Thus once the sensory limb of the reflex successfully activated the efferent component, *all* mammary glands reacted. This study was thus not only critical in addressing both the necessity of spinal pathways to transmit the suckling stimulus but in determining the manner of the efferent limb of milk ejection. Having already ruled out the relative importance of the autonomic nervous system for lactation,[30] the latter result was best explained through a humoral factor, independent of motor innervation of the glands. A similar recognition of sensory nerve involvement in mammary gland function (although through prolactin release), came from Selye and coworkers[45,46] who noted the ability of suckling in intact teats to maintain mammary gland engorgement in others with nipple excision (and thus, not suckled), the ability of newborn pups to maintain gland development after weaning the original litter, and the ability of suckling to maintain the gland even when milk retrieval is prevented. This sensory/humoral link was again demonstrated in mice by Hooker and Williams,[47] who found that even without nursing, stimulating even a few nipples with turpentine (a known skin irritant) was sufficient to retard involution in all the glands, and that nipple excision did not prevent a particular gland from engorgement, so long as other intact nipples were suckled.

While varying concepts of a milk "let down" reflex, in the vein of spinal cord mediated reflexes, were proffered as early as 1915 by Gaines,[48] and summarized by Hammond[49] in his extensive review, Ely and Petersen[29] are credited with first suggesting that the efferent limb involved OT release and not nerves innervating the gland. In their classic experiment, the sympathetic motor nerves of one half of a cow's udder were sectioned

without altering gland development or milk yield during milking from that half. The sensory innervation remained intact throughout their experiments, which led to the stimulated release of OT from the hypothalamus that would reach both intact and denervated areas. These authors also suggested the reflex could be classically conditioned and that sensory information from the teat was just one source of afferent stimuli that could evoke OT release. Finally, the similarity of the increase in intramammary pressure recorded during milking to that recorded with the oxytocic extract Pitocin convinced these workers that the efferent limb was humoral. Folley[50] crystallized this view and clearly separated the phenomena of milk secretion (which includes milk synthesis and its release into the alveolar lumen) from the discharge of milk occurring during lactation, convincingly arguing a change from the "make-shift term letdown" to something that reflected the active process of the contracting alveoli forcing milk into ducts, cisterns, or sinuses for retrieval upon the suckling stimulus. The term "milk ejection", with its more active connotation, was officially proposed by Cowie et al. in 1951[51] and has been thereafter adopted by most workers in the field.

Thus the milk ejection reflex is atypical in at least three ways from classic spinal reflexes. Firstly, the latency to the response is relatively slow and variable. In anesthetized rats, for example, milk ejection may be delayed several minutes, even tens of minutes, after suckling onset. Secondly, as just discussed, the efferent limb has a humoral component following neuronal activation that requires OT transport in circulating blood. And thirdly, milk ejection is *pulsatile* in the face of a continuous suckling stimulus in virtually all species studied,[39,52] including humans[53–56] (Figure 13.1).

Interestingly, the young typically stimulate the nipples much more strongly *after* OT has reached the mammary gland and altered intramammary pressure. This pressure change, detected in all species studied both during milk ejection and in response to intravenous OT injection, is sensed by the nursing young and excites them to suckle more vigorously and withdraw milk. In animals with repetitive, periodic milk ejections, like the rat, nipple attachment for the minutes between ejections is critical to instigate and to maintain the reflex, but intense suckling is only present after intramammary pressure increases.[38] Often, pups detach from the nipple after withdrawing the milk, and then avidly move to reattach (Figure 13.1).

Although many of the earliest studies focused on rabbits and ruminants,[15] in no species has CNS involvement in milk ejection reflex been studied as intensively as it has in rats. This resulted not only from their general cost efficiency but also more importantly from the finding that the reflex was present for long periods under various anesthetic agents in this species[38,52] (Figure 13.1).

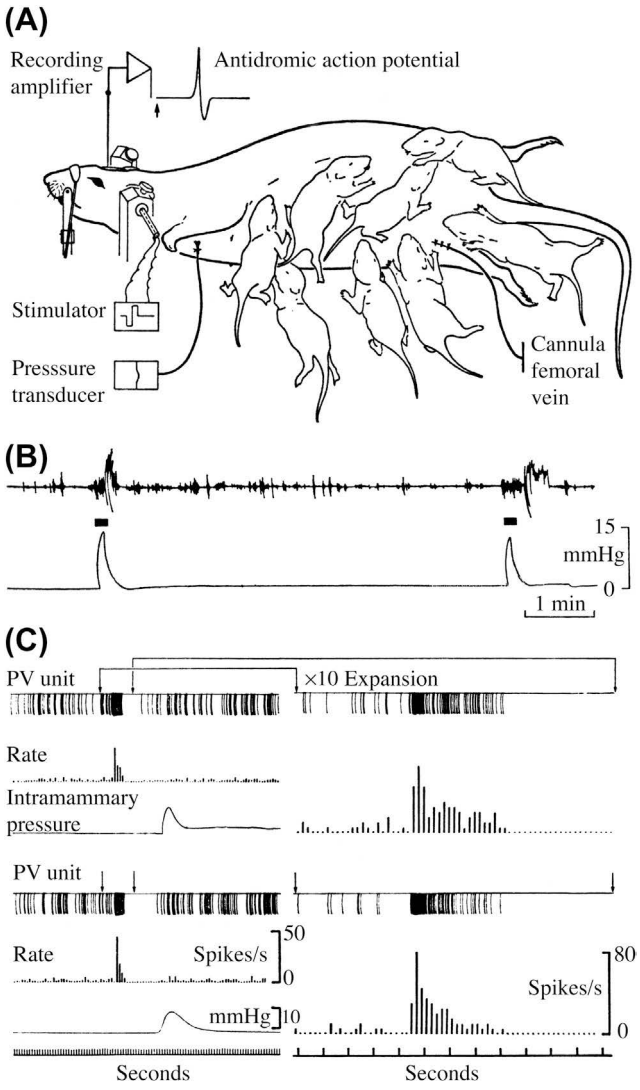

FIGURE 13.1 Features of the milk ejection reflex in anesthetized lactating rat. (A) Schematic showing simultaneous recording of antidromically identified action potentials in the PVN and intramammary pressure during suckling. The stimulating electrode was placed in the neurohypophysis transaurally through the hollow ear bar of the stereotaxic apparatus. The femoral vein is cannulated so oxytocin can be administered to calibrate the change in intramammary pressure. An antidromic spike is shown from stimulation (arrow) of neurohypophysis. *(Source: Redrawn from Ref. 57 with permission.)* (B) Activity record of pup movement (top trace) recorded simultaneously with intramammary pressure during suckling, showing two milk ejections. The pup's stretch response upon sensing the intramammary pressure increase is indicated by the bar, and is followed by even larger movements when detached pups search for a nipple, which often occurs after withdrawing milk. *(Source: Redrawn from Ref. 38 with permission.)* (C) Recordings from two antidromically identified PVN neurons during the milk ejection response. There are three traces for each unit. Arrows point to the burst of action potentials in the pen record (top trace) and the integrated rate (middle trace). Lower trace shows the intramammary pressure change signaling arrival of oxytocin at the gland. At the right for each neuron are expansion of the pen recording and rate meter. Note the: (1) abrupt onset and exponential decay of the spike discharge; (2) the peak frequency >50 Hz; (3) the period of after-inhibition; (4) the latency between burst discharge and milk ejection; and (5) the similarity in the response of the two neurons. *Source: Redrawn from Ref. 57 with permission.*

Even in mice, the milk ejection reflex has not been well described, and there are no apparent studies on the behavior of OT neurons during release. One exception is rabbits,[58–60] to be discussed below.

THE BEHAVIOR OF OT NEURONS DURING MILK EJECTION—THE RAT MODEL

The Milk Ejection Burst Established in PVN Neurons

The demonstration that neurosecretory neurons could be antidromically identified in vivo opened the gates for a flood of research utilizing this technique to study their activity during hormone release. Although nipple stimulation had been shown to alter neuronal activity in the region of the PVN in lactating cats, and to evoke release,[61,62] it was Wakerley and Lincoln[57] who first combined antidromic identification with a fully functioning and periodic milk ejection reflex, which they previously had demonstrated possible in anesthetized rats[38,52] (Figure 13.1). About 30 min after applying the pups to the dam milk ejections, as monitored by abrupt changes in intramammary pressure recorded from two cannulated teats, began to occur at regular intervals from 10 to 20 min. Coincident with the transient increase in intramammary pressure signaling milk ejection, the pups became more active and exhibited a stretch response, wherein they suckled vigorously with outstretched limbs and an arched back, as described in detail by Lincoln et al.[57] It is during this period that the pups withdrew milk—so vigorously that they often detached themselves and attempted to find another nipple. Within 30 s, this activity had subsided and the pups were again somnolent. The increase in intramammary pressure indicative of OT release was preceded by a burst of activity for 2–4 s in more than half the identified neurons (Figure 13.1). Peak firing rates in the burst (measured over 0.5 s intervals) ranged from 24 to 84 spikes/s and were characterized by a range of increase over background firing levels of 338–11,000%! The transient form of the increase in intramammary pressure was mimicked by a bolus injection of 1 milliunit (1/1000 international unit) of OT, and by electrical stimulation of the neurohypophysis (4 s, 40 Hz). The latency to the increase in intramammary pressure from IV injection was ~10 s, and that to electrical stimulation (~16 s) was similar to the average delay from milk ejection bursts (~18 s). Importantly, other nearby hypothalamic neurons appeared unrelated to the reflex, as did the remaining antidromically identified PVN neurons. In the latter category were several phasically bursting neurons previously speculated as possible OT neurons.[63] However, the phasic bursts of these neurons were not only temporally unrelated to milk ejections, they were much longer (10–30 s), had a faster periodicity (10–30 s) and were asynchronous. These neurons, classified initially as "non-milk ejection" neurons, were soon identified as VP secreting owing to their response to other stimuli.[64,65] Indeed, OT appears to be selectively released over VP during lactation in rabbits[4,66] and in rats.[67] The seminal result of Wakerley and Lincoln[57] was later achieved in awake, lactating rats with chronically implanted recording and stimulating electrodes,[68] and has been since verified in a number of studies.[65,69]

The association of antidromically identified PVN neurons and milk ejection has also been studied in awake and freely moving rabbits, apparently the only other species beside rats studied in this regard.[58–60] Although the nursing pattern is dramatically different in the two species—rabbits typically nurse once or twice a day, and for only a few minutes—putative OT neurons in the PVN burst just prior to the increased sucking of the young (mammary glands were not cannulated for obvious reasons, but the activity of the pups was monitored to record the reflex). These bursts are similar in duration to those in rat (1–4 s), but are more frequent: bursting 5–9 times during the short session (~5 min). Interestingly, the dams often groom their nipples following a nursing session, and this stimulation also slightly raised neuronal activity in the same neurons that burst during nursing, reaffirming the sensory transmission to the hypothalamus observed by others,[61,70] seen as well with direct mammary nerve stimulation.[71]

The SON Also Contains Milk Ejection Neurons

The initial electrophysiological studies during lactation focused first on the PVN, undoubtedly due to the lingering supposition that OT may derive largely from there, rather than the neuroendocrine counterpart, the SON. This supposition seems today based primarily on studies wherein large lesions of the PVN strongly reduced the oxytocic activity of the neural lobe, with little effect on antidiuretic activity.[72–74] However, while electrical stimulation of the PVN promoted OT release in goats[75] and rabbits,[32] the same stimulus also promoted antidiuresis.[75] And as noted by Lincoln and Wakerley,[76] oxytocic and antidiuretic activity had been found in extracts of both the PVN and SON, and lesions of either nucleus seemed to deplete both peptides from the neural lobe. Deafferentation of the PVN also failed to block milk ejection.[77]

Using the method described previously in rats, Lincoln and Wakerley[76] found milk ejection bursts in about half of the SON neurons, which were indistinguishable from those in the PVN; given its larger size, this suggested an importance of the SON equal if not greater than the PVN in importance for OT release. The localization

of both hormones in both nuclei in the rat was confirmed the following year with the seminal utilization of specific antibodies for VP and OT in immunohistochemical studies,[78–80] and has since been confirmed in many species, albeit with varying estimated proportions. Cell counts by Swaab et al.[78] and Rhodes et al.[81] each revealed that the SON contained more OT neurons than did the PVN, with Swaab et al.[78] reporting an average of 2019 ± 71 OT neurons in the SON compared to 842 ± 48 in the PVN, and Rhodes et al.[81] reporting 1440 SON OT neurons and 1174 PVN OT neurons. Whereas both authors found about the same numbers of VP as OT neurons in the PVN (~1000), the SON contained 1.5–2x as many VP as OT neurons. Thus numerically the SON is more important than the PVN for OT, but still even more important for VP. A final caveat for this quantitative consideration relates to the accessory neurosecretory nuclei, which can add >1000 more neurons to the system, and probably more OT than VP neurons.[81] This is certainly true of the anterior commissural nucleus, which is overwhelmingly OT containing (another 616 OT, but only 15 VP neurons reported in this nucleus[81]). Like other accessory nuclei, the anterior commissural nucleus also projects to the neural lobe.[82] It is unknown to what extent its neurons, separated from the main portion of the PVN by 300–400 μm, have been sampled in any of the electrophysiological studies of the PVN considered herein. Finally, while in this chapter the assumption will be made that both nuclei contribute OT during milk ejection in most mammals, this is based overwhelmingly on work in the rat.

Phasic-bursting "non-milk ejection" neurons (see previous discussion) were again recognized in the SON (76) and were, for the most part, not correlated with milk ejection. However, a few of these neurons did have an "on" phase correlated with milk ejection, something that would occasionally be observed in future studies by these and other investigators.[83] Still, these studies, coupled with immunocytochemical investigation, gave credence to the one hormone-one cell hypothesis. While we now understand the genetic capability of most magnocellular neurons to possess mRNA for both peptides,[84] there are only small amounts of peptide co-expression reported in unchallenged animals. Based on the selective OT release during lactation, however, co-secretion of VP during milk ejection in significant amounts seems unlikely, even during this upregulated state when co-expression may reach 15–20%.[85] Thus the importance of OT-VP expression remains largely undetermined.

Milk Ejection Bursts are Synchronous and Highly Periodic

Lincoln and Wakerley[76] not only confirmed the similar behavior of SON and PVN milk ejection neurons and the resulting probable numerical importance of the former over the PVN regarding OT release but they first reported, from one double recording and multiunit recordings, synchronous bursting in neighboring neurons. This synchrony was later confirmed from a larger number of double recordings between the two nuclei (and from between the right and left halves of the same nucleus) from separate electrodes[86,87] (Figure 13.2). Thus some 13–16 s following these 2- to 4-s bursts in both nuclei, a milk ejection response in the mammary gland can be recorded, the lag reflecting diffusion within the neural lobe to fenestrated capillaries and vascular circulation. Burst onset between paired recordings can vary from 0 to 680 ms, but the average lag time between cells is relatively short (~200 ms), and the lag-to-peak firing rate even shorter (~122 ms).[87] Although paired recordings revealed units that may even switch regarding which of the two neurons fired first, in the great majority of cases, whichever cell fired first did so at a higher frequency than the second cell in the pair (also see Ref. 86). This intimated some type of communication among OT neurons, something that had been suggested from this and earlier studies showing that central OT facilitated, whereas its antagonism suppressed, bursting activity.[88,89] The role of locally released OT will be discussed in detail below.

Several aspects of the pulsatile milk ejection reflex suggest a central gating mechanism. Lincoln and Wakerley[70] first examined this in detail by varying the number of pups whilst simultaneously recording the bursts and intramammary pressure. In the urethane-anesthetized rat, a threshold of ~5 pups was needed to generate the reflex. While increasing the number of pups increased the amplitude of bursts and the resulting intramammary pressure, it had little effect on periodicity. Even when milk ejection bursts were precipitated earlier than expected based on the ongoing periodicity by stimulating an individual gland, the

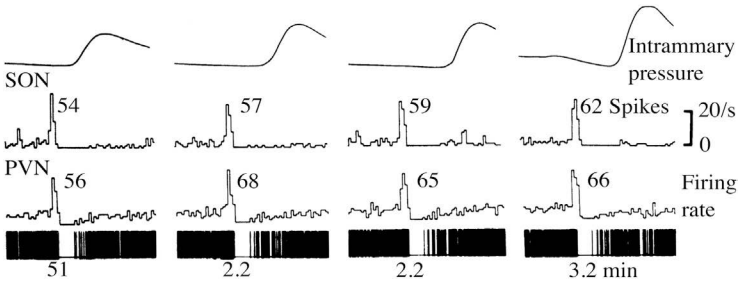

FIGURE 13.2 Simultaneous single unit recordings from SON and PVN neurons during suckling. Note the synchronization of bursts in the two units, each of which was recruited at the onset of milk ejections, 51 min after pups were applied. The time between bursts thereafter is noted beneath the spike record for the PVN neuron (bottom trace). Note also the progressive increase in burst amplitude (numbers of spikes in each burst) in both neurons, and the progressive increase in intramammary pressure. *Source: Redrawn from Ref. 87 with permission.*

session was reset and the prior periodicity was resumed. Thus afferent summation controlled a cell's response, and the amount of OT released per burst, but not necessarily the periodicity. In later experiments weak, but constant, electrical stimulation of nipples also resulted in periodic milk ejections.[90] Whereas transient stimulation of dorsal spinal cord sensory pathways can also elicit a single milk ejection, continuous stimulation of the cord was not accompanied by periodic release,[91] suggesting that gating occurs more rostral in the CNS. Wang et al.[92] found that increasing pup numbers also increased burst amplitude, especially pups contralateral to the recorded OT neuron. However, these authors also noted that rats suckled bilaterally had shorter interburst intervals, suggesting afferent summation may have some influence over periodicity.

THE AFFERENT PATHWAY MEDIATING MILK EJECTION

It should be stated at the outset that the precise sensory pathway from mammary gland to OT neurons underlying the milk ejection reflex is still unknown. There may even be multiple ways by which mammary sensory information could reach OT neurons. This subject may benefit from newer tracing methods allowing for more robust transynaptic transport from the nipple, but as of this writing this has not been done. Intense work in the past, summarized following, has relied heavily on deficits following lesions that varied in size and location, sometimes coupled with axonal tracing methods.

Spinal Cord and Brainstem

The innervation of the mammary gland is much denser than the adjacent skin and has been examined in many species, including human.[27] The nerve supply is from both smaller myelinated and unmyelinated axons and a small percentage of larger myelinated axons that largely terminate in free nerve endings and are most numerous in the tip of the nipple. These sometimes occur in bundles and may be associated with an enveloping Schwann cell. Electrical recordings from either the mammary nerve or spinal cord indicate a range of conduction velocities from <1 m/s–60 m/s, with the fastest myelinated fibers being very sensitive to both rapid cheek movements and the slower myelinated fibers to slower jaw movements associated with sucking.[93–95] Recordings from the dorsal spinal cord indicate the sensory fibers may adapt fairly rapidly.[95,96] The slowest, unmyelinated fibers appear to give rise to a late response to nipple stimulation or nerve stimulation, with a higher threshold. It is unknown to what extent different fiber types play in activating pathways essential for OT release, however, in nursing rats, unmyelinated fibers were larger diameter than in virgin animals.[94]

Within the spinal cord, lesion studies coupled with suckling tests in many different animals indicate a predominately ipsilateral pathway.[97–100] Application of the sensitive tracer, wheat germ agglutinin conjugated to horseradish peroxidase to the mammary nerve or nipple directly appears to give different results regarding the precise terminus in rats. Haller[93] reported abdominal (T11-12) mammary nerve projections primarily to Clarke's column (typically regarded as spinocerebellar) and to the lateral spinal nucleus, a source of spinothalamic, spinohypothalamic, and spinomesencephalic fibers.[101,102] Tasker et al.[103] reported segmental projections from nipples on one side directly to the dorsal horn, primarily superficially to the substantia gelatinosa but also to lamina II and deeper. Haller[93] reported a small amount of contralateral labeling in the cord, whereas Tasker et al.[103] found none. Although neither study reported labeling in the dorsal columns, Tasker et al.[103] did find some sparse labeling in dorsal column nuclei.

Lesion studies uniformly find that the dorsal column–medical lemniscal somatosensory pathway is not critical to the milk ejection reflex.[97–100,104] Even in sheep, in which lesions of the dorsal columns in the thoracic regions do impair the reflex, rostral cord lesions of the columns do not.[99] The afferent pathway appears to travel in the dorso- or ventrolateral funiculus[97,98,100,104,105] and could originate from the dorsal horn, as well from the lateral spinal and lateral cervical nuclei. The latter two nuclei may get direct dorsal root ganglion projections, but it is likely that most sensory projections are routed first through the dorsal horn.

Somatosensory projections from the spinal cord to the thalamus are probably not involved in the milk ejection reflex. Large lesions of the ventrobasal-ventral posterolateral thalamus had no effect on milk ejection in sheep[99] or rat.[104] Similarly, section of the compact portion of the medial lemniscus failed to block milk ejection.[99,106] These results should not be interpreted to mean that sensory information from the nipple does not reach the thalamus, or for that matter, pass through the dorsal columns at some point—only that the dorsal-column pathway is not critical for milk ejection. Indeed mammary afferents may reach dorsal column nuclei,[103] and nipple stimulation can evoke c-Fos expression (the protein resultant from the proto-oncogene c-*fos*, thought to indicate neuronal activation) activity in both the lateral and medial cuneate in sheep, in addition to the dorsal horn and lateral cervical nucleus.[107]

The target of the spinal cord neurons conveying suckling information necessary for milk ejection neurons is not well understood. What is agreed upon is that the information is transmitted largely contralaterally through the brainstem; the precise point of crossing is unknown. The pathway is largely discerned from lesion studies as hinted before. In contrast to ineffective

thalamic lesions, even relatively small bilateral lesions of the midbrain lateral tegmentum significantly slowed or blocked the reflex,[104–106] and unilateral lesions impaired the suckling stimulus from the contralateral side of the animal[106,108] (Figure 13.3). Stimulation of mesencephalic lateral tegmentum has been shown to facilitate OT release in guinea pig and rabbits,[109,110] and a study of lactating rats revealed that stimulating this region excited milk ejection neurons when in the presence of central OT.[111] Thus a contralateral sensory pathway conveys the suckling stimulus to the hypothalamus, which does not involve the thalamus and does not require cortical activity.[36] Spinal cord projections from the region of the lateral cervical nucleus and including the dorsal horn, as well as other spinal afferents from fibers of passage in the lateral funiculus, converge in the external inferior colliculus, the intercollicular zone, and the deep layers of the superior colliculus, near the region of effective blockade,[104,105] and these are all targets of somatosensory projections (e.g., Ref. 112) (Figure 13.4). Importantly, Hansen and Kohler[113] directly addressed the issue of fibers of passage versus cell group importance by injecting the neurotoxin ibotenic acid in the lateral midbrain tegmentum in approximately the same regions highlighted by the effective lesions. These more specific "cellular" lesions blocked milk ejections as measured by decreased pup weight during 2 h of nursing in these mothers (as well as sexual behavior in both male and female rats), whereas control injections in overlying structures had no effect. There was little difference between the effects of large (0.5 µl) versus small (0.2 µl) injections in the effective region. Repetition of these experiments while recording the periodic release of OT using mammary cannulation, and/or OT milk ejection bursts, could be most revealing.

Tracer injections into effective lesion sites in the midbrain tegmentum retrogradely labeled cuneate-gracile, dorsal horn, and lateral cervical neurons contralaterally, as well as many other brainstem regions, and also labeled sparse anterograde axonal projections to the lateral hypothalamus, zona incerta, and Fields of Forel, but failed to label the SON and PVN.[104] However, in sheep, injections into the PVN directly labeled the lateral cervical nucleus, which in turn received dorsal horn projections.[114]

Thus regardless of species differences, it appears that a contralateral spinomesencephalic pathway is involved in transferring suckling information to the SON and PVN, but the number of connections between the cord and these nuclei is unknown. There is even the possibility of a direct spinal pathway to the PVN in sheep and rat.[115] However, spinal projections that were followed to the hypothalamus clearly pass through mesencephalic lateral tegmentum near the effective lesion placements discussed before[115] and could make synapses there as well.

Although the midbrain lateral tegmentum appears critical for transmitting the contralateral suckling stimulus to the hypothalamus, the point of bilateral sensory integration, necessary to activate both sides of the hypothalamus, is unclear. The midbrain lateral tegmentum may have some bilateral hypothalamic projections.[116]

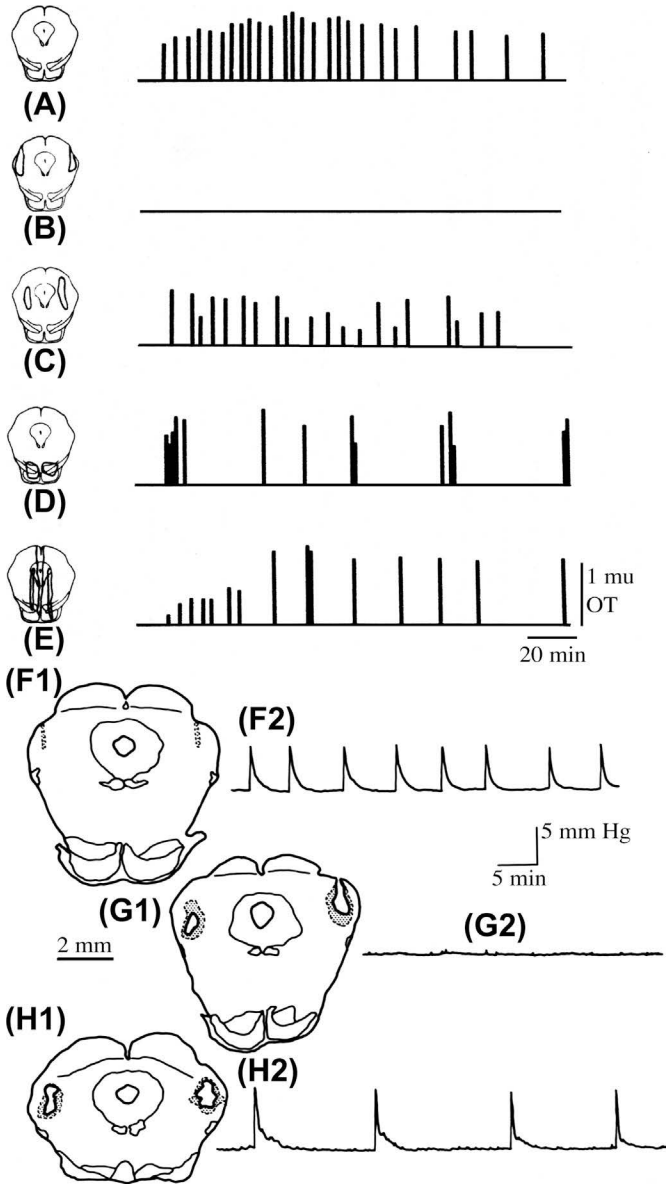

FIGURE 13.3 Lesions in the intercollicular zone of the midbrain lateral tegmentum block the milk ejection reflex. (A–E) Drawings from lesion sites (left) and associated patterns and amplitudes of intramammary pressure change (right) in four different experimental animals (B–E) and a control rat (A). *(Source: Redrawn from Juss and Wakerely Ref. 106 with permission.)* Note that some lesions produced changes in the reflex pattern, but only that in (B) blocked the reflex. (F–H) Results from a similar study by Dubois-Dauphin et al.[105] (F1) Small, ineffective bilateral lesions in the intercollicular zone. (F2) Tracings from intramammary pressure recordings during lactation show frequent milk ejections. (G1) Lesions in the intercollicular zone that completely blocked milk ejections (G2). Note the similarity in location to the lesions blocking milk ejections in the Juss and Wakerley[106] study shown in (B) above. (H1) Lesions involving the posterior aspect of the medial geniculate nucleus, just rostral to those shown in (G1), which failed to block milk ejections (H2). *Source: Modified from Ref. 105 with permission.*

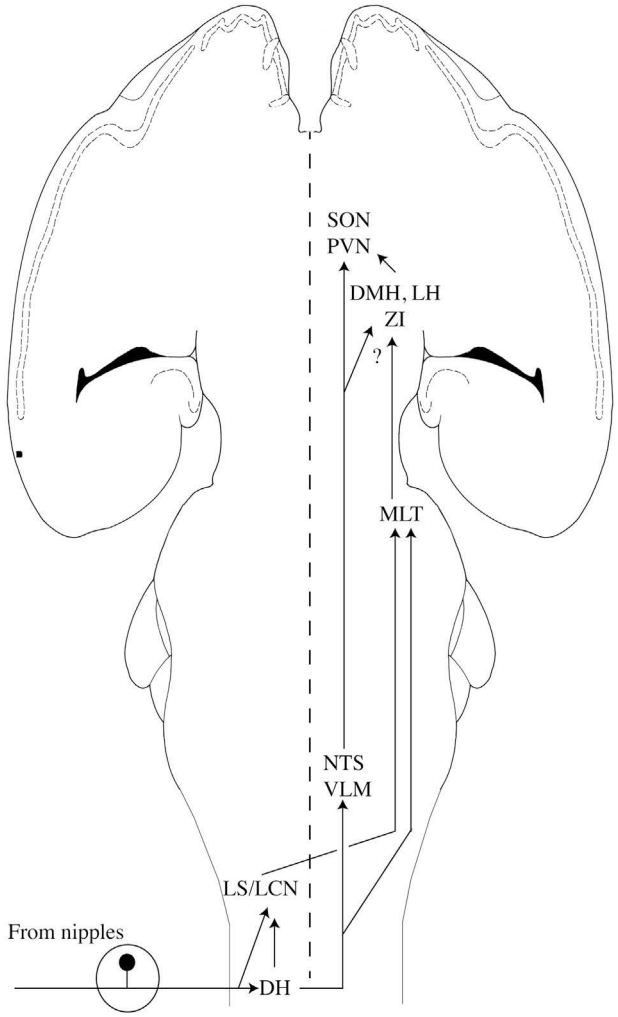

FIGURE 13.4 Schematic diagram illustrating some possible routes of suckling-associated sensory stimulation to the hypothalamus. Spinal (mammary) nerve inputs terminate in dorsal horn (DH), lateral spinal (LS), and lateral cervical (LCN) nuclei. The LS and LCN may also receive inputs ipsilaterally from DH. Axons from the LS, LCN, and DH project contralaterally to the midbrain lateral tegmentum (MLT), and to the nucleus of the solitary tract (NTS) and ventrolateral medulla (VLM). The NTS and VLM are known to project directly to magnocellular SON and PVN neurons, and may also project to nearby regions of the hypothalamus (perhaps through the MLT), such as the dorsomedial nucleus (DMH), lateral hypothalamus (LH), mammillary nuclei (MAM, not shown) and zona incerta (ZI). These areas may then project to OT neurons in SON and PVN, or perhaps immediately adjacent areas such as the PNZ of the SON or the parvocellular PVN (not shown). The MLT has no known direct projections to the SON and PVN, but projects to LH, ZI, and DMH. The MLT includes several areas, such as the intercollicular zone, the external nucleus of the inferior colliculus, and the paralemniscal nucleus, which could be damaged with the MLT lesions that block the milk ejection reflex (Figure 13.3). While pathways such as those from the NTS and VLM to the hypothalamus may have some bilateral components, they are primarily ipsilateral.

However, unilateral midbrain transections block afferent stimulation from the contralateral side but do not block the synchronized milk ejection activities of the SON bilaterally when pups are allowed to suckle ipsilateral to the lesion.[108] In intact rats allowed to suckle only on one side, sufficient to activate SON and PVN bilaterally, the milk ejection activity of the OT neurons in the contralateral SON was stronger than in the ipsilateral SON.[92] Thus while it's clear that a crossed pathway from the nipples to as far the midbrain is critical, what happens rostral to the midbrain is at this point unknown.

Some other brainstem areas receiving somatosensory input deserving exploration regarding the milk ejection reflex include the A2 noradrenergic cell group in the nucleus of the solitary tract (NTS) and the A1 group in ventrolateral medulla, both of which project directly to the SON and PVN (see Ref. 117,118 for review) (Figure 13.4). These projections are strongly ipsilateral with a weaker but present contralateral input—thus, if important to the reflex, it would be obvious that the relevant spinal inputs will have crossed by the lower medulla. These cell groups, and perhaps even the locus coeruleus (A6 cell group),[118,119] may be of particular importance given the suggested role of noradrenaline in mediating OT cell activation during the reflex. The NTS does receive somatosensory spinal cord afferents from the dorsal horn, and the pattern of dorsal horn labeling after NTS tracer injections is similar to that of spinomesencephalic projections.[120] The NTS-A2 projection may even favor OT neurons.[121–123] The NTS-A2 pathway may be important in mediating the specific OT release that occurs in rats with peripheral cholecystokinin (CCK) injection.[124,125] Synaptic adrenergic (or noradrenergic) profiles making contact with OT neurons have been observed.[126] Another NTS potential peptide transmitter, activin, favors innervation of OT regions and has been implicated in OT release.[127]

While it is unclear whether the CCK data suggesting a more viscerally related yet apparently specific involvement of the NTS in OT release is relevant to milk ejection, this area remains important for further study. A large number of NTS catecholaminergic neurons projecting to the PVN or SON expressed c-Fos following peripheral CCK injection,[125,128] and the noradrenergic transmission during CCK activation is critical for magnocellular activation.[125,129] Although noradrenaline is also released in the PVN during suckling and blocking adrenergic receptors within the nucleus suppress the OT release,[130] it is unknown which of the catecholaminergic cell groups are responsible for this release. Li et al.[131] found that suckling-induced c-Fos expression was prominent in the A1 and A6 cell groups but not in the NTS, whereas Moos et al.[132] reported activation of both A1 and A2 cell groups in the medulla and found numerous noradrenergic neurons could be labeled that projected to the SON. However, Moos et al.[132] further indicated that the only medullary cell group that projected bilaterally to the SON was a noncatecholaminergic group in the ventromedial region between A1 and the raphé obscurus. This region appears to have strong ipsilateral

projections and some contralateral hypothalamic connections, the latter of which cross within the optic chiasm to approach the SON. Although the evidence is strong that the noradrenergic innervation of the PVN (or SON) may be important for the milk ejection reflex (see below), it may not be these areas that provide afferents through the midbrain lateral tegmentum. Hansen and Kohler[113] found that injection of the catecholamine toxin 6-HODA into the midbrain lateral tegmentum had no effect on the amount of milk intake in a 2-h nursing test (see also previous discussion). However, these authors did not verify whether the A1 or A2 cell groups were depleted.

Caution should be exerted in interpreting c-Fos or other early intermediate gene products used to indicate neuronal activity. In the magnocellular system for example, electrical activation of PVN or SON neurons alone (with antidromic stimulation) is insufficient to increase c-Fos expression, whereas direct transmitter receptor activation does,[133] and stimuli involving synaptic activation such as suckling,[131] parturition, or osmotic stimulation (e.g., Ref. 134) or peripheral CCK administration[135] are effective in this regard. The absence of a c-Fos response may be an issue of sensitivity rather than lack of involvement. And while c-Fos may indicate a structure's eventual involvement after stimulation, the sequence of events is unknown due to its slow temporal response. Increased electrical activity may not be assumed, even if generally correlated with its expression.

With that caveat, suckling induces c-Fos expression in a number of other brainstem regions, including the parabrachial nucleus (which also projects to the PVN but not the SON), periaqueductal gray, and midbrain lateral tegmentum nucleus.[131,136] Although the precise location of midbrain neurons was not identified by Lin et al.,[136] the paralemniscal nucleus identified by Li et al.[131] is near, but more ventral to and more posterior to, the regions of the mesencephalic lateral tegmentum that effectively block or impair milk ejection when lesioned[105,106] (Figure 13.3). The most dorsal and anterior extent of paralemniscal nucleus, or its rostral projections, may have been damaged by lesions of the midbrain that disrupted milk ejection patterning but that failed to block the reflex.[106] Although most often associated with the auditory system, the paralemniscal region probably has diverse functions and even provides descending inputs to the spinal cord via the dorsolateral funiculus.[137] It is possible that midbrain tegmental lesions could interfere with the sensory gating apparent in producing the milk ejection reflex rather than simply blocking the afferent pathway. In this regard, the PVN is known to project to the spinal cord, including the dorsal horn, and some of these projections are OTergic.[138] Even a brief period of suckling increases OT release in the spinal cord, and OT-positive fibers are found in spinal lamina near c-Fos-activated neurons after the suckling bout.[139] This raises the possibility that central gating of afferent input could come from the PVN. In all likelihood, these OT axons would not be collaterals of neurohypophysial axons but probably a separate parvocellular system also involved in preautonomic innervation[82,140] or limbic system projections.[141]

Hypothalamic Circuitry

Some extrahypothalamic regions aside from those in the brainstem or spinal cord could be involved in the milk ejection reflex and will be considered next. Here it is pertinent to discuss whether other hypothalamic structures, aside from the PVN and SON, participate in and perhaps may even be necessary for the reflex. The structure for which the most evidence exists is the dorsomedial hypothalamic nucleus (DMH) (Figures 13.5 and 13.6). Although more often implicated in feeding behavior, the DMH is strongly activated by suckling as indicated by c-Fos expression[131,143] and by upregulation of neuropeptide Y (NPY).[144,145] This activation has supported the suggested involvement of the DMH in lactation-associated hyperphagia, consistent with its putative role in obesity.[143] The DMH is densely interconnected with many other hypothalamic nuclei, most notably

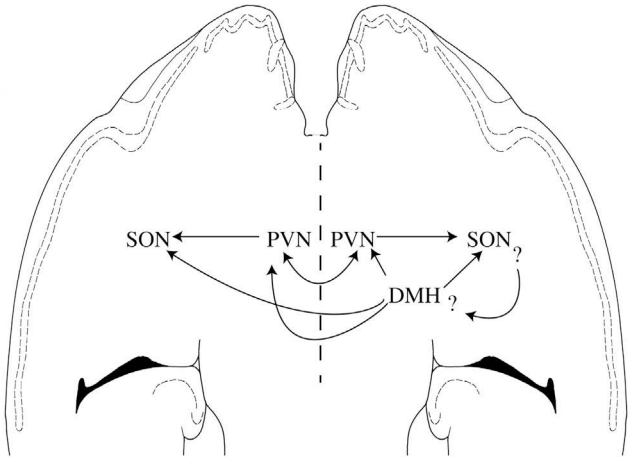

FIGURE 13.5 Schematic diagram illustrating two possible intrahypothalamic pathways that could contribute bilateral connectivity to OT neurons. The dorsomedial hypothalamic nucleus (DMH) is thought to project to both the SON and the PVN, bilaterally, is critical to the reflex, and receives brainstem inputs from regions also thought to be involved in the reflex (see Figure 13.4). The two PVN are thought to be connected, and the PVN may connect to the SON. The outputs from PVN to the SON are likely from parvocellular neurons, but this is not completely determined. The DMH is also thought to connect with other hypothalamic nuclei, such as the LH, that receive brainstem inputs (Figure 13.4). OT injections into the SON, or its electrical stimulation, are known to affect contralateral OT neurons. However, these effects may be due to stimulation of nearby neurons, which may then connect with a region such as the DMH that is known to project bilaterally. The vagueness of this SON intrahypothalamic connectivity is illustrated by question marks for source and target.

with the parvocellular regions of the PVN,[146–148] connections that dwarf the diverse yet sparser extrahypothalamic connections. Projections from the DMH to the SON have also been reported,[148,149] and although ipsilateral connections are strongest, the DMH also projects contralaterally to the SON with fibers passing beneath the third ventricle, and to the PVN, using fibers dorsal to the ventricle.[148] It is noteworthy that the DMH receives ascending projections from the brainstem, in particular the A1-A2 catecholaminergic regions that travel in the midbrain lateral tegmentum,[148] and also directly from the spinal cord.[115] A significant number of the PVN afferents from the DMH are glutamatergic, and an even larger number come from the nearby lateral hypothalamus,[150] which is the recipient of some suckling afferents (see previous discussion).

The suckling-induced increased c-Fos expression in the DMH may be directly related to a change in the activity of DMH neurons observed during the milk ejection reflex. Takano et al.[151] recorded hypothalamic neurons near the PVN during the reflex, all of which could be antidromically identified from ipsilateral SON stimulation but did not project to the neurohypophysis. About a third of these neurons recorded during the milk ejection reflex exhibited a bursting pattern similar to OT neurons, and some of these were in the DMH, as further documented by Honda and Higuchi[142] (Figure 13.6). Electrical stimulation of the DMH facilitates OT neuronal activity in the SON.[152,153] Even though the antidromic DMH projections to the region of the SON are more strongly ipsilateral,[142] DMH stimulation can activate the SON bilaterally.[152] Unilateral electrolytic lesions of the DMH completely block suckling to contralateral (but not ipsilateral) suckling.[154] However, the importance of the DMH per se is still clouded by the possibility that fibers of passage are responsible for both orthodromic and antidromic responses to SON stimulation, as well as lesion effects. Furthermore, when targeting the DMH specifically, Honda and Higuchi[142] reported that although a few DMH neurons showed bursting activity during milk ejections, the overwhelming majority did not. Finally, the DMH is just one of many other areas immediately surrounding the PVN that produce excitatory and inhibitory inputs to magnocellular (and parvocellular) neurons when stimulated with locally applied glutamate.[155,156]

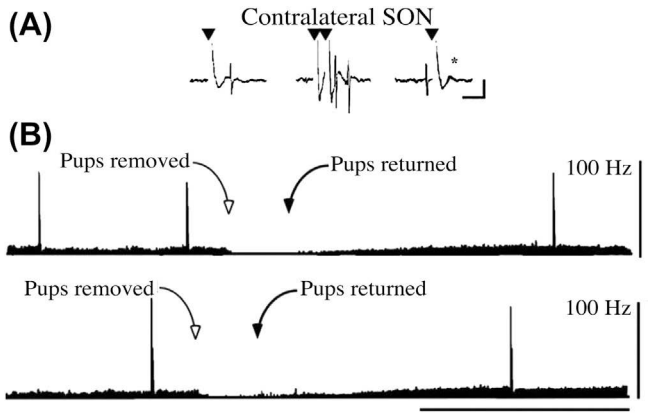

FIGURE 13.6 A dorsomedial hypothalamic neuron projecting to the contralateral SON and exhibiting bursts prior to milk ejections. (A) Oscilloscope traces showing the antidromic response criteria of constant latency (left), high frequency following (middle), and collision with orthodromic spike (right) following SON stimulation (arrowheads). * Indicates expected location of antidromic spike following collision with orthodromic spike from the dorsomedial nucleus. Scale, 1 mV, 1 s. (B) Bursts (large vertical deflections on ratemeter), and their dependence on pups suckling (arrows). Horizontal scale, 10 min. *Source: Redrawn from Ref. 142 with permission.*

An additional hypothalamic area proffered to mediate activation of the SON and PVN during suckling is an area just dorsomedial to the optic chiasm. Neurons in this region project both to the SON and PVN.[157] However, these projections appear largely ipsilateral, and there is no other indication of their importance to milk ejection. This region is near what is commonly referred to as the SON perinuclear zone (PNZ), which also has documented projections to the SON (see Refs. 117,158 for review). In addition, while potentially projecting to both nuclei, the lack of contralateral projections from this region still leaves the question of how the four nuclei communicate. The afferent intrahypothalamic connections of the PVN and SON have been difficult to document due to the nuclei's small size—nevertheless, hypothalamic connections with the PVN, including the lateral hypothalamus, which does receive projections from the midbrain lateral tegmentum, are thought to be extensive,[147,159] whereas afferent connections to the SON are sparse but do include the DMH projecting to OT-rich parts of the nucleus.[147]

Regardless, interhypothalamic communication is critical for full expression of bursting.[132,160,161] For example, hypothalamic midline knife cuts prevent most OT neurons on the side ipsilateral to the nursing pups from expressing milk ejection bursts, whereas bilateral suckling, or placing pups on the contralateral side to nurse, produces relatively normal bursting, although burst amplitudes are reduced.[161] Moos et al.[132] however, found that lactating rats suckling bilaterally, but with extensive hypothalamic hemisection, failed to show OT burst synchronization, and the bursting that was observed was dramatically reduced in amplitude compared to controls. Partial cuts allowed some synchronous bursting but with reduced burst amplitudes, similar to the results of Wang et al.[161]

Recently, the mammillary region of the hypothalamus has been suggested to mediate the burst synchronization.[162] The tuberomammillary nucleus and related nuclei have been shown to project bilaterally to the SON[163]—these are largely histaminergic neurons. Lesions involving the mammillary complex (tuberomammillary and supramammillary nuclei, mammillary body) produced

gross desynchronization of pair-recorded OT-bursting neurons during lactation, as did caudal hypothalamic hemisection.[162] Rostral hemisections similar to those performed by Moos et al.[132] produced some impairment of paired bursting. Since the mammillary lesions produced electrolytic damage that would destroy fibers of passage, it's not certain whether damage to these nuclei per se, or an ascending tract, is responsible for this effect. In addition, the extent of damage is difficult to assess from schematic, rather than histological, representation, but there was no reported damage to the DMH or the arcuate nucleus. The effects of these more discrete lesions suggest that a more compact region and/or pathway in the ventromedial hypothalamus (VMH) is critical to bilateral distribution of suckling information.

Another area of potential interest is the arcuate nucleus, which projects to the PVN and SON using peptide transmitters typically thought involved with feeding such as pro-opiomelanocortins and neuropeptide Y (NPY), or agouti-related protein (AGRP) (see Ref. 164 for review), and the innervation of which favors OT neurons.[165] Stimulation of the arcuate nucleus produces biphasic inhibition-excitation of OT neurons,[166] some of which is probably due to co-localization of arcuate neurons with glutamate or gamma amino butyric acid (GABA). Photostimulation of arcuate AGRP axons in the PVN strongly inhibits OT neurons through release of GABA, but it is unknown whether magnocellular and parvocellular OT neurons are both affected—the presumption is that parvocellular neurons projecting extrahypothalamically are the primary target as these neurons are involved in the suppression of feeding.[167] Arcuate dopaminergic neurons (which project axons to the external layer of median eminence) are clearly sensitive to suckling when they are profoundly inhibited and release dopamine's tonic inhibition of prolactin in the adenohypophysis (Ref. 168; also see Chapter 12). However there are no data, positive or negative, to suggest whether the arcuate nucleus is critical for the milk ejection reflex.

Perhaps the densest hypothalamic input to the SON and PVN comes from the region of the organum vasculosum of the lamina terminalis and the median preoptic nucleus (see Ref. 158 for review). While this region seems critical to osmoregulatory and cardiovascular duties of the PVN and SON and provides them both excitatory and inhibitory inputs, extensive lesions in this region to do not impair the milk ejection reflex,[169] compatible with the results of rostral hypothalamic deafferentation discussed earlier.[162]

Interconnections of the PVN and SON

It has often been speculated that the SON and PVN interconnect, either ipsilaterally or between the nucleus on one side and its contralateral counterpart. While there is evidence for polysynaptic communication, especially for OT neurons, direct connections have been difficult to document. Early retrograde tracing experiments reported ipsilateral projections from the SON to the PVN, and between the two PVN,[118,170] but no such interconnections were reported for the two SON.[119,149] Tribollet et al.[118] also reported projections from some accessory neurosecretory nuclei to the PVN, such as the anterior commissural nucleus (which contains a great majority of OT neurons). In later studies, smaller injections of retrograde tracers into the PVN failed to label the SON, and vice versa.[147]

Electrical stimulation of the SON on one side excites neurons in the contralateral SON[171] or produces both inhibitory and excitatory responses in the ipsilateral PVN,[172] but these appear to be through polysynaptic connections and may not involve magnocellular neurons but possibly those in the PNZ or dorsal chiasmatic area near the SON. Dyball and Leng[173] found synaptic responses from neurons near the SON following neurohypophysial stimulation, but their activity was generally unrelated to milk ejections. Interestingly, Takano et al.[171] reported that most contralateral OT neurons recorded in the SON were excited by SON stimulation, whereas a much smaller number of VP neurons were affected, and of these an equal number were inhibited. Some collaterals of magnocellular axons have been observed near the PVN,[174] in the PNZ of the SON,[175] and for OT neurons, at least, in the dorsolateral hypothalamus,[176] but the origin is unknown. OT-positive synapses were reported in the SON by Theodosis[177]—these might likely be intrahypothalamic, as such synapses are present in hypothalamic organotypic explants,[178] but again, the origin is undetermined. Morphologically, processes immunoreactive for neurophysin can be observed crossing the midline from one PVN to the other.[158] While these have the appearance of dendrites, this is not confirmed. In hypothalamic slices, a small number of PVN neurons can be excited by local glutamate or noradrenaline application to the contralateral PVN, or to the ipsilateral caudal SON.[179] The precise origin of these projections from either nucleus is unknown, and they could derive from parvocellular PVN neurons or PNZ neurons near the SON. In this regard, Thellier et al.[157] reported that parvocellular PVN neurons projected to the ipsilateral SON and to the contralateral PVN. Application of OT to one SON or PVN also potentiates OT neuronal activity in their contralateral counterparts during lactation[160,180] (also oxytocin below), and as mentioned earlier, electrical stimulation of the SON affects the contralateral SON. With the paucity of anatomical data showing magnocellular SON projections outside the neurohypophysis, it seems likely that the PNZ or dorsal chiasmatic areas may provide important connections, perhaps through a nucleus known to have bilateral projections and to affect OT neurons, such as the DMH (Figure 13.5). And while there is good evidence for some type of PVN to PVN

connections, the PVN per se appears to not be essential for synchronized bursting in the SON, since lactating rats with large PVN lesions still show milk ejection bursts in the SON,[181] albeit with a slower frequency and smaller amplitude. In addition, intracerebroventricular (ICV) OT was still able to facilitate the reflex with these PVN lesions. OT's role in the reflex will be considered in more detail later. Some possible connections underlying bilateral communication between the SON and PVN are summarized in Figure 13.5.

Using a modern, molecular biological approach involving adenovirus transfection of OT neurons, OT-specific pathways from the PVN to the amygdala have been demonstrated.[141] This approach has powerful ramifications for physiological experiments as well, since transfecting a gene expressing the light-sensitive channel rhodopsin was tied to the OT promoter and used to specifically release OT within the amygdala. A similar approach will undoubtedly prove useful for determining interconnectivity of the SON and PVN and their accessory neurosecretory nuclei.

Forebrain Regions Modulating Milk Ejection Activity

While forebrain regions may modulate milk ejection frequency and amplitude, they are not likely critical for generating the reflex. For example, the septum projects both to the PVN (primarily parvocellular) and to the PNZ of the SON,[147,149,182,183] but its destruction does not influence the milk ejection reflex, even though its stimulation can inhibit OT neurons and delay milk ejection bursts.[184]

The bed nucleus of stria terminalis (BNST) is a complicated area with multiple subdivisions, most of which project particularly strongly to anterior, parvocellular regions of the PVN,[185,186] many of which do contain extrahypothalamically projecting OT (and VP) neurons. The anteromedial BNST projects to PVN regions containing magnocellular OT neurons.[187] While many divisions project to the PNZ of the SON, the anteromedial division appears to have direct, if somewhat sparse, connections to the SON.

Large lesions encompassing the septum and BNST do not block the milk ejection reflex,[184,188] consistent with data showing the rostral separation of the hypothalamus from the forebrain with extensive knife cuts also fails to block the OT neuronal burst synchronization.[162] However, stimulation of the BNST either electrically or with OT injection facilitates the reflex,[188] and this region contains a high density of OT receptors that increase postpartum.[189] BNST lesions do impair, but do not block, the ability of ICV OT to facilitate the reflex (see the following on OT's role in milk ejection), and antagonism of OT receptors within the BNST slows burst frequency.[188] Some OT-positive fibers have been traced into the BNST and OT excites some BNST neurons, especially those stimulated orthodromically by PVN stimulation.[190] Interesting, none of the antidromically activated BNST neurons from PVN stimulation were affected by OT. Some BNST neurons subtly change their level of activity during milk ejection, but there are not strictly timed correlations with OT neuron bursting as has been observed in some DMH neurons.[191] Thus the BNST remains a site of interest as a target for central OT actions facilitating the reflex, but it would appear the output of the OT-excited BNST neurons is probably polysynaptic to OT milk ejection neurons, and the overall importance of this structure to the reflex per se is unclear.

The olfactory bulb has projections to the hypothalamus,[192,193] clearly plays a role in maternal behavior,[194] and shows c-Fos activation at parturition.[195] It has been speculated that mitral cells directly innervate neurosecretory neurons in the SON. While retrograde tracing studies from the SON suggest a bulb and an accessory bulb projection to at least near the SON,[195,196] the evidence for direct synaptic innervation of the SON from the bulb is partial. In slices, stimulation of the cut lateral olfactory tract elicited monosynaptic, glutamatergic excitatory postsynaptic potentials (EPSPs) in SON neurons,[197] but current spread and fibers of passage remain an issue with that result. Anterograde tracing studies indicate that the olfactory bulb and accessory bulb send projections to the ventral and lateral dendritic zone of the SON, which extends toward the periamygdaloid cortex.[196,198] A recent study using transynaptic tracing suggests bulb projections might be specific to VP neurons in both the SON and PVN.[193] To date, electron microscopically verified synapses between bulb efferents and magnocellular neurons have not been documented. Nevertheless, inducting maternal behavior in nulliparous female rats by housing pups nearby is sufficient to induce some of the morphological changes associated with plasticity of the OT system during pregnancy and lactation.[199]

There are other important inputs to the SON and PVN, both from more rostral and more caudal areas, but to date none has been strongly implicated in the milk ejection bursting of OT neurons. Some of these inputs are very dense, such as those from preoptic area (median preoptic and organum vasculosum of the lamina terminalis) and subfornical organ, but appear to relate to the role of both OT and VP in cardiovascular homeostasis. Other brainstem inputs of possible importance are the lateral parabrachial nucleus (projection primarily to the PVN) and serotonergic inputs from the raphé system.[158] There is evidence for some involvement of serotonin in OT bursting, to be reviewed in the following discussion.

Summary of Afferent Pathway

Although the precise sensory pathway from nipple to OT neuron is still unknown, there is agreement that the sensory pathway is largely contralateral, probably

crossing in the lower brainstem or upper spinal cord, that it passes in the lateral columns but not the dorsal columns of the spinal cord, that a synapse in dorsal horn, lateral spinal nucleus, or lateral cervical nucleus is likely, and that processing through conventional sensory centers, such as sensory thalamus and cortex, is unnecessary (Figure 13.4). Indeed, cortical activation in rodents inhibits the reflex. Within the brainstem, it appears likely that the NTS and ventrolateral and ventromedial medulla are involved, but it is unclear whether these nuclei directly transmit suckling information to OT neurons, even though they can make direct projections with them. Once crossed, the pathway in pons is unknown, but in the midbrain there is large agreement that afferents utilize the midbrain lateral tegmentum either as a passageway for fibers or make synapses there. This region is multisensory, does have neurons projecting to hypothalamus (perhaps even directly to the PVN), some of which are activated by suckling. Furthermore, lesions sparing axons of passage in this area do impair OT release. Nevertheless the possibility of many relevant sensory pathways simply passing through this area must be entertained. Although some medullary brainstem neurons project bilaterally and have been suggested to mediate bilateral transmission of nursing, they are typically more strongly ipsilateral, and unilateral lesions in posterior hypothalamus or midbrain lateral tegmentum block OT release and OT neuron bursting from contralateral suckling.

There is little agreement about how, once past the midbrain, sensory afferents eventually transmit bilaterally to OT neurons within the hypothalamus. Bilateral hypothalamic connections are critical to burst synchronization, but from which nuclei? The DMH exhibits some electrical activity correlated with milk ejection bursts, has bilateral projections to both the SON and PVN, impairs the reflex when destroyed, and has many neurons expressing c-Fos during suckling (Figures 13.5 and 13.6). It remains to be seen whether DMH axons directly innervate OT neurons, but this seems a possibility. The intrahypothalamic pathways are likely to be somewhat diffuse (typically large hemisections are required to disrupt the reflex), probably involving both supra- and subventricular crossings, and may involve more than one nucleus. In addition to the DMH, the medial dorsal chiasmatic area, the lateral hypothalamus, and the PVN are likely candidates for making such a distribution, but to date these connections are thought to be largely ipsilateral.

NEUROTRANSMITTERS/ NEUROMODULATORS MEDIATING THE MILK EJECTION REFLEX

Rather than explore in detail all transmitters or neuromodulators known to affect OT or VP neurons, the following discussion will focus on those thought to modulate the milk ejection reflex, especially at the OT neuron itself. The strongest evidence exists for glutamate and noradrenaline for transmitting information to the hypothalamus, and to OT itself for its role in facilitating and coordinating the reflex. These three have been implicated as necessary for the reflex, whereas many other transmitters can clearly modulate the amplitude or frequency of OT bursting.

Glutamate

As in most regions of the CNS, glutamate is a ubiquitous excitatory neurotransmitter in the hypothalamus, including neuroendocrine nuclei.[200] There is abundant evidence that both OT and VP neurons are heavily endowed with various glutamate receptors, most of which are excitatory, and which have been implicated in a variety of physiological processes, including synaptic plasticity during lactation (see "Synaptic Plasticity During Lactation" below). Glutamate receptors further mediate the EPSPs that can be recorded from OT neurons in vitro[201] and which are modulated during lactation.[202,203] However, the best evidence that glutamate is involved in transferring the suckling stimulus rests primarily on the results of the use of antagonists during lactation, and the data are surprisingly sparse. Injection of AMPA glutamate receptor antagonists into the third ventricle blocked suckling-induced OT release.[204] However, the range of diffusion of the antagonist is undetermined, thus it is possible the synaptic blockade was not at the OT neuron, and as indicated before, glutamatergic synapses are ubiquitous. Even though identified OT neurons contain AMPA-mediated EPSPs[201] and AMPA evokes OT release from lactating rats when directly injected into the SON,[204] these data are just further evidence that OT neurons have glutamate receptors and receive glutamatergic synapses, not necessarily for specific involvement in the reflex at the OT neuron. Moos et al.[205] recorded milk ejection bursts from OT neurons and applied the NMDA receptor antagonist, AP-5, locally in the SON. NMDA antagonism reduced background firing and burst amplitude but did not block bursts or reduce their periodicity, consistent with other in vivo work showing the interfering with NMDA receptor activation attenuated suckling induced OT release.[206] Unfortunately, AMPA-antagonists were not tested by Moos et al.[205] NMDA-mediated EPSPs are present on OT neurons[201] and may be involved in the synaptic plasticity occurring during lactation (Ref. 207, also see "Synaptic Plasticity During Lactation" below). According to Parker and Crowley,[206] there is a synergism between NMDA and AMPA-receptor activation controlling OT release.

A second line of evidence comes from the only in vitro system wherein synchronous OT bursts reminiscent of those during milk ejection have been observed.[208] In

this preparation, hypothalamic slices were taken from pups of unidentified sex at 5–7 days of age and organ-cultured for 4–7 weeks. Pairs of neurons were recorded and later identified as OT or VP subtypes. Many pairs of OT, but not VP, neurons were found to synchronously burst in a manner similar to that observed in lactation (Figure 13.7). Bursts were found underlain by synchronous volleys of AMPA-receptor mediated, glutamatergic EPSPs. OT facilitated both bursting and synaptic activities (also see below). This result suggests the circuitry regulating milk ejection bursts is intrahypothalamic.

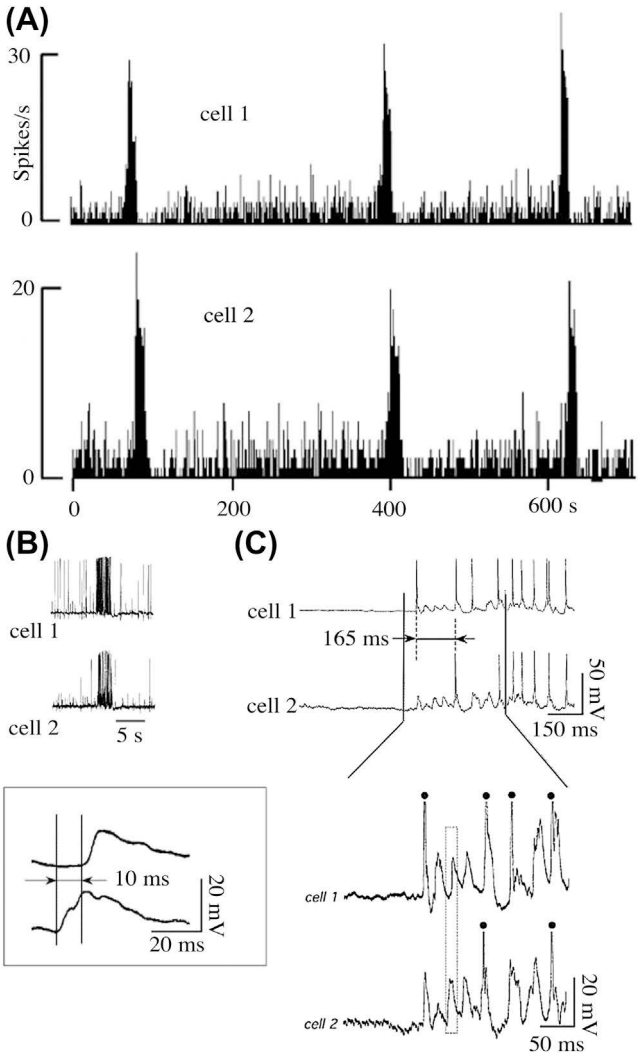

FIGURE 13.7 OT neurons with milk ejection-type bursts in organotypic cultures of hypothalamus, driven by glutamatergic EPSPs. (A) Two neurons exhibiting synchronous burst discharges characteristic of OT neurons in these cultures, similar to those occurring during lactation in vivo. (B) Another pair of neurons with simultaneous bursts. (C) The sweeps are expanded to show that the occurrence of the first action potentials in each is delayed by 165 ms. Below, the traces are further expanded to show the underlying synaptic activity driving the burst. EPSPs are highly synchronized, delayed by ~10 ms (see boxed inset). Dots show truncated action potentials. *Source: Redrawn from Ref. 208 with permission.*

While it should be noted that such cultures are known to make inappropriate connections, it is nevertheless astounding that a pattern like this should emerge. Since the sex of the donors is unknown, it is unlikely to involve steroid preconditioning or other sex-dependent electrophysiological and morphological changes known to occur with OT neurons during pregnancy and lactation (see "Synaptic Plasticity During Lactation" below). The clue to its relationship to milk ejection bursts in vivo may in fact be the massive amount of excitatory synaptic activity present in the organotypic slice. In adult hypothalamic slices, synchronous OT bursting has never been observed, even from lactating rats, although pharmacologically induced bursts of individual OT neurons has been reported, even in male rats.[209,210] However, tonic excitatory synaptic activity in hypothalamic slices is low, is largely from miniature EPSPs and is insufficient to alter OT firing patterns.[211] Perhaps increasing this excitatory activity in adult slices would be a means of further testing the role of glutamate in burst generation.

Where would the local glutamatergic inputs arise? It is useful to recall here that both the SON and PVN do receive excitatory connections from neighboring regions, such as the PNZ of the SON[156,212] and regions surrounding the PVN, including the DMH, VMH, and the lateral hypothalamus.[150,152,155,156] Indeed the number of hypothalamic regions suggested to provide glutamatergic inputs to the SON is large, and in addition to those mentioned earlier, includes mammillary structures, the PVN, and the suprachiasmatic nucleus.[212] Thus there would appear to be ample opportunity in the organotypic culture for local glutamatergic neurons to develop synapses with OT and VP neurons.

Noradrenaline

A case has long been made for noradrenaline as the principal transmitter mediating the milk ejection reflex.[213] As mentioned before, there is adequate evidence for noradrenergic synaptic input, primarily from the NTS (A2) and A1 regions of the medulla, to both nuclei, but NTS input favors OT neurons. Activation (c-Fos expression) of A1, A2, and A6 (locus coeruleus) neurons has been reported in response to suckling.[131,132] Similarly, there is abundant evidence of the presence of various adrenergic receptors on OT neurons.[117,213,214]

Suckling increases turnover of noradrenaline in the SON and PVN, and local destruction of catecholaminergic inputs blocks suckling-induced OT release.[215] Microdialysis studies indicate noradrenaline is released in the PVN in response to suckling, but such release was not detected in the SON.[130] Third ventricular administration of α_1-but not β-adrenergic receptor blockers likewise blocks the milk ejection reflex,[213] but local applications of adrenergic antagonists within the SON or PVN have

not been used to study the response of milk ejection bursts per se. Indeed, these investigations indicate that β-adrenergic receptors appear to tonically inhibit OT release. Local application of either class of antagonists blocks the intranuclear, suckling-induced OT release in the PVN,[130] and noradrenaline, as well as glutamate, may play critical roles in local OT release (see below).

Although noradrenaline appears to excite OT (and VP) neurons via α_1 receptors in vitro,[216,217] direct effects may be no more important than the simultaneous presynaptic excitation of glutamatergic inputs.[218] It is unknown whether direct connections between brainstem catecholamine and OT neurons actually mediate the milk ejection reflex. There are no data demonstrating the electrophysiological responses of brainstem catecholaminergic neurons to suckling, and no data demonstrating that a selective impairment of any one of these cell groups would block suckling-induced OT release—even though such an experiment could prove difficult due to the involvement of these nuclei in other important physiological functions, such as cardiovascular homeostasis. Finally, the milk ejection-like bursting response of the organotypic explant[208] is clearly not dependent on an intact noradrenergic system, even if this model system may be an aberrant representation of the physiological network. While catecholaminergic inputs to OT may be activated during suckling, their precise role in controlling the bursting activity is still debatable. It should be mentioned that other, non-catecholaminergic brainstem neurons project to the SON and PVN, including a group in the ventromedial medulla that have bilateral projections,[132] and the NTS has other neurons with peptides associated with OT activity, such as activin,[127] which has been implicated in suckling-induced OT release.

Noradrenaline, through α_1 receptors, has recently been found to produce milk ejection–type bursts in OT neurons in hypothalamus slices from lactating rats.[219] The significance of this action to OT neurons during lactation is unclear, however, since a similar phenomenon has been observed in male rats.[209,210] The bursts are thought to not be synchronously activated in this preparation, and the studies of Wang and Hatton[209,219] were performed in an abnormal slice medium (low in Ca^{++}), which itself promotes atypical bursting in these neurons.[220]

Oxytocin

Clearly the most exciting work on the mechanisms underlying the milk ejection bursting has come from the demonstration that central OT itself is an important player. ICV injections of OT were found to dose-dependently facilitate the reflex in two important ways[88,89] (Figure 13.8). Firstly, OT increased background firing, the burst amplitude in the PVN (increased number of spikes/burst), the intramammary pressure associated with release, and the frequency of the periodicity. Secondly, neurons that were not correlated with OT release initially could be recruited into the bursting pattern by OT. VP had no effect in this regard, and a later study showed ICV administration of an OT antagonist not only blocked OT's effect but also suppressed the ongoing reflex[89] (Figure 13.8). Freund-Mercier and Richard[89] further found that: (1) quantities of OT as low as 10 pg were effective; (2) injection into the third ventricle was more effective than the lateral ventricle; (3) the effects were dependent on pups suckling; (4) OT could instigate reflex onset in cases where it failed to show within the first hour of suckling; and (5) VP neurons were unaffected. The results of the OT antagonist suggested that the effect of ICV OT was probably not pharmacological, that OT released centrally during suckling was critical to reflex expression. These seminal findings have been repeated several times, are true for both SON and PVN OT neurons, and have led to vigorous research concerning the mechanism and location of action of OT, as well as its source.

Shortly following the seminal studies of Freund-Mercier and Richard,[88,89] it was discovered that OT was released in vitro from tissue containing either the SON or PVN,[221,222] and that OT agonists facilitated this local OT release.[221] Using push–pull cannulae, Moos et al.[223] demonstrated the release of OT in vivo from the SON during suckling, release that was facilitated by neurohypophysial stimulation mimicking OT bursts and by OT agonist injection (Figure 13.9). Intranuclear release of OT during parturition and suckling has since been repeated with finer microdialysis probes in both the SON and PVN, appears to result from release within or very near these nuclei,[130,224] and is first increased at low levels after pup application but *before* milk ejection bursts commence, when it increases further.[223] In addition, local retrodialysis of OT antagonists suppressed the local OT release and the milk ejection reflex.[225] Further evidence that the action of OT is likely within the PVN and SON was suggested by the effectiveness of small amounts of OT in facilitating bursts when injected directly into the SON or PVN, but not in adjacent regions of the SON.[160] Tellingly, these injections facilitated OT neuronal bursting in the *contralateral* nuclei as well, but only with an intact midline, suggesting the importance of hypothalamic intercommunication referred to earlier[160] (Figure 13.8). Complementarily, local injection of an OT antagonist into either the PVN or SON reduced bursts from all neurons tested within the injected nucleus, and the majority of neurons in the *contralateral* PVN or SON, and reduced the amount of OT released.[180] Thus information about OT release within either a single SON or PVN nuclei is somehow communicated ipsi- and contralaterally, but as mentioned previously, the precise connections are unknown. Electrical or osmotic stimulation

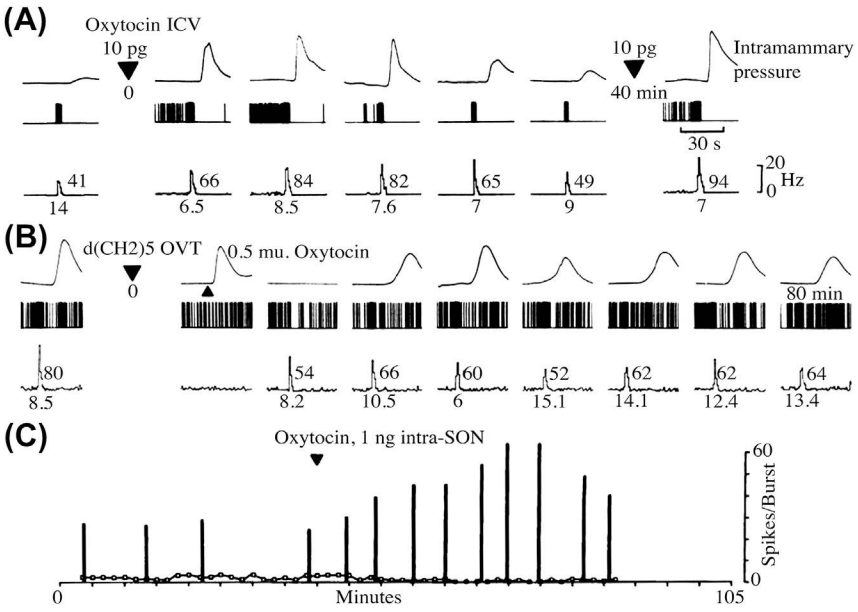

FIGURE 13.8 Oxytocin (OT) facilitates the milk ejection reflex. (A) OT delivered intracerebroventricularly (ICV) increased the burst amplitude and decreased interburst interval of an antidromically identified PVN neuron, and simultaneously increased the amount of OT released during each milk ejection. *Top traces*, intramammary pressure indicating OT release at each milk ejection; *middle traces*, pen recording of single unit activity of the PVN neuron; *bottom traces*, ratemeter histograms of firing rate. The number at the side of each burst represents its amplitude, or spikes/burst. The number below represents the number of minutes between bursts. (B) An OT antagonist, $d(CH_2)_5$ OVT injected ICV (downward arrowhead) blocked the next milk ejection burst in a PVN neuron and the milk ejection reflex. To ensure the mammary gland was responsive, OT was injected intravenously (upward arrowhead). The burst in this neuron returned 8.2 min later, but was reduced in amplitude and was not accompanied by the milk ejection reflex. The reflex returned 10.5 min later. *(Source: (A) and (B) Redrawn from Ref. 89 with permission.)* (C) OT injected directly into the SON facilitated burst of an OT neuron in the *contralateral* SON. Injections near the SON were ineffective (not shown). Note the increase in burst amplitude and the much faster interburst interval following the injection. *Source: Redrawn from Ref. 160 with permission.*

of the SON unilaterally, for example, has no such effect on OT bursts in the other nuclei, suggesting activation of an OT-sensitive circuit that probably does not involve direct PVN-SON connectivity of magnocellular OT neurons. Thus it is possible that neurons near magnocellular neurons, such as PNZ neurons in the SON, the DMH, or parvocellular PVN neurons, receive a suckling-specific OT signal from neurohypophysial projecting neurons, and communicate this among the nuclei.

To date, however, the source and particularly the target of the intranuclear OT-facilitating OT–milk ejection bursting are under debate. The current ongoing hypothesis concerning the source is that OT release is dendritic, from the same magnocellular neurons projecting to the neurohypophysis. This is a parsimonious conclusion and enjoys much evidence.[226] In addition to evidence for local OT release from the SON and PVN, and the effects of locally applied OT agonists and antagonists on milk ejection bursting, magnocellular dendrites have clusters of dense core vesicles (DCVs). Stimulation produces DCV exocytosis,[227] as well as calcium-dependent DCV mobilization and associated actin mobilization.[228,229] Some requisite molecules associated with vesicular release have been found in OT or VP dendrites, such as syntaxin-1 and munc-18.[229,230] Considering more conventional sites of release, axon collaterals of immunoreactive OT and VP axons have been reported near the SON,[175] but collaterals are not commonly observed from intracellularly filled SON neurons.[117] Collateral branching is, however, prevalent among PVN parvocellular neurons,[174] and it is possible that some of these could be OT containing. As previously mentioned, there is some evidence for OT-positive synaptic terminals in the SON,[177] but this is not commonly reported and their source is unknown.

Thus the current wisdom suggests that OT is released from dendrites at nonsynaptic locales during suckling. While diffusion within the third ventricle to remote sites of action is possible, the evidence favors more limited diffusion within the SON, PVN, or to nearby nuclei, for effects. Local OT release is not easily produced by antidromic stimulation, but a large release can be evoked after calcium mobilization with thapsigargin that is thought to prime (i.e., move toward the plasma membrane) the DCVs for release.[226] However, this result may be a question of detection sensitivity. Antidromic stimulation can evoke bursts in OT neurons,[173,231] again dependent on pups suckling, and in some labs, trains of antidromic spikes have been shown to release OT in the SON without priming.[223] The effects of antidromic facilitation on OT neurons are independent of invasion in the recorded neuron, as stimulation adjusted to collide with orthodromic action potentials from the OT neuron still

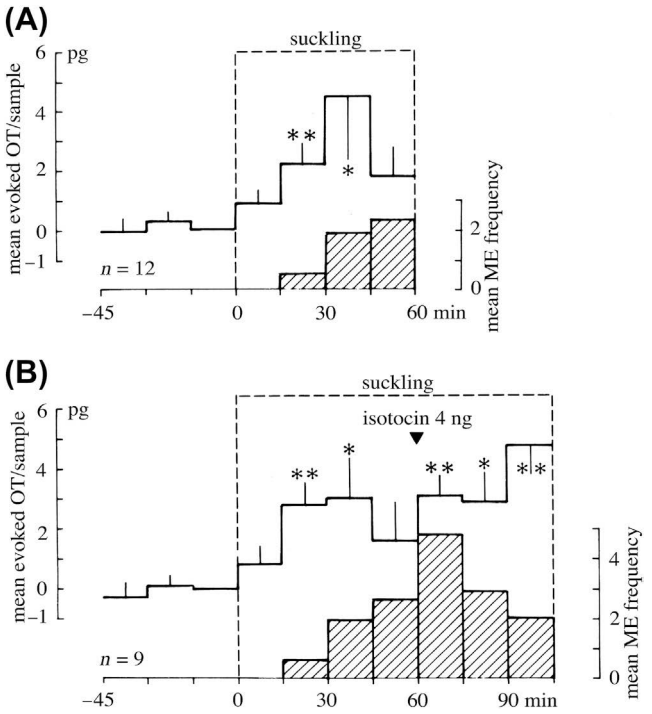

FIGURE 13.9 Evoked oxytocin (OT) release in the SON measured using a push–pull cannula in the nucleus during the milk ejection (ME) reflex. The mean number of ME events was calculated for each 15-min push–pull sampling session. (A) Mean increase in intranuclear release during the ME reflex. Note the increased release during suckling. (B) Mean increase during suckling and following facilitation of the reflex with the OT agonist isotocin delivered intraventricularly. *, $p<0.05$; **, $p<0.01$, Student's paired *t*-test. *N* = number of rats tested. *Source: Redrawn from Ref. 223 with permission.*

evokes bursting[231] (Figure 13.10). In putative but unidentified OT neurons, depolarization during whole cell recording by direct voltage steps[232] or by NMDA application increased somatodendritic exocytosis as measured with capacitance changes—the latter effect of which was upregulated from neurons taken from lactating rats.[233]

It should be noted here that there are multiple groups of OT neurons in the hypothalamus that project to the neural lobe,[158] including many accessory neurons such as the anterior commissural nucleus, implicated in the BNST-OT connection.[188] While the assumption based on their neurohypophysial projection would be the participation in most if not all aspects of the OT functions typically ascribed to SON and PVN neurons, there are no reported in vivo electrophysiological studies of these neurons during lactation, and the difficulties in observing c-Fos activation during lactation compared to parturition in large numbers of OT neurons, even in the SON and PVN,[134,136] make their participation in the reflex difficult to assess.

As for the target of OT's actions, OT neurons have been shown to possess the OT receptor (OTR) based on several lines of evidence, and this would be consistent with local effects, from local release. The increase in intracellular Ca^{++} evoked by OT or agonists in dissociated OT neurons is blocked with a specific OT antagonist.[234] OT applied to hypothalamic slices excited putative OT neurons in the SON, an effect that remained, albeit smaller, in low Ca^{++}-Hi Mg^{++} solution thought to block synaptic transmission.[235] Specific binding of radiolabeled OT antagonists has been observed in the SON during lactation[236] and late gestation.[237] OTR mRNA has been located in both the SON and PVN,[238–241] although there is disagreement as to whether OTR mRNA is upregulated in both the SON and PVN during gestation or at parturition.[239,241]

Despite the strength of the evidence that OT activates OT neurons to facilitate the reflex, aside from the study of Yamashita et al.,[235] there are few studies demonstrating OT's *direct* effects on membrane potential or membrane currents of OT neurons, unlike the extensive results obtained in extrahypothalamic targets possessing OT or VP receptors.[242] Better documented is the effect of OT on synaptic inputs to OT neurons. Originally described by Kombian et al.,[243] OT is thought to *suppress* glutamatergic synaptic inputs. The suspected targets of OT initially were presynaptic OTRs, but of late many of the presynaptic effects of OT on glutamatergic synaptic inputs have been attributed to OT's ability to release cannabinoids from OT neurons, presumably due to OT's ability to increase intracellular Ca^{++}.[244] Cannabinoids so released are then thought to act on CB_1 receptors presynaptic to OT neurons, again, to suppress EPSPs. However, there are no data concerning any differential effects of OT, or cannabinoids for that matter, on EPSPs impinging on OT neurons in lactating animals compared to control animals. Thus it is not clear what role OT's indirect means of suppressing glutamatergic synapses would play in lactation. There are studies showing that glutamatergic transmission may undergo plasticity during lactation, but results are not uniform (see below under "Synaptic Plasticity During Lactation").

Interestingly, ICV-administered OT does unveil excitatory effects on milk ejection burst that occur ~100 ms after stimulating the midbrain lateral tegmentum,[111] an effect observed only when pups are suckling. This effect was not observed when stimulating excitatory inputs from the medial septum, and was not observed with general excitation of OT neuronal background firing (with osmotic stimulation). This is consistent with antidromic stimulation's,[223] or OT's ability to enhance OT bursts and background firing *only* when pups are suckling, and not with generalized excitation.[89] The facilitation observed with midbrain tegmental stimulation followed the time course of the OT-induced bursting facilitation, and was greatest prior to an expected burst and lowest immediately after a burst. A similar phenomenon was observed when stimulating the DMH during

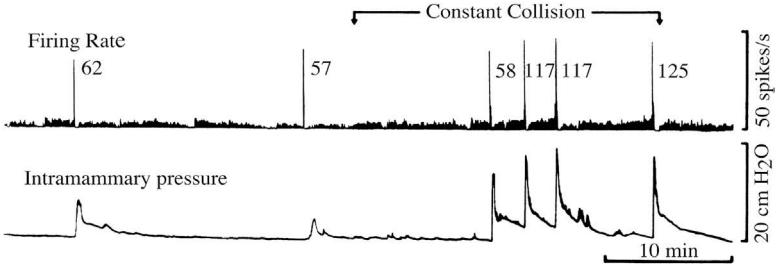

FIGURE 13.10 Antidromic activation of PVN neurons facilitates milk ejection bursts from OT neurons during suckling. *Top trace*, ratemeter from an antidromically identified PVN neuron showing milk ejection bursts before (two at left) and after neurohypophysial stimulation. *Bottom trace*, intramammary pressure indicating milk ejections. When the neurohypophysis was given a single shock after each orthodromic action potential, milk ejection bursts and OT release were facilitated even though the antidromic spike from the recorded neuron did not reach the PVN. Note the increased frequency of bursts and the increase in burst amplitude (spikes/burst) shown beside each burst. Thus the facilitation of the OT release during antidromic stimulation is not dependent on invasion of the recorded neuron but instead mostly likely derives from the back propagation of spikes in other magnocellular neurons. *Source: Redrawn from Ref. 231 with permission.*

lactation.[153] However, a long latency to this effect, similar to that of midbrain lateral tegmentum stimulation, was reported. Indeed, some short latency (~10 ms) excitatory responses to DMH stimulation were not potentiated by OT. Thus the location of OT's action is unknown in regard to both studies, and may not be at the OT neuron or even at presynaptic terminals directly on these neurons, but perhaps elsewhere in the afferent circuitry. Given the multiple locations of OTRs in the brain (see below), it is possible that other sites known to project to the SON or PVN could be involved in the effects of *exogenous* OT administration.

The results from in vitro experiments support a critical role for local OT in regulating the reflex, probably through glutamatergic inputs. In organotypic hypothalamic explants that show synchronous OT neuronal bursting with patterns similar to those observed in vivo during lactation, OT and its agonists facilitate this bursting both in amplitude and periodicity. OT antagonism blocks the effects of endogenous OT and suppresses spontaneous bursting, but primarily by increasing interburst intervals and not burst amplitude.[245] As discussed earlier, the OT bursting is underlain by glutamatergic EPSPs that are highly synchronized when driving bursts[208]—indeed, EPSP synchronization is significantly tighter than that of action potential onset (Figure 13.7). OT's actions on bursting are likewise dependent on glutamatergic synapses. However, in this preparation, OT has no obvious effect on EPSPs (even the presynaptic inhibition reported by others in slices), but instead is suggested to act presynaptically at GABAergic terminals at low concentrations.[246] This enhancement of IPSPs is thought to then contribute to rebound action potentials that are generated from low threshold (T-type) Ca^{++} currents and to the increased background firing of OT neurons that is also characteristic of OT's actions.

A change in background firing, expressed as an increase in rate and an increased irregularity, has been noticed in OT neurons in vivo prior to OT bursts,[247] as has an increase in coordinated activity.[248] This change may reflect an increase in synaptic activity or a change in its pattern from neurons presumptively driving the bursts, but there is no direct evidence of this. In the organotypic culture, basal firing also increases with OT application and also prior to bursts, but there has been no demonstration that GABAergic activity was necessary for OT bursting, or even for OT's ability to facilitate bursting. As for the presence of T-channels in OT neurons, this is inconsistently reported in the literature. An absence of low threshold currents was noted in the PVN magnocellular neurons by Luther and Tasker,[249] but they did find this current characteristic of one class of PVN parvocellular neuron, and this has been likewise observed in enkephalinergic neurons near the PVN.[250,251] In the rat SON, Foehring and Armstrong[252] found no evidence of low threshold Ca^{++} currents, but such currents were reported by Fisher and Bourque,[253] and in guinea pig SON VP, but not OT neurons, by Erickson et al.[254]

In hypothalamic slices, OT has been found to produce brief burst discharges in OT neurons[255] similar to those evoked by noradrenaline discussed earlier. Although these experiments were performed in slices from lactating rats, there was no comparison with virgin rats as to the efficacy of OT in this regard. Surprisingly, OT concentrations in the fM range were effective in this study, which is a couple of orders of magnitude below the reportedly low nM K_d of the historically well-characterized OT receptor.[256,257] The effects of OT involved progressive membrane depolarization and were blocked by AMPA-receptor antagonists, and like noradrenaline, did not promote burst synchronization. More recent studies suggest that OT's direct effect on OT neurons may involve actin mobilization,[258] which could relate to OT's ability to prime its own somatodendritic release.[226,259]

Given that (1) OT's action on the milk ejection neurons is greater for third ventricular compared to lateral

ventricular injections, (2) OTRs have been shown to be autoreceptors on OT neurons, and (3) the reflex is maintained when other important regions with OTRs, such as the BNST, are separated from the hypothalamus, it seems likely that central OT's role in milk ejection minimally requires some action in the magnocellular nuclei. However, in considering OT's central effects, it should be remembered that the OTR has been located in other regions in hypothalamus besides the SON and PVN, some with great density.[260] The densest distribution of OTR is in the VMH, which has no obvious tie to the milk ejection reflex, but the OTRs of which are sensitive to reproductive state and estrogen.[189,261,262] Additional regions of interest include the preoptic area and some members of the mammillary complex, the latter of which have been implicated in controlling the reflex.[162] Thus it is possible that exogenously administered OT may act in multiple regions to modulate the reflex. But if the prime source of released OT during milk ejection is dendritic, then diffusion to more remote regions becomes problematic due to the fast enzymatic degradation of released OT.[243]

Gamma Amino Butyric Acid

Like glutamate, GABA is a ubiquitous transmitter in the CNS, is likely responsible for at least one half of the synapses on magnocellular neurons,[263] and its effects (largely inhibitory) on magnocellular neurons have been well characterized.[117,214] The sources of GABAergic inputs to OT neurons could be intrahypothalamic, even near the SON or PVN, as well as some well-known extrinsic afferents such as the preoptic area, the BNST, the mammillary complex, the subfornical nucleus, and the organ vasculosum of the laminar terminalis.[158] GABAergic synapse numbers increase during lactation and are part of well-documented reproductive plasticity in this system (see Plasticity below).

Moos[264] and Voisin et al.[265] addressed the specific role of GABA in the milk ejection reflex in vivo. Moos[264] found that whereas local GABA or GABA agonist applications to the SON decreased baseline firing as expected, they actually *precipitated* OT milk ejection bursts, whereas the specific $GABA_A$ receptor antagonist GABAzine considerably delayed the occurrence of the next expected burst. In contrast, Voisin et al.[265] reported that both the $GABA_A$ receptor agonist muscimol and the $GABA_A$ antagonist bicuculline inhibited the reflex, whether injected ICV or into the SON. Aside from implying the importance of GABA activity to the reflex, it is difficult to interpret these two studies mechanistically.

Perhaps the role of GABA in the reflex rests on OT's actions on GABAergic synapses, which are largely inhibitory, either postsynaptically[266] or presynaptically.[232] These actions, accompanied by increased Ca^{++} somatodendritic release of OT during lactation,[232] are largely interpreted as OT's ability to retrogradely shape inputs, and permit the increased excitatory input needed for OT release at parturition and lactation.[267] However, OT's presynaptic inhibition of GABA-mediated IPSPs appears almost solely due to OT's action on the OT cell itself, releasing cannabinoids to reach presynaptic CB1 receptors on GABAergic terminals. High-frequency activation of these inputs results in powerful OT neuronal inhibition that is dependent on cannabinoid action.[268] Although not tested in lactating rats, this suggests that the powerful inputs driving each burst, probably from glutamatergic synapses, would release OT sufficient to shut down any competing GABAergic activity both pre- and postsynaptically. However, given the needed time for cannabinoid diffusion following its release for local OT action, it would seem that this inhibition might arrive late to facilitate any burst associated with massive local OT release, at least at burst onset. However, it is possible that OT release from glutamatergic inputs actually *precedes* burst onset, allowing some local OT the time to shape the burst.

Serotonin and Dopamine

Based on light microscopy, the serotonergic innervation from the median and dorsal raphé nuclei to the PVN and SON may favor OT neurons.[269] Iontophoretically applied serotonin (5-hydroxytryptamine, or 5HT) inhibits OT neurons during suckling-induced bursting,[270] and both $5HT_{1A}$[271] and $5HT_{1B}$ receptors[272] have been found in magnocellular neurons of the SON and PVN. Pharmacological data suggest a role of 5HT in modulating milk ejection bursts, but it is unlikely to be the primary neurotransmitter,[273] and there is no evidence to suggest that suckling affects raphé neurons. However in rats, the apparent necessity of sleep-like EEG to allow milk ejections suggests that pharmacological manipulations of 5HT levels could influence the reflex indirectly. The actions of 5HT agonists and antagonists on the reflex were opposite in anesthetized compared to conscious animals, although both expressed the milk ejection reflex.[273] Thus 5HT's role in the reflex remains undetermined.

There are dopaminergic inputs with identified synapses in both the SON and PVN, although the input to the PVN is much denser,[274,275] and a specific projection to OT neurons has not been identified. The source of the dopamine to the PVN is likely the medial zona incerta,[276] but also could derive from parvocellular PVN groups. Dopamine has direct depolarizing actions on SON neurons; mediation through both D_1 and D_2 type receptors has been suggested.[277,278] ICV injection of the dopamine agonist apomorphine facilitates OT milk ejection bursting, although not as powerfully or as immediately as does OT[279,280]—on the other hand, dopamine antagonists inhibited milk ejection bursts[279] and suckling induced OT release.[281]

In addition to its direct depolarizing effects on magnocellular neurons, dopamine also inhibits both IPSPs[282] and EPSPs[283] presynaptically in the SON, effects thought mediated by D_4 receptors. According to Balmoukhametova et al.,[284] OT neurons in normal animals show short-term facilitation of repetitively activated GABAergic synapses, but dopamine did not appear to impact this effect, in contrast to its ability to prevent short-term depression in VP neurons. While neither the synaptic nor the direct depolarizing effects of dopamine have been examined on OT neurons from lactating rats, it is of interest that the dopamine neurons of the medial zona incerta are extremely close to the PVN and adjacent structures thought to modulate bursting, such as the DMH. OT from PVN dendrites could diffuse to the zona incerta and thereby modulate dopaminergic inputs. Furthermore, medial hypothalamic lesions and knife cuts that are thought to affect milk ejection bursts may easily impinge on this region.

Histamine

Another transmitter that is released into the PVN and SON by suckling is histamine.[285] Direct injection of histamine into the PVN releases OT both peripherally and locally,[286] and histamine H_1 receptor antagonists suppress suckling-induced OT release.[287] However, the data are not so clear regarding mechanisms. Oddly, both H_1 and H_2 receptor antagonists blocked the histamine-induced intranuclear release,[285] and the excitatory effect of histamine on both local and peripheral OT was in addition blocked by an α_1 noradrenergic receptor antagonist.[286] Although histamine has direct excitatory effects on VP neurons through H_1 receptors,[288,289] Yang and Hatton[290] found evidence for direct inhibitory actions of histamine on OT neurons that were mediated by H_2-type receptors, carried by monosynaptic inputs from the tuberomammillary nucleus, and histamine has been shown to induce dye coupling in OT neurons.[291] Since CNS histamine is made solely in the tuberomammillary and adjacent tuberal nuclei in the hypothalamus, the recent results from Wang et al.[162] showing that small lesions in this region block suckling-induced OT release may yet herald an important role for this region, and should be repeated with neurotoxic destruction of this region to avoid issues of fibers of passage.

Other Neurotransmitters/Neuromodulators

There is a wide variety of other peptides, neuromodulators, and hormones that might not be critical for, but nevertheless do influence, the milk ejection reflex based on their known actions in the SON and PVN, and these are reviewed elsewhere.[117,210,213,214,292,293] Among these, the steroids estrogen and progesterone, as well as the neurosteroid allopregnanolone, will be dealt with in the section Synaptic Plasticity During Lactation. The normally inhibitory actions of local nitric oxide on OT release appear to be greatly reduced at parturition, suggesting, like that of GABAergic control,[267] a release from inhibition when OT demand is acutely high.[210] While the role of this gaseous transmitter has not been studied specifically within the SON or PVN during the reflex, recent studies show it behaves as a retrograde messenger in these nuclei, capable of facilitating GABAergic inputs to magnocellular neurons.[294–296]

An intriguing peptide of interest is α melanocyte-stimulating hormone (MSH), which is synthesized in the arcuate nucleus, which has well-documented connections to the PVN and suggested projections to the SON. Locally applied α-MSH was found to selectively inhibit the electrical activity of OT (not VP) neurons in female rats in the SON even while promoting an increase in c-Fos expression, an increase in local OT release, and an increase in intracellular Ca^{++}, probably from internal stores.[297] This study shows the difficulty in interpreting results from increased c-Fos expression as excitatory, showing a clear separation of function of somatodendritic depolarization from electrical activity. The most likely scenario is that the increase in dendritic intracellular Ca^{++} promotes a Ca^{++}-dependent afterhyperpolarization in these neurons, similar to what has been observed in substantia nigra by some dendritic inputs.[298] Clearly the role of α-MSH deserves more study in the regulation of OT bursting during lactation.

The peptide neurotensin causes OT neurons to adopt an irregular firing pattern,[299] similar to that which occurs prior to milk ejection bursts.[247,248] However, OT neuron burst initiation was not reported by Johnstone et al.[299]—indeed neurotensin exerted no effects on OT neurons during lactation. Thus firing irregularity, while highly correlated with an impending burst, seems to reflect some other change in the system, but may not itself lead to, or even signal, an impending burst.

ELECTROPHYSIOLOGICAL PROPERTIES OF OT NEURONS AND THEIR PLASTICITY DURING LACTATION

An obvious question regarding the mechanism of OT milk ejection bursts is whether intrinsic membrane properties play a role in this activity. The short answer is that intrinsic properties, even those known to change during lactation, are probably insufficient to underlie milk ejection bursts, but they could certainly shape them to an important degree.

The first comparison of membrane properties of OT and VP neurons identified few differences in input resistance, spike parameters, or afterhyperpolarizing potentials in male rats.[300] Both types were also found to possess

a slow (1–2 s) depolarizing afterpotential (sDAP) thought to underlie the phasic bursts of VP neurons and which was more prominent in VP neurons, especially after treatments blocking an overlapping spike afterhyperpolarization (AHP). However, the amplitude and form of sDAPs in OT neurons was not different from those in VP neurons.

Stern and Armstrong[301] described a sustained outwardly rectifying potassium current (SOR) that was much more prominent in OT neurons and which was increased during lactation (Figure 13.11). The SOR is of interest because it contributes to spike frequency adaption, and also promotes a rebound depolarization, part of which is Ca^{++} dependent, that could contribute to the onset of OT bursts.[302] The studies showing that IPSP-induced hyperpolarizations lead to rebound spikes,[246] combined with the facilitating effect of GABA on OT bursting while also reducing background firing,[264] suggest that strategically placed hyperpolarizations could precipitate bursting, and perhaps the SOR could facilitate this. However, Israel et al.[246] found that bursts were not coincident with OT's actions on rebound firing, but instead found that OT contributed to spike firing irregularity and frequency via this mechanism. Li et al.[211] found that blocking randomly occurring IPSPs in OT neurons regularizes firing, supporting a role for GABAergic synapses in shaping the background firing that changes dramatically during interburst intervals.[247,248] However, since irregularity can be separated from bursting, these changes in background firing observed in vivo may reflect ongoing synaptic activity relevant to the oncoming burst, but do not necessarily lead to burst discharge.

Other changes were noted during lactation by Stern and Armstrong,[301] including an increase in the size of AHPs following spike trains (Figure 13.12), an increased spike width and a reduced spike height. Enhanced AHPs during lactation were specific to OT neurons and have been observed in other studies,[303,304] but the increased spike width and reduced height has also been seen with

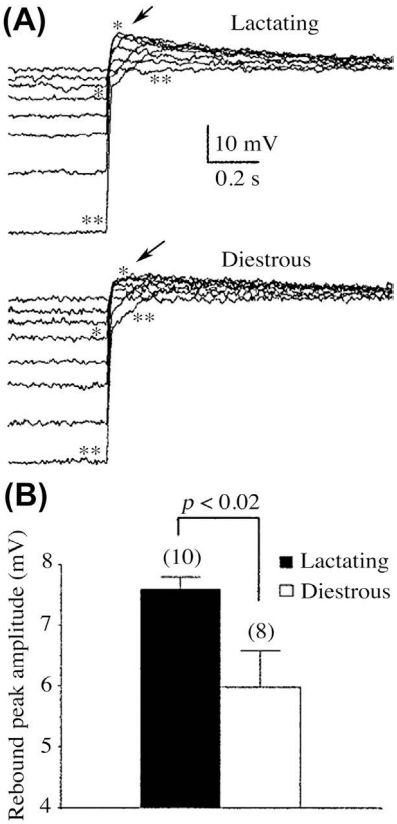

FIGURE 13.11 The peak amplitude of the rebound depolarization observed in OT neurons is enhanced during lactation. (A) The rebound depolarization following deactivation of a sustained outward rectifying potential elicited at the offset of 1.5 s hyperpolarizing pulses in OT neurons is shown for a lactating and a diestrous rat. Arrows point to the peak rebound. All traces were taken in the presence of 0.5 μM tetrodoxin, which blocked fast sodium action potentials and thus allowed appreciation of the rebound's amplitude. Neurons were current clamped at approximately −45 mV. Note that the largest rebounds are associated with relatively weak hyperpolarizations turning off the sustained outward rectification (*), whereas strong hyperpolarizations are associated with the smallest rebounds (**). (B) The rebound peak amplitude is enhanced during lactation ($p < 0.02$; Student's *t*-test). *Source: Redrawn from Ref. 301 with permission.*

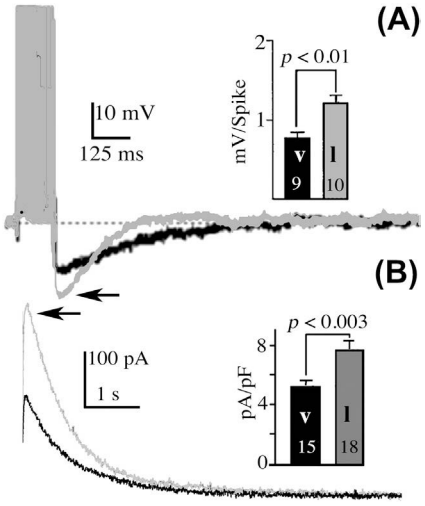

FIGURE 13.12 AHPs are larger in OT neurons during lactation. (A) Example traces from an OT neuron from a virgin (black) and a lactating (gray) rat. Note the larger AHP (arrow) in the neuron from the lactating rat versus that in a virgin rat following a spike train triggered by a 180-ms depolarization. *Inset*, Histogram showing the mean difference between lactating (L) and virgin (V) rats. Amplitude was calculated per spike because trains could have different spike numbers. *(Source: Redrawn from 301 with permission.)* (B) The current underlying the apamin-sensitive AHP in voltage clamp is enhanced in OT neurons during lactation. As with the AHP in (A), the I_{AHP} is larger (arrow) in lactating (gray trace) compared to in virgin rats (black). The I_{AHP} was evoked by a 200 ms depolarizing step to +10 mV from a holding potential of −70 mV. Traces are the averages from all neurons recorded. *Inset*, Histogram showing the mean difference between lactating (L) and virgin (V) rats. The I_{AHP} was calculated as current density to account for larger whole-cell capacitance observed during lactation in OT neurons. *Source: Redrawn from Ref. 303 with permission.*

VP neurons during lactation.[304] However, spike height and rise time are more sensitive to membrane potential in OT than in VP neurons, likely due to the fact that the fast sodium current underlying spikes in OT neurons is much less dense than that in VP neurons, probably reflecting fewer sodium channels.[305] OT spike height is thought to rapidly decrease during milk ejection–type bursts pharmacologically induced in vitro.[219]

The increase in AHPs observed by Stern and Armstrong[301] and Teruyama and Armstrong[303,304] involves two types of potentials following spike trains, one of medium duration (mAHP) (tau 100–200 m) and a slow AHP (tau 1.5–2 s) (sAHP). The mAHP is mediated by an apamin-sensitive, SK3-type potassium channel, and the current density underlying the mAHP was increased during lactation[303] (Figure 13.12). This increase was not accompanied by an increase in intracellular Ca^{++} during spike trains, or in whole cell Ca^{++} current under voltage clamp. Thus these authors could not confirm the increase in Ca^{++} current from unidentified SON neurons reported by De Kock et al.[232] during lactation. Both AHPs appear to first enlarge during late pregnancy,[304,306] suggesting that suckling is not the triggering stimulus.

The increase in AHPs in OT neurons in late pregnancy and lactation suggests that intrinsic inhibition is important to sculpting the burst. OT neurons fire during milk ejection bursts at rates not observed with other forms of activation, such as osmotic stimulation; bursts are typically ~4 s and reach rates from 50 to 80 Hz in the first second.[65] Synchronous bursting releases a bolus of OT that maximally and transiently stimulates mammary myoepithelial cells, avoiding OTR desensitization, and burst termination and the rapid reduction in firing rate needed to rapidly shut off OT release would be aided by these increased AHPs.[301,304] In addition, OT neurons undergo a post-burst inhibition[65,247,258] that is likely a combination of these enhanced AHPs and of OT's abilities, perhaps through cannabinoid release, to transiently suppress excitatory inputs.

What governs this plasticity? A popular theory is that OT neurons and the circuits controlling their activity may be programmed for adaptations needed at parturition and during lactation by the changing sex steroid milieu known to occur in late pregnancy.[307] Thus the rising levels of progesterone and estradiol (E2) during pregnancy, followed by a precipitous fall in progesterone during the last 24–48 h before birth, may trigger several brain events, presumably via central steroid receptors. In steroid replacement models in ovariectomized females, the withdrawal of progesterone in the continued presence of E2 is accompanied by increased maternal behavior,[307] and by upregulation of OTR binding[237] and in OT mRNA[213] in the SON and PVN. These indices, as well that of OTR mRNA,[241] are known to increase naturally in late pregnancy (also see Chapter 43), and increased OTR receptor binding is evident in the SON during lactation.[236] Thus even though local OT release appears to not increase over baseline until parturition[224] and then again during lactation,[223,224] the increased OTR presence could serve to enhance the effect of any constitutive OT release even before the enhanced OT release begins. The precise site of the estrogen and progesterone receptors in the brain mediating these effects is undetermined. While OT neurons have estrogen receptor ß,[308] they do not have estrogen receptor α or progesterone receptors, although these may be in regions connecting to the SON and PVN, such as the medial preoptic area,[309] BNST[310] and PNZ of the SON.[311] In addition, E2 is known to upregulate OTRs.[239,312] There is also the possibility that a novel membrane receptor for estrogen could participate in some manner in OT neuronal behavior.[313]

The steroid replacement model was used by Montagnese et al.[314] to determine the factors involved in the morphological plasticity of the OT system known to occur in lactation, well documented for over 30 years.[315,316] Changes involve hypertrophy of OT neurons, an increase in synaptic density and in the number of so-called shared synapses (terminals that contact more than one postsynaptic element), and an increase in close appositions related to the withdrawal of astrocyte processes. Much of the plasticity begins late in pregnancy, just prior to parturition. Interestingly, OT itself delivered ICV can induce this plasticity, but only in female rats in constant diestrous, or in ovariectomized animals receiving progesterone treatment followed by E2.[314] ICV OT had no effect in animals treated with progesterone or E2 alone. While the role of endogenous OT was not determined, the studies nevertheless implicated the peptide in the restructuring of its own system.

Teruyama et al.[306] investigated the role of central OT in AHP plasticity. Pregnant rats were infused ICV for about a week during late gestation starting on day 13 with the specific OT antagonist desGly-NH2-d(CH2)5[D-Tyr2, Thr4]OVT (OTA) or vehicle. In slices made from these animals sacrificed at days 19–22, the enhanced AHPs of OT neurons in vehicle-treated animals were absent in OTA-treated rats (Figure 13.13). In an in vitro model, Langle et al.[317] found that a 1-h OT (100 nM) treatment was sufficient to induce morphological plasticity when applied to slices from day 19 pregnant rats, an effect enhanced by relatively high doses of E2 (16.5 µM) and blocked by the OTA. GABA synapses were increased by this treatment, demonstrated both morphologically and electrophysiologically.[318] Armstrong et al.[319] found that using this model, OT (10 nM) and E2 (500 pM) i.e., at or near physiological doses, also enhanced sAHPs specifically in OT neurons. These studies suggest that autoregulation of OT neurons in combination with sex steroid changes plays a role in OT neuronal plasticity, beginning

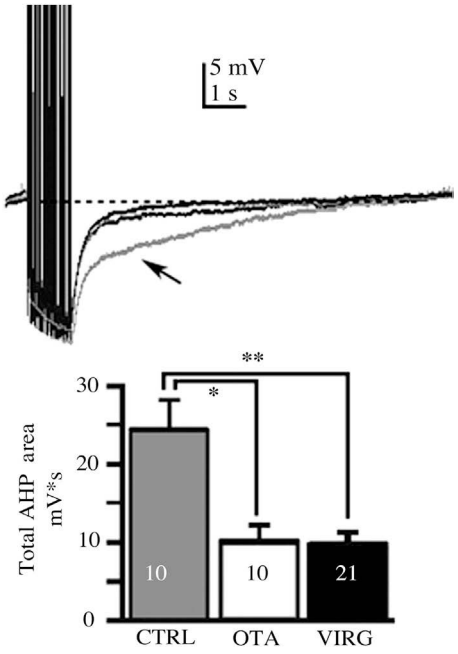

FIGURE 13.13 Enhanced AHPs during late pregnancy were blocked by intraventricular OT receptor antagonist (OTA) administration. The OTA ($d(Ch_2)_5$, $Tyr(Me)^2$, Orn^8-vasotocin) was delivered for 7–9 days at 200 ng/μl at 5 μl/h during late pregnancy via osmotic minipump. OT neurons from pregnant rats (days 19–21) treated with the OTA or artificial cerebrospinal fluid vehicle were compared with virgin rats. *Top*, Averaged traces of AHPs generated from a 20-Hz spike train for 1 s are shown. Note that OTA-treated pregnant animals had AHPs similar to virgin rats, whereas pregnant rats treated with vehicle (gray trace, arrow) were enhanced as shown previously.[304] Spike heights are clipped for convenience. *Bottom*, Histogram showing the mean difference between the three groups in the total area of the AHP. *, $p < 0.0009$; **, $p < 0.0001$. *Source: Redrawn from Ref. 306 with permission.*

in late pregnancy. Thus OT may behave in ways beyond those that underlie acute changes affecting electrophysiological or synaptic properties, actions that would be considered more akin to those exerted by growth factors.[316] This concept is not new and has been put forth to explain other long-lasting effects of OT in peripheral target organs that may involve mitogen-activated protein kinases.[320,321]

SYNAPTIC PLASTICITY DURING LACTATION

As discussed earlier, OT and VP neuronal systems undergo remarkable plasticity when challenged, with changes in the OT system appearing in late pregnancy and extending through lactation.[315,316,322] One of the first changes appreciated was the increased close appositions among magnocellular neurons and their dendrites, both in appositional length as well is in the number of elements involved, and the concomitant withdrawal of astrocyte processes that normally separate these processes. These findings, observed first with dehydrational challenge, led to speculation that appositions might underlie gap junctional or even ephaptic (i.e., electric field) communication among neurons, which might facilitate synchronization.[323] However, there has appeared no evidence for increased *electronic* communication among OT neurons in lactation, despite reported increases in dye coupling (thought to be mediated by gap junctions) among them,[315] and the presence of gap junction proteins.[324] Indeed, the evidence for electrical coupling is weak in the SON[325] and thought to be absent in synchronously bursting OT neurons in vitro.[208] Ephaptic interactions are possible but have not been reported, but could be subtle and also mediated in part by connexin hemichannels, such as occurs in retina.[326]

The change in morphology is accompanied by a significant decrease in astrocyte transmitter buffering near synapses (see following discussion), a reduction in the size and tortuosity of the extracellular space,[327] and in a small amount of extracellular buildup in potassium during synchronous bursting, the latter of which may permit weak depolarizations across immediately neighboring OT neurons.[328] Morphological changes may thus contribute to at least some of the reported physiological differences in synaptic transmission, discussed later.

Glutamate

Given the prominent role of glutamate-regulating milk ejection-related OT release, a natural question is whether glutamatergic transmission is altered during lactation. El Majdoubi et al.[329] first found that axosomatic synapses increased proportionately with somatic membrane of OT neurons, and a later study indicated an increased density of synapses in the neuropil of the SON[330]—in both studies, it is apparent that the number of shared, or double synapses, also increases. This plasticity appears to be permitted by adhesion molecules, primarily located on astrocytic membranes, like polysialated (PS) NCAM (neural cell adhesion molecule). While PS-NCAM does not increase during lactation, inhibiting its activity prevents astrocyte withdrawal and synaptic plasticity.[316]

Since the number of contacts per unit length of membrane appears to be static, it could be argued that the increase in synapse numbers simply compensates for the hypertrophy of OT neurons, an argument made for the increase in GABA synapses in this system.[331] On the other hand, the increase in shared synapses could reflect the closely timed synchronization of excitatory inputs inducing bursts.[208] Stern et al.[202] noted a doubling in the frequency of miniature EPSCs (mEPSCs) impinging on OT neurons in the SON of lactating rats, possibly reflecting this increase in synapse number or perhaps reflecting some constitutive increase in release probability. Using

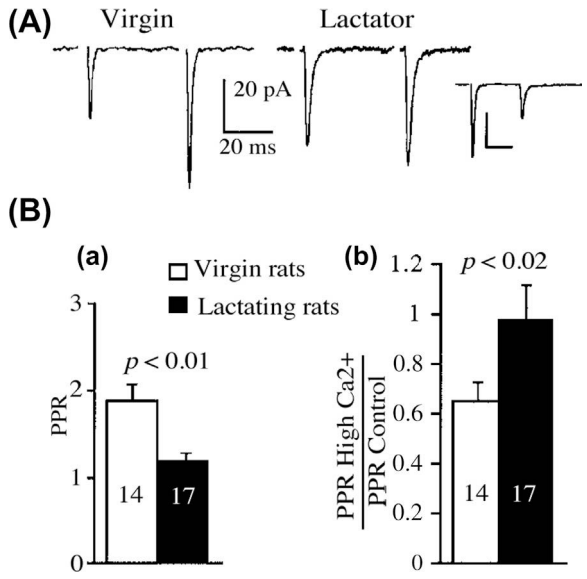

FIGURE 13.14 Paired-pulse facilitation (PPF) is decreased in OT neurons during lactation. PPF indicates an increased amount of transmitter is released to the *second* volley of action potentials produced by two closely spaced stimuli. A decrease in the ratio of the second response (PP2) to the first (PP1) is taken as an increased probability of release to the first stimulus. (A) Representative examples of averaged responses ($n = 100$) to pairs of extracellular stimuli in OT neurons in virgin and lactating rats. Note that the PPR ratio (PP2/PP1) decreases in lactation. *Inset*, In 36% of cases, a switch from PPF to paired-pulse depression was noted during lactation. (Scale: 20 pA, 20 ms). (Ba) PPF was significantly reduced in OT neurons during lactation. (Bb) The PPR in high $[Ca^{++}]_o$ compared to controls is shown for both virgin and lactating rats. Note the decreased sensitivity to increased $[Ca^{++}]_o$ in lactating rats. *Source: Redrawn from Ref. 202 with permission.*

paired-pulse stimulation of glutamatergic synapses (a standard method of evaluating synaptic potentiation or inhibition to repeated axonal stimulation), Stern et al.[202] found that glutamate release probability was likely increased during lactation, as the paired-pulse facilitation of consecutive EPSCs normally observed in virgin rats was decreased specifically in OT neurons during lactation, and a greater number of neurons actually showed paired-pulse depression (Figure 13.14). Increasing extracellular Ca^{++} in virgin rats reduces the paired-pulse ratio consistent with an increase in release probability, but this treatment has little effect in the ratio from lactating rats, whose glutamate release probability is presumably already enhanced.

These results are disparate from a similar study by Oliet and Poulain,[203] who found a *greater* paired-pulse facilitation in unidentified SON neurons during lactation, indicative of a lower probability of release. By pharmacologically manipulating extracellular glutamate uptake, this change was attributed to a reduced buffering of ambient glutamate during lactation due to astrocyte process withdrawal, elevating glutamate enough to increase presynaptic inhibition at glutamatergic terminals through group III metabotropic glutamate receptors (mGluRs). This theory is consistent with the reduced tortuosity and extracellular volume, both of which also would enhance the level of released glutamate.[327] However, the frequency of mEPSCs was not examined by Oliet and Poulain,[203] nor were neurons identified as OT or VP containing. While one might argue that an increased probability of release would maximize the initial EPSPs needed to drive burst onset,[202] in this alternative scenario of reduced glutamate release probability, the initial excitation would be filtered out, and synaptic facilitation would increase release through a spike train. The reduced glial coverage during lactation is also thought to allow potentiation of the NMDA receptor component of EPSPs from repeated EPSP volleys during lactation, through reduced astroglial release of the NMDA co-agonist D-serine,[207] although it is unknown whether this effect is specific to OT neurons. Finally, another consequence of glial withdrawal and the increased levels of ambient glutamate appears to be a switch in the activity of presynaptic glutamate kainate receptors on GABAergic terminals, which normally mediate facilitation of GABAergic transmission, but which during lactation appear to mediate inhibition specifically on OT neurons.[332] This would increase excitability of OT neurons.

Gamma Amino Butyric Acid

Like glutamatergic synapses, GABAergic synapses on OT neurons specifically have been shown to increase in number in the SON during lactation, including an increase in shared synapses.[330] As will be clear when dealing with noradrenergic synapses (discussed below), this suggests a general increase in synaptic numbers that may relate more to the hypertrophy of OT neurons than to any specific role in milk ejection bursts. Nevertheless, GABAergic synaptic transmission undergoes other significant and specific alterations during the reproductive cycle. The biggest documented change appears to be in sensitivity of $GABA_A$ receptors to the allosteric modulator, allopregnanolone, a progesterone metabolite considered a neurosteroid. In virgin animals and in late pregnancy, allopregnanolone prolongs the synaptic decay of mIPSCs on putative OT neurons in the SON (probably by increased $GABA_A$ receptor channel open time) whereas during lactation, it has little effect[267,331,333] (Figure 13.15). IPSC decays were found prolonged (without allopregnanolone) during lactation, returning to normal postlactation.[331] Interestingly, during late pregnancy and continuing through early lactation, mIPSC frequency is doubled from levels in virgins.[331] However, the prolonged increase in mIPSC frequency beginning near parturition and continuing through the first part of lactation suggests that total synaptic impact of GABA per se remains relatively constant, when considered with the hypertrophy of OT neurons.

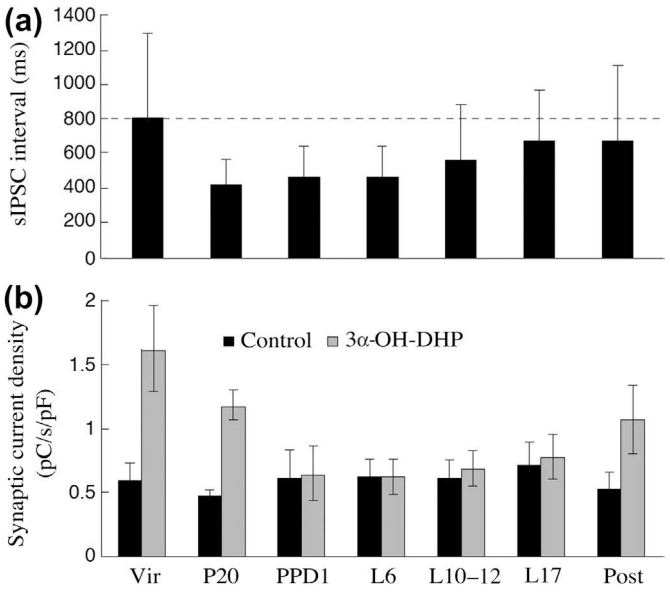

FIGURE 13.15 Histograms of spontaneous inhibitory postsynaptic current (IPSC) intervals and the relative synaptic-current densities of $GABA_A$ receptors on OT neurons during the pregnancy–lactation reproductive cycle. (A) The decreased IPSC interval during pregnancy and early lactation indicates that an increase in the number of GABAergic boutons on oxytocin neurons occurs at this time—consistent with morphological results.[330] (B) The sensitivity of IPSCs to the neurosteroid allopregnanolone (3α-OH-DHP) changes dramatically through the reproductive cycle. In order to estimate the impact of $GABA_A$ receptor-mediated synaptic transmission on OT neurons, the monoquantal IPSC amplitude, frequency, decay, and response to 3α-OH-DHP were combined to provide relative synaptic-current-density indices. This shows that the reduced sIPSC interval at the time of pregnancy has only a small impact on $GABA_A$ receptor efficacy (compare Vir and P20 in absence of 3α-OH-DHP). By contrast, the raised levels of 3α-OH-DHP enhance $GABA_A$ receptor mediated transmission substantially only in late pregnancy (P20). The switch to a 3α-OH-DHP insensitive receptor immediately prior to parturition (PPD1–L17) would provide a powerful mechanism of disinhibition that is involved in the activation of OT neurons at birth and during lactation. Abbreviations: L, lactation day; P, pregnancy day; Post, postlactation; PPD, postparturition day; Vir, virgin. *Source: Redrawn from Ref. 267,331 with permission.*

While initially these changes during lactation were thought correlated with a switch in the ratio of α_1/α_2 $GABA_A$-receptor subunits, favoring more α_2 at parturition and lactation,[267,331,333] more sensitive measures suggest that subunits do not change in amount, but there is an increased clustering of α_2 subunits at many GABA synapses.[334] As for the steroid sensitivity, it seems more likely that local OT itself alters phosphorylation of the $GABA_A$ receptor via protein kinase C inhibition, rendering the receptor steroid insensitive.[335] Thus OT neurons would be maximally inhibited by steroid in late pregnancy, perhaps to avoid premature release of OT, but with the fall of progesterone coupled with increased local OT release at parturition and into lactation, this steroid potentiation of GABAergic effects would be absent.

As a final caveat, however, Armstrong et al.[319] found that the decays of mIPSCs of *both* identified VP and OT neurons were prolonged in early lactation, so specificity of these changes to OT neurons could be questioned. Stern et al.[202] also reported prolonged mEPSCs in *both* cell types during lactation. $GABA_A$ receptors are also subject to heterosynaptic inhibition from glutamate release and the activation of mGluRs, but only during enhanced glutamate release.[327] Thus GABA transmission might be suppressed selectively during strong glutamatergic activation of OT neurons during milk ejection.

An increase in GABA synapses[317] and mIPSC frequency[318] has been induced by OT and potentiated by E2 in an in vitro model using hypothalamic slices from rats taken at day 19 of pregnancy. While these changes are mediated by the OTR, and dependent on Ca^{++} and glutamatergic transmission, they are presynaptic in origin and are not accompanied by changes in mIPSC decay. However, the precise target of OT's action is unknown—it is possible that OTR on astrocytes could promote astrocyte process withdrawal through increased Ca^{++} and consequent cytoskeletal changes, and thus "permit" synaptic increases.[258,336,337] The increased frequency of mIPSCs observed during lactation[333] and in this model is of interest since this tonic activity is much greater on OT compared to VP neurons and contributes to OT firing irregularity.[211] Since OT's ability to enhance GABAergic transmission also was found to contribute to firing regularity,[246] it is tempting to speculate that the increased frequency and increased irregularity of background OT neuron firing that precedes milk ejection bursts[247,248] may herald a dynamic change in synaptic transmission that favors burst onset. Whatever ultimately controls this change is undetermined, but clearly it must relate to continuous stimulation at the nipple provided by suckling pups.

Although its role has not yet been demonstrated in lactation, taurine is a neuroactive amino acid binding to glycine receptors (which are ligand-operated Cl^- channels, as are $GABA_A$ receptors) and is tonically released from astrocytes in the SON, providing a constitutive inhibitory tone.[338,339] Astrocytes are osmotically sensitive, and in response to hyperosmotic challenge, reduce their taurine release to lift this inhibitory tone. However, it seems likely that even without acute, osmotically mediated changes in taurine release, morphological astrocyte process withdrawal during lactation could reduce this inhibitory tone through a spatial change in the taurine concentration gradient.[339]

Noradrenaline

A quantitative microscopy study has indicated that noradrenergic innervation also contributes to synaptic plasticity, increasing specifically on OT neurons in both

the SON and PVN during lactation.[340] Although synapses were estimated from noradrenaline-positive varicosities with light microscopy, when examined these varicosities were typically associated with symmetrical synapses. Although it is tempting to conclude that noradrenergic effects are enhanced during lactation since, the increase in number of noradrenergic varicosities appears to match OT hypertrophy (much like glutamatergic and GABAergic synapses), suggesting again a compensatory innervation to match the increased postsynaptic membrane. These synaptic increases might relate to the increase in noradrenaline turnover[215] and release[130] observed during suckling, but rather than signaling a special role in lactation, a larger number of terminals might be necessary simply to equivalently impact hypertrophied OT neurons.

Conclusion of Synaptic Plasticity

Given that synaptic plasticity occurs during osmotic activation on both VP and OT neurons,[341] and can occur as fast as 30 min following a hyperosmotic stimulus,[342] increased synaptic numbers on OT neurons during lactation should not be viewed as a unique phenomenon. In this regard, while astrocyte process withdrawal facilitates synaptic proliferation, such withdrawal may be instigated by multiple factors, one of which could be OT.[317,318] Thus it seems plausible that OTR on astrocytes may mediate this withdrawal in lactation at least, although this is not certain. It is difficult to attribute the particular change in OT neuronal behavior during lactation to synaptic plasticity, either physiologically with regard to pre- and postsynaptic regulation of transmitter release, or in terms of increased synaptic numbers, although all of these could impact the burst response. It seems most likely that synaptic plasticity in lactation is geared primarily to ensure the now larger OT neurons are adequately impacted by whatever the final relevant stimuli are that drive bursts during suckling. The periodicity assumed in glutamatergic transmission to underlie OT bursts is likely a network phenomenon and may involve synaptic rearrangement at many locations aside from those in the SON and PVN. This seems likely since the *synchronous* bursting response is, as far as has been demonstrated, unique to lactation (although some evidence exists for synchronized bursts during parturition[68]), both of which involve specialized sensory inputs from structures modified by reproductive state.

Neurohypophysial Plasticity

Although the bursting pattern of OT neurons during lactation is a function of interactions within magnocellular nuclei, the terminal environment also undergoes a similar structural rearrangement.[315,316] Normally, pituicyte (modified astrocytes) processes separate neurosecretory terminals from the capillary bed and then withdraw these processes with strong activation as occurs during parturition, dehydration, and lactation. As with the SON and PVN, adhesion molecules on pituitcytes such as PS-NCAM may play a role in this plasticity.[316] It is also possible that OT, via OTRs on pituitcytes, might affect this plasticity through adenosine- and Ca^{++}-dependent changes in stellation[343] similar to that described for VP and $V1_A$ receptors.[344,345] However, to date these factors have not been specifically implicated in changes associated with lactation. Pituicyte withdrawal would give OT quicker diffusional access to fenestrated capillaries, but the limiting step of diffusion for OT's peripheral actions would be 10–20 s needed for vascular transport of the hormone to the mammary gland or uterus—much slower than any diffusion within the neurohypophysis to fenestrated capillaries. The more important consequence of these changes to OT release may relate to the access of terminals to presynaptically neuroactive compounds released from neighboring axons into the perivascular extracellular space, such as co-released dynorphin, CCK, or other peptides and neuromodulators. However, there is thus far little evidence that these factors play a physiological role in the neurohypophysis during lactation.

A MODEL FOR MILK EJECTION

Computational models have increased our understanding of neuronal activity both at the single-cell and network level. Single-neuron models have been developed for SON neurons based on many known properties, with a focus on VP neurons and their phasic bursting activity,[346,347] or on the osmotic response of VP and OT neurons.[348] Recently a very robust network model was developed that successfully produces synchronous bursting with amplitudes and periodicities similar to milk ejection bursts.[349] The model successfully reproduces the background firing of OT neurons as well, including the progressive switch to irregularity prior to bursts. The key features of the model are the priming produced by OT during its slow, progressive release between bursts (producing the long interburst intervals as well), and relatively weak dendritic bundling that allows intercommunication among OT neurons. Synaptic feedback from OT's release of cannabinoids, and AHPs, also play significant roles in shaping post-burst silent periods and the changeable background activity. However, the strong depolarization producing a burst in the model appears primarily due to OT's depolarizing effect on OT neurons and not from glutamate. There is little evidence from recording studies to support such a

powerful, direct ability of OT in this regard. Indeed the OT-induced effects on bursting in slices in vitro involve relatively weak depolarizations and are completely dependent upon glutamatergic transmission underlying the burst.[208,255] Nevertheless, this model is an excellent starting point for interactive studies between computer and experiment that should lead to future refinement and more insights.

CONCLUSION

Although it should be evident from this chapter that great advances have been made in our understanding of the CNS control of milk ejection, there are major gaps in our knowledge. Firstly, at least three neurotransmitters/neuromodulators are deemed essential to the reflex, presumably from their actions within the hypothalamus, if not directly upon OT neurons themselves, but how these interact to influence OT bursting remains a mystery. For example, there is a great deal of evidence to suggest that the suckling stimulus works through noradrenergic afferents—but this system is absent in the only in vitro model that successfully reproduces the synchronous, periodic OT bursting resembling that of the milk ejection reflex. On the other hand, this model may still be a window into the mechanisms of the oxytocin pulse generator, a presumed circuit of neurons that would normally be activated selectively by suckling, but which, in the absence of many normal synaptic inputs, operates due to an increase in excitatory connections that are either aberrant in number or simply lack the normal gating mechanisms that come with connectivity in the adult rat. While these inputs are clearly modulated by somatodendritically released OT, another "essential" neuromodulator for the reflex, we do not understand yet how OT induces, or permits, bursting, despite knowing many of the things that OT does both directly to OT neurons as well as to synaptic inputs.

Related to the importance of neuroactive substances are the locations of critical CNS regions transmitting suckling afferents. While there is general agreement that suckling is carried ipsilaterally in the lateral columns in the spinal cord, and that the pathway crosses to arrive contralaterally in the hypothalamus, the precise players are still not determined. While there are many ascending bilateral inputs to the PVN and SON from the brainstem, most are dominated by ipsilateral connections, suggesting that this crossing likely occurs in the lower medulla or rostral spinal cord. Experiments are still needed to determine, for example, which brainstem noradrenergic populations are *critical* to transferring this information to the SON and PVN, and not simply activated by the stimulus. For example, experiments like those performed in the midbrain lateral tegmentum, showing that neurotoxic lesions sparing fibers of passage reproduced the effects of knife cuts or electrolytic lesions blocking milk ejection, could illuminate the critical role of certain noradrenergic or nearby brainstem cell groups, when comparing the toxins specific to catecholaminergic transmission, for example, with those of ibotenic acid.

Within the hypothalamus, these signals are finally shared bilaterally, but the mechanism of transfer is unknown. The fact that OT injected into the SON recruits contralateral SON OT neurons into the reflex makes it unlikely that bilateral brainstem inputs are critical to bilateral SON and PVN activation. It seems more likely that somatodendritically released OT has access to the hypothalamic pulse generator, which likely connects bilaterally with the SON and PVN. Direct connections among the four SON and PVN nuclei cannot be ruled out, but are not yet well documented. The pulse generator may not be a single entity but may include different neuronal groups that provide interhypothalamic connections through both supra- and subventricular pathways. While some candidates are emerging, including the DMH and adjacent lateral hypothalamus, the PNZ or dorsal chiasmatic area of the SON, much work lies ahead to determine if these regions are essential for OT bursting, or its synchronicity, during the milk ejection reflex.

CHAPTER

14

Testicular Development

Peter O'Shaughnessy

Institute of Biodiversity, Animal Health and Comparative Medicine, University of Glasgow, Glasgow, UK

INTRODUCTION

In 1947 Alfred Jost reported that castration of fetal rabbits prevents masculinization of the fetus thereby demonstrating that the fetal testis determines the phenotypic sex of the individual.[1] Jost later went on to show that the factors involved in this process are testosterone and anti-Mullerian hormone (AMH) secreted by the somatic cells of the developing testis.[2] This chapter describes development of the testis during this period after initial differentiation when it acts to alter the phenotype of the fetus and up until early puberty when spermatogenesis is beginning. This time span covers most of the critical stages of testis growth and functional differentiation with only the completion of meiosis and the process of spermiogenesis occurring later. The major developmental landmarks and circulating hormone levels during testicular development in the mouse (as a representative model) are shown in Figure 14.1. Overall, the emphasis of this chapter will be on the functional differentiation of the somatic cells and how they affect germ cell development.

In most eutherian mammals the gonads differentiate and start to develop during the first quarter of gestation. For example, in the human (gestation 40 weeks) the gonads develop at about six weeks while in the sheep (gestation 145 days) development is around 30–35 days. In rodents, testis development is a little later at just after half way through pregnancy, starting at 11.5 days postcoitum (dpc) in the mouse and 12.5 in the rat.[4] Initially, differentiating pre-Sertoli cells migrate into the developing gonad from the coelomic epithelium where they aggregate with primordial germ cells that have traveled from the yolk sac (see Chapter 7). Interactions between endothelial cells migrating from the mesonephros and interstitial cells lead to the formation of sex cords from the Sertoli/germ cell aggregates, and these cords will go on to form the seminiferous tubules.[5–7] Around 13.0 dpc in the mouse the peritubular myoid cells start to differentiate from interstitial cells, and they go on to form a cellular layer surrounding the developing tubules.[6] At around the same time another major somatic cell type, the Leydig cell, starts to differentiate within the interstitial spaces from cells that originated in either the coelomic epithelium or the mesonephric-gonadal border.[8] This differentiation phase is fairly rapid in the male, and the essential structure of the testis is in place by eight weeks in the human, 35 dpc in the sheep, and about 14 dpc in the mouse. As the testes differentiate morphologically, they start to masculinize the fetus in the process described by Jost through secretion of androgen from the Leydig cells and AMH from the Sertoli cells.

Following initial differentiation, a number of landmark events occur in the testis prior to puberty (Figure 14.1). Fetal testis development is characterized largely by Sertoli cell proliferation and androgen production by the fetal Leydig cells, both of which are essential for masculinization and subsequent fertility. Later in fetal or in early neonatal life, the primordial germ cells migrate to the basement membrane of the seminiferous tubules and give rise to the spermatogonial stem cells (SSC) from which full spermatogenesis will develop after puberty. Shortly after migration of the primordial germ cells, at about postnatal day 7 in the mouse, a second, adult population of Leydig cells develops, which goes on to secrete the high postpubertal levels of testosterone required for fertility and normal male behavior. Finally, in this period, the Sertoli cells stop proliferating as puberty starts and undergo a maturation process that forms the blood–testis barrier and allows spermatogenesis to progress. These events are considered in more detail in the following discussion.

ANATOMICAL, HISTOLOGICAL, AND MORPHOMETRIC DEVELOPMENT

As the testis develops, the sex cords form a flattened, interconnected plexus in the region of the testis next to the mesonephros; this develops into the rete testis. At the

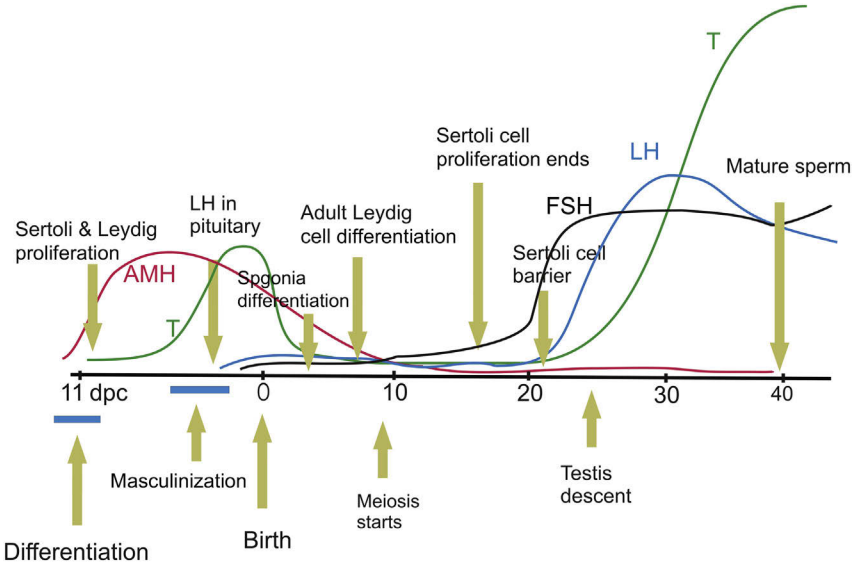

FIGURE 14.1 Major developmental landmarks and relative circulating hormone levels in the mouse during fetal, neonatal, and pubertal growth. This schematic shows the development of the mouse testis from initial differentiation around 11 dpc until puberty. Major changes in the testis (or relevant developmental events in the whole animal) are indicated by arrows. Relative levels of AMH, FSH, LH, and testosterone (T) are shown. *Source: Modified from Ref. 3.*

same time, cords developing away from this region form looped structures originating and returning to the developing rete testis.[9] The 3D structure of these cords is quite complex, with a central group of cords surrounded by an outer group of parallel cords, and fusion and branching occurring throughout (Figure 14.2). In the mouse the total number of these cords is between about 12 and 18.[9] It is the expansion and elongation of these structures, firstly through Sertoli cell proliferation and then as spermatogenesis begins, that causes growth of the testis through fetal and postnatal development. Interestingly, the asymmetric nature of cord development to form the rete testis and precursors to the seminiferous tubules appears to be dependent on G protein-coupled receptor 56 (GPR56), which is present on the Sertoli cells, although the ligands that activate this receptor in the testis remain unknown.[10]

Histological section of the fetal testis shows the presence of the developing seminiferous tubules (Figure 14.3), with the Sertoli cells forming an epithelial lining and the large primordial germ cells lying within the lumen of the tubules. Around the tubules there is a single (rodents, pigs) or multiple (human) layer of peritubular myoid cells lying in contact with the basement membrane that supports the Sertoli cells. The interstitial tissue between the tubules contains the fetal population of Leydig cells, mesenchymal cells, macrophages, and fibroblasts. Also present within the interstitium are blood and lymphatic vessels and nerves. One of the characteristics of the developing testis is the formation of the coelomic blood vessel, which is generated by migrating endothelial cells coming from the mesonephros.[12,13] Branches of this vessel track through the interstitial tissue lying in the space between the developing testis cords. In the ovary, development of this artery is inhibited by Wingless-related MMTV integration site 4 (WNT4).[14,15] Arrangement of the lymphatic vessels in the testis varies between species; in rodents there are large lymphatic spaces present within the interstitium, while in other species the lymphatic vessels are more discreet,[16–18] and in humans they are apparently restricted to the septa dividing the testicular lobes.[19] Testicular nerve types and the structures innervated vary somewhat between species and their function within the testis remains uncertain, although there is evidence that they may regulate testicular blood flow and affect Leydig cell function.[20–22] A detailed and comprehensive review of testicular anatomy can be found in a previous edition of this book.[23]

Morphometric Development

Sertoli Cells

In mammalian species for which we have reliable morphometric data (mouse, human, rat, sheep, monkey), Sertoli cell number increases exponentially during at least part of fetal development. This is followed by a further postnatal increase in numbers, which is either continuous with fetal development or follows on after a period of quiescence.[24] In rodents, Sertoli cell number increases continuously after initial testis differentiation, until early puberty at about day 15 in rats and mice with no further change thereafter.[25–28] Final Sertoli cell numbers in rodents are about 3×10^6 in mice and 38×10^6 in rats. In the ram there is a similar pattern of development with Sertoli cell proliferation extending for between 6 and 12 weeks after birth,[29–31] while in the boar it extends up to 17 weeks[32] and in the bull until about 20 weeks.[33] In these species the germ cells enter meiosis at around the same time as Sertoli cell proliferation ceases, the likely connection being formation of the blood–testis barrier. In rhesus monkeys there is a short proliferative phase after birth, which may or may not be

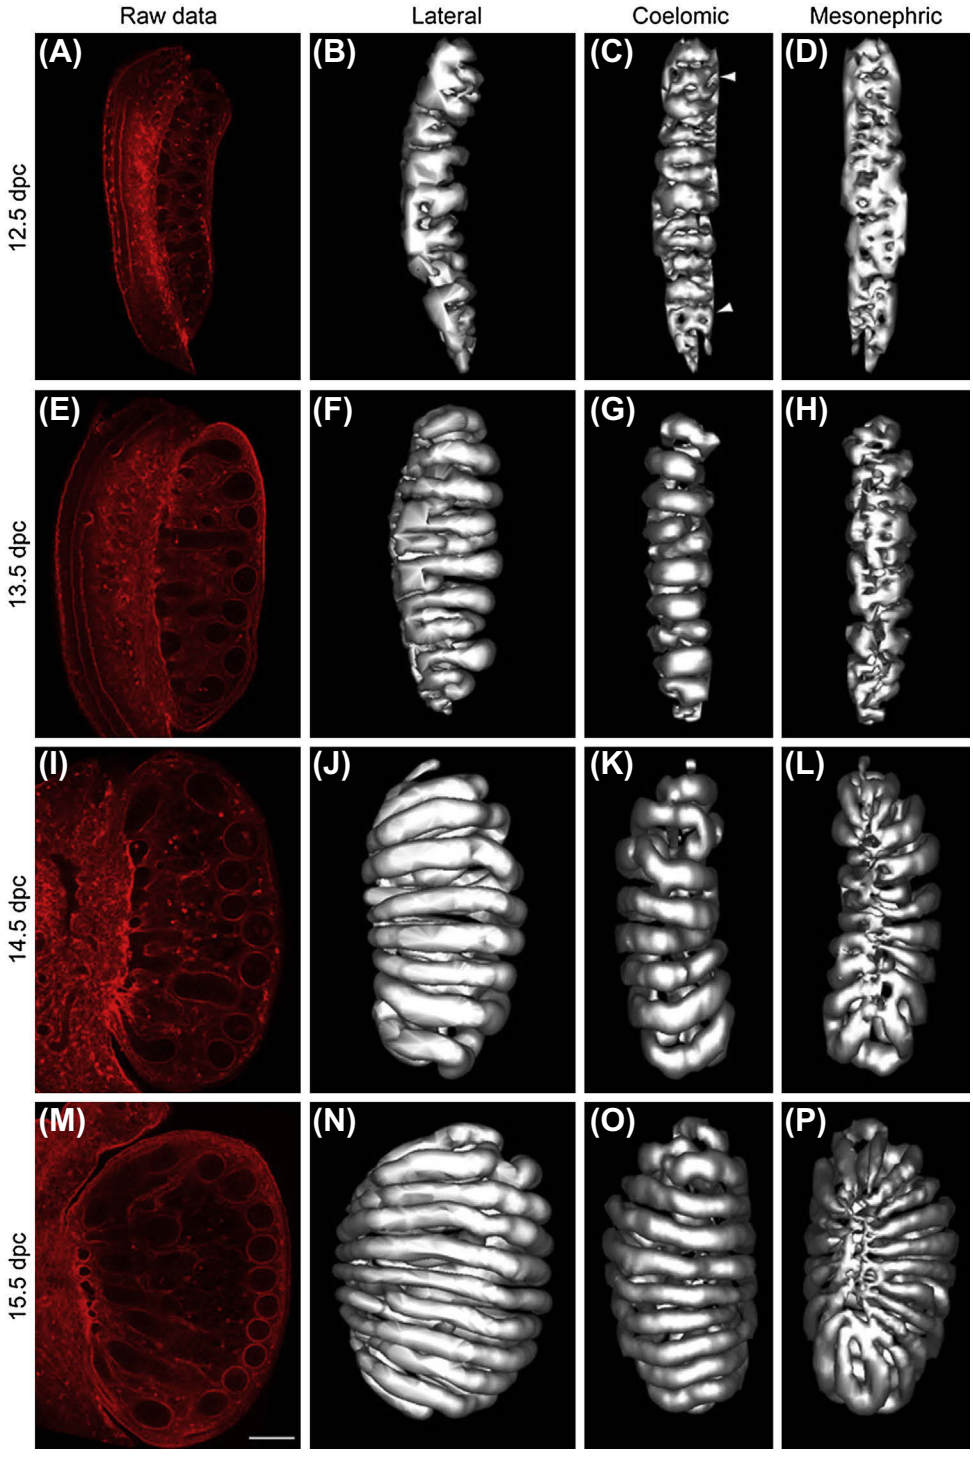

FIGURE 14.2 Modeling of testicular cord development in the mouse. This figure is reproduced in color in the color plate section. This figure is taken from Ref. 9 and shows lateral (B, F, J, N), coelomic (C, G, K, O), and mesonephric (D, H, L, P) views of models generated from testis cord outlines prepared from whole mount testis. The left panel in each row (A, E, I, M) is a representative image from the data set used to compile the models. The results show that cords initially form as a network of irregular cell clusters that are subsequently remodeled to form regular parallel loops, joined by a flattened plexus at the mesonephric side. Branched, fused, and internalized cords are commonly observed. Parts A–D, E–H, I–L and M–P show models of testicular development at 12.5, 13.5, 14.5 and 15.5 dpc, respectively. Scale bar, 100 μm. *Source: Modified from Ref. 9.*

continuous with the fetal phase of development.[34] This is followed by a period of relative quiescence when Sertoli cell number only increases gradually in the prepubertal period.[35] As the animal enters puberty, however, there is renewed proliferation of the cells and a marked increase in Sertoli cell number.[34,36] Data for the human would suggest that Sertoli cell development follows a similar pattern to the rhesus monkey, although the pubertal increase may be less marked. Fetal Sertoli cell number in the human doubles about every two weeks from week 7 of gestation to week 19.[37,38] Thereafter, the rate of proliferation drops, and Sertoli cell number doubles three more times in the remaining 19 weeks of pregnancy to reach about 130×10^6 cells/testis at birth.[37,39] After birth there is a further six-fold increase in cell number that peaks at three months,[39] remains

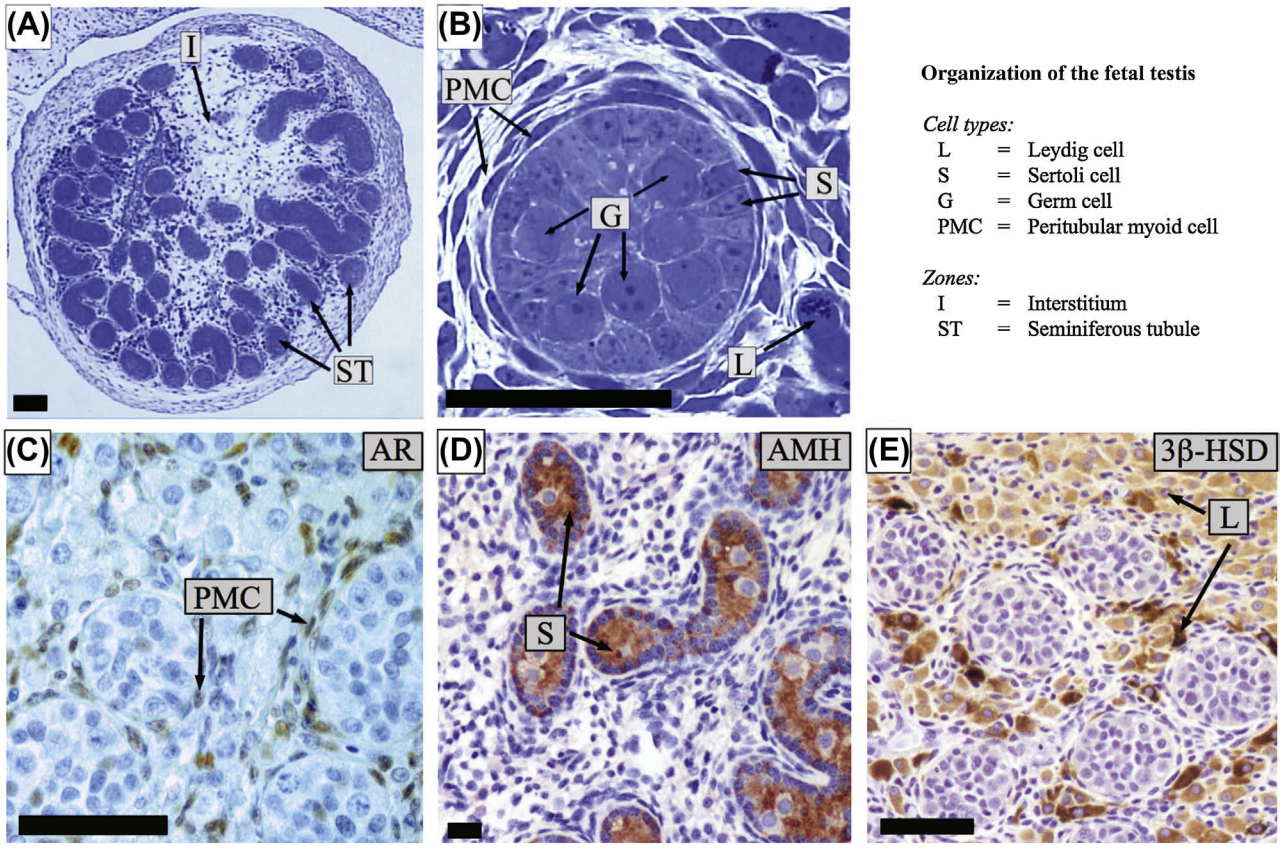

FIGURE 14.3 Histology of the fetal testis. This figure is reproduced in color in the color plate section. (A) Fetal mouse: low magnification of a semithin section showing seminiferous tubules and interstitial tissue (I). (B) Fetal mouse: higher magnification of (A) showing gonocytes (G) in the central part of the sex cord with the Sertoli cells (S) around the periphery. The peritubular myoid cells (PMC) form a concentric layer around the cord, and Leydig cells (L) are present within the interstitium. (C) Fetal human: immunohistochemically labeled for the androgen receptor (AR), which is clearly expressed in PMC and in some interstitial cells. (D) Fetal sheep: immunohistochemically labeled for anti-Mullerian hormone (AMH), which is strongly expressed in fetal Sertoli cells. (E) Fetal human: immunohistochemically labeled for 3β-hydroxysteroid dehydrogenase (HSD3B), which is localized exclusively in the Leydig cells. In all photomicrographs, the bar represents 50 μm. *Source: Reproduced from Ref. 11. © Society for Reproduction and Fertility (2011). Reproduced by permission.*

stable until about 10 years,[39,40] and then doubles again at puberty to reach a final number of about 1800×10^6 cells/testis. In general the rate of Sertoli cell apoptosis is low during the developmental period.[41,42] Thus the increase in cell numbers leading up to puberty will be due largely to changes in cell proliferation rates rather than a change in the balance between proliferation and apoptosis. Interestingly, humans with *ATRX* (alpha-thalassemia, mental retardation, X-linked) syndrome have small testes,[43,44] which appear to be due largely to increased apoptosis in the fetal Sertoli cells,[45] indicating that ATRX is required for Sertoli cell survival. Mutation in the microtubule-associated protein, sperm associated antigen 5 (SPAG5), has also been shown to increase Sertoli cell apoptosis due to disorganization of the spindle apparatus.[46] Control of Sertoli cell proliferation is discussed in the following section.

An interesting question that has recently been raised is whether the adult Sertoli cell represents a terminally differentiated cell (i.e., does not divide, shows no changes in phenotype, and performs a specific function) or an arrested proliferating cell.[47,48] Generally, the Sertoli cell is referred to as terminally differentiated, but data from seasonal breeders show that adult Sertoli cells will undergo proliferative activity in these species.[49,50] In other species, where there is no clear seasonal pattern to spermatogenesis, the blood–testis barrier and presence of tight junctions after maturation may prevent Sertoli cells from reentering the cell cycle,[48] and a balance may exist between cell cycle inhibitors and inducers that in the normal in vivo situation keeps the cells quiescent. If the cell–cell interactions are broken, however, by isolating the cells and placing them in vitro they will show proliferative activity.[48]

Whether or not the adult Sertoli cell is terminally differentiated, in most species postnatal development of Sertoli cells is limited, and the number of Sertoli cells in the adult testis will be critically dependent upon numbers that develop during fetal development. The number of adult Sertoli cells, in turn, will determine adult testis

size and sperm production since each Sertoli cell will only support a limited number of germ cells.[51]

Leydig Cells

There is strong evidence that two distinct populations of Leydig cells arise during development in rodents. The first or "fetal" population of cells develops soon after Sertoli cell differentiation and is present throughout fetal development and into the neonate. The second or "adult" population starts to develop in late neonatal life (about day 7 in mice[52,53]) and persists through the remaining lifespan of the animal. The evidence that these are distinct populations in rodents depends primarily on morphological and functional differences between the cells and the presence of adult Leydig cell stem cells in the adult animals (see the section The Leydig Cell below). While this is largely convincing, until the fate of the fetal Leydig cells can be established through specific labeling of the cells, it remains possible that fetal and adult cells represent different phases of the same population. The presence of distinct Leydig cell populations in other species is largely inferred by reference to the rodent models, but it is certainly the case that two distinct periods of Leydig cell activity, in fetal and adult life, can be seen in other mammals, which would be consistent with this model. There is additional morphological evidence in humans, such as the presence of Reinke crystals, to suggest that adult and fetal cells represent different populations.[54–56] In humans, other primates, and the boar it has also been postulated that there is a third population of Leydig cells that arises during neonatal life,[57–59] but it is not clear whether these are a distinct population or fetal Leydig cells reactivated by a postnatal rise in luteinizing hormone (LH).[60]

In rodents, fetal Leydig cell number increases rapidly after initial differentiation and is then maintained, relatively unchanged, at about 2.5×10^4 in mice and 5.5×10^4 in rats through fetal and neonatal life.[25,26,61] Between postnatal days 10 and 20 in the mouse, there is a marked increase in Leydig cell numbers as the adult Leydig cells differentiate and adult levels (1.5×10^6 in mice and 20×10^6 in rats[25,26,61]) are reached by about day 30. In humans, Leydig cells are first detectable at week 8,[62] and numbers increase exponentially during the first half of the second trimester reaching a maximum number of about 2×10^6 around 18 weeks.[37] Thereafter, Leydig cell numbers decline in the human fetus through a process of dedifferentiation or degeneration.[55,63–66] After birth, Leydig cell numbers increase again in the human at three months (caused by an increase in LH levels due, probably, to altered steroidal feedback at the hypothalamic–pituitary axis after birth) followed by another decline after four months.[65] The cells become very scarce until six to eight years of age when they begin to increase to adult levels, reported as ~800×10^6.[67] Other, nonhuman, primates are reported to show the same fetal, neonatal, and pubertal peaks of testosterone and changes in Leydig cell number during development.[68–75] Leydig cell development in the boar also appears to go through three stages of development (fetal, neonatal, and pubertal),[32,58,59] but evidence from other species is generally lacking. In sheep there is an exponential rise in Leydig cell number from days 40–60 of gestation, and numbers then remain relatively stable until birth.[29] Leydig cell numbers in the neonatal period have not been measured in sheep, but there is no evidence for a neonatal peak in testosterone levels.[76]

Peritubular Myoid Cells

Currently we know little about development of the peritubular myoid cells, although evidence is starting to accumulate suggesting that these cells may play a significant role in normal testis development and function.[77,78] The peritubular myoid cells form shortly after testis differentiation in the mouse (at about 13.5 dpc[79]) and a little later in the human between weeks 9 and 12 pc.[80] There is evidence to suggest that formation of the peritubular myoid cells is dependent on Desert hedgehog (DHH) signaling.[81] In rodents there is normally a single layer of peritubular myoid cells surrounding the seminiferous tubules, although in the human several layers exist.[82] The peritubular myoid cells lie between two layers of basement membrane in rodents,[83] with the Sertoli cells on one side and lymphatic endothelial cells on the other.[16] Cell numbers have been measured in the mouse; they are reported to increase markedly from about postnatal day 18, reaching a maximum number at the end of puberty at about day 30.[26] Whether this increase in cell number is simply a response to expansion of the seminiferous tubules as spermatogenesis develops or whether it plays a more functional role in tubule and testicular development remains to be determined.

Testicular Macrophages

Macrophages are first seen in the testicular interstitium around birth in rodents,[84] and numbers increase slowly until the start of puberty when they show a rapid increase that then declines again after puberty.[26] Interestingly, testicular macrophages are reported to form digitations with Leydig cells in which long, microvillus-like processes from the Leydig cells are inserted within coated pits of the macrophage.[85] These digitations initially form during puberty,[86] at the time when macrophage number is showing a marked increase.

Germ Cells

The primordial germ cells are formed in the caudal yolk sac and migrate to the developing gonad where their fate is determined by the gonadal environment. Primordial germ cells that migrate to an ovary will differentiate into primary oocytes, and in rodents most of them proceed to the diplotene stage of meiosis by around the time

of birth.[87] In contrast, primordial germ cells that migrate to a developing testis do not enter meiosis until after birth.[88] Since germ cells that migrate to non-gonadal tissues will enter meiosis,[89] it has been proposed that the testis produces a meiosis inhibitory factor,[90,91] although it is only in recent years that mechanisms regulating entry into meiosis have started to become clearer. In 2006 two groups reported that retinoic acid, coming from the mesonephros, acts as a meiosis-inducing substance in female gonads but is prevented from acting in the developing testis through degradation by Cytochrome P450 26b1 (CYP26B1) in Sertoli cells.[92,93] CYP26B1 certainly appears to be involved in this process as germ cells will enter meiosis in CYP26B1-deficient mouse testes,[92,94] but the role of retinoic acid (RA) has been challenged.[95,96] A number of other factors have now also been reported to affect germ cell differentiation.[97–102] It has been suggested that germ cell fate in the male is affected through both inhibition of RA signaling and by factors produced by the Sertoli cells.[103]

In humans, germ cell number shows an exponential increase during fetal development from the initiation of testis differentiation until the end of the second trimester.[37,38,104] The rate of increase in germ cell numbers is greatest from 6 until 10 weeks and is then reduced until the end of the second trimester.[105] The reason for the reduced rate of proliferation after 10 weeks is not clear but may be related to the number of Sertoli cells. Proliferation of the Sertoli cells is slower than the germ cells during the second trimester which is seen as a doubling in the germ cell/Sertoli cell ratio from the first to the second trimester.[37] If germ cell number depends on Sertoli cell number at this stage of testis development, as it does in the adult,[51] then germ cells will be limited by Sertoli cell numbers. The undifferentiated fetal germ cells (gonocytes) undergo development in the fetal and neonatal stages toward formation of the SSC and spermatogonia[106–109] in a process that appears to be similar between humans and marmosets.[110] This process is gradual and asynchronous in primates, which means that while spermatogonia form in fetal life, undifferentiated germ cells at different stages of development will still be present through fetal and neonatal development. Studies in the monkey show that there is a marked increase in undifferentiated spermatogonia (presumably including SSC) between birth and puberty, perhaps as a result of an increasing number of Sertoli cell niches.[36] Germ cell numbers in the sheep increase exponentially during fetal development in a process that lasts through most of gestation.[29] In rodents there is marked proliferation of germ cells in the period immediately after testis differentiation, and then proliferation declines sharply by 15 dpc.[111] Germ cell numbers then remain stable through gestation before proliferation starts again after birth as the gonocytes differentiate into spermatogonia.[25]

CONTROL OF TESTIS DEVELOPMENT

The rodent has been the mainstay of research into testicular development, and use of mutant and transgenic mice, in particular, has led to enormous advances in our understanding of the events and mechanisms involved. In terms of the endocrine regulation of fetal testicular development, however, current evidence suggests that the rodent may have limitations as a model for other mammalian species.[11] In the postnatal testis it is well established that LH from the pituitary regulates Leydig cell function, while pituitary follicle-stimulating hormone (FSH) and androgen from the Leydig cells control Sertoli cell activity (see below). During fetal life, however, testicular development and function in rodents does not require pituitary gonadotropins.[112–114] In contrast, in most other species testicular development is dependent upon pituitary hormone stimulation during at least part of fetal life while some, such as the human, have evolved an additional placental LH-like hormone (chorionic gonadotropin; CG), which regulates Leydig cell function early in development.[11] The rodent will, however, fit the general pattern if it is accepted that testicular development in the mouse is a compressed version of that seen in many other species and that it is born "early" in terms of testicular development[112] (Figure 14.4). The description of testicular control that follows rests very heavily on the mouse because of the unprecedented power of the genetic models available, but caution needs to be maintained when extrapolating to other species because of this compressed nature of development, particularly with respect to the endocrine control of development.

The Sertoli Cell

Hormonal Control of Cell Proliferation

Data from rats and mice indicate that proliferation of Sertoli cells during fetal and neonatal development is regulated largely by androgens. For example, studies using the androgen receptor (AR) deficient *Tfm* mouse and the ARKO mouse show that Sertoli cell number at birth is significantly reduced in the absence of androgen action.[27,113,115] Similarly, induced reduction of androgen levels in fetal or neonatal rats significantly reduces Sertoli cells number.[116–118] Interestingly, studies on the Sertoli cell-specific ARKO (SCARKO) mouse show that these effects of androgen are not mediated directly through the Sertoli cells.[27,115,119] This is consistent with AR expression in the rodent during fetal development, which is limited to interstitial cells and peritubular myoid cells, indicating that androgen action on the Sertoli cells is likely to be mediated through these cells in the fetus.[120,121] The role that FSH plays in determining Sertoli cell number during fetal development is less certain. Early studies reported

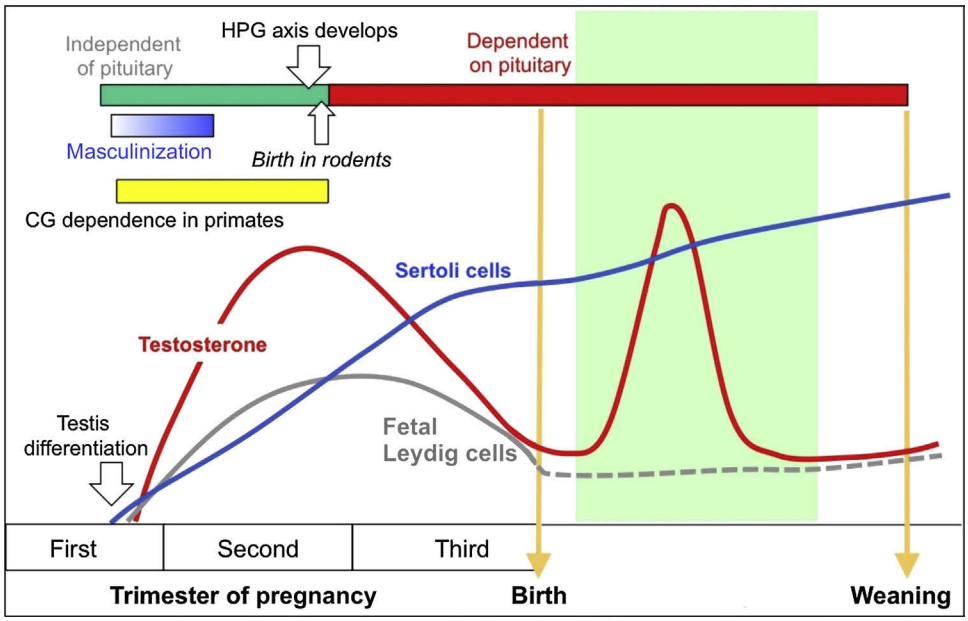

FIGURE 14.4 Schematic representation of the regulation of testicular function during fetal and perinatal development in the mammal. This is a composite diagram of data from several species. It is not meant to represent any single species but is a generalized view of how testicular control develops. Changes in Sertoli cell and fetal Leydig cell numbers and testosterone levels are shown, and dependence on pituitary gonadotropins is indicated along the top. After birth there is a rise in testosterone levels in some species (e.g., primates) caused probably by altered steroid feedback at the hypothalamic-pituitary level. The fate of the fetal Leydig cells after birth is largely unknown, and this is indicated by a dotted line. The arrow indicating birth in rodents suggests that these species follow the same general developmental plan but are born "early" (see text). Similarly, primates follow the same general plan as other species but have additional control from chorionic gonadotropin. *Source: Adapted from Ref. 11. © Society for Reproduction and Fertility (2011). Reproduced by permission.*

that Sertoli cell proliferation in the late fetal rat is regulated by FSH,[122] but subsequent morphometric analysis of Sertoli cell numbers in newborn mice lacking FSH or the FSH receptor (FSHR) failed to see any change in Sertoli cell number.[25,113] Subsequently, an effect of FSHR ablation on fetal Sertoli cell development was shown, but this was only evident when exacerbated by loss of the AR.[27] This led to the view that FSH is relatively unimportant in regulating fetal Sertoli cell numbers in rodents, but the underlying data has recently been challenged[123] and further studies will be required before a consensus is reached. Nothwithstanding this controversy, studies using ARKO, FSHRKO, and compound ARKO.FSHRKO mice indicate that after birth and up to early puberty Sertoli cell number is regulated largely by androgens and hormone-independent mechanisms, with an uncertain contribution coming from FSH.[27] Sertoli cells normally stop proliferating at early puberty in rodents, and numbers remain static thereafter, but in mice lacking FSHR there is a postpubertal decline in Sertoli cell numbers.[27,113] This indicates that FSH is essential for maintaining Sertoli cell numbers postpubertally in mice, either through prevention of apoptosis or through maintenance of cell attachment to the basement membrane.[124] In rats, there is more evidence that FSH may play an important role postnatally in regulating Sertoli cell number. Neonatal treatment of intact rats with recombinant FSH, for example, will increase adult Sertoli cell numbers,[125] while neonatal suppression of FSH by passive immunization will decrease Sertoli cell number without affecting circulating androgen levels.[126]

The relative roles that FSH and androgen play in determining Sertoli cell numbers in other species is more difficult to determine as many of the treatments that affect one hormone (e.g., long-acting gonadotropin releasing hormone agonist [GnRHa] treatment) will also affect the other hormone, and specific genetic models are generally lacking. In sheep and pigs, for example, fetal hypophysectomy, fetal decapitation, or fetal GnRHa treatment[29,58,127–131] will decrease testicular weight in late fetal life or at birth[127,129] with a reduction in Sertoli cell number.[11,29,131] In anencephalic fetal humans, the testes are generally smaller, which is an indication that Sertoli cell number is probably reduced.[132–135] Similarly, treatment of fetal cynomolgus monkeys with GnRHa reduces testis size at birth,[136] indicating that gonadotropins are required for Sertoli cell proliferation in fetal life. AR is not expressed in the Sertoli cells in fetal primates/humans,[137,138] although, as we have seen in the mouse, androgens may still be essential for Sertoli cell development. Generally the data indicate that in all species, apart from rodents, pituitary gonadotropins are essential for fetal Sertoli cell development. It remains uncertain, however, whether FSH or (LH dependent) androgens

are of greater importance during this period. Postnatally, the increase in Sertoli cell number in primates and the subsequent quiescent period correlate with levels of circulating gonadotropins suggesting an obligatory role in Sertoli cell proliferation.[139] Certainly, in the juvenile period of primate development current evidence suggests that both FSH and LH/testosterone will stimulate Sertoli cell proliferation leading up to puberty.[140–142] Evidence from adult humans lacking FSH indicates that there is a reduction in Sertoli cell number[143] in these individuals, though, again, changes in androgen levels may contribute to any reduction in Sertoli cell number.

It is now also clear that thyroid hormone (TH) is involved in the establishment of final Sertoli cell numbers. Sertoli cells express TH receptors,[144–147] and it has been shown that transient neonatal/prepubertal hypothyroidism delays Sertoli cell final maturation, prolongs the period of Sertoli cell proliferation, and leads to an increase in the final Sertoli cell number in the adult testis.[145,148–150] High circulating TH during the same period has an opposite effect, leading to premature Sertoli cell maturation, an end to Sertoli cell proliferation and smaller adult testes.[151,152] The effects of TH on the Sertoli cells are through the α1 isoform of the receptor and appear to be mediated through regulation of the Cyclin-dependent kinase 4/Jun D proto-oncogene/c-myc pathway.[153] Other effects of TH occur through an increase in the levels of connexion 43 (Cx43), the major testicular gap junction protein and a powerful regulator of Sertoli cell maturation.[154,155] Effects of TH on Sertoli cell proliferation have also been seen in other species,[156–158] and in the prepubertal human thyroid failure is associated with testicular enlargement.[159,160] It is clear therefore that TH, and triiodothyronine in particular, acts to regulate Sertoli cell development, although it could be argued that this is a general permissive effect of the hormone—the difference with gonadotropins, for example, being that lack of LH and/or FSH has specific effects on gonadal development while lack of TH affects multiple body systems.

Finally, there are data to suggest that locally produced activins may regulate Sertoli cell proliferation in vitro,[161–163] while local knockout of testicular activin A, or downstream components of the transforming growth factor (TGFβ) signaling pathway, reduces Sertoli cell proliferation.[164]

Sertoli Cell Function during Development

REGULATION OF TESTIS DEVELOPMENT

The question of what Sertoli cells do during testis development is particularly interesting and one to which we do not yet have a clear and complete answer. Initial testis differentiation is a story of Sertoli cell differentiation as described in Chapter 7, and this depends on sex determining region Y (SRY), SRY-box 9 (SOX9), and nuclear receptor subfamily 5A1 (NR5A1).[165,166] Since the Sertoli cell is the only cell type that requires the male-specific sex-determining factor SRY,[167] it is generally assumed that the Sertoli cell then orchestrates subsequent testicular development. For some early events such as sex cord development this appears self-evident, and there is good evidence to suggest that the Sertoli cells are involved in fetal Leydig cell and peritubular myoid cell recruitment through secretion of DHH.[81,168–171] This is unlikely to represent the whole story, however, since it has been shown that the Aristaless related homeobox gene (ARX) is required for fetal Leydig cell differentiation[172] and ARX expression is limited to peritubular myoid cells, endothelial cells, and fibroblast-like cells in the fetal testis. Sertoli cells may also act to ensure that germ cells in the testis follow a male pattern of development and do not enter into meiosis through expression of CYP26B1,[173] although this enzyme is also expressed in the fetal peritubular myoid cells[174,175] (see below).

The role that the Sertoli cell population plays in stimulating the major landmarks of testis development following differentiation, and its importance in maintaining testicular structure up until puberty, is unclear. Evidence for a continued orchestrating role for Sertoli cells beyond initial testis development is patchy, and other somatic cell types of the testis may play important functions in regulating development. For example, it is likely (though it has not been shown) that the Sertoli cells are essential for differentiation of the spermatogonial stem cells, through formation of Sertoli cell niches (see below), and it is clear that they regulate and maintain subsequent spermatogenesis. It remains uncertain, however, whether the Sertoli cells are essential for the activity of the fetal Leydig cells during the pituitary-independent phase of development, whether they trigger development of the adult Leydig cell population, whether they play any role in maintenance and function of the mature Leydig cells, or, indeed, whether they act to limit Leydig cell precursor differentiation.

Recent studies of gonadal differentiation/identity have highlighted the interrelationship between the Sertoli cell and the ovarian granulosa cell and have provided some further clues to the role of the Sertoli cell in testis development. It has been shown that deletion of a single factor, Forkhead box L2 (FOXL2), leads to reprogramming of granulosa cells into Sertoli-like cells,[176] even in adult animals, with some evidence that the reverse reprogramming can also occur following deletion of Doublesex and mab-3-related transcription factor 1 (DMRT1) in Sertoli cells.[177] Interestingly, reprogramming of granulosa cells into Sertoli cells in the adult animal is also associated with an apparent transformation of the theca cells to Leydig cells. This transformation may be a direct consequence of FOXL2 depletion in the theca cells but may also be a consequence of Sertoli cell

differentiation, suggesting that Sertoli/granulosa cells regulate theca/Leydig cell fate. There is also some older evidence to suggest that the adult Sertoli cells can regulate Leydig cell function following differentiation,[178,179] although whether this regulation is of physiological importance in the adult is not clear. Finally, there is one study suggesting that Sertoli cells are required for Leydig cell survival in the longer term.[180] This evidence comes from B-cell CLL/lymphoma 2-like 2 (BCL2L2)-deficient mice, which gradually lose Sertoli cells up to 6–8 months of age and then become depleted of Leydig cells. Since BCL2L2 is not expressed in Leydig cells, this suggests that Sertoli cells may act to maintain the adult Leydig cell population. Evidence exists, therefore, to implicate the Sertoli cells in most aspects of testis development and function, but in all cases this evidence remains far from conclusive.

CHANGING SERTOLI CELL ACTIVITY DURING DEVELOPMENT

During the period of Sertoli cell proliferation, which lasts from initial testis differentiation until near puberty in most species (with or without a quiescent interval), Sertoli cell functional activity is generally low. As the cells stop proliferating, the activity associated with specific differentiated function increases markedly and the cells start to develop the junctional complexes associated with adult Sertoli cells. This can be seen in Figure 14.5 where changing expression of putative Sertoli cell-specific mRNA transcripts in the testis is shown during postnatal development in the mouse. Expression of all transcripts is low until about days 5–7, and as Sertoli cell proliferation comes to an end transcript levels increase markedly. The one notable exception is AMH, which is secreted early in Sertoli cell differentiation and then decreases as the Sertoli cells mature and become androgen sensitive through expression of the AR.[182–184] A critical step in testis development, therefore, is the Sertoli cell switch from a proliferative cell to one showing specific, active, differentiated function. Normal maturation of the Sertoli cells is likely to be androgen dependent as precocious expression of the AR in Sertoli cells appears to accelerate developmental changes, while Sertoli cell-specific knockout of the AR reduces adult transcript levels.[115,185] Another essential factor in the process of Sertoli cell maturation appears to be retinoblastoma protein (Rb), since mice lacking Rb in the Sertoli cells show continued cycling activity and reduced differentiated function.[186] Maturation of Sertoli cells also requires testicular expression of NR5A1[187] while, interestingly, adult cx43-deficient Sertoli cells seem to proliferate while maintaining expression of mature markers.[188]

THE SERTOLI CELL BARRIER

Sertoli cells are typical epithelial cells in that they sit on a basement membrane, attached by hemidesmosome junctions, but they differ in the mature animal by the presence of specialized junctions between adjacent Sertoli cells near to the basement membrane. These junctions form the blood–testis barrier (or Sertoli cell barrier), which acts to restrict movement into the seminiferous tubules and allows the Sertoli cells to regulate the internal environment of the tubules.[189] The structures of these junctional complexes in the Sertoli cells have been covered in a series of excellent recent reviews, particularly from Cheng et al.[189–192] The blood–testis barrier develops in rodents between 15 and 19 days,[193–195] shortly before spermatocytes enter the first meiotic division. Formation of the barrier is an essential step in development of spermatogenesis. Any delay will prevent the onset of meiosis,[195,196] while disruption of the barrier in the adult leads to infertility due to an inability of the spermatogonia to differentiate into spermatocytes.[197,198] The actin filament

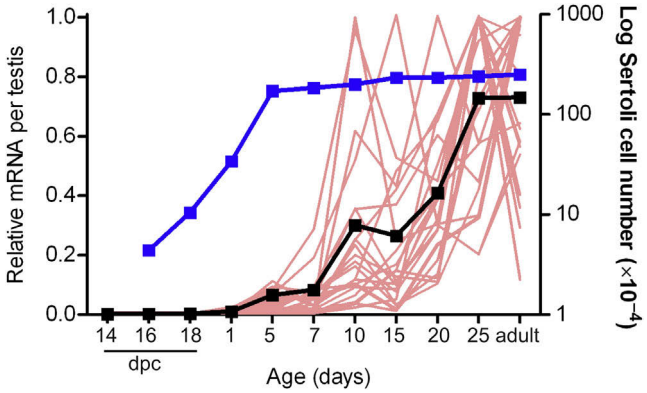

FIGURE 14.5 Changes in Sertoli cell number and transcriptional activity during fetal and pubertal development in the mouse. Data show that Sertoli cell number increases exponentially during fetal development, reaching a maximum before puberty. Sertoli cell activity, in terms of mRNA transcript levels, is shown as thin lines with each line representing a specific Sertoli cell transcript. The thick black line is the mean level of all transcripts combined. Results show that transcript levels start to rise markedly as Sertoli cell proliferation comes to an end. Days postconception (dpc). *Source: Data is taken from Refs 25,26,113,181.*

crosslinker, filamin A, appears to be a critical regulator of blood–testis barrier development through recruitment of adhesion protein complexes (e.g., F11 receptor (tight junction protein 1) and N-cadherin-beta-catenin) and reorganization of actin filaments at the basal ectoplasmic specializations.[199] It is also likely that filamin A works with other actin binding and regulatory proteins to control the assembly of the blood–testis barrier during development and during spermatogenesis.[189,200–203]

Regulation of Peripubertal Sertoli Cell Development and Maturation

ACTIONS OF FSH AND ANDROGEN ON THE SERTOLI CELL

Early studies of the effects of hypophysectomy and hormone replacement identified FSH and testosterone as critical regulators of spermatogenesis.[204–206] Subsequently, in the 1970 and 1980s, and despite occasional reports to the contrary, it was shown that receptors for FSH and androgen are not expressed in the germ cells and that these hormones act through their effects on the Sertoli cells.[120,207–209] More recently, it has also become clear that androgen action through the peritubular myoid cells is an essential requirement for Sertoli cell function and spermatogenesis.[77]

EFFECTS OF FSH With respect to hormonal control, there has been considerable debate about whether FSH or androgen is more important in terms of Sertoli cell development and initiation of spermatogenesis. Over the last decade or so, however, study of mutant and transgenic mice has allowed us to determine the role that each of these hormones plays in these processes, at least in the mouse. At the most basic level, mice lacking the FSHβ subunit or the FSHR are fertile, albeit with a reduced germ cell number, while animals lacking AR, either ubiquitously or specifically in the Sertoli cells are infertile.[27,115,210–216] More-detailed studies of adult animals have shown that FSH increases spermatogonial cell numbers and the entry of these cells into meiosis, while androgens increase the number of germ cells entering meiosis and, critically, enable these cells to complete meiosis.[214,216,217] In the adult, therefore, it is clear that androgens are more important for maintaining spermatogenesis and fertility, but FSH may play a more important role during the initiation of spermatogenesis.[27] In the normal animal, many germ cells undergo apoptosis at the spermatocyte stage during the first wave of spermatogenesis in an event that appears to be essential for subsequent normal adult spermatogenesis.[218] Current evidence suggests that FSH normally acts to limit the extent of the germ cell apoptosis during this first spermatogenic wave.[27,126,219] Whether increased germ cell apoptosis during the first spermatogenic wave in mice lacking FSH explains subsequent defects in adult spermatogenesis remains to be determined. Androgens are also reported to reduce spermatocyte apoptosis during this period,[220] but the effect is probably not mediated primarily through the Sertoli cells.[27]

While both FSH and androgen play essential roles in the control of Sertoli cell and germ cell development, the cellular mechanisms involved remain unclear. Early work showed that FSH would stimulate synthesis of a number of specific proteins such as androgen binding protein, inhibin, AR, transferrin, DMRT1, and inducible cAMP early repressor.[221–227] More recently, FSH has been shown to stimulate nociceptin production,[228] and it has been suggested that FSH regulates protein translation in Sertoli cells.[229] Two studies have used arrays to examine the effects of FSH on testicular transcript levels in the hypogonadal (*hpg*) mouse, which lacks circulating gonadotropins through a mutation in the GnRH gene.[230,231] While results showed that a number of putative Sertoli cell transcripts[232] are FSH sensitive, they did not identify clear mechanisms by which FSH may regulate germ cell development through the Sertoli cells.

One distinct effect of FSH that did emerge from the *hpg* arrays, however, was stimulation of Leydig cell transcript expression within 4 h of hormone treatment.[231] Since FSH receptors are only found on the Sertoli cells[233] and recombinant FSH was used for the studies (i.e., no contamination with other hormones), it must be assumed that FSH stimulation causes Sertoli cells to release a factor or factors that can stimulate Leydig cell development and function. This is a phenomenon that has been described a number of times; early studies with hypophysectomized rats showed that FSH treatment would stimulate androgen production[234–239] and increase Leydig cell numbers,[238,239] while similar effects could be seen in the *hpg* mouse[230,240,241] and in culture.[242] The effects of FSH in these rodent models appear to be largely on the steroidogenic pathway components, increasing enzyme levels and the capacity of the cells to produce androgen but without having a major acute effect on steroidogenic activity.[240] This indirect stimulatory effect of FSH on the Leydig cells is not restricted to rodent models. There is supporting in vitro evidence from rabbit, pig, and human Leydig/Sertoli cell cocultures[243–246] and limited human/primate in vivo evidence.[247–250] The in vivo human evidence is contradictory with two studies in favor[247,248] and one against the hypothesis,[249] but it should be pointed out that in all three human studies, under the same experimental conditions we would expect to see little or no effect in rodent models described herein. In other primates the in vivo evidence supports an indirect effect of FSH on Leydig cell function since FSH will act to increase circulating testosterone in the presence of constant LH.[250] However, while there is strong evidence for an indirect

effect of FSH on Leydig cell function mediated through the Sertoli cells, the developmental and physiological role of such an effect remains unclear and probably will remain so until the pathway is characterized. In terms of developmental relevance the evidence from transgenic mouse models and from human mutations is not particularly illuminating, but there are suggestions that the effects of FSH may be of importance to Leydig cell development. In FSHRKO mice, for example, both Leydig cell number and androgen levels are reduced, although Leydig cell numbers and androgen levels are normal in FSHβKO mice.[179] Of relevance, it has been reported that short-term immunoneutralization of FSH in adult rats will decrease Leydig cell function,[251] suggesting that in FSHβKO mice there may be long-term compensation for the loss of FSH that does not occur in the absence of the receptor. In humans, one adult individual with an FSHβ mutation has been shown to have prepubertal androgen levels despite high LH levels,[252] while in others with an inactivating FSHR mutation testosterone levels were in the low-normal range but with high LH.[253] While the nature of the factor or factors involved in Sertoli–Leydig communication remains unknown, it is likely that they are secreted by the Sertoli cell (there is no direct connection between Sertoli cells and Leydig cells) and, given the speed of the response, it is likely that they act directly in the Leydig cells.

EFFECTS OF ANDROGEN Despite early and abundant evidence that androgen action is required to ensure normal development of the seminiferous tubules, it is only recently that the potential mechanisms by which androgen may act to regulate this process have become more apparent. Early studies showed that androgens can affect Sertoli cell function in culture,[254] but these effects were not marked, and in many studies androgens did not appear to have any direct effect in vitro. More recently, however, a number of array studies have been carried out using a variety of mouse models that have identified potential mechanisms by which androgens may regulate Sertoli cell development and function.[181,255–258] Differences between the mouse models used (i.e., total or Sertoli cell only AR ablation) and the age of the animals studied has meant that there has been a wide variation in the regulated transcripts identified, but some common mechanisms of androgen action have emerged. These include retinoic acid metabolism, protease/protease-inhibitor balance, and development of cytoskeletal and junctional components.[3,259] It is this last action of androgens, on Sertoli cell junctions and blood–testis barrier formation, that has probably been most actively studied. Early work using the (androgen resistant) *Tfm* mouse indicated that the blood–testis barrier was defective in these animals,[260] while more recent studies have indicated that in mice lacking Sertoli cell ARs there is altered expression of junctional proteins leading to failure of an intact barrier to form.[261,262] Another study has also suggested, however, that in these Sertoli cell-specific ARKO mice the disturbances are more subtle, and a functional blood–testis barrier does form but the formation is delayed and partially disturbed.[263] Since androgen treatment of *hpg* mice will initiate tight junction formation[264] and development of a functional blood–testis barrier, it appears likely that androgens act through *both* the Sertoli cells and the peritubular myoid cells to induce normal and timely barrier formation.

One transcript that is consistently altered in transcript arrays of testes from AR-deficient mice is reproductive homeobox 5 (*Rhox5*). This gene is expressed specifically in Sertoli cells, and transcript levels rise markedly as the Sertoli cells come to the end of the proliferative phase.[265,266] Targeted mutation of RHOX5 in male mice leads to subfertility, which is marked by increased germ cell apoptosis, a reduction in sperm number, and reduced sperm motility.[267] More recent studies suggest that RHOX5 serves as an intermediate transcription factor that directs some of the actions of the AR.[268] Activation of RHOX5 by androgens depends on the chromatin-remodeling protein ATRX,[45] which may also have a general role to enhance the expression of androgen-dependent genes through physical interaction with AR. An interesting recent observation that androgens regulate the production of several specific microRNAs by the Sertoli cells[269] may offer an alternative/additional mechanism of androgen action in these cells.

OTHER FACTORS

In addition to FSH and androgen, other hormones and growth factors have been reported to alter Sertoli cell function including, notably, TH and the TGFβ superfamily.[270,271] Most recently, it has been shown that microRNAs are essential for postnatal Sertoli cell development.[272–274] Sertoli cell deletion of Dicer, an enzyme essential for processing microRNAs into their mature form, leads to defective Sertoli cell development and massive apoptosis starting around postnatal day 3.[272,273] This would suggest that miRNAs are essential either for regulating the apoptotic pathway during Sertoli cell development or that dicer, itself, may be required for the establishment of differentiation-dependent heterochromatin marks.

The Leydig Cell

Fetal Leydig Cells

It has been shown that LH will stimulate fetal Leydig cell androgen production in the mouse,[275–277] but *hpg* mice (which lack circulating gonadotropins), LuRKO mice (which lack the LH receptor), and LHβKO

mice (which lack LH) are normally masculinized at birth[114,278–280] with normal intratesticular levels of testosterone.[112,281] This shows that LH is not required during fetal development in mice for normal activity of the fetal Leydig cells. Available evidence would also suggest that fetal Leydig cell development in rats is largely independent of LH stimulation. LH secretion into the circulation, for example, does not start in significant levels until 19.5 dpc, by which time testosterone levels have already reached a peak,[277,282] while fetal decapitation before 19.5 dpc does not significantly affect testosterone levels.[283,284]

Interestingly, in NK2 homeobox 1 (NKX2-1)-null mice (which lack a pituitary gland), intratesticular androgen levels are reduced significantly at birth,[285] suggesting that other pituitary hormones may stimulate fetal Leydig cell function in the absence of LH. ACTH has subsequently been shown to stimulate fetal Leydig cells directly,[276,286] but double knockout mice lacking ACTH and the LH receptor have normal testosterone levels during fetal development.[3] Currently there is no evidence that other pituitary hormones can stimulate fetal Leydig cell function, and it appears more likely that reduced androgen production in NKX2-1-null mice is related to other effects of NKX2-1 depletion.[11] This suggests that androgen production by the fetal Leydig cells in the mouse is either constitutive or is regulated by other endocrine or local trophic factors. A number of factors have been reported that will stimulate fetal Leydig cell activity. These include vasoactive intestinal peptide, adenylate cyclase activating polypeptide 1, and corticotropin releasing hormone,[277,287] though, as we have seen with LH and ACTH, this is no guarantee that they are physiologically essential. An alternative, endocrine factor that may be involved in fetal Leydig cell function is osteocalcin. This bone-derived hormone, secreted by osteoblasts, acts through the G-protein-coupled receptor 6A (GPRC6A) (see below)[288] and has been shown to play a significant role in regulating Leydig cell function in the adult. It is not known whether *Gprc6A* is expressed in fetal Leydig cells or whether osteocalcin affects Leydig cell activity, but it is of interest that in GPRC6A-null mice the anogenital distance (AGD) is reduced in adults.[289] AGD is a measure of androgen exposure during fetal life and is set at that time, so a reduced adult AGD is indicative of reduced fetal androgen levels in mice lacking GPRC6A.[290]

The alternative possibility, that constitutive activity may be of importance during fetal Leydig cell development, has also been strengthened recently by the suggestion that steroidogenesis in these cells is driven by an effective increase in NR5A1 stimulation following downregulation of the competitor Chicken Ovalbumin Upstream Promoter-Transcription Factor II (COUP-TFII), an orphan nuclear receptor of the steroid/thyroid hormone receptor superfamily.[291,292] This study also suggested that factors that reduce fetal testosterone production (such as xenotoxicants) may do so through increasing expression of COUP-TFII in the fetal Leydig cells.[291]

Based on the timing of external masculinization and development of the hypothalamic–pituitary axis, data available from the boar, rabbit, stallion, bull, ram, and dog would suggest that fetal Leydig cell function also develops, at least initially, without a need for LH stimulation in these species.[11] Unlike rodents, however, the available evidence suggests that the fetal Leydig cells become pituitary dependent (probably meaning LH dependent) during the second half of gestation. The evidence for this comes from studies using fetal hypophysectomy, fetal decapitation, and treatment with GnRH analogs.[29,58,129,130,293,294] As a general rule, therefore, it appears that in most mammals the fetal Leydig cells go through an initial pituitary-independent phase and then become pituitary dependent later in gestation (Figure 14.4). In humans, however, it is clear that fetal Leydig cell development is critically dependent upon stimulation through LH receptors for most of fetal development. XY individuals with an inactivating mutation of the LH receptor are pseudohermaphrodites, indicating lack of androgen production in fetal life—particularly during the critical masculinization programming window (MPW).[295–300] This contrasts to individuals with an inactivating mutation in the LHβ gene in which fetal masculinization and testis descent takes place,[301,302] indicating that hCG (which acts through the LH receptor) is the main regulator of fetal Leydig cell function during the first and second trimesters.[301–303] Interestingly, in individuals lacking functional LH receptors, epididymidal remnants remain,[295,298] suggesting that the fetal Leydig cells probably go through an early period in the MPW (which probably starts late in the first trimester in humans[300]) when they can function independently of LH/hCG. This is supported by in vitro studies which have shown that testes from first-trimester human fetuses will show significant testosterone production in the absence of LH.[304] Fetal testosterone levels in vivo peak early in the second trimester in humans, shortly after the peak in hCG,[290,305,306] and then decline slowly over the second trimester.[306] Pituitary LH starts being released into the circulation in significant amounts during the second trimester,[11,290,305–309] and it is likely that the Leydig cells become dependent on this LH as the hCG levels decline. Evidence for LH dependency during this period comes from anencephalic humans in which an apparent loss of fetal Leydig cells occurs during the late second and third trimesters.[310] In addition, the external genitalia are often small in newborn anencephalics,[132–135] which is consistent with reduced testosterone levels in the third trimester, a period essential for androgen-dependent growth of the penis.[290] Evidence from the rhesus monkey has also shown that hypophysectomy in the last third of gestation reduces the overall percentage of Leydig cells at term.[311]

In a number of species, including the human, monkey, and the pig, there is activation of the hypothalamic–pituitary–testicular axis shortly after birth, leading to increased LH and a sharp transient rise in fetal/neonatal Leydig cell activity and circulating androgen levels[312–315] (Figure 14.4). It has been suggested that this surge in androgen may play a role in imprinting sexual orientation and behavior and priming target tissues for subsequent growth and maturation.[316]

It is likely that at least some fetal Leydig cells share a common origin with fetal adrenal cells,[317] and, consistent with this, both cell types show a high degree of overlap in the pattern of transcript expression. This includes expression of the ACTH receptor *Mc2r*[286] and the "adrenal" enzymes cytochrome P450, family 11, subfamily B, polypeptide 1 (*Cyp11b1*) and cytochrome P450, family 21, subfamily A, polypeptide 1 (*Cyp21a1*)[286,317–319] in the fetal Leydig cells. Interestingly, it has also been shown that steroidogenic cells can migrate from the adrenal to the testis during early gonadal development,[320,321] and a population of cells can be identified in the fetal testis, which is more characteristically "adrenocortical" than "Leydig",[321] although the origin of these cells and their relationship to the canonical Leydig cells remains to be determined. In humans with congenital adrenal hyperplasia there is, commonly, development of testicular tumors that resemble adrenocortical tissue.[322] These adrenal rest tumors may arise from the ectopic adrenal cells in the testis through stimulation by the high levels of ACTH that are associated with this condition.[322]

The fate of the fetal Leydig cells in the adult testis remains unclear. In terms of overall cell numbers, fetal Leydig cells present in the neonatal mouse testis are just over 1% of the total number of Leydig cells present in the adult testis,[25] and so the fetal cells may persist, largely unnoticed, in the adult testis.[171,323] Alternatively, they may degenerate as the adult Leydig cells develop,[324,325] but clear evidence either way is currently lacking.

Steroidogenic Pathways in the Developing Testis

In the adult testis the Leydig cells synthesize testosterone through the Δ^4 or Δ^5 pathway shown in Figure 14.6. The particular pathway used is species dependent (e.g., the mouse and rat use Δ^4 predominantly, while dog, pig, rabbit, and human use Δ^5)[326–331] and the Leydig cells are self-sufficient in that they express all of the enzymes necessary for testosterone production. Androgen production in the fetal testis, however, appears to be a more complex process, at least in the mouse and the human.

In the mouse, the final step in testosterone synthesis is reduction of androstenedione catalyzed in the testis largely by the enzyme HSD17B3. Two separate studies have now shown that fetal Leydig cells in the mouse lack HSD17B3 and that these cells are unable to synthesize testosterone.[332,333] Instead, androstenedione produced by the fetal Leydig cells is converted to testosterone by HSD17B3 in the Sertoli cells.[332,333] It is not clear whether this two-cell pathway is specific to the mouse or is more generally utilized, but it is of interest from an evolutionary perspective. It has been proposed, for example, that the Leydig cells evolved relatively late in the vertebrate testis and that prior to this the Sertoli cells were the major steroidogenic cell type.[334,335] Under this scenario, once the Leydig cells evolved (perhaps from modified adrenal cells) the Sertoli cells lost most of their steroidogenic

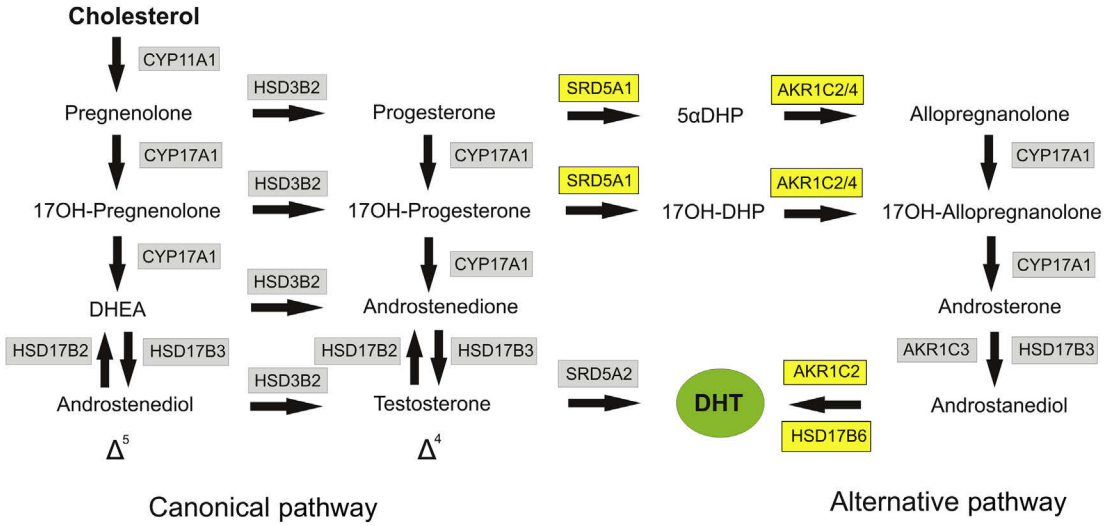

FIGURE 14.6 Potential steroidogenic pathways leading to formation of dihydrotestosterone (DHT) in the testis. The canonical pathway through Δ^4 and Δ^5 steroids is shown on the left with the alternative (backdoor) pathway on the right. Enzymes shaded in gray are required for the canonical pathway (with a number also required for the alternative pathway). Enzymes boxed in black are specific to the alternative pathway.

potential, although in the fetal mouse testis at least, they remain a critical component in the production of bioactive androgen.

Another peculiarity of fetal androgen production is the use of the "backdoor/alternative" pathway by the human fetal testis. In 2003 a novel testicular biosynthetic pathway was described in the tammar wallaby, which generated the potent bioactive androgen dihydrotestosterone without using testosterone as an intermediate[336,337] (Figure 14.6). The relevance of this pathway to human testicular function and fetal masculinization became clear when disordered sexual development in a number of XY individuals was shown to be linked to mutations in *AKR1C2* and *AKR1C4* that encode critical enzymes within the alternative pathway[338] (Figure 14.6). Results from this study indicate that both pathways of testicular androgen biosynthesis are essential for normal human masculinization.[338] Interestingly, the alternative backdoor pathway to androgen synthesis is present in the pubertal mouse testis but not the fetal mouse testis,[333,339] while *AKR1C2* and *AKR1C4* are not expressed in the adult mouse testis.[338] This suggests that the alternative testicular pathway to androgen synthesis is probably widespread in mammals, but the importance of it during fetal development may be species dependent.

Adult Leydig Cells

The development of the adult Leydig cells has been described in some detail in a number of publications.[61,340–344] The cells start to differentiate from stem cells at some point after birth and before puberty, the timing depending on the species. In mice we can time the initial differentiation fairly accurately to around seven days after birth. This comes from studies in which fetal Leydig cell expression of *Insl3* was inhibited by exposure to estradiol in utero.[53] After birth, expression of insulin-like 3 (*Insl3*) can be seen again at seven days, indicating differentiation of the adult Leydig cell population. It could be argued that exposure to estradiol may have altered adult Leydig cell development, but the overall timing fits in with expression of hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 6 (*Hsd3b6*), a marker of adult Leydig cells, which starts at about day 10.[52] The adult Leydig cell progenitor cells are small, spindle-shaped fibroblast-like cells that develop over the course of pubertal development into easily recognizable polygonal Leydig cells.[342] The origin of these progenitor cells is likely to be the peritubular region, although there may also be some that originate from the perivasculature.[341,345–349] The progenitor cells express some steroidogenic enzyme mRNA transcripts but appear to lack transcripts encoding the LH receptor.[342] As the progenitor cells develop, they enlarge, take on a rounder appearance that is associated with an increase in smooth endoplasmic reticulum, and start to express higher levels of the enzymes required for androgen synthesis.[343,344,350–352] Final maturity of the Leydig cells in rodents occurs during puberty, and these cells do not appear to undergo further cell division,[353] although the adult Leydig cell population will regenerate from stem cells if a significant number of the mature cells are destroyed.[354,355]

Control of adult Leydig cell development remains an area of uncertainty. We are beginning to understand some of the processes involved, but that understanding is very patchy and large areas of uncertainty remain. For example, there is good evidence that platelet-derived growth factors (PDGFs) (and especially PDGFA) are required for adult Leydig cell differentiation,[356–358] but PDGFA is localized to most of the testicular somatic cells[359] and the particular cell–cell interactions involved are not certain. In DHH-null mice, and in rats with a mutation in the DHH gene, there is also failure of adult Leydig cell development although the effect in mice appears to be somewhat variable and strain dependent.[168,171,360] Interpretation of the role that both PDGFs and DHH play in the development of the adult Leydig cell population is also complicated by the effect that knockout of these factors has on early testis development. In both cases there is limited fetal Leydig cell development and/or a reduction in adult Leydig cell stem cells that may be the underlying cause of later defects in adult Leydig cell development. It is of interest, however, that putative Leydig cell stem cells will differentiate down a steroidogenic cell lineage when exposed to PDGF, LH, and other general growth factors.[292] Interesting data has also come from animals in which COUP-TFII has been deleted. If deletion occurs prior to puberty there is a clear and marked failure of adult Leydig cell development,[361] and it is suggested that this factor is involved in both development of Leydig cell progenitors and maturation of the differentiated cell.

In addition to a general uncertainty of the local factors that regulate adult Leydig cell differentiation, we do not know what stimulus drives the whole process—e.g., is there a change in the endocrine environment that initiates progenitor formation from the stem cell? It has been known for many years that LH is essential for adult Leydig cell development, and this can clearly be seen in mice which lack LH (*hpg* and LHβKO) or the LH receptor (LuRKO). In each case androgen levels are very low or undetectable[112,114,278,280,362] and Leydig cell number is markedly reduced.[25] Treatment of *hpg* mice with LH, in turn, has been shown to stimulate steroidogenesis and to induce Leydig cell proliferation.[362] Evidence from *hpg* and LuRKO mice suggests, however, that LH (and FSH) is not required for the initial differentiation of the adult Leydig cells since a number of cells in these animals will start expressing transcripts characteristic of the adult population in the absence of hormone treatment.[281,363]

In addition, the early pattern of adult Leydig cell development suggests that these cells start to show differentiated function before they become LH sensitive.[341] The evidence shows, therefore, that once Leydig cell differentiation has started LH is essential for completion of the process and for activity in the mature cells but that it does not initiate the process. The other major endocrine regulator of Leydig cell function that has been identified recently is bone-derived osteocalcin.[288] To date, published studies have shown that Leydig cell function is reduced in mice lacking osteocalcin, but Leydig cells clearly form in these animals so it is unlikely that osteocalcin is essential for the initial regulation of cell development.[288] Another endocrine factor that may be involved is thyroid hormone as both high and low circulating levels can have marked effects on adult Leydig cell development.[364–366] The nature of these effects suggests, however, that thyroid hormone probably plays a permissive role in normal Leydig cell development, as it does in the Sertoli cells, rather than acting as a trigger for the whole process. There is evidence to suggest that AMH may act as an inhibitory regulator of adult Leydig cell development as Leydig cell differentiation is reported to be reduced in AMH-overexpressing mice.[367] The normal prepubertal decrease in circulating AMH levels may, therefore, be necessary to allow normal Leydig cell development.[184]

Of compelling interest, with respect to Leydig cell development, are the large number of studies carried out using the cytotoxic drug ethane dimethane sulphonate (EDS), which specifically causes Leydig cells in the adult testis to undergo rapid apoptosis.[354,368] Over a three-to-four week period after EDS treatment, the Leydig cell population recovers in a process that appears to mimic normal adult Leydig cell development.[369] This powerful model has allowed us to examine the endocrine requirements for Leydig cell redevelopment more clearly[369] but has, so far, failed to identify what factors are inducing Leydig cell differentiation when the normal population is ablated. It appears likely, however, that this model, or something similar, offers the best current opportunity to understand control of Leydig cell development, particularly as it has been shown recently that some of the effects of EDS can be replicated in vitro.[355] Overall, the weight of available evidence would currently suggest that Leydig cell differentiation is most likely to be initiated by other somatic cells in the testis (the germ cells do not appear to be directly involved as adult Leydig cells develop in germ cell-free testes). Which particular cells are involved and how the cell–cell interactions take place are fundamental questions of testis biology that need to be addressed.

Peritubular Myoid Cells

The peritubular myoid cells have received considerably less research scrutiny than either the Leydig cells or the Sertoli cells (e.g., a PubMed search shows papers concerning myoid cells are about 5% of the total number of papers on testicular somatic cells), but it is likely that this cell type plays a fundamental role in testis development and function. Exactly what those functions are and how they are controlled is now starting to become clearer, largely through study of transgenic mice. We now know, for example, from study of peritubular myoid cell-specific ARKO mice that androgen action through the peritubular myoid cells is essential for normal Sertoli cell and Leydig cell development and for maintenance of spermatogenesis.[77,78] It has also been shown using knockout mice that DHH is required for normal peritubular myoid cell development, and in the absence of DHH there are multiple developmental abnormalities in the testis that may be related to abnormal peritubular myoid cell regulation.[171] Known functions of the cells include contractile activity that is involved in the transport of spermatozoa and testicular fluid through the seminiferous tubules, and a number of factors have been identified that can stimulate or inhibit this activity.[82] In rodents, another recognized function of the peritubular myoid cells is the significant contribution they make to the blood–testis barrier. Studies have shown that in up to 85% of tubules, markers of barrier integrity are blocked at the peritubular myoid cells layer and do not penetrate to the Sertoli cells.[370,371] In primates and probably humans, however, the barrier generated by the peritubular myoid cells appears to be less effective.[372] The presence of a barrier at the level of the peritubular myoid cells in rodents is also of interest as it is likely to inhibit free movement of large molecules between the interstitial compartment (and the blood and lymph) and the Sertoli cells, which may have implications for both endocrine and paracrine regulation in the testis. Another barrier-type role of the peritubular myoid cells may be to regulate movement of retinoic acid into the tubules through expression of CYP26B1. Retinoic acid in the seminiferous tubules can either enter from the interstitium or be synthesized in the Sertoli cells, and it is likely that levels are tightly regulated as both increased and decreased levels of retinoic acid are known to be deleterious to spermatogenesis.[373,374] In the postnatal testis CYP26B1 is localized exclusively in the peritubular myoid cells,[174,175] and the role of this enzyme may, therefore, be to prevent retinoic acid from the interstitium entering the tubules, thereby allowing the Sertoli cells to control intratubular levels. While a number of functions of the peritubular myoid cells are known or suspected, the mechanisms by which the peritubular myoid cells act to regulate Sertoli cell and Leydig cell function remain unknown and will constitute an interesting area of future research.

Testicular Macrophages

Given the intimate connections between macrophages and Leydig cells it is not surprising that macrophages have been postulated to play a role in Leydig cell development. For example, in experimental models with impaired macrophage function it has been reported that there is an absence or delay in Leydig cell development.[375,376] Similarly, depletion of macrophages from the neonatal testis prevents adult Leydig cell development.[375] It has also been reported that adult testosterone production is reduced when macrophages are removed from the testis,[377–380] and it has been suggested that the active factor in this case may be 25-hydroxycholesterol (a potential substrate for testosterone production) secreted by the macrophages.[381] Macrophage production of this sterol is greatest during the prepubertal period, so it may be an active factor in the developmental control of the adult Leydig cell population.[382] It has also been reported that macrophages can inhibit Leydig cell function through the production of nitric oxide, tumor necrosis factor, and/or interleukin-1,[383] although this may be of greater importance under pathological conditions. The characteristics and role of testicular macrophages are discussed further in Chapter 19.

GERM CELLS

Initiation of Spermatogenesis

During fetal development the gonocytes lie within the lumen of the seminiferous tubules, but at some point prior to the start of spermatogenesis they undergo proliferation, extend cytoplasmic processes, and migrate to the basement membrane.[384] This migration appears to be essential for germ cell survival as gonocytes remaining in the lumen of the tubules will undergo degeneration.[385] Once the gonocytes reach the basement membrane they will give rise to the SSCs (A-single spermatogonia; As) in rodents or part of the A-dark (Ad) and/or A-pale (Ap) spermatogonia in primates (see Chapter 15), which are able to undergo either self-renewal to maintain the SSC population or development into spermatogonial cells committed to differentiate into spermatozoa.[386,387] In rodents gonocyte migration/differentiation occurs soon after birth, while in humans it starts toward the end of the second trimester and lasts up to eight months postnatally.[388] The differentiation step from gonocyte to SSC is particularly important as it has been reported that carcinoma in situ cells arise from arrested/dysfunctional gonocytes.[389] The regulatory mechanisms involved in this process remain uncertain, but there is evidence that PDGFs are involved in the migration of the gonocytes,[390] and it has also been suggested that male germ cell miRNAs may act to coordinate the differentiation of gonocytes.[391] Once differentiated, the SSC sit next to the basement membrane in a niche that we assume is contributed to largely by the Sertoli cells, although, interestingly, SSC niches appear to be more frequent in areas of the tubule that border interstitial tissue.[392,393] This may be an indication that Leydig cells contribute to the niche through production of testosterone and possibly other factors,[394] or may simply be a consequence of the presence of blood vessels in the interstitium. Contributions from peritubular myoid cells to the SSC niche are also possible but remain speculative. Once committed, the SSC in rodents gives rise to a pair of a type A spermatogonia (Apr) connected by intercellular bridges, which in turn proliferate to form A-aligned (Aal) spermatogonia. Once spermatogonia become committed to spermatogenesis they undergo proliferation, which is followed by entry into meiosis as primary spermatocytes once the animals start puberty. SSC activity and the process of spermatogenesis are described in greater detail in Chapter 15.

TESTICULAR DEVELOPMENT AND ADULT HEALTH

This chapter started with the seminal studies of Jost who showed that the testes are essential for normal masculinization of the fetus. Studies since then have reinforced the reproductive importance of testis development, but evidence is now also accumulating to suggest that testis development may also have an importance for adult male health and well-being beyond reproductive health. A number of studies have shown, for example, that low adult testosterone is linked to increased incidence of metabolic syndrome (MetS)—a collective group of disorders that increase the likelihood of an individual developing cardiovascular disease, diabetes, and dementia during aging.[395–397] From prospective studies, androgen ablation studies, and testosterone-replacement therapy it is clear that in at least a number of these cases it is the reduction in testosterone that is likely to be causative.[398–402] While it remains to be established, it is highly likely that adult testosterone levels will be dependent on events during pubertal, prepubertal, and even fetal life. For example, it has been shown that AGD in men is significantly correlated with adult testosterone,[403] an effect also seen in rats.[404] This is highly relevant because AGD reflects fetal androgen exposure and is fixed by the time of birth,[299] so a correlation between AGD and adult testosterone levels suggests that adult levels may be dependent on fetal testosterone production. Other studies using sheep, rat, or nonhuman primate models have also shown that reducing Leydig cell function in fetal or neonatal life will reduce adult testosterone levels.[294,405–408] Understanding

of normal testicular development and the control mechanisms involved may, therefore, be essential for understanding processes in later life that can alter male health and well-being.

CONCLUSION

Correlation and integration of data from a number of species on the regulation of somatic cell proliferation and function during fetal and early neonatal life has led to the development of a general model of fetal testis development[11] (Figure 14.4). This model suggests that in all species there is an early period of fetal testicular growth that is independent of pituitary hormone stimulation. This lasts until about half to two-thirds of the way through pregnancy in most species and covers the MPW.[290,299] In the final third of gestation, both Sertoli cells and Leydig cells become pituitary dependent. Within this model rodents and humans have to be treated as special cases, and it is unfortunate that both ourselves, who have to be treated as the primary species of interest, and the model species for mechanistic development fall into this category. In rodents, gestation is short and the pups are born at the end of the pituitary-independent phase, just as the hypothalamic pituitary axis is starting to regulate testicular function. This means that rodents are not good models for the later period of fetal testicular development seen in most other species. Humans and a number of other primate species[409] secrete CG, and following a likely short period of constitutive function, the Leydig cells become highly CG dependent early in testis development. In the last third of gestation, however, CG levels fall markedly, and so the testes probably become LH dependent at this time although the role of FSH remains unclear. Since rodents are not a good model for the pituitary dependent phase of fetal testicular development, what we critically lack at the moment is a clear and detailed understanding of the importance of the fetal pituitary hormones for testicular development in utero and for programming later testicular function and male reproductive health. This chapter has highlighted the enormous progress that has been made in our understanding of testicular cell development and the role of endocrine and local factors in controlling that development. It has also, however, identified some of the more obvious and significant gaps in our knowledge that require to be filled. Outstanding questions include:

- How do the somatic cells interact to regulate testicular development and function?
- What functions do the Sertoli cells have in the period between early fetal and pubertal development?
- Do Sertoli cells regulate Leydig cells in the adult animals and, if so, how?
- What controls adult Leydig cell differentiation?
- What is the overall role of the peritubular myoid cells?
- What regulates gonocyte differentiation?
- How, and to what extent, do changes in fetal or neonatal testicular development alter adult reproductive health and adult well-being?

INTRODUCTION

Spermatogenesis is a highly organized process that produces millions of sperm each day in postpubertal mammals.[1–3] This productivity is dependent on the activity of spermatogonial stem cells (SSCs)—adult tissue stem cells in the testes that balance self-renewing divisions with differentiating divisions, which maintain the stem cell pool and fuel spermatogenesis, respectively.[4,5] When SSCs differentiate, they give rise to spermatogonia, which undergo a species-specific number of transit amplifying mitotic divisions, followed by two meiotic divisions and spermiogenesis, to produce terminally differentiated sperm (Figure 15.1(A)). SSCs reside in a specialized niche located on the basement membrane of the seminiferous tubules where they are in direct contact with Sertoli cells, which produce some of the paracrine factors required to regulate self-renewal and differentiation fate decisions (Figure 15.1(B) and (C)). Stem, progenitor, and differentiating spermatogonia are all located on the basement membrane of the seminiferous tubules. Differentiating spermatogonia give rise to spermatocytes that initiate meiosis and migrate off the basement membrane, producing spermatids and then sperm (Figure 15.1(C)).

Our current knowledge of the staging of spermatogenesis (discussed in more detail below), including multiple types of spermatogonia and their sequential differentiation, was established in the rat by Leblond and Clermont at McGill University (Montreal, Canada) in the early 1950s.[6,7] In these papers, the authors presented historical perspectives of spermatogenesis research; for example, the stages of the seminiferous epithelium cycle were first reported in 1885.[6] Furthermore, they clearly used the term *stem cells* in their 1952 paper: "These act as stem cells for the next generation. This theory, referred to as 'stem cell renewal,' is described in detail elsewhere."[6] This casual use of the terms *stem cells* and *renewal*, with no references cited, indicates that the concept of stem cells and associated terminology seemed to be relatively familiar to the researchers in the early 1950s.

In a 2007 article, Ramalho-Santos and Willenbring stated that "the early uses of the term stem cell were made in the late nineteenth century in the context of fundamental questions in embryology: the continuity of the germ-plasm and the origin of the blood system".[8] According to these authors, Pappenheim used the term *stem cell* in 1896 for the hematopoietic lineage in the same sense as we use it today.[9] Hematopoietic stem cells are often considered to be the criterion standard of stem

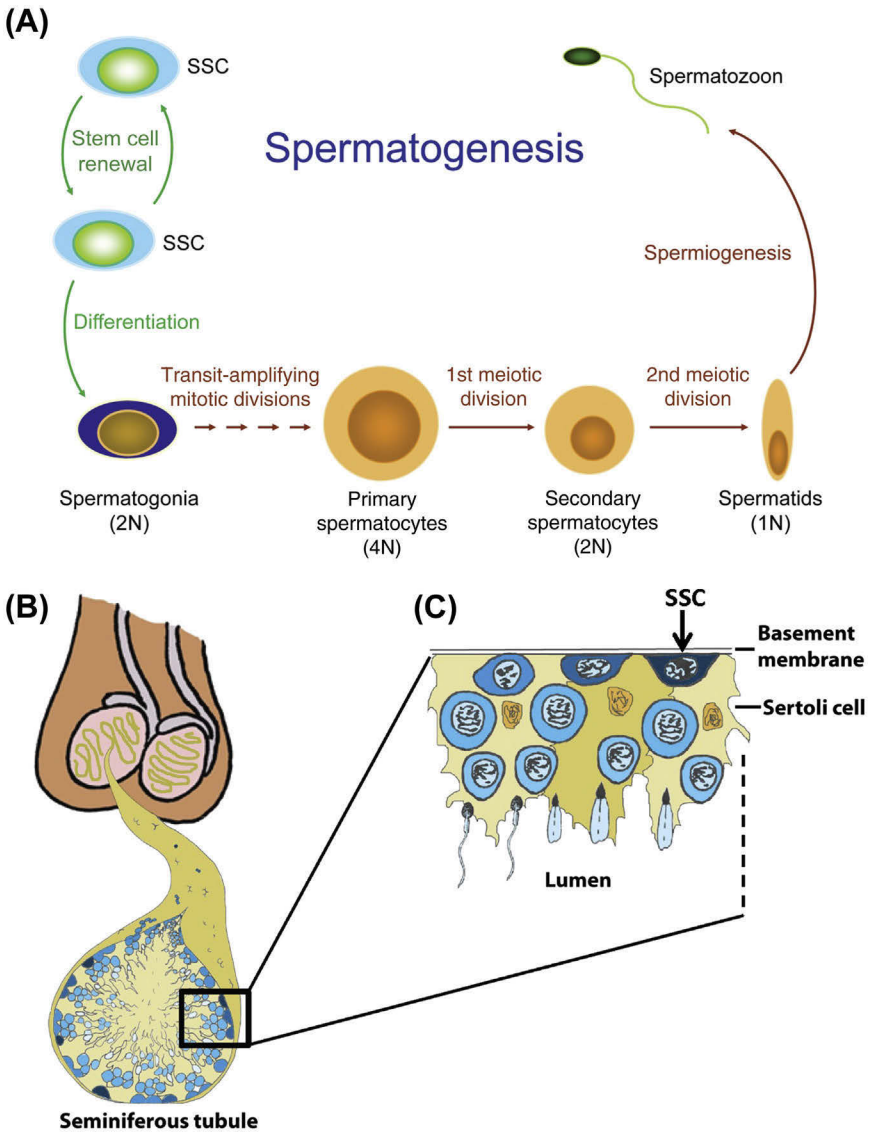

FIGURE 15.1 Mammalian spermatogenesis. (A) The pool of diploid (2N) spermatogonial stem cells (SSCs) balance self-renewing and differentiating divisions to maintain the stem cell pool and also continuously produce sperm. Once committed to differentiate, SSCs give rise to undifferentiated and differentiating spermatogonia (2N), which undergo a variable species-dependent number of transit-amplifying mitotic divisions that can dramatically increase the yield of sperm from a single stem cell. Differentiating spermatogonia give rise to primary spermatocytes (4N), which undergo two meiotic divisions to produce haploid spermatids (1N). The meiotic divisions are followed by spermiogenesis to produce terminally differentiated sperm. (B) Spermatogenesis takes place inside the seminiferous tubules of the testis. (C) Cut out of the seminiferous epithelium. Spermatogonia (including SSCs) located on the basement membrane of seminiferous tubules give rise to primary spermatocytes, which initiate meiosis and migrate off the basement membrane. Two meiotic divisions and spermiogenesis give rise sequentially to secondary spermatocytes, spermatids, and terminally differentiated sperm, which are released into the lumen of the seminiferous tubule. Adapted with permission from Valli et al., Ref 332.

cells, due to pioneering work by Till and McCulloch at the University of Toronto, Canada, which established the concept that stem cells are defined by their function.[10–13] We consider, however, that the concept of stem cells was initially proposed in studies of germ cells. In the 1940s, Leblond initiated autoradiographical investigations into stem cells mainly using spermatogenesis and the intestinal epithelia as a model.[14–17] Thus, we here wish to address when spermatogenesis was recognized as a stem cell system and when the term *spermatogonial stem cell* appeared for the first time in its research history.

Leblond and Clermont stated that "the complete series of successive cellular associations has been named the 'spermatogenic cycle' by von Ebner[18] and Regaud[19]" and that "Regaud in 1901 had already observed spermatogonia of two main types—currently referred to as A and B—the former (type A) being the more primitive which divided to produce the more differentiated type B cells which, in turn, divided to give rise to spermatocytes".[7,20]

When we look at von Ebner's paper from 1888,[18] we find the term *Stammzelle* ("stem cell" in German) but only as a reference and to clarify terminology, and the stem cell itself is not the subject of discussion. The paper he cited was by Biondi from 1885.[21] There, Biondi introduced the term *Stammzelle* for cells at the basal membrane (the first zone) and described how a stem cell divides to produce Mutterzelle (mother cell) in the 'second zone', which in turn produces two daughter cells (*Tochterzelle*) in the third zone, translated as follows: "The spermatozoa often arise, without the appearance of daughter cells, directly from the cells of the first (stem cell) and the second zones (mother cell); then, they protrude as a bundle all from one cell, with their heads closely together."[21] Biondi made these descriptions using rats based on the cell classification that he developed with bull testes and

concluded that spermatozoa are generated by the stem cell. We are, however, uncertain if Biondi identified spermatogonia as stem cells, because he concluded that "the basal nucleus of the Sertoli cell is exactly the same as the stem cell nucleus".[21]

On the other hand, Regaud[19] clearly used the term *stem spermatogonia*' in 1901, in the way we use the term today, as shown in the following translated excerpts from this paper:

"The term *spermatogonia* applies to several distinct generations, at least two. The more primitive—and hence the *origin* of the entire spermatogenic lineage—is formed of cells that possess very little cytoplasm and whose nuclei contain almost no chromatin; I have termed them dusty spermatogonia. Mitotic division of these cells (1st mitotic division) gives rise to a new generation, which I have termed crust spermatogonia, because during the interval between mitotic divisions, the chromatin of the nucleus is arranged like small crusts at its rim, initially safranophilic (stained with saffron), and subsequently hemateiphilic (stained with hemalun)."

Regaud further stated:[19]

"Let us suppose for a moment that, in a seminiferous tubule, the productivity of the seminal epithelium becomes arrested, that the 'developing' spermatogenic lineage completes its evolution (differentiation to spermatozoa) and that in the end, there remains within the syncytial protoplasm between the nuclei of Sertoli nothing save a small number of *stem spermatogonia* that must ensure the future repopulation of the epithelium."

Note that Regaud believed that Sertoli cells formed a syncytial structure and thus preferred calling them "the nurturing syncytium and the nuclei of Sertoli."[19] Interestingly, the cessation of spermatogenesis that Regaud proposes here is not a hypothetical premise, and he takes spermatogenesis in a seasonal breeder as one example. This makes us realize that Regaud considered the functionality of cells—regeneration—to define stem cells in spermatogenesis. Hence, Regaud identified morphological differences among spermatogonia in 1901 and expressed the concept of the cell of origin—the cells that allow for spermatogenic 'regeneration' after depletion of committed germ cells—by calling them *spermatogonies souches*, the exact term that means "stem spermatogonia" in French.

As Leblond and Clermont stated,[6] van Hoof confirmed in 1912 the sequence of spermatogonial differentiation that Regaud identified and also introduced the term *cellules de réserve pour la division suivante*, meaning "reserve cells for the next cell division."[22] This is, to our knowledge, the first introduction of the reserve stem cell concept. Further, van Hoof used the general term *stem cell* (rather than stem spermatogonia) in a phrase where he speculated the following, as translated: "But we do not believe that the stem cell divides only twice to give rise to such a large number of spermatocytes. We therefore think, as does Duesberg[23], that the number of cell divisions is greater than two."[22]

These pioneering papers indicate that researchers in the late 1800s, and at least in 1885 as seen in Biondi,[21] had a grasp of the stem cell concept, and the term *spermatogonial stem cells* was used by 1901 in the way we use it now. It is particularly striking to realize that Regaud's recognition of SSCs was based upon regenerative activity seen in a naturally occurring phenomenon of spermatogenic regeneration in seasonal breeders.

It is also interesting to note that the major descriptive observations of morphological development of spermatogonia presented in these papers survived over time and are very similar to those that we know today. In reading these papers, we further recognize the budding ideas and concepts that later evolved to various theories and models of spermatogonial development and stem cells proposed from the 1960s through early 1980s, most of which were put forth by the pupils of the spermatogenesis study group at McGill University that was founded by Charles Leblond.

In the section Spermatogonial Stem Cells and Spermatogenic Lineage Development of this chapter, we will review the seminal studies that established the models of SSCs and spermatogenic lineage development and provide the framework for our current understanding of mammalian spermatogenesis. We will also review how our current understanding of spermatogenic lineage development in nonhuman primates and humans is similar and how it is different than rodents. In the section Experimental Tools for Studying Spermatogonial Stem Cells, we will describe the experimental tools that are used to study SSCs and spermatogenic lineage development. We will discuss how data generated using those tools should be interpreted as well as the knowledge that has been generated. The section The Spermatogonial Stem Cell Niche will describe factors and cells contributing to the SSC niche and provide examples of how those components regulate SSC self-renewal and differentiation fate decisions. Intrinsic factors that regulate SSC function will be discussed in the section Molecular Mechanisms Governing SSC Developmental Fate to provide a molecular phenotype to the cell-based models of SSCs and spermatogenic lineage development. The section Spermatogonial Stem Cell Aging will discuss the mortality of SSCs and whether aging of SSCs and/or the SSC niche contribute to spermatogenic decline and the paternal age effect. Finally, the sections Transgenesis and Regenerative Potential of Spermatogonial Stem Cells and Translation to the Clinic will discuss ways in which the unique biology of SSCs can be exploited to produce transgenic animals and to treat male infertility.

SPERMATOGONIAL STEM CELLS AND SPERMATOGENIC LINEAGE DEVELOPMENT

Rodents

A_s Model of Spermatogonial Stem Cells

Working independently in the early 1970s, Huckins, Oakberg, and de Rooij proposed a linear model of spermatogenic lineage development for rodents, in which SSCs reside in a population of isolated spermatogonia located on the basement membrane of seminiferous tubules.[24–26] These cells were originally termed $A_{isolated}$ (A_{is}) or A_{stem} (A_s), but the terminology has gradually evolved and most investigators recognize A_{single} (A_s) as the term to describe stem cells in rodent testes. These A_s spermatogonia are rare, comprising 0.03% of all germ cells in the mouse testis;[5] they are evenly distributed along the basement membrane of seminiferous tubules, with a relatively large nuclear to cytoplasmic ratio and diffuse chromatin (lacking heterochromatin). A_s spermatogonia divide to produce A_{paired} (A_{pr}) spermatogonia that either undergo complete cytokinesis to produce two new A_s spermatogonia (self-renewal) or remain connected by an intercytoplasmic bridge and produce a chain of four $A_{aligned}$ (A_{al4}) spermatogonia at the next division. The A_{pr} to A_{al4} transition is considered by many in the field to represent a commitment to differentiate because there is no unequivocal evidence that A_{al} spermatogonia fragment to produce new A_s under steady-state conditions[5,27–32] (Figure 15.2(B)). Successive divisions produce chains of 8, 16, and

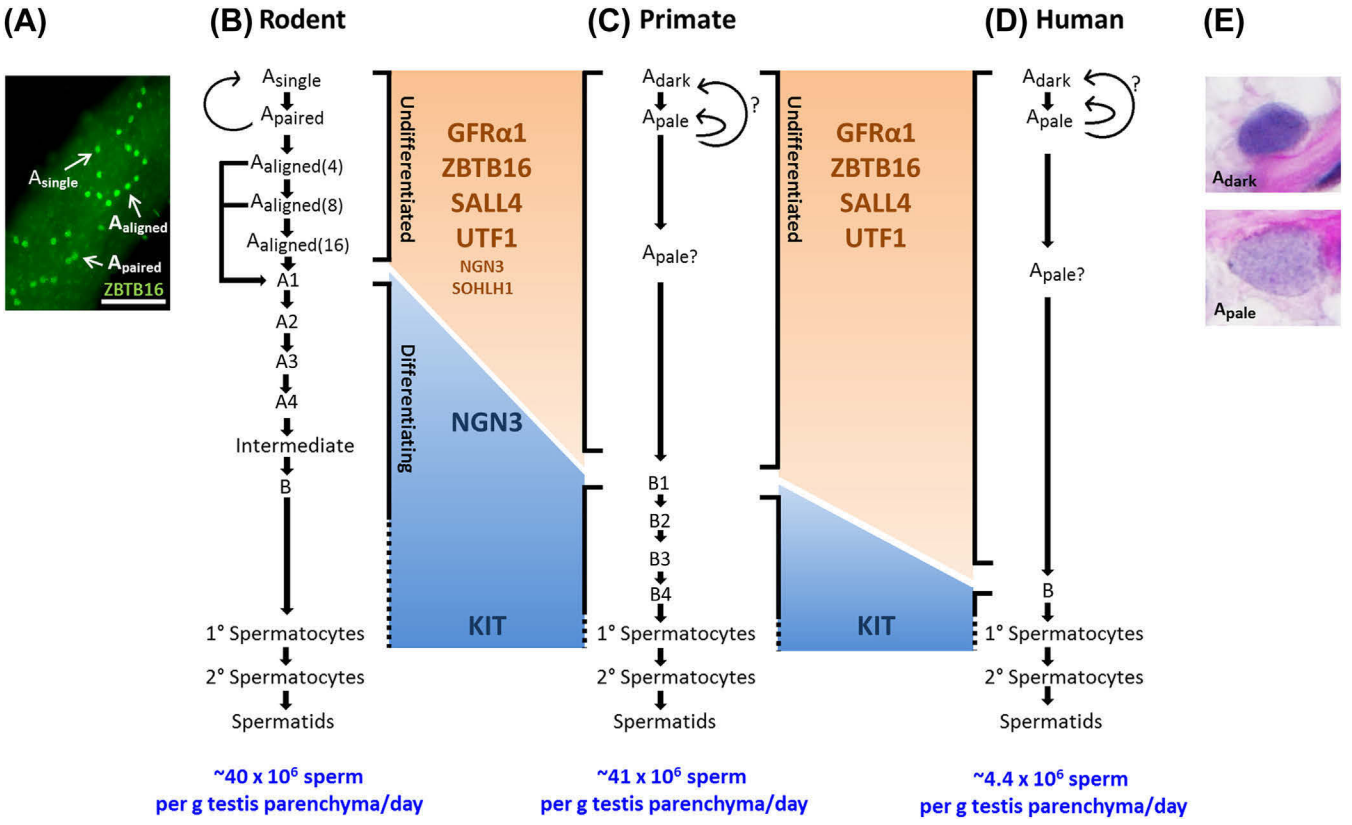

FIGURE 15.2 Current model of rodent, nonhuman primate, and human spermatogenesis. This figure is reproduced in color in the color plate section. (A) Whole-mount immunohistochemistry staining for ZBTB16 in adult mouse seminiferous tubules. ZBTB16$^+$ spermatogonia are identified as A_{single}, A_{paired} or $A_{aligned}$. Scale bar = 100 μm. (B) Rodent undifferentiated spermatogonia, including the SSC pool, is comprised of A_{single} and some A_{paired} spermatogonia and based on whole-mount staining analysis their phenotype is of GFRα1$^+$, ZBTB16$^+$, SALL4$^+$, UTF1$^+$, NGN3$^{+/-}$, and KIT$^-$. Transit amplifying progenitors include some A_{paired} spermatogonia and $A_{aligned}$ spermatogonia (chains of 4–16 cells), with a phenotype of GFRα1$^+$, ZBTB16$^+$, SALL4$^+$, UTF1$^+$, NGN3$^{+/-}$, and KIT$^{+/-}$. The differentiating spermatogonia that are made up of A1–A4, intermediate, and B spermatognia have a phenotype of GFRα1$^-$, ZBTB16$^-$, SALL4$^-$, UTF1$^-$, NGN3$^{+/-}$, and KIT$^+$. (C and D) In nonhuman primate and human testis, the undifferentiated spermatogonia are the type A spermatogonia that are designated A_{dark} and A_{pale} based on nuclear staining intensity with hematoxylin. The B spermatogonia are considered to be the differentiating spermatogonia and in nonhuman primates; they go through four divisions before producing primary spermatocytes, whereas in human there is only one division of B spermatogonia. (E) Sections of human testis stained using periodic acid-Shiff method and counterstained with hematoxylin to show nuclear morphology. ZBTB16, zinc finger and BTB domain containing 16; GFRα1, GDNF family receptor alpha-1; UTF1, undifferentiated embryonic cell transcription factor 1; SALL4, Sal-like 4; NGN3, neurogenin 3; SOHLH1, spermatogenesis and oogenesis specific helix-loop-helix 1. *Adapted from Ref. 75.*

sometimes 32 A_{al} spermatogonia. The synchronized development of spermatogonial clones is facilitated by protein and messenger RNA exchange via the intercytoplasmic bridges that connect the individual cells.[33] Types A_s, A_{pr}, and A_{al} spermatogonia are collectively termed type $A_{undifferentiated}$ (A_{undiff}) spermatogonia (Figure 15.2(B)) and may also appropriately be termed stem and progenitor spermatogonia. Here, we define "stem cells" as cells that have a virtually unlimited capacity for self-renewal and differentiation and "progenitors" as cells that have an undifferentiated appearance but a limited capacity to undergo self-renewing divisions before differentiating.

A precise balance between the self-renewal and differentiation fates among the population of A_{pr} spermatogonia would in principle provide the basis for homeostatic maintenance of the stem cell pool and continuous sperm production. Indeed, Huckins[34] observed after labeling with [^{3}H]-thymidine, "Many of these pairs were subsequently seen to divide again in a second wave of labeled mitoses to form a chain of A_{al} spermatogonia. On the other hand, other daughter cells of A_{is} divisions became separated from one another, and were therefore classified as two new A_{is} spermatogonia". Nakagawa and colleagues recently suggested that the stem cell pool might be expanded to include A_{al4} and possibly larger chains and that these larger clones may fragment to contribute to renewal of A_s spermatogonia and, thus, the stem cell pool. This mode of self-renewal was rarely observed under normal circumstances but occurred more frequently under conditions of regeneration during recovery from cytotoxic damage.[35,36]

Although A_s and A_{pr} spermatogonia are evenly distributed along the basement membrane of the seminiferous epithelium, the differentiation of A_{al} spermatogonia into A1 spermatogonia occurs at specific intervals along the seminiferous tubules and these intervals define the cycle of the seminiferous epithelium.[37,38] One complete cycle of the mouse seminiferous epithelium is depicted in Figure 15.3 and is comprised of 12 stages that are defined by specific associations of spermatogonia, spermatocytes, spermatids, and sperm. Differentiation to type A1 spermatogonia typically occurs from A_{al} chains of 4, 8, or 16 and always occurs at stage VIII of the seminiferous epithelium cycle in mice. This transition initiates a wave of spermatogenesis and is marked by reduced expression of stem and progenitor (A_{undiff}) markers such as GFRα1 (GDNF family receptor alpha-1) and ZBTB16 (zinc finger and BTB domain containing 16, also known as PLZF) and increased expression of differentiation markers such as KIT (also known as cKIT, CD117) (see Table 15.1; spermatogonial markers are discussed in greater detail below). KIT$^+$ A_s and A_{pr} spermatogonia are observed occasionally[35,39] and may indicate that differentiation to A1 spermatogonia can sometimes occur from these small clones, but these events are rare. In Figure 15.3, a clone of A_{al16} spermatogonia in stage VII differentiates (without a mitosis) to a chain of 16 A1 spermatogonia in stage VIII followed by sequential transit amplifying mitotic divisions to produce 32 A2 spermatogonia in stage IX, 64 A3 spermatogonia in stage XI, 128 A4 spermatogonia in stage I of the ensuing cycle of the seminiferous epithelium, 256 intermediate spermatogonia in stage II, 512 B spermatogonia in stage IV, and 1024 preleptotene spermatocytes in stage VI, which enter meiosis and migrate off the basement membrane. Two subsequent meiotic divisions will produce a total of 4096 haploid spermatids, in theory. Note that in the midst of this large clone (colored blue in the online material; open arrow in print), smaller clones underwent SSC self-renewal (black clone; black arrow in stage XI) as well as transit amplifying mitoses (red clone in the online material; arrowhead in print in stages X and I) that will fuel clonal expansion in the next cycle of the seminiferous epithelium. For example, the clone of 8 cells in stages I to VI (red clone in the online material; arrowhead in print) will divide to produce chains of 16 cells, 32 cells, and so on, in the next cycle of the seminiferous epithelium. The clone of two cells (black; black arrow) will either undergo cytokinesis to produce two new A_s spermatogonia or remain connected and produce a chain of four A_{al} spermatogonia at the next division.

Depending on whether the transition from A_{al} to differentiating A1 spermatogonia occurs from A_{al} chains of 4, 8, 16, or 32 spermatogonia, a clone generated from a single SSC can theoretically give rise to between 1024 and 8192 sperm.[40,41] Therefore, a single clone can fill a substantial portion of the seminiferous tubule and the series of successive clones fill in the layers of the seminiferous epithelium and collectively help to define the boundaries of individual stages (see cross-section and longitudinal section views in Figure 15.3). The actual yield of sperm is 50–80% less than what would be predicted by the clonal amplification scheme described above, due to apoptosis that occurs primarily in the A2–A4 spermatogonia in rodents.[26,42–44] The regulation of germ cell loss in differentiating spermatogonia may be "density dependent" and mediated by p53, BCL-2 (B cell leukemia/lymphoma 2) family proteins, and FAS[45–48], as reviewed in Refs 49 and 50.

Each cycle of the seminiferous epithelium in mice takes 8.6 days, and four cycles are required for the differentiation from A1 spermatogonia to mature sperm. Thus, approximately 35 days are needed to produce sperm from the pool of undifferentiated stem and progenitor spermatogonia. This concept is beautifully illustrated in a publications by Huckins and Oakberg[42] and Klein and coworkers in 2010.[51]

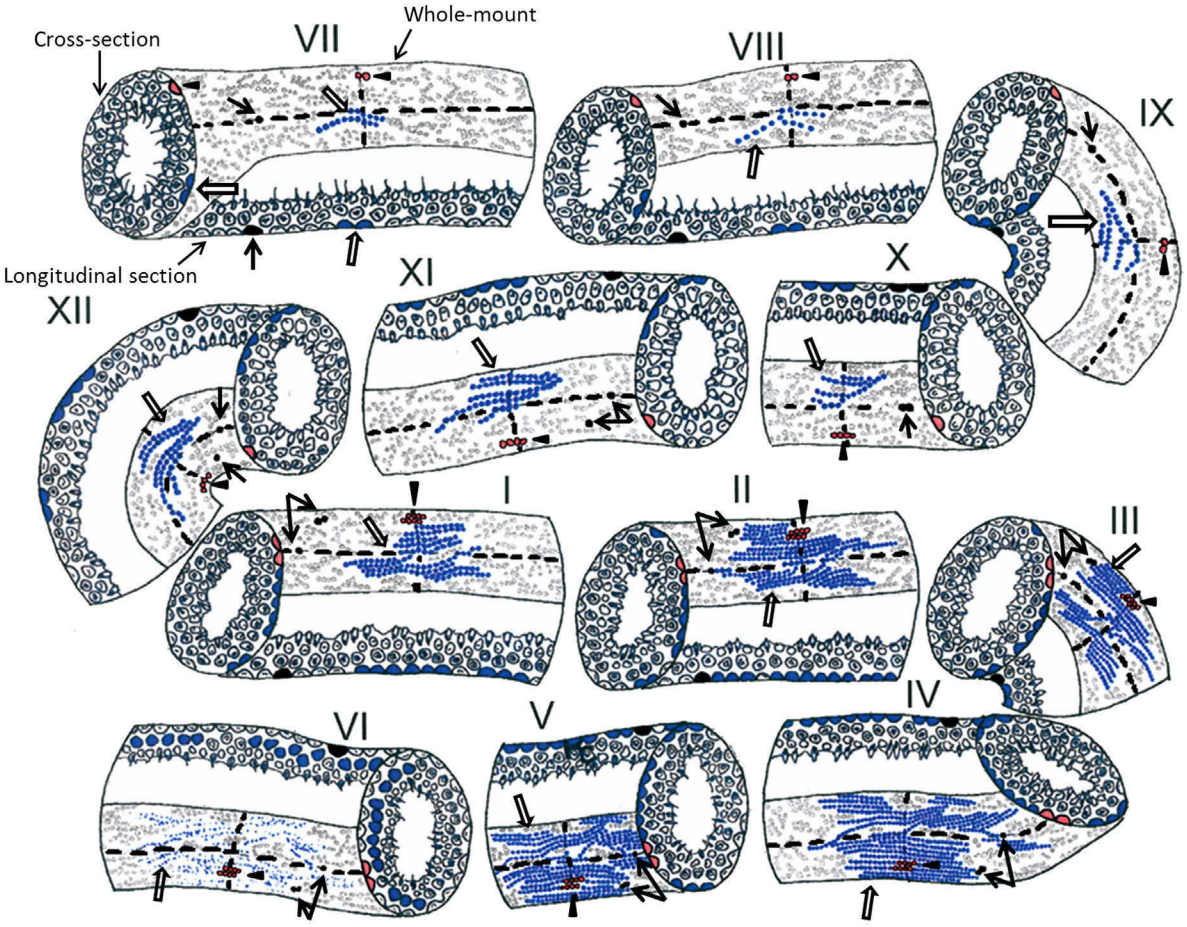

FIGURE 15.3 Schematic of mouse spermatogenic clone development by stage. This figure is reproduced in color in the color plate section. The seminiferous epithelial cycle of the mouse contains 12 stages (I-XII). Each stage is shown in cross-sectional, longitudinal, and whole-mount perspectives (labeled in stage VII). Three putative spermatogonial clones are highlighted in blue (open arrow), red (arrowhead), and black (black arrow). These clones are only representative examples and do not imply A_{single} spermatogonia divide only in stages X and I. A_{single} and A_{paired} spermatogonia are present in all stages of the seminiferous epithelium and tend to divide more frequently in early and late stages than middle stages. The dotted lines in the whole-mount perspective indicate planes of the cross-section and longitudinal section views. Cells that lie on the focal plane in the whole mount appear in the corresponding cross-section and longitudinal section views; this is indicated by matching color or arrows (arrows shown for stage VII only). For example, in stage VII, the red cell (arrowhead) is in the vertical line and therefore appears in the cross-sectional view. A black cell (black arrow) is in the horizontal line, so it is observed in the longitudinal section view. The development of three putative clones (blue/open arrow, red/arrowhead and black/black arrow) through one cycle of the seminiferous epithelium is shown. Stage VII: $A_{al\text{-}16}$ (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage VIII: A1 (clone of 16) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage IX: A2 (clone of 32) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage X: A2 (clone of 32) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{pair} (black/black arrow); stage XI: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage XII: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage I: A4 (clone of 128) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage II: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage III: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage IV: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage V: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage VI: primary spermatocytes (lifting off the basement membrane) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow). *Reproduced with permission from Ref. 28.*

While 12 stages of the seminiferous epithelium have been described for mice,[38,52] 14 have been described for rats,[6,20] 12 for rhesus macaques,[53,54] and 6 for humans.[55–57] The identification of specific stages may be somewhat arbitrary and investigator dependent. Using a modified staining approach, Muciaccia and colleagues[58] recently were able to identify 12 distinct stages of the human seminiferous epithelium as defined by acrosomal development based on acrosin staining. These authors suggested that staging should be normalized among species to facilitate interspecies comparisons.

A0/A1 Model of Spermatogonial Stem Cells

It is important to recognize that there is an alternative model to describe stem cells and spermatogenic lineage development in rodents that predated the A_s model and

continues to influence our understanding of spermatogenesis in higher primates today (discussed below). The A0/A1 model was described by Clermont and Bustos-Obregon in 1968 and identified five types of A spermatogonia (Figure 15.4).[59] A1 spermatogonia were found in stages II–VIII and were arranged in clusters of 4, 8, and sometimes 16 cells (similar to A_{al} spermatogonia in the A_s system). The A1 cells divided sequentially to produce A2 cells in stage IX, A3 cells in stage XII, and A4 cells in stage XIV of the cycle of the rat seminiferous epithelium. A4 cells divided at stage I of the ensuing cycle, and the authors proposed that they yielded two types of spermatogonia: intermediate and new type A1. Thus, the pool of A1–A4 spermatogonia collectively exhibited the requisite self-renewal and differentiation functions that define stem cells. The authors also recognized a fifth type of spermatogonia (representing 20% of all type A spermatogonia), termed A0, that were arranged as isolated or paired cells, had a darkly stained fine granular chromatin, and rarely divided. Because A0 did not appear to actively self-renew, they were considered to be "reserve stem cells" that could "rebuild the spermatogonial population" after noxious insult. This notion was supported by observations of Dym and Clermont that A0 cells were resistant to radiation-induced damage and could repopulate the seminiferous tubules with A1 spermatogonia that were depleted by radiation treatment.[60] Correlations between the A0/A1 model and A_s model can be inferred because the clonal arrangement of cells in both models has been clearly described (Figure 15.4).

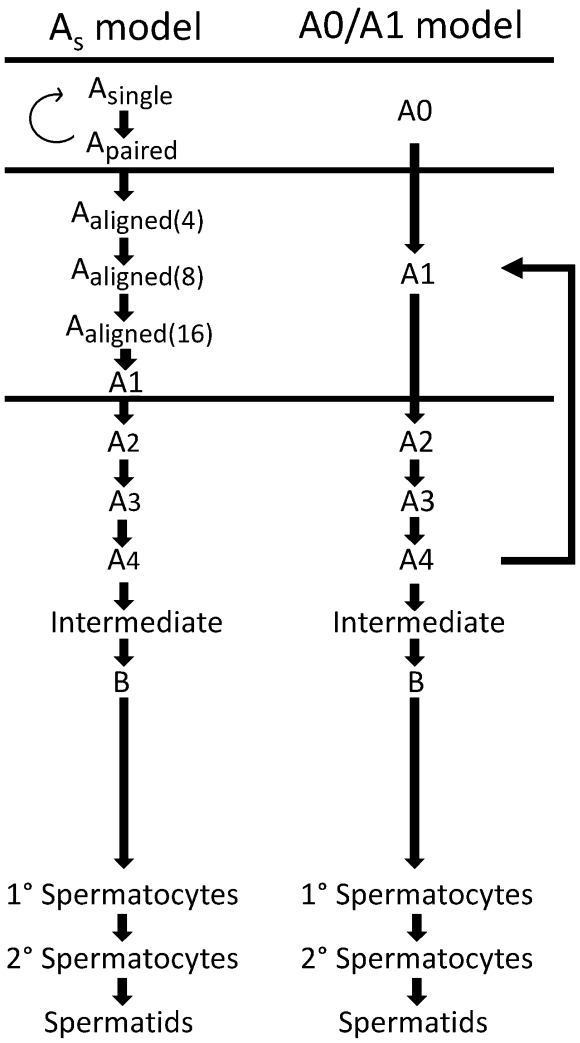

FIGURE 15.4 Comparison of the A_{single} (A_s) model and the A0/A1 model. In the A_s model, the stem cell activity is thought to reside in the A_s population. The A_s spermatogonia divide to produce A_{paired} (A_{pr}) spermatogonia that either undergo complete cytokinesis to produce two new A_s spermatogonia (self-renewal) or remain connected by an intercytoplasmic bridge and produce a chain of four $A_{aligned}$ (A_{al4}) spermatogonia at the next division. In the A0/A1 model, by clone size, these cells would correlate to the A0 spermatogonia. The A0 are thought to be the reserve stem cells that can regenerate spermatogenesis after noxious insult. In the A0/A1 model, the stem cell activity is thought to reside in the A1–A4 spermatogonia pool. The A4 spermatogonia can either produce intermediate or new A1 spermatogonia. The A1 pool correlates to A_{al4}-A1 spermatogonia in the A_s model. When the A_{al4} divide, they give rise to A_{al8} and A_{al16}. The chain of A_{al16} then differentiates into A1 spermatogonia, which will go through several meiotic divisions to eventually produce sperm.

Some differences between the A_s model and A0/A1 model appear to be semantic. A0 spermatogonia appear to correspond to A_s and A_{pr} spermatogonia and the A1 spermatogonia in the A0/A1 system appear to correspond to chains of 4, 8, and 16 $A_{aligned}$ spermatogonia in stages II–VII of the A_s system as well as the differentiating A1 at stage VIII. The critical difference in these models that is not semantic is the identity of the stem cell pool, A_s spermatogonia versus A1–A4 spermatogonia.

Regarding the A0/A1 reserve stem cell model, Oakberg[25] argued that (1) "it is difficult to visualize the selective value of a system which relegates 20% of the type A spermatogonia" to an inactive role; (2) derivation of A1 spermatogonia from A4 spermatogonia that have heterochromatic granules associated with the nuclear membrane would "involve dedifferentiation of cells well-advanced" in the developmental sequence; and noted that (3) the mechanisms that gave rise to chains of A1 spermatogonia were not demonstrated in the study of Clermont and Bustos-Obregon.[59] In this regard, the most compelling evidence supporting the A_s model are the following:

(1) A0 are mitotically active. All undifferentiated A spermatogonia, including A_s and A_{pr}, labeled after repeated administration of [^{3}H]-thymidine. Some isolated stem cells retained label for long periods, but eventually became mitotically active, giving rise to labeled A_{pr} and A_{al}, leading to a gradual disappearance of label.[61]

(2) There is a 10-fold reduction in the population of undifferentiated A_s, A_{pr}, and A_{al} spermatogonia coincident with the appearance of A1 spermatogonia after stage VIII. This population rebuilds until stage VIII of

the ensuing cycle, suggesting that A1 arise from A_{undiff} spermatogonia.[24–26]

(3) The number of intermediate spermatogonia in stage IV is twice the number of A4 in stage II, suggesting that all A4 undergo mitosis to produce intermediate spermatogonia.[24,26]

Nonhuman Primates and Humans

A_{dark}/A_{pale} Model of Spermatogonial Stem Cells

Primate testes contain two morphologically distinct types of undifferentiated (Type A) spermatogonia, which were initially identified as A1 and A2 but are now more commonly classified as A_{dark} and A_{pale}, based on differences in nuclear architecture and staining with hematoxylin in histological sections (Figure 15.2(E)).[37,53,55,62,63] A_{dark} and A_{pale} are both found on the basement membrane of primate seminiferous tubules. However, in contrast to rodents (Figure 15.2(A) and (B)), there are limited data describing their molecular characteristics or clonal arrangement[53,55,64] and conflicting views on whether one or both populations function as active stem cells in steady-state spermatogenesis.[40,55,65–68]

Clermont initially proposed for nonhuman primates[53] and humans[55] that A1 (A_{dark}) were SSCs that undergo self-renewing divisions to maintain the stem cell pool and give rise to A2 (A_{pale}) that subsequently generate differentiated type B spermatogonia. He further proposed that A_{pale} and B spermatogonia were the progressively "more differentiated elements giving rise to preleptotene spermatocytes."[55] However, the same group subsequently revised this A_{dark} stem cell–A_{pale} progenitor model based on observations in the vervet monkey that A_{dark} failed to label with [^{3}H]-thymidine.[65] Since A_{dark} did not appear to self-renew under steady-state conditions, he proposed that A_{dark} and A_{pale} represented reserve and active stem cells, respectively.[63,65] In this reserve stem cell model (Figure 15.2(C)), spermatogenesis is maintained by the "active" pool of A_{pale} SSCs that self-renew to maintain the A_{pale} pool and differentiate to produce type B spermatogonia.[66,69] It is not known whether A_{pale} undergo exactly one self-renewing division or whether they undergo additional division(s) before differentiating into B1 spermatogonia (Figure 15.2(C)). Similar to the A0/A1 model in rodents, Clermont proposed that the reserve A_{dark} SSCs are quiescent and are only activated when the A_{pale} pool is depleted by noxious insult.[65] This notion is supported by observations of de Rooij and colleagues, who noted that X-irradiation caused a rapid decline in A_{pale} spermatogonia. A_{dark} exhibited a delayed decline in numbers that correlated with a resurgence in the numbers of A_{pale} and B spermatogonia.[70] A similar progression of spermatogonial depletion and recovery after X-irradiation has been described in humans.[71–73]

Since Clermont's 1969 study,[65] six additional studies have been performed to quantify the mitotic activity of type A spermatogonia in monkeys. While all reported labeling ([^{3}H]-thymidine, BrdU (bromodeoxyuridine), PCNA (proliferating cell nuclear antigen) staining) in A_{pale} spermatogonia, only four reported labeling in A_{dark} spermatogonia, ranging from 0.6% to 18%.[63,74–77] Consistent with the results of Clermont,[65] two studies failed to observe labeling in the A_{dark} fraction.[78,79] Therefore, the question of whether A_{dark} divide in the adult testis and actively participate in spermatogenesis under normal conditions can still be debated. It is important to note that all of these previous studies were conducted with a single administration of ^{3}H-thymidine or BrdU and most evaluated only a few stages in the cycle of the seminiferous epithelium. Thus, studies similar to those that Huckins performed in rats,[61] with repetitive or chronic administration of the mitotic label to adult monkeys followed by a period of washout are needed to identify slow cycling cells that retain label for an extended period of time—a characteristic that is suggestive of stem cell activity.[80–82] This is a study that could be performed in nonhuman primates as a model for stem cell activity in man.

There is limited information about how dark and pale descriptions of nuclear morphology correlate with molecular phenotype or clone size. A_{dark} and A_{pale} appear to be present in equal numbers in the testes of monkeys and men.[53,55,75,78,83] While A_{dark} are equally distributed along the length of the seminiferous epithelium (similar to rodent A_s and A_{pr}), A_{pale} exhibit a more active, stage-dependent proliferation that results in peak numbers at mid-cycle (stages VII–IX, similar to rodent A_{al}) that precedes the appearance of differentiating B1 spermatogonia in stage X.[74,78] Using three-dimensional reconstruction of serial cross-sections[53] and camera lucida drawings of whole-mount seminiferous tubules,[65] Clermont and colleagues concluded that A_{dark} and A_{pale} existed only in even-numbered clusters, with pairs and groups of four being the most frequent. The arrangement of even-numbered groups suggests a clonal development scheme similar to that described for rodent spermatogonia. The observation of groups of four indicates that there can be at least two transit amplifying divisions that precede differentiation to B1 spermatogonia in primates. Van Alphen and colleagues described the dynamics of spermatogonial depletion and regeneration following low-dose radiation treatment in rhesus macaques.[54,70,84] In the regenerating seminiferous epithelium, the authors observed that both A_{dark} and A_{pale} could be observed as clones of 1, 2, 4, 8, and ≥16.[84] These observations may suggest that undifferentiated spermatogonia in primates can fluctuate between dark and pale phenotypes during clonal expansion, because the only way for an A_{dark} spermatogonia (which do not divide) to attain a chain size of 2, 4, 8, or 16 would be through an A_{pale} intermediate

that does divide. If that is true, is it reasonable to assign different "stemness" identities to these spermatogonial types? Alternatively, it is possible that A_{dark} spermatogonia do divide in the germ cell depleted testes, as has been previously reported for juvenile monkey testes,[85] but that has not been formally demonstrated.

In 2009, we conducted a study to begin unraveling the molecular phenotype of A_{dark} and A_{pale} spermatogonia in rhesus macaques with the objective to gain additional insights about the identity of the stem cell pool.[68] We found that A_{dark} and A_{pale} spermatogonia share many characteristics with A_s, A_{pr} and A_{al} spermatogonia in rodents (Table 15.1). Almost all A_{dark} and A_{pale} expressed the consensus stem and progenitor markers, GFRα1 and ZBTB16. NGN3 (neurogenin 3), which appears to be a transition marker in rodents,[35] is absent in A_{darks}, but expressed by 50% of A_{pales}. Similarly, KIT, the marker of spermatogonial differentiation in rodents, is absent in A_{darks} and expressed in only 25% of A_{pale} spermatogonia. Based on these results, all A_{dark} and 75% of A_{pale} spermatogonia in nonhuman primates share the phenotype GFRα1$^+$/ZBTB16$^+$/NGN3$^{+/-}$/KIT$^-$, which is comparable to the phenotype of most A_s and A_{pr} spermatogonia in rodents (Figure 15.5). GFRα1 and SALL4 (Sal-like 4) appear also to be conserved in A_{dark} and A_{pale} spermatogonia of human testes.[86,87] Based in part on their phenotypic similarities, we have speculated that A_{dark} and A_{pale} spermatogonia may be the same cell at different stages of the cell cycle (i.e., G0 versus G1/S/G2/M).[68] If this is true, it would help to explain why A_{dark} rarely label with [^{3}H]-thymidine or BrdU in the adult testis. In contrast to the adult, A_{dark} do appear to undergo mitosis in the developing testes of juvenile monkeys.[85]

If we accept that (1) rodent SSCs reside primarily in the pool of A_s and A_{pr} spermatogonia, (2) that molecular phenotype predicts function, and (3) that phenotype/function relationships are evolutionarily conserved, then it may be reasonable to suppose that most A_{dark} and A_{pale} spermatogonia in primate testes are stem cells because they are phenotypically similar to rodent A_s and A_{pr} spermatogonia. If that is true, the stem cell pool in rhesus macaques, where A_{dark} and A_{pale} comprise 4% of germ cells in the testis,[68,83,88,89] is substantially larger than in rodents, where A_s and A_{pr} comprise 0.09% of germ cells in the testes.[5,68] Using the same logic, the pool of transit-amplifying progenitor spermatogonia in primates is substantially smaller than rodents. Cells with the phenotype GFRα1$^+$/ZBTB16$^+$/NGN$^+$/KIT$^{+/-}$ comprise 89%

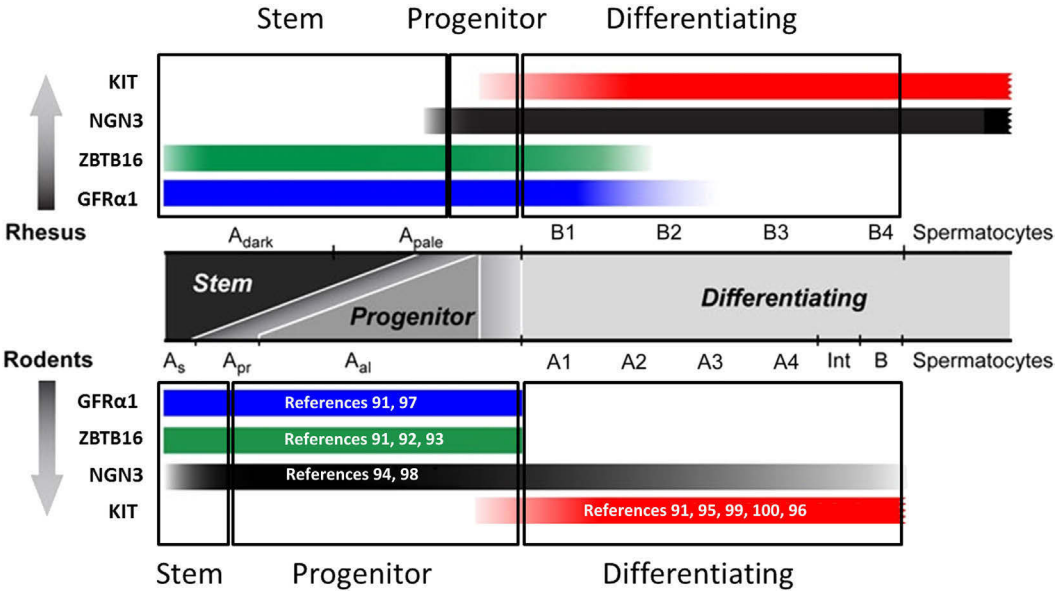

FIGURE 15.5 Correlation between established molecular markers of rodent SSCs (GFRα1, ZBTB16, NGN3, KIT) and morphologically classified spermatogonia (A_{dark}, A_{pale}, B) in the rhesus testis. Sections of adult rhesus testes were evaluated by immunohistochemistry for GFRα1, ZBTB16, NGN3, and KIT.[68] Subsequently, sections were counterstained by the PAS-Hematoxylin to reveal nuclear morphology and identify A_{dark} and A_{pale} spermatogonia, as well as differentiating B spermatogonia. Bars (GFRα1, ZBTB16, NGN3, KIT) indicate the extent of marker expression in the adult spermatogenic lineage for the rhesus monkey (top) rodent (bottom).[95] Stem, Progenitor, and Differentiating functional descriptors, based on rodent data, are indicated in the middle gray bar and may identify rhesus spermatogonia with corresponding phenotype and function. The transitions from stem to progenitor or progenitor to differentiating are noted by gradient shading between these functional categories. Citations for rodent marker expression profiles are indicated within each bar and are as follows.[90–94,96–99] The following abbreviations are used for rodents: A_s, A_{single}; A_{pr}, A_{paired}; A_{al}, $A_{aligned}$. Reproduced by permission of Oxford University Press based on data from Hermann et al.[68] (rhesus, top) or review of the literature (rodents, bottom). Citations for rodent marker expression profiles are indicated within each bar and are as follows.[90–99] Abbreviations: ZBTB16, zinc finger and BTB domain containing 16; GFRα1, GDNF family receptor alpha-1; NGN3, neurogenin 3.

of undifferentiated A_s, A_{pr} and A_{al} spermatogonia in rodents[5,90–99] compared to only 25% of undifferentiated A_{dark} and A_{pale} in primates (Figure 15.5; reviewed in Refs 68 and 75). Despite these differences, adult mice and adult monkeys produce the same number of sperm per gram of testis parenchyma per day (~40 million/gram/day).[1–3] Thus, it appears that pools of stem and progenitor spermatogonia in rodents and primates employ different strategies to meet similar biological demands for sperm production. While rodents have a relatively small stem cell pool with many transit amplifying divisions that precede meiosis, primates have a large stem cell pool with relatively fewer transit amplifying divisions (compare Figure 15.2(C) and (D)).

Based on the onset of KIT expression (Figure 15.2) differentiating A1–A4, intermediate and B spermatogonia in rodents appear to be roughly equivalent to B1–B4 spermatogonia in monkeys. Depending on whether there are zero, one, or two transit amplifying divisions that precede the transition of A_{pale} spermatogonia to B1 in nonhuman primates,[63,78] a single stem cell can theoretically give rise to between 64 and 256 terminally differentiated sperm. In contrast to the four generations of differentiating B spermatogonia in primates, humans have only one generation of B spermatogonia[37,55,57] and this may explain why sperm production in the human testis is approximately eightfold lower than in primates (Figure 15.2(D)). Using the same clonal development logic as we applied to nonhuman primate spermatogenic lineage development above, a single human stem cell can theoretically give rise to between 8 and 32 sperm. The small clone sizes in humans[40] also explain why stages of the seminiferous epithelium in humans are described with a patchy or spiral organization along the length of the seminiferous epithelium.[57] The individual clones are too small to fill an entire segment of seminiferous tubules. Therefore, each human seminiferous tubule cross-section can contain two to three different stages of the seminiferous epithelium.

EXPERIMENTAL TOOLS FOR STUDYING SPERMATOGONIAL STEM CELLS

In rodents, SSCs are identified by the following characteristics, in increasing order of experimental stringency: (1) SSCs are undifferentiated cells with a large nuclear to cytoplasmic ratio and diffuse chromatin located on the basement membrane of seminiferous tubules; (2) SSCs are arranged as individual cells or possibly small chains of interconnected cells; and (3) SSCs have the capacity to regenerate spermatogenesis after toxic insult (e.g., chemotherapy or radiation) or when transplanted into the testes of infertile recipients. Prior to the 1990s, undifferentiated spermatogonia, including SSCs, were identified in histological sections and whole-mount preparations of seminiferous tubules by their morphological characteristics and topographical arrangement along the seminiferous tubule basement membrane. Using these criteria and without the benefit of modern molecular tools, researchers established the models for stem cell maintenance and spermatogenic lineage development that have withstood the tests of time and experimental inquiry. Unfortunately, classic morphologic assessments are becoming a lost art, which is due in part to the fact that they are tedious and time consuming and in part because modern experimental tools (as described below) are now available. Insights about the molecular features of stem and progenitor spermatogonia began to emerge in the 1990s from investigations that employed SSC transplantation as the criterion standard stem cell assay combined with germ cell sorting techniques and genetic or experimental mouse models of male infertility.

Spermatogonial Stem Cell Transplantation

The SSC transplantation technique was developed by Brinster and colleagues in 1994.[100,101] In those pioneering studies, germ cells were isolated from the testes of donor mice and then transplanted into the seminiferous tubules of infertile recipient mice. Examination of recipient testes several months after transplantation revealed normal spermatogenesis and functional sperm arising from donor germ cells. Using transgenic donor cells that express reporter genes (e.g., *lac*Z or *Gfp*) allows the investigator to unequivocally identify colonizing events that arise from the donor cells (see result from *lacZ* donor in Figure 15.6(A) and Figure 15.7(A)–(C)). Infertility in the recipient mouse can be due to a genetic defect (e.g., the *Dominant white spotting* (*W*) mice with a mutation in the KIT receptor tyrosine kinase[102]), or it can be induced experimentally (e.g., Busulfan chemotherapy or radiation treatment[101,103]). SSC transplantation can be used to evaluate the spermatogenic potential of any experimental cell population[104] (e.g., testis cell suspensions, cultured cells, germ cells derived from induced pluripotent stem cells). By definition, only a stem cell can produce and maintain a colony of spermatogenesis and each colony arises from the clonogenic proliferation and differentiation of a single SSC.[105–107] The one-SSC/one-colony relationship was clearly demonstrated by Zhang and colleagues,[106] who mixed testis cells from two different transgenic donor mouse lines in a 1:1 ratio before transplantation. Genotyping of donor-derived colonies from recipient mice indicated that colonies were from one transgenic donor or the other, but not of mixed origin, providing that cells were transplanted at a low enough concentration to prevent colony merging. Kanatsu-Shinohara and coworkers[107] marked donor SSCs with retroviral vectors that integrate randomly into the target

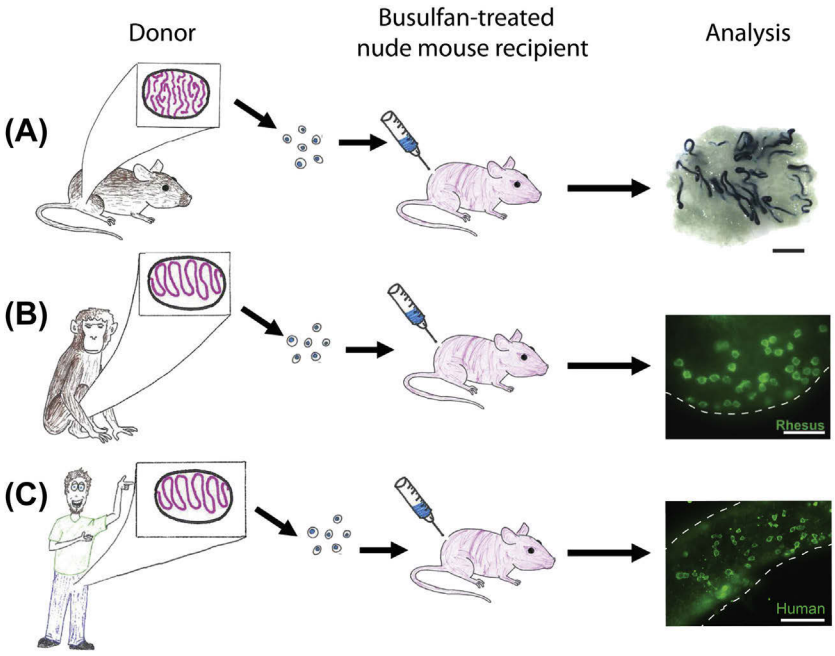

FIGURE 15.6 Spermatogonial stem cell (SSC) transplantation assay. This figure is reproduced in color in the color plate section. The only way to definitively identify SSCs is to analyze SSC function. (A) In this case, a testicular cell suspension is produced from a *lacZ* donor mouse. The cells are injected into the testis of an infertile recipient mouse and the results are analyzed two to three months after transplantation for *lacZ* expressing donor spermatogenesis (dark colonies). Scale bar = 2 μm. (B, C) Xenotransplantation of nonhuman primate (B) and human (C) testicular cells into busulfan treated nude mouse can be used as an assay to identify SSCs by their ability to initiate the early steps of spermatogenesis in the mouse testis. The colonies of spermatogonia are identified by staining with anti-primate antibody that only recognizes primate cells. The colonies of SSCs are identified by the following criteria—they are located on the basement membrane of the seminiferous tubules, they have four or more cells, and the cells are within 100 μm of each other. Scale bars = 100 μm. In the B and C analysis panel, broken lines indicate the borders of seminiferous tubules.

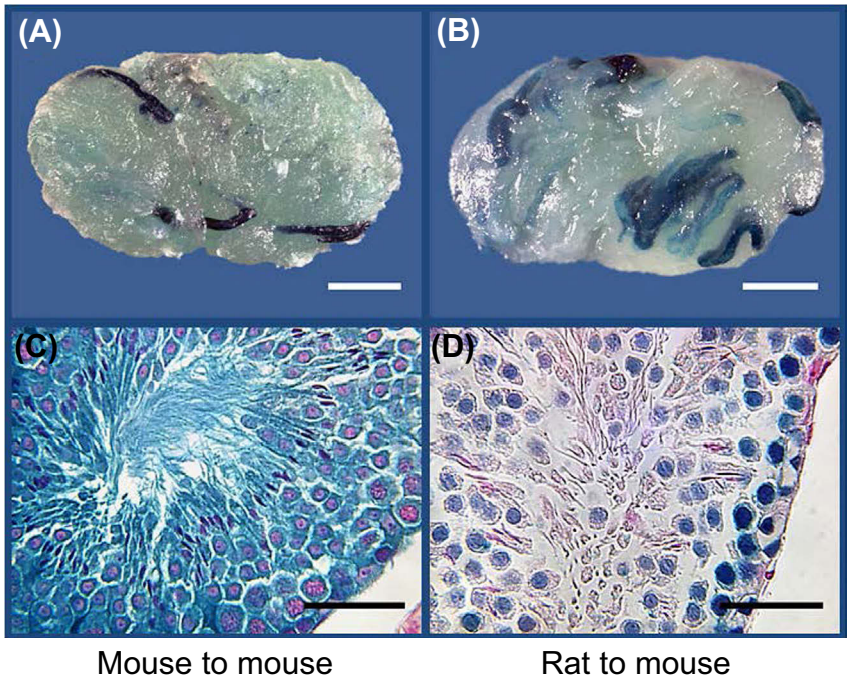

FIGURE 15.7 Macroscopic and histologic appearance of recipient testes transplanted with mouse and rat adult donor testis cells expressing *lacZ*. This figure is reproduced in color in the color plate section. NCr nude (spontaneous mutant T cell deficient mice) recipient mouse testes were stained with X-gal 3 months after transplantation to visualize mouse (A and C) and rat (B and D) donor-derived spermatogenic colonies. Both mouse and rat donor testis cells generated complete spermatogenesis, characterized by multiple germ cell layers and mature spermatozoa, in recipient testes. Note that the lacZ stain is localized in the cytoplasm of ROSA26 mouse testis cells (C) and the nucleus of MT-lacZ rat testis cells (D). Nuclear fast red counterstain (C and D). Bar = 1 mm (A and B), 40 μm (C and D). *Reproduced with permission from Ref. 134.*

cell genome. Haploid germ cells were collected from independent colonies and used to fertilize eggs and create offspring. Offspring generated from the germ cells in the same colony had a common viral integration pattern, while offspring from different colonies had different integration patterns. Therefore, the SSC transplantation provides a quantitative functional assay to characterize SSC activity in any donor cell population.[104]

Mouse-to-mouse SSC transplantation has become routine and, as mentioned above, is the criterion standard for assaying spermatogonial stem cells.

Rat-to-rat transplantation has also been performed to quantify stem cell activity using recipients that were rendered infertile by chemotherapy,[108–111] genetic mutation,[112] or a combination of chemotherapy and genetic manipulation.[113] However, recipient preparation in rats

is more complicated than mice because rats are more sensitive to the systemic toxicity of chemotherapy[109] and radiation treatment appears to damage the somatic environment in rat testes.[114] In total, homologous species SSC transplantations have now been reported in mice, rats, pigs, goats, bulls, sheep, dogs, and monkeys, including the production donor-derived embryos or offspring in mice, rats, goats, sheep, and monkeys.[102,115–123]

For SSC transplant in rodents, the testes are accessed via a mid-ventral abdominal incision. The donor cells are injected via the efferent ducts into the rete testis space, which can be visualized on the surface of the testis and is contiguous with all seminiferous tubules (Figure 15.8(A)–(C)).[124] Testis anatomy in large animals is different than in rodents, with the rete testis being more centrally localized and therefore more difficult to visualize and access. To address this challenge, Schlatt and colleagues pioneered the use of ultrasound-guided rete testis injection into rat, bovine, monkey, and human testes, ex vivo.[125] This technique has now been applied for in situ SSC transplantation in several large animal species, including goats, pigs, sheep, bulls, and monkeys (an example from monkeys is shown in Figure 15.8(D)–(F)).[118–123,126–129] In a recent ex vivo study, Faes and coworkers[130] demonstrated that this approach should be feasible in humans. In contrast to the method used in rodents, ultrasound-guided injection does not require surgery; the injection needle is simply inserted through the scrotal skin and testicular parenchyma into the rete testis space.

Spermatogonial Stem Cell Xenotransplantation

Homologous species transplantation as a routine bioassay for SSCs is only established in rodents. Animal and housing costs, difficulty in preparing infertile recipients, and animal-to-animal variability in outbred large animal species preclude the use of homologous transplantation in those species for quantitative assessment of stem cell activity. To address these challenges, xenotransplantation of cells from various species into the testes of infertile, immune-deficient recipient mice has emerged as an experimentally tractable and cost-effective alternative SSC assay.

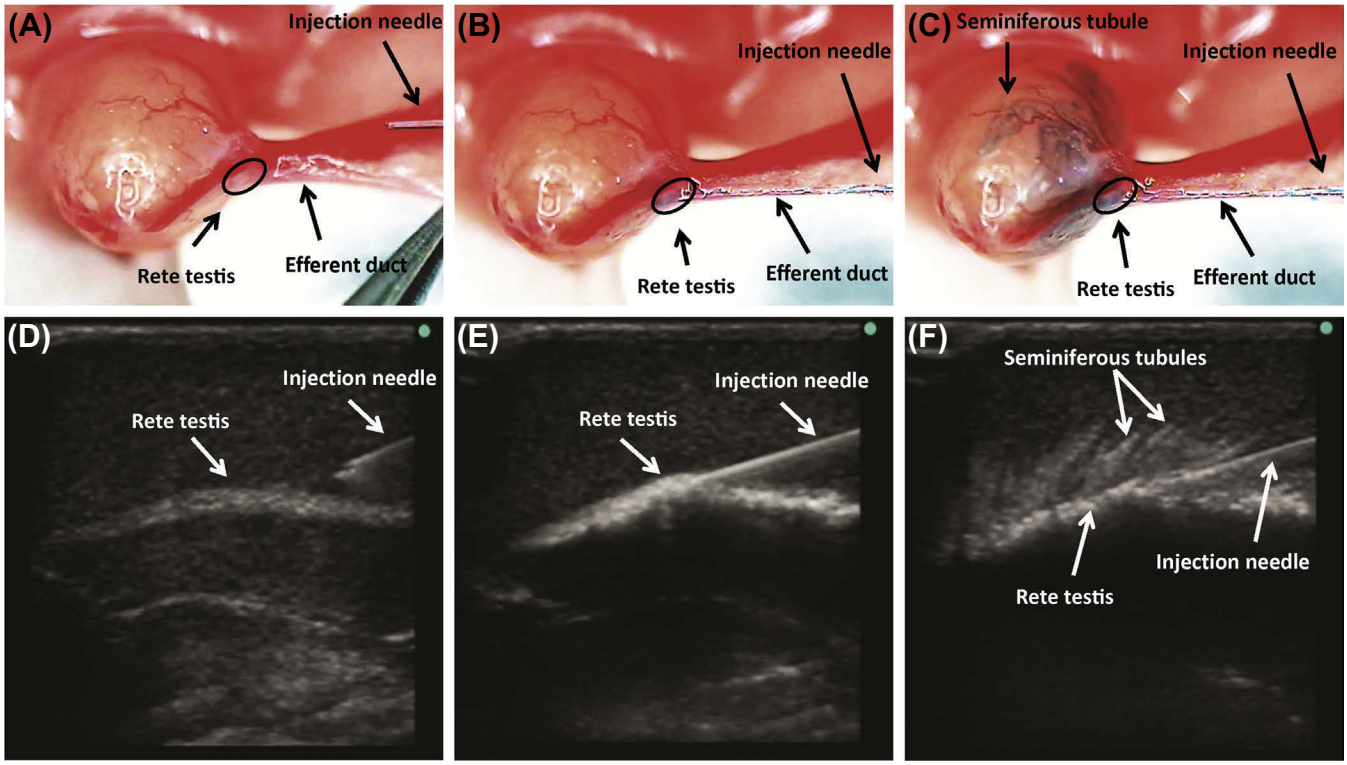

FIGURE 15.8 Testicular cell transplantation. This figure is reproduced in color in the color plate section. (A–C) In rodents, the testicular cells are injected via the efferent ducts into the rete testis space, which can be visualized on the surface of the testis and is contiguous with all seminiferous tubules. (C) Trypan blue is injected with the testicular cells to visualize the filling of the seminiferous tubules. (D–F) Testis anatomy in large animals is different than rodents, with the rete testis being more centrally localized and therefore more difficult to visualize and access. Therefore, ultrasound is used to guide injections. (D) Rete testis (echo-dense structure) is visible on ultrasound. The injection needle is inserted under ultrasound guidance through the scrotal skin into the rete testis space, which is continuous with the seminiferous tubules. (E) Positive pressure is applied to the needle, so the cells are slowly injected into the rete testis and seminiferous tubules. (F) The filling of the seminiferous tubules is observed using microbubbles.

Transplanted mouse SSCs produce chains and networks of spermatogonia on the basement membrane of recipient mouse seminiferous tubules by 2 weeks after transplantation, which subsequently differentiate to produce multiple layers of donor-derived germ cells and sperm within a few months after transplantation (Figure 15.9(A) and (B)).[104] In a similar fashion, rat SSCs can colonize the seminiferous tubules of infertile, immune-deficient recipient mice, giving rise to complete spermatogenesis (Figure 15.7(B) and (D)) and functional rat sperm, despite over 11 million years of evolutionary divergence between these rodent species.[131–134] Interestingly, spermatogenesis from transplanted rat SSCs proceeded according to the cycle of the rat seminiferous epithelium (a new population of A1 spermatogonia produced every 12.9 days) rather than the mouse (8.6 days per cycle, see above).[135] These results indicate that it is the germ cells and not the somatic environment that control the timing of spermatogonial differentiation. Furthermore, rat sperm produced in mouse seminiferous tubules were competent to fertilize rat oocytes by intracytoplasmic sperm injection (ICSI), giving rise to healthy offspring.[132] Thus, rat-to-mouse xenotransplantation can be used as a routine assay for rat SSCs,[108,134,136–142] which reduces animal costs and circumvents the challenges of preparing infertile recipient rats for transplantation. The reciprocal experiment, mouse SSCs transplanted into infertile, immune-deficient rats, also results in the production of donor-derived mouse sperm.[109] SSCs from hamsters, which diverged from mice over 16 million years ago,[143,144] can also colonize the testes of infertile, immune-deficient recipient mice and produce spermatogenesis. However, the hamster spermatids and sperm produced in recipient mouse seminiferous tubules were morphologically abnormal.[143]

Dobrinski and coworkers[145] investigated the effect of increasing phylogenetic distance between donor and recipient by transplanting testis cells from rabbits and dogs into the seminiferous tubules of infertile immune-compromised recipient mice. Donor rabbit and dog cells, which diverged from mice approximately 60 million years ago,[145,146] produced chains and networks of spermatogonia connected by intracellular bridges on the basement membrane of mouse seminiferous tubules. These colonizing events persisted for periods exceeding 1 year, but did not progress to produce complete

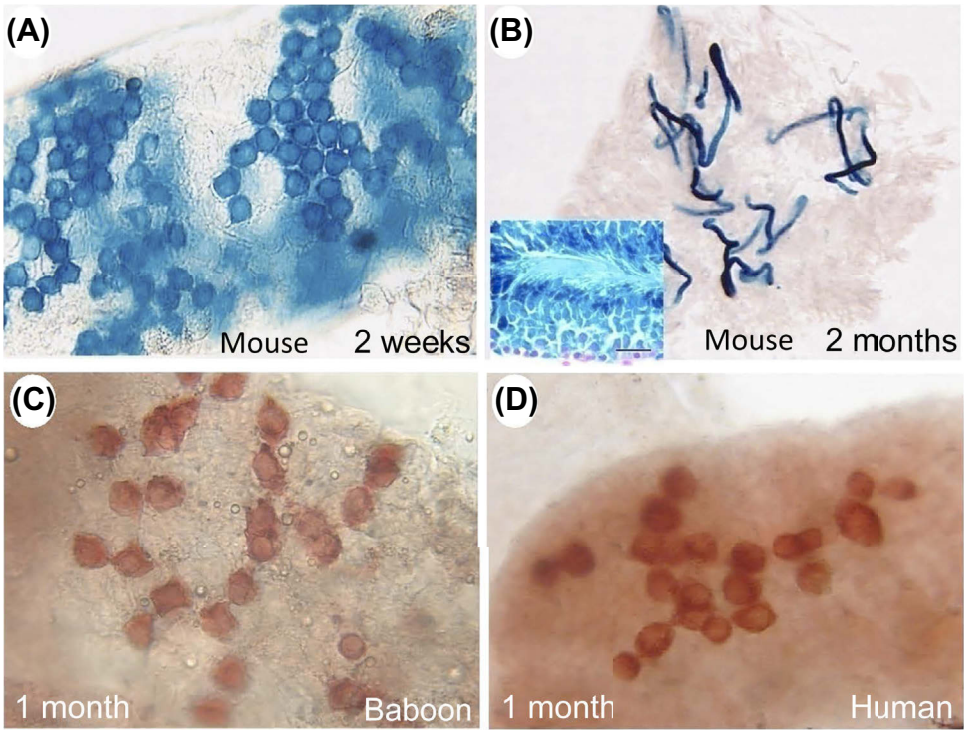

FIGURE 15.9 Colonization of recipient testis. This figure is reproduced in color in the color plate section. (A) Two weeks after transplantation of transgenic mouse donor cells (stained blue) into a recipient mouse seminiferous tubules, small groups of cells can be seen at low magnification. (B) Two months after the transplantation of mouse donor cells, the blue areas are dark in the center, indicating multiple layers of germ cells and development of spermatogenesis. (B inset) Cross-section of a transplanted mouse seminiferous tubule 2 months after transplant. Scale bar = 30 μm. (C and D) Detection of baboon and human germ cells transplanted into the seminiferous tubules of recipient mouse, using an antibody raised against baboon testis cells. One month after the transplant, clusters of baboon (C) and human (D) germ cells are located on the basement membrane of mouse tubules and exhibit characteristics of undifferentiated spermatogonia. The clusters are similar to the ones seen in mouse 2 weeks after the transplant. *Modified with permission from Refs 104 and 149.*

spermatogenesis, as meiotic cells did not emerge. Similar colonizing events have been reported after transplanting porcine, bovine, equine, primate, and human germ cells (Figure 15.9) into recipient mouse seminiferous tubules.[147–150] It is noteworthy that the colonizing events by these nonrodent cells appear very similar to early mouse colonies 2 weeks after transplantation (compare Figure 15.9(A)–(C) and (D)). Although donor germ cells from distantly related mammals do not produce complete spermatogenesis in mouse seminiferous tubules, they do exhibit several characteristics that are consistent with SSC activity: (1) they migrate to the basement membrane of recipient seminiferous tubules, (2) they proliferate to produce characteristic chains and networks of spermatogonia, and (3) they persist for a periods of time ranging from several months to more than 1 year. Based on these criteria, xenotransplantation to mouse seminiferous tubules is becoming a routine bioassay for nonhuman primate and human SSCs[68,148,149,151–157] and should have similar application for other species.

In contrast to mouse and rat donors, testis cells from most species will not have transgenic reporter genes (e.g., *lacZ* or *GFP*) to facilitate identification of donor-derived colonizing events. Therefore, it is necessary to generate species-specific antibodies[145,147,148,152] or preload the donor cells with a fluorescent marker (e.g., PKH26 or CFDA) prior to transplant.[158,159] Using these tools, SSC xenotransplantation can proceed in a manner very similar to mouse-to-mouse transplantation. Testicular tissue from the donor species is digested to produce a cell suspension that is then transplanted into the seminiferous tubules of infertile, immune-compromised recipient mice. Testes of recipient mice are analyzed between a few weeks and a few months after transplantation for colonies of spermatogenesis (Figures 15.7(A) and (B); 9(B)) or colonies of spermatogonia (Figures 15.6(B) and (C); 9(C) and (D)). When the fluorescent dye loading approach is used, earlier analysis (2–3 weeks) is required to minimize the dilution of dye through cell divisions.[158,159]

Molecular Characteristics of SSCs Learned from Mouse Genetic Models

Several mouse models exhibit male infertility with histology that indicates the absence of spermatogenesis in many or all tubules, a phenotype that may suggest defects in the spermatogonial compartment. Three examples are the spontaneous (luxoid mutant) or targeted deletion of the *Zbtb16* (*Plzf*) locus;[91,160] the *Dominant white spotting* (*W*) mice with a mutation in the KIT receptor tyrosine kinase;[94,161] and mice with overexpression or underexpression of the glial cell line derived neurotrophic factor, *Gdnf*.[162]

ZBTB16 encodes a zinc finger transcription factor that is expressed by a subpopulation of spermatogonia (including single, paired, and aligned) located on the basement membrane of seminiferous tubules.[91,160] Most seminiferous tubules in these mice had a Sertoli cell only phenotype (no germ cells) or had a severely disorganized seminiferous epithelium; SSC transplantation indicated that these defects were associated with a depletion of the SSC pool.[91,160] ZBTB16 is a widely accepted marker of SSCs and appears to be conserved in rodents, nonhuman primates, and humans (Figure 15.10(A)–(C)).

Similar to *Zbtb16* mutant mice, adult *W* (*Kit* mutant) mice are infertile with small testes and seminiferous tubules that lack spermatogenesis. This phenotype is due in large part to a failure of primordial germ cells to survive and proliferate during embryonic development. *Kit* mRNA and protein are also expressed by spermatogonia in postnatal testes,[94,161] but unlike ZBTB16, KIT is not expressed in SSCs. Systemic administration of an anti-KIT monoclonal antibody to block KIT signaling in adult mice resulted in rapid depletion of differentiating spermatogonia, while undifferentiated spermatogonia were unaffected.[161] Furthermore, by combining fluorescence-activated cell sorting with SSC transplantation, Shinohara and coworkers demonstrated that the majority of SSC activity resides in the KIT negative fraction of mouse testes.[163] KIT is now widely recognized as a marker of spermatogonial differentiation[95,161] and it is conserved in rodents, nonhuman primates, and humans.[68,157,161,164,165] Based on these studies, mouse SSCs can be partially defined by the phenotype ZBTB16$^+$/KIT$^-$.

GDNF is a distant member of the transforming growth factor-β (TGFβ) family that is secreted by Sertoli cells and signals through a receptor complex that includes the GDNF family receptor α1 (GFRα1) and the RET receptor tyrosine kinase that are expressed by spermatogonia.[162] *Gdnf*, *Gfrα1*, and *Ret* null mice are embryonic lethal, but Meng and coworkers demonstrated that mice with one *Gdnf*-null allele exhibited disrupted spermatogenesis, including some tubules with a Sertoli cell-only phenotype and apparent absence of spermatogonia. In contrast, overexpression of *Gdnf* led gradually to atrophy of the seminiferous tubules and accumulation of undifferentiated (KIT$^-$) spermatogonia.[162] Subsequent sorting and transplant studies revealed that some SSC activity is recovered in the GFRα1$^+$ fraction of rodent testis cell suspensions, confirming that GFRα1 is a marker of SSCs. However, SSC activity is also consistently recovered in the GFRα1$^-$ fraction, which suggests that the stem cell pool may be heterogeneous with respect to GFRα1 expression.[86,166,167] GDNF is the critical growth factor required to maintain rodent SSCs in culture,[110,140,168,169] as will be discussed in more detail below.

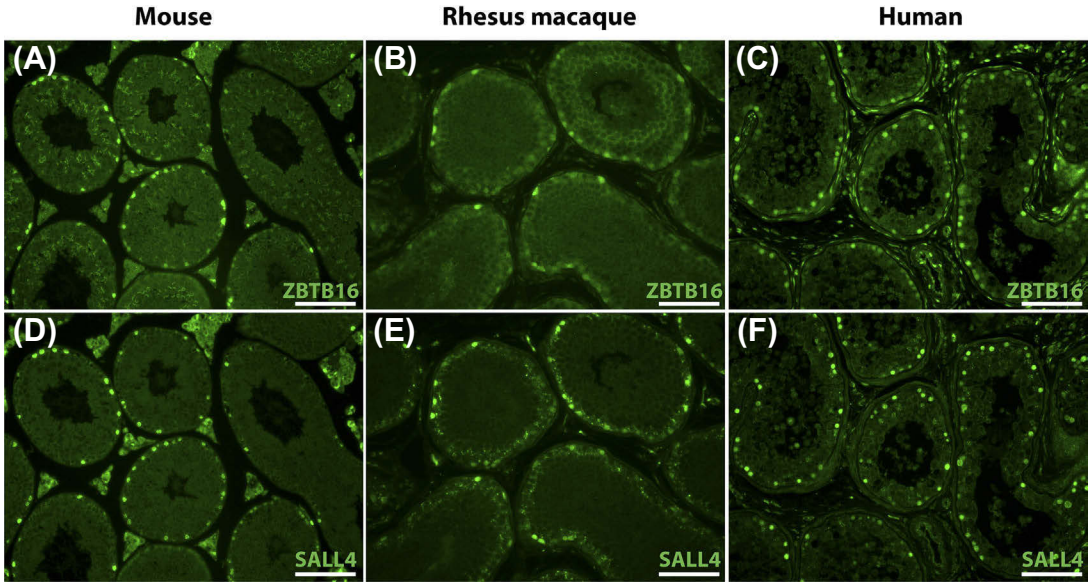

FIGURE 15.10 Conservation of stem and progenitor markers ZBTB16 and SALL4 from mouse to human. This figure is reproduced in color in the color plate section. ZBTB16 (A–C) and SALL4 (D–F) staining in cross-sections of seminiferous tubules from mouse, rhesus macaque, and human testes shows expression of these transcription factors on the basement membrane of the tubule. Both ZBTB16 and SALL4 are conserved markers from mouse to rhesus macaque to human. Scale bar = 100 μm. ZBTB16, zinc finger, and BTB domain containing 16; SALL4, Sal-like 4.

Molecular Characteristics of SSCs Learned from Sorting and Transplantation

As indicated in the KIT and GFRα1 examples above, the SSC transplantation technique is especially powerful for dissecting the molecular phenotype of functional SSCs when it is combined with fluorescence-activated cell sorting (FACS) or magnetic activated cell sorting (MACS) (Figure 15.11(A)). Briefly, a heterogeneous cell suspension is labeled with a vital dye (e.g., Rho123, Hoechst) or with a fluorescent (for FACS)- or paramagnetic microbead (for MACS)-tagged antibody raised against a cell surface antigen. The population is then fractionated based on the level of labeling using a FACS machine or magnetic field. To assess relative stem cell activity, each fraction is transplanted into infertile recipient mice and colonies of donor-derived spermatogenesis are typically quantified 2 months later (Figure 15.11(A)). Based on several studies using this approach, mouse SSCs are now characterized as a subpopulation of testis cells defined by the phenotype ITGB1 (β1-integrin, CD29)$^{+}$, ITGA1 (α6-integrin, CD49f)$^{+}$, THY-1 (CD90)$^{+}$, CD9^{+}, GFRα1^{+}, CDH1 (cadherin 1)$^{+}$, MCAM (melanoma cell adhesion molecule)$^{+}$, FZD3 (frizzled family receptor 3)$^{+}$, Hoechst side population^{+}, Rhodamine 123 (Rho123)^{low}, ITGAC (αv-integrin, CD51)$^{-}$, KIT (CD117)$^{-}$, MHC-I (major histocompatibility complex class I)$^{-}$, EPCAM (epithelial cell adhesion molecule)$^{low/-}$, CD45^{-}, ALDH (aldehyde dehydrogenase) activity^{-}[90,138,163,166,170–180] (Table 15.1). In nonhuman primates, the xenotransplantation technique was utilized to demonstrate that enhanced colonizing activity resides in the SSEA-4 (stage-specific embryonic antigen 4)$^{+}$, THY-1^{+}, CD45^{-} subpopulations of rhesus macaque testes.[68,159,181] Similarly, FACS and MACS sorting in conjunction with human-to-nude mouse xenotransplantation have revealed that human SSCs can be defined in part by the cell surface phenotype, CD9^{+}, EPCAM^{+}, SSEA-4^{+}, HLA-ABC^{-}, CD49e^{-}.[151,156,157] The approach using sorting and transplantation to define the molecular phenotype of functional SSCs is limited primarily to cell surface markers. Although it is feasible to sort a fixed cell suspension based on the expression of intracellular antigens, this method is not compatible with transplantation to evaluate stem cell function because the cells are not viable after fixation. Three studies have shown that it is also possible to isolate and enrich SSCs based on their cellular function (e.g., dye efflux, mitochondrial membrane potential, and aldehyde dehydrogenase)[139,174,177]

Immunohistochemistry to Validate SSC Markers

For candidate SSC markers that are not expressed on the cell surface, immunohistochemistry can be used to determine whether the marker has an expression pattern that is consistent with stem and progenitor spermatogonia. For example, if a candidate marker is expressed by cells located on the basement membrane of seminiferous tubules and co-expressed in cells with established SSC markers (e.g., ZBTB16, GFRα1, CDH1) that have been validated by transplantation,[90,91,160,166,177] then this expression pattern is consistent with SSCs. SALL4 (Sal-like 4) is a zinc finger transcription factor

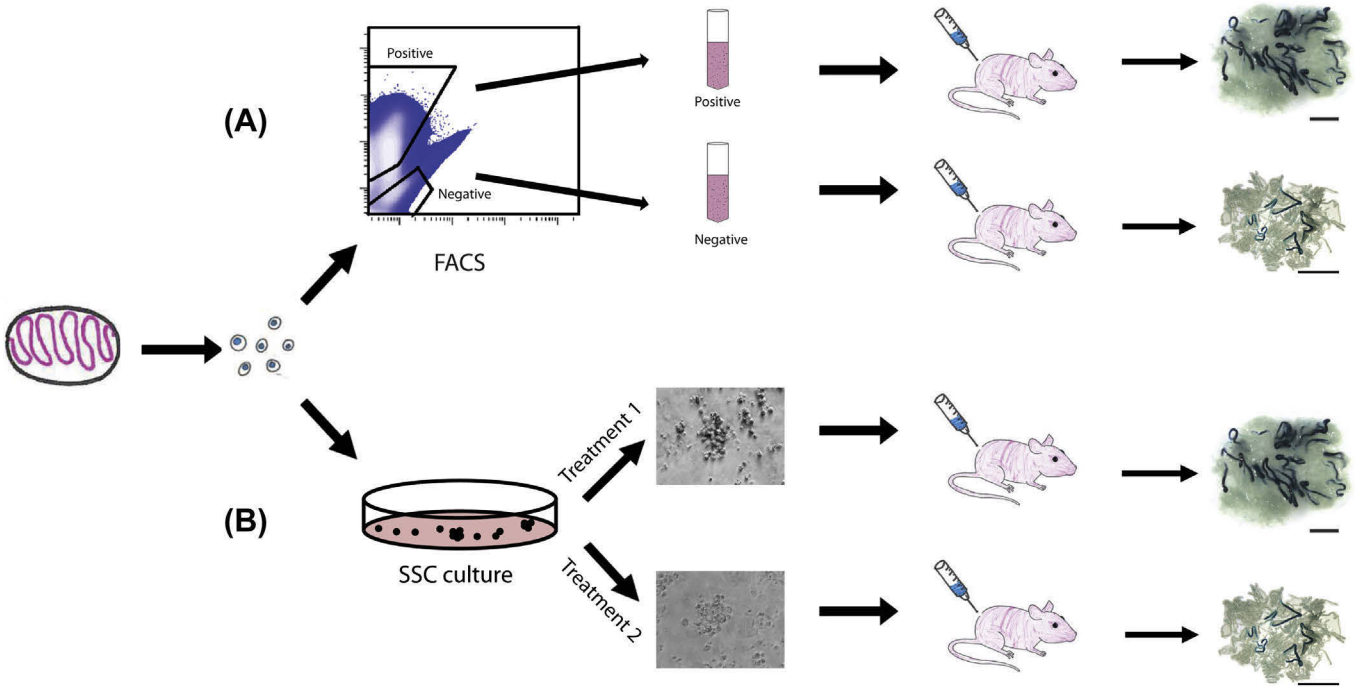

FIGURE 15.11 Experimental designs to study seprmatogonial stem cells. This figure is reproduced in color in the color plate section. SSC transplantation is used to analyze the effectivness of (A) fluorecsence-activated cell sorting (FACS) for a cell-surface protein or (B) a treatment of SSC culture. (A) FACS is used to fractionate the testicular cell population stained with an antibody against a cell-surface protein, based on marker$^+$ and marker$^-$ status. The sorted fractions can then be transplanted into infertile nude mice to determine which fraction contains the SSCs. (B) SSC cultures are used to identify factors important for SSC self-renewal and maintenance or for SSC differentiation. For example, GDNF can be removed from the culture media to determine whether or not it has an effect on SSC self-renewal and/or maintenance. The cells cultured with or without GDNF are then transplanted into testis of infertile recipient mice and, 2 months later, the testis are analyzed for colony formation. that is expressed by cells on the basement membrane of mouse, monkey, and human seminiferous tubules (Figure 15.10(D)–(F)) and exhibits nearly complete overlap of expression with ZBTB16 (Figure 15.10(A)–(C)). Based on these criteria, several markers of stem and/or progenitor spermatogonia have been identified, including ZBTB16, SALL4, GFRα1, CDH1, NANOS2 (nanos homolog 2), NANOS3, UTF1 (undifferentiated embryonic cell transcription factor 1), ID4 (inhibitor of DNA binding 4), LIN28 (TEX17), NGN3, GPR125 (G protein-coupled receptor 125), SOHLH1 (spermatogenesis and oogenesis specific helix-loop-helix 1), SOHLH2 (spermatogenesis and oogenesis specific helix-loop-helix 2), and UCHL1 (ubiquitin carboxyl-terminal esterase L1, also known as PGP9.5) (see references and other markers in Table 15.1). It is important to note that no precise molecular definition of the SSC pool has been determined; this may be a difficult task to achieve because there appears to be some molecular plasticity or heterogeneity in the stem cell pool,[39,90,182–184] which will be discussed in more detail below. In some circumstances, stem cell activity is even observed in cells expressing KIT,[182] which is an established marker of spermatogonial differentiation.[95,161] In histological cross-section, it is not possible to correlate molecular markers with clone size (i.e., A_s, A_{pr} or A_{al}) because observation is restricted to a single plane of view.

Whole Mount Immunohistochemistry to Define Molecular Characteristics of Undifferentiated A_s, A_{pr}, and A_{al} Spermatogonia

Immunohistochemistry analysis in whole-mount preparations of seminiferous tubules allows the investigator to correlate molecular marker expression with clone size (i.e., A_s, A_{pr}, A_{al}). An example of this approach is shown in Figure 15.12, where mouse tubules are co-stained with SALL4 and KIT (Figure 15.12(A), (D) and (G)) while monkey and human tubules are co-stained with UTF1 and KIT (Figure 15.12(B), (C), (E), (F), (H) and (I)). In Figure 15.12(G), smaller clones of undifferentiated spermatogonia exhibit a SALL4$^+$/KIT$^-$ phenotype, while larger clones of transit amplifying differentiating spermatogonia are SALL4$^-$/KIT$^+$. A similar progression is observed in monkeys and humans with small clones of spermatogonia exhibiting an undifferentiated phenotype (UTF1$^+$/KIT$^-$) and larger clones exhibiting a more differentiated phenotype (UTF1$^-$/KIT$^+$). To date, no molecular marker has been identified with expression restricted to

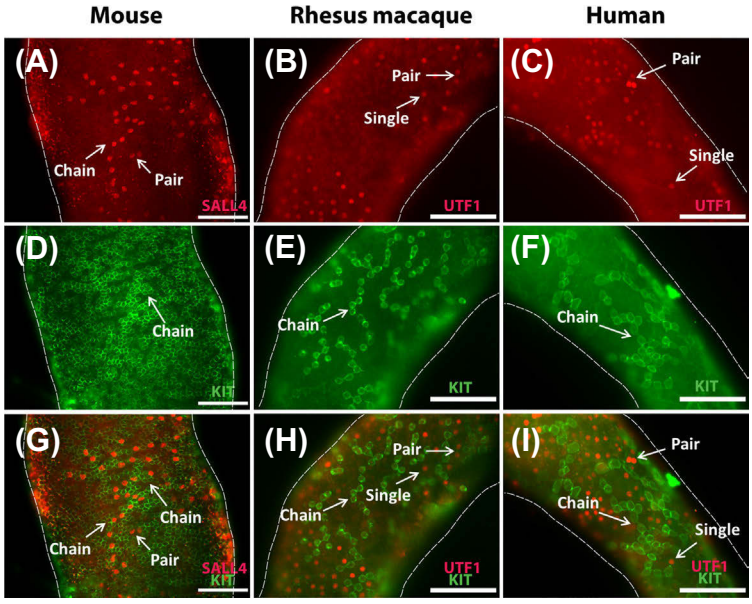

FIGURE 15.12 Whole-mount immunohistochemistry of seminiferous tubules from mouse, rhesus macaque, and human testes. This figure is reproduced in color in the color plate section. Whole-mount immunofluorescence analysis of the undifferentiated spermatogonia marker, SALL4 (A), differentiating spermatogonia marker, KIT (D) and co-staining of SALL4 and KIT (G) in mouse. Whole-mount immunofluorescence analysis of undifferentiated spermatogonia marker UTF1 (B, C), differentiating spermatogonia marker KIT (E, F), and co-staining of UTF1 and KIT (H, I) in the rhesus macaque (B, E, H) and human (C, F, I). Arrows indicate spermatogonia arranged as single cells, pairs, and larger chains for each species. Scale bar = 100 μm. transplantable SSCs. However, whole-mount analyses indicate that the ID4 protein is restricted to A_s spermatogonia[185] and GFRα1, NANOS2, and UTF1are restricted to small clones of A_s, A_{pr} and A_{al4} spermatogonia.[35,39,186–188] Generally, the stem cell pool is considered to reside in the pool of A_s and some of the A_{pr} spermatogonia, whereas larger chains of A_{al} are thought to be committed to differentiation. However, a number of investigations have revealed that clones of rodent spermatogonia exhibit some degree of phenotypic and functional heterogeneity.[90,183,188] GFRα1 is not expressed by all A_s[39,86] and NGN3 is expressed by a subset of transplantable stem cells.[184,189,190] Furthermore, phenotypic heterogeneity has been observed within individual clones of spermatogonia, in which some individual cells within a clone appear different from the rest of the clone.[39,86,90,184,191] The functional significance of the phenotypic heterogeneity is not known, but these observations raise the question of whether clone size alone is adequate to define the stem cell pool. Nakagawa and colleagues suggested that A_{al} clones as large as 16 may be capable of fragmenting and contributing to the stem cell pool.[35]

Spermatogonial Stem Cell Culture

SSC culture has many important applications for human health, animal management, and also basic stem cell research. Culturing SSCs provides new approaches to investigate the molecular mechanisms and cell-signaling pathways that regulate SSC function. It also allows amplification of SSC numbers, which can be beneficial for increasing cell numbers prior to transplantation into testes and may serve as a foundation for experiments to develop a system for in vitro spermatogenesis.

In rodents, SSCs can be maintained in long-term culture with significant expansion in numbers. Cultured SSCs remain competent to produce spermatogenesis and restore fertility upon transplantation.[110,113,140,168,169,192] Several factors were critical to the establishment of long-term SSC cultures. First, methods were needed (e.g., FACS or MACS and/or differential attachment and replating) to enrich the SSCs and remove somatic cells that overproliferate and overwhelm the culture. Second, development of a serum-free, defined medium facilitated the discovery of essential growth factors, specifically the necessity of GDNF to maintain and expand rodent SSCs in culture.[168,192,193] The effects of GDNF in mice and rats is enhanced by the addition of soluble GFRα1 (the receptor for GDNF) and fibroblast growth factor 2 (FGF2).[140,169] Third, STO (SIM mouse embryo-derived thioguanine and ouabain resistant) fibroblast or MEF (mouse embryonic fibroblast) feeder cells are often needed for the survival of rodent SSCs. Although it is possible to maintain mouse SSCs in feeder-free conditions.[194] SSC cultures are often established from mouse pup testes (5–12 days postpartum) because SSCs are enriched at this stage of development due to the absence of differentiating germ cells and because SSCs are predisposed to active cell cycles.[195] However, SSC cultures can be established from all ages (from neonates to adults).[168,169]

Stable SSC culture provides a valuable tool for dissecting mechanisms that regulate SSC renewal and differentiation. For example, through withdrawal and addition of GDNF to mouse SSC cultures in combination with the transplantation assay, it was confirmed that GDNF is an important growth factor for SSC cultures (this experimental design is represented schematically in Figure 15.11(B)) and that GDNF action is mediated by SRC (v-src avian sarcoma)

family kinase/AKT (protein kinase B)-dependent pathways.[196,197] Additionally, the use of a gene specific siRNA enables temporary knockdown of the target gene.[198,199] Thus, through genetic manipulation and transplantation of cultured SSCs, it is possible to identify regulatory pathways required for SSC self-renewal and differentiation. In addition, Yeh and colleagues[200] suggested that SSC culture can be used as a quantitative assay for SSCs based on their observation that there is a linear relationship between the number of germ cell clusters formed in culture and the number of colonies that are produced by transplantation. Elhija et al. reported that testicular cells from 7-day-old mice could be expanded in a three-dimensional soft agar culture system and differentiated to produce post-meiotic germ cells, including morphologically normal sperm.[201] Additional studies are needed to confirm that the resulting sperm are functionally competent.

Several groups have reported extending the SSC culture to large animal species[202–206] and a number of laboratories have even reported culturing human SSCs,[153–155,207–211] including three from the testes of prepubertal patients.[153,155,209] These human culture studies are promising, but they are also challenged by the inability to evaluate cultured cells by homologous species transplantation. To date, each laboratory has used a different approach to culture human SSCs and different methods to assess outcomes. These results need to be replicated in other laboratories and evaluated using robust markers of human spermatogonia and by xenotransplantation to nude mice. Ideally, SSC cultures in humans can serve several purposes. First, similar to rodents, it could be a valuable tool to dissect the molecular-mechanism and cell-signaling pathways that regulate SSC self-renewal and differentiation. Second, it could theoretically be employed to amplify the number of SSCs available for experimentation or clinical application. Third, it could be used to establish a system for in vitro spermatogenesis. The production of spermatozoa in vitro would revolutionize assisted reproductive techniques and would allow the production of spermatozoa without the need for SSC transplantation.

Xenografting

In contrast to SSC transplantation, which involves disaggregation of SSCs from their cognate niches, testicular tissue grafting maintains the integrity of the stem cell/niche unit. Dobrinski, Schlatt, and their colleagues demonstrated that testicular tissues obtained from newborn mice, pigs, and goats could produce complete spermatogenesis when grafted under the skin of nude mice[212] and later reported the production of offspring from sperm obtained after ectopic (under the skin) grafting of mouse testicular tissue.[213] Testis tissue from prepubertal rhesus macaques also produced complete spermatogenesis with fertilization competent sperm after ectopic xenografting into nude mice.[214] Several groups have reported xenografting of human tissue to nude mice, and so far none have observed complete spermatogenesis or haploid gametes.[215–220] However, if the xenograft approach is optimized for humans, it could provide a tool for evaluating the effects of therapies or toxic insults on spermatogenic lineage development in humans or other large animals, using a mouse host. In addition, the xenografting approach may provide an option to preserve and/or restore fertility of boys who are at risk for infertility (e.g., due to cancer treatment). Thus, a testicular tissue that contains only undifferentiated stem and progenitor spermatogonia at the time of biopsy could potentially differentiate to produce fertilization competent haploid human sperm in a mouse host. Survival and spermatogenesis from adult testicular tissue grafts have been less successful to date than immature grafts.[221] Two studies also evaluated autologous testicular grafting in marmoset monkeys,[222,223] and reported that complete spermatogenesis was obtained in orthotopic (in the scrotum), but not in ectopic (under the skin) grafts. Perhaps spermatogenic development from autologous human testicular tissue grafts will be more successful than the human-to-mouse xenografts that have been studied to date.

THE SPERMATOGONIAL STEM CELL NICHE

An SSC niche is a complex entity that is comprised of cells, extracellular matrix, and soluble factors that regulate stem cell dynamics and spermatogenic lineage development. SSCs are in close proximity with elements at the basement membrane of the seminiferous tubules, including Sertoli cells and peritubular myoid cells, which line the inside and outside of the basement membrane, respectively (Figure 15.13).[28,224] These cells secrete the basement membrane components and the adhesion molecules that mediate the interaction of SSCs with their environment.[225] Sertoli cells are polarized columnar epithelial cells that support the SSCs and differentiating germ cells by providing nutrients and mediating external signals to support spermatogenesis.[226] Tight junctions between the Sertoli cells are the anatomical basis of the blood–testis barrier (BTB), which divides the seminiferous epithelium into basal and adluminal compartments and plays an important role in the regulation of germ cell differentiation[227] (Figure 15.13(A)). Sertoli cells must mediate the migration of germ cells from the basal compartment, across the blood–testis barrier to the adluminal compartment without disturbing the integrity of the BTB. This process, described in detail by Smith and Braun,[228] involves the establishment of a new blood–testis barrier beneath a clone of differentiating germ cells before the old BTB degenerates.

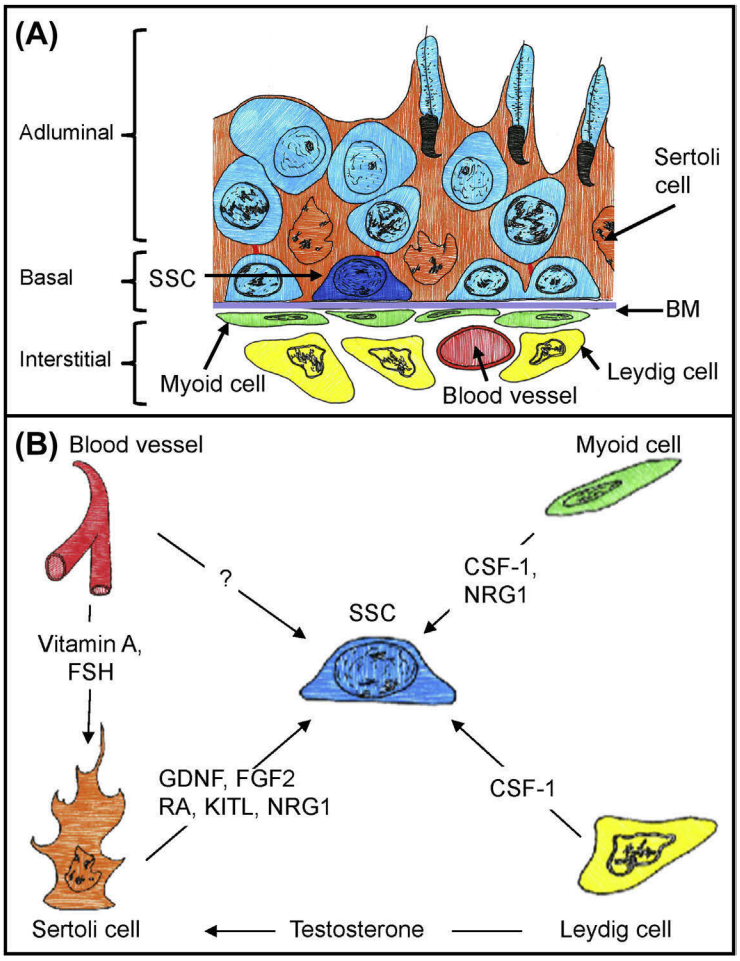

FIGURE 15.13 Spermatogonioal stem cell (SSC) niche. The SSC is diagrammed in its physical niche (A) surrounded by Sertoli cells and differentiating germ cells within the seminiferous tubule. Niche components outside the tubule itself include myoid cells, blood vessels, and Leydig cells. The components of the niche and some factors known to be provided by each are shown in (B). Although some factors are known to act directly on the SSC, such as GDNF, others, such as testosterone, are important for spermatogenesis but act indirectly on the SSC (see Chapter 16). SSC, spermatogonial stem cell; BM, basement membrane; FSH, follicle-stimulating hormone; GDNF, glial cell-derived neurotrophic factor; FGF2, fibroblast growth factor 2; RA, retinoic acid; KITL, KIT ligand; NRG1, neuregulin 1; CSF-1, colony stimulating factor 1. *Modified with permission from Ref. 28.*

In the SSC transplant paradigm, SSCs must migrate from the seminiferous tubule lumen to reach a niche on the basement membrane of seminiferous tubules. In an elegant series of experiments, Shinohara's laboratory used the transplant assay to identify factors important for migration, homing, and attachment to the SSC niche. Their results indicate that ITGB1 expression, both by SSCs and by Sertoli cells, is essential for homing to the seminiferous tubule basement membrane, in vivo. In addition, ITGB1 is required for attachment to laminin, a principle basement membrane component, in vitro.[229] The combination of ITGA6 and ITGB1 comprise a laminin receptor and both molecules are expressed by SSCs.[163] While ITGB1 is essential for attachment to the basement membrane, a separate study from the Shinohara group indicated that the small G-protein, RAC1 (RAS-related C3 botulinum substrate 1), is required for migration across the BTB.[230] The authors reported that passage through the BTB is the key factor that limits homing efficiency, which may explain why transplant efficiency in pup recipient testes that do not have a BTB is significantly greater than in adult testes.[115] *Rac1*-deficient SSCs did not colonize adult recipient testes but were able to engraft and regenerate spermatogenesis in pup recipient testes that lack a BTB.[230] Finally, the Shinohara group identified CXCL12 (chemokine (C-X-C motif) ligand 12) as a chemokine that attracts SSCs to the niche.[231] Overexpression of *Cxcl12* in the Sertoli cells of recipient mice leads to enhanced colonization from transplanted SSCs. The authors also identified CXCR4 (chemokine (C-X-C motif) receptor 4) as a chemokine receptor that is induced by GDNF and expressed more frequently by A_s and A_{pr} than A_{al} spermatogonia. Inhibition or conditional knockout of *Cxcr4* in donor SSCs significantly reduced colonizing efficiency in recipient testes.[232] Targeted disruption of the Ets variant gene 5 (*Etv5*) shows an apparently normal spermatogenesis at the initiation of puberty but eventually results in the loss of germ cells in the older animals.[233] ETV5 is a transcription factor that is expressed in Sertoli cells and loss of ETV5 seems to impair the ability of Sertoli cells to support spermatogonia. Decrease in CLDN5 (claudin-5) in mutant mice indicates that the defect is possibly due to disrupted BTB function.[234] In Sertoli cells, ETV5 is upregulated by FGF2 in vitro, which is important for SSC renewal in culture.[168,169,235]

Around the periphery of seminiferous tubules, undifferentiated spermatogonia (including SSCs) tend to be located in regions adjacent to the interstitial space, rather than regions that are adjacent to neighboring tubules.[97,236,237] Furthermore, using three-dimensional reconstruction of serial cross-sections and real-time in vivo imaging, Yoshida and coworkers demonstrated that undifferentiated spermatogonia were most frequently observed near blood vessels and migrated away from these sites during clone expansion.[97] These observations probably indicate that factors in the general circulation are required for maintaining the pool of stem and progenitor spermatogonia. Factors from the interstitium or blood may have direct effects on spermatogonia or indirect effects that are mediated by other cells, including Sertoli or myoid cells.

Niche Factors Supporting SSC Maintenance and Renewal

Sertoli cells are in direct contact with all SSCs and are the primary target in the testis of follicle stimulating hormone (FSH; see Chapter 16).[238] FSH stimulates the production of GDNF by Sertoli cells,[239,240] and this occurs in a stage-dependent manner with highest levels of FSH receptor expression,[241,242] FSH binding,[243] and GDNF production[244] between stages XIII and I of the rat seminiferous epithelium. These stage-specific increases in FSH receptor expression and GDNF production proceed the maximal proliferation of type A_s spermatogonia in stages I and II.[34] As indicated above GDNF is essential for maintenance and renewal of SSCs in vitro[110,140,153,168,169,192,245] and in vivo.[162,246] Therefore, FSH signaling via the Sertoli cells provides a mechanism for regulating the dosage of GDNF. GDNF signaling is thought to be mediated by both the PI3K (Phosphatidylinositol-4,5-bisphosphate 3-kinase)/AKT (also known as protein kinase B) pathway and the SRC and RAS (rat sarcoma)/ERK1/2 (extracellular signal-regulated kinases) pathway.[196,197,247,248]

WNT5A (wingless-related MMTV integration site 5A) was recently identified as a paracrine cell-extrinsic factor that participates in the control of SSC maintenance.[180] In vitro, WNT5A supports SSC maintenance at least in part by promoting cell survival. Although intracellular signaling mechanisms downstream of WNT5A are not well understood, the JNK (c-Jun N-terminal kinase) pathway was activated upon WNT5A stimulation in cultured spermatogonia, while blocking this signaling pathway negated the cell survival effect of WNT5A. This growth factor is expressed by Sertoli cells in vivo as well as in Sertoli cell lines, but not by germ cells. The WNT5A receptor is expressed by spermatogonia.[180] Interestingly, O'Shaughnessy and coworkers reported that WNT5A expression by Sertoli cells in vivo is transiently augmented within 5 days after a single administration of busulfan, which selectively kills spermatogonia.[249] GDNF transcripts are similarly upregulated after busulfan injection.[250,251] Because busulfan is known to kill SSCs, it is tempting to speculate that the loss of spermatogonia, including SSCs, may be sensed by Sertoli cells, which in turn secrete GDNF and WNT5A to protect and sustain the pool of undifferentiated spermatogonia.

The peritubular myoid cells play a role in spermatogonia maintenance by secreting CSF1 (colony stimulating factor 1). Gene expression profiling showed high expression of the receptor for CSF1 (CSF1R) in a $THY1^+$ spermatogonia population, whereas the CSF1 ligand is expressed in Leydig cells and a subset of myoid cells.[252] Subsequent experiments showed that the addition of CSF1 to SSC culture media significantly enhances the self-renewal of mouse SSCs.[252] Another study by Kokkinaki et al.[253] demonstrated that a $GFR\alpha1^+$ cell fraction isolated from prepubertal mouse testis had higher expression of CSF1R compared to other testis cells. It was suggested that CSF1 may cooperate with GDNF in supporting the maintenance of SSCs.

Niche Factors Promoting SSC Differentiation

In addition to SSC maintenance and renewal factors, Sertoli cells produce KIT ligand (KITL)[254,255] and retinoic acid (RA),[256,257] which are both required for spermatogonial differentiation. Similar to the regulation of GDNF expression in Sertoli cells, FSH regulates the expression of KITL by Sertoli cells[258,259] and KITL levels are highest in stages II-VI that precede the differentiation of A_{al} to A1 spermatogonia in stages VII and VIII[260] in rats. KITL stimulates spermatogonial proliferation[261] and prevents apoptosis.[45] Mice and rats that are maintained on a diet deficient in vitamin A (the dietary precursor of RA) are infertile with seminiferous tubules that contain only undifferentiated KIT^- spermatogonia.[95,256,257,262–264] Treatment of vitamin A deficient (VAD) animals with retinol or all *trans*-RA causes the upregulation of KIT protein expression[95] and restoration of spermatogenesis.[256,257,264] Vitamin A circulates primarily as retinol bound to RBP (retinol binding protein) and is taken up by Sertoli cells in a STRA6-dependent manner.[265] Interestingly, STRA6 is upregulated in later stages of the seminiferous epithelium (stage VII onward in mice) coinciding with the differentiation of A_{al} into A1 spermatogonia.[266] Thus, the coordinated expression of self-renewal (GDNF) and differentiation (KITL and RA) niche factors by Sertoli cells helps to determine the developmental fate of individual stem and progenitor spermatogonia.

Neuregulin 1 (NRG1), which is produced by peritubular myoid cells in rats[267] and Sertoli cells in mice,[268] is a member of the epidermal growth factor (EGF) family that is essential for spermatogonial proliferation and

meiotic initiation. Conditional inactivation of NRG1 in Sertoli cells of 14-day-old mice caused degeneration of the seminiferous tubules, reduced incorporation of BrdU in spermatogonia and spermatocytes, and increased apoptosis. Degenerated tubules contained only Sertoli cells and undifferentiated spermatogonia. In addition, FSH and RA induced proliferation of spermatogonia and initiation of meiosis was blocked in spermatogonia/Sertoli cell aggregation cultures from *Nrg1*$^{Ser-/-}$ mice.[268] Hamra and colleagues[269] demonstrated that rat germ cells express the NRG1 receptor ERRB3 and its signal transducer, ERRB2, and that NRG1 in combination with GDNF are required for formation of longer chains of spermatogonia ($A_{al16-32}$) in cultures of rat spermatogonia.

MOLECULAR MECHANISMS GOVERNING SSC DEVELOPMENTAL FATE

Signal Transduction

GDNF, acting through its cognate co-receptor complex GFRα1/RET on undifferentiated spermatogonia, is critical for SSC maintenance and/or self-renewal. Treatment of cultured SSCs with GDNF leads to rapid phosphorylation of AKT[197,248] and SRC family kinases.[196] GDNF-induced AKT phosphorylation is blocked by treatment with the PI3K inhibitor LY294002 or with SRC family kinase inhibitor SU6656.[197] Oatley and colleagues demonstrated that treatment with LY294002 resulted in loss of germ cell cluster formation in culture and increased apoptosis, suggesting that PI3K/AKT signaling is important for survival. In contrast, SU6656 caused reduced cluster size but no increase in apoptosis, suggesting that SRC family kinase signaling is important for self-renewal. Treatment with either inhibitor reduced the number of transplantable stem cells in culture.[197] Furthermore, Lee and coworkers demonstrated that conditional activation of AKT (myristoylated AKT) can replace GDNF and support long-term maintenance of functionally normal SSCs in culture.[248]

Lee and colleagues reported that the mitogen-activated protein kinase pathway (MEK/ERK) is also activated by GDNF treatment of cultured SSCs, but inhibition of this pathway using the MEK inhibitor PD098059 did not impact the amplification of germ cell clusters in culture.[248] In contrast, using the same inhibitor, He and coworkers[247] reported that PD098059 inhibited GDNF-induced ERK phosphorylation, BrdU incorporation (proliferation), and activation of *c-Fos* expression in the immortalized C18-4 SSC line.[270] Neither study reported the effects of MEK inhibition on transplantable stem cell activity. In vivo, Hasegawa and colleagues[271] observed a stage-dependent activation of ERK1/2 in GFRα1 positive spermatogonia, with higher ERK1/2 phophorylation in stages I–III and lower phosphorylation in stages VII–VIII of the seminiferous epithelium. These investigators injected the MEK inhibitor PD0325901 into the seminiferous tubules of adult mice and observed decreased expression of RET in ZBTB16 positive spermatogonia 6 h later. However, the study did not clearly demonstrate whether this reflected a direct effect on spermatogonia or was mediated indirectly by inhibition of MEK/ERK signaling in Sertoli cells. Therefore, the importance of MEK/ERK signaling for SSC function has not been clearly established.

KIT is expressed by differentiating spermatogonia and is required for the proliferation and survival of these cells.[45,261,272] Interestingly, KIT activates both the PI3K and MEK pathways,[261,273–275] similar to GDNF. Inhibition of either pathway using chemical inhibitors blocks the KIT-mediated proliferative response in differentiating spermatogonia. However, inhibition of MEK and PI3K pathways did not affect the anti-apoptotic effect of KIT signaling in these cells, indicating that the proliferative and anti-apoptotic effects are mediated by different pathways.[261] How is it possible that that self-renewal (GDNF) and differentiation (KITL) factors from the SSC niche signal through the same pathways in spermatogonia to cause different developmental outcomes? One possibility is that the PI3K and MEK pathways mediate proliferation in both undifferentiated and differentiating spermatogonia, but not necessarily "stemness." Future studies will likely identify co-regulatory molecules that modulate signaling through these and other pathways to tip spermatogonial developmental fate toward self-renewing divisions versus differentiating divisions.

Cell Cycle Regulation

Cell cycle regulation is clearly important for both self-renewing and transit-amplifying divisions. Lee and coworkers[276] discovered that GDNF stimulates RAS in an SRC family kinase-dependent manner and upregulates the expression of the cell cycle regulator, cyclin D2. Therefore, these investigators hypothesized that cyclin D2 may mediate the effects of GDNF on SSC self-renewal. However, Beumer and colleagues[277] had previously demonstrated that cyclin D2 was expressed specifically in spermatogonia at stage VIII of the seminiferous epithelium when A_{al} transition to A1 spermatogonia, suggesting the cyclin D2 may be involved in spermatogonial differentiation. Furthermore, cyclin D2 was absent in the undifferentiated spermatogonia in the testes of VAD mice, but was induced by administration of RA. Nonetheless, Lee and colleagues demonstrated that constitutive activation of h-RAS or expression of cyclin D2 + cyclin E1 could stimulate SSC proliferation in culture, even in the absence of cytokines (GDNF, bFGF, EGF). Neither cyclin D1 + E1 nor cyclin D3 + E1 could

mimic this effect, but both combinations could compensate for GDNF when cells were grown in the presence of bFGF and EGF. Cells with activated RAS or cyclin D2E1 transfectants (but not the cyclin D1E1or D3E1 transfectants) colonized recipient mouse testes and indicated a significant amplification of SSC numbers in culture. However, spermatogonial differentiation was disrupted and colonies eventually gave rise to tumors. The authors concluded that RAS and cyclin D2 are important and sufficient for SSC self-renewal, but speculated expression levels relative to other molecules is important to regulate the balance between SSC maintenance and tumorigenesis.[276] These activities may be balanced in part by co-regulation of p21 and p27 cyclin-dependent kinase inhibitors, which compromised proliferation of cultured SSCs.[278]

Cyclins are also important for proliferation of differentiating spermatogonia. Treatment of isolated spermatogonia with KITL results in activation of the PI3K/AKT and MEK/ERK pathways, and this is followed by migration of cyclin D3 to the nucleus and phosphorylation of the retinoblastoma (RB) protein. RB is a pocket protein that is expressed by proliferating spermatogonia in the testis and binds E2F family transcriptional regulators that are involved in transcriptional control and cell cycle progression.[272] These events were associated with cell cycle progression of KIT$^+$ spermatogonia and are abolished by treatment with the PI3K or MEK inhibitors.[261,275]

Two studies recently demonstrated that the retinoblastoma tumor suppressor gene (RB1) is required for maintaining the SSC pool[279,280]. Conditional inactivation of RB1 with VASA-Cre did not affect the establishment of the initial SSC pool or proliferation of GFRα1 positive A_s spermatogonia. However, the balance between self-renewing and differentiating divisions was disrupted, with all divisions giving rise to transit amplifying progenitors rather than new SSCs. In addition, RB1 depletion led to an overproliferation of ZBTB16$^+$, LIN28$^+$, and KIT$^+$ transit amplifying spermatogonia. However, this overproliferation was balanced by increased "density-dependent" apoptosis in RB1-deficient spermatogonia, so the number of spermatocytes was similar to controls. There was no block to terminal differentiation to sperm, so RB1-deficient mice were initially fertile, but gradual depletion of the SSC pool led to infertility by 2 months of age. In contrast, conditional inactivation of RB1 in transit-amplifying spermatogonia using NGN3-Cre or STRA8-Cre disrupted spermatogenic lineage development, leading to tumorigenesis.[280]

Transcriptional Regulation of SSCs

To identify intrinsic factors regulated by GDNF signaling in SSCs, Oatley and colleagues used a microarray approach to identify genes regulated by GDNF withdrawal and replacement in mouse SSC cultures.[281] Three transcription factors showing the greatest level of GDNF regulation included *Bcl6b* (B cell CLL/lymphoma 6, member b), *Lhx1* (Lim homeobox protein 1), and *Etv5* (Ets variant gene 5). *Bcl6b* encodes a BTB/POZ domain transcriptional repressor, similar to ZBTB16. Knockdown of *Bcl6b* expression in SSC cultures using siRNAs impaired SSC maintenance, increased apoptosis, and reduced colonizing activity following transplantation into infertile recipient mice.[197] In vivo, *Bcl6b*$^{-/-}$ mice have smaller testes compared to wild-type mice from the same age and contain seminiferous tubules with degenerating spermatogenesis.[281] *Lhx1* encodes a transcription factor that is important for anatomical morphogenesis in the mouse.[282] Knockdown of *Lhx1* in mouse SSC cultures with siRNA reduced the number of transplantable SSCs, suggesting that *Lhx1* is important for SSC maintenance.[197] ETV5 (also known as ETS related molecular; ERM) is an ETS family transcription factor that is expressed in several tissues, including the testis[283] where it is expressed by both Sertoli cells[233] and undifferentiated spermatogonia.[197] *Etv5* knockout animals produce the first round of spermatogenesis, but this is followed by progressive depletion of germ cells such that most tubules are devoid of germ cells by 10 weeks of age. Furthermore, *Etv5*$^{-/-}$ spermatogonia failed to produce spermatogenesis upon transplantation into infertile recipient mice, which is associated with a decreased level of RET receptor expression per germ cell and decreased proliferation in vitro and in vivo.[284]

In addition to BCL6B, LHX1, and ETV5, undifferentiated spermatogonia express the transcriptional regulators, ID4, UTF1, ZBTB16, POU3F1 (POU class 3 homeobox 1) SALL4, FOXO1 (forkhead box O1), SOHLH1, SOHLH2, NGN3, STAT3, and TAF4b, which may coordinate signals from the niche and activate distinct gene expression networks related to self-renewal and/or differentiation.[39,91,93,160,185,186,285–292] The expression patterns of several of these factors in the pool of undifferentiated (A_s, A_{pr} and A_{al}) spermatogonia are diagrammed in Figure 15.14. ID4 and UTF1 have the most restricted expression patterns, suggesting that they may identify the most undifferentiated spermatogonia with high "stemness" potential.[183,185,186,188] ZBTB16 and POU3F1 are required for the maintenance and/or renewal of the SSC pool.[91,160,285] In contrast SOHLH1, SOHLH2, NGN3, and STAT3 have been implicated in spermatogonial differentiation.[35,93,286–289,292–294] Despite their different functions, many of these factors are expressed simultaneously in undifferentiated spermatogonia, suggesting that these cells may be poised to self-renew or differentiate depending on signals from the local niche. For example, ZBTB16 and SOHLH1 are co-expressed in the majority of undifferentiated spermatogonia, even though they

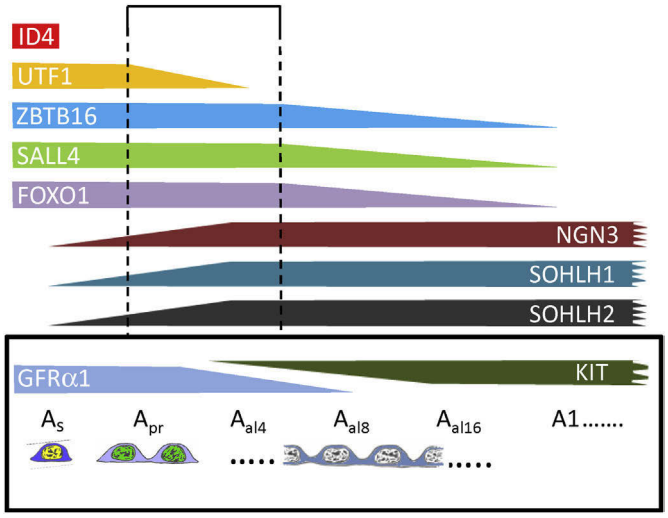

FIGURE 15.14 Summary of transcription factor expression in mouse spermatogonia. Bars indicate the extent of marker expression in the adult mouse spermatogonial lineage based on the data from Table 15.1. ID4, inhibitor of DNA binding 4; UTF1, undifferentiated embryonic cell transcription factor 1; ZBTB16, zinc finger and BTB domain containing 16; SALL4, Sal-like 4; FOXO1, forkhead box O1; NGN3, neurogenin 3; SOHLH1, spermatogenesis and oogenesis specific helix-loop-helix 1; SOHLH2, spermatogenesis and oogenesis specific helix-loop-helix 2; KIT, cKit receptor tyrosine kinase; GFRα1, GDNF family receptor α1. POU3F1, STAT3 and ETV5 are required for SSC maintenance and differentiation, respectively; however, there are no data to correlate the expression of these markers to clone size, so these factors are not shown.

have opposing functions in the regulation of *Kit* expression. ZBTB16 suppresses *Kit* expression and maintains an undifferentiated state, while SOHLH1 activates *Kit* expression and promotes spermatogonial differentiation.[294,295] These cells also express SALL4,[39,87,296] which has been shown to bind ZBTB16. Hobbs and colleagues proposed a model in which SALL4 sequesters ZBTB16 away from the *Kit* promoter, perhaps facilitating access by SOHLH1 to stimulate *Kit* transcription and spermatogonial differentiation.[296] FOXO1 is an effector of PI3K/AKT signaling in undifferentiated spermatogonia and exhibits nearly complete co-expression with ZBTB16. Knockout data suggest that FOXO1 is required for spermatogonial expansion during the first week of life and is also required for the induction of KIT expression, although that regulation may be indirect because there is limited co-expression of FOXO1 with KIT. Direct targets of FOXO1 may include *Sall4*, *Lhx1*, *Ret*, *Egr2*, *Egr4* and *Tex19*. In gonocytes of newborn animals, the FOXO1 protein is located primarily in the cytoplasm but translocates to the nucleus as gonocytes give rise to spermatogonia in the first week of life, which coincides with the onset of *Kit* expression and initiation of the first round of spermatogenesis.[290] A similar cytoplasmic-to-nuclear transition has been reported for SOHLH1 during pubertal development in the monkey, when spermatogonial differentiation is initiated in this primate.[297] The cytoplasmic to nuclear shuttling for these transcription factors appears to be related specifically to the initiation of spermatogenesis because FOXO1 and SOHLH1 are exclusively nuclear in adult spermatogonia.[290,294,297]

Posttranscriptional Regulation of SSCs

Kit mRNA is present in undifferentiated spermatogonia, while the KIT protein is absent.[95,198,281,298] This observation could suggest that SSCs are poised for differentiation and that the production of the KIT protein is initiated by a post-transcriptional mechanism. MicroRNAs (miRNAs) are important posttranscriptional regulators. Two studies demonstrated that inactivation of DICER, the enzyme that catalyzes the processing of miRNA precursors into mature 18–23 bp miRNAs, disrupts spermatogenesis and fertility.[299,300] This activity appears to be independent of the argonaute protein (AGO2) because AGO2 knockout in germ cells does not impact spermatogenesis or fertility, which suggests that DICER may have miRNA independent functions in the testis.[299] Nonetheless, there are dramatic changes in miRNA expression patterns during testicular development that occur in concert with the changing population of germ cells.[301]

Using cultured SSCs, Yang and coworkers[198] demonstrated that disruption of *microRNA 221* and *222* function in undifferentiated spermatogonia causes their transition from a KIT^- to KIT^+ phenotype and loss of potential to regenerate spermatogenesis in recipient mice. They further demonstrated that GDNF, FGF2, and CSF-1 stimulated *miR221/222* expression while treatment with RA reduced *miR221/222* expression, commensurate with increased *Kit* mRNA expression and concomitant increases in KIT protein levels. Overexpression of *miR221/222* inhibited the RA-induced differentiation of undifferentiated spermatogonia. In a similar series of experiments, Huszar and Payne[302] demonstrated that *miR146* inhibits RA-induced spermatogonial differentiation; this is regulated by direct downregulation of mediator complex 1 (*Med1*) expression, which is a co-regulator of retinoid receptors. He and colleagues[303] reported that *miR20* and *miR106a* are also involved in maintenance and renewal of SSCs acting in part by suppression of *Stat3* and *Ccnd1* expression. *MiR21* and the *miR17-92* (*Mirc1*) and *miR106b-25* (*Mirc3*) clusters are overrepresented in the $THY1^+$ fraction of mouse testis cells.[304,305] Knockdown of *miR21* in SSC cultures leads to increased apoptosis and loss of transplantable stem cell activity. ETV5 directly targets the *miR21* promoter and promotes *miR21* expression in SSC cultures.[304] Treatment of $THY1^+$ germ cell cultures

or VAD mice with RA resulted in the downregulation of most members of the *Mirc1* and *Mirc3* clusters. In addition, germ cell specific knockout of the *Mirc1* cluster reduced testis weight, disrupted spermatogenesis and reduced the number of sperm in the epididymis. However, the overall impact on fertility compared to controls was modest. The authors speculated that *Mirc3* family miRNAs may partially compensate for loss of *Mirc1* because *Mirc3* shares several potential genetic targets with *Mirc1* (including *Kit* and *Stat3*) and the *Mirc3* cluster was dramatically upregulated in the *Mirc1* knockouts.[305]

In contrast to *miR221/222*, *MiR20* and *miR106*, *miRlet7* appears to mediate RA-induced differentiation.[305] Tong and colleagues demonstrated that *miRlet7* is expressed by spermatogonia and spermatocytes. RA treatment of VAD mice in vivo and in THY1$^+$ spermatogonia in vitro caused a significant increase in *miRlet7* expression, and this was associated with a significant reduction in LIN28 expression. LIN28 is an evolutionarily conserved small RNA binding protein[306,307] and "stemness" factor[308] that is expressed by undifferentiated spermatogonia and specifically interferes with the DICER-mediated processing of *let7* precursor miRNAs into mature *miRlet7* in cultured SSCs.[184] Tong and colleagues[305] demonstrated that RA regulation is mediated by direct binding of RARα and RARγ to the *Lin28* promoter and also identified *Ccdn1*, *Col1a2*, and *Mycn* as potential targets of *miRlet7* that are known to be involved in spermatogonial development.[196,277,309,310] Similar to LIN28, NANOS2 and NANOS3 (Nanos homolog 3) are RNA binding proteins specific to germ cells in the mouse testis,[311] with expression restricted to A_s, A_{pr} and some A_{al} spermatogonia.[183,188] Immunohistochemical staining in whole mount preparations of seminiferous tubules indicate that NANOS2 may be more prevalent in smaller clones of undifferentiated spermatogonia and NANOS3 may be more prevalent in larger clones. Deletion of *Nanos2* or *Nanos3* caused infertility characterized by a complete absence of germ cells. This is due to the loss of primordial germ cells in the fetal testes and the spermatogenic lineage is never established in the postnatal testis.[311] Sada and coworkers[188] used lineage tracing experiments to demonstrate that NANOS2 is specifically expressed by SSCs in the postnatal testes. Conditional deletion of *Nanos2* at four weeks of age caused a rapid loss of GFRα1$^+$ and ZBTB16$^+$ spermatogonia which led to a complete loss of germ cells by 12 weeks of age. Conditional overexpression of *Nanos2* in the postnatal testis resulted in an accumulation of undifferentiated spermatogonia and a virtual absence of KIT$^+$ differentiating spermatogonia; the authors concluded that this resulted from a block to differentiation rather than increased proliferation or decreased apoptosis of undifferentiated spermatogonia.

SPERMATOGONIAL STEM CELL AGING

In the spermatogenic system, aging is manifested as a decrease in sperm number and quality of sperm in men.[312–315] Aging in the testis is also associated with declines in the number of Leydig and Sertoli cells, thickening of the basement membrane of the seminiferous tubules, and arrested divisions of germ cells.[316] A fundamental question is whether age-related deficits in spermatogenesis are due to deterioration of SSC function, niche function, or both.

Two studies reported a significant decline of stem cell activity (both concentration and total SSCs per testis) by 2 years of age in mice, which as associated with a significant decrease in testicular weight and atrophy of the seminiferous tubules.[250,317] Zhang and colleagues also reported that the length of donor-derived colonies produced in young recipients from 2-year-old donors was significantly reduced, indicating an intrinsic decrease in stem cell activity. In the reciprocal experiment, young SSCs could regenerate spermatogenesis leading to increased testis size in 1-year-old recipients with age-atrophied testes, but could not restore testis size in 2-year-old atrophied testes. These results suggest that there is also an age-related decline in SSC niche function.[317] Consistent with these results, Ryu and colleagues used a serial transplantation approach in which young SSCs were maintained in a perpetually young environment by retransplanting into new young recipients every 3 months. In this context, SSC continued to produce spermatogenesis in recipient testes for more than 3 years with no significant decline in stem cell concentration or colony length. The authors concluded that SSCs are very long-lived and that age-related declines in male fertility can be attributed in large part to a deteriorating niche.[250] The mechanisms of the age-related decline in the SSC niche are not clear, but Ryu and colleagues[250] reported a significant decrease in GDNF expression in aged, atrophied testes, despite the fact that Sertoli cell concentration is relatively increased in the atrophied testis. Additionally, Kokkinaki and coworkers[318] performed microarray analysis for GFRα1$^+$ cells from the testes of young and old mice and observed an age-related increase in genes that are involved in DNA repair (*Ercc1*, *Rcc5* and *Rad18*) or induced by DNA damage (*Gadd45b*) or oxidative stress (*Osgin2*). Whether these changes in gene expression are causes or consequences of SSC aging is not known.

TRANSGENESIS

SSCs are the only stem cells in the postnatal animal that contribute genes to the next generation. Therefore, they are not only crucial for the continuation of the

species, but they are also potentially a vehicle for germline modification and production of transgenic animals. Several groups have attempted to genetically modify SSCs by introducing transgene vectors (plasmid DNA or viral vectors) directly into the testes, similar to the approach used for SSC transplantation. However, in most cases these approaches, which employed viral vectors, lipofection or in vivo electroporation did not lead to efficient genetic modification of SSCs with persistent transgene expression, which indicates that the transgene was not stably integrated into the SSC genome.[319–322] Sertoli cells are likely the major obstacles that prevent transgenic vectors from reaching the target SSCs.

To address this challenge, Nagano and coworkers conducted a series of experiments to determine whether SSCs could be genetically modified when displaced from their cognate niche in the seminiferous tubules.[195,321] The most efficient approach evaluated in those studies involved repeated administration of retroviral or lentiviral vectors carrying a *lacZ* reporter gene to cultured SSCs. Transduction efficiency was greatest using mouse pup donor cells, which was likely due to the fact that spermatogonia are more proliferative at that stage of development. Upon transplantation, the genetically modified SSCs produced colonies of spermatogenesis with *lacZ* expression that persisted for periods ranging from 2 to 6 months. Similar results were obtained in rats.[136] The same group subsequently demonstrated in both mice and rats that recipients of retrovirus or lentivirus treated SSCs could sire transgenic offspring (F0) and that the transgene was passed to the F1 and F2 generations with the expected frequency. Transgenic efficiency in those studies was 4.5% in mice and 6% in rats, calculated as the percent of total offspring produced by the transplant recipient males.[116,323] The advent of SSC culture in 2003[168] expanded the possibilities for germline genetic modification because it allowed for targeted mutagenesis and clonal expansion of modified SSCs.[324,325] Whether germ cell-mediated transgenesis provides advantages relative to the more established pronuclear injection or embryonic stem cell-based approaches in rodents can probably be debated. Nevertheless, these approaches expand the available tools for rodent transgenesis and may be particularly valuable in large animal species where pronuclear injection is inefficient or impossible and ES cell technologies are not available.

Transgenic chicken have been produced by genetic modification (electroporation and *piggyBac* tranposon) and transplantation of germline competent chicken primordial germ cells (PGCs).[326,327] This approach is facilitated by the accessibility of the avian embryo in the egg and by the fact that PGCs can simply be injected into the vasculature of the developing embryo, where they migrate to the embryonic gonad and produce functional eggs and sperm. Zeng and colleagues also reported the production of transgenic pigs using adeno-associated virus and lentivirus constructs to modify SSCs, ex vivo. The transduced SSCs were transplanted into busulfan-treated recipient pigs by ultrasound-guided rete testis injection. Ejaculated sperm from transplant recipients was used to fertilize eggs by in vitro fertilization and gave rise to transgenic embryos.[328] Honaramooz and coworkers also previously demonstrated the feasibility of producing transgenic goats by this approach.[118] In addition to their value for fundamental research, transgenesis in large animals has the potential to improve health and production characteristics of food animals, produce novel bioreactors to generate large quantities of pharmaceutical proteins in eggs and milk and provide tissues and organs for transplantation in humans.

While genetic modification of SSCs by the in vivo approaches is very inefficient (as indicated above), Sertoli cells are efficiently transfected/transduced after injection of transgene vectors into recipient mouse seminiferous tubules,[329–331] and this may be a viable approach for niche therapy treatment of male infertility. Three groups used the rete testis injection approach typically employed for SSC transplantation to introduce adenoviral vectors[331], lentiviral vectors,[330] and plasmid DNA[329] containing *Kitl* cDNA into the *Kitl*-deficient Sertoli cells of infertile *Steel (Sl)* mice. In each case, spermatogenesis was established from latent endogenous SSCs in a portion of the seminiferous tubules in recipient *Sl* mice. Furthermore, sperm collected from the testes of adenovirus and lentivirus-treated recipients were functionally competent to fertilize mouse eggs by intracytoplasmic sperm injection and produced normal offspring.[330] None of the offspring carried the transgene, suggesting that virus-mediated Sertoli cell gene therapy may be a safe treatment for some cases of male infertility. However, the sample size was relatively small (a total of 33 mouse pups were produced in both studies), so additional studies are required before this gene therapy approach can be safely translated to the fertility clinic.

REGENERATIVE POTENTIAL OF SPERMATOGONIAL STEM CELLS AND TRANSLATION TO THE CLINIC

Due to their regenerative potential and the availability of the transplantation method, SSCs may have application for treating some cases of male infertility,[332–335] such as that caused by chemotherapy or radiation treatments for cancer or other conditions. Improved cancer therapies have resulted in a growing population of long-term survivors. Unfortunately, due to its highly prolific nature, the spermatogenic system is an unintended target of chemo- and radiotherapies,[336,337] and some cancer treatments such as high-dose chemotherapy, whole-body

radiation, or radiation to the gonads can cause permanent infertility.[338] The extent that the fertility of a patient is affected depends on the age of the patients as well as the dose, type, and frequency of treatment.[338] There has been significant progress in minimizing the unwanted side effects of the cancer treatment by adjusting and modifying the therapeutic regimens without compromising the efficiency of oncologic treatments.[339] In addition, several rodent studies indicate that suppression of gonadotropins and testosterone using gonadotropin-releasing hormone antagonists stimulated the recovery from endogenous SSCs that survived chemotherapy or radiation treatment.[340–347] However, the results in human clinical trials have been mixed (reviewed in Ref. 348), with only one study reporting successful protection of human spermatogenesis using hormone suppression.[349]

Pubertal and adult males have the option to cryopreserve sperm prior to oncologic treatment. Unfortunately, only a small percentage of men pursue this option prior to initiating treatment.[350] Furthermore, this is not an option for the prepubertal boys, who are not yet making sperm. However, these young patients do have SSCs in their testes that are poised to initiate sperm production at puberty (see Chapter 32). There are several stem cell technologies in the research pipeline that may give rise to new fertility options and allow infertile patients to have their own biological children.

As described above, homologous SSC transplantation has been successfully performed in several animal species, including mice, rats, pigs, goats, bulls, sheep, dogs, and monkeys.[102,113,115–123,126,127,168] Furthermore, Shetty and coworkers[129] recently demonstrated that spermatogenesis from transplanted SSCs was enhanced by hormone suppression with GnRH antagonist in chemotherapy-treated monkeys. This progress suggests that SSC transplantation in humans may be feasible and could provide a new option for patients that have no other alternatives to preserve or restore their fertility. Results in mice, rats, and nonhuman primates indicate that SSCs from donors of all ages, newborn to adult, can regenerate spermatogenesis and produce functional sperm[108,115,123] and SSCs can be cryopreserved and retain their spermatogenic potential upon thawing and transplantation.[68,123,145,147] Wu and colleagues demonstrated that mouse SSCs were competent to regenerate spermatogenesis and produce fertile offspring after 14 years of cryostorage.[351]

Thus, prepubertal boys or adult men should be able to cryopreserve testicular tissue containing SSCs prior to treatment and have these cells reintroduced into their testes at a later date to regenerate spermatogenesis. Several clinics worldwide are already cryopreserving testicular tissue for patients in anticipation that new stem cell therapies will be available in the future. To date testicular tissues or cells have been cryopreserved for over 150 patients that are documented by published reports;[128,154,155,335,352–355] and personal communications (K.E.O.) indicate that the actual number is much higher. Therefore, it is critical for researchers and physicians to responsibly and safely develop new fertility treatments toward clinical application.

In 1999, Radford and colleagues introduced the autologous SSC transplantation technique to the human clinic.[128] Testicular tissue from 12 male non-Hodgkin's lymphoma patients was cryopreserved as a cell suspension prior to initiating chemotherapy. At later dates, seven patients had the cells injected back into their testes.[355,356] To date, there have been no follow-up reports on the fertility status of those patients, so the outcome of the experiment is unknown. Even if the men had fathered children, it would be difficult to demonstrate definitively (in the absence of a unique genetic marker) that those offspring resulted from sperm produced by transplanted stem cells rather than from surviving endogenous stem cells. There have not been other reports of SSC transplantation in humans since 1999, but these initial cases demonstrated that patients are willing to pursue experimental stem cell options to achieve fertility.

Clinical translation of the SSC transplantation technique appears imminent considering the success in several large animal models; however, several questions and challenges remain. First, the small amount of tissue that is obtained from a biopsy from a prepubertal boy may contain a relatively small number of stem cells. Second, in the cancer survivor paradigm, it is essential to eliminate the risk of introducing malignant cells.

In rodents, SSCs can be expanded substantially in culture and maintain competence to produce spermatogenesis and restore fertility upon transplantation.[113,140,168,169] Several groups have reported extending SSC culture to large animal species[202–206] and a number of laboratories have reported progress culturing human SSCs[153–155,207–211] (see the previous section on culture). This approach could theoretically be employed to amplify the small number of stem cells that can be obtained from a biopsy and also to demonstrate the absence of malignant contamination.

Autologous testicular tissue grafting is also an option to restore fertility (see the previous section on Xenografting). Results from monkey studies[222,223] suggest that autologous transplantation may be an option if suitable cryopreservation conditions are developed. Similar to SSC transplantation, autologous grafting will be problematic in cases where malignant contamination of the testicular tissue is suspected. Xenografting of human testicular tissue into animals could circumvent this problem, but it is associated with additional concerns about xenobiotics and has been unsuccessful to date.[215–220]

Additional strategies to remove malignant contamination include FACS sorting the testicular cell suspension

and organ culture. Several groups have demonstrated that it is possible to isolate germ cells and remove malignant contamination from heterogeneous testicular cell suspension using FACS and a combination of germ cell and/or cancer cell markers.[151,172,181,357,358] Despite these promising reports, caution is warranted because even low levels of contamination can lead to cancer and current assays may lack the sensitivity to detect very rare malignant cells.[359,360]

An alternative approach that would eliminate the risk of introducing malignant cells into patients is to produce haploid gametes, in vitro. Sato and coworkers[361] described a method for testicular organ culture in which SSCs are maintained in their niches in the seminiferous tubules. The authors demonstrated that testicular tissue from immature mice could be maintained for several weeks in culture on an agarose platform that was submerged in medium. In this way the testicular tissue was suspended at the air/liquid interface, a method originally described in the 1950s.[362] From immature testicular tissue that initially contained only undifferentiated spermatogonia, haploid round spermatids and sperm were generated by 23 and 42 days in culture, respectively, and used to fertilize mouse oocytes by ICSI or round spermatid injection (ROSI). The fertilized embryos were transferred to recipient females and gave rise to healthy offspring. If these results can be translated to humans, testicular organ culture would circumvent the need to put tissues or cells back into patients and may be a safe option for patients with malignancies that contaminate the testes.

For males who did not preserve sperm or testicular tissue prior to gonadotoxic treatment, generation of transplantable germ cells (primordial germ cells or SSCs) or haploid gametes from embryonic stem cells (ESCs) or induced pluripotent stem cells (iPSCs) has been explored. Several groups have reported the generation of germ cells from nonhuman primate ESCs[363,364] and human ESCs and/or iPSCs,[365–369] including evidence of rare haploid cells in some cases. The safety and feasibility of this system still needs to be evaluated in animal models due to the inability to test the function of the resulting germ cells in human system.

CONCLUSION

Spermatogonial stem cells are at the foundation of spermatogenesis and may have practical applications for producing transgenic animals and treating some cases of male infertility. These adult tissue stem cells can only be definitively identified by their biological potential to produce and maintain spermatogenesis after transplantation or by their ability to regenerate spermatogenesis after toxic treatment. These are retrospective analyses and there is currently no universally accepted method to prospectively identify the entire population of spermatogonial stem cells.

The jargon used to describe SSCs and their progeny is important because it impacts the interpretation of experimental results and, by extension, knowledge in the field. The definition of SSCs is precise and irrefutable. A cell that can produce and maintain spermatogenesis is an SSC. The definitions of progenitor and differentiating spermatogonia may be less obvious. The main distinction between stem and progenitor cells is that stem cells can theoretically replicate indefinitely (or at least for a very long time; see the section on aging), while progenitors have a more limited replicative potential.[370] Progenitor cells are undifferentiated cells that have a *tendency* to differentiate into one or more lineages within a tissue. Note that tendency does not indicate an absolute commitment to differentiate and reflects a populational probability to commitment. For example, most NGN3$^+$, undifferentiated spermatogonia have a tendency to differentiate, but a portion of the NGN3$^+$ cells retain the potential to regenerate spermatogenesis upon transplantation or when spermatogenesis is depleted by toxic treatment.[35,189] SOHLH1, SOHLH2, and NANOS3 have expression patterns very similar to NGN3 and therefore might also be considered markers of progenitors in the spermatogenic lineage. Whether the pools of SOHLH1, SOHLH2, and NANOS3 positive spermatogonia have transplantable stem cell activity remains to be demonstrated, however. When a study is clearly focused on a population of spermatogonia with an undifferentiated phenotype, but it is not possible to determine the population's stem cell activity using the transplantation assay, we suggest that it may be most appropriate to use terms such as "stem and progenitor spermatogonia" or "undifferentiated spermatogonia." Using accurate vocabulary should not compromise the importance of the science and will help to strengthen hypotheses for future studies.

It is also important to understand the biological differences between stem and progenitor spermatogonia to determine which cell type is most appropriate for therapeutic applications. There is relative consensus that differentiating spermatogonia can be identified morphologically by the accumulation of heterochromatin in the nucleus and by expression of specific markers, including STRA8 and KIT. In contrast to progenitor spermatogonia, differentiating spermatogonia have committed to differentiate with no long-term potential to regenerate and maintain spermatogenesis.

There has been significant progress identifying molecules that regulate SSC function; this progress has been fueled in large part by the use of genetically modified animals, the SSC transplantation technique, and SSC culture. However, there remains a very limited understanding of how these individual molecules interact to transduce signals from the SSC niche and coordinate

intrinsic pathways within the SSC that lead to self-renewal versus differentiation developmental fates. Continued discovery of molecules that regulate SSC fate will help to fill the knowledge gaps, and progress will be facilitated by accurate interpretation of results relative to stem, progenitor, and differentiating terminology.

Although spermatogonial clone size (e.g., A_s, A_{pr}, A_{al}) can be indicative of stem cell potential, clone size cannot absolutely define the stem cell pool. The stem cell pool in rodents is generally considered to be comprised of A_s and some A_{pr} spermatogonia (reviewed in Ref. 27). However, several studies have revealed molecular heterogeneity within the pools of A_s and A_{pr} spermatogonia.[35,39,90,183,184] Does molecular heterogeneity suggest functional heterogeneity? It should be possible in future studies to cross different transgenic reporter lines to facilitate isolation of subpopulations of cells with distinct molecular phenotypes within the stem and progenitor pool and determine their relative stem cell activity by transplantation.

A_{dark} and A_{pale} are considered to be the SSCs in nonhuman primate and human testes. In rhesus macaques, all A_{dark} and half of A_{pale} spermatogonia share the undifferentiated phenotype GFRα1$^+$/ZBTB16$^+$/NGN3$^-$/KIT$^-$. Half of A_{pale} also express NGN3 and 25% of A_{pale} express KIT.[68] Does this indicate that the pool of A_{pale} spermatogonia also includes progenitor and early differentiating spermatogonia, such as A_{pr} and A_{al} spermatogonia in rodents? A_{dark} spermatogonia have the potential to regenerate spermatogenesis after noxious treatment with radiation and therefore satisfy the formal definition of SSCs. The potential of A_{pale} to regenerate spermatogenesis in this paradigm has not been demonstrated because A_{pale} are destroyed by radiation.[70,84] In the future, it may be possible to isolate A_{dark} and A_{pale} spermatogonia based on unique molecular phenotypes and then transplant to determine relative stem cell activity. To date, there are no cell surface markers that clearly distinguish A_{dark} and A_{pale} spermatogonia; generation of several transgenic reporter lines in monkeys is possible[371,372] but probably not realistic.

Examination of SSC activity in higher primates is further complicated because it is difficult to test the ability of a test cell population to produce and maintain spermatogenesis after transplantation. Xenotransplantation into nude mouse testes is a valuable tool for studying SSCs in nonhuman primate and human testes,[148,149,151,152] but it is limited because it does not reconstitute complete spermatogenesis. Monkey-to-monkey transplant is feasible and can test the full regenerative potential of a test cell population,[123] but it is too cumbersome and expensive to use as a routine biological assay. Perhaps in the future it will be possible to primatize or humanize mouse testes to support complete spermatogenesis from monkey and human cells. Humanized mice have been valuable for translational studies on human hematopoiesis and immunity.[373] Development of robust functional assays for putative human germ cells will become increasingly important to validate the exciting discoveries that human pluripotent stem cells can be induced to differentiate down spermatogenic lineage.

The SSC field has grown dramatically in the past two decades, due in part to the development of the SSC transplantation technique[100,101] and in part to the explosive development of the stem cell field in general after the discovery of human pluripotent stem cells.[374,375] The SSC transplantation technique has facilitated hundreds of fundamental investigations and opened new opportunities for germline preservation and animal transgenesis as well as pharmaceutical and clinical applications. On the heels of the past discoveries detailed in this chapter, we believe it is reasonable to expect that SSCs or other stem cells will be used to preserve and restore the germlines of valuable domestic species and treat human male infertility in the coming decades.

INTRODUCTION

The process of spermatogenesis is essential to maintain male fertility. The signals originating from hormones drive intercellular communication and intracellular processes that are required for spermatogenesis. Although there are dissenting opinions,[1] evidence is accumulating that indicates sperm counts are decreasing for men in developed countries. A compilation of human sperm count studies for North American men determined that sperm density decreased by about 40% over the 40 years previous to 1990.[2] For European men, there was a 65% decrease over the same period. If the current trend continues, by 2020–2040 sperm count for the average European man will be 20 million/ml. This level of sperm production is defined as oligospermic and is the level at which decreases in fertility are observed.

It is proposed that environmental influences including endocrine disruptors such as environmental estrogens are major contributors to the decrease in sperm production due to their interference with normal hormone signaling in the testis. These observations highlight the importance of understanding the molecular mechanisms by which hormones support spermatogenesis. Fortunately, transgenic mouse studies have provided better definitions of the physiological and cellular functions of various hormones in specific cell types in the testes. Also, advances have been made in defining the specific genes, proteins, and signaling pathways that are regulated by individual hormones. It is obvious that these advances as well as additional information will be required to counteract the trend of decreasing sperm counts.

We have known for more than 80 years from Greep's pioneering work that two hormones derived from gonadotrophs in the anterior pituitary, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), have separate sites of action in the testis and work in concert to control spermatogenesis.[3] As explained in this chapter, both of these gonadotropin hormones act indirectly to promote the initiation of spermatogenesis, germ cell proliferation, development, and differentiation. FSH acts on the Sertoli cell to activate gene expression and signaling pathways that support the process of sperm production. LH acts on the Leydig cell to promote the production of testosterone that is essential for maintaining spermatogenesis, in addition to its wider role in masculinization and the maintenance of male secondary sexual characteristics. Testosterone acts upon Sertoli cells and other testicular cells to regulate gene expression and the activation of signaling pathways that are required for supporting spermatogenesis. Although Smith first reported in 1930 that testosterone could substitute for the pituitary gland,[4,5] the molecular mechanisms by which testosterone can independently support the development, retention, and release of germ cells is still only partially understood. Additional circulating hormones and testis-derived factors provide needed communication between testicular cells and contribute to maximizing fertility.

In this chapter, we review the intracellular and intercellular signals initiated by the complex milieu of hormonal factors in the testis. The physiological functions of LH and the molecular mechanisms by which LH activates the genes and enzymes required for the production of testosterone are discussed. The multifaceted actions of testosterone in nearly all cells of the testis except

germ cells and the testosterone-induced communication between testis cells are described from the perspective of transgenic mice lacking the receptor for testosterone in specific cell types. The genes and signaling factors regulated by testosterone are then examined. The multiple signaling pathways regulated by FSH in Sertoli cells are described as well as the differences in FSH signaling that occur in proliferating versus differentiated Sertoli cells. A comparison of signals originating from FSH and testosterone is then made to characterize the synergism shown by the two hormones in the maintenance of spermatogenesis. We also review the signaling pathways by which thyroid hormone regulates the proliferation of Sertoli cells and thus determines the capacity for sperm production.

Interestingly, none of the major endocrine drivers of spermatogenesis (LH, testosterone, and FSH) act directly on germ cells, but instead cause the production of factors that function locally in the testis to enhance the germ cell niche. We discuss the functions of three of these locally acting factors: estrogen, which is derived from testosterone, as well as activin and inhibin, which are regulated by FSH. Finally, a summary is provided of the known contributions of other hormones that fine-tune the testis environment, including osteocalcin, insulin and related factors, glucocorticoids, mineralocorticoids, leptin, and prolactin.

Anatomy of the Testis

Germ cell development and sperm production occur in the seminiferous tubules that feed into the rete testis and then the epididymis (Figure 16.1(A)). Between the tubules in the interstitial space are blood vessels and lymphatic vessels. Leydig cells that produce testosterone are also found in clusters within the interstitial space between the tubules (Figure 16.1(B)), alongside resident macrophages. The seminiferous tubules are surrounded by peritubular myoid (PTM) cells that contract to force released sperm in the tubule toward the rete testis and into the epididymis.

Within the seminiferous tubules, somatic Sertoli cells extend from the basement membrane adjacent to PTM cells to the lumen and surround the developing germ cells (Figure 16.1(C)). Germ cells are present throughout the seminiferous tubule epithelium, with the most immature and undifferentiated cells, including spermatogonial stem cells (SSCs), present on the basement membrane and the most mature germ cells localized to the tubule lumen. At all stages of development, germ cells are in contact with the somatic Sertoli cells that provide niches to support stem cell renewal and differentiation. Sertoli cells also provide growth factors and nourishment for more mature germ cells. During puberty, specialized adhesion junctions are created between each adjacent Sertoli cell that in total form the blood–testis barrier (BTB) near the base of the seminiferous tubules. The BTB divides the seminiferous tubule into the basal and adluminal compartments such that only factors smaller than 1 kDa are able to pass through the barrier. Because of the BTB, Sertoli cells provide a defined, protected microenvironment for the germ cells that are on the luminal side of the BTB. These luminal germ cells do not have access to the outside environment and are dependent upon the Sertoli cell for nourishment, growth factors, as well as other signals required for survival and the development into spermatozoa.[7]

Brief Overview of Spermatogenesis

Details of the process and regulation of spermatogenesis are provided in previous editions of this book. In brief, spermatogenesis is initiated with SSCs located along the basement membrane dividing to produce undifferentiated spermatogonia that are committed to becoming spermatozoa. The undifferentiated spermatogonia undergo a series of mitotic divisions with incomplete cytokinesis to form chains of spermatogonia. The number of spermatogonia divisions is species specific. In rodents, there is extensive amplification of spermatogonia through numerous sequential mitoses. In contrast, there are fewer divisions of spermatogonia in nonhuman primates and humans. A final spermatogonia mitosis gives rise to preleptotene spermatocytes that are programmed to undergo meiosis. During the preleptotene stage of meiosis, spermatocytes detach from the basement membrane and "pass through" the BTB. More precisely, a new series of adhesion sites is formed on the basal side below the preleptotene spermatocyte, after which the BTB on the luminal side of the germ cell is dissolved. Once beyond the BTB, meiosis is completed with the production of haploid spermatids. The resulting spermatids undergo extensive differentiation (spermiogenesis) to become spermatozoa, including condensation of the nucleus, acrosome formation, termination of gene expression, elimination of much of the cytoplasm, cell elongation, and development of a flagellum. Spermatogenesis is completed with the release of spermatozoa into the lumen of the seminiferous tubule (reviewed in Ref. 8).

The seminiferous epithelium is highly organized in the adult testis. Well-defined groups of germ cells appear along the tubule sequentially or at single points on the tubule at specific recurring time points. For example, in rats, within any one region of the seminiferous tubule, the initial transition of undifferentiated spermatogonia to differentiating spermatogonia occurs once every 12.9 days. The length of this cycle is 8.6 days in the mouse and 16 days in humans (reviewed in Ref. 9).

The regular timing of the transition from undifferentiated to differentiated spermatogonia and the

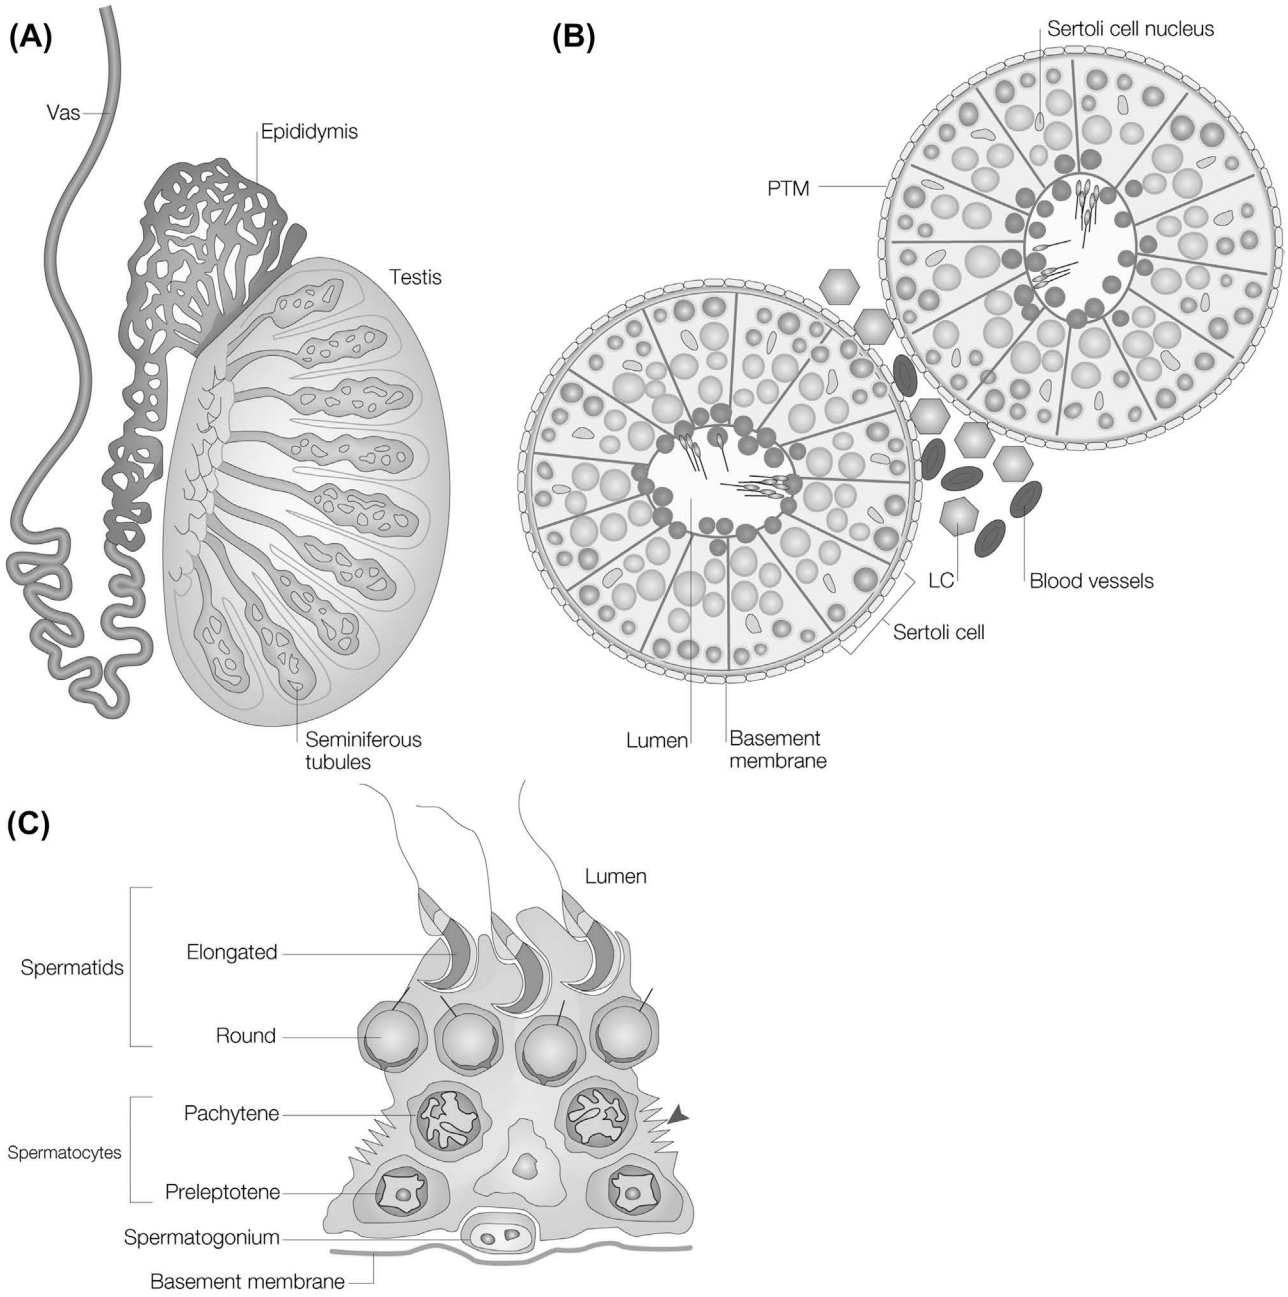

FIGURE 16.1 Schematics of the structure of the testis and seminiferous tubule. (A) The testis consists of lobules that originate from and then return to the rete testes (left side of the testis shown). The rete testis provides a passageway for sperm and fluid to the epididymis. (B) A diagrammatic cross-section through two seminiferous tubules shows germ cells at different stages of development embedded in Sertoli cells. Maturing spermatozoa are shown in the lumen of the tubules. Peritubular myoid (PTM) cells line the outside of the seminiferous tubule. Leydig cells (LC) and blood vessels are located in the interstitial space between seminiferous tubules. (C) A single Sertoli cell and associated germ cells. A region of tight and adherens junctions that forms the blood–testis barrier between Sertoli cells is denoted with an arrowhead. Sertoli cells extend from the basement membrane to the lumen of the seminiferous tubule. The cytoplasm of a Sertoli cell surrounds germ cells during all stages of germ cell development. Spermatogonia lie on the basement membrane of the seminiferous tubule. As germ cells progress through their developmental steps (spermatogonia, preleptotene spermatocytes, pachytene spermatocytes, round spermatids, and elongated spermatids), they move toward the lumen and are released as spermatozoa. *Source: Reproduced with permission from Ref. 6.*

synchronized, clonal pattern of development for each cohort of germ cells result in different generations of germ cells that form associations. Arbitrarily defined associations of the generations of germ cells at various stages of development with defined physiological characteristics are called cell association stages of the cycle of the seminiferous epithelium.[10] There are six stages in humans (I–VI), 12 in mice (I–XII), and 14 (I–XIV) in rats

(Figure 16.2). The cell association stages occur in repeating cycles, with four and one-half cycles of 12.9 days being required in the rat to produce mature sperm from an undifferentiated spermatogonium.[12,13] Along the seminiferous tubule in most rodents and some primates, the stages follow each other in a wavelike fashion[14] (Figure 16.3). In men, the wave occurs as a spiral down the tubule. The results of this cycle of the seminiferous epithelium are that spermatozoa are released at any given point along the tubule once each cycle, and spermatozoa are asynchronously released along the length of the tubule to provide a constant supply of sperm.

Hormone Action

Spermatogenesis is dependent upon hormonal inputs that result in a complex pattern of intratesticular signaling pathways. These hormonal inputs affecting the testis and spermatogenesis can be initiated by the production of hormones at distant tissues, with the transport of the hormones via the circulatory system (endocrine actions). More localized hormonal effects are achieved with the production of hormones by testicular cells and their action on nearby or adjacent cells (paracrine actions) or their secretion from and stimulus of the same cell (autocrine action).

In general, there are two major types of hormones: protein–peptide hormones that act upon receptors at the cell surface, and lipophilic hormones that bind to receptors predominately located in the cytoplasm or the nucleus. Peptide hormones binding to their receptors initiate intracellular signaling pathways that usually activate or inhibit specific kinases, phosphatases, or ion channels, resulting in altering of cellular functions and gene expression (Figure 16.4(A)). Lipophilic hormone binding to their receptors often results in the translocation of the ligand–receptor complex to specific regulatory DNA sites in the genome and the alteration of gene expression patterns (Figure 16.4(B)). However, it is now established that the binding of many lipophilic hormones with their receptors can also cause the activation of kinases within target cells.[15]

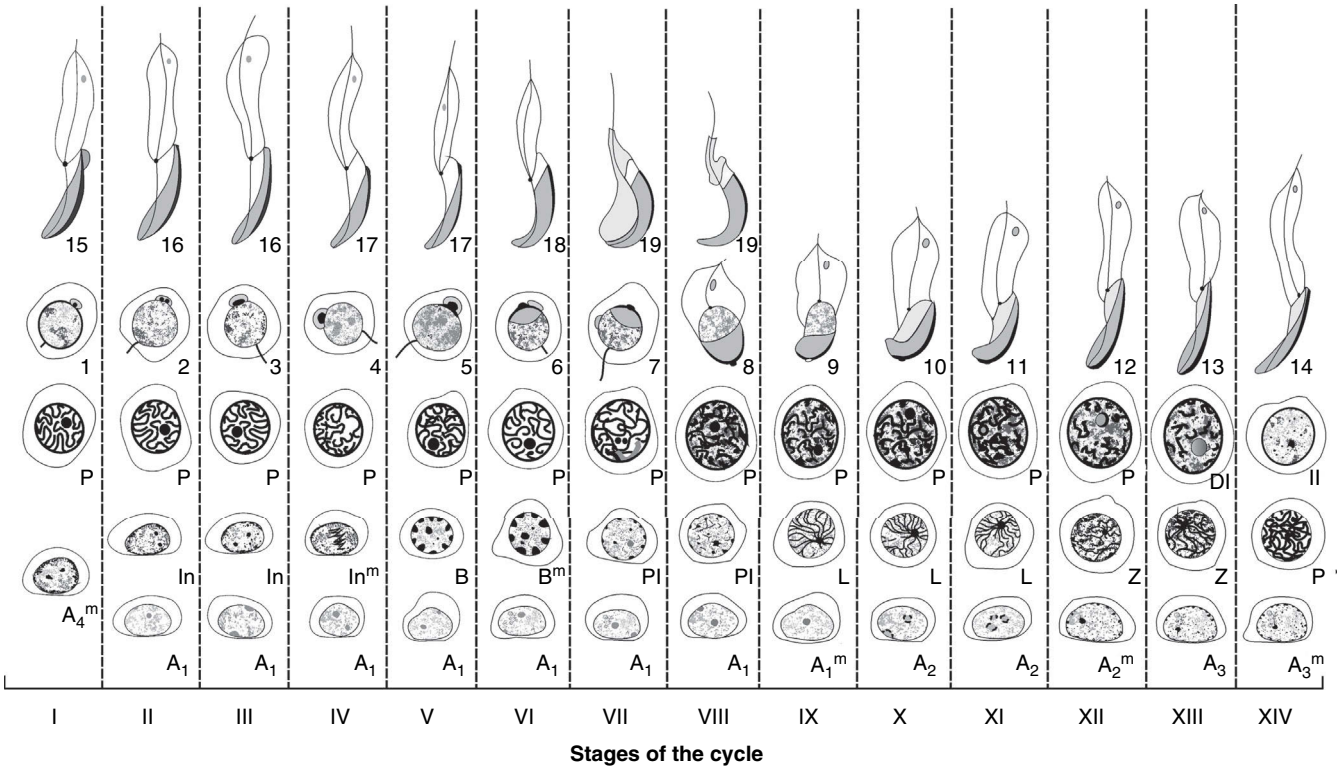

FIGURE 16.2 The cell associations comprising the XIV stages of the cycle of the rat seminiferous epithelium. Each column numbered with a Roman numeral shows the cell types present in one of the cellular associations found in cross-sections of seminiferous tubules. The cellular associations or stages of the cycle succeed one another in time in any given area of the seminiferous epithelium in the rat. Following cellular association XIV, cellular association 1 reappears, so that the sequence starts over again. The stages of the cycle were identified by means of 14 of the 19 steps of spermiogenesis (numbers 1–19). These steps were defined by the changes observed in the nucleus and in the acrosomic structure (the acrosome and head cap are seen applied to the surface of the nucleus). Letters: A_1, A_2, A_3, and A_4 represent four generations of type A spermatogonia; In: intermediate spermatogonia: B: type B spermatogonia; the subscript m next to a spermatogonium indicates occurrence of mitosis; P1: preleptotene spermatocyte; L: leptotene spermatocyte; Z: zygotene spermatocytes; P: pachytene spermatocyte; Di: diakinesis of primary spermatocytes; and 11: secondary spermatocyte. The type A_s, A_{pr}, and A_{al} undifferentiated spermatogonia, present in all stages of the cycle that give rise to type A_1 differentiated spermatogonia, were not included in this drawing. *Source: From Ref. 11 with permission.*

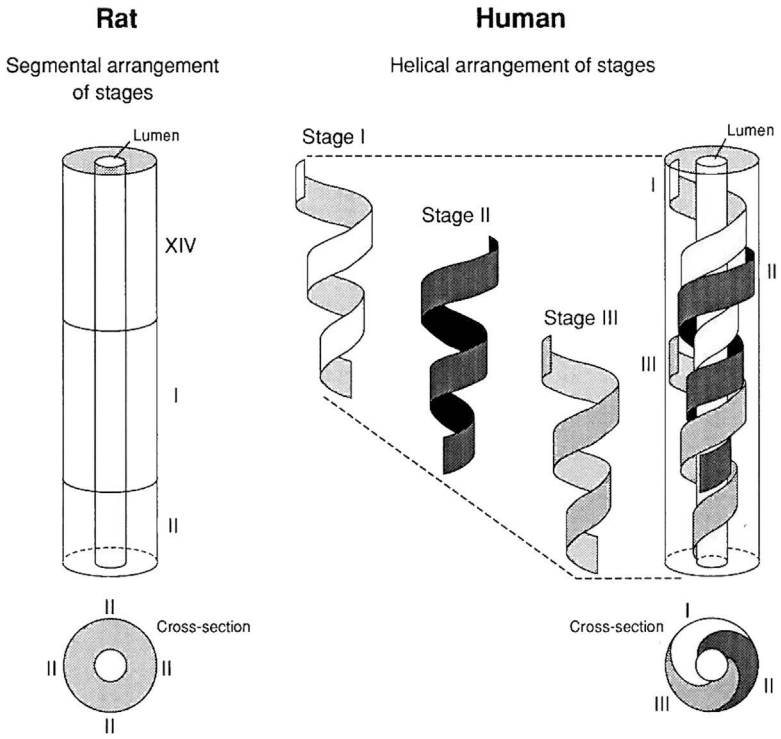

FIGURE 16.3 **Diagram of the progression of germ cell associations (stages of the semiferous epithelial cycle) as a wave along the seminiferous tubule in rat and human.**

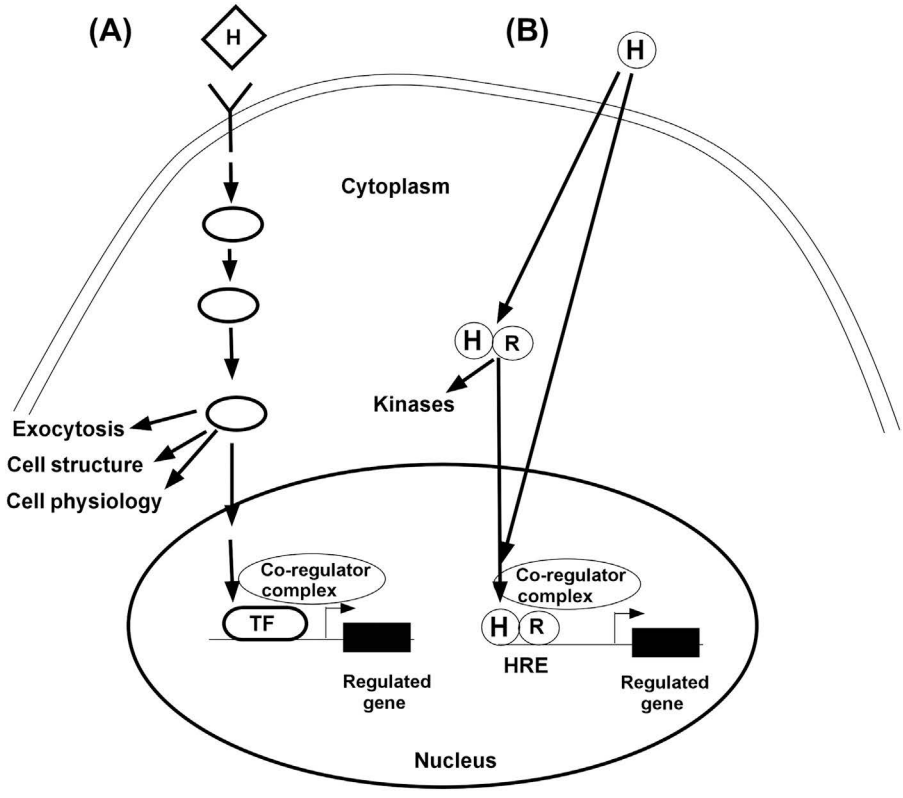

FIGURE 16.4 **Hormone action.** (A) Protein and peptide hormones (H in a diamond) usually bind to membrane-spanning receptors and then alter receptor structure to activate kinase activity, cause dimerization with other receptors, or recruit proteins to the receptor. Often, a series of adaptor proteins are recruited and/or kinases activated that result in changes to cell physiology, cell structure, and/or the exocytosis of regulatory factors. Signals can also be sent to the nucleus to alter transcription factors (TFs) or other members of the gene regulatory machinery to alter gene expression. (B) Lipophilic hormones such as steroids (H in a circle) pass through the plasma membrane to bind receptors (R in a circle) present in the nucleus or in the cytoplasm that then translocate to the nucleus. In the nucleus, the lipophilic hormone–receptor complex acts to alter gene expression. Some lipophilic hormone–receptor complexes are also capable of activating kinases to alter cell function. HRE: hormone response element.

In the testis, LH acting on the Leydig cell and FSH acting on the Sertoli cell are the major endocrine regulators of spermatogenesis. There hormones either directly alter the function of target cells to support spermatogenesis, or result in the production of paracrine and autocrine factors that act on germ cells and other supporting cells to increase sperm production. The hormones regulating spermatogenesis and the

signaling pathways that they initiate are the focus of this chapter.

LUTEINIZING HORMONE

LH and FSH, along with thyroid-stimulating hormone (TSH), are members of the glycoprotein hormone family, each of which shares a common α subunit and a specific β subunit that confers biological specificity. LH is secreted into the bloodstream by the gonadotropes located within the anterior pituitary, upon gonadotropin-releasing hormone (GnRH) stimulation (described in Chapter 28). The primary function of LH in the testis is stimulation of testosterone production by the Leydig cells. This is achieved by binding LH to its cognate receptor, luteinizing hormone–chorionic gonadotropin receptor (LHCGR), on Leydig cells, activating the production of enzymes that is required for the biosynthesis of testosterone from a cholesterol substrate. LHCGR is a member of the seven-transmembrane domain G-protein coupled receptor (GPCR) superfamily (reviewed in Refs 16–18). Treatment of *hpg* mice (which lack gonadotropins) with testosterone restores qualitative spermatogenesis. This effect of testosterone-mediated support of spermatogenesis can also be replicated by exogenous human chorionic gonadotropin (hCG) treatment (which also binds and activates LHCGR) in *hpg* mice, demonstrating that testosterone is the key trophic factor produced by Leydig cells under the control of LHCGR stimulation.[19]

Testosterone release into the bloodstream acts to regulate LH secretion by the pituitary through a negative feedback loop. Elevated circulating testosterone concentrations feed back at the level of the hypothalamus and pituitary to suppress LH secretion by the pituitary, which subsequently reduces LHCGR-mediated stimulation of Leydig cells and thereby reduces testosterone production. Conversely, a fall in circulating testosterone concentrations induces LH secretion by the pituitary and a concomitant increase in testosterone production by the Leydig cells.

LHCGR Localization

Although LHCGR expression has been observed in several tissues in the male, including the seminal vesicles, skin, adrenals, neural retina, neuroendocrine cells, thyroid, and brain, and in certain tumors (reviewed in Refs 16,18,20), the primary site of expression in the normal male is the Leydig cells, both fetal and adult-type Leydig cells. In rodents, LHCGR is expressed in fetal Leydig cells from around embryonic day 16 (e16),[21,22] whereas in humans expression begins within the first trimester. Importantly, germ cells do not express LHCGR at any age, and thus LH control of the seminiferous epithelium is mediated indirectly.

Structure and Function of LHCGR

Expression of LHCGR is controlled by two functional Sp1/Sp3 binding domains identified in both rodents and humans,[23–26] and an upstream imperfect estrogen response element (ERE) direct repeat, with gene expression controlled by a complex balance of repression–de-repression mechanisms, which include suppression by the orphan nuclear receptors EAR2 and EAR3–Coup-TFI, and activation by TR4.[27,28] More recently, epigenetic changes in local chromatin structure have been shown to control gene expression, which works in concert with demethylation of promoter CpG sites to maximize gene expression[29,30] (reviewed in Ref. 18). Several splice variants of LHCGR have been identified across several species (reviewed in Ref. 31). Following translation, the LHCGR protein is shuttled to the surface membrane of Leydig cells, where, like other seven-transmembrane GPCRs, it spans the surface membrane. LHCGR contains an N-terminal extracellular domain that binds LH (and hCG) with high affinity and specificity. This domain contains a number of leucine-rich repeats (LRRs) that are thought to contain successive β-strands and α-helices organized into a horseshoe-shaped structure, with the β-strands forming a parallel β-sheet along the concave surface (reviewed in Refs 16,31). The N-terminal domain is linked to the seven-transmembrane domains that are responsible for signal transduction. These domains are held together by ionic bonds, which are broken upon ligand binding of LHCGR, inducing a conformational change in the receptor. Co-expression of a binding-deficient form of LHCGR and a signaling-deficient form of the receptor was able to rescue the phenotype of an LHCGR-deficient mouse, suggesting that dimerization may perform a functionally important role in LH signaling,[32] as is the case for FSH signaling.[33] However, this interpretation has recently been questioned[34]; thus, the significance and specific function of such dimerization remain to be established, as many GPCRs do not appear to function as dimers (reviewed in Ref. 35).

Role of LH in Adult Leydig Cell Development—Mouse Models

LH signaling in the postnatal testis plays two major roles, controlling both adult-type Leydig cell development and function. In postnatal life, LH expression is upregulated as puberty initiates, while at the same time, the population of adult Leydig cells begins to develop from adult Leydig cell precursor cells (reviewed in Ref. 36). This process of initial differentiation occurs in *hpg* mice that

lack gonadotropin and as such is independent of LH signaling.[37] However, following initial differentiation, these progenitor cells begin to express LHCGR, and LH becomes the most important trophic factor driving adult Leydig cell development. The significance of LH signaling for adult Leydig cell development was firmly established through analysis of several mouse models. In 2001, two groups independently published knockouts of LHCGR: one by targeted deletion of exon 1[38] and one by disruption of exon 11, which encodes the transmembrane and intracellular domains of LHCGR.[39] Both strategies result in models with complete ablation of LHCGR function and with broadly similar phenotypes (reviewed in Refs 40,41). Male mice lacking LHCGR develop normally up to birth, in keeping with the observations that LH signaling is dispensable for prenatal development in rodents.[42–44] The phenotype of the knockout mice remains similar to that of littermate controls up to two weeks of age, but it becomes radically different as the mice enter puberty. Postpubertal LHCGR knockout mice express steroidogenic enzyme genes (including steroidogenic acute regulatory protein (StAR), p450scc, and 17β-HsDIII and Insl3 (insulin-like 3) at very low levels,[45] which is associated with a gross failure of proliferation and maturation of adult Leydig cells and with infertility. The LHCGR phenotype can be partially rescued by testosterone replacement therapy.[46] A similar phenotype is observed in transgenic mice engineered to lack LHβ, demonstrating a clear ligand–receptor interaction.[47] However, because these animals retain a functioning LHCGR, treatment of these animals with exogenous hCG rescues the phenotype.[48] Together with the investigations using *hpg* mice, which demonstrate differentiation of the adult Leydig cell precursors in the absence of LH signaling,[37] these data confirm that LH–LHCGR signaling is essential for the proliferation and function of adult Leydig cells, although it is not required for their initial differentiation.

Overstimulation of LH signaling has also been attempted in various guises (reviewed in Ref. 41). In mouse studies, transgenic overexpression of LH in female mice results in infertility, polycystic ovaries, and ovarian tumors,[49] but male mice were only minimally affected by overstimulation by LH signaling, with mild impairment of adult Leydig cell differentiation.[50,51] Ramping up the system such that transgenic hCG is expressed at 2000-fold the normal elevated circulating LH–hCG bioactivity resulted in focal Leydig cell hypertrophy and increased testicular androgen production, with progressive seminiferous tubule degeneration as the animals aged, but it failed to produce testicular tumors in adult animals (although the animals were infertile, probably due to functional urethral obstruction).[52] Interestingly, overstimulation with hCG during fetal life did result in Leydig cell tumors arising from fetal Leydig cells, but these regressed naturally in line with the normal lifespan of fetal Leydig cells.[53] The most intriguing observation from these overstimulation studies, however, is that chronic overstimulation with hCG failed to advance sexual maturation, despite significantly raised testosterone concentrations.[51,53] The observation that such chronic hCG stimulation interferes with the developmental programming of the hypothalamic–pituitary–gonadal (HPG) axis may provide at least some explanation for this.[54] The situation differs in humans, where activating mutations of LHCGR do cause precocious puberty (if untreated) due to ligand-independent upregulation of testosterone production, reflecting key differences in induction of puberty between rodents and humans.[55–57]

Role of LH in Adult Leydig Cell Development—Humans

In humans, the requirement for LH signaling in fetal life for masculinization makes investigation of the role of postnatal LH signaling complex. In addition to the constitutively activating mutations in LHCGR that drive precocious puberty,[55–57] several loss-of-function alleles and polymorphisms in either LHβ or LHCGR are associated with undermasculinization and aberrant adult Leydig cell development, whereas no inactivating mutations have been identified in hCGβ, presumably due to its essential role in early pregnancy (reviewed in Refs 58,59). Only two reports of men with homozygous missense inactivating mutants in LHβ have been published, and their scarcity is consistent with the fundamental role of LHβ in fertility.[60,61] Complete absence of LHβ results in hypogonadism, associated with hypoplastic seminiferous tubules with greatly reduced spermatogenesis and hypoplastic Leydig cells. However, because hCG remains present to stimulate masculinization, phenotypic effects are limited to postnatal life. Conversely, complete absence of LHCGR (thus preventing both LH and hCG signaling) leads to disorders of sexual development, consistent with the essential role of LHCGR-mediated signaling for masculinization of the human male fetus (reviewed in Refs 58,59).

LH Signaling in Adult-Type Leydig Cell Function

In the adult-type Leydig cell, LH signaling plays an essential role in controlling testosterone production. Briefly, LH binding to the LHCGR leads to stimulation of gene expression of several key steroidogenic enzymes within the Leydig cells, stimulating testosterone production. The intracellular region of LHCGR is associated with heterotrimeric guanonucleotide stimulatory proteins (reviewed in Ref. 16). The best characterized pathway associated with adult Leydig cell function is the Gs–adenylyl cyclase–cyclic adenosine monophosphate

(cAMP)–protein kinase A (PKA) pathway (Figure 16.5). Binding of ligand to LHCGR leads to stimulation of adenylate cyclase, upregulation of cAMP, and subsequent phosphorylation of downstream proteins via PKA (reviewed in Refs 62,63) or protein kinase C (PKC).[64] The cAMP–PKA pathway subsequently induces steroidogenesis in Leydig cells by activating several transcription factors, including cAMP response element binding (CREB) protein, cAMP response element modulator (CREM) protein and GATA4,[65,66] leading to expression of downstream target genes. Production of cAMP also activates a calcium-signaling pathway via increasing concentration of intracellular Ca^{2+} ions,[67,68] a process modulated by PKA and PKC.[69] Although less is known about the molecular cascade triggered by increased intracellular Ca^{2+} and stimulation of the Ca^{2+}–calmodulin (CaM) protein kinase pathway in Leydig cells, recent evidence has demonstrated that expression of StAR is regulated not only by cAMP but also by intracellular Ca^{2+} concentrations. Increasing Ca^{2+} also induces expression of Nur77 (NR4a1), which acts as a mediator of hormone-stimulated StAR expression.[70] Another of the second messenger systems stimulated through LHCGR is PKA-dependent extracellular signal-regulated kinases 1 and 2 (ERK1/2).[71] LH-induced cAMP–PKA signaling transactivates epidermal growth factor receptor (EGFR), which then activates ERK1/2.[72] ERK then promotes expression of StAR[73] and also supports activation of the StAR protein,[74] a process that is modulated by mitogen-activated protein (MAP) kinase phosphatases (MKPs), which act to attenuate ERK1/2 signaling.[75,76] ERK signaling is also important in transducing the proliferative signal that LH–LHCGR binding confers on developing Leydig cells, a role that has been demonstrated both in primary Leydig cell cultures[77] and in mice lacking MEK (MAP kinase kinase, the upstream regulator of ERK1/2) that display Leydig cell hypoplasia.[78] Interestingly, although both LH and hCG ligands activate the same pathways, emerging evidence from in vitro studies suggests that hCG and LH stimulate different intracellular pathways with different efficacies, with hCG weighted toward cAMP, whereas LH favors ERK.[79]

Genes Regulated by LHCGR Signaling

The production of testosterone by Leydig cells requires coordinated expression and function of several transcription factors and steroidogenic enzymes, many under the overarching control of LH. LH achieves this either via posttranslational modification of transcription factor proteins or via de novo induction of transcription factor gene expression (e.g., NR4a1).[80] Regardless of the method of activation, LH stimulation of cAMP-signaling pathways recruits NR5A, GATA, and often CREB–CREM, NR4A, or Sp1 transcription factors to regulatory regions of each gene's promoter to elicit the transcription of genes that is necessary for steroid biosynthesis (reviewed in Refs 81–83).

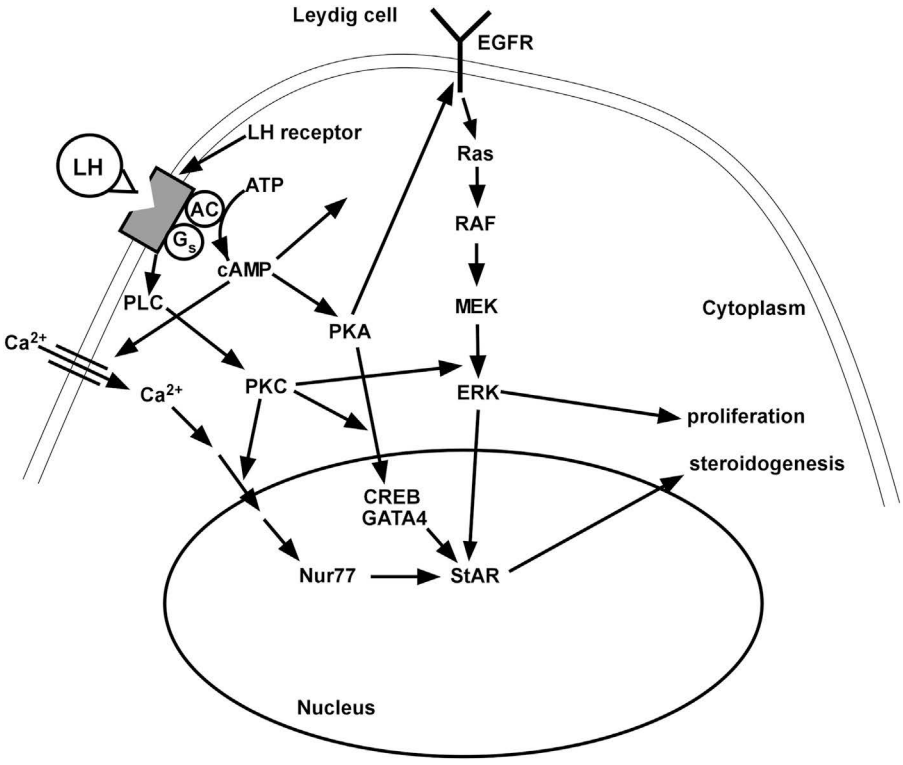

FIGURE 16.5 LH-mediated signaling in a Leydig cell. The major pathway regulated by LH binding to its receptor is the activation of adenylate cyclase (AC) via G_s proteins. The resulting increase in cAMP causes the activation of protein kinase A (PKA) that can directly regulate transcription factors such as CREB or GATA4 to increase the transcription of genes required for steroidogenesis, including *StAR*. LH stimulation can also cause the activation of the MAP kinase pathway (from Ras to ERK), in part via PKA-mediated activation of the epidermal growth factor receptor (EGFR). Activation of ERK increases the expression and phosphorylation of StAR and promotes the proliferation of Leydig cells. Ca^{2+} influx into Leydig cells increases in response to LH and results in the activation of the Nur77 transcription factor that induces *StAR* transcription. LH-mediated increases in phospholipase C (PLC) and then protein kinase C (PKC) activity facilitate the activation of ERK and result in the amplification of ERK, Ca^{2+}, and PKA stimulation of StAR activity.

Several promoters of target genes activated by LH signaling contain cAMP response elements (CREs), an eight-base-pair palindromic sequence (or variant thereof) that can be bound by CREB, CREM, and activating transcription factor 1 (ATF1) to drive gene transcription (reviewed in Ref. 84). The ability of these proteins to activate transcription from CRE-regulated promoters is enhanced upon cAMP–PKA-mediated phosphorylation of the transcription factors. CRE-binding sites have been identified in the promoters of several key genes involved in steroid hormone biosynthesis, and CREB is able to promote transcription of *StAR*, *Cyp11a1*, and *3β-Hsd*.[85] Leydig cell–specific ablation of CREB in transgenic mice leads to downregulation of expression of these three genes in addition to reducing expression of *Cyp17*.[86] The StAR protein is key for the regulation of steroidogenesis transporting cholesterol from the outer to the inner membrane of the mitochondria. Interestingly, the promoters of several steroid biosynthesis genes modulated by cAMP, including StAR, lack a consensus CRE.[87] Instead, control of StAR gene expression is modulated by interactions between several different transcription factors (reviewed in Ref. 82). Steroidogenic factor 1 (SF1; NR5A1) is a member of the orphan nuclear receptor superfamily that has been shown to be involved in the cAMP-regulated expression of many genes, and NR5A1 functions cooperatively with CREB–CREMτ to promote the transactivation of the StAR gene,[88] in addition to its role in induction of steroidogenic enzymes (reviewed in Ref. 83).

TESTOSTERONE

LH exerts its effects upon spermatogenesis principally via promoting testosterone secretion from the Leydig cell, with the androgen acting as a paracrine factor within the testis. Testosterone is a lipophilic steroid hormone that is essential for maintaining spermatogenesis and male fertility.[8,89] Testosterone deprivation studies performed in rodents have established that testosterone is essential for germ cells to progress beyond meiosis and that testosterone is required for the release of mature spermatids (reviewed in Ref. 8). Withdrawal of testosterone or knockout of the androgen receptor (AR; NR3C4) results in three major impairments to spermatogenesis. First, the integrity of the BTB is disrupted. The result of this insult causes meiotic and postmeiotic germ cells, formerly in a secluded specialized environment, to be exposed to autoimmune attack and cytotoxic factors.[90,91] Second, conversion of round spermatids to elongated spermatids is inhibited due to defects in cell adhesion that cause the premature detachment of round spermatids from Sertoli cells.[92–94] Third, fully mature spermatozoa cannot be released from Sertoli cells, and the germ cells are phagocytosed by the Sertoli cells.[94] Together, these findings confirm that testosterone is required for numerous processes that are essential to maintain male fertility.

Testosterone is the major androgen in the testis that regulates spermatogenesis. Androgen effects are mediated by AR, a 110 kDa protein encoded by a single gene on the X chromosome (Figure 16.6). The AR is a member of a large family of ligand-activated nuclear receptors. AR is a modular protein with four structurally and functionally distinct domains, including a poorly conserved N-terminal domain (NTD) encoded by exon 1, a highly conserved DNA-binding domain (DBD) encoded by exons 2 and 3, and a moderately conserved ligand-binding domain (LBD) that is produced from exons 4–8. A portion of exon 4 encodes a short hinge region that separates the LBD from the DBD and also contains part of a bipartite ligand-dependent nuclear

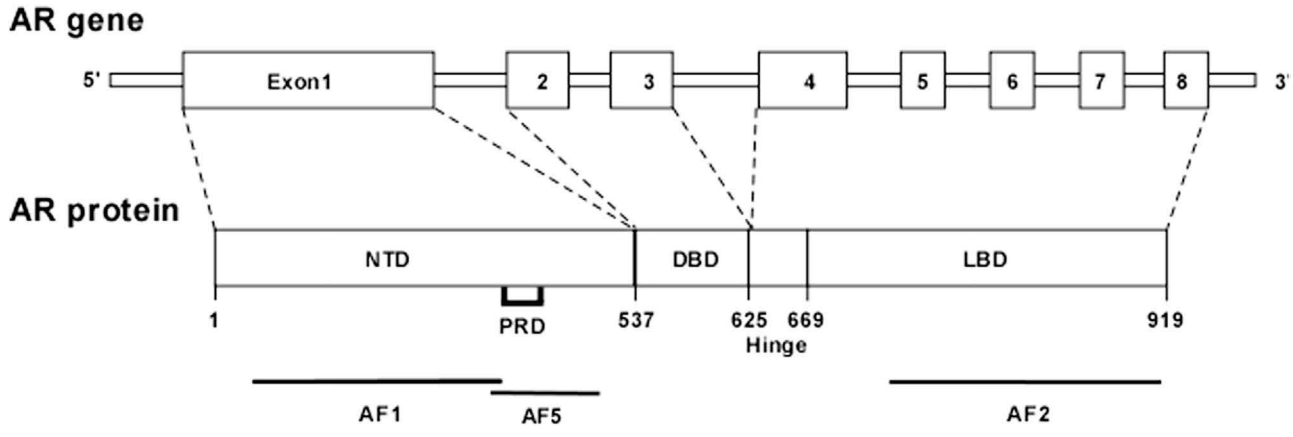

FIGURE 16.6 **Human androgen receptor (AR) structure.** The eight exons of the human AR are located on chromosome X bands q11–12. Exon 1 encodes the amino terminal domain (NTD), exons 2 and 3 encode the DNA-binding domain (DBD), and exons 4 through 8 encode the hinge region and ligand-binding domain (LBD). Also shown is the proline-rich domain (PRD) used to interact with Src kinase, as well as the transcription activating function domains 1, 2, and 5 (AF1, AF2, and AF5). Amino acid residues that separate the domains are shown below the AR protein.

localization signal (NLS) for AR nuclear transport (reviewed in Refs 95,96). Activation domains required for the regulation of gene expression are located in the NTD and LBD. The NTD also contains a proline-rich domain that is required to interact with and activate Src kinase.

AR Expression in the Testis

There are reports of AR expression in germ cells; however, the idea that AR is expressed in germ cells is not commonly accepted because there are other studies showing that AR is not detected in germ cells (reviewed in Ref. 97). Furthermore, at least three functional studies provide evidence indicating that if AR is expressed in germ cells, it is not required for spermatogenesis: (1) In one study, chimeric mice having both AR defective and wild-type germ cells produced pups from the AR defective germ cells[98]; (2) in another, AR defective germ cells transplanted into the testes of recipient wild-type mice rendered azoospermic by treatment with Busulphan were able to form colonies of donor cells undergoing spermatogenesis[99]; and (3) in a third, knockout of AR specifically in germ cells did not alter spermatogenesis or fertility.[100] Together, these results indicate that AR is not required in germ cells to maintain spermatogenesis. Instead, testosterone must support fertility by acting through somatic cells in the testis that express AR.

In the testis, AR is expressed in Sertoli, Leydig, PTM, arteriole smooth muscle, and vascular endothelial cells. In humans and rodents, AR is expressed in PTM cells at high levels from the fetal period throughout adulthood.[101–104] Adult Leydig cells also express AR at a constant level.[105] AR expression in the Sertoli cell is first detected in humans at the age of 5 months but remains weak until 4 years of age.[101–104] In mice and rats, AR in the Sertoli cell is first expressed 3–5 days after birth.[106–109] AR expression in postpubertal Sertoli cells is related to the stages of the cycle of the seminiferous epithelium. In men, AR levels are highest in stage III of the six stages, although AR was easily detected in all other stages.[110] In the adult rat, the expression of AR in the Sertoli cell is similarly cyclical. AR mRNA and protein expression progressively increases during stages II–VII and then declines sharply during or immediately after stage VII to become barely detectable in stages IX–XIII.[107,111,112] Because AR expression is greatest during stage VII, this stage is thought to be the most regulated by, and sensitive to, testosterone.[113] Various models of testosterone withdrawal from rats confirm that progressive germ cell loss begins during stage VII in the absence of testosterone.[8]

Testosterone Levels and Functions in the Seminiferous Tubule

Testosterone levels in the testes of men are 25–125-fold greater (340–2000 nM) than those in serum (8.75–35 nM). Testosterone levels are similarly elevated in the rodent testes.[114–118] One-third of testicular testosterone is tightly bound to sex hormone–binding globulin (SHBG, which has the same amino acid sequence as androgen-binding protein (ABP)) and is not readily available. However, two-thirds of testicular testosterone is free or bound to albumen and is bioavailable.[119,120] The bioavailable levels of testosterone in the testis far exceed those required for function as the binding affinity of testosterone for AR is approximately 1 nM, and the levels of testosterone required to regulate gene expression via AR binding to gene regulatory regions are 1–10 nM.[121] However, sperm counts decrease at a logarithmic rate as testosterone levels fall below 70 nM in the rodent.[122] Thus far, the biology underlying the necessity for the high levels of testosterone in the testis is poorly understood. One possibility is that the higher levels of testosterone may be required to activate recently identified nongenomic mechanisms of testosterone action that have been found to regulate processes required for spermatogenesis.[123]

Testosterone-Signaling Pathways

Genomic (also known as classical) testosterone signaling initiates with testosterone diffusing through the plasma membrane, followed by binding to AR that is often sequestered in the cytoplasm by heat shock proteins. When bound by androgen, AR undergoes a change in conformation that allows it to be released from the heat shock protein complex. To transmit classical testosterone signaling, AR then translocates to the nucleus, where it binds as a dimer to specific DNA sequences called androgen response elements (AREs) (Figure 16.7, pathway 1). AR binds to AREs using the DBD region encoded by exons 2 and 3, which form two zinc finger domains. AREs may be located in promoter regions near the transcription start sites of genes or at a distance far from the gene. When bound to the DNA, AR recruits co-activators or co-repressor proteins and protein complexes that together modulate gene expression. This classical pathway of testosterone action requires at least 30–45 min to alter gene expression and at least 1 h to produce nascent proteins.[125]

In addition to the classical pathway of testosterone signaling, there is evidence in Sertoli cells of more rapid, nonclassical (also called nongenomic) pathways of testosterone action. The nonclassical pathway requires seconds to initiate, and cellular effects can be assayed within minutes. Thus far, studies of nonclassical signaling by

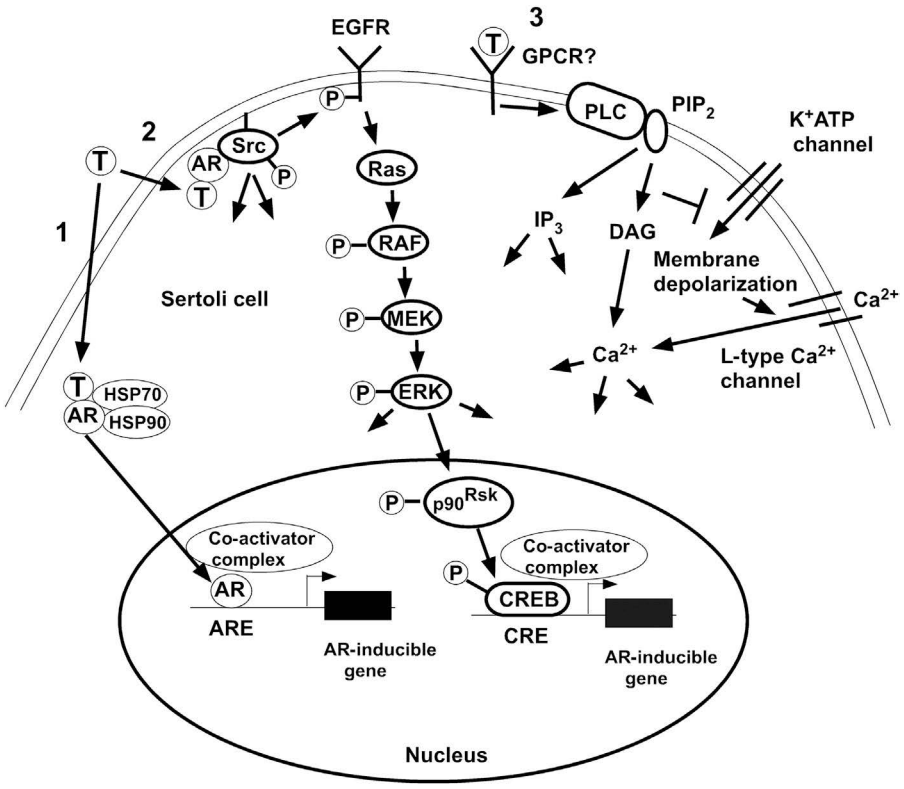

FIGURE 16.7 **Testosterone-signaling pathways.** (1) The classical testosterone-signaling pathway. Testosterone diffuses through the plasma membrane and binds with the AR. The AR undergoes an alteration in conformation that allows it to be released from heat shock proteins in the cytoplasm. AR then is able to translocate to the nucleus, where it binds to specific DNA sequences called androgen response elements (AREs). AR binding to an ARE allows the recruitment of co-activator and co-repressor proteins that alter the expression of genes to alter cellular function. (2) The nonclassical kinase activation pathway: testosterone interacts with the classical AR that then is able to recruit and activate Src, which causes the activation of the EGF receptor via an intracellular pathway. The EGF receptor then activates the MAP kinase cascade, most likely through Ras, resulting in the sequential activation of RAF and MEK and then ERK that activates $p90^{Rsk}$-kinase, which is known to phosphorylate CREB on serine 133. As a result, CREB-regulated genes such as lactate dehydrogenase A (*LDH-A*), early growth response 1 (*Egr1*), and *CREB* can be induced by testosterone. (3) The nonclassical Ca^{2+} influx pathway: testosterone interacts with a receptor in the plasma membrane that has characteristics of a G_q-coupled G protein–coupled receptor (GPCR). Phospholipase C (PLC) is activated to cleave PIP_2 into IP_3 and DAG. Lower concentrations of PIP_2 inhibit K^+_{ATP} channels, causing membrane depolarization and Ca^{2+} entry via L-type Ca^{2+} channels. *Source: Reproduced with permission from Ref. 124.*

testosterone have focused on two rapidly activated pathways in the Sertoli cells (Figure 16.7, pathways 2 and 3). First, testosterone acts via AR to activate a series of kinases, including Src and the mitogen-activated protein kinase (MAPK) cascade, as well as the CREB transcription factor and CREB-mediated transcription (reviewed in Ref. 123). Second, testosterone also can depolarize the Sertoli cell and cause Ca^{2+} influx, resulting in activation of intracellular signaling factors (reviewed in Ref. 126). It has not been established whether AR or another receptor is required to initiate this second pathway. Both classical and nonclassical signaling are discussed in greater detail in this section.

Cell-Specific Ablation of AR in the Testis

To examine the cell-specific roles of AR signaling, several groups have exploited the Cre–loxp systems to ablate AR in a cell-specific manner. At least five "floxed" alleles of AR have been generated[94,127–130] (reviewed in Refs 131,132), and the specific idiosyncrasies of this allelic series have proved far more informative than a single allele ever could. Two models target exon 1,[94,128] and systemic recombination of the floxed allele results in the expected phenotype, similar to the spontaneous AR mutant—the testicular feminized (Tfm) mouse.[133] However, one of these mutants has been engineered to retain a neomycin selection cassette that reduces AR expression in nonrecombined cells. These animals represent an important and novel model of partial androgen insensitivity, although interpretation of the cell-specific ablation of AR on this background is complex.[94] Far from proving problematic, however, this allele has provided a series of important observations,[91,134,135] especially when compared to similar cell targeting of AR in other floxed models of this receptor (reviewed in Ref. 131). Two further

models target exon 2.[127,130] In the absence of recombination, these floxed male mice are indistinguishable from nontransgenic males. In contrast, Cre-mediated ablation of exon 2 causes a frame shift mutation, which introduces a premature stop codon into the mRNA transcript that is quickly degraded. No AR protein is observed. The fifth floxed allele of AR deletes exon 3 upon Cre-mediated recombination.[129] Whereas deletion of exon 3 removes the second zinc finger of the DNA-binding domain, splicing remains in frame, and thus a truncated version of the AR protein is produced. The mutant protein is unable to bind to AREs in target genes and may have utility for discerning nonclassical roles of AR. Interestingly, in the absence of recombination, this allele confers slight hyperandrogenism on the mouse.[136] Together, these five AR alleles have been widely exploited to paint a very detailed picture of androgen signaling in the testis (reviewed in Refs 97,131,132,137–139).

AR in Sertoli Cells

The first use of the floxed AR alleles was to target AR in Sertoli cells, which have been acknowledged for many years as the key cell type supporting spermatogenesis. Three different groups published descriptions of independently generated Sertoli cell–specific AR knockout (SCARKO) models within 6 months of each other in 2004.[94,127,140] Although different floxed alleles of AR were employed, two of the three groups[127,140] chose to utilize the same Amh–MIS–Cre line, which is highly regarded for its specific and efficient Sertoli cell–targeting properties.[141] The third group generated an independent Amh–Cre line, which also targeted Sertoli cells with high efficacy.[94] Sertoli cell expression of AR begins at approximately postnatal day 4 in wild-type mouse testis.[142] However, both Amh–Cre lines ablated AR in fetal life. Thus, in all three models, Sertoli cells were never exposed to androgen–AR stimulation.

One of the most important outcomes from the SCARKO mouse studies versus those of total ARKO or Tfm mice was that restricted ablation of AR from Sertoli cells did not prevent testicular descent, due to continued androgen action at the level of the gubernaculam.[143] This result highlights the advantages provided by conditional gene targeting, as for the first time it was possible to examine the cell-specific role of androgens within the testis, without the confounding factor of cryptorchidism.

As both total-ARKO and Tfm mice display a significant reduction in Sertoli cell number, a similar reduction in Sertoli cell number was expected to arise from rendering Sertoli cells insensitive to androgens. Consistent with this hypothesis, testis weight was significantly reduced in SCARKO mice. Because Sertoli cells can simultaneously support only a fixed number of germ cells, a reduction in Sertoli cell number would reduce quantitative spermatogenesis, explaining the weight loss. However, surprisingly, this was not the case. SCARKO mice developed normal numbers of Sertoli cells that underwent appropriate maturation at the correct pubertal time point, demonstrating that Sertoli cell AR is dispensable for final Sertoli cell number and maturation.[144] The profound conclusion arising from this observation is that androgens must act via a different cell type to control the final Sertoli cell number, which was the first indication that a wider androgen-dependent paracrine-signaling network was at play in the testis.

Despite the Sertoli cell number being unaffected, SCARKO mice were completely infertile in all three models. Ablation of Sertoli cell AR did not impact the numbers of spermatogonia. However, spermatocytes were slightly reduced in number, and postmeiotic spermatids were significantly reduced or absent, consistent with a block in spermatogenesis during meiosis. This phenotype was later confirmed in a fourth model of Sertoli cell AR ablation.[145] These results were similar to the block in spermatogenesis observed in models with suppressed testosterone production.[146] This phenotype cannot be rescued in hpg.SCARKO mice treated acutely with exogenous androgens.[147] Together, these findings suggest that the primary effects of androgens acting via AR in Sertoli cells during adulthood are to support meiotic and postmeiotic germ cell development. In addition to the block in spermatogenesis, loss of Sertoli cell AR impacted several Sertoli cell–dependent functions, including defects in intact junctional complex formation, which perturbs the permeability of the BTB and compromises the immune privilege of the adluminal compartment[90,91,148,149] (Figure 16.8, pathway a–c).

In at least one model, ablation of Sertoli cell AR also leads to a significant reduction in the number of adult Leydig cells, suggesting that androgens function via Sertoli cells to influence Leydig cell development (Figure 16.8, pathway d). However, this reduction in Leydig cell number is compensated by increased testosterone production per Leydig cell, to maintain normal circulating testosterone concentrations.[150]

AR in Peritubular Myoid Cells

PTM cells interact intimately with Sertoli cells, for example to direct deposition of basement membrane components that surround the seminiferous epithelium.[151,152] Loss of PTM cells results in abnormal spermatogenesis,[153] although the roles that androgens play in this process remained a mystery for many years. In mice, AR is expressed in PTM cells throughout life,[154] and two models of AR ablation in PTM cells have been published. Differences in the choice of Cre recombinase lines used to target this cell type, however, resulted in widely different phenotypes. Further analysis suggested that one

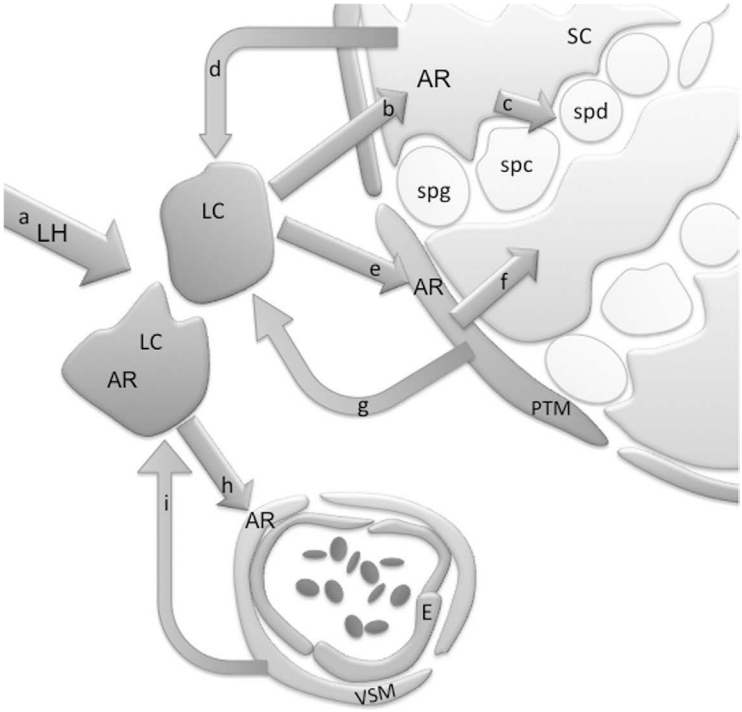

FIGURE 16.8 Androgen signaling within the testis. Androgen receptor (AR) is not expressed in germ cells, and as such, mediation of the testosterone signal on germ cells is via somatic cells that express AR. The cell-specific roles of AR signaling have been established through conditional gene targeting, revealing a complex paracrine signaling system at work in the testis that can be summarized as follows: LH enters the testis, binding LHCGR to stimulate testosterone production by Leydig cells (LC) (a). Testosterone binds AR in Sertoli cells (SC), promoting development of the blood–testis barrier (b) and supporting postmeiotic germ cell development (c). Unknown paracrine factors stimulated by SC-AR signal to control the final Leydig cell numbers (d). Stimulation of AR in PTM cells promotes PTM development and function (e), and the release of unknown paracrine-signaling molecules that support SC maturation and function, which in turn supports spermatogenesis (f). Furthermore, stimulation of AR in PTM cells also feeds back to promote differentiation of adult Leydig cells (g). Testosterone signaling to AR in vascular smooth muscle (VSM) promotes testicular vasomotion and fluid regulation in the interstitium (h), whereas AR activation in vascular smooth muscle cells supports overall Leydig cell function (i). E: endothelial cells, surrounding an arteriole; Spg: spermatogonia; Spc: spermatocyte; Spd: spermatid.

of the two models poorly targeted the PTM cells,[155] and thus the second model has become accepted as providing a more robust characterization of AR ablation from PTM cells.[154] In mice with cell-selective ablation of AR from PTM cells from embryonic day 17, testes are indistinguishable from littermate controls at postnatal day 12, suggesting that AR signaling in PTM cells is dispensable for initial testis development. However, at day 15, there was a significant reduction in testis weight, with gross and multiple impacts on testicular architecture and function.[154] Adult PTMAR knockout (PTMARKO) males are infertile, with significant reduction in numbers of spermatocytes and spermatids. The function of PTM cells in adults is directly impacted by the loss of AR, with changes in the expression and localization of several proteins such as the intermediate filament desmin and basement membrane protein laminin (Figure 16.8, pathway e). Sertoli cell function is also impacted, as evidenced by a reduction in lumen diameter (a measure of seminiferous tubule fluid secretion), and significant changes in gene expression of several key genes, including those previously identified as responsive to AR signaling within Sertoli cells[154,155] (Figure 16.8, pathway f). Loss of AR in PTM cells also impacts adult Leydig cell development. Whereas PTMARKO mice have normal numbers of adult Leydig cells (defined as 3βHSD positive cells), Leydig cell differentiation remains incomplete in PTMARKO mice, with significant numbers of precursor Leydig cells present in testes in adult mice[154,156] (Figure 16.8, pathway g). Interestingly, PTMARKO mice are able to maintain circulating testosterone concentrations within the normal range, but increased LH input is required. PTMARKO mice have a fourfold increase in intratesticular testosterone, suggesting that testosterone secretion by the Leydig cells within PTMARKO mice is perturbed,[154,156] or that the vascular system is impacted in some way that impairs movement of testosterone out of the testis.

AR in Leydig Cells

Data derived from a variety of sources identify several key functions of AR in Leydig cells, including the regulation of their final adult numbers, normal morphological development and maturation, and control of steroidogenic gene expression (reviewed in Ref. 157). However, much of these data derive from analysis of the ARKO mouse, which not only has a 40% reduction in numbers of Leydig cells compared to littermate controls, but also is limited by the ablation of AR signaling in all cell types of the body from fetal life, cryptorchidism, and low circulating testosterone. A Leydig cell–specific AR ablation (LCARKO) model has been reported,[100,158] although the phenotypic analysis of this mutant is complicated by the choice of Cre (anti-Mullerian hormone receptor 2 (AmhR2–Cre))[159] used to ablate AR. The AmhR2–Cre mouse has previously been utilized to target genes in both Sertoli cells and Leydig cells (reviewed in Ref. 160), and the reported LCARKO mutant displays some features consistent with SCARKO ablation models, which are therefore difficult to attribute to loss of AR specifically in Leydig cells. Thus, the functional role of AR signaling specifically within Leydig cells remains to be established.

AR in the Testicular Vasculature

Vasomotion is an androgen-dependent rhythmical contraction–relaxation mechanism present in several tissues, including the testis, that regulates fluid and nutrient exchange between the vascular system and peripheral tissues.[161,162] Direct evidence for the effector cell type of this androgen action has come from vascular cell–specific AR ablation models. Whereas AR expression in vascular endothelial (VE) cells appears to be dispensable for normal testis function, as shown with vascular endothelial androgen receptor knockout mice,[163] AR ablation from vascular smooth muscle (VSM) cells (smooth muscle cell-specific AR knockout mouse (SMARKO)) subtly impairs testis function.[164] Gross reproductive development is normal in SMARKO mice, but adult testis weight is reduced compared to that of littermates. Despite this, SMARKO mice are fully fertile. Cell-specific ablation of AR from VSM leads to a significant increase in interstitial fluid volume within the testis, due to impairment of testicular vasomotion[164] (Figure 16.8, pathway h). This is associated with slightly diminished Leydig cell function (Figure 16.8, pathway i), possibly a consequence of changes in testicular fluid exchange and microvascular blood flow within the testis.

Inducible AR Ablation and Adult Testis Function

One of the limitations of each of the published cell-specific ARKO models is that the timing of AR ablation is within fetal life. As a result, it is difficult to unequivocally assign phenotypic effects to perturbations in adult function. This situation is further complicated by the concept of fetal programming, where events in fetal life can influence phenotypic outcomes many weeks (in the case of rodents) or years (in the case of humans) later. Indeed, the concept of the Male Programming Window—the time period during fetal life in which androgen action is essential to program later developmental events—as demonstrated in the rodent,[165–169] is now widely accepted as a relevant paradigm for all male reproductive organs, including the testis.

To circumvent the temporal limitations of AR ablation and examine the role of androgens in adult testis function requires the separation of development and adult function. To achieve this requires the development of inducible models of AR ablation. A ubiquitously expressed tamoxifen-inducible Cre recombinase has been exploited to permit study of the testis following global ablation of AR in adulthood.[170] Analysis of the testis following inactivation of AR in adulthood revealed spermatogenic arrest when examined 50 days post treatment with tamoxifen. This was associated with decreases in expression of known AR target genes and impaired Sertoli cell function. However, tamoxifen, a potent estrogen receptor (ER) alpha agonist in the testis and elsewhere, itself resulted in changes in Leydig cell gene expression. In particular, control animals treated with tamoxifen showed changes in expression of genes associated with steroid hormone synthesis, along with a reduction in circulating FSH, LH, circulating testosterone, and intratesticular testosterone.[170] Whereas tamoxifen-induced ablation of AR (or, indeed, any gene in the testis) is a valid approach, the strategy provides additional challenges in terms of interpretation of phenotypic outcomes. Alternative approaches include doxycycline-inducible systems, cell-specific expression of dominant-negative forms of AR, and miRNAs targeted against AR; although each has been utilized in vitro, none has yet been exploited to target AR in vivo.

In males, it has long been thought that the AR in the testis is saturated with testosterone, because the concentrations of the steroid are orders of magnitude higher than in the circulation. Conceptually, therefore, modulation of AR abundance or AR signaling could provide the rheostat for androgen action. Whereas patients with completely versus partially inactivating mutations in AR demonstrate that this can be the case in terms of reduced AR action, it is only recently that the timing of AR expression has emerged as a paradigm for the study of AR action in the testis. Premature expression of *AR* mRNA in Sertoli cells has been induced by driving an *AR* cDNA transgenically from the *Abp* promoter. This transgene directs AR expression from e17,[145] while endogenous AR is detectable in mouse Sertoli cells at postnatal day 4.[142] Early expression of AR results in a reduction in Sertoli cell numbers in adulthood, despite increased expression of FSH and FSH receptor, and premature maturation of seminiferous tubules. There also was increased support for meiotic cells, but with reduced numbers of postmeiotic cells,[171] which is probably the result of increased AR expression causing the premature termination of Sertoli cell proliferation and the initiation of Sertoli cell differentiation. As a result, the fewer Sertoli cells produced support fewer germ cells. Importantly, this study also suggests that the close association between induction of AR expression and downregulation of *Amh* expression in Sertoli cells may be coincidental, with no direct causal link (at least in mice), which has been a long-held paradigm of interaction between the two hormone pathways.[172]

Testosterone-Regulated Gene Expression in the Testis

Testosterone may mediate gene expression changes via classical and nonclassical signaling pathways. Thus far, relatively few testosterone-regulated genes have been investigated to determine which pathway is required to alter their expression. Nonetheless, a number

of testosterone deprivation and replacement studies as well as AR mutant and knockout models have provided extensive information regarding testosterone-mediated gene expression in the testis.

Animal models with altered testosterone secretion have been used to identify testosterone-regulated genes. Several survey studies using various rodent models have been performed to assay gene expression in the presence and absence of testosterone signaling. In the first microarray studies that compared testis gene expression in normal 8-day-old neonatal mice versus mice injected with testosterone propionate, about 220 genes had expression changes of at least twofold, with 37, 45, and 50% of the genes being downregulated by testosterone 4, 8, and 16 h after androgen administration, respectively.[173]

Another study employed the *hpg* mouse model lacking FSH, LH, and therefore testosterone inputs. The mice were injected with testosterone propionate to increase testicular content of the steroid for 4, 8, 12, or 24 h. At each time point except for 24 h, testosterone resulted in more downregulated than upregulated genes. Groups of genes encoding milk proteins were activated, perhaps due to testosterone being aromatized to estrogen, which in turn upregulated pituitary prolactin secretion (discussed further in this chapter). Class I major histocompatibility complex (MHC) genes were activated that may contribute to the immunosuppression observed in testes.[174] A more recent study, also using an *hpg* model, found that 10 days of treatment with a nonaromatizable androgen (Dihydrotestosterone) increased the expression of Claudin 3 and Claudin 11 genes encoding transmembrane proteins required for the BTB and resulted in the formation of tight junctions in the *hpg* mice.[175]

Overall, the use of rodent models with altered testosterone levels in these initial studies identified many testosterone-regulated genes, with a high percentage being downregulated by the steroid. However, the genes identified by these survey studies showed relatively little overlap, the number of more highly regulated genes (> twofold) was limited, and few of the identified genes had known fertility phenotypes (reviewed in Ref. 138).

Identification of Testosterone-Regulated Genes Using AR-Deficient Models

A study using 20-day-old *tfm* mice having inactive AR in all cells identified 4700 differentially expressed genes in the testis as compared to normal mice.[176] From this database, 42 genes were found to be expressed by somatic cells of seminiferous tubules. Of the 42 genes, 26 were assayed: 20 were downregulated in *tfm* testes, and six were upregulated. Many of these genes were associated with vitamin A metabolism, solute transportation, or cytoskeletal function.[176] Unfortunately, this model is not ideal because it compares normal testes with those from *tfm* mice that do not descend into the scrotum and have arrested germ cell development. Thus, most of the genes identified were found to be of germ cell origin.

Studies comparing the transcriptional profiles of adult wild-type mice with AR hypomorph mice and AR hypomorphs having Sertoli cell–specific ablation identified 46 and 57 testis-expressed genes, respectively, that were regulated at least twofold by testosterone. About twice as many genes were found to be downregulated by testosterone than upregulated.[135] Genes involved in metabolic processes and signal transduction were identified as classes of genes found to be regulated via AR. In this study, it was determined that 65% of AR-regulated genes were associated with a conserved ARE within 6 kb of their transcription start sites, and at least 23% of the identified genes were previously shown to be regulated by validated AREs.[135] These findings confirm that testosterone and AR act directly via the classical signaling pathway through AREs to regulate a substantial percentage of testosterone-regulated genes in the testis. However, the lack of AREs associated with all testosterone-regulated genes suggests that some genes are regulated indirectly after initial stimulation of ARE-dependent genes, via posttranscriptional processes, or by other mechanisms such as nonclassical testosterone signaling.

AR-Dependent Regulation of Gene Expression in Sertoli Cells

In the first study of gene expression using SCARKO mice 10 days after birth, 40 genes showed a difference of at least twofold, with 28 downregulated by testosterone and 12 upregulated. Of the 40 differentially regulated genes, three (*Galgt1*, *PCI*, and epididymal protease inhibitor (*Eppin*)) are known to be required for fertility, but none completely block functions specific to seminiferous tubules, which are required for spermatogenesis.[155] *Galgt1* (*β1,4-N-acetylgalactosaminyltransferase*) encodes an enzyme required for the formation of complex gangliosides. Galgt1-deficient mice cannot complete spermatogenesis due to the inability to produce a specific class of fucoylated glycosphingolipids that may be required for the formation of the unique plasma membrane of haploid germ cells and for the transport of testosterone from Leydig cells to the seminiferous tubules and the bloodstream.[177,178] *PCI* encodes a serine protease inhibitor, and *PCI* knockout mice have spermatogenesis defects, including detached germ cells, disruption of the BTB, and damage to Sertoli cells; however, sperm are produced, but they are incapable of fertilization.[179] *Eppin* has not been shown to be required for spermatogenesis, but it is required for fertilization of the egg by sperm and has been the target of contraceptive development.[180] Functional analysis of a larger group of 692 differentially regulated genes found that of the 396 downregulated

genes, there was an overrepresentation of genes associated with MAPK activity and serine endopeptidase inhibitor activity. Functions overrepresented in the 296 upregulated genes included signal transduction, cell adhesion, Ca^{2+} binding, Ca^{2+}-dependent phospholipid binding, insulin-like growth factor (IGF) binding, and serine protease inhibition.[155]

A follow-up study using the same mouse model determined that differences in gene expression in SCARKO mice were first detected 8 days after birth.[142] Further analysis of gene expression in SCARKO mice 8–20 days after birth showed that genes encoding proteases, cell adhesion proteins, cytoskeletal elements, and extracellular matrix components were differentially expressed during the initiation of spermatogenesis, supporting the idea that the restructuring of seminiferous tubules and changes in cell junctional dynamics are triggered by testosterone during early puberty.[90,155]

Another group using a similar SCARKO mouse model and a more directed quantitative polymerase chain reaction (qPCR) assay approach found that genes encoding tight junction proteins of the BTB (claudin 11, occludin, and gelsolin), basement membrane components, tissue-remodeling factors, paracrine factors for support of germ cells, as well as transport proteins (transferrin, fatty acid–binding protein (FABP), and ABP) were regulated by AR 10.5 days after birth.[149] The genes identified and their expression differences from controls overlapped nearly completely with a similar qPCR-based study using the first SCARKO mouse model.[144]

A different SCARKO model was constructed using a juvenile spermatogonial depletion mutant (*jsd*) background. The *jsd* mice become sterile after the first few waves of spermatogenesis such that spermatogenesis does not subsequently proceed beyond the undifferentiated type A spermatogonia stage of development.[181] Thus, the creation of *SCARKO–jsd* mice permitted direct comparison of gene expression with *jsd* mice to determine the effects of AR knockout specifically in adult Sertoli cells in the absence of differentiating germ cells for both models. Compared to the *jsd* mice, 157 genes were downregulated and 197 genes upregulated in the *SCARKO-jsd* mice. Genes involved in cell adhesion, signal transduction, nuclear localization, and meiosis were differentially regulated in the absence of AR. Genes known to be expressed in differentiating spermatogonia were repressed in the absence of AR, which was consistent with the previous finding that suppression of testosterone in *jsd* mice supported spermatogonial differentiation.[134]

Genes Regulated by Classical Testosterone Signaling

Androgens mediate classical testosterone signaling by facilitating AR binding to AREs associated with androgen-regulated genes. The first AREs (classical AREs) were identified as inverted repeats of 5′-TGTTCT-3′-like motifs separated by three base pairs. These classical AREs can be occupied by AR as well as other steroid hormone receptors. An additional class of AREs (selective AREs) have been identified that bind AR more selectively. Selective AREs are direct rather than inverted repeats of 5′-TGTTCT-3″ (reviewed in Ref. 182).

Mice were engineered to express an AR that can bind classical but not selective AREs (the specificity affecting AR knockin (SPARKI) mouse). SPARKI mice display a 35% reduction in the size of the testis, and they are subfertile, as reflected by a 50% reduction in litter size. Spermatogenesis appears to occur normally up to meiosis in SPARKI mice because the number of spermatocytes is near normal. However, there are 53 and 56% decreases in the number of round and elongated spermatids, respectively. Sertoli cell numbers also are reduced by 32%. These results indicate that testosterone signaling through selective AREs contributes to Sertoli cell proliferation and/or survival. The percentages of germ cells completing meiosis and transitioning to become elongated spermatids were reduced 29 and 37%, respectively, in SPARKI mice. This reduced spermatogenesis efficiency in the absence of signaling from selective AREs is due to both the decreased ability of Sertoli cells to support germ cell maturation and the decrease in Sertoli cell number.[183] Analysis of testosterone-regulated gene expression in the SPARKI mouse testis revealed that expression levels of the *Rhox5*, *Tsx*, and *Drd4* genes were severely reduced, but expressions of *Spinlw1*, *Eppin*, *PCI*, and *Tubb3* were not affected. The gene expression studies suggest that in the testis, some genes are directly regulated through classical AREs, whereas other genes are regulated by selective AREs or by another mechanism. No studies of the specific effects of blocking testosterone regulation via classical AREs have been reported.

An Overview of AR-Regulated Gene Expression in the Testis

Overall evaluation of the various surveys of AR-regulated genes reveals at least four trends. First, all of the survey studies identify large sets of genes that are regulated by testosterone but relatively few that are regulated by more than twofold. This finding suggests that testosterone may maintain spermatogenesis via altering the expression of a broad spectrum of genes and that the sum of many small changes may be required to support fertility.

Second, of the differentially expressed genes, a large percentage appears to be downregulated by testosterone signaling. Downregulation of gene expression after testosterone stimulation is likely to occur in many instances due to indirect actions such as gene regulation downstream of the initial transcriptional regulatory event, due to post-transcriptional regulation, or in response to the activation of kinases by nonclassical testosterone signaling.

Third, there are few highly testosterone-responsive expressed genes that are commonly identified by the various models. For example, only the four highly regulated genes *Rhox5*, *Lrp4*, *Drd4*, and *Fhod3* are quantitatively regulated in the same direction in studies employing the SCARKO, SCARKO-jsd, and *tfm* models.[184] Also, few genes identified in the SCARKO model matched those that are rapidly induced by androgens in the testes of *hpg* mice or 8-day-old wild-type mice.[142] The lack of overlap is likely due to the differences in the ages of the mice, the duration of androgen stimulation or deprivation, hormone levels, and the germ cell constitution of the testes in the models that were used. Nevertheless, comparisons of differential gene expression across some models reveal some shared AR-regulated genes (Table 16.1). For example, several genes related to retinoic acid metabolism were identified in the *tfm* and AR hypomorph models, including alcohol dehydrogenase I, which is the rate-limiting step in the conversion of vitamin A to the potent signaling factor, retinoic acid. The transition from undifferentiated type A spermatogonia to differentiated type A1 spermatogonia, the entry into meiosis, and establishment of the cycle of the seminiferous epithelium are regulated by retinoic acid.[185–187] In the SCARKO and *tfm* models, seven highly regulated genes are found in common: *Rhox5*, *Drd4*, *Lrp4*, *Tsx*, and three serine endopeptidase inhibitors (*Eppin*, *Serpina 3N*, and *PCI*). Genes encoding cell adhesion proteins and cytoskeletal elements were also shared by the SCARKO and *tfm* models. Finally, *claudin 3*, which contributes to the formation of the BTB, is differentially expressed in both the AR hypomorph and SCARKO models (reviewed in Ref. 138).

The fourth trend observed from the gene survey studies of AR-regulated genes expressed in Sertoli cells is that their deletion rarely results in lack of sperm production, although there are examples of reduced fertility. Mice lacking the most highly inducible testosterone-regulated gene, *Rhox5*, which was identified in all models, are still capable of completing meiosis and retain some fertility.[188] As discussed in this chapter, the testosterone-regulated *Galgt1*, *PCI*, and *Eppin* genes are required for fertility but may not directly affect spermatogenesis.[177–180] Also, the lack of *Lrp8* causes sperm defects that develop in the epididymis.[188,189] Together, these findings reinforce the idea that testosterone support of fertility can occur via the regulation of functions that occur outside of the seminiferous tubules and that, in the absence of testosterone, it is likely that spermatogenesis is disrupted due to the combined effects on multiple genes.[184]

TABLE 16.1 Selected AR-Regulated Genes in Sertoli Cells, Their Functions, and Their Expression in the Absence of AR

AR-regulated gene	Function and expression without AR	
ADH1[a] Alcohol dehydrogenase	Conversion of vitamin A to retinoic acid	+
Aqp8[a]	Water transport	–
Car7[a]	Carbonic anhydrase	–
Cdo1[a]	Cysteine diogenase1	–
Claudin 3[a]	BTB	–
Claudin 11[a]	Adhesion protein	–
Drd4[a]	Dopamine receptor D4	–
eFABP	Fatty acid–binding protein	–
Eppin–Spinlw1[a]	Serine protease inhibitor	–
Fhod3[a]	Regulates actin cytoskeleton	+
Galgt1	Testosterone carrier	–
Gelsolin	Sperm release	–
Lrp4 = Corin[a]	Protease	–
Lrp8[a]	Apo-lipoprotein E receptor	–
MAKPK 13[a]	Kinase	+
Myoz 2[a] Myozenin 2	Binds actinin and filamin	–
Occludin	Adhesion	–
PCI = Serpin5[a]	Protein kinase C inhibitor	–
Rhox5[a]	Transcription factor	–
Scinderin	Actin severing	+
Serpina 3N[a]	Protease inhibitor	–
Tsx testis specific X-linked	Long noncoding RNA	–

Genes whose expression is decreased (–) or increased (+) in the absence of AR are denoted on the right margin.
[a] *Denotes genes shown to be regulated in more than one study of AR-defective or SCARKO mice.*

Nonclassical Testosterone Signaling

It has been proposed that only classical testosterone signaling is required for spermatogenesis because germ cell development is halted during meiosis in transgenic mice in which exon 3 of the AR containing a portion of the DNA-binding domain was removed.[145] However, the nonclassical activity of the exon 3–deleted AR mutation was not reported in the study. Analysis of nonclassical testosterone signaling in a Sertoli cell line lacking endogenous AR expression but expressing a recreated AR mutant lacking exon 3 showed that ERK phosphorylation did not increase in response to testosterone stimulation (WW, unpublished data). This result indicates that the removal of 39 amino acids of AR in this model may alter the structure of AR to inhibit both nonclassical and classical activity.

Testosterone activates two nonclassical pathways. In the first pathway, testosterone rapidly activates a series of kinases in Sertoli cells that are known to regulate spermatogenesis. Stimulation of Sertoli cells with levels of testosterone (10–250 nM) that are similar to or lower than

those found in the testis causes AR to transiently localize to the plasma membrane and results in AR interacting with and activating Src tyrosine kinase (Figure 16.7, pathway 2).[190] Studies employing RNA interference strategies and the use of AR-defective Sertoli cells indicate that AR and not a novel membrane receptor is required to transmit nonclassical testosterone signals.[191] Androgen stimulation triggers the direct association of the proline-rich region of AR (amino acids 352–359) and the SH3 domain of Src.[192] Testosterone-mediated activation of Src causes the phosphorylation and stimulation of EGFR via an intracellular pathway. Stimulation of EGFR is required to activate the MAPK cascade (Raf, MEK, and ERK) that causes $p90^{Rsk}$ kinase to phosphorylate the CREB transcription factor.[190] Activation of the nonclassical pathway induces the expression of CREB-regulated genes that are not regulated by AREs.[191] In contrast to the classical pathway, induction of ERK and CREB phosphorylation by testosterone is rapid (within 1 min) and can be sustained for at least 12 h.[191]

The release of mature sperm from Sertoli cells is regulated by Src kinase that is activated by nonclassical signaling. Culturing seminiferous tubule fragments in the presence of a Src kinase inhibitor decreased the relative numbers of sperm released. These results are consistent with earlier studies showing that during stages VII–VIII, when sperm are released, activated Src levels increase in the vicinity of the specialized Sertoli-elongated spermatid adhesion complex called the ectoplasmic specialization (ES).[193–195] Src also is known to phosphorylate focal adhesion kinase (FAK), β-catenin, and, *N*-cadherin proteins that contribute to the formation of the adhesion complexes between Sertoli cells and the mature elongated spermatids.[196–198] The redistribution of proteins required for the formation, dissolution, and reformation of the BTB may be dependent upon nonclassical testosterone signaling as testosterone stimulation of *hpg* mice caused the rapid redistribution of claudin 11 to the area of the forming BTB prior to activating the transcription of genes encoding BTB components.[175] Also, kinases that are known to regulate the dynamics of tight and adherens junctions[199–201] are regulated by nonclassical testosterone signaling.[190,202]

In the second nonclassical testosterone-mediated pathway (Figure 16.7, pathway 3), testosterone rapidly induces the influx of $[Ca^{2+}]$ into Sertoli cells within 20–40 s through L-type $[Ca^{2+}]$ channels.[203,204] Testosterone-mediated $[Ca^{2+}]$ influx occurs via the activation of an unidentified G_q-type GPCR and the subsequent activation of phospholipase C (PLC), which then hydrolyzes PIP_2 in the plasma membrane to produce IP_3 and diacylglycerol (DAG). The decrease in the levels of PIP2, an inhibitor of adenosine triphosphate (ATP)-mediated activation of K^+_{ATP} channels, promotes the closing of these channels, causing an increase in membrane resistance and depolarization of the cell. As a result, voltage-dependent L-type Ca^{2+} channels open and allow the influx of Ca^{2+}, which may alter many cellular processes.[205,206] Thus far, potential cellular targets and spermatogenesis processes regulated by the testosterone-mediated $[Ca^{2+}]$ influx pathway have not been investigated.[207]

Androgen Regulation of Micro-RNAs in Sertoli Cells

Testosterone regulates the expression of several micro-RNAs (miRNAs) in Sertoli cells that can decrease the half-life or translation of mRNAs that are highly expressed in Sertoli and germ cells. Using a testosterone-deprivation model in which mice were treated with the anti-androgen flutamide and the GnRH antagonist acyline, the expression of 28 miRNAs was found to be highly altered.[208] In the same study, many of the 28 miRNAs were similarly regulated in hypoandrogenic mice lacking LHβ. At least nine of the miRNAs were developmentally expressed such that their expression peaked on postnatal day 13 or 21 during the androgen-dependent steps of spermatocyte progression though meiosis I or the initiation of spermatid differentiation. Pathway analysis suggested that testosterone-regulated miRNAs targeted genes required for cell junction restructuring and cell signaling, two androgen-dependent processes required for germ cell development. Further analysis showed that the miR-471 miRNA binds to the 3′ UTRs and downregulates the Sertoli cell genes *Foxd1*, a forkhead–winged-helix transcription factor that is important in Sertoli metabolism, and desmocollin 1 (*Dsc1*), a desmosomal cadherin that is required for Sertoli–germ cell adhesion.[208] The downregulation of gene expression by testosterone-regulated miRNAs may be one explanation for the relatively high percentage of genes that are inhibited by testosterone signaling.

Proteomic Analysis of Testosterone-Regulated Meiotic Proteins

The completion of meiosis requires testosterone signaling via AR in the Sertoli cell (reviewed in Ref. 97). Thus far, gene expression surveys have provided relatively little information regarding the genes and proteins that are regulated during meiosis as a result of testosterone signaling through somatic cells. However, a proteomics study employing rat models having various levels of testosterone depletion and replenishment has provided long-needed information regarding the proteins and processes that are regulated in spermatocyte germ cells during meiosis.[209] The meiotic cell proteins that are indirectly regulated by testosterone include those having roles in metabolism and response to stress, including disulfide–isomerases, and heat shock proteins

as well as proteins associated with the unfolded protein response and DNA damage. Further study determined that spermatocytes are subjected to oxidative DNA damage after testosterone withdrawal. Consistent with the fact that androgen suppresses apoptosis, testosterone withdrawal altered the expression and posttranslational regulation of proteins involved in apoptosis. Proteins with roles in RNA splicing and processing as well as posttranslational processing and DNA repair also were identified. Finally, a number of proteins involved in cell division and meiosis were differentially expressed in response to altered testosterone levels.

FOLLICLE-STIMULATING HORMONE

FSH is a protein hormone that is produced by the anterior pituitary and transported to the testis via the circulation. In the testis, only Sertoli cells express the FSH receptor. Thus, all spermatogenesis-supporting functions of FSH are mediated through Sertoli cells. FSH binds to the curved inner surface of the FSH receptor ectodomain in a handclasp fashion resembling a right hand (receptor) grasping an American football.[33,210] The ligand-bound FSH receptors form dimers with the two ectodomains interacting with each other. Resulting signals from conformational changes in the seven transmembrane domains of the receptor are transmitted to the cytoplasmic portion of the receptor and elicit guanine nucleotide exchange in associated heterotrimeric G proteins.[33,211,212]

FSH Receptor Expression in the Testis

In the male adult rat, plasma FSH levels are relatively steady.[213,214] In contrast, the expression of mRNA encoding the FSH receptor is dependent on the stage of the seminiferous epithelial cycle, with levels being highest during stages XIII–II and lowest at stages VI–IX.[215–217] FSHR protein levels vary by more than threefold during the cycle in the rat, with the most receptors present in stages XIII–II and the fewest during stages VII–VIII.[215,218] As a result, there is a cyclical activation of FSH-mediated signaling pathways. For example, FSH-induced cAMP production closely follows the levels of FSH receptor, with the highest levels observed in stages XIV–V and the lowest levels in stages VII–XI.[219]

The expression of the FSH receptor is largely regulated at the level of transcription initiation from its promoter. Although binding sites for NR5A1, SMAD3, ETF, GATA1, and ETS transcription factors have been implicated in regulating *FSH receptor* transcription, an E-box element shared by the rat, sheep, and human *FSH receptor* gene promoters is a major determinant of transcription activity (reviewed in Ref. 220). USF1 and USF2, members of the E-box family transcription factors, bind to the E-box motif and activate the *FSH receptor* promoter in Sertoli cells.[221–223] Binding of USF proteins to the *FSH receptor* promoter increases during Sertoli cell differentiation.[224,225] FSH or cAMP transiently induces the expression of a USF inhibitor in Sertoli cells named ID2 (inhibitor of DNA binding and differentiation) to cause negative feedback on FSH receptor levels. The ID2 protein dimerizes with USF proteins and blocks USF DNA-binding activity, resulting in decreased FSH receptor promoter activity. However, long-term stimulation with FSH restores USF binding to the promoter, as well as promoter activity and *FSH receptor* mRNA levels.[225,226] This FSH-mediated mechanism to transiently decrease *FSH receptor* transcription may explain the cyclical changes in FSH receptor expression that occur in Sertoli cells during the cycle of the seminiferous epithelium in vivo.

Sequences required for activation of the *FSH receptor* gene in vivo are still not fully characterized, but extensive information in addition to that present in the promoter are required. Transgenic mouse studies have determined that a 413 kb region encompassing the *FSH receptor* gene plus 98 kbp upstream and 80 kbp downstream of the gene was not sufficient to provide appropriate temporal and spatial expression of the FSH receptor.[227] The binding of octomer transcription factor 1 (Oct1; POU2F1) to a site in the first intron of the *FSH receptor* gene may contribute to silencing expression of the gene in inappropriate cells.[228]

FSH-Signaling Pathways

FSH is capable of regulating at least five specific intracellular signaling pathways in Sertoli cells: the cAMP–PKA, MAPK, PI3K–AKT–mTOR–p70S6K, Ca^{2+}, and phospholipase A_2 pathways (Figure 16.9).

The cAMP–PKA Pathway

FSH binding to its receptor facilitates coupling of the activated receptor to a heterotrimeric G protein. The subsequent exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the G_s subunit leads to the dissociation of G_α from the receptor and the $G_{\beta\gamma}$ subunits. There are four families of G_α proteins (i.e., $G_{\alpha s}$, $G_{\alpha i/o}$, $G_{\alpha q/11}$, and $G_{\alpha 12/13}$) that are activated when bound by GTP. $G_{\alpha s}$ stimulates the adenylate cyclase enzyme to produce cAMP from ATP, whereas $G_{\alpha i/o}$ decreases adenylate cyclase activity and lowers cAMP levels (reviewed in Ref. 230).

Increased intracellular cAMP levels arising after FSH binds to its receptor cause the release of the catalytic subunit of PKA from the regulatory subunits and result in the phosphorylation of numerous PKA target proteins. One target of PKA is a family of transcription factors that bind to CREs, including the CREB transcription

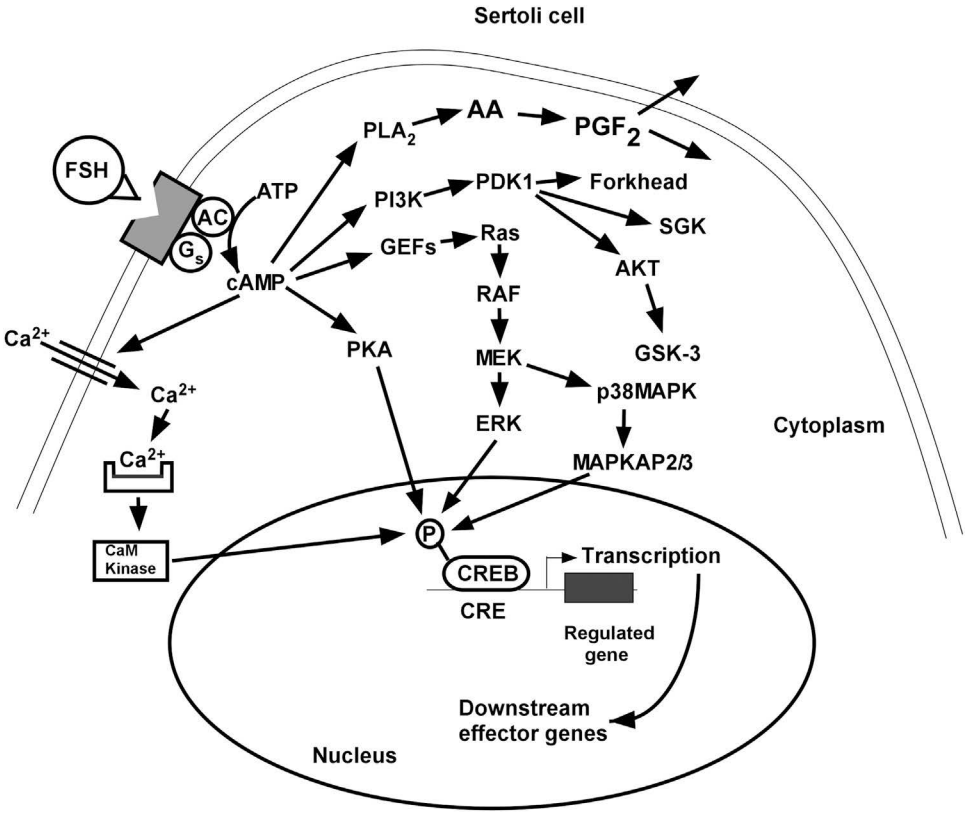

FIGURE 16.9 **FSH-signaling pathways.** Initially, FSH binding to the FSH receptor causes receptor-coupled G proteins (Gs) to activate adenylate cyclase and increase intracellular cAMP levels. Multiple factors can be activated by cAMP in Sertoli cells, including PKA that can phosphorylate a number of proteins in the cell and also regulate the expression and activity of numerous transcription factors, including CREB. FSH also causes Ca^{2+} influx into Sertoli cells that is mediated by cAMP and perhaps PKA modification of surface Ca^{2+} channels. Depolarization of the cell is also involved in Ca^{2+} influx. Elevated Ca^{2+} levels can activate calmodulin (CaM) and CaM kinases that have multiple potential downstream effects, including the phosphorylation of CREB. FSH activates or represses the MAPK cascade and ERK kinase in Sertoli cells in a developmental stage–specific manner. Inhibition of the pathway is not well characterized. Activation is most likely via cAMP interactions with guanine nucleotide exchange factors (GEFs) and activation of Ras-like G proteins followed by sequential activation of RAF, MEK, and ERK kinases. ERK is capable of activating CREB and other transcription factors, including SRF, and c-jun (not shown). In granulosa cells, FSH also activates the p38 MAPK. FSH and cAMP also likely act through GEFs to activate PI3K and then phosphoinositide-dependent protein kinase (PDK1) and PKB in Sertoli cells. Studies of granulosa cells identified Forkhead transcription factor (Forkhead), SGK (glucocorticoid-induced kinase), and GSK-3 (glycogen synthase kinase-3) as additional downstream targets of the PI3K pathway. FSH also mediates the induction of PLA2, the subsequent release of arachidonic acid, and the activation of eicosanoids such as PGE2 that may act as intracellular or extracellular signaling agents. *Source: Modified from Ref. 229.*

factor that is a central regulator of metabolic processes in Sertoli cells required to support germ cells. In Sertoli cells isolated from 15-day-old rats, FSH stimulation rapidly causes CREB to be phosphorylated on serine 133. Elevated cAMP levels increase CREB phosphorylation within 2 min, but CREB phosphorylation and activation are lost quickly (within 5 min) after the removal of stimulation.[231] The importance of phosphorylated CREB in Sertoli cells for the maintenance of fertility was demonstrated with in vivo studies in which a mutant CREB that could not be phosphorylated was overexpressed exclusively in Sertoli cells of rat testes. In seminiferous tubules infected with adenoviruses expressing the mutant CREB in Sertoli cells, disrupted spermatogenesis was observed due to the apoptosis of spermatocytes and subsequent loss of more than 75% of spermatids.[232]

The MAPK Pathway

The MAPK cascade is initiated with RAS stimulation of RAF kinases that phosphorylate MEK, which then phosphorylates ERK (Figure 16.9). FSH can activate the MAPK pathway rapidly and transiently via a $G_{\alpha s}$–PKA pathway and by a slower, more sustained mechanism through β-arrestins.[233] ERK then phosphorylates numerous proteins, including those that regulate cell adhesion, migration, differentiation, metabolism, transcription, and progression through the cell cycle.[234]

FSH activation of the MAPK pathway is thought to be a major promoter of Sertoli cell proliferation during the first 2 weeks of life in rats. In Sertoli cells, FSH activates ERK in proliferating Sertoli cells isolated from 5- to 11-day-old rats. FSH effects on ERK are reversed

coinciding with the end of the Sertoli cell proliferation period. Specifically, stimulation of 19-day-old Sertoli cells with FSH inhibits ERK.[235] Thus, whereas FSH initially supports proliferation, at puberty FSH begins to act to limit ERK activation and repress proliferation.

In the adult rat, FSH receptors are expressed in a cyclical manner such that low levels of FSH receptor and FSH signaling are present during stages VI–VIII. In the stages in which FSH receptor levels are low, less FSH-mediated inhibition of ERK would be expected. This idea is supported by the finding that phosphorylated ERK levels in Sertoli cells in vivo are elevated during stages VI–VIII.[193] The relief of FSH-mediated ERK inhibition may be part of a program that includes testosterone-mediated stimulation of ERK during stages VI–VIII.[202] ERK activity in Sertoli cells has been shown to be required for the progression of spermatocytes through meiosis.[236] ERK regulation of spermatogenesis-regulating processes is also focused in stages VI–VIII. During these stages, activated ERK may contribute to the disassociation of elongated spermatids from Sertoli cells (reviewed in Ref. 200), and disruption of the BTB is associated with activation of ERK.[237] Sertoli–germ cell anchoring dynamics are also regulated by ERK.[201] These findings suggest that FSH signaling during most of the cycle of the seminiferous epithelium may prevent the overactivation of ERK that otherwise would promote the proliferation of Sertoli cells in an already full epithelium and cause inappropriate changes to the BTB and Sertoli–germ cell adhesion.

Pathways Involving PI3K, AKT, mTOR, and p70S6K

Phosphoinositide 3 kinase (PI3K) signaling contributes to many processes, including cell cycle progression, cell growth, survival and migration, and intracellular vesicular transport.[238] G protein–coupled receptors such as the FSH receptor use associated G proteins to activate PI3K, a heterodimer composed of an 85 kDa regulatory subunit and a catalytic subunit of 110 kDa. PI3K then generates phosphorylated phosphatidylinositol intermediates that result in the activation of effector kinases, including AKT–protein kinase B (PKB).[238] FSH was shown to act through cAMP and PKA to activate AKT in a PI3K-dependent manner in Sertoli cells. The activation of PI3K contributes to metabolic processes in Sertoli cells that support germ cell functions. Specifically, FSH-mediated PI3K activation promotes: (1) the uptake of glucose that is required for conversion into lactate, (2) the induction of lactate dehydrogenase (LDH) that is required to produce lactate for germ cells, and (3) the production of γ-glutamyl transpeptidase (γ-GTP), a transporter of amino acids across the membrane and the secretion of transferrin required for iron transport to germ cells.[239] In immature (10-day-old) Sertoli cells, the PI3K pathway is required for FSH-dependent estradiol production, FSH-stimulated aromatase mRNA (*Cyp19a1*), and protein production derived from a ubiquitous NAPDH–cytochrome P450 reductase and a specific cytochrome P450 aromatase (encoded by the *Cyp19a1* gene) in Sertoli cells that irreversibly transforms androgens into estrogens.[240]

The specific pathways by which FSH activates PI3K and AKT in Sertoli cells have not been fully characterized. However, information from the related granulosa cells of the ovary provides potential signaling mechanisms. In granulosa cells, the seven-transmembrane domain of the FSH receptor has been shown to interact with the adaptor protein APPL1 (adaptor protein–containing PH domain, PTB domain, and leucine zipper motif) that, in turn, interacts with the p100α subunit of PI3K and AKT.[241] More recently, it was found that FSH signals through a preexisting growth factor receptor bound protein 2 associated binding protein-2 (GAB2) signalsome complex consisting of GAB2, PI3K, insulin response substrate 1 (IRS1), and PKA. FSH-mediated increases in cAMP levels and activation of PKA lead to phosphorylation changes for the proteins in the signalsome and activation of the PI3K–AKT pathway.[242]

FSH-mediated stimulation of PI3K also results in the activation of mammalian target of rapamycin (mTOR), which in turn activates p70S6K, which phosphorylates ribosomal S6 protein, resulting in increased mRNA translation and cell proliferation. FSH also can act via PKA to upregulate p70S6K activity and the phosphorylation of S6.[243,244] AMP-activated protein kinase (AMPK) is a negative regulator of p70S6K. FSH regulation of AMPK in Sertoli cells is not well characterized. However, AMPK, an inhibitor of granulosa cell proliferation, is inhibited by FSH in the ovarian cells.[245,246] Mutations that disrupt the AMPK–mTOR–p70S6K pathway in humans cause Peutz–Jeghers syndrome, which results in defective spermatogenesis, including severe loss of germ cells, vacuolated Sertoli cells, a Sertoli cell–only phenotype, and proliferating Sertoli cells that crowd the seminiferous tubules.[247,248] The knockout of upstream participants in the AMPK–mTOR–p70S6K pathway in Sertoli cells and the subsequent overactivation of mTOR and p70S6K signaling caused defects in Sertoli cell junctional complexes and cell polarity.[249]

FSH-mediated activation of mTOR and p70S6K also has important implications for the regulation of mRNA translation, as FSH causes the recruitment of mTOR and p70S6K to the 5′ cap of mRNAs and increases the phosphorylation of the eukaryotic initiation factor 4B, a target of p70S6K. The combined effects of this signaling pathway increase recruitment of eukaryotic initiation factors to the mRNA, facilitate mRNA association with polysomes enhance overall protein synthesis within 90 min of FSH stimulation, and may support mRNA-selective translation.[250]

Intracellular Ca^{2+} Pathway

FSH stimulation of immature Sertoli cells causes increases in the levels of intracellular Ca^{2+} within seconds.[251–254] One mechanism by which FSH-mediated changes in Ca^{2+} levels could affect Sertoli cell function is activation of calmodulin and Ca^{2+} calmodulin-dependent kinases that may alter the cytoskeletal structure of Sertoli cells, Sertoli–Sertoli tight junctions, and cell junction dynamics as well as the phosphorylation of transcription factors, including CREB.[255–259]

Studies of freshly isolated Sertoli cells held in suspension determined that FSH-mediated influxes of Ca^{2+} from external sources occurred via both voltage-gated and voltage-independent calcium channels.[252] In cultured Sertoli cells, FSH stimulation also caused Ca^{2+} release from intracellular stores that then resulted in Ca^{2+} influx due to Ca^{2+} release currents.[254] Under both conditions, it was found that increasing cAMP levels and PKA activity contributed to altering channel activity.[252–254] Further investigation determined that FSH causes a short (5 s) hyperpolarization of the Sertoli cell membrane that is dependent upon ATP-sensitive K^+ channels, followed by a prolonged depolarization (more than 6 min) that is dependent upon the uptake of Ca^{2+} by L-type voltage-dependent Ca^{2+} channels.[260–262] It has been proposed that FSH acts via G_i proteins to activate L-type voltage-gated Ca^{2+} channels required for Ca^{2+} entry and hyperpolarization of the plasma membrane and via $G_{\alpha s}$ G protein subunits to convert ATP to cAMP, which opens K^+_{ATP} channels.[263,264] Other studies argued against FSH acting through G_α or G_i to mediate calcium influx but found evidence for a phospholipase C-δ1 (PLC-δ1) pathway that activates T-type Ca^{2+} channels independently of intracellular calcium release.[265,266] It has been reported that FSH-regulated Ca^{2+} uptake through voltage-dependent Ca^{2+} channels is observed only in immature Sertoli cells and thus may be responsible for the differential responses of immature and adult Sertoli cells to FSH stimulation.[267]

Phospholipase A_2 (PLA_2) Pathway

FSH activation of PLA_2 leads to the release of arachidonic acid and its subsequent metabolism to prostaglandin E_2 and other eicosanoids that function as intracellular signals. As a result, adenylate cyclase activity and androgen aromatization are stimulated in Sertoli cells,[268] as well as Sertoli cell apoptosis and proliferation.[269] Further studies are required to better characterize the physiological importance of the PLA_2 pathway in Sertoli cells.

Desensitization of the FSH Receptor

Prolonged exposure of target cells to FSH results in a decreased response with time (desensitization). For example, a 2 h treatment with FSH reduces a subsequent FSH-mediated induction of cAMP production by 70% or more.[270,271] Desensitization can initiate within minutes of FSH binding to the FSH receptor due to phosphorylation of the first and third intracellular domains of the receptor by G protein–coupled kinases. Arrestin proteins are then allowed to bind to the receptor and uncouple the receptor from G proteins, preventing further signal transduction. Arrestins also facilitate internalization of the receptors by interacting with clathrin and concentrating receptors in clathrin-coated pits.[271–274] Long-term exposure of Sertoli cells to FSH also results in the upregulation of phosphodiesterase activity that decreases cAMP levels[275] and downregulation of FSH receptor expression.[276] The FSH-mediated activation of phosphodiesterase, the desensitization and downregulation of the FSH receptor, as well as the stage-specific control of FSH receptor levels suggest that limiting FSH signaling is important for Sertoli cell function. In support of this idea, a mouse transgenic model of constitutive FSH action displays elevated testosterone levels and is infertile.[277]

Differential FSH Signaling in Proliferating versus Differentiated Sertoli Cells

The function of FSH shifts during the development of Sertoli cells. FSH promotes the proliferation of Sertoli cells prior to puberty.[278,279] After puberty, when Sertoli cells do not divide or do so only very rarely in vivo, FSH acts through Sertoli cells to support germ cell viability.[280–282] There is evidence from the rat that FSH acts through the differentiated Sertoli cell to support the survival of spermatogonia,[280,283,284] although it is not clear whether FSH acts only to decrease apoptosis[280,285,286] or to also increase spermatogonia proliferation.[287,288]

FSH promotes Sertoli cell proliferation in rats beginning on day 19 or 20 of fetal life, but most Sertoli cell proliferation is halted 15–20 days after birth in the rat. During this period, circulating FSH levels and the expression of FSH receptors on Sertoli cells remain relatively constant.[278,289–294] Although FSH signaling potential apparently is unchanged, FSH can have opposing effects on proliferating and differentiated Sertoli cells. Alterations to FSH-mediated signaling pathways are thought to be responsible for the differing effects of FSH that occur during Sertoli cell differentiation.

During the proliferating and differentiating stages of Sertoli cell development, FSH effects on cAMP production and activation of the proliferation-promoting MAPK pathway are very different. In proliferating Sertoli cells cultured from 5- to 12-day-old rats, FSH had little effect on cAMP levels but activated the MAPK pathway in a PKA-dependent manner, as shown by increased phosphorylation of the ERK.[235] The FSH-mediated activation of ERK resulted in increased expression of cyclin D1 that

promotes proliferation.[235] In contrast, FSH simulation of differentiating 15- to 20-day-old Sertoli cells increased cAMP levels but decreased ERK activity.[235,244,295,296]

FSH also has been shown to activate the PI3K–AKT–mTORC1–p70S6K signal transduction pathway in Sertoli cells cultured from 8-day-old Sertoli cells. Furthermore, inhibition of the pathway blocked Sertoli cell proliferation.[297] In the 8-day-old Sertoli cells, FSH stimulation also decreased activity of the AMPK that is associated with increased expression of the cell cycle inhibitors $p19^{INK4A}$, $p21^{Cip1}$, and $p27^{Kip1}$.[297] In other studies, FSH stimulation of 5-day-old Sertoli cells increased the levels of PIP3, a downstream target of PI3K signaling. High basal levels of PIP3 were not further increased by FSH in 19-day-old Sertoli cells. These data suggest that FSH can induce PI3K activity in proliferating Sertoli cells, but PI3K activity is less responsive to FSH in differentiating cells.[244]

FSH-mediated increases in the levels of phosphatase and tensin homolog deleted in chromosome 10 (PTEN), an inhibitor of the proliferation-promoting PI3K–AKT signaling pathway, may contribute to blocking the proliferation of differentiating Sertoli cells. In differentiating Sertoli cells isolated from 19-day-old rats, FSH stimulation increases the levels of PTEN. Knockdown of PTEN by RNA interference allows FSH to induce the transcription of genes that are associated with proliferation.[298]

It has been known for some time that the effects of FSH on Sertoli cell proliferation is dependent in part on IGF1[299,300] and activin, which in the testis is produced by Sertoli, Leydig, and PTM cells.[301–304] FSH and IGF1 synergize to increase the activity of the growth-promoting AKT kinase in Sertoli cells,[305] and elimination of the IGF1 receptor in cultured Sertoli cells reduced proliferation, as indicated by BrdU incorporation.[306] More recent studies of mice lacking the insulin receptor and/or the IGF1 receptor confirm that FSH requires the insulin–IGF signaling pathway to mediate proliferative effects on immature Sertoli cells. In the absence of insulin–IGF1 signaling, Sertoli cell proliferation rates were reduced at embryonic day 17 and postnatal day 5, resulting in a delay of Sertoli cell maturation and in small testis.[307] Activin plus FSH stimulation cause synergistic increases in Sertoli cell proliferation,[282,308,309] and the combination of activin plus FSH is thought to prolong Sertoli cell proliferation beyond the period in which FSH is effective alone.[309] The decline in activin levels observed at puberty correspond with the halting of Sertoli cell proliferation and the initiation of differentiation (reviewed in Ref. 310).

The sum of all the changes in FSH regulation of signaling pathways during Sertoli cell development provides insight into the regulation of Sertoli cell proliferation and differentiation. However, the mechanisms responsible for causing the developmental stage–specific intracellular signaling changes in response to FSH have not been fully characterized.

Knockout of FSHβ and FSHR, and the Regulation of Sertoli Cell Proliferation in Mice

Historically, FSH has been shown to provide the major stimulus for Sertoli cell proliferation. Suppression of FSH levels in rats reduces Sertoli cell numbers,[311,312] whereas administration of FSH increases the number of Sertoli cells.[278,292,294,313–315] One time course of FSH immunosuppression in vivo found no effects on Sertoli cell numbers 3 days after birth, but the Sertoli cell population was decreased by FSH immunoneutralization at 9 days after birth. At the time point 18 days after birth, Sertoli cell numbers were not altered but germ cell apoptosis increased. These data indicate that FSH differentially affects Sertoli cells and (indirectly) germ cells in an age-dependent manner, promoting Sertoli cell proliferation during a time span centered around 9 days after birth but supporting only germ cell viability by day 18 in the rat.[280]

More recent studies from one group that employed knockout mouse models have provided information conflicting with the historical data that placed FSH as a central regulator of Sertoli cell proliferation in rodents. Specifically, comparisons of the numbers of Sertoli cells present in FSH-β knockout (FSHβKO) and FSH receptor knockout (FSHRKO) mice with wild-type mice 1 and 5 days after birth revealed no significant differences, suggesting that FSH signaling was not required for Sertoli cell proliferation in late-fetal and neonatal development.[316,317] The number of Sertoli cells was reduced in FSHβKO and FSHRKO mice between 5 and 20 days after birth and more dramatically in the adult. These data suggest that FSH acts only postpubertally to regulate the Sertoli cell number in mice. In contrast, both *tfm* mice lacking AR activity and AR null mice have significantly fewer Sertoli cells 1, 5, and 20 days after birth and in adulthood, suggesting that androgens are important mediators of Sertoli cell proliferation and/or survival,[316,317] although, as discussed in this chapter, the mechanism underpinning this remains unknown.

A second group studying FSHRKO mice has provided data supporting the idea that FSH contributes to prenatal Sertoli cell proliferation. In these studies, the number of Sertoli cells present at birth was reduced by 22% and BrdU incorporation in Sertoli cells was lower in the FSHRKO mice than in intact mice.[318] Other parameters of maturation at birth and 8 days after birth indicated that Sertoli cells were less differentiated in the FSHRKO mice. These results support the idea that FSH signaling contributes to Sertoli cell proliferation and differentiation in the fetal and neonate testis. However, there is a relatively small effect of FSHRKO on the number of

Sertoli cells in mice during one of the most prolific periods of Sertoli cell proliferation.[293]

Explanations for the differing paradigms of FSH regulation of Sertoli cell proliferation obtained from historical studies versus the new results from FSHβKO and FSHRKO mice will require further study. However, it should be noted that whereas the knockout studies were performed in the mouse model, most of the historical studies of FSH effects on Sertoli cell proliferation were performed using rats. One potential difference in these animal models is the patterns of serum FSH level present during development. In rats, FSH levels remain at or above adult levels from birth through 35 days after birth.[213,214] In contrast, serum concentrations of FSH in the neonate mouse are retained at low levels (2–3 ng/ml) before rising four- to fivefold to adult levels between 10 and 25 days after birth.[319] Other studies provide confirmation that FSH levels in adult mice are much lower than those in the adult rat.[320,321] Although direct comparisons of rat and mouse bioactive FSH levels were not performed in these studies, the data available indicate that rat FSH levels during the time period of Sertoli cell proliferation are at adult levels, whereas mouse serum FSH concentrations are at least fourfold lower than adult levels and 100-fold lower than those present in rats. Together, these data raise the possibility that FSH contributes less to testis development in the mouse and that perhaps mice and rats have differing strategies for supporting Sertoli cell proliferation. The developmental pattern of nonhuman primates best matches the rat model in that most Sertoli cell proliferation occurs immediately after birth and again during puberty only when FSH is present at adult levels.[322]

Gene Regulation by FSH Signaling

Surveys of FSH-regulated gene expression have been performed using various model systems, including FSH stimulation of cultured Sertoli cells,[323] immunosuppression of FSH in the rat in vivo,[280] FSH stimulation of *hpg* mice lacking gonadotropins,[324] and FSH stimulation of irradiated rats lacking germ cells.[325] Whereas the survey studies identified novel gene targets of FSH signaling, they also confirmed the regulation of previously described FSH-regulated transcripts required for normal testicular function. These genes include the FSH-stimulated *StAR* gene required for steroid synthesis, the cell cycle promoter *cyclin D2*, and *ABP*. Confirmed FSH-inhibited genes include IGF binding protein 3 (*IGFBP-3*), *HNF-3*/forkhead, endothelin-1, and cathepsin-L.[280]

Studies of gene expression in the testes of FSHβKO and FSHRKO mice indicate that most FSH regulation of genes that are required for supporting germ cells does not initiate until between 5 and 20 days after birth. These models demonstrated that FSH stimulates genes encoding the tight junction components ZO-1 and claudin 11, the tissue remodelers Cys-TE and tissue plasminogen activator (tPA), the ligand-binding protein (fatty acid binding protein), as well as the growth factors, platelet-derived growth factor A (PDGF-A) and kit ligand (also called the stem cell factor or Steel factor). Studies using the FSHβKO mouse also confirmed that FSH is required for the expression of the FSH receptor.[316]

Independent studies have identified other FSH-inducible genes in Sertoli cells that encode proteins having direct effects in supporting spermatogenesis, including DMRT, which has been implicated in sex determination and testis differentiation[326]; transferrin, which is required to transport iron to germ cells[327,328]; as well as VEGF,[323] which may act on receptors present on germ cells from the spermatogonia to round-spermatid stages of development.[329] FSH acts via cAMP and PKA to stimulate the transcription of the inhibin α subunit and secretion of inhibin B,[521–523] which in turn acts on the anterior pituitary to decrease FSH secretion and in the testis to counteract the actions of activins.[330]

FSH-mediated activation of PKA results in the phosphorylation and activation of the CREB transcription factor. CREB is able to activate transcription from the promoters of numerous genes in Sertoli cells. Two examples include the CREB gene promoter[231] and an internal promoter within the highly homologous CREM gene that results in the production of the inducible cAMP early repressor (ICER) that represses CRE-mediated transcription.[331,332] Rapid expression of ICER in response to elevated cAMP levels causes the transient downregulation of CREB transcription, but later ICER-mediated inhibition of ICER expression permits delayed induction of CREB promoter activity. The mutual control of CREB and ICER expression may explain the oscillating cAMP-mediated CREB mRNA expression that was observed in Sertoli cells during the spermatogenic cycle[333] and may provide for stage-specific expression of FSH-regulated mRNAs. Additional genes known to be regulated by FSH-inducible cAMP and CREB include lactate dehydrogenase (*LDH-A*), which controls the synthesis of the major fuel source for germ cells[334]; aromatase[335]; *tPA*[336]; and *IGF1*.[337]

Expression of kit ligand that potentiates the survival and expansion of spermatogonia[338] is also potentiated in Sertoli cells by FSH via cAMP. Elevated cAMP levels cause a complex of at least three proteins to bind to a cAMP-responsive −55 to +8 region of the *kit ligand* promoter by a mechanism that does not include CREB.[339,340] The kit ligand produced by Sertoli cells binds to its receptor c-kit on germ cells. The maintenance and mitosis of differentiating type A spermatogonia are absolutely dependent on Kitl and c-kit, but differentiation of type B spermatogonia into preleptotene spermatocytes is independent of c-kit.[341] Signaling through c-Kit also

promotes the progression into meiosis and survival during the pachytene stage of meiosis.[342–345] Kitl alters the expression of genes known to be up- or downregulated in spermatogonia during the transition from the mitotic to the meiotic cell cycle, which is consistent with the need for Kitl to activate c-Kit for the entry into meiosis.[346]

FSH rapidly and transiently induces the activity of the AP1 transcription factor by stimulating the transcription of the AP1 components c-fos and jun-B while inhibiting c-jun.[347] AR is also induced by FSH, and thus FSH regulates the androgen responsiveness of Sertoli cells.[348–351] In granulosa cells, FSH induces LRH1 (the orphan nuclear receptor liver homolog 1)[352] and HIF1 (hypoxia inducible factor 1) via the PI3K pathway.[353] The potential significance of FSH regulation of LRH1 and HIF1 has not yet been investigated in Sertoli cells. FSH stimulation also results in the translocation of the NF-κB transcription factors to the nucleus due to the release of NF-κB from its cytoplasmic anchoring partner IκB, most likely due to PKA phosphorylating IκB and marking it for degradation.[354–356]

Although studies of FSH-regulated gene expression have provided important information, they have been limited by the requirement to use models in which the germ cell complement is reduced or absent. Further understanding of FSH gene targets required to support germ cells will be forthcoming with the use of models in which FSH signaling can be transiently blocked in the adult Sertoli cell and stage-specific gene expression can be assayed.

FSH Regulation of GDNF in Sertoli Cells

FSH also upregulates GDNF (glial cell line–derived neurotrophic factor), a 15 kDa member of the transforming growth factor beta (TGF-β) superfamily that is essential for the proliferation of germinal stem cells.[357] GDNF was the first factor found to be required for the self-renewal and survival of SSCs.[358,359] Expression of GDNF in adult rat Sertoli cells in vivo is cyclical. The highest levels of GDNF mRNA are present during stages XIII through XIV and I in the rat,[360] corresponding to the stages in which FSH receptor levels and FSH binding by Sertoli cells are greatest[215,218] and immediately before and during the stages showing maximal replication of a type A single (A_s) class of spermatogonia that includes stem cells.[360,361] These data suggest that stage-specific increases in GDNF production by Sertoli cells likely cause proliferation of A_s spermatogonia that results in self-renewal. In contrast, during stages in which GDNF levels are decreased, division of A_s spermatogonia and their transit amplifying progeny tends to result in cells committed to becoming differentiated A1 spermatogonia.[360] It is possible that germ cells produce signals that inhibit GDNF expression in Sertoli cells to cause the stage specificity of GDNF production because *Gdnf* mRNA expression is increased in testes that are severely depleted of germ cells.[357]

Integration of the FSH and Testosterone-Signaling Pathways

FSH and testosterone both initiate signaling pathways that contribute to the support of spermatogenesis, and the hormones share some common characteristics. One characteristic that is shared by FSH and testosterone in young rats is the elevation of Ca^{2+} in Sertoli cells, although the mechanisms by which elevated Ca^{2+} might support spermatogenesis are not yet known.

In prepubertal rodents, either testosterone or FSH can independently increase the number of Sertoli cells,[362] although FSH is apparently more effective.[292,316,363–365] The similar stimulation of Sertoli cell proliferation by FSH and testosterone may be due to the shared ability of these hormones to activate the MAPK pathway in prepubertal Sertoli cells. In contrast, only FSH is capable of activating other proliferation-promoting signaling factors, including PI3K and AKT, which may explain the more effective proliferation-promoting properties of FSH.

Regulation of the CREB transcription factor may be another example of how testosterone and FSH synergize to provide the factors that are required to maintain spermatogenesis. Phosphorylated CREB in Sertoli cells was shown to be essential for spermatocyte survival.[232] FSH is about twofold more effective than testosterone in phosphorylating CREB.[191] The less efficient phosphorylation of CREB in the presence of testosterone alone may be one contributing factor responsible for the reduced fertility observed with androgens in the absence of FSH. Also, testosterone-mediated CREB phosphorylation would be restricted to only stages VI–VIII. For full fertility, it may be necessary for CREB to be phosphorylated during all stages of the spermatogenetic cycle, thus providing one explanation for the out-of-phase cycling of FSH receptor and AR expression that permits FSH and testosterone to enhance CREB phosphorylation throughout the entire cycle of the seminiferous epithelium.

FSH and testosterone also can act in opposition on specific signaling pathways to support spermatogenesis. In pubertal and postpubertal rats, FSH acts to inhibit testosterone-mediated activation of ERK in mature Sertoli cells. Testosterone-mediated activation of ERK is inhibited by FSH as FSH stimulation of Sertoli cells increases cAMP levels that activate PKA, which then blocks activation of RAF1, an initial member of the MAPK cascade[202] (see Figure 16.9). Because FSH receptor and AR levels are cyclically expressed in an out-of-phase manner during the cycle of the seminiferous epithelium, FSH would be expected to limit ERK activation during

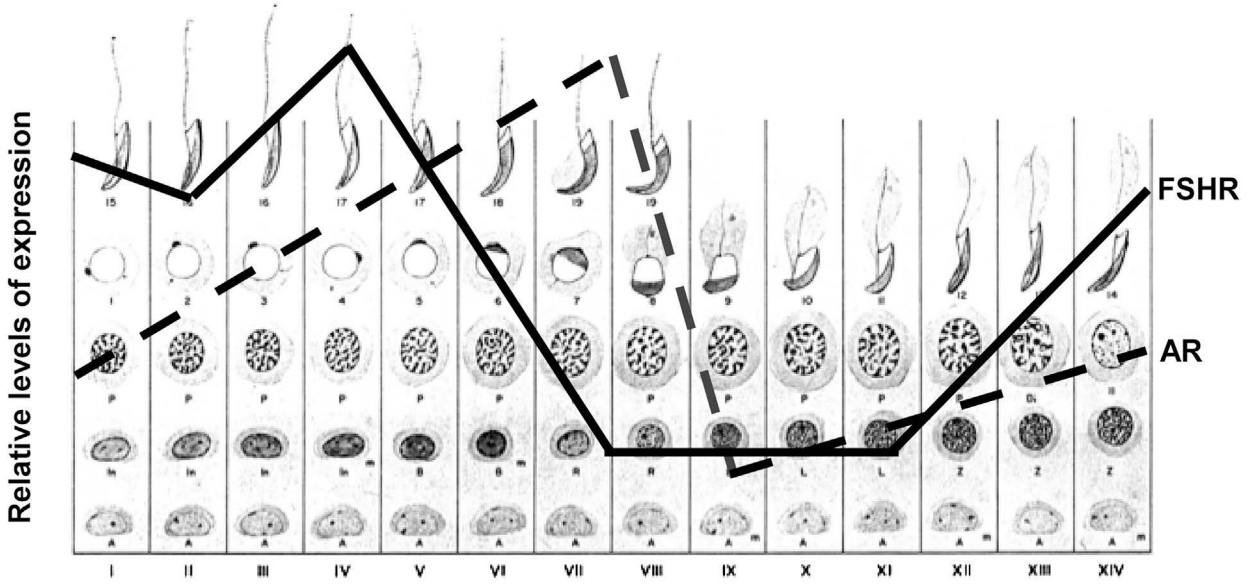

FIGURE 16.10 The expression patterns of FSHR and AR during the cycle of the seminiferous epithelium in rats. The relative levels of expression for FSHR (solid line) and AR (dashed line) are shown throughout the 14 stages (I–XIV) of the seminiferous epithelium cycle in the rat. *Source: Adapted from data provided by Refs 107,366.*

much of the cycle except during stages VII–VIII, when FSH receptor levels are lowest and AR levels are highest[107,111,112,215–217] (Figure 16.10). In agreement with this idea, activated ERK levels are elevated in stages VII–VIII adjacent to the heads of elongated spermatids in the process of being released and in adluminal regions adjacent to developing germ cells.[193] It is possible that this combination of FSH and testosterone signaling is one mechanism by which testosterone and FSH synergize to better support spermatogenesis. In this case, FSH would limit ERK activation in Sertoli cells to only the stages in which testosterone-mediated ERK activation is required for remodeling of Sertoli–germ cell attachments. In the absence of this synergism, the correct Sertoli–germ cell adhesion junctions might not be formed and germ cells would be released prematurely.

FSH, but not testosterone, has been shown to stimulate the PLA_2-signaling pathways in Sertoli cells (Figure 16.9), but thus far the function of PLA_2 signaling in maintaining spermatogenesis is not understood. Another difference between the two major hormonal regulators of Sertoli cells and spermatogeneis is that testosterone does not upregulate cAMP production in Sertoli cells.[191] These findings suggest either that elevated cAMP levels in Sertoli cells are not required for spermatogenesis or that redundant mechanisms are present. Finally, although FSH and testosterone activate some genes similarly, differences in their regulation of gene expression likely contribute to the synergistic effects of the hormones.

Testosterone and FSH also synergize to promote Sertoli cell proliferation. However, testosterone actions must be indirect because the proliferating fetal and neonatal Sertoli cells do not express androgen receptors (ARs).[107,109] Supporting this idea is the finding that knockout of AR in all cells reduces the number of Sertoli cells, whereas Sertoli cell–specific knockout of AR does not affect the population of Sertoli cells.[144] One possible explanation of these results is that androgen effects are mediated via PTM cells that express AR during fetal development.[109] Studies in nonhuman primates indicate that either FSH or androgen can cause Sertoli cell proliferation as treatment of juvenile monkeys with either FSH or LH resulted in a precocious increase in number of Sertoli cells, which is normally associated with the initiation of puberty.[362,367]

THYROID HORMONE

Thyroxine (T4) is the major form of thyroid hormone secreted by the thyroid gland, but 3,5,3-triiodo-L-thyonine (T3) is produced in target tissues by deiodination of T4.[368] Most actions of thyroid hormones are mediated by nuclear thyroid hormone receptors that are ligand-dependent transcription factors.[369] The thyroid hormone receptors (TRs) bind to specific conserved DNA sequence elements in gene promoters and recruit either co-activators or co-repressor proteins to regulate gene transcription.

Thyroid Hormone Receptor Expression in the Testis

Two genes (*Thra* and *Thrb*) encode the TRα1and TRβ1 receptors for T3 (reviewed in Ref. 370), and both receptors are expressed in Sertoli cells.[371–374] The TRβ1 receptor is also found in Leydig, PTM, and germ cells during neonatal development and in the adult.[374–376] Studies of transgenic mice lacking either TRα1 or TRβ1 receptors revealed that T3 acts predominately through the TRα1 receptor to regulate Sertoli cell proliferation and maturation.[377] Interestingly, TRα1 expression is high in rat Sertoli cell nuclei during the proliferation phase of Sertoli cell development, decreases after proliferation ceases, and remains low in adulthood.[375,376] Thus, the expression pattern of TRα1 matches the period of greatest response of Sertoli cells to thyroid hormone.[378]

Regulation of Testis Development by Thyroid Hormone

Knockout of TRα1 or expression of a dominant-negative form of TRα1 in only the Sertoli cells of transgenic mice results in increased testis weight and sperm production. Sertoli cell density also increased as a result of a higher proliferative index at postnatal days 0 and 3. These studies also suggested that T3 acts through the TRα1 receptor to downregulate the JunD–c-myc–Cdk4 pathway that promotes proliferation.[379]

Thyroid hormone is an established regulator of testis development prior to puberty. Hypothyroidism in neonatal rats results in impaired testicular development affecting testicular growth, germ cell maturation, and seminiferous tubule formation[380,381] that, when followed by subsequent recovery to euthyroidism, resulted in an 80–140% increase in adult testis size and daily sperm production.[382,383] The increases in testis size and sperm production were found to occur due to hypothyroidism-induced extension of the Sertoli cell proliferation period and delayed Sertoli cell maturation.[380,384–388] In contrast, hyperthyroidism results in premature halting of Sertoli cell proliferation, stimulation of maturation, and a 50% decrease in the size of the adult testis.[388] Further studies of neonatal mice established that T3 acts directly on Sertoli cells to decrease proliferation and initiate maturation.[389,390] Thyroid hormone also regulates Leydig cell differentiation and steroidogenesis in postnatal rat testis (reviewed in Refs 391,392).

The lack of T3 delays sexual maturation. In the hypothyroid state, completion of the first wave of spermatogenesis requires two- to threefold longer as compared to normal animals, but normal spermatogenesis does finally occur normally.[390] Prolonged depletion of thyroid hormone in the adult causes progressively degenerative changes to the seminiferous tubules, including decreased germ cell number and the release of fewer live sperm.[393,394] However, it is difficult to know whether the effects of prolonged hypothyroidism in the adult are due to the direct testicular effects of T3 depletion or the resulting decreased secretion of LH, FSH, growth hormone, and testosterone.[373,395–400]

Regulation of Sertoli Cell Number by Thyroid Hormone

One mechanism by which T3 limits the proliferation of Sertoli cells is by increasing the expression of cyclin-dependent kinase inhibitors (CDKIs) that are negative regulators of cell cycle progression. Specifically, the $p27^{Kip1}$ and $p21^{Cip1}$ CDKIs that are known to inhibit Sertoli cell proliferation[401,402] are regulated by T3. $p27^{Kip1}$ expression is increased and decreased by hyperthyroidism and hypothyroidism, respectively.[403] Furthermore, T3 stimulation of neonatal rat Sertoli cells increases the expression of the $p27^{Kip1}$ and $p21^{Cip1}$ proteins.[404]

Thyroid hormone also has been associated with the expression of the connexin 43 gap junction protein, and Sertoli cell–specific knockout of connexin 43 is linked to continued Sertoli cell proliferation that is maintained into adulthood, resulting in greater numbers of Sertoli cells. TRα1 levels are elevated in the Sertoli cell–specific connexin 43 knockout mice,[405] perhaps reflecting a less mature Sertoli cell phenotype. In agreement with these results, induced hypothyroidism in neonatal mice decreased connexin 43 expression, whereas T3 stimulation increased the size and number of gap junction plaques.[406]

Downstream Targets of T3 in Sertoli Cells

A compilation of genes regulated by thyroid hormone in the testis has been prepared elsewhere.[407] One thyroid hormone–regulated gene in Sertoli cells is aromatase (cytochrome P450 19 (*CYP19*)). The loss of aromatase activity is a marker for the completion of Sertoli cell maturation. Thyroid hormone decreases aromatase activity by directly inhibiting the transcription of the aromatase gene in Sertoli cells.[408] Thyroid hormone also downregulates the expression of neural cell adhesion molecule (NCAM), another marker of Sertoli cell maturation that is no longer expressed after differentiation.[409] Similarly, T3 decreases the expression of mRNA encoding Mullerian-inhibiting substance (MIS) (also known as anti-Müllerian hormone (AMH)), which is another transcript that decreases sharply with Sertoli cell maturation.[410] T3 increases androgen binding of Sertoli cells[411] and AR mRNA levels in immature rat Sertoli cells,[410] suggesting that T3 may contribute to the postnatal increase in AR expression that is associated with the maturation of Sertoli cells. Major components of the basement membrane

are regulated by T3 in cultured Sertoli cells, including laminin and entactin–nidogen (induced) as well as type IV collagen (inhibited),[412] raising the possibility that T3 alteration of the basement membrane may contribute to the differentiation of Sertoli cells. In Sertoli cells, thyroid hormone stimulates the conversion of glucose to lactate[390] that is used by germ cells as an energy source. The mechanism by which thyroid hormone stimulates lactate production is not known, but T3 increases the mRNA levels of the Glut1 glucose transporter, which are associated with elevated lactate production.[413]

Nongenomic Actions of Thyroid Hormone in Sertoli Cells

Thyroid hormones T3 and T4 use different mechanisms to promote amino acid accumulation[414] and stimulate protein synthesis in immature Sertoli cells.[415] T3 action is blocked by the protein synthesis inhibitor cyclohexamide, whereas T4 effects are unaltered by the inhibitor. These results indicate that T4 effects on protein synthesis are modulated by nongenomic pathways. Additional nongenomic actions of thyroid hormones have been reviewed recently.[416] These nongenomic actions include T4 stimulation of a rapid and transient Ca^{2+} influx into Sertoli cells.[415] One result of the Ca^{2+} influx is that the intermediate filament protein vimentin is hyperphosphorylated, causing increased accumulation of vimentin in the cytoskeleton.[417]

T3 Regulation of Leydig Cell Differentiation and Function

T3 receptors have been identified in Leydig cells, and thyroid hormone regulates the final number of Leydig cells as well as their steroid production (reviewed in Ref. 418). Chemically induced transient hypothyroidism in neonates results in increased numbers of Leydig cells in the adult testis[419,420] either by increasing the proliferation of existing Leydig cells[421] or by arresting Leydig cell differentiation and increasing the number of precursor mesenchymal cells that are generated and are available later for differentiation after euthyroidism is restored.[422] In contrast, hyperthyroidism accelerates Leydig cell differentiation and lowers the final population of Leydig cells.[423,424]

Acute T3 stimulation of cultured Leydig cells increases steroidogenesis, as shown by increased progesterone and testosterone production.[425–427] Short-term stimulation of Leydig cells also activates the transcription of the *StAR* gene that controls the first rate-limiting step for steroidogenesis. Chronic T3 treatment decreases *StAR* transcription and progesterone production in association with decreased delivery of cholesterol to the inner mitochondrial membrane. There is evidence that T3 regulates the *StAR* gene promoter via the NR5A1 transcription factor, but the mechanisms by which NR5A1 transactivation capabilities are altered by T3 are not yet understood.[426,428,429] In cultured Leydig cells, genes encoding steroidogenic enzymes also are regulated by T3, with *p450SSC* mRNA levels being upregulated but *p450C17* and *3β-HSD* mRNAs being inhibited after chronic T3 treatment,[428] in agreement with previous in vivo studies of hypothyroid rats.[430] *LHCGR* mRNA levels and LH binding to Leydig cells were similarly increased and decreased by acute and chronic T3 stimulation, respectively.[428]

ESTROGEN

Estrogen Production—Aromatase

The important role of estrogens in male reproductive development and function is now widely accepted (for reviews, see Refs 431–436). The classical pathway of estrogen action involves binding of the steroid hormone to the ligand-activated nuclear transcription factors ER-alpha (NR3A1) and ER-beta (NR3A2), which can function as independent homodimers or heterodimers, to bind specific target sequences, and EREs in promoters of target genes, as context-dependent transcriptional activators or repressors. Both receptors conform to the classical structure of nuclear receptors, with an N-terminal domain for co-factor interaction, a DNA-binding domain, a hinge region, and a ligand-binding domain.

The concentration of estrogens within the rete testis and testicular venous blood is significantly higher than in the general circulation in a variety of species, supporting a model of local estrogen production within the testis, although circulating estrogens can still impact testicular function via modulation of endocrine feedback mechanisms (for reviews, see Refs 433,435). In the testis, estrogens are generated locally via conversion from testosterone by aromatase. In the rat postnatal testis, aromatase is expressed in both Sertoli and Leydig cells, but with different temporal profiles. Immature Sertoli cells express high levels of aromatase during proliferation, with expression reducing at terminal differentiation.[437] In contrast, aromatase expression in Leydig cells increases as they mature, and Leydig cells are thought to be the major site of estrogen biosynthesis in the adult testis (reviewed in Ref. 438). However, aromatase is also produced by germ cells in the postnatal testis,[439] from the pachytene spermatocyte stage onward, making germ cells an important site of estrogen biosynthesis (for reviews, see Refs 431,433) that is responsible for a significant proportion of total testicular estrogen biosynthesis.[440]

Control of Aromatase Expression

The nuclear receptors NR5A1 and NR5A2 (LRH1) bind to recognition sites within the promoter region of the Cyp19 gene to drive tissue-specific expression of several aromatase transcripts, each with a unique 5′UTR but with a conserved open reading frame.[441,442] Mutation in Cyp19 is associated with male fertility disorders in humans.[434] In mice, ablation of aromatase (ArKO) results in progressive testicular degeneration.[443–445] Testicular anatomy and function are indistinguishable from those of littermate controls up to 4.5 months of age, suggesting that estrogens are dispensable for testis development and initiation of spermatogenesis.[445] Between 4.5 months and 1 year of age, however, a noticeable degeneration in seminiferous tubule integrity is apparent; it is associated with loss of postmeiotic germ cells, suggesting that chronic estrogen suppression perturbs spermatogenesis. Indeed, treatment with phytoestrogens is able to partially rescue the impacts on spermatogenesis.[443] ArKO mice sire fewer litters than control animals, although this could in part result from behavioral problems, as ArKO mice show reduced copulatory mounting behavior.[444] It is important to note one caveat to the information that the ArKO model provides in terms of understanding testicular estrogen signaling. ArKO mice not only have an absence of estrogens but also, because of the failure of aromatase action, have increased concentrations of testosterone within the testis. It is not known whether chronic overabundance of testosterone plays any part in the late-onset phenotype observed in these mice.

Transgenic mice overexpressing aromatase have also been generated.[446,447] These animals have increased circulating estradiol, combined with significantly reduced testosterone and FSH levels, and increased prolactin and corticosterone.[447] These animals display a variety of reproductive phenotypes from early postnatal life, including cryptorchidism, Leydig cell hyperplasia, dysmorphic seminiferous tubules, and disrupted spermatogenesis. However, because some phenotypes resemble those observed in models of exogenous estrogen exposure in perinatal life, it is challenging to dissect the relative impacts of the changes in the hormonal milieu as many of the phenotypes share similarities with models of hypoandrogenism (e.g., cryptorchidism and vestigial seminal vesicles). Chronic overexpression of aromatase in these mice is associated with continued Leydig cell hypertrophy and hyperplasia and the development of nonmalignant Leydig cell adenomas.[446] Furthermore, at 15 months of age, a marked increase in the numbers of activated macrophages was observed, which is associated with Leydig cell depletion and suggests activation of an inflammatory process not unlike orchitis, which is associated with cases of infertility in men.[446]

An important model that may resolve some of these confounding factors is the estrogen sulfotransferase (EST) knockout animal, which fails to deactivate estrogens via sulfation, resulting in increased local concentrations of bioactive estrogens without the confounding factor of reduced androgens.[448] EST is expressed abundantly in the testis of mouse, rat, and human, and has been localized to the Leydig cells in mouse,[449] where its expression is regulated by cAMP and androgens.[450] EST-KO mice exhibit a similar testicular phenotype of late-onset seminiferous tubule atrophy (associated with Leydig cell hypertrophy and hyperplasia and macrophage activation) to that observed in the aromatase-overexpressing mouse testis,[446,448] supporting the notion that the phenotype observed in the aromatase-overexpressing mouse is the direct result of increased local estrogen signaling. Together, these data suggest that either a reduction or increase in estrogens within the testis perturbs normal testicular function.

Estrogen Action

In postnatal life, both ER-α and ER-β are expressed within the testis. In the rodent, ER-α expression is restricted to the Leydig cell lineage,[451] whereas ER-β has a wider spatial expression[452] and is localized to cell nuclei of germ cells (spermatogonia, spermatocytes, and spermatids), PTM, Sertoli cells, and Leydig cells from early postnatal life.[453–455]

Whereas ERβKO males show no overt morphological differences from wild-type littermates and are fully fertile,[456] the testes in ER-αKO males develop normally but begin to degenerate from 20 to 40 days, and by day 150 the testicular seminiferous tubules are atrophic.[457,458] This testicular phenotype of the ER-αKO is complicated by the ablation of ER-α in the efferent ducts, loss of which leads to reduced fluid resorption within the efferent ducts[459] and fluid back-pressure into the testis, which may in part account for the testicular phenotype. This conclusion is supported by characterization of ENERKI mice,[460] which retain the ligand-independent activity of ER-α but lack classical estrogen-dependent signaling capability. These mice fail to develop the efferent duct phenotype seen in the ER-αKO mice, confirming that the efferent duct phenotype found in the ER-αKO mice is an estrogen-independent activity of ER-α.[460] However, the critical role of ER-α in the efferent ducts does not completely explain the observed testicular phenotype. Despite lacking the efferent duct defect, ENERKI mice also show similar late-onset testicular degeneration as the ER-αKO mice, with focal areas of seminiferous tubule atrophy apparent by 20 weeks of age (~day 150) and increasing in frequency over time.[460] This confirms a role for estrogen–ER-α signaling in control of testis function, although the global nature of these models

does not preclude an extratesticular site of action of estrogens, with concomitant knock-on effects occurring locally within the testis. Both the ER-αKO and ENERKI mice exhibit impacts on the HPG axis, which are proposed to result from a lack of negative feedback at ERs in the brain; a knock-on effect of this includes significant increases in circulating testosterone.[457,460] It therefore remains feasible that a proportion of the phenotype observed in the testes of these animals arises from perturbation of downstream factors.

However, a direct effect of ER-α in the testis has been recently elucidated. Mice carrying floxed alleles of ER-α have been described,[461] and conditional ablation of ER-α from Leydig (and a proportion of adrenocortical) cells has been carried out.[462] Loss of ER-α from Leydig cells enhances testosterone production.[463] Conversely, ER-α overexpression suppresses the cAMP-induced and Nur77-activated promoter activity of steroidogenic enzyme genes via the suppression of transactivation by Nur77.[463] Thus, estrogen signaling within Leydig cells appears to function as a modulator of androgen production.

Nongenomic Effects of Estrogens

In addition to acting directly on the DNA transcriptome, estrogens are able to mediate a rapid nongenomic effect on cells. The mechanism for this, however, remains contentious. Identification of a novel, widely expressed GPCR (GPR30; G protein–coupled estrogen receptor 1 (GPER)), with an apparent high affinity for estrogens,[464,465] provided new hope for understanding rapid estrogen signaling. Proving that GPR30 is responsible for nongenomic actions of estrogens, however, has proven problematic (for reviews, see Refs 431,466–468). Based upon the method employed, GPR30 has been localized to either the endoplasmic reticulum[465,469] or the plasma membrane[470,471] (reviewed in Ref. 468); GPR30 fails to bind radiolabeled E2, and E2 does not stimulate cAMP or calcium release.[472] Several mouse models with ablation of GPR30 have been generated,[473–476] but none displays (female) phenotypes similar to those of either the ER-αKO or aromatase knockout mice. Double and/or triple knockouts in combination with ER-α and/or ER-β have not been described; thus, the possibility of functional redundancy remains.

GPR30 has been shown to work with ER-α via EGFR–ERK–fos signaling to mediate estrogen-dependent proliferation of a spermatogonial cell line in vitro.[477] In the rat testis, GPR30 has been localized to pachytene spermatocytes and to spermatids, and has been demonstrated to work alongside ER-α to activate the EGFP–ERK–c-jun signaling cascade, triggering an apoptotic mitochondrial pathway with increased Bax and reduced cyclin A1 and B1, which are involved in the balance between cellular proliferation and apoptosis.[478,479] However, the role of GPR30 as an estrogen receptor remains far from proven[466]; the most recent data suggest that GPR30 in fact has a role as a collaborative partner to nuclear estrogen receptors, rather than acting as an estrogen receptor in its own right (reviewed in Ref. 467). Further investigations to fully elucidate the role of GPR30 both in general and specifically within the testis are clearly warranted.

To further assess the role of nongenomic estrogen signaling, a mouse model was recently created that expresses the E domain of ER-α at the plasma membrane in the absence of ER-α (membrane-only estrogen receptor (MOER)).[480] Liver cells from these animals retained the ERK and phosphatidylinositol response to 17-β-estradiol stimulation, which is lost in ERαKO mice, providing initial evidence of a wider influence of estrogens on cells via modulation of the Gq, PKC, and calcium-signaling pathways (reviewed in Ref. 481).

ACTIVIN AND INHIBIN

Components of the Inhibin–Activin Signaling System

The actions of testosterone and FSH to regulate spermatogenesis are mediated, in part, by members of the TGF-β peptide family. These family members include bone morphogenic proteins (BMPs), AMH, the growth and differentiation factors (GDFs), activin, inhibin, and the more distantly related glial cell line–derived neurotrophic factor (GDNF) (reviewed in Ref. 482). The important paracrine actions of TGF-β peptide family members in the fetal and neonate testis are well characterized (reviewed in Ref. 483). This section will focus on the inhibin and activin regulation of Sertoli cell proliferation and maturation as well as germ cell development in the testis because these factors are the major paracrine-acting members of the TGF-β peptide family in the pubertal and adult testis.

Inhibin proteins consist of a dimer of the α inhibin subunit with one of either activin β_A or β_B subunits forming inhibin A or inhibin B, respectively. Activins are composed of dimers of β_A or β_B subunits termed activin A ($\beta_A\beta_A$), activin AB ($\beta_A\beta_B$), or activin B ($\beta_B\beta_B$). Most of the cellular expression data for inhibin, activin, and their receptors has been collected from rodents. However, the available information indicates that the expression patterns for activins and their receptors in humans are similar to those described for rodents (reviewed in Ref. 484).

The principle site of inhibin B production is the Sertoli cell,[485–487] although there is evidence that Leydig cells can produce inhibin.[488,489] Activin A is produced by Sertoli cells, Leydig cells, and PTM.[301–304] Immunoreactivity for activin B has been identified in germ cells, including spermatogonia, spermatocytes, and round spermatids,

as well as Sertoli cells and Leydig cells.[319,490–492] However, it has not yet been demonstrated that germ cells are a physiologically relevant source of activins in the testis. Activin B appears to be a weaker agonist, which has been attributed to its lower affinity for the activin receptor complex.[493] There is little information available regarding the expression and function of activin AB.

Activins and other TGF-β peptide family members act through a receptor complex of type I and type II receptors. Activins can bind to two activin type II receptors (ActRIIA and ActRIIB) and three type I activin-like kinase (ALK) receptors: ALK2, ALK4 (by activin A), or ALK7 (by activin B).[494–496] The mRNAs encoding receptors for activin are present in Sertoli cells, spermatocytes, and round spermatids.[497,498] Type I and the type II ActIIB receptors are expressed in germ cells and in Sertoli cells.[498–500]

Activin binds first to an activin type II receptor that recruits a type I receptor. The type II receptor then phosphorylates and activates the type I receptor.[494] Activin-mediated activation of type I receptor kinase activity facilitates the recruitment and phosphorylation of the downstream signaling proteins, SMAD2 and/or SMAD3. The phosphorylated SMADs bind to SMAD4 to produce a complex that translocates to the nucleus, binds to specific promoters, associates with transcriptional co-regulators, and alters gene transcription (reviewed in Ref. 310). The relative levels of SMAD2 and SMAD3 as well as inhibitory SMADs such as SMAD6 and SMAD7 provide fine-tuning of transcriptional responses in response to activin stimulation.

A specific receptor for inhibin has yet to be identified. Inhibin can interact with activin receptors with the assistance of a third receptor subunit called TGF-β receptor III or betaglycan.[501] At the pituitary level, the betaglycan-enhanced binding of inhibin to type II activin receptors blocks activin binding and prevents dimerization with type I receptors.[502] However, similar inhibitory effects of inhibin in the testis are less well characterized.

Inhibin and Activin Functional Studies

Inhibin and activin have opposing actions on spermatogenesis. Injection of partially purified inhibin into the testis of Chinese hamsters decreased the numbers of differentiated spermatogonia in an FSH-independent manner.[503] In contrast, treatment of co-cultures of rat spermatogonia and Sertoli cells with activin A or activin B stimulated the proliferation of spermatogonia.[504] Activin A also stimulated DNA synthesis in spermatogonia and leptotene spermatocytes in cultured seminiferous tubule fragments from adult rats,[505] but inhibited the survival of SSCs cultured from adult mouse testes.[506] The "condensed-type" mitochondria of rat pachytene spermatocytes was maintained in culture by activin A, suggesting the ability to regulate meiotic development.[507]

Activin can independently increase Sertoli cell proliferation in the rat during the developmental window of 5–13 days after birth.[282,309,404] Activin acts directly on day 6–11 Sertoli cells to induce proliferation, but younger cells are unresponsive, although they respond to FSH.[282,404] Activin and FSH can act synergistically during the later stages of Sertoli cell development to increase proliferation.[282,308,309] The developmental stage specificity of activin signaling on Sertoli cell proliferation has been attributed to the upregulation of the ActIIB mRNA between 7 and 11 days after birth.[309] Furthermore, knockout of inhibin results in uncontrolled proliferation of Sertoli cells,[508] and the elevation of activin levels in vivo reinitiates Sertoli cell proliferation and dedifferentiation in adult mice.[509]

Developmentally regulated responses of Sertoli cells to activin also correspond to a change in activin signaling from the utilization of only SMAD3 by immature, proliferating Sertoli cells to the use of both SMAD2 and SMAD3 in maturing Sertoli cells.[510,511] Although not essential for fertility because *Smad3* null mice are fertile,[512] SMAD3 is likely a key mediator of activin-induced proliferation of Sertoli cells, and downregulation of SMAD3-mediated signaling is associated with transition to the terminal differentiation of Sertoli cells. Supporting this idea is the finding that removal of one or both copies of *Smad3* from mice lacking inhibin resulted in normal, terminally differentiated Sertoli cells and did not allow the formation of Sertoli cell tumors that occur due to elevated activin signaling.[513] Other consequences of activin A stimulation of cultured Sertoli cells include inhibition of androgen binding, decreased basal and FSH-induced AR mRNA expression, as well as FSH-mediated aromatase activity, but activin A did not alter FSH receptor expression.[302]

Inhibin and Activin Transgenic Mouse Models

Mice lacking the inhibin α-subunit due to deletion of the *Inha* gene (and therefore of inhibin production) develop Sertoli cell tumors because the loss of the activin signaling inhibitor results in unrestrained proliferation and failure to mature. These mice die from cachexia, a wasting syndrome.[508] Unfortunately, except for the finding that inhibin acts as a tumor suppressor, little information about the normal function of inhibin in the testis has been obtained from this model because of the disruption of the testis architecture by the tumors.

Deletion of the *Inhba* gene encoding the βA-subunit results in perinatal death and thus does not provide any information regarding the function of activin A in the testis.[514] Studies of mice lacking the *Inhbb* gene indicate that Inhibin B is not essential for spermatogenesis because these mice survive to adulthood, are fertile, and have a normal testis phenotype.[515] Knockout of the ActIIA

receptor that compromised activin and BMP signaling reduced testis size and delayed fertility onset. However, FSH levels were reduced in this model animal, causing assignment of activin functions to be more complex.[516]

To better understand the function of activin, the *Inhba* gene encoding the βA-subunit was replaced with *Inhbb* encoding the βB-subunit so that activin A was not expressed and only the less potent activin B could be produced. The mouse model, called BK mice, had lower testis weights and volumes as well as delayed onset of fertility, indicating that activin contributes to establishing spermatogenesis in the mouse. Sertoli cell numbers 7 days after birth were also lower, consistent with the known actions of activin in promoting Sertoli cell proliferation.[517] Studies of the BK mice also revealed that activin inhibits expression of the differentiation marker KIT by spermatogonia and the differentiation of spermatogonia.[518]

Further evidence for activin regulation of spermatogenesis was provided by transgenic mice overexpressing the human activin βA-subunit. In these mice, ectopic expression of the βA-subunit was observed in pachytene spermatocytes and round spermatids after 3 weeks of age. The mice were initially fertile but became sterile by 10 weeks due to the vacuolation of the testis as the number of spermatocytes and maturing spermatids were reduced, and no mature sperm could be produced.[519] Overexpression of the repressive activin-binding protein follistatin in mice caused a significant decline in testis weight even in transgenic lines with normal serum FSH.[520] Together, the transgenic models assessed thus far indicate that activin is not essential for fertility, but the hormone contributes to the processes of Sertoli cell proliferation and spermatogonia differentiation.

Regulation of Inhibin and Activin Activities

The production of inhibin and activin is regulated in reciprocal manners in Sertoli cells by FSH and cytokines. Expression of α-subunit mRNA in Sertoli cells is stimulated by FSH through cAMP and PKA.[521–523] FSH–cAMP–PKA also stimulate expression of the βB-subunit in Sertoli cells to a lesser extent.[524,525] The sum of FSH action on Sertoli cells is to increase inhibin B production. Sertoli cells also produce the βA-subunit that is not regulated by FSH.[302,526,527] In contrast, stimulation of Sertoli cells with the cytokines interleukin 1 (IL1) or tumor necrosis factor alpha (TNF-α) that are produced by Sertoli cells, germ cells, and macrophages[172] or via activation of Toll-like receptors (TLRs) inhibits the expression of the α-subunit and the βB-subunit, thus suppressing inhibin B production.[526–529]

βA-subunit expression and activin A secretion in rat Sertoli cells are potently stimulated via stress and inflammation signaling pathways through the TLRs and IL1 receptors that mediate the pro-inflammatory actions of IL1 and pathogenic molecules, including LPS and bacterial lipoproteins.[526,527,530,531] The TLRs and IL1 receptors interact with the adaptor protein MyD88 that activates a signaling pathway leading to TRAF6 and the activation of the MAPKs p38 and JNK as well as the transcription factors NF-κB and AP1.[532] TNF-α also activates activin A production using similar downstream signaling factors.[529,533] Together, these findings indicate that cytokines and proinflammatory signals decrease inhibin production but induce activin secretion. In contrast, FSH stimulates the production of inhibin B while inhibiting activin A.

As would be predicted from the FSH regulation of the α- and β- subunits of inhibin, the production of the peptides closely follows the cyclical changes in FSH receptor levels and FSH signaling within the seminiferous epithelium. Inhibin B and its subunits are constantly produced during the cycle, but expression is significantly reduced during stages VII–VIII, when FSH signaling is lowest.[492,534] Activin A and β_A subunit expression is low throughout most of the cycle but increases dramatically after stage VIII and reaches a maximum at stages IX–XI. Maximal β_B subunit mRNA levels are observed during stage XIII.[498,525] Further stimulation of activin subunit production may occur due to the production of inflammatory cytokines (IL1α and IL6) by Sertoli cells in response to the shedding of residual bodies of cytoplasm by maturing spermatozoa during the process of spermiation in stage VIII (reviewed in Ref. 535).

Activin-Regulated Gene Expression in Sertoli Cells

Gene expression analysis of activin-stimulated Sertoli cells cultured from 6- to 15-day-old mice revealed alterations in the expression of genes related to a diverse range of biological processes, including DNA and chromatin modification, the ubiquitin cycle, protein transport, RNA processing, and ion transport. Similar genes were found to be regulated in more focused studies of juvenile mice with excessive activin signaling and reduced activin bioactivity.[510]

Transduction of adult mouse muscle tissue with a virus expressing activin A increased serum levels of activin A by fourfold and reduced testis mass by 23%. The hypospermatogenic phenotype observed with this model is consistent with the failure of Sertoli cells to support spermatogenesis. Closer inspection revealed that the elevated activin levels potently disrupted tight junction formation and BTB integrity. The disruption of barrier formation may be the result of activin-mediated dedifferentiation of Sertoli cells that were found to display evidence of proliferation, expression of juvenile markers, and loss of mature markers. Microarray

analysis of Sertoli cells isolated from this model of elevated serum activin revealed that 425 genes were regulated by activin, including groups of genes associated with anchoring junctions, cell adhesion, regulation of cell division, as well as tissue morphogenesis metabolism and morphology. These results indicate that activin signaling must be strictly regulated to maintain mature Sertoli cell function.[509] The findings further support the idea that the decrease in activin levels observed during puberty contributes to the halting of Sertoli cell proliferation.[319]

OTHER HORMONES

Osteocalcin

Sex steroids have been known for many years to modulate skeletal development and integrity (reviewed in Ref. 536). However, until recently, a reciprocal mechanism whereby the skeleton influences sex steroid production remained elusive. Osteocalcin has recently been identified as a bone-derived hormone with significant functional impacts on sex steroid production by the testis, completing the circle of mutual interdependence between the skeletal system and gonad (for reviews, see Refs 536–538).

A suggestion of skeletal impact on the testis via osteocalcin was first identified in a mouse model with osteocalcin ablation.[539] Osteocalcin−/− mice show a severe decrease in testis and epididymal weights, and reduced sperm counts associated with a reduction in circulating testosterone (and increased circulating estrogens, possibly due to increased adiposity).[86]

The first direct evidence for a direct gonadal role of osteocalcin was derived from ex vivo cell assays in which a factor secreted by osteoblasts, but not other cells of mesoderm origin, was found to significantly increase testosterone production *by* Leydig cells and testis explants.[86] These observations were independently verified in vivo in a mouse model lacking osteoblasts, which displayed reduced circulating testosterone concentrations.[540] Osteocalcin was identified as the essential hormonal factor through additional culture models in which use of osteocalcin−/− osteoblasts resulted in a significant reduction of testosterone biosynthesis compared to control osteoblasts, which could be rescued by the addition of exogenous active osteocalcin,[86] an observation replicated in vivo in mice lacking either osteoblasts[540] or osteocalcin.[86] Furthermore, circulating testosterone concentrations were increased above controls in a transgenic mouse model (Esp−/−) where deactivation of osteocalcin is reduced. Esp or protein tyrosine phosphatase receptor type V normally functions to deactivate osteocalcin.

The cognate receptor for osteocalcin has been identified as the G protein–coupled receptor GPRC6A,[86] which is expressed on the surface of Leydig cells. GPRC6A−/− mice phenocopy osteocalcin−/− mice.[86,541] Osteocalcin is able to bind to the surface of Leydig cells (producing an intracellular increase in cAMP), but not to Leydig cells from GPRC6A−/− mice (associated with no increase in cAMP levels).[86] Interestingly, GPRC6A is not expressed in ovarian cells, which may explain the male-specific impacts on sex steroid production.

Upon binding to GPRC6A, osteocalcin causes an increase in intracellular cAMP, which promotes CREB phosphorylation and binding to promoter regions of the genes encoding the steroid biosynthesis enzymes StAR, Cyp11, 3β-HSD, and Cyp17 to drive transcription of these genes.[86]

Together, these combined data demonstrate that osteocalcin may be an important hormonal regulator of testosterone biosynthesis. Importantly, circulating LH was increased in osteocalcin−/− mice (which continue to have low circulating testosterone), suggesting that LH signaling is not sufficient to rescue inhibition of osteocalcin-directed testosterone biosynthesis, and thus that each of these two pathways acts at least somewhat independently. Further investigation of the clinical importance of osteocalcin for male reproductive health and fertility is an essential future requirement.

Insulin–IGF–Insl3 Signaling

Insulin is a member of the wider insulin–IGF–relaxin superfamily. Members share structural features, although sequence variability among family members is high. Insulin, IGF1, IGF2, and Insl3 are the key members associated with testis development and function. The impact of insulin–IGF–relaxin signaling on the testis has been established over a number of years, and forms a key part of the hypogonadism–adiposity–insulin resistance feedback system associated with certain aspects of metabolic syndrome (reviewed in Ref. 542).

IGF Signaling in the Testis

The IGF studied in most detail in the testis is IGF1 (also called somatomedin C) (reviewed in Ref. 543). Growth hormone (GH) is the main driver of IGF1 production throughout the body, with IGF1 mediating many of the trophic actions of GH. Indeed, IGF1 signaling is absolutely required for sexual development and attainment of reproductive competence, but absence of GH signaling generally does not preclude male (or female) fertility (reviewed in Ref. 544). IGF1 not only arrives at the testis from the systemic circulation but also is produced locally in the testis by both Sertoli and Leydig cells,[545,546] under

the control of gonadotropins as the testicular secretion of IGF1 increases following LH and FSH treatment.[547,548]

In postnatal life, IGF1R is localized to Leydig, Sertoli, PTM, and germ cells of the testis.[306,549] IGF1 signaling promotes postnatal Leydig cell development by functioning as an inhibitor of Leydig cell apoptosis. Phosphorylated IGF1R increases from birth to day 20 of postnatal life, remaining high in the adult testis. IGF1 decreases the level of apoptosis in Leydig cells at all stages of development. In contrast, the selective inhibitor of IGF1R, picropodophyllin, blocks this antiapoptotic effect in the presence and absence of IGF1, demonstrating that signaling via the IGF1R plays an important role in Leydig cell survival.[550] Consistent with this observation is that mice with null mutations in IGF1 display reduced numbers of adult Leydig cells,[551] which is associated with perturbed proliferation of progenitor and immature Leydig cells,[552] whereas excess secretion of IGF1 driven by increased endogenous GH in transgenic mice expressing human growth hormone–releasing hormone (GHRH)[553] significantly increases testis weight and testosterone production.[543] The mechanism underlying the antiapoptotic action of IGF1 involves the phosphatidylinositol 3-kinase–Akt pathway, and in immature Leydig cells, this growth factor enhances the expression of Bcl2 and cellular inhibitor of apoptosis proteins 2, while preventing activation of caspase-3 by cleavage.[550] Furthermore, investigations using IGF1 replacement and gonadotropin stimulation in IGF1 null mice suggest that the trophic role of LH on Leydig cell proliferation is in part mediated by IGF1 signaling.[551] Inactivation of IGF1 receptor in primary Sertoli cells leads to reduced Sertoli cell numbers, through both a reduction in proliferation and an increase in apoptosis, suggesting a similar trophic role for IGF1 receptor signaling in Sertoli cells.[306]

IGF1 signaling not only is important for Leydig cell development but also plays an autocrine role in the control of adult Leydig cell function.[554] IGF1 null mice initially increase androgen production compared to littermate controls between d4 and d12. However, the IGF1 null mice then fail to further increase androgen production, and they produce 30% of normal circulating androgens in adulthood.[555] IGF1 null mice display reduced Leydig cell expression of P450 SCC, P450c17, RLF–Insl3, 17β-HSDIII, 3β-HSD IV, and StAR at both days 35 and 50 (adult).[555] Whether these changes in gene expression result from developmental perturbation or indeed do represent the adult function of IGF1 remains an open question, and whereas IGF1 replacement in IGF1 null mice promotes Leydig cell proliferation, IGF1 treatment is unable to restore normal circulating testosterone concentrations.[551] These results suggest that the developmental role of IGF1 has knock-on effects on later testicular steroidogenesis. However, IGF1 does play a role in testicular steroidogenesis in adult Leydig cells. Studies suggest that IGF1 enhances LH-mediated stimulation of steroidogenesis in adult Leydig cells.[551,556] IGF1 has been shown to increase LHCGR density and promote P-450scc and 17 alpha-hydrolyase expression in cell culture.[557] In addition, in adult Leydig cell culture, regulation of StAR by IGF1 has been demonstrated to be mediated by the PKC pathway involving phosphorylation of both CREB and c-Jun.[558] In summary, IGF1 produced both locally and systemically is an essential factor in Leydig cell development and function, not only promoting Leydig cell proliferation but also supporting Leydig cell function in adulthood.

IGF2 is also known to also regulate cell proliferation, growth, migration, differentiation, and survival, mainly during embryogenesis (reviewed in Ref. 559). Data suggesting a role for IGF2 in postnatal testis development and function are limited, although IGF2 has been associated with early postnatal growth of the testis in humans.[560]

The physiological effects of IGFs are profoundly affected by six IGF-binding proteins (IGFBPs) that affect IGF signaling in a dose-dependent manner. In the testis, IGFBPs are produced by Leydig, Sertoli, and PTM cells, and of the six IGFBP proteins, only IGFBP1 is not produced within the testis (reviewed in Ref. 543). Establishment of the physiological impacts of IGFBPs in the testis is an ongoing process, although their role as a key modulator of testis function was established some time ago (reviewed in Ref. 561). IGFBP3 and IGFBP4 have been shown to impact Leydig cell function by inhibiting IGF1-induced androgen production,[562] whereas overexpression of IGFBP1 and IGFBP6 impacts testosterone secretion and spermatogenesis in vivo,[563,564] although this is likely to be due to modulation of the HPG axis at a central level.

Insulin

Along with IGF1, IGF2 and high concentrations of insulin also evoke phosphorylation of IGF1R and, like IGF1, enhance the expression of StaR by Leydig cells.[550] Transgenic overexpression of insulin in Leydig cells, driven by the Insl3 promoter, has minimal impact on the testis until 8 months of age, when a significant proportion of tubules in 8-month-old and a large majority of tubules in 12-month-old transgenic mice show impairment of spermatogenesis, with the formation of vacuoles, the release of premature germ cells, and focal as well as full degeneration of germ cells.[565] However, under normal physiological conditions or diabetic pathologies, the major site of action of insulin impacting testicular function appears to be at the level of the brain, through influencing pituitary LH secretion.[566]

Insl3

Insl3 is a member of the relaxin family of protein hormones. Several members of this family are associated with the testis (reviewed in Ref. 567) and are produced exclusively by both fetal and adult Leydig cells. Expression begins at the latter stages of Leydig cell development, and thus Insl3 has long been used as a biomarker of Leydig cell maturation.[568,569] Insl3 binds its cognate receptor, the GPCR LGR8–RXFP2[570] (reviewed in Ref. 571). LGR8–RXFP2 is expressed in the gubernaculum during fetal life, and loss of function of either Insl3 or LGR8–RXFP2 results in failure of gubernacular development and arrested testis descent.[572] In the postnatal testis, LGR8–RXFP2 is expressed in meiotic and particularly postmeiotic germ cells and in Leydig cells, although not in Sertoli or PTM cells,[573] suggesting that Insl3 signaling plays an important role in germ cell maturation. However, recent investigations of Insl3 signaling in the adult testis have revealed that specific ablation of LGR8–RXFP2 in male germ cells does not affect spermatogenesis, or fertility in adult males,[574] suggesting either that Insl3 plays a minimal role in spermatogenesis or that functional redundancy exists and the role of Insl3 can be compensated for by another, unknown factor.

Glucocorticoid Signaling

Glucocorticoids secreted by the adrenal in response to adrenocorticotrophic hormone (ACTH) can influence fertility at three levels: (1) in the hypothalamus, to suppress release of GnRH; (2) in the pituitary, to perturb LH and FSH secretion; and (3) within the testis, to influence steroidogenesis and spermatogenesis directly (reviewed in Ref. 575). The role of glucocorticoids in control of the reproductive axis has long been associated with reallocation of resources during the stress response; the concept is that direct suppression of the HPG axis gives a higher priority to an individual's survival than to their need to reproduce. Evidence in support of this concept is widespread. Men with Cushing's syndrome (chronic hypercortisolemia) present with low plasma testosterone.[576] A similar reciprocal relationship between increased glucocorticoids and reduced plasma testosterone is observed during anesthesia, surgery, anticipation of battle, or physical training[577,578] (reviewed in Ref. 575). Several cells of the testis express glucocorticoid receptor (GR), a member of the steroid receptor transcription factor superfamily (reviewed in Ref. 579), and as such are responsive to glucocorticoids. These include Leydig cells, macrophages, vascular endothelial cells, and PTM cells. Furthermore, GR is strongly expressed in spermatogonia and primary spermatocytes, suggesting a direct influence on spermatogenesis, but GR is not expressed in Sertoli cells or in more mature germ cells.[580]

In the postnatal testis, glucocorticoids function to directly inhibit transcription of the steroidogenic enzymes, P450SCC, StAR, and Cyp17.[581–583] Whereas ligand-bound GR functions primarily as a transcription factor, promoting or repressing expression of downstream targets by binding to glucocorticoid response elements (GREs) in the promoter region, the evidence for a mechanism of suppression of steroidogenesis by glucocorticoids invokes several nongenomic mechanisms. For example, ligand-bound GR has been shown to bind to and inactivate NR4a1 (Nur77), thus antagonizing a cAMP-mediated activation pathway leading to suppression of transcription of StAR.[584] A similar impact is seen on progenitor Leydig cells, where glucocorticoids inhibit production of androsterone, which suggests that Leydig cells are sensitive to glucocorticoid-mediated perturbation throughout postnatal development and not just in adulthood.[585]

A further mechanism underpinning glucocorticoid control of steroidogenesis is the finding that intracellular concentrations of glucocorticoids themselves may be controlled within Leydig cells. The two enzymes 11β-HSD1 and 11β-HSD2 act as either oxidoreductase or oxidative enzymes, respectively, to interconvert between corticosterone (in the rat; cortisol in humans) and its biologically inert derivative, 11-dehydrocorticosterone (11-DHC)[586,587] (cortisone in humans). 11β-HSD1 requires NADPH for reductase activity, which catalyzes the conversion of 11DHC to corticosterone, and NADP+ for oxidase activity that catalyzes the conversion of corticosterone to 11DHC. Meanwhile, 11β-HSD2 exploits a distinct cofactor NAD+ to catalyze its oxidase activity. Thus, variation of activity of these enzymes permits modulation of the concentration of glucocorticoids available to bind GR. This fast-acting mechanism works within Leydig cells in a cooperative cycle. 17β-HSD3 is able to couple with 11β-HSD1 and drive 11β-HSD1 oxidase activity, thus reducing the adverse effects of corticosterone on testosterone production. At the same time, 11β-HSD1 generates NADPH that promotes testosterone biosynthesis by stimulating 17β-HSD3, a situation that can perpetuate as long as androstenedione is available as a substrate. As availability of the substrate drops, the reductase activity of 11β-HSD1 increases, suppressing further testosterone production (reviewed in Ref. 588). The role of 11β-HSD2 is less well established, although it is believed to play a semiredundant role in supporting the oxidation of corticosterone to 11DHC, as a drop in 11β-HSD2 during aging is thought to expose Leydig cells to increased glucocorticoid-mediated suppression of steroidogenesis, which may prove an important factor in age-related reduction in testosterone production by the testis.[589]

Further to their role in suppression of testosterone production, chronic exposure to glucocorticoids can induce Leydig cell apoptosis[590] (reviewed in Ref. 591)

via a mechanism that includes activation of the Fas system, cleavage of procaspase-3, loss of mitochondrial membrane potential, and increased ROS generation.[592] Adenovirus microRNA-induced downregulation of GR expression in vitro alleviates the glucocorticoid-induced increase in apoptosis of Leydig cells, demonstrating the involvement of GR in this process.[593]

Glucocorticoid action also induces apoptosis of spermatogonia.[594] Although the mechanism for this remains unknown, germ cell apoptosis is associated with the induction of proapoptotic proteins such as Bax, an effect that can be blocked by inhibition of GR.[595] Whereas expression of GR within spermatogonia and primary spermatocytes suggests that germ cells are direct targets of glucocorticoids,[580,594] apoptosis of germ cells could simply be the result of suppressing testosterone production by the Leydig cells (a well-established mechanism for induction of germ cell apoptosis), as germ cells are most sensitive to dexamethasone-induced apoptosis in stages VII–VIII of the spermatogenic cycle, stages that are also consistent with androgen-dependent viability (reviewed in Ref. 575).

Mineralocorticoids

Very little is known regarding the role of mineralocorticoid signaling in the testis. The mineralocorticoid receptor (another member of the ligand-activated transcription factor superfamily) has been identified in Leydig cells, and aldosterone acting via MR has been shown to enhance LH-driven steroidogenesis via a synergistic pathway.[596] Further investigation of mineralocorticoid signaling is clearly warranted.

Leptin Signaling

The polypeptide hormone leptin is transcribed from the leptin (OB) locus produced primarily by adipocytes and acts in the brain to control key parameters such as regulation of body weight, food ingestion, body temperature, and metabolic rate associated with metabolism (reviewed in Ref. 597).

Leptin deficiency is also associated with male infertility in both humans and animals (reviewed in Refs 598,599). Leptin-deficient male mice are also sterile, and this is associated with impaired spermatogenesis, increased germ cell apoptosis, and upregulated expression of proapoptotic genes within the testes.[600] However, fertility can be restored by administration of exogenous leptin, suggesting that leptin provides functional support to spermatogenesis throughout life.[601,602]

Leptin acts at all levels of the HPG axis, and although leptin control of fertility is believed to be primarily mediated at the hypothalamic–pituitary level, leptin is also able to act directly within the testis (reviewed in Ref. 603). The testis produces endogenous leptin and expresses several isoforms of the leptin receptor (Ob-R). In 5-day-old mice, leptin is produced primarily in gonocytes and confined to spermatogonia at day 10. From day 20 onward, stage-specific expression of leptin is restricted to stages VII–XII of the cycle.[604] In situ hybridization analysis shows a scattered pattern of cellular expression of the Ob-R gene within the adult rat testis, including Leydig and Sertoli cells. In addition, assessment of the pattern of expression of Ob-R subtypes revealed that the long Ob-Rb isoform was abundantly expressed in adult rat testis. However, variable levels of expression of Ob-Ra, Ob-Re, and Ob-Rf mRNAs also were detected, whereas those of the Ob-Rc variant were nearly negligible[605] (reviewed in Ref. 604).

Leydig cells appear to be the key cell types responsive to leptin signaling (reviewed in Ref. 604). During postnatal development, prepubertal Leydig cells express the Ob-Rb form of leptin receptor and are thus a direct target of this hormone. Treatment with leptin in cell culture conditions reduces Leydig cell proliferation and induces premature expression of differentiation markers, suggesting that leptin may function to control final numbers of Leydig cells.[606] In cultured testis sections from adult rat, leptin decreased the hCG-stimulated mRNA expression levels of SF-1, StAR, and P450scc enzyme in a dose-dependent manner, but failed to alter those of 17β-HSD type III, suggesting that decreased expression of several upstream elements in the steroidogenic pathway may contribute to leptin-induced inhibition of testicular steroidogenesis.[605] Leptin's control of testosterone production is mirrored by testosterone-mediated suppression of leptin production by adipose tissue, which results in reduced LH secretion by the pituitary and reduced testosterone production by the testis.[607] Thus, leptin is able to modulate the testosterone-driven negative-feedback loop, acting via the HPG axis (reviewed in Refs 603,608). Evidence is emerging that other metabolic hormones such as adiponectin[609] and ghrelin[610–613] may play similar roles in testis function, strengthening the links between control of metabolic parameters and testicular function.

Prolactin

A further hormone that influences testis function is prolactin. Prolactin is produced in the anterior pituitary and, within the testis, by Leydig cells and germ cells.[614] Prolactin signals via the prolactin receptor, expression of which is controlled by NR5A1 in Leydig cells.[615] Prolactin functions in support of LH-driven testosterone production, both at the level of the pituitary and in the Leydig cells themselves, where it increases the activity of 3β-HSD (in rats) and 17β-HSD (in mice).[616–618] Administration of prolactin increases Leydig cell number[619] and circulating testosterone levels,[620] suggesting that

prolactin has a trophic role in testosterone production. However, despite prolactin receptors being found in Leydig cells,[621] where they appear to function to support expression of LHCGR,[622] a complete knockout of prolactin receptor in mouse has no observable testicular phenotype,[623] suggesting that while prolactin signaling supports testosterone production, it is not an essential requirement.

CONCLUSION

The testis has two major functions: the production of functional gametes and the synthesis of steroid hormones, in particular testosterone. These two roles are inextricably linked, as spermatogenesis is also dependent on a high concentration of intratesticular testosterone. In fact, it could be argued that the primary role of the testis is to produce testosterone, as testosterone synthesis proceeds in the absence of germ cells, but spermatogenesis cannot be completed without testosterone. Thus, the testis primarily functions as an endocrine organ that both influences other body systems to maintain homeostatic mechanisms and is itself responsive to stimuli received from extragonadal body systems. This complex hormonal milieu, coming together to act within an organ with a simple, primary, albeit essential role that is needed for the preservation of species, is both elegant and yet challenging to dissect. Despite this complexity, we already know much about how these interwoven stimuli and suppressors act (Figure 16.11).

Hormones and Spermatogenesis

Maintenance of spermatogenesis and male fertility is dependent upon the direct and indirect actions of numerous hormones. The two most critical endocrine effects are mediated by LH and FSH. Both of these hormones act indirectly to support germ cell development by acting on their respective targets—the Leydig cell and Sertoli cell, respectively—through signaling pathways that are relatively well characterized. The major function of LH signaling is to increase the efficiency of testosterone production, which in turn acts upon the Sertoli cell to facilitate the production of factors that are required for germ cells to pass through specific stages of development. FSH supports and complements testosterone actions to increase spermatogenesis efficiency. FSH acts in a similar manner to testosterone in Sertoli cells to cause the production of regulators of germ cell development and maintenance. The lack of direct action of the major spermatogenesis regulating hormones upon germ cells is an interesting mechanistic choice. Perhaps the additional level of control at the site of the Sertoli cell allows for better integration of signals from all hormone and environmental inputs. Other hormones and paracrine factors, including thyroid hormone and activin, respectively, increase spermatogenesis efficiency by regulating signaling pathways that control Sertoli cell growth and differentiation to determine the ultimate number of Sertoli cells and therefore the upper limit of germ cells and sperm that can be supported.

Hormones and Steroidogenesis

Another group of hormones (osteocalcin, IGF1, glucocorticoids, and leptin) provide fine-tuning and environmental input adjustments to spermatogenesis output. Interestingly, these hormones are similar in that in many cases, they act to alter testosterone production as a mechanism to regulate spermatogenesis efficiency. Whether their impact on spermatogenesis is the primary driver behind these hormones' abilities to modulate testosterone production, or is simply an endpoint response to increased testosterone production, remains to be established, but as discussed in this chapter, testosterone not only is required to support spermatogenesis but also acts bodywide to modulate a variety of parameters associated with male secondary sexual characteristics and adult homeostasis, perturbation of which is increasingly recognized to be associated with pathologies. The influence of these hormones on the testis may therefore reflect a wider signaling network, whereby the systems of the body are at least to some extent able to modulate testosterone production to their own ends.

Recently, the development of knockout mouse models with cell-specific ablation of hormone receptors has provided important physiological information regarding the spermatogenic processes that are regulated by individual hormones. However, often the knockout models are limited to providing information regarding initial developmental processes. In the future, additional inducible adult knockout models may permit a better understanding of hormone regulation throughout the spermatogenesis process and on wider testis function.

Unanswered Questions

A number of questions remain to be answered regarding the pathways by which hormonal signals regulate spermatogenesis. Although testosterone has been known to be essential for spermatogenesis for at least eight decades, the molecular mechanisms by which testosterone acts to maintain spermatogenesis are only beginning to be resolved. Important future questions to be answered include: How does testosterone act to maintain the BTB as well as Sertoli cell–germ cell attachment and germ cell release? What are the relative contributions of classical and nonclassical testosterone signaling in relation to testosterone-regulated stages of

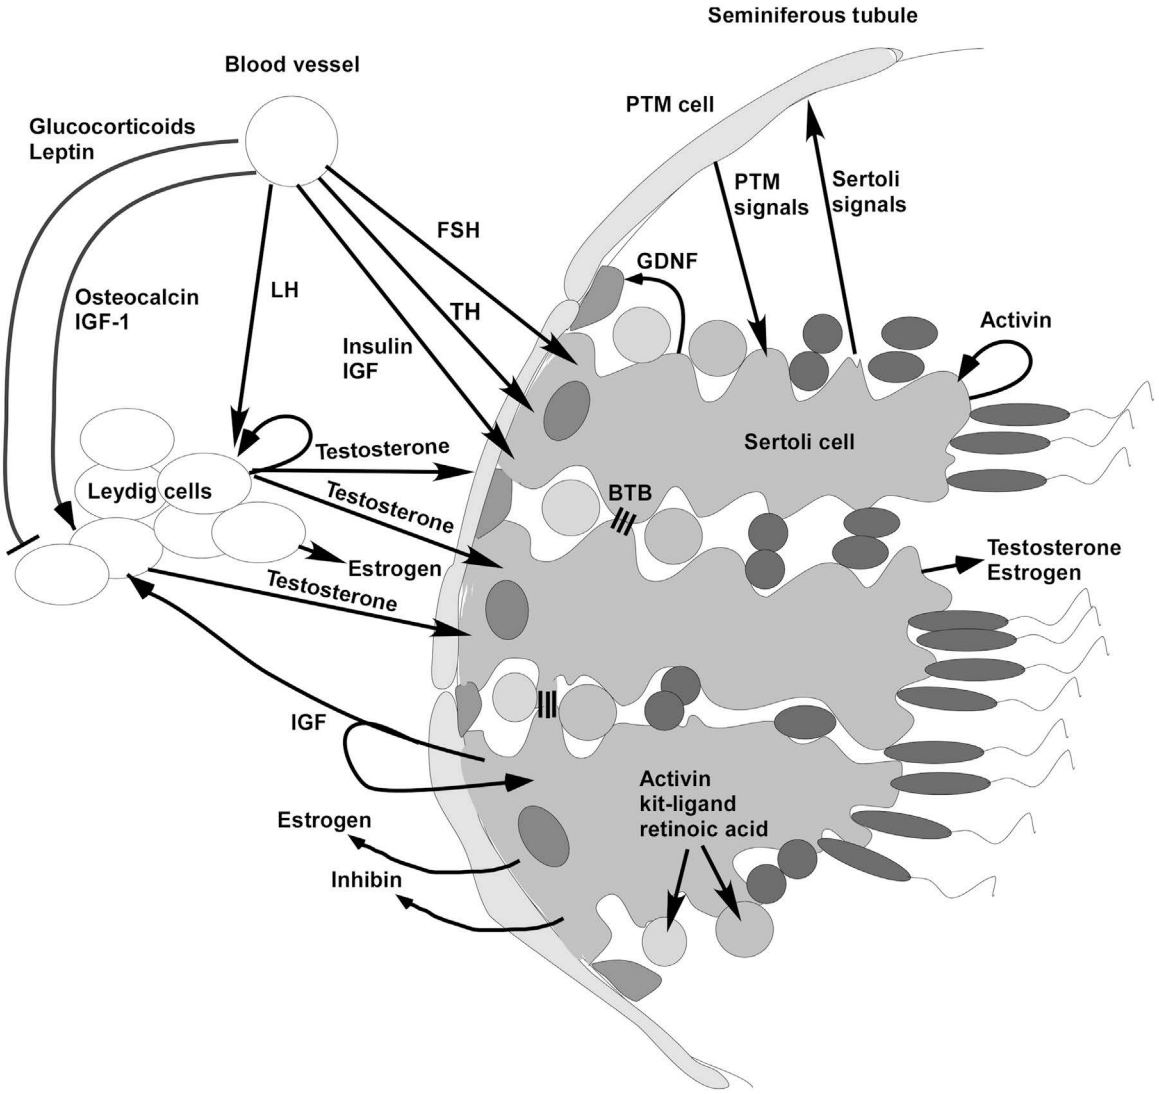

FIGURE 16.11 **Summary of hormone signaling in the testis.** Hormones derived from the circulation, including follicle-stimulating hormone (FSH) and thyroid hormone (TH), act on Sertoli cells to regulate Sertoli cell proliferation and support spermatogenesis. LH acts on Leydig cells to promote testosterone production. Osteocalcin and insulin-like growth factor 1 (IGF1) increase testosterone production, whereas glucocorticoids and leptin oppose testosterone production. Testosterone acts upon Leydig, peritubular myoid (PTM), and Sertoli cells to support the survival, development, attachment, and release of germ cells as well as maintain the blood–testis barrier (BTB). Estrogen produced by Leydig cells and Sertoli cells provides additional signals required to maintain fertility. Sertoli and Leydig cells produce activin that increases the duration of Sertoli cell proliferation and supports spermatogonia proliferation. In response to hormonal and paracrine signals, Sertoli cells produce glial cell line–derived neurotrophic factor (GDNF) to maintain spermatogonial stem cells, as well as activin, kit ligand, and retinoic acid that support the differentiation and proliferation of spermatogonia and entry into meiosis. Inhibin produced by Sertoli cells prevents uncontrolled Sertoli cell growth and provides feedback information to the pituitary gland to regulate FSH secretion. Less well-characterized signals are transmitted between PTM and Sertoli cells.

germ cell development? What is the relative importance of testosterone-regulated miRNAs in the regulation of spermatogenesis?

It has been established that FSH is not required to maintain fertility—at least in rodents. There are new arguments based on knockout mouse models that FSH contributes less than expected to Sertoli cell proliferation in mice. Hopefully, additional studies will clarify the relative contribution of FSH toward supporting the proliferation of Sertoli cells in the mouse versus the rat and primate. Another interesting new development is the finding that PTM cells relay testosterone signals to Sertoli cells prior to the expression of Sertoli cell AR. What are the signals being sent by the PTM cells? Also of interest is the function of estrogen in the testis. Does the loss of estrogen signaling only cause misregulation of fluid movement, or are there specific targets of estrogen in germ cells or supporting cells that regulate spermatogenesis? Finally, will the recent explosion in knowledge about the regulation of spermatogonial stem cell proliferation and differentiation

provide additional information about how hormonal signals regulate stem cell fate decisions and the maintenance of the stem cell niche?

Whereas the scientific community has generated an incredible amount of data relating to the influence, roles, and actions of individual hormones and paracrine factors in the testis, the future challenge is undoubtedly to work toward understanding the integration of these signaling systems, and how they act in concert to support testicular function. The experiments required to address this overarching question in vivo would be prohibitively expensive. It is the advent of increased computing power and the development of computer simulations that will allow integration of these disparate data sets and facilitate the identification of new testable hypotheses. Only by pooling these data to examine the system in its entirety, from the gross influence of circulating hormones to the cell–cell interactions and the intracellular signaling pathways, will we begin to comprehend the wonderful complexity and beauty that underpin the hormonal control of testis function.

INTRODUCTION

Since the publication of the chapter on The Epididymis in the third edition of *Knobil and Neill's Physiology of Reproduction* in 2006,[1] a continued striking series of events has marked the growth in our knowledge and understanding of the epididymis—a long, complex, convoluted duct connecting the efferent ducts to the vas deferens. We have progressed from having gained a basic appreciation of the structures, functions, and physiological regulation of this tissue to beginning to acquire an in-depth knowledge of the molecular events governing the development of the excurrent duct system and of the functions it controls. This tissue can no longer be considered the "abandoned child" of the male reproductive system.[2]

Five international conferences dedicated to this tissue have been held since 1988 (with a sixth one being planned) with proceedings ensuing for four of these.[3–6] A comprehensive, multi-authored volume dedicated to the epididymis has been published,[7] as well as a volume on changes in spermatozoa as they mature in the epididymis.[8] The yearly number of research publications on this tissue has increased at a remarkable rate. It has grown from a few hundred per year until the early 2000s to more than 1000 publications every year since 2005; PubMed currently lists over 15,000 publications related to the epididymis (over 24,000 if the efferent ducts and vas deferens are also considered as part of this system). Therefore, in preparing the current review, we have chosen (1) to narrow the scope by placing most of the emphasis on the epididymis itself, as opposed to the other components of the excurrent duct system, (2) to exclude some topics that have been extensively reviewed recently such as changes in spermatozoa during epididymal transit, innervation and vasculature of the duct system, and pathology of the epididymis, and (3) to focus on some of the more exciting recent developments in this field and provide supplemental information in an alternate format. Several of the subjects covered in the first and third editions are updated; however, due to space limitations, we have chosen not to include most of the plates that depict the histological organization and structure of the various epididymal epithelial cells from the first edition, but rather to place them on a Website (http://www.medicine.mcgill.ca/PhysiolReprodEpididymis/). Along with these plates, this Website contains color versions of plates from the third edition of this chapter and a number of tables, including some containing detailed information about specific epididymal proteins and genes as well as their regulation. We have intentionally chosen not to include such tables within the chapter not only because of space limitations but also because of the need to update this information regularly. We also felt that the review should focus on our ideas, philosophy, and viewpoints on what we believe is important and where the field should go.

As early as the fourth century BC the epididymis was described by Aristotle in his *Historia Animalium*, while the first recorded description of a dissected epididymis was made by de Graaf in 1668 in his monograph *Tractatus de Virorum Organis Generationi Inservientibus* (reviewed in Ref. 6). De Graaf noted that "…the semen … was watery and ash-like in the testis and becomes milky and thick in the epididymis".[9] Between 1888 and 1928 a number of scientists described the histological features of the epididymal epithelium, and surmised, from the images of secretion that they observed, that epididymal secretions

"nourished" the spermatozoa in the epididymal lumen. In 1913, Tournade,[10] showed that spermatozoa released from the proximal epididymis were not motile when diluted in saline, but spermatozoa released from the distal epididymis were fully motile. In the bat, spermatozoa were observed to survive for several months in the cauda epididymidis during hibernation, presumably protected by epididymal secretions,[11] while rabbit spermatozoa survived in the epididymis for 30–60 days,[12] and bull spermatozoa for 2 months,[13] after ligation of the efferent ducts. The implication of these observations was that the epididymis conditioned the development of sperm motility and was important for sperm survival.

The consensus of these early investigations can be summarized by the last sentence of Benoit's classic 1926 monograph: "The role of epididymal secretions is to maintain sperm vitality, to permit the development of sperm motility, and possibly to protect them against noxious agents."[14] In a series of four papers between 1929 and 1931, Young[15–18] showed that during epididymal transit spermatozoa not only acquire a mature motility pattern but also become fertile; based on some poorly designed and interpreted studies, he concluded, erroneously, that the changes spermatozoa undergo during their transit through the epididymis represent a continuation of changes that start while spermatozoa are still attached to the germinal epithelium and are not conditioned by some specific action of the epididymal secretion.[19] Nevertheless, by 1931, most of the problems and questions relating to epididymal physiology had been recognized and most of the work done since then has been to provide the experimental evidence to flesh out the insights of earlier investigators.

Few studies were published on epididymal physiology between the 1930s and the 1960s. Those that appeared focused primarily on establishing the length of time necessary for spermatozoa to transit through the epididymis.[20,21] The apparent disinterest in the epididymis during this 20–30 year span is puzzling. After the work of Benoit in 1926[14] and Young in 1931,[15–18] there was a clear controversy that needed to be resolved. In 1965, only 43 papers on the epididymis were published. Whatever the reason for this disaffection, in 1964 Thaddeus Mann, in his book *The Biochemistry of Semen*,[2] refers to the epididymis as the abandoned child of the reproductive system.

In the mid to late 1960s a resurgence of interest in the epididymis was spearheaded independently by Bedford and Orgebin-Crist. They demonstrated that the key event in sperm maturation was not the passage of time, as proposed by Young, but exposure to the luminal environment of the epididymis.[22,23] Thanks to these and other studies, by the end of the 1960s, it was established that the potential for sperm motility and fertilizing ability is acquired as spermatozoa pass from the proximal to the distal epididymis; that the maturation process does not end with the acquisition of fertilizing ability, because spermatozoa that have just become fertile induce a higher rate of embryonic mortality when inseminated in vivo; that the maturation process is dependent on an androgen-stimulated epididymis; and that the maturation process includes changes in sperm organelles (reviewed in Ref. 24).

Since the 1980s, we have seen an explosion of studies on the presence, characterization, immunolocalization, and regulation of a large number of proteins and their mRNAs known to be specific to the epididymis, to be expressed at particularly high levels in some segments of the tissue, or to control key molecules that regulate epididymal function. The objective of many of these studies has been to develop ways of modifying epididymal function so as to alter the ability of this tissue to perform its function with respect to rendering spermatozoa fully mature and motile and to protect them from noxious factors, thus providing potential leads for male contraception or the management of male infertility. In the course of these studies, it has become clear that this tissue presents a novel model for studying cell-, segment-, and region-specific gene expression; for understanding mechanisms of aging; and for identifying processes for selective protection from infections and cancer.

DEVELOPMENT OF THE EPIDIDYMIS

Formation of the Mesonephric/Wolffian/Nephric Duct and Tubules

Many of the studies focusing on the specification and regulation of mesonephric duct and tubule formation have been examined in chick, frog, and zebrafish embryos, with some more recent studies using the mouse embryo. Space limitations prevent a comprehensive review of the development of the urogenital system, but there are several excellent resources with detailed descriptions of these events.[25,26] What follows is a basic summary of the embryonic and postnatal development of the epididymis.

The urogenital system is derived from the intermediate mesoderm, which, in the chick and mouse, is the result of a complex interaction between the intermediate and paraxial mesoderm. The expression of two key transcription factors, paired box 2 (*Pax*2) and *Pax 8* plays a vital role in this process because mice that lack these two genes fail to form a mesonephros and, therefore, later structures of the urogenital system; Bouchard et al.[27] suggest that *Pax 2* and *Pax 8* are critical regulators that specify the nephric lineage. At approximately gestation day 8 or 9 in the mouse and stage 16 in the developing chick, the mesonephric duct (Wolffian/nephric) develops as a cord of epithelial cells that express c-*Sim-1* (chick) and *Pax 2*[28,29] undergoes the formation of a lumen and rapidly extends throughout the length of the embryo in a cranial to caudal direction.

There is considerable evidence to suggest that, in some species, elongation of the nephric duct is the result of cell rearrangements rather than proliferation or changes in cell shape.[30] Interestingly, for proper nephric duct formation but not elongation, bone morphogenic protein 4 (BMP4) expression in the surface ectoderm appears to be critical.[31] Retinoic acid is also crucial for nephric duct formation as the duct does not form in retinaldehyde dehydrogenase 2 (*Raldh2*), a retinoic acid synthetic enzyme, knockout mice.[32] The *Tbx* family of T-box transcription factors may also play a role in the development of the Wolffian duct.[33] Interestingly, a case report in which a human fetus carried a mutation in the protein-tyrosine phosphatase 2 (*Shp2*) gene showed absent Wolffian ducts although the testes and external genitalia were present.[34] In another case report, a patient with unilateral absence of the epididymis and vas deferens was identified, but the precise gene mutation(s) in that patient is not known.[35]

As the mesonephric duct elongates, it induces the nearby mesenchyme to form the mesonephric tubules.[36] The tubules have a characteristic J- or S-shape and resemble developing nephrons. Without the Wolffian duct, the mesonephric tubules do not form.[31] It is clear that those cranial mesonephric tubules that lie in close proximity to the testis survive, and the distal ends grow toward the gonad, whereas the proximal ends contact the Wolffian/mesonephric duct. However, several fundamental questions remain. What are the mechanisms by which the mesonephric tubules are induced by the mesonephric duct? This process involves a complex mesenchyme to epithelial transition, and there is evidence to suggest that leukemia inhibitory factor (LIF), members of the wingless-type MMTV integration site (*Wnt*) family (*Wnt 6* and *Wnt 4*) and fibroblast growth factor (FGF) 2 are responsible for mesenchymal cell aggregation and the formation of the renal nephron (reviewed in Ref. 37). Whether this is recapitulated during the formation of the mesonephric tubules is unclear. Lambot et al. published an informative series of three-dimensional models of the mouse efferent ducts.[38] Alarid et al.[39] have shown that FGF 2 is important for epididymal development because the epididymis fails to develop when embryonic urogenital ridges and sinuses are cultured under the kidney capsule in the presence of FGF 2 antibodies. Studies by Sainio et al.[40,41] showed that the expression of the *Wilms Tumor 1* gene is important in the formation of the most caudal mesonephric tubules. Kitagaki et al. have shown the importance of FGF8, but not the tyrosine kinase receptor, rearranged during transfection (RET) during the development of the cranial mesonephric tubules and thus the efferent ducts. Loss of leucine-rich repeat containing G protein-coupled receptor 4 (LGR4) results in shortened and less convoluted efferent ducts. Further, the duct was infiltrated with immune cells, thereby blocking the duct and preventing flow of fluid and spermatozoa.[38,42,43] The *Von Hippel-Lindau* gene is important for normal mesonephric tubule development because mutations in this gene with an activation of hypoxic-inducible factor 1 (HIF1) and HIF2 result in maldeveloped efferent ducts that can result in the adult epididymis having cysts and microscopic epithelial nodular formations called tumorlets.[44,45] Notch signaling may also play a key role in setting up the boundary between the efferent ducts and the rete testis.[46]

What are the mechanisms by which only those tubules close to the gonad survive, yet others cranial and caudal to the gonad degenerate? Evidence suggests that the caudal tubules normally undergo apoptosis, so we can speculate that those tubules close to the gonad express the anti-apoptotic genes required to survive, but this remains to be established.

What controls the migration and differentiation of cells of the distal tubule into the rete testis? Earlier studies by Upadhyay et al.[47] provided evidence that, in the mouse, the cells within the distal end of the mesonephric tubules contribute directly to the rete testis and undergo differentiation, and that fusion between the mesonephric tubules and the testis did not occur. This finding is perhaps not too surprising in light of the extensive contribution of the mesonephros to the developing testis.

Which portions of the mesonephric tubule and duct form the discrete regions of the initial segment and the first part of the caput epididymidis[14] (Figure 17.1)? There is some evidence to suggest that cells of the Wolffian duct contribute to a small part of the proximal portion of the mesonephric tubule, but again it is not clear whether this represents the junction between the caput and the initial segment. For a more complete overview of the processes described above, the reader should refer to the reviews by Sainio,[40] Vazquez et al.,[49] and Jones.[50]

It is intriguing that the development of the mesonephric tubules may recapitulate the development of the renal vesicle into the renal proximal and distal tubules. It would not be too surprising to find that many genes that regulate this process also play a role in the formation of the efferent ducts and/or initial segment (see Ref. 51 for expression of genes in the mesonephric tubules). For example, members of the *Wnt* family (*wnt 4*)[52] and cadherins[53] play a role in the proximal/distal patterning of the renal proximal and distal tubules. Cadherin 6 is expressed in the proximal tubule progenitors, E-cadherin is expressed in the distal tubule and P-cadherin is expressed in the glomerulus.[54] The initial segment fails to develop in *c-Ros* mutants[55] and in *Sxr* (*XXSxr*) mice,[56] suggesting that the defect may lie in the origin and/or development of the mesonephric tubules. However, studies by Avram and Cooper[57] would suggest that *c-Ros* plays a critical role in the development of the initial segment during the postnatal period. Although it is well recognized that androgens play an important role in epididymal development, the initial segment fails to

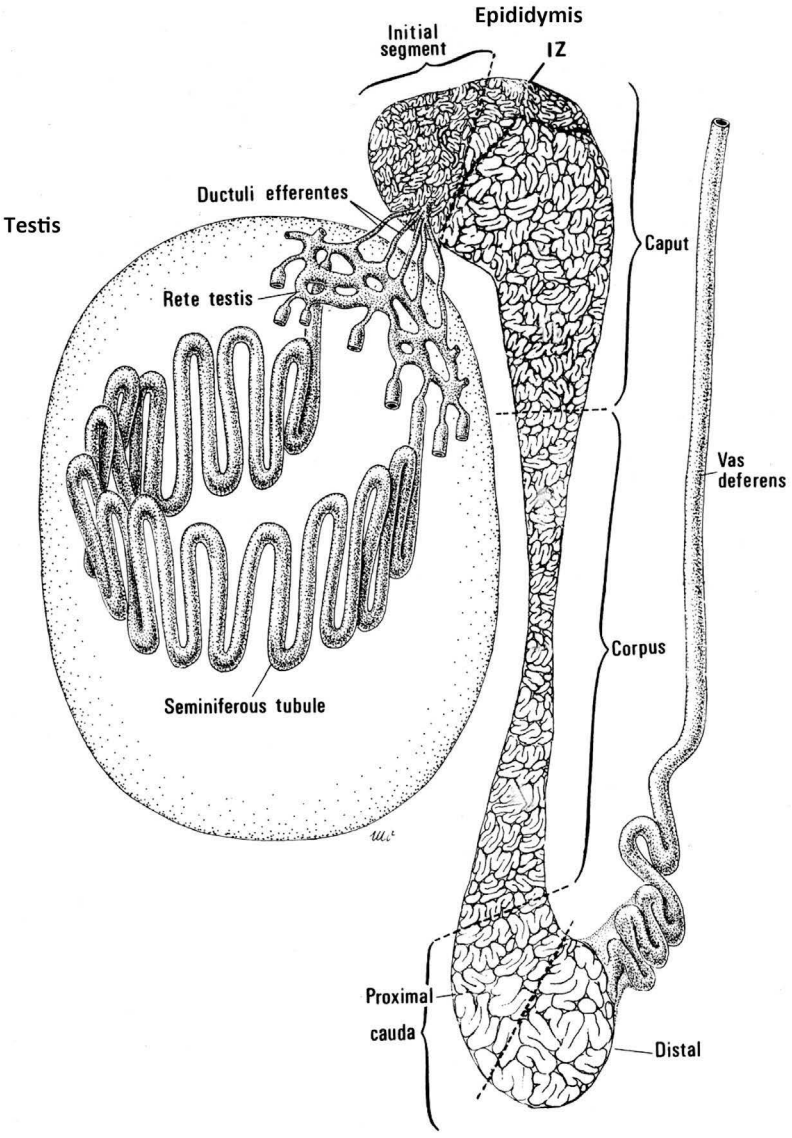

FIGURE 17.1 Diagrammatic representation of the testis and male reproductive tract showing a seminiferous tubule and the rete testis, the ductuli efferentes, the epididymis and vas deferens. The major regions of the epididymis, i.e., the initial segment, intermediate zone, caput, corpus, and proximal and distal cauda, are indicated. *Source: Adapted from Ref. 48.*

develop in a normal androgen environment in the *Sxr* mice;[56] the reason for this developmental defect is not known. This may suggest that additional factors, such as growth factors, may be important for mesonephric tubule/initial segment development. Interestingly, in both of these mutants, the prominent vascular system that supplies the initial segment also fails to develop,[55,58] indicating that there is an intimate relationship between epithelial and endothelial development. Again, this is perhaps not surprising in view of the formation of the renal glomerulus at the tip of the renal proximal tubule where endothelial cells are recruited to this site.

The embryonic origins of the different regions of the epididymis have received some attention; it appears that the efferent ducts are derived from the mesonephric tubules whereas the caput epididymidis to the vas deferens regions are derived from the mesonephric duct (reviewed in Ref. 50). However, the embryonic origins of the initial segment warrant further investigation because it is not entirely clear if the cells are of mesonephric tubule or duct origin. The cells of the initial segment are quite distinct from either the efferent ducts or the distal epididymal regions, but they function similarly to the efferent ducts in that they are actively involved in water reabsorption. Hence, it is possible that the initial segment may be of mesonephric tubule origin.

Elongation and Coiling during the Embryonic Period

Although there have also been some studies examining Müllerian duct elongation and coiling,[59] one of the last biological tubes to be examined regarding mechanisms and regulation of these parameters of growth/maturation is the Wolffian duct. Elongation and coiling are not trivial considering that the adult human epididymis is approximately

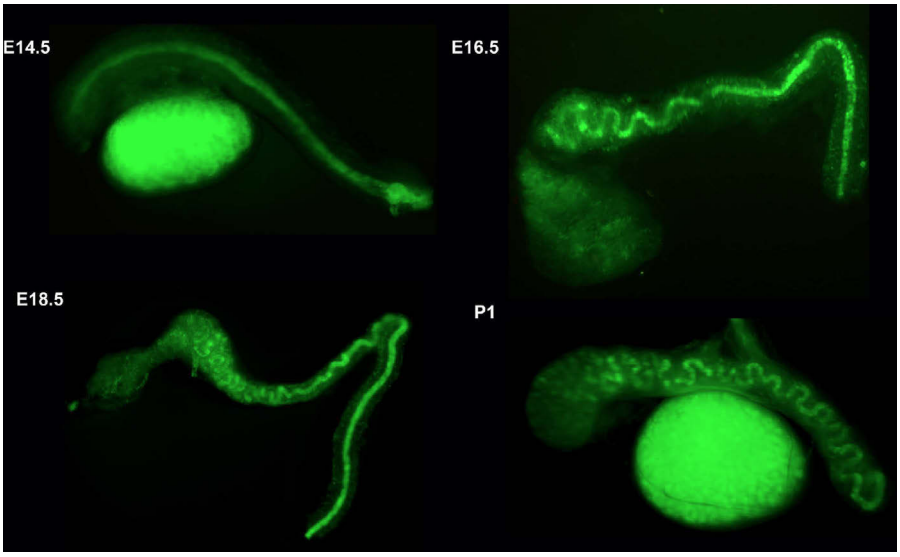

FIGURE 17.2 Wolffian ducts collected from hoxb7-gfp mice at different developmental stages, embryonic (E) days 14.5, 16.5, 18.5 and postnatal (P) day 1. This figure is reproduced in color in the color plate section. Note how the coiling proceeds from proximal to distal with three-dimensional coiling beginning around 18.5. *Source: Image from Ref. 60.*

6 m in length, the adult rat epididymis is approximately 3 m and the adult mouse epididymis is approximately 1 m.[1,60] Presumably, an epididymis that has failed to elongate and coil appropriately will lead to poor sperm maturation and, therefore, male infertility. Further, the failure of the vas deferens and portions of the epididymis to develop appropriately in patients with cystic fibrosis transmembrane conductance (*CFTR*) mutations[61,62] and the failure of the tubules from the human caput epididymal region to reach the testis (epididymal dysjunction)[63] can be hypothesized as a failure of ducts to elongate during development. Interestingly, Zvizdic et al.[63] showed that 30–79% of boys with an undescended testis also showed Wolffian duct abnormalities, of which 25% displayed epididymal disjunction.

Biological tubes can elongate via a number of mechanisms (see Refs. 64,65) and include cell shape change, cell rearrangements such as convergent and extension,[66] spatially restricted proliferation, generalized proliferation and cell recruitment, such as mesenchymal to epithelial transition.[65] There is evidence to suggest that the Wolffian duct elongates via generalized cell proliferation and cell rearrangements, but cell shape change cannot be ruled out.[60] Movement of mesenchymal cells into the Wolffian duct as a means to elongate the Wolffian duct does not seem to occur as shown by the absence of beta-galactosidase specific staining of mesenchymal cells (beta-galactosidase reporter gene driven by a mesenchymal cell-specific retinoic acid receptor beta promoter) in the Wolffian duct epithelium.[67]

Little is also known regarding the patterning of Wolffian duct coiling and how the epididymis reaches its final size. Figure 17.2 shows clearly that coiling begins around E16.5 in the mouse, but interestingly, coiling is only observed in the most proximal region. With time, coiling progresses more distally, with two-dimensional coiling first observed followed by three-dimensional coiling. This would suggest that a morphogenetic gradient is established and certainly inhibin beta A is a prime candidate as a modulator.[26,68] Given the role of members of the Hippo kinase family in dictating organ size[69,70] and the observation that members of this family have been identified in the developing Wolffian duct,[71] would suggest that this family may play a role in regulating size of the epididymis. As the Wolffian duct elongates and coils, it is held firmly by a proximal ligament attached to the kidney and basally to the gubernaculum. Presumably, these attachments will impart some tension as the Wolffian duct develops, and this may play a role in the regulation of cell proliferation, coiling, shape, and size. It has been shown that mechanical forces[72] and morphogen gradients[73] regulate the Hippo pathway in several tissues, and thus it is reasonable to propose that these regulatory mechanisms are acting in concert to regulate Wolffian duct development.

Although testicular luminal fluid factors appear to play a role during postnatal Wolffian duct development, they do not play a role during the embryonic period. Wolffian ducts elongate and coil in vitro without a testis although androgens are necessary.[60]

Postnatal Development

A more complete picture of the postnatal development of the epididymis has emerged over the years, with the majority of studies focused on the mouse, rat, and human, although other species have been studied, for example, bull, dog, rabbit, marmoset, and boar (reviewed in Ref. 74). Perhaps the most detailed description of postnatal epididymal development is that of the rat, and the studies by Sun and Flickinger,[75] and Hermo et al.[76] provide the basis for the following brief overview. There appears to be three major stages of epididymal development: the undifferentiated period, the period of differentiation, and the period of expansion.

By birth, the epididymis has undergone considerable coiling in the proximal regions (initial segment to corpus) and the cauda has yet to complete coiling (Figure 17.2). In the next 1–2 days, individual septa are seen delineating the tubule into segments.[60] The epithelium is undifferentiated and is characterized by columnar cells containing numerous mitotic figures. There is considerable growth of the rat epididymal duct from its embryological origins to postnatal day 15, when it reaches almost 2 m in length.[76,77] The period of differentiation has been examined extensively. Undifferentiated cells differentiate into the classically described cells of the adult epididymis: principal, halo, narrow (pencil), basal, and clear (light) cells; these cells as well as the newly identified dendritic cells are described below. Key changes in development in the rat are as follows: at postnatal day 14, there is the appearance of halo cells; on day 15, one observes narrow and columnar cells; by day 28, the columnar cells differentiate into basal and principal cells; from day 36 onwards, there is the appearance of narrow and clear cells and by approximately day 49, all epididymal cells are fully differentiated. Figure 17.3 outlines the differentiation of the rat epididymal epithelium from birth to adulthood. The period of expansion describes the continued growth of the duct and the appearance of spermatozoa in the lumen.

The mechanisms that regulate the growth and differentiation of the epididymal duct during the postnatal period are unknown, although it is clear that the expression of many epididymal genes is developmentally regulated. Certainly, luminal and circulating androgens (see below) play a critical role, but luminal fluid factors other than androgens also may be important. Early studies by Alexander (1972),[78] and Abe et al.[79] provided evidence that luminal contents produced by the testis and/or proximal regions of the epididymal duct may regulate epididymal epithelial differentiation, although the candidate regulators were not identified. There is evidence to suggest that testicular luminal fluid growth factors (e.g. FGFs) regulate initial segment function and that the same growth factors may regulate postnatal Wolffian duct development. It is tempting to speculate that luminal growth factors (e.g. BMPs, FGFs, NGFs) may also regulate epididymal epithelial differentiation. Loss of *Bmp4, 7,* and *8a*[80,81] and *Alk3*,[82] a gene encoding a putative BMP4 receptor, results in the loss of epididymal integrity during development. This suggests the importance of BMPs during epididymal morphogenesis. Certainly, luminal factors play a role in cell proliferation during the postnatal period because loss of such factors by ligating the efferent ducts leads to an immediate cessation of cell proliferation. Initially, it was suggested that a phosphatase, dual-specific phosphatase 6 (DUSP6), may be a key regulator of cell proliferation in this epididymal region, but results from Xu et al.[83] show that it played a greater role in the caput and corpus regions. It was hypothesized that the reason for region-specific regulation of cell proliferation was caused by differences in the balance of activities of pro- and anti-proliferative signaling pathway, of which members of the MAPK pathway played an integral role. Further, data suggested that the phosphatase and tensin homolog (PTEN) and members of the SRC family of kinases play a role in regulating cell proliferation in the initial segment.[83] SRC may also play a role in regulating cell proliferation in the cauda region.[84] In addition, the microRNA MiR-29a and nuclear autoantigenic sperm protein are potential regulators of epididymal cell proliferation during the postnatal period.[85]

Understanding the mechanisms of epididymal cell proliferation may provide clues as to why the epididymis rarely succumbs to cancer.

Role of Androgens

Interestingly, many of the findings showing that androgens play a role during Wollffian duct development have

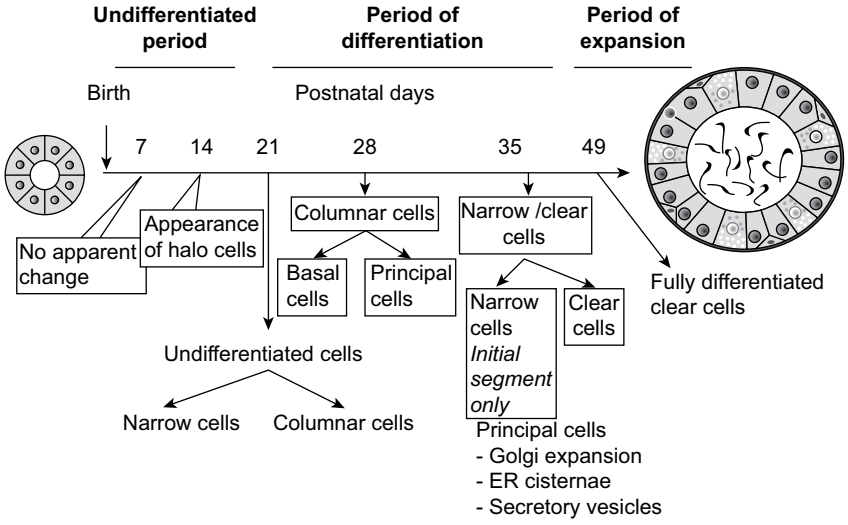

FIGURE 17.3 Diagram outlining the differentiation of the rat epididymal epithelium from birth until adulthood. Epididymal epithelial cells are undifferentiated until approximately day 21 when both narrow and columnar cells are first observed. At approximately day 28, the columnar cells differentiate into basal cells and principal cells. Narrow cells are seen within the initial segment only, but clear cells are observed throughout the epithelium from approximately day 36 onwards. By day 49, all epididymal epithelial cells are fully differentiated.

come from toxicological studies[86–93] and, more recently, from studies using androgen-knockout mice[94,95] or from the systemic administration of androgens.[96,97] However, the precise mechanisms underlying how androgens regulate downstream cellular targets that, in turn, regulate Wolffian duct development are not known.

STRUCTURAL ORGANIZATION OF THE EPIDIDYMIS

Anatomy

Seminiferous tubules converge to form the rete testis, which in turn gives rise to the efferent ducts (ductuli efferentes)—a series of tubules that, depending on the species, number from 4 to 20.[98,99] These tubules converge to form a single highly coiled duct, the epididymis (from the Greek for "on or adjacent to the testis") that is extremely long and varies from 1 m in mice,[100] 3 m in rats,[101] 3–6 m in man,[102] and up to 80 m in horses.[103]

The epididymis is usually divided into four gross anatomical regions: the initial segment, head (caput), body (corpus), and tail (cauda), as first described by Benoit in 1926.[14] Subsequently, a number of other schemes have been proposed for dividing the epididymis into different regions and/or segments, including a number of zones.[104–107] In the rat, there is an intermediate zone between the initial segment and caput epididymis with well-characterized cells.[108] However, in the present review, we will retain the most commonly used nomenclature for the four regions described above. In all mammalian species examined to date, each region of the epididymis is further organized into lobules separated by connective tissue septa. These septa serve not only as internal supports for the organ but have been proposed to also provide a functional separation between lobules, which allows selective expression of genes and proteins within individual lobules and may play a role in creating specialized septa-specific micro-environments where individual substances, such as growth factors, could have differentiated roles.[109–111] The extension of the epididymis is a straight tube, the vas deferens, which is surrounded by a very thick muscular layer. The vas deferens connects with the urethra which empties to the outside of the body. A schematic representation of the testis, efferent ducts, epididymis, and vas deferens is shown in Figure 17.1.

Epididymal Cell Types and Specific Markers

There are several types of epithelial cells that line the epididymis; some are located throughout the duct (e.g. principal cells), whereas others are found either exclusively or primarily in specific regions (e.g. narrow cells). We will provide a brief description of the major cell types along the epididymis, discuss the potential functions of these cells, and demonstrate the presence of specific markers for each cell type. Several detailed reviews of the histology of the epididymis for a number of species ranging from mouse to man and including dog, camel, elephant, opossum, bull, ram, hamster, mouse, and monkey have been published.[14,48,79,105,106,112–124] Together, these publications provide increasing evidence that similar regions and cell types are present in most mammals, including man. These cell types appear in the appropriate regions, share similar structural features and functions, including regional differences, and show very similar patterns of expression of some secretory proteins.[125–132] The comprehensive set of light and electron microscopy plates prepared for this volume are available at: http://www.medicine.mcgill.ca/PhysiolReprodEpididymis. Schematic representations of the organization of all the cell types and their known functions are represented in Figure 17.4. Key components of epithelial cells in the initial segment and in the remainder of the epididymis as observed at the electron microscope are depicted in Figures 17.5 and 17.6, respectively.

Principal Cells

The main cell type found in the epididymis of all mammals is referred to as the principal cell. These cells appear along the entire duct but show structural differences in each region.[48,134] The most striking feature of these cells is their highly developed secretory and

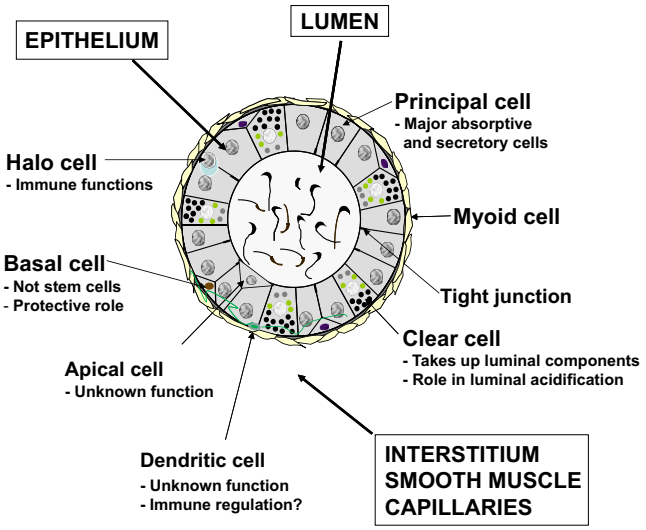

FIGURE 17.4 Schematic organization of the major cell types in a cross section of the epididymis as observed at the light microscope. The three epididymal compartments as well as the relative position and distribution of each of the main cell types are illustrated. The major function(s) associated with each cell type is also identified.

endocytic machinery and their basally aligned nuclei. Depending on the segment examined, principal cells comprise approximately 65–80% of the total epithelial cell population of the epididymis.[134] Both their structure and functions vary dramatically between the different segments.[48,114,135] These differences are reflected in the appearance and organization of their secretory apparatus (endoplasmic reticulum (ER), Golgi apparatus, and secretory granules) and endocytic apparatus (coated pits, endosomes, multivesicular bodies, and lysosomes). The precise characterization of the secretory granules, epididymosomes, and Golgi apparatus of these cells, as well as the identification of organelles and mechanism of uptake of luminal substances, have been well described.[133,136] In addition, one other major difference is the abundance of lipid droplets found only in the corpus epididymis (Figure 17.6), the exact significance of which is still poorly understood.

Principal cells synthesize a large number of proteins that are then either retained within the cells or actively secreted into the luminal compartment.[48,135,137–147] They also play an active role in endocytosing proteins found in the luminal compartment of the epididymis.[133] A schematic representation of these processes is depicted in Figure 17.7.

Apical Cells

Apical cells are found primarily within the epithelium of the initial segment and intermediate zone,[148–150] although they have been seen occasionally in other segments in aging rats.[151] These cells have a characteristic apically located ovoid nucleus and do not contact the basement membrane (Figure 17.5). They differ clearly from adjacent narrow and principal cells in terms of their protein expression profile.[149] However, little is known about the specific functions of these cells, aside from their ability to endocytose substances from the lumen, as revealed by the examination of these cells in β-hexosaminidase A knockout mice,[120] and the observation that they contain many proteolytic enzymes and a high density of mitochondria.[149,150]

Narrow Cells

In the rat and mouse, narrow (pencil) cells of the adult epididymis appear only within the epithelium of the initial segment and intermediate zone.[148,149] These cells are narrower than the adjacent principal cells, attenuated, and send a thin process of cytoplasm to reach the basement membrane (Figure 17.5). They are characterized by numerous apically located cup-shaped vesicles that are involved in endocytosis and function in secreting H^+ ions into the lumen by recycling to and from the apical plasma membrane.[151,152] Similar cells have also been reported within the same regions in numerous other species, including bovine, hamster, echidna, and humans.[112,116,117,127,151,153] Narrow cells are distinct from apical cells in their

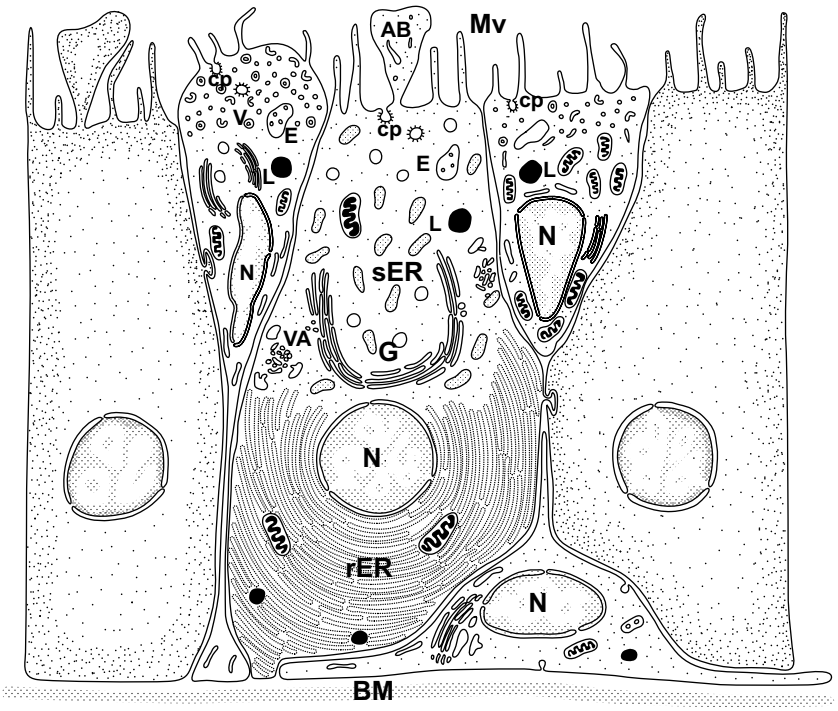

FIGURE 17.5 Schematic representation of cells found in the epithelium of the initial segment of the epididymis, as visualized in the electron microscope. Narrow cells, represented on the left, are elongated cells tapering toward the basement membrane (BM); they show numerous small apical cup shaped vesicles (v), coated pits (cp) and occasional endosomes (E) and lysosomes (L). Principal cells are columnar in appearance and show coated pits (cp), endosomes (E) and lysosomes (L), components of the endocytic apparatus. They also contain numerous parallel cisternae of rough endoplasmic reticulum (rER) located basally and dilated, irregularly shaped cisternae of ER sporadically dispersed in the apical and supranuclear regions of the cell (sER). The Golgi apparatus (G) is elaborate and located supranuclearly. Principal cells show blebs of cytoplasm emanating from their apical cell surface, referred to as apical blebs (AB) and small vesicular tubular aggregates (VA) occupying regions adjacent to the Golgi apparatus. Also illustrated on the right is an apical cell that, unlike the narrow cell, does not extend to the basement membrane and shows few coated pits (cp), apical vesicles, endosomes and lysosomes (L). A basal cell stretches along the basement membrane and sends a thin process up toward the lumen. N, nucleus; Mv, microvilli. *Reproduced with permission from Ref. 133.*

morphological appearance, relative distribution and expression of different proteins. They also differ dramatically from neighboring principal cells and display region specific expression of proteins such as the glutathione S-transferases (GSTs) and lysosomal enzymes.[149]

Clear Cells

Clear cells are large active endocytic cells present only in the caput, corpus, and cauda regions of the epididymis and are found in many species, including humans.[48,114,154] These cells are characterized by an apical region containing numerous coated pits, vesicles, endosomes, multivesicular bodies, and lysosomes and a basal region containing the nucleus and a variable amount of lipid droplets (Figure 17.6).[48,155,156] After injection of tracers into the lumen of the cauda epididymidis, the apical vesicles, endosomes, multivesicular bodies, and lysosomes of clear cells are found labeled, thus indicating an endocytic role for these cells; this endocytic activity is much greater in clear cells than in the adjacent principal cells, particularly in the cauda epididymis.[156,157] Clear cells normally take up the contents of cytoplasmic droplets released by spermatozoa as they traverse the duct.[48,156] Cytoplasmic droplets are formed at the time of the release of spermatozoa and contain Golgi saccular elements that may be involved in modification of the plasma membrane of spermatozoa.[158] Clear cells also endocytose a number of different proteins, but often in a region-specific manner.[137,141,159,160] These cells become abnormally large and filled with lysosomes after various experimental conditions that disrupt the normal functioning of the testis and epididymis.[134]

The acidification of the luminal fluid (see below) is thought to be mediated by clear and narrow cells. Indeed, key proteins for this process, H^+ATPase (or vacuolated V-ATPase), carbonic anhydrase II, and soluble bicarbonate sensitive adenylate cyclase (sAC), are selectively localized to these cells (Figure 17.8).[161,162] Further, ClC-5, a member of the voltage-gated CIC chloride channel family, is also expressed exclusively in clear cells and partially co-localizes with the H^+ATPase in their apical region.[163] Breton's group has proposed that, in narrow and clear cells, apical membrane accumulation of V-ATPase is triggered by a sAC-dependent rise in cAMP in response to alkaline luminal pH and that these cells play a specific role in luminal acidification.[164] Studies provide evidence that inhibition of RhoA or its effector ROCKII favors the recruitment of V-ATPase to the apical region of clear cells.[165]

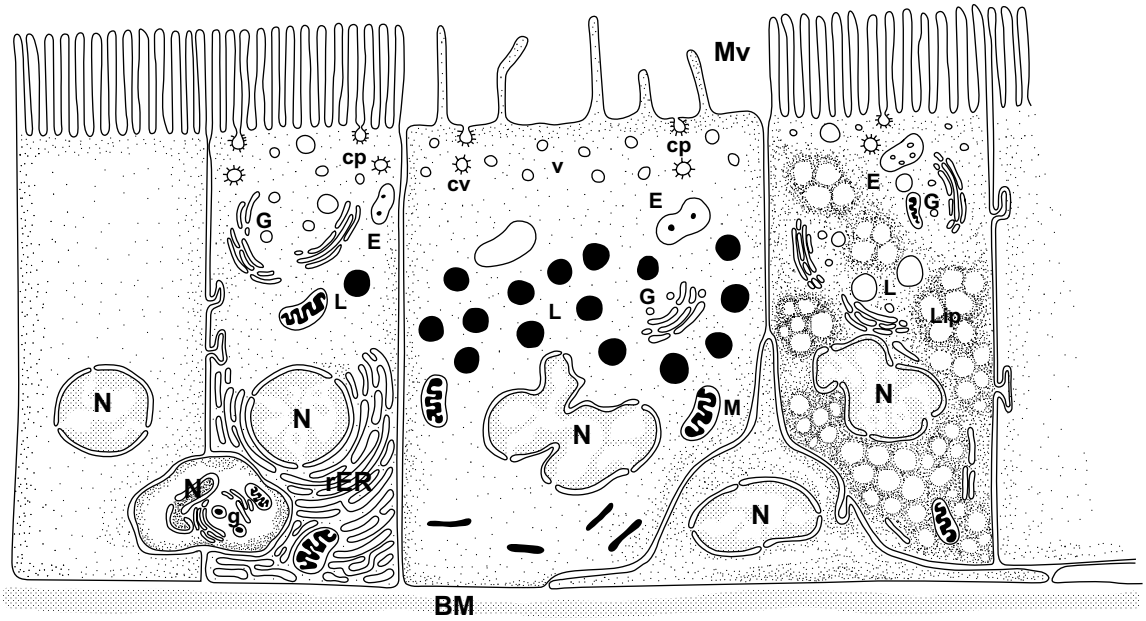

FIGURE 17.6 Schematic representation of a principal cell of the caput epididymidis on the left and a principal cell of the corpus epididymidis on the right, with a clear cell in between, as visualized in the electron microscope. Also represented is a halo cell and a basal cell. Principal cells of both regions contain coated pits (cp), endosomes (E) and lysosomes (L) and an elaborate Golgi apparatus (G). Rough endoplasmic reticulum (rER) occupies the basal region of the principal cell of the caput, while numerous lipid droplets (lip) occupy the cytoplasm of the principal cells of the corpus region. The clear cell shows few microvilli (Mv), but numerous coated pits (cp), small apical vesicles (v), coated vesicles (cv) endosomes (E) and lysosomes (L), all involved in endocytosis. The halo cell is inserted between adjacent principal cells, located basally and contains small dense core granules (g), while the basal cell stretches itself along the basement membrane (BM). N, nucleus. *Source: Reproduced with permission from Ref. 133.*

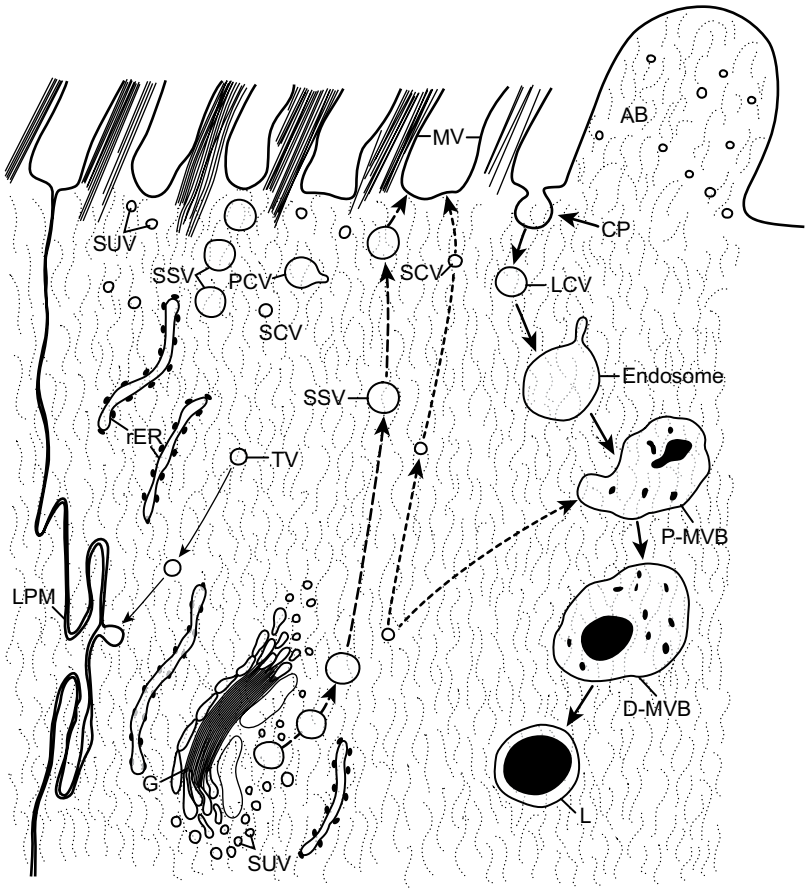

FIGURE 17.7 Schematic representation of the apical and supranuclear cytoplasm of a principal cell of the epididymis. The Golgi apparatus (G) is formed of several saccules packed on top of each other, from which the smooth surfaced secretory vesicles (SSV, 150–300 nm) and small coated vesicles (SCV, 60–70 nm) are derived. The SSV are destined for the apical cell surface with which they will fuse, delivering their content into the epididymal lumen in a regulated manner, by a process described as merocrine secretion. The SCV are targeted from the Golgi apparatus to multivesicular bodies (MVBs), delivering their lysosomal contents therein, while some may be destined for the cell surface. The endocytic apparatus consists of coated pits (CP), large coated vesicles (LCV), endosomes, pale (PMVB) and dense (DMVB) MVBs and lysosomes (L). Small uncoated vesicles (SUV, 60–70 nm) are also indicated, some of which may be Golgi derived and involved in constitutive merocrine secretion by fusion with the apical cell surface. An apical bleb (AB) is also indicated and contains mainly polysomes and small vesicles, the origin of which may be Golgi derived. Apical blebs appear to detach from the apical cell surface and upon fragmentation in the epididymal lumen liberate their contents therein for functions involved in sperm maturation. Mv, microvilli; PCV, partially coated vesicle; rER, rough endoplasmic reticulum; LPM, lateral plasma membrane; TV, small vesicles involved in the transcytosis or passage of substances from the lumen to the lateral intercellular space. *Source: Reproduced with permission from Ref. 133.*

Basal Cells

Basal cells appear in all species studied to date, including humans.[48,114,166,167] Hemispherical in appearance, they adhere to the basement membrane and do not have direct access to the lumen of the duct, although processes of these cells extend at times toward the lumen (Figures 17.5 and 17.6) as first reported by Veri et al.[167] and subsequently confirmed.[168] Like principal cells, basal cells are not thought to divide rapidly in adults nor are they thought to act as stem cells to replenish principal cells.[169]

Basal cells possess thin attenuated processes that extend along the basement membrane from their main hemispherical cell body to collectively cover a large proportion of the circumference of the epididymal tubule.[167,168] However, after ligation and castration, these cells transform into large bulbous dome-shaped cells that are closely packed together and show few short lateral processes.[170] Due to the dramatic decrease in size of the epididymal tubules after these treatments, it is likely that the shape and arrangement of basal cells in normal animals is governed in part by the volume and pressure exerted upon the tubular epithelium by luminal fluids and sperm derived from the testis. Consistent with this hypothesis is the observation that, in rats, during postnatal development, basal cells are transformed from dome-shaped cells to flattened cells that exhibit processes as spermatozoa and fluids arrive in the corpus and cauda epididymidis by days 49 and 56, respectively.[166]

Basal cells possess coated pits on the plasma membrane face that opposes the basement membrane and overlying principal cells, suggesting there is receptor-mediated endocytosis of factors derived from the blood or principal cells. Basal cells also show an accumulation of a secretory material within Golgi saccules and distinct secretory granules appear next to the Golgi apparatus, as seen in other typical secretory cells.[171] The destiny of the secretory material may be to regulate principal cell function or enter the circulation for functions as yet to be determined.

Studies from Wong's group (reviewed in Ref. 172) have proposed an additional function for basal cells; they suggest that these cells may have a role in regulating electrolyte and water transport by principal cells. This process is proposed to be mediated by the local formation of prostaglandins and requires the participation of the transient receptor potential (Trp) proteins. The latter serve as transmembrane pathways for Ca^{++} influx, while cyclooxygenase 1 (COX-1) is a

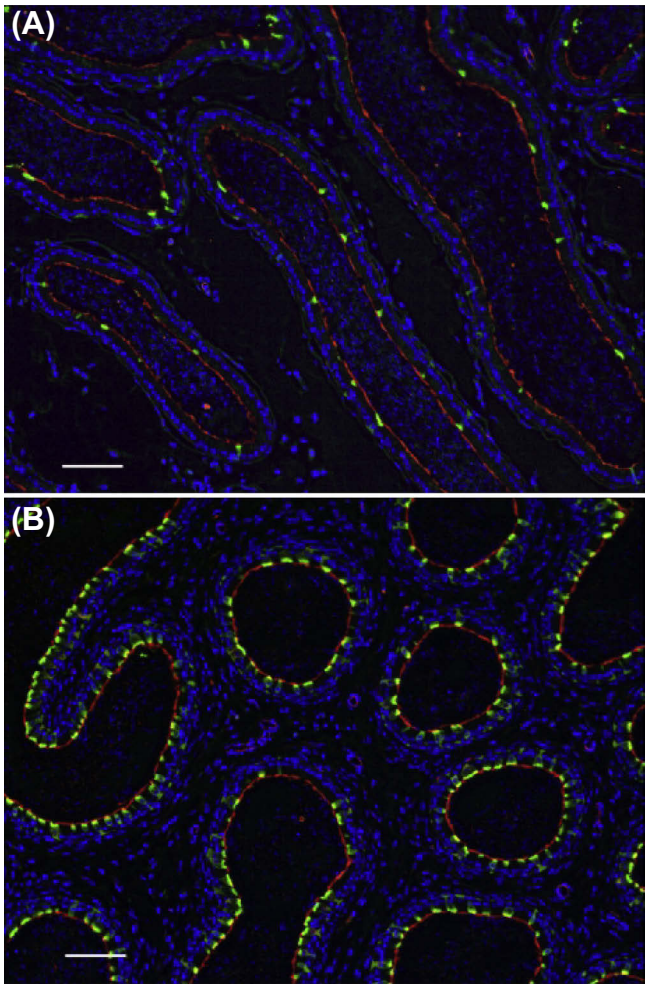

FIGURE 17.8 Relative numbers of clear cells in the rat caput (A) versus cauda (B) epididymidis. This figure is reproduced in color in the color plate section. Rat epididymis was stained for the V-ATPase B1 subunit (green) to label clear cells, and NHERF1 (red). Nuclei and spermatozoa were stained with DAPI (blue). NHERF1 is located in the apical membrane of both principal cells and clear cells. Clear cells positive for the subunit B-1 or V-ATPase are much more numerous in the cauda (B) than in the caput (A) epididymidis. Scale bars, 50 μm. *Source: Reproduced with permission from Ref. 164.*

key enzyme in the formation of prostaglandins. Both of these proteins are exclusively expressed in basal cells.

Halo Cells

Halo cells are small cells with a narrow rim of clear cytoplasm and are present throughout the epididymal epithelium (Figure 17.6).[48] These cells are usually located at the base of the epithelium and contain variable numbers of dense core granules. Halo cells have been described either as lymphocytes,[48] or monocytes;[173] these two cell types are difficult to distinguish using the light microscope due to their similarity in size and nuclear morphology. Although the exact nature of halo cells has been controversial since they were first described in 1957 by Reid and Cleland,[106] subsequent studies by Flickinger et al.[174] and Serre and Robaire[175] have resolved this issue by immunolabeling the main types of immunocompetent cells. It is now clear that, in young adult animals, halo cells consist of helper T lymphocytes, cytotoxic T lymphocytes, and monocytes, but not B lymphocytes. With age, there is a region specific increase in the number of each of these immune cell types, as well as the occasional appearance of eosinophils and B lymphocytes.[153] It is interesting to note that in the epididymal epithelium of young rats, the number of cells that stain for antibodies against monocytes-macrophages (ED1+), helper T lymphocytes ($CD4^+$) and cytotoxic T lymphocytes ($CD8^+$) is equivalent to the number of halo cells,[175] suggesting that halo cells are, under normal conditions, the primary immune cell in the epididymis (see also Chapter 19).

Dendritic Cells

Using specific markers for a sub-category of immune cells, recent studies by Da Silva et al.[176] have demonstrated the presence of another cell type in the epididymal epithelium. Dendritic cells are specialized antigen-presenting cells that are key regulators of immune responses in many tissues.[177,178] Although previously reported to not be present in this tissue,[179] several advances have allowed the clear demonstration that these cells are present in the epididymis. The finding that there are extensive networks of dendritic cells visualized in the epididymis of CD11c-EYFP[180] and CX3CR1-GFP[181] reporter mice, combined with the use of thick section (50-μm sections) for confocal microscopy allowed Da Silva et al.[176] to demonstrate that there is a network of these dendritic cells all along the epididymis, that there are multiple types of these cells in the epididymis, and that isolated CD11c+epididymal dendritic cells have strong antigen-presenting properties. These cells are likely to interact with both halo cells and the lymphatic system to serve in immune monitoring of the epididymis.

Cell–Cell Cross Talk in the Epididymal Epithelium

Each of the above cell types do not function in isolation. To create the specialized microenvironments needed to mature and store sperm throughout the epididymis (discussed below) requires extensive communication between adjacent cells and among different cells types. There are many such interactions. Basal cells form junctions with principal cells and halo and dendritic cells appear to monitor the entire epithelium.[48,182,183] We will focus on two such examples of this type of communication: the interaction between clear, basal and principal cells in regulating

intraluminal pH and, in the next section, cell–cell interactions in the formation of the blood–epididymis barrier.

Through an elegant series of experiments, the Breton laboratory has implicated a number of actors in clear, principal and basal cells that interact to regulate intraluminal pH in response to various stimuli (Figure 17.9).[184] These include sAC, proton-pumping ATPase (V-ATPase), guanylate cyclase (sGC), sodium bicarbonate cotransporter (NBC) in clear cells; protein kinase A (PKA) and cystic fibrosis transmembrane conductance regulator (CFTR) in principal cells, and angiotensin II receptor (AT2) prostaglandin E2 (PGE2) in basal cells. Briefly, it is proposed that basolateral activation of principal cells during sexual arousal triggers the secretion of bicarbonate and ATP into the lumen, a process that is mediated by CFTR and that then induces sAC in clear cells, resulting in proton-pumping ATPase (V-ATPase) accumulation in apical microvilli and consequent increase in proton secretion. Luminal angiotensin II stimulates AT2 in basal cells and induces the production of nitric oxide, which diffuses to produce cGMP in clear cells via activation of soluble guanylate cyclase (sGC). The cGMP triggers the apical accumulation of VATPase and increases proton secretion.

The Blood–Epididymis Barrier

Given the presence in spermatozoa of proteins that are recognized by the body as foreign, it only stands to reason that there should be a continuation beyond the testis of a functional barrier. The probable existence of a blood–epididymis barrier was discussed as early as 1976,[185] and several reviews describing different aspects of the barrier have appeared since.[186–194]

Structure

The junctional complex between adjacent epididymal principal cells is composed of apically located gap, adherens, and tight junctions. Tight junctions between adjacent principal epithelial cells at their luminal surface form the blood–epididymis barrier,[187,195] while gap junctions allow communication between adjacent principal cells. These tight junctions form a continuous belt around the cell, sealing the spaces between the epithelial cells, so that the luminal compartment and the intercellular spaces become separate physiological compartments.[196] The tight junctions begin to form at the time of differentiation of the Wolffian duct.[197] Using lanthanum nitrate as an electron opaque tracer that is blocked at tight junctions, the postnatal development of the blood–epididymis barrier was shown to be gradual; its

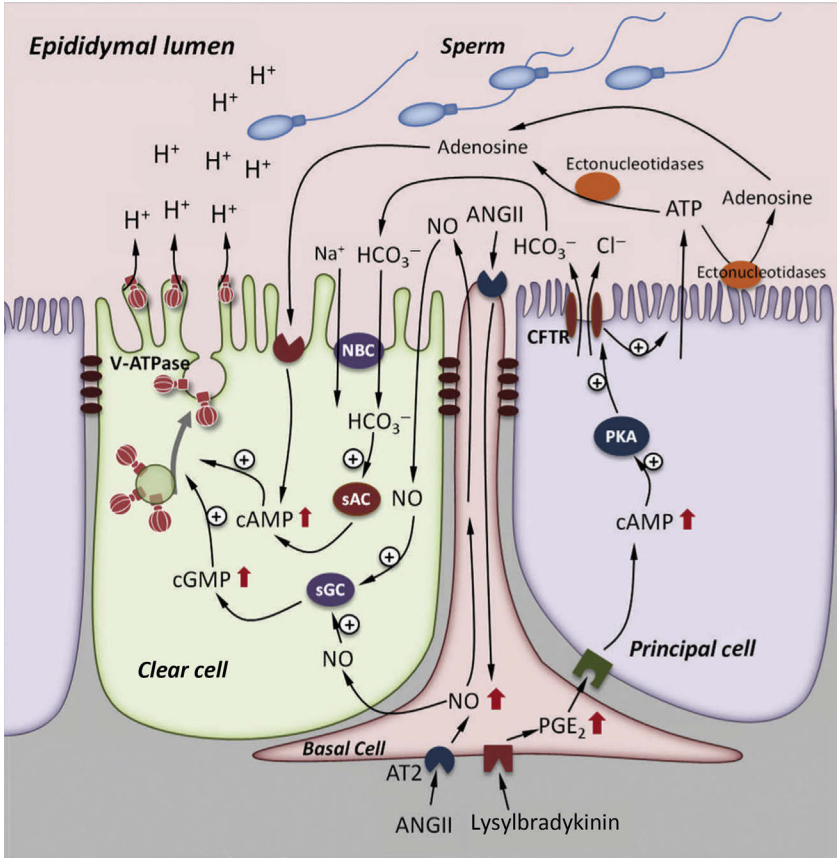

FIGURE 17.9 Schematic representation of cell–cell cross talk in the epididymis. Basolateral activation of principal cells during sexual arousal triggers the secretion of bicarbonate and ATP into the lumen, a process that is mediated by cystic fibrosis transmembrane conductance regulator. Stimulation of bicarbonate-sensitive adenylyl cyclase (sAC) and purinergic receptors in clear cells induces proton-pumping ATPase (V-ATPase) accumulation in apical microvilli, followed by an increase in proton secretion. Basal cells can extend a narrow body projection toward the lumen, and they form a new tight junction with adjacent epithelial cells. Luminal angiotensin II (ANGII) stimulates ANGII type II receptor (AT2) in basal cells and induces the production of nitric oxide (NO), which then diffuses out to produce cGMP in clear cells via activation of guanylate cyclase (sGC). The cGMP triggers the apical accumulation of VATPase and increases proton secretion. Simulation of basal cells by basolateral factors, including lysyl bradykinin, was shown to increase bicarbonate and chloride secretion in principal cells via prostaglandin E2 (PGE2) stimulation. NBC indicates sodium bicarbonate cotransporter; PKA, protein kinase A. *Source: Reproduced with permission from Ref. 184.*

formation was virtually complete by postnatal day 21 in rats.[196]

Changes in the structure of the junctional complex have been observed with the electron microscope when comparing the initial segment to the other segments of the epididymis. In the initial segment, the tight junctions span a considerable length of the apical plasma membrane and have few desmosomes.[187] As one progresses toward the caudal end of the epididymis, a general decrease in the number of tight junctional strands was noted; the span of merging plasma membranes was considerably reduced, but numerous desmosomes were found in the apical region.[187,197]

Junctional Proteins

Adheren junctions form a continuous belt and hold neighboring cells together through a family of calcium-dependent cell–cell adhesion molecules called cadherins, which mediate calcium-dependent homotypic interactions.[198–200] The cadherins have also been implicated in the formation and maintenance of tight junctions.[198,201–209] The cytoplasmic domain of cadherins forms a tight complex with several proteins, which either link cadherins to the cytoskeleton or are involved in signal transduction pathways. These include catenins, actinin, vinculin and zonula occludens (ZO-1). The cadherin-catenin complex is essential for cadherin mediated cell adhesion. Cyr et al.[210] reported the presence of E-cadherin and P-cadherin mRNA in the rat epididymis. Immunogold labeling using the electron microscope indicates that E-cadherin is localized in the extracellular space between the lateral plasma membranes of adjacent principal cells at the level of apically located junctional complexes in the adult rat epididymis,[187,211,212] as well as in the deeper underlying regions of the extracellular space between the lateral plasma membranes. Similar observations were noted in the human and mouse epididymis.[213–215] Although it was shown that in the normal adult rat epididymis, there was immunostaining for three anticatenin antibodies (alpha, beta-, and p120ctn) along the lateral plasma membranes (LPM) between adjacent epithelial cells,[216] the composition of the catenin-adhering junctional family of proteins and their relationship with cadherins remain to be established.

Claudins are another protein family involved in the formation of epididymal apical tight junctions. Claudin1 is found throughout the epididymis and is localized to epididymal tight junctions; it is regulated by androgens, but only in the initial segment of the tissue.[217] Claudin-7 is localized along the entire lateral membranes of the epididymal epithelium, including the apical junctional region throughout the epididymis, but claudin-8 is restricted to the apical junctional region.[218] The specific role of each of these various proteins in the formation of tight junctions throughout the epididymis remains to be established.

In addition to adherens and tight junctions, the epididymal junctional complex also contains gap junctions.[189,195,219,220] Gap junctions, made up of proteins termed connexins, mediate communication between cells by allowing small molecules to pass from cytoplasm to cytoplasm of neighboring cells, thereby metabolically and electrically coupling them together.[221] Connexin subunits oligomerize in the *trans*-Golgi network to form hemichannels or connexons. In the epididymis, gap junctions containing connexin 43 (Cx43) were first localized between principal and basal cells.[222] Although the presence of multiple connexins in specific cell types is not unique to the epididymis, the large number of different connexins[182,190,220,223–225] is suggestive of complex communication among epididymal cells. The structural aspects of the blood–epididymis barrier are referred to as the anatomical blood–epididymis barrier.

It is clear that the anatomical aspect of the blood-epididymis barrier is not static but highly dynamic. For example, basal cells have been shown to extend projections into the lumen[164,167] yet junctional complexes are maintained.[164] Presumably, the complexes must be formed de novo upon projection extension and rapidly degraded upon projection retraction.

Functions

The composition of epididymal luminal fluid is distinctly different from that of blood plasma. The blood-epididymis barrier keeps the two fluids in separate compartments.[144] The blood–epididymis barrier also maintains a specialized luminal microenvironment for the maturing spermatozoa by restricting the passage of a number of ions, solutes, and macromolecules across its epithelium.[186,226] For instance, molecules such as inositol and carnitine can be concentrated ten- to a hundred-fold in the lumen of the caput epididymidis, while others, such as inulin, L-glucose and albumin, are effectively excluded (reviewed in Refs 48,139). The blood–epididymis barrier carefully controls the microenvironment so that spermatozoa are bathed in an appropriate fluid milieu at each stage of maturation as they travel through each segment of the epididymis.[139] This is achieved by regulating the influx and efflux of solutes across the basolateral and apical membrane via specific transporters.[192] How each transporter is individually regulated and how they are coordinated to provide a unique and ever-changing microenvironment along the duct is unclear. This functional aspect of the blood–epididymis barrier is referred to as the physiological blood–epididymis barrier.[192]

In addition to the anatomical and physiological aspects of the blood–epididymis barrier, there is also an

immunological component.[191,192] This aspect of the barrier prevents the entry of immunoglobulins and immune cells into the lumen.[227,228] Further, the epididymis sequesters sperm antigens and so protects the spermatozoa as they progress along the duct. Very little is known regarding the immunological aspects of the blood–epididymis barrier compared to the blood–testis barrier[191,192,229,230] (see also Chapter 19) and more studies are obviously needed to understand how sperm are protected from the immune system. Interestingly, the epididymal interstitium has some immune protective abilities, although not as extensive as those of the interstitium of the testis.[229] Another possibility is that the dendritic cell network within the epithelium of the mouse epididymis[176] plays a role in the immunological blood–epididymis barrier, but this remains to be explored.

Although it would appear that the blood–epididymis barrier is resistant to the administration of various substances, such as gossypol[231] and estradiol,[232] the administration of the alkylating agent, cyclophosphamide (see later), to efferent duct ligated rats resulted in damaged spermatozoa.[233] This would suggest that this particular drug could enter the epididymal lumen and modify spermatozoa.[233] Treatment of adult mice with polychlorinated biphenyls (PCBs, Aroclor 1254) results in increased permeability of the blood–epididymis barrier and alters the expression of several tight junction proteins, such as occludin.[234] It has also been shown that there is a loss of integrity of the anatomical blood–epididymis barrier in mice that are mutant for Cathepsin-A, and this loss of integrity may be due to changes in the localization of claudins.[235] The inability of this barrier to maintain its tightness under conditions of stress, such as aging,[212] may help explain some of the deleterious effects of stressors on sperm function and fertility. However, many more studies are needed to establish the role played by this barrier in protecting spermatozoa from stressors and toxic substances.

FUNCTIONS TAKING PLACE IN THE LUMINAL COMPARTMENT

The main four functions of the epididymis are: the transport of spermatozoa, development of sperm motility, development of sperm fertilizing ability, and the creation of a specialized luminal environment conducive of the maturation process through the absorptive and secretory activities of the epididymal epithelium.

Transport of Spermatozoa

Once released in the lumen of the seminiferous tubule, spermatozoa are transported through the rete testis and efferent ducts and begin their journey down the epididymis. Several methods have been used to measure the duration of this transit. The most direct method is to incorporate a labeled isotope into the DNA of germ cells at the spermatogonia and preleptotene spermatocyte stages and follow the progression of the first wave of labeled spermatozoa down the epididymis. This approach gives the minimal time required for sperm passage through the epididymis. Total transit time, or transit through each epididymal segment, may also be estimated from the ratio of epididymal sperm reserves and daily testicular sperm production,[236] assuming that there is no sperm resorption and no difference in transit speed between segments. Despite some minor discrepancies between estimates obtained with these two techniques, it appears that, irrespective of the size of the animal, its sperm production, or its epididymal sperm reserves, the minimal time required for spermatozoa to transit through the epididymis is approximately 10 days (Figure 17.10, Table 1, supplemental material at http://www.medicine.mcgill.ca/PhysiolReprodEpididymis/). In most species, the average transit time of the majority of labeled spermatozoa is longer than that of the sperm vanguard; for example, in bulls the transit time is14 days as the average for the majority of sperm as opposed to 8 days for the leading vanguard.[236] As a result, there is some mixing of spermatozoa of different ages in the distal part of the epididymis.[237] There are two notable exceptions to the 10-day minimum transit time. In man and chimpanzee, the first labeled spermatozoa pass through the epididymis in 1 and 2 ± 1 days, respectively (Table 1 supplemental material at http://www.medicine.mcgill.ca/PhysiolReprodEpididymis/). These values give the most rapid transit time, but the average transit time is 12 days in man,[238] a value comparable to that found in other species.

When one follows the progression of labeled spermatozoa in the different regions of the epididymis, the transit time through the caput and the corpus is quite similar in all species studied, including man; most of the difference among species comes from transit through the cauda epididymis (Figure 17.10). Surprisingly, in species where this was tested, frequency of semen collection did not influence transit time through the epididymis markedly.[236,240,253] In bulls, daily sperm collection must exceed twice the daily testicular sperm production in order to observe an acceleration of sperm transit of only 3 days for the first wave of labeled spermatozoa,[236] while in rabbits different frequencies of ejaculation ranging from once per week to four times in one day had no effect on sperm reserves in the caput and corpus epididymis but dramatically reduced sperm reserves in the cauda epididymis and vas deferens.[254]

Spermatozoa enter the epididymis propelled by testicular fluid and possibly the beat of the ciliated cells of the efferent ducts. However, in the epididymis, the epithelium is lined by immotile stereocilia and the massive

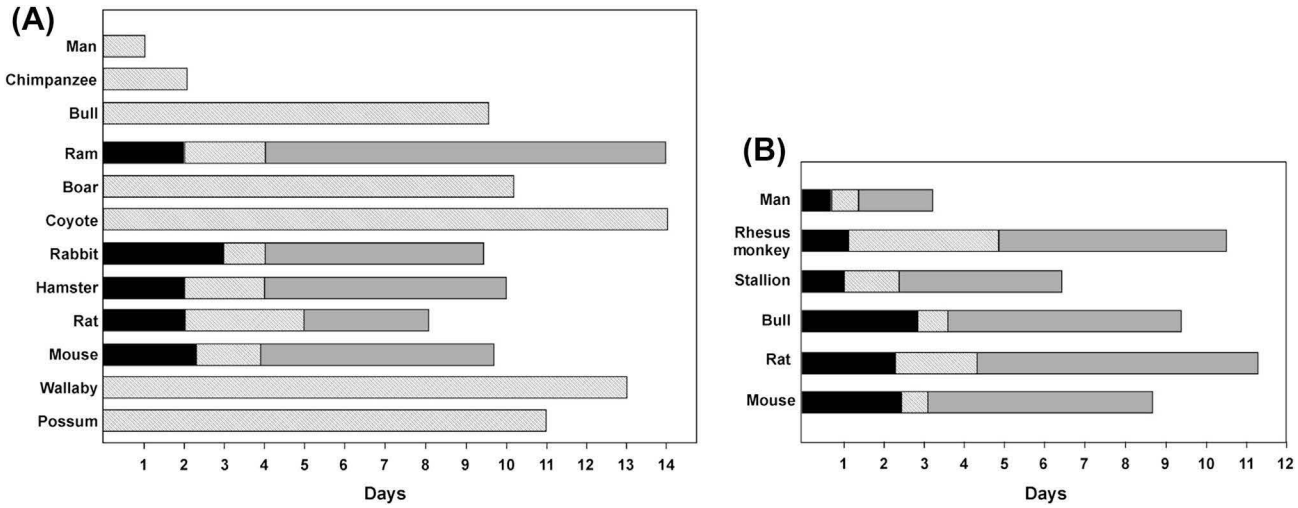

FIGURE 17.10 (A) Minimal time for epididymal transit determined by the progression of the first wave of labeled spermatozoa after isotope injection. Transport through the caput region (black bars), corpus region (light gray bars) and cauda region (dark gray bars) for the following species: (man;[238] chimpanzee;[239] bull;[236] ram;[240] boar;[241] coyote;[242] rabbit;[237] hamster;[243] rat;[244] mouse;[245] tammar wallaby and brushtailed possum[246]). (B) Duration of sperm transit through the whole epididymis and each segment determined by the ratio epididymal sperm reserves/daily testicular sperm production (man;[247,248] rhesus monkey;[249] stallion;[250] bull;[21,251] rat;[252] mouse;[245]).

fluid uptake taking place in the ductuli efferentes and the initial segment of the epididymis reduces drastically this fluid flow.[255] Sperm transport takes place against an increasing hydrostatic pressure gradient from testis to cauda epididymidis,[256] and proceeds even when fluid flow from the testis is prevented by ligation of the ductuli efferentes.[18,257]

The epididymis is surrounded by a smooth muscle layer of increasing thickness and alpha adrenergic innervation from proximal to more distal regions.[258] Therefore, the mechanism responsible for driving the contents through the lumen of the resting epididymis has been attributed primarily to the rhythmic muscular contractions of the smooth muscle lining the epididymal tubule.[259–262] Utilizing isolated epididymal tubules and measuring electrical activity via suction electrodes and injecting oil droplets into the lumen, the authors were able to show a relationship between the electrical and contractile activities of the epididymal tubule and the progression of the oil droplets. The droplets do not move in a linear fashion, but back and forth in a pendular manner. The movement forward starts when the spread of electrical activity approaches the droplet and stops or reverses when the electrical activity wanes or changes direction. Because the electrical pacemakers are randomly distributed and the electrical pulse spreads in both directions, droplets injected at the same time may spread in the lumen and follow different courses. The net distance covered during each pendular movement is small. Nevertheless, the droplets progress downward toward the vas deferens where the frequency of electrical activity is lower than in the caput epididymidis.[259,261] The rate of luminal flow is not uniform in the different segments of the epididymis.[260–262] The progression of droplets decreases from 420 mm/2 h in the initial segment to 64 mm/2 h in the distal caput and 25 mm/2 h in the cauda epididymis and vas deferens.[261] It is likely that the progression of oil droplets mimics that of spermatozoa in the epididymis. In bulls, labeled gold-coated beads injected in the rete testis are grouped in the distal caput epididymis 2 days after injection and in the cauda 5 days after injection, a transit time comparable to that of labeled spermatozoa; howeverbut 6 days after injection, beads are spread throughout the cauda.[236] Therefore, the progression of the epididymal luminal content is a dynamic process, resulting in a mixing of luminal content, and is controlled by the electrical and contractile activity of the epididymal tubule.

The smooth muscle contractions of the epididymal tubule and transit of spermatozoa therein are influenced by several factors, both hormonal and neuronal. Castration depletes epididymal sperm reserves,[263–265] and increases intraluminal pressure, contractility of the epididymis,[266] and sperm transport.[244] Testosterone treatment reverses the effect of castration, indicating that androgens control the contractility of the epididymal tubule to ensure an optimal rate of sperm transport. Estrogen, on the other hand, speeds up murine sperm transport drastically from 9.7 to 2.1 days[245] and act via a RhoA/Rho-kinase pathway.[267] Administration of chemicals that increase sympathetic tone, such as sibutramine (a neurotransmitter reuptake inhibitor), will also accelerate, up to 2-fold, the transport of spermatozoa through the epididymis,[268] while drugs that decrease sympathetic tone decrease sperm transport through the tissue.[269]

Contractility of the epididymal tubule is also influenced by prostaglandins.[270,271] These studies showed that physiological concentrations of $PGF_{2\alpha}$ increase the frequency and amplitude of contractions in proximal epididymis tubules while PGE_2 decreases contractions.[271]

Neurohypophysial peptides, such as oxytocin and vasopressin, and endothelin mediated by receptors present in the epididymis,[272–276] also increase epididymal contractility both in vitro,[277–281] and in vivo.[275,282] In several species, this results in an increase in the number of ejaculated spermatozoa and/or spermatozoa transported through the epididymis, including man.[275,283–289] Although the relative effect of oxytocin and vasopressin may vary among species, depending on the dose of the peptide or on the epididymal segment used in the in vitro studies,[282,289] it is clear that neurohypophysial peptides regulate both basal contractility of the epididymis and, upon release in the peripheral circulation around the time of ejaculation,[290–294] transport of spermatozoa through the vas deferens. Interestingly, the effect of oxytocin on epididymal motility is regulated by estrogens in part by an up-regulation of the oxytocin receptor gene and protein.[267,275] This may account for the estrogen induced accelerated sperm transport,[245] and suggests an interplay between steroids and neurohypophysial hormones in the regulation of epididymal contractility.

Neuronal regulation is also involved in epididymal contractility and sperm transport. This was first demonstrated by Simeone in 1933[295] using surgical sympathectomy and confirmed in later studies using either surgical[269,271] or guanethidine-induced chemical sympathectomy.[269,296,297] Surgical removal of a single neuronal ganglion, the inferior mesenteric ganglion that provides sympathetic innervation to the cauda epididymidis, is sufficient to slow down sperm transport through the epididymis.[298] Indeed, adrenergic and cholinergic drugs affect contractility of the epididymis both in vitro,[299] and in vivo.[300–302] Inhibition of phosphodiesterase 5 with drugs such as sildenafil citrate rapidly inhibits epididymal contractility presumably by blocking cGMP-hydrolysis thereby promoting relaxation of smooth muscle cells.[303] Temperature also affects epididymal contractility: a switch from scrotal to body temperature increases the frequency and spread of electrical activity of the smooth muscle of the epididymis,[304] and significantly speeds up sperm transport through the epididymis,[305] thus having potential deleterious effects on sperm maturation and fertility.

Although a neuromuscular mechanism may not be the only one responsible for sperm transport in the various segments of the epididymis and in all species, it appears to be the main mechanism responsible for sperm transport through the epididymis in mammals.

Maturation of Spermatozoa

Fertilizing Ability

In higher vertebrates, spermatozoa become functionally mature as they pass through the epididymis. They acquire the ability to move forward when released from the epididymis, ascend the female genital tract, undergo the acrosome reaction and bind to and penetrate the egg vestments, to finally achieve syngamy with the female gamete.

In all species examined thus far, a gradient of fertilizing potential is observed as spermatozoa traverse the epididymis (Figure 17.11). Although there is some species variation with respect to the exact site at which spermatozoa first gain their fertilizing potential, it is clear that to be competent to fertilize in vivo, spermatozoa leaving the testis have to pass through some part of the proximal epididymis.

This fertility profile can be altered somewhat using in vitro fertilization (IVF) techniques that bypass some or all steps in the normal fertilization process. For example, rabbit spermatozoa from the caput epididymis that do not fertilize more than 2% of the eggs after in vivo insemination,[23] fertilize 8% of the eggs after in vitro insemination.[320] A similar shift in fertility profile is observed when mouse spermatozoa are inseminated in vivo, in vitro, or after subzona injection (Figure 17.12). Testicular spermatozoa injected directly into the oocytes can even achieve a fertilization rate of 94% (Figure 17.12).[321] Fertilization also can be achieved when round spermatids are injected or electrofused with oocytes,[322] or when secondary or even primary spermatocytes are injected into the ooplasm.[321,323] However, the fertilization rates are lower than after injection of testicular spermatozoa.

Moreover, it appears that the acquisition of fertilizing potential is not a simple "on" or "off" state. Initial studies with rabbits,[23,308] rats,[314] and rams,[327,328] showed that after spermatozoa first gain the ability to fertilize eggs,

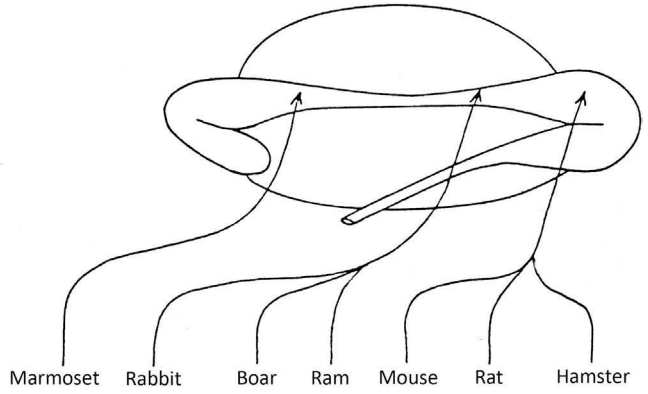

FIGURE 17.11 Approximate site within the epididymis where spermatozoa acquire their fertilizing ability. *Source: Information for each species, as brought together by Orgebin-Crist,[306] was obtained from the following sources: marmoset,[307] rabbit,[23,308,309] boar,[310] ram,[311] mouse,[312,313] rat,[263,314,315] and hamster.[316–319]*

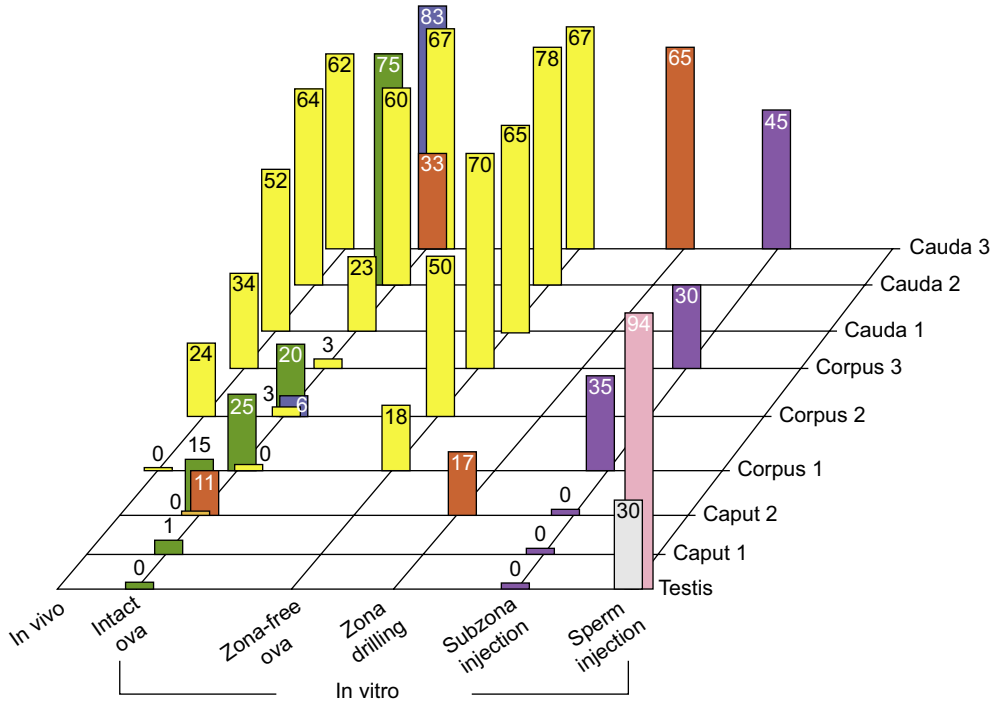

FIGURE 17.12 Fertilizing capacity of mouse spermatozoa from successive segments of the epididymis. The ability of spermatozoa to fertilize oocytes was assessed after either in vivo insemination (left column)[312] or in vitro[324] under different conditions: with intact ova,[312,313] zona-free ova,[313] after zona drilling,[325] or subzonal sperm injection or sperm injection.[326]

further transit through the epididymis is necessary for spermatozoa to acquire the ability to produce complete litters of viable offspring. Orgebin-Crist noted an increase in both pre- and postimplantation loss when rabbits were inseminated with corpus versus ejaculated spermatozoa;[23] this is apparently due to a delay in the fertilization of eggs,[23,329] and in the first zygotic division.[330] Although Overstreet and Bedford,[331] were unable to confirm these observations, subsequent studies in mice,[325] reported that only 8% of oocytes fertilized by caput epididymal spermatozoa were capable of developing to blastocysts in vitro compared with 48% of oocytes fertilized by cauda spermatozoa; Lacham-Kaplan and Trounson's group[324] confirmed that a high rate of embryonic arrest and retarded development occurs in mouse oocytes fertilized by epididymal spermatozoa that have just gained their fertilizing capacity. Although testicular spermatozoa and spermatids fertilize 94% and 37% of eggs, respectively after injection into the oocytes, only 54% and 28% of the fertilized eggs develop into live offspring when transferred into foster mothers.[321] Collectively, these experiments show that passage through the epididymis endows spermatozoa with the ability to ascend the female genital tract and interact with the egg. This maturation process can be circumvented since spermatid-injected oocytes develop into live offspring, but the chances of normal development are higher following injection of more mature spermatozoa.

The experimental protocol of insemination of equal numbers of spermatozoa from succeeding segments of the epididymis from one individual is obviously not possible in humans. However, in cases of obstructive azoospermia, epididymovasostomies have been done to recanalize the epididymis. The cumulative results show a low pregnancy rate when the anastomosis is done proximally and an increased incidence of pregnancies resulting from more distal connections.[332,333] These results, although not directly comparable with the animal studies, imply that in human, as in other species, there is a progressive maturation of sperm fertilizing ability in the epididymis. They also suggest that the fertility profile may be shifted more proximally when compared to other species. Pregnancies have been achieved even after reanastomosis of the efferent ducts to the vas, but the post-operative interval before pregnancy occurred was longer (2 years),[334] than after corpus-vas anastomosis (6–13 months).[333] If spermatozoa from the efferent ducts had the same level of maturity as spermatozoa from the corpus, one would expect the same postoperative interval, but the small number of cases precludes any generalization.

In cases of obstructive azoospermia or congenital vas agenesis, spermatozoa can also be aspirated from the epididymis and inseminated in vitro.[335] There is a statistical difference in fertilization rates with spermatozoa retrieved from different levels of the epididymis,[336] confirming the progressive maturation of human spermatozoa in the epididymis observed after reanastomosis.[332] After IVF and transfer, pregnancies have been reported with spermatozoa recovered from the corpus epididymidis,[337–339] and the proximal caput epididymis.[340,341] However, it should be stressed that the consequences of either pathological conditions of obstructive azoospermia or

congenital vas agenesis on the structure and functions occurring along the epididymal epithelium have not been investigated.

If immature human spermatozoa bypass normal sperm ascent in the female genital tract and sperm–egg interaction and are injected directly into the ooplasm (intracytoplasmic sperm injection, ICSI), they can form zygotes.[342–344] As in other species, the overall fertilization rate is similar or higher to that seen after conventional IVF.[344] Even testicular spermatozoa achieve fertilization rates of approximately 50%. Although several studies have reported fertilization of oocytes using round or elongated spermatids, the live birth rate using these methods is extremely low.[344–346] The overall fertility and delivery rates have been studied for several years and remained near 30% and 20%, respectively, for most countries.[347]

The congenital malformation rate and the developmental outcome of children born after ICSI with testicular, epididymal, or ejaculated spermatozoa are similar to that of children born after conventional IVF;[348–350] however, whether these ART procedures increase the rate of congential anomalies above that of the general population is not resolved.[351,352] Collectively, these clinical studies indicate that, as in other mammalian species, sperm capacity for optimal fertility in vivo increases during epididymal transit and procedures bypassing critical steps of the natural process of fertilization permit fertilization with immature spermatozoa. However, unlike other species, the fertility profile of human epididymal spermatozoa appears to be shifted more proximally because pregnancies have been reported with spermatozoa from the proximal epididymis.

Motility

Concomitant with the acquisition of fertilizing ability, a number of sperm characteristics undergo maturational changes. The first one to be recognized last century by Tournade[10] was the epididymal maturation of the sperm potential for motility. This was subsequently confirmed in numerous species of higher vertebrates from lizard,[353,354] to mouse,[355] rats,[314,315,356–362] hamster,[363–365] guinea-pig,[366] rabbit,[21,367,368] boar,[369] goat,[370] ram,[371,372] bull,[373,374] monkey,[375–377] and man.[126,378–380] The acquisition of motility is observed whether the testis and epididymis are located in the scrotum or in the abdomen, as in the elephant,[381] the hyrax,[381,382] and the armadillo.[382] The maturation of sperm motility potential involves both a quantitative increase in the percentage of spermatozoa that gain the potential for motility and a qualitative difference in motility patterns. Testicular spermatozoa are either immotile or display only a faint twitch of the flagellum. Spermatozoa released from the caput epididymis swim in a circular pattern, while spermatozoa released from the cauda move progressively and vigorously forward.

Other Maturational Changes

In addition to the development of the capacity for progressive motility, epididymal spermatozoa develop the capacity to undergo the acrosome reaction (mouse,[383] ram,[384] pig,[385] dog,[386] horse,[387] monkey,[388] and human[389,390]) recognize and bind to the zona pellucida and fuse with the vitelline membrane.[391–393] Concomitant with these functional changes, spermatozoa undergo structural changes during epididymal transit: migration of the cytoplasmic droplet along the sperm flagellum, acrosomal reshaping, changes in the sperm nuclear chromatin and some tail organelles, changes in the sperm plasma membrane, and fusion epididymosomes.[394–399] Collectively, these changes underpin the functional maturation and subsequent storage of spermatozoa in the epididymis, but none of these changes have been shown to be the only determinant of the acquisition of fertilizing ability.

Regulation of Sperm Maturation

Benoit[14] demonstrated that the function of the epididymis, and the maturation and survival of spermatozoa within it, depended on hormones secreted by the testis. After bilateral castration, not only the epididymal epithelium dedifferentiated, but epididymal spermatozoa died quickly, whereas after unilateral castration spermatozoa maintained their potential for motility on the castrated side 2 months after the operation. Experiments conducted by Bedford[22] and Orgebin-Crist[24,400] showed that while immature rabbit spermatozoa develop the capacity for motility and fertility when retained by ligatures in the proximal corpus, they do not become fertile when retained in the caput, although they develop a mature pattern of forward motility. This indicates that sperm maturation is a multi-step process and shows that, if the development of a mature pattern of motility is necessary, it is not sufficient to render a spermatozoon able to fertilize. It shows also that while some of the maturational changes such as motility, may be intrinsic to the sperm cell and develop with time, whereas others, such as the ability to interact with the egg, depend on the epididymal environment. The latter is conditioned by testicular androgens because sperm maturation occurs after castration, hypophysectomy, or in organ culture only when androgen is administered in vivo or included in the culture medium.[263,401–403]

Studies of co-incubation of epididymal spermatozoa with epididymal epithelial cell cultures have confirmed the role of the epididymis in promoting sperm maturation. In such cultures brushtail possum and tammar wallaby spermatozoa from the proximal caput underwent the morphological maturational change in head orientation accompanied by the development of progressive motility, normally only observed in vivo.[404,405] In hamsters, mice, and humans, co-cultures of immature

spermatozoa from the caput or corpus epididymis with cauda cells not only increased their motility, but also increased their capacity to bind to salt stored zona pellucida, to fertilize, and to support the development of embryos (sired by corpus spermatozoa).[300] These maturational changes are promoted by androgen-dependent factors from epididymal principal cells, because cocultures maintained in the absence of androgens fail to induce maturation.[406–408] The overwhelming evidence from all these experimental studies, both in vivo and in vitro, is that the final stages of the sperm maturation process in all mammalian species studied to date, including humans, depend on the epididymis.

However, reports of human pregnancies in two cases where the vasa efferentia was anastomosed to the vas deferens, therefore bypassing the entire epididymis, led to a challenge to the concept that the epididymis is necessary for the acquisition of fertilizing ability.[334] As discussed above, subsequent reports noted that the more distal the anastomic site, the greater the chances of fertility, confirming that the epididymis provides the milieu necessary for optimal fertility. Nevertheless, Temple-Smith[409] revisited the issue in elegant experiments using epididymovasostomies at different levels of the epididymis in rabbits and rats to assess the fertility of these animals. In both of these species, anastomosis of the distal initial segment to the vas, bypassing the distal caput, corpus and cauda epididymis, resulted in a significant reduction in sperm viability, motility, and fertility, confirming that spermatozoa require exposure to the epididymal environment for normal development of fertilizing ability. Interestingly, in rats, bypass of the distal caput and proximal corpus, either by epididymo-epididymostomy or graft of a vas bridge, had no effect on sperm motility, viability, or fertility. These studies show clearly that the epididymis plays a major role in the posttesticular maturation of spermatozoa, but they also show that exposure to the initial segment may be sufficient or that the lack of exposure to the epididymal regions where spermatozoa normally become fertile may be compensated by secretions from other epididymal regions. As discussed below, epididymal spermatozoa are exposed to a highly complex environment, but the nature of the specific changes induced by epididymal transit that are required to promote optimal fertilization still remains to be established.

Storage of Spermatozoa

The major site for storage of spermatozoa within the excurrent duct system of mammals is the cauda epididymidis. Though normal transit time in mammals through the cauda epididymidis is in the range of 3–10 days (Figure 17.10; Table 1 supplemental material at Website, see above), spermatozoa can be stored in this tissue for long periods of time extending beyond 30 days;[410] in bats, spermatozoa may be stored in this tissue for many months and retain their function.[411] Upon storage in the cauda epididymis, a loss in fertilizing ability occurs before a loss in motility.[412] Interestingly, spermatozoa that were aged in the male reproductive tract of rabbits, presumably in the cauda epididymis, induced a 10-fold higher incidence of chromosomal abnormalities in the resulting blastocysts than did their fresh counterparts.[413]

Based on studies in a number of mammalian species (reviewed in Ref. 414), Amann noted that 50–80% of spermatozoa present in the excurrent ducts were found in the cauda epididymis and that approximately 50% of these spermatozoa were available for ejaculation.[414] When animals (rabbits, stallions, and bulls) were at sexual rest, (i.e. seven or more days without ejaculation), the number of stored spermatozoa that were available for ejaculation was three to five fold greater than the daily sperm production rate and two to three fold greater than that found in a "typical" ejaculate; frequent ejaculation, that is one ejaculate every 1–2 days, did not result in a change in sperm production rate but did markedly decrease caudal epididymal sperm reserves and the number of spermatozoa in the ejaculate.[414] In contrast, man, whose sperm production rate is well below that of most other mammals, has a sperm reserve that is only about equal to the number of spermatozoa found in an ejaculate, whether at sexual rest or not.[414,415]

One would expect that the luminal environment required for the storage of spermatozoa in the cauda epididymis versus that required for the acquisition of fertilizing ability would be different. Though many differences have been described in the luminal make-up of ions, small organic molecules, proteins and glycoproteins between the cauda and the rest of the epididymis (see below), those special conditions that allow for the storage of spermatozoa in a quiescent state for long time periods in this tissue have not yet been elucidated, although changes in pH,[164,416,417] in several species and the presence of immobilin in the rat and hamster[416,418] have been proposed to be major factors.

Although it is clear that the major function of the distal segments of the epididymis is to store mature, live spermatozoa, other functions have been ascribed to this tissue. Abnormal appearing or dead spermatozoa have often been seen within the cauda epididymidis,[419,420] and the ability to recognize such spermatozoa and then to develop a mechanism to neutralize or destroy them has been proposed by several groups. Sutovsky et al.[421] proposed that the cell-surface ubiquitination of defective spermatozoa supplies the necessary signal for these cells to be phagocytosed by epididymal principal cells, thus providing a mechanism for sperm quality control. However, based on extensive histological observations of the normal epididymal epithelium and the rarity with which sperm phagocytosis is observed, it is apparent that

phagocytosis of spermatozoa is an unlikely mechanism for the disposal of the large number of spermatozoa produced daily.[422] The release from rat semineferous tubules of a large number of immature germ cells induced by the administration of a microtubule inhibitory agents such as colchincine results in the phagocytosis of immature germ cells by epididymal epithelial cells, but this is limited to the initial segment and is observed only when such stressors are applied.[423] In the mouse, Ramos-Ibeas et al.[424] reported that all epididymal segments have the ability to phagocytose immature germ cells, but that this is is a rare event under normal physiological conditions. Although these studies leave open the possibility that the epididymis may serve as the first selective barrier for the exclusion of abnormal gametes along the male genital tract, it is likely that if a quality control system is present in the epididymis, it is subtle and requires further investigation.

Studies from Olson's group[425,426] have identified a fibrinogen like protein (FGL2) that is secreted selectively in the proximal cauda epididymis of the hamster and that binds to and coats nonviable, but not viable, luminal spermatozoa. Unlike the hypothesis of Sutovsky's group, these investigators propose that the epididymis possesses a specific mechanism to identify and envelop defective spermatozoa with a protein complex containing the fibrinogen-like protein FGL2 that remains within the epididymal lumen. Both of these novel mechanisms require that epididymal epithelial cells have the ability to somehow recognize and tag defective spermatozoa. Although conceptually appealing, more extensive studies using different species and means of creating "abnormal" spermatozoa, such as drug treatments, are required to establish this as a function of the normal epididymis.

Jones[427] has hypothesized that following androgen withdrawal, either by orchidectomy or as a result of seasonal variation in seasonal breeders, a death pathway is activated that leads to the dissolution of spermatozoa. Such a mechanism would ensure that the epididymis is cleansed of defective and dead spermatozoa in preparation for the next breeding period. How androgen withdrawal would activate such a pathway remains to be determined, but it is interesting to note that many genes are activated in the epididymis after orchidectomy.[428,429]

In a series of studies on the evolution of the scrotum, Bedford proposed that the prime moving force behind the formation of the scrotum was the need to store spermatozoa at a low temperature;[305,430,431] he suggested "that migration to a scrotal site has been ordained primarily by the sperm storage region—the cauda epididymis—and that the function of the testis has only been an incidental factor in this evolutionary development."[431] This proposal was based on anatomical observations and on some physiological studies where the epididymis was placed abdominally while the testis remained in the scrotum; the rate of sperm passage through the cauda epididymis was found to increase about twofold in the rabbit after such a procedure. This hypothesis has been re-examined by several investigators. Werdelin and Nilsonne[432] proposed that the scrotum evolved before mammals and has been lost in many species because testicular descent is a "costly process" and that it is replaced when an alternative solution to the problem of the temperature sensitivity of spermatogenesis is available. Kleisner et al.[433] proposed that the diversity in the position of the testis-epididymis results from the need to provide conditions suitable for sperm development and storage. Although all of these theories are plausible, the fact remains that sperm are stored in the cauda epididymis, in most mammalian species, at lower than core or testicular temperatures.

Sperm Protection

It is clear that the blood–epididymis barrier allows for the production of a specialized luminal fluid microenvironment that is important for sperm maturation. However, another critical role played by this barrier is protection of the maturing spermatozoa. In addition, a series of elaborate defense mechanisms that help to protect spermatozoa from the immune system, harmful xenobiotics and reactive oxygen species have been developed in the epididymis. The defense mechanisms include restricting the types of compounds that can enter the epididymal lumen, the synthesis and secretion of specific proteins such as the defensins and defensin-like molecules, rapid elimination of potential harmful agents through the synthesis and secretion of antioxidant and conjugating enzymes, and the synthesis and secretion of antioxidant compounds such as glutathione and taurine. Because spermatozoa mature in a hyperosmotic environment, the epididymis also ensures that the spermatozoa are protected from potential rapid changes in osmolality and that spermatozoa can regulate their cell volume.

By 1950, it was shown that spermatozoa are highly susceptible to oxidative damage and that hydrogen peroxide was responsible for loss of motility and cell death.[434,435] Through a series of well-designed studies, Jones et al. clearly showed that when spermatozoa were incubated under aerobic conditions, they produced an organic peroxide and released a substance that was believed to be a lipid.[436–439] When incubated in the presence of lipid peroxides, spermatozoa became irreversibly immotile and released numerous intracellular enzymes. From these series of studies, it was suggested that incubation of spermatozoa under aerobic conditions resulted in lipid peroxidation by peroxides and/or lipid radicals that were responsible for structural damage, loss of motility, decline in metabolic activity and release of intracellular enzymes.

Since mammalian spermatozoa have a high content of polyunsaturated fatty acids in their membranes, they are highly susceptible to lipid peroxidation by reactive oxygen species (ROS).[438–441] It is crucial that spermatozoa be protected from the deleterious effects of too high a production of ROS as they progress along the epididymal duct; lipid peroxidation of membranes has been correlated with mid-piece defects,[442] decreased motility due to axonemal defects and reduced intracellular ATP levels,[443–445] as well as impaired capacity for fertilization (reviewed in Refs 442,446). There exists a delicate balance between the formation of ROS needed for sperm function and production of too much ROS that will damage sperm membranes and DNA Spermatozoa can protect themselves from ROS via the presence of superoxide dismutase, catalase, glutathione peroxidases, glutathione transferases, and other enzymes regulating the balance between the production and elimination of ROS.[445–448] These enzymes protect spermatozoa from lipid peroxidation by ROS via dismutation of the reactive oxygen to hydrogen peroxide and water; hydrogen peroxide is then rapidly converted to water via the enzymes catalase and/or glutathione peroxidase; alternatively it is conjugated to glutathione.[442,446,449–453]

In a continuing effort to prevent the oxidative damage to spermatozoa, the epididymis has developed an elaborate system to ensure that spermatozoa are protected as they mature along the epididymal duct. Each region or segment of the epididymis has developed its own sperm protective mechanisms primarily because (1) the metabolic activity differs from one region to the next, thereby producing different ROS species that need to be eliminated appropriately, and (2) spermatozoa are in a different state of maturity in each region, and therefore differ with respect to susceptibility to oxidative damage. For example, spermatozoa need to be especially protected from ROS as they enter the initial segment. The luminal fluid in this region is highly oxygenated,[454] the epithelial cells are surrounded by a dense capillary network,[455] with blood flow exceeding that of the distal epididymal regions,[456,457] and the initial segment cells are highly metabolically active (reviewed in Ref. 458). This unique combination results in the generation of ROS from several sources, including the endothelial and initial segment epithelial cells (reviewed in Refs 442,446). Therefore, it is not surprising that the initial segment expresses antioxidant enzymes. In the distal epididymal regions, the epithelial cells are still metabolically active, and the spermatozoa are continually exposed to an oxygen-rich environment; however, the degree of vascularization is less compared to the initial segment. Hence, spermatozoa are still subjected to ROS production, but the type of ROS may well be different from the types produced in the initial segment. Hence, the distal epididymal regions have alternative strategies to protect spermatozoa.

The major antioxidant enzymes present in the epididymis include superoxide dismutase,[459,460] gamma-glutamyl transpeptidase,[461–466] glutathione peroxidases,[467–471] glutathione transferases,[167,472–475] peroxyredoxins,[475–478] and indoleamine dioxygenase.[479] In addition, the lumen of the epididymis contains antioxidant molecules including glutathione, taurine, and tryptophan as the substrate for indolamine dioxygenase. Each of these antioxidant enzymes and molecules is found to varying degrees throughout the length of the epididymis.

Hence, the epididymis plays a critical role in the protection of spermatozoa from oxidative stress and from harmful xenobiotics. Interestingly, the processes by which the epididymis protects spermatozoa have also been considered to be a prime target for the development of a male contraceptive.[442]

The Microenvironment for Maturation, Storage and Protection

From the previous discussion it is clear that the epididymis plays an important role in sperm maturation. Although the actual time spent in the epididymis may be important for the maturation process, spermatozoa must still undergo considerable remodeling and be protected and stored in a specialized luminal fluid milieu. Crabo[255] first recognized the importance of the epididymal microenvironment, "The consensus today is doubtless that the epididymis actively promotes maturation of spermatozoa. The natural way for the epididymis to exert this influence would be via regulation of the sperm cells' environment, i.e., epididymal plasma: the environment in the caudal portion should favor maximal survival time of the spermatozoa which may be stored there for relatively long periods, without losing their fertilizing power and motility." In view of several published comprehensive reviews on the formation of the epididymal luminal microenvironment,[189,226,480–486] this section will summarize the contributions of ions, organic solutes and proteins to the specialized luminal fluid milieu. Although much is known concerning the composition of the epididymal luminal fluid, more studies are needed to understand the precise contribution of each component toward sperm maturation.

Perhaps the most under-appreciated role of the epididymis is the manner by which the epididymis forms the microenvironment. To do this formidable task, the epithelium must be structured in a way such that it prevents and regulates the entry of blood-borne substances into the lumen; has the ability to synthesize, secrete and absorb components; and is arranged so that spermatozoa come into contact with the appropriate environment

at the appropriate time (this is the most challenging aspect to understand because it implies that each cell along the duct knows precisely what its neighbor(s) is doing); and can respond to spermatozoa, which in turn regulate the microenvironment. Hence, there is a series of complex and ever-changing interactions between the epididymal epithelium, the microenvironment and spermatozoa from the beginning to the end of this tube that is several meters in length.

Water Movement and Its Influence on the Formation of the Luminal Microenvironment

Before discussing the composition of the luminal fluid microenvironment, it is important that water movement be discussed. The efferent ducts and the epididymis are water transporting epithelia. Hence, the concentrations of ions, small organic solutes and proteins are dependent on the movement of water into and out of the lumen. Thus, the measured concentrations of any ion, small organic solute or protein in epididymal luminal fluid are not only due to direct secretion into the lumen but also to the amount of water that is being reabsorbed. Water movement out of the duct is quite extensive. For example, the water transporting ability of the efferent ducts of the quail almost matches that of the rat renal nephron, while in the rat it is only 5–10 times less than that of the proximal kidney tubule.[375] Remarkably, in several species, 70–96% of the fluid leaving the testis is reabsorbed in the efferent ducts; for example, 96% is reabsorbed in rats;[487] 90% in boars;[255] 87% in the tamar wallaby;[488] and 96% in the elephant,[489] with concomitant declines in sodium and chloride concentrations but increases in potassium and hydrogen ion concentrations from the rete testis to the caput region. Within 24 h of efferent duct ligation in the rat, there is a remarkable increase of nearly 50% in testicular weight due to accumulated fluid, thus demonstrating how effective the efferent ducts and epididymis are at removing large volumes of water.[490] From the caput region onwards, 95% of the remaining 5–10% water is reabsorbed, ultimately increasing the concentration of spermatozoa from approximately 10^4/ml in rete testis to 10^9/ml in the cauda epididymis.

Hence, when analyzing the concentration of various ions, small organic solutes, and proteins, it is important to take into account the reabsorption of water. For example, the increase in the concentration of some organic solutes seen from the caput to cauda epididymis may not necessarily be due to an increase in the secretion of that solute but entirely to water movement. Examples of this include carnitine and inositol.[491,492] However, if water reabsorption is taken into account when calculating what the total protein concentration should be, a much higher value is calculated compared to the actual value measured.[493] This would indicate that considerable protein is indeed being reabsorbed, a well-known role of the epididymis. A simple analysis of this kind may help determine the extent, if any, of movement of any solute across the epididymal epithelia from proximal to distal regions. It should be emphasized that the measured concentration of any ion, small organic solute or protein in the luminal fluid of any epididymal region is not only a product of secretion, absorption, and water reabsorption but also of sperm uptake, degradation, and/or metabolism.

Ionic Microenvironment

Crabo[255] and Levine and Marsh[494] were the first to show that the ionic luminal fluid composition of the epididymal duct is distinctly different from blood plasma. However, through a more thorough analysis of epididymal luminal fluid collected by micropuncture, we now have the exact ionic composition to which spermatozoa are exposed as they progress along the duct.[485,495–498] Briefly, spermatozoa move from an environment in the seminiferous tubule, which has a pH of approximately 7.3 and lower sodium concentration but higher potassium concentration compared to blood plasma (reviewed in Refs 485,497), to an environment in the initial segment/caput region with pH 6.5 and sodium and potassium concentrations closer to those measured in blood plasma. Spermatozoa then move into a progressively lower ionic environment from the caput to the cauda but into a progressively higher organic solute and protein environment (reviewed in Refs 482,485,486,497,499). Sodium, chloride, calcium and magnesium concentrations decline from the caput to cauda epididymidis but phosphorus (as phosphate) and potassium increase in concentration (Figure 17.13). The physiological importance of the ionic microenvironment is unclear, but it may be involved in the development of sperm motility and in keeping spermatozoa in a quiescent state as they mature.[500–503] More studies are needed to test the hypothesis that ions play a critical role in sperm maturation.

Organic Solute Microenvironment

As well as analyzing the luminal fluid ionic microenvironment, Levine and Marsh[494] also measured the osmolality of fluid collected from each epididymal region and then compared these values to the sum of osmotically active ions in each region. They noted a difference. This osmotic difference increased from the caput to cauda epididymis to reach over 250 mOsm/kg water; the investigators suggested that this difference was due to the presence of organic solutes. Later studies by several groups showed that this was indeed the case with the identification of solutes such as glutamate, taurine, L-carnitine, myo-inositol, glycerylphosphorylcholine, phosphorylcholine, sialic acids and many other amino acids being present

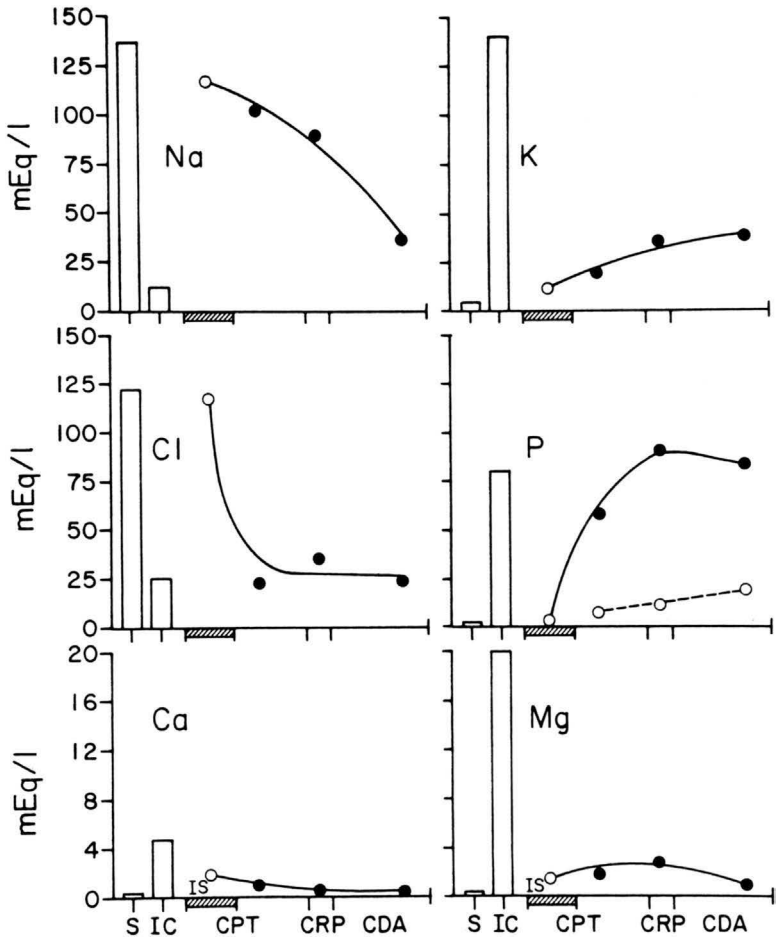

FIGURE 17.13 Serum, intracellular, and intraluminal concentrations of sodium, potassium, chloride, phosphorus, calcium, and magnesium in the rat epididymis. Serum (S) and intraluminal values are from Jenkins et al.[496] Intracellular (IC) values are those expected in typical somatic cells[504] and represent anticipated values in the epididymal epithelial cells; initial segment (IS), caput (CPT), corpus (CRP), and cauda (CDA) epididymidis. Data connected by hatched lines in the P panel are inorganic phosphate.[483]

in different concentrations through the epididymal duct of many species including man (reviewed in Refs 139,226,483,486).

The total concentration of organic solutes in the luminal fluid of the rat testis and epididymis increases from approximately 10–20 mM in the seminiferous tubule to 100–150 mM in the caput and to over 200 mM in the cauda epididymidis. The manner by which the epididymal epithelium forms an organic solute-rich environment is not completely understood, but there is considerable evidence to suggest that at least several transporters are involved in moving the solute from the blood into the lumen; in addition, the epididymis synthesizes and secretes solutes into the lumen. For example, L-carnitine is transported into the epididymal cells and lumen reaching concentrations as high as 50–60 mM in some species.[505–508] The high intraluminal concentration of L-carnitine translates into a remarkable 2000-fold gradient of L-carnitine across the epididymal epithelium. Several studies suggest that the distal caput, corpus and proximal cauda epididymidis are the regions involved in the active transport of L-carnitine.[509–513] The mechanism of L-carnitine transport in the epididymis is still not fully resolved, but it has been suggested that it involves an active transport system,[509,510,512,514] and that the transport is androgen-dependent.[512,515]

Some studies have suggested that L-carnitine is transported from blood into cells via the transporter OCTN2[516] and that its transcriptional activity is regulated by osmotic stress.[517] L-carnitine would then presumably move from cells into the lumen via the transporter CT2 that has been identified in the human epididymis.[518] Several transporters, such as OCTN2 and SMIT, a sodium-myo-inositol transporter, have *TonE* binding motifs on their promoters which bind a transcription factor TonEBP (Rodriguez and Hinton, unpublished observations) that is expressed during periods of hypertonicity; these data suggest that the organic solutes play a role in the regulation of water movement across the epididymal cell membranes. This is particularly important because in the epididymis of most species, spermatozoa are exposed to a hyperosmotic environment. Disruption of the ability of spermatozoa to regulate their cell volume has been suggested to cause male infertility.[519]

Although virtually nothing is known as to the roles of each solute, evidence suggest that these solutes play a critical role in the protection of spermatozoa and the epididymal epithelium from osmotic stress, similar

to the role played by these solutes in the kidney.[520,521] However, the high levels of organic solutes measured in the cauda epididymal fluid of several species would suggest that these high levels play a similar role in long term storage of spermatozoa in this region. Likewise, in bats that store spermatozoa in the cauda epididymis for up to 6 months, the spermatozoa are stored in a supra-physiologically high osmotic environment with luminal fluid osmolality being measured at greater than 1000 mOsm/kg water;[522] the mechanisms for generating and maintaining such a high osmolality are not known. Taurine and glutathione are both found in epididymal luminal fluid;[523,524] because both of these compounds have been implicated in protecting cells from oxidative stress, it would not be surprising if they have a similar role in the epididymis.

The transport of sugars and amino acids including inositol, 3-O-methyl-D-glucose, 2-deoxy-D-glucose (nonmetabolizable forms of glucose) and alpha-aminoisobutyric acid (AIB; a nonmetabolizable neutral amino acid) have been studied in the rat epididymis.[525–530] From these studies several observations were noted. First, glucose entered via a facilitated diffusion mechanism and this uptake appeared to be similar across all epididymal regions. Second, glucose transport was inhibited by the male infertility agents, alpha-chlorhydrin, 5-thio-D-glucose and 6-chloro-6-deoxy-glucose. Third, transport of inositol and AIB was highest in the initial segment compared to the rest of the epididymis. Finally, transport of inositol and AIB was saturable and, presumably, transport of inositol was via active transport whereas that of AIB was via a facilitated diffusion mechanism. Presumably, the glucose and amino acid needs of the epididymis reflect its metabolic needs and that of maturing spermatozoa. However, more studies are needed to examine the roles played by each solute. The role of known specific ion and organic solute transporters that have been identified in the epididymis will be discussed in greater detail later in this chapter.

The androgen luminal fluid microenvironment has received little attention recently but past studies have revealed that the spermatozoa are exposed to a complex rich androgen environment as they progress along the duct.[483] In several species, including rat, human, hamster, stallion and bull, the epididymal luminal fluid concentrations of testosterone and dihydrotestosterone (DHT) were shown to exceed the blood concentrations,[531–533] with DHT concentration being very high in the caput region. Presumably, the high luminal fluid androgen concentrations are maintained by androgen binding protein (ABP). It has been proposed that the ABP-androgen complex plays a role in epididymal function,[534] but confirmatory experiments have yet to be designed to test this hypothesis.

Protein Microenvironment

The protein composition of epididymal luminal fluid has been well studied for a number of species.[147,535–537] Spermatozoa are exposed to varying protein concentrations as they move along the seminiferous tubule (approximately 6–10 μg/μl) to the rete testis (approximately 1 μg/μl) to the caput and cauda epididymis (approximately 25–30 μg/μl). Because water is being absorbed along the epididymal duct a higher protein concentration would have been expected in the cauda compared to the caput epididymis. Hence, to account for this difference, proteins are presumably being absorbed and/or being degraded and/or being utilized by the spermatozoa. However, even though the net movement of protein is via absorption, many proteins are still being synthesized and secreted into the duct.

The proteomic profiles in epididymal luminal fluid have been analyzed by one and two-dimensional gel electrophoresis,[538] generating characteristic patterns of protein profiles for several species. Using an in vivo split-drop stopped-flow microperfusion technique together with two-dimensional gel electrophoresis and both silver staining and western blot analyses,[539] showed in vivo protein secretion into the lumen of discrete epididymal segments and regions. Later studies by Turner and colleagues,[540,541] showed similar data when the interstitium was perfused with radiolabeled methionine and luminal fluid collected by micropuncture and analyzed for radiolabeled proteins. Many of the proteins in the lumen of several species have now been identified using mass spectrophotometric methods.[536,537,542]

Epididymal luminal fluid contains a large repertoire of proteins including enzymes, growth factors, lipid-binding proteins, iron-binding proteins, proteins that may be involved in protection or in sperm–egg binding, and other proteins such as the lipocalins, clusterin, lactoferrin, or CTP/HE1.[543] Many of these families of proteins will be discussed below.

REGULATION OF EPIDIDYMAL FUNCTIONS

Hormones

In 1926, pioneering studies by Benoit demonstrated that the epididymis is dependent on an unknown testicular substance for maintenance of its structure and functions; he showed that the ratio of nucleus/cytoplasm in the mouse epididymis decreased after birth as the epididymis differentiated, and increased dramatically after orchidectomy, as the epididymis dedifferentiated.[14] This regulatory substance was identified five years later as testosterone.[544] Since then, more than a thousand papers have appeared on the response of the epididymis

in numerous mammals to androgen withdrawal and replacement on a wide variety of endpoints, ranging from morphological to biochemical and molecular.

The main approach to understanding the effects of androgen withdrawal on the epididymis has been removal of the testis. It is clear that this approach causes not only loss of androgens but also estrogens and any other testicular factor that may affect the epididymis. Orchidectomy causes a decrease in epididymal weight that is less marked than that of sex accessory tissues such as the prostate or seminal vesicles.[545,546] Unlike the case with other androgen-dependent male reproductive tissues, testosterone replacement, even at supraphysiological levels, only partially restores epididymal weight; this is due to the large proportion (nearly half) of the epididymal weight that is attributable to spermatozoa and the luminal fluid bathing them.[546,547] In the androgen-deprived state, spermatozoa do not gain the potential for motility, lose the ability to fertilize and eventually die.[14,263,548] Administration of antiandrogens, such as flutamide, to adult animals or to animals going through puberty, results in an accelerated sperm transit time through the epididymis, impairment of sperm motility and decreased ability of the cauda epididymis to store sperm[549,550]

After orchidectomy, the luminal diameter and epithelial cell height decrease and the intertubular stroma increases.[551,552] The smooth endoplasmic reticulum content is dramatically reduced, whereas the extent of the decline in the Golgi apparatus is less pronounced.[553–555] Morphological changes in principal cells suggest that these cells are particularly sensitive to androgen levels, in contrast to the other epithelial cell types, which appear to be less affected by orchidectomy.[157] The secretory function of principal cells becomes compromised in the androgen-deprived state. In addition to the virtual disappearance of endoplasmic reticulum from their apical cytoplasm, principal cells undergo a striking loss of apical microvilli from their surface, as well as lysosome accumulation, vacuolization, disappearance of vesicles from the cell apex, and increased endocytosis.[157,402] Epididymal androgen receptors and 5α-reductase activity are both decreased in the androgen-deficient state,[546,556–558] suggesting that the mechanisms of androgen action are compromised by androgen-withdrawal. Total epididymal protein, RNA and DNA content are reduced following orchidectomy but DNA concentration is apparently increased.[559] The relative increase in DNA concentration is attributed to the concomitant decline in cell volume; this is thought to be the principle mechanism by which the epididymal epithelium regresses after orchidectomy.

Restoration of circulating testosterone levels appears sufficient to reverse regressive changes in the caput, corpus and cauda epididymidis after orchidectomy but not in the initial segment, even when supraphysiological doses of testosterone are administered.[546,552,555,560–563] At three days following orchidectomy with testosterone or dihydrotestosterone (DHT) replacement to circulating levels, a time at which the prostate shows maximum rates of DNA synthesis, the epididymal labeling index, measured either by ^{3}H-thymidine incorporation or bromodeoxyuridine incorporation and mitotic index, is low except in the corpus region.[552,564] The small effect of androgens on mitotic index in the epididymis of the adult animal was similar for all cell types and distinguishes this tissue from other androgen-dependent tissues such as the prostate and seminal vesicles where androgens have a dramatic effect on proliferation.[552] This characteristic of the epididymal epithelium suggests that it may contain anti-proliferative signals that inhibit cellular proliferative capacity in response to androgen-stimulation or other stimuli. Interestingly, B-MYC, a transcription factor known to inhibit cellular proliferation, is highly expressed in the epididymal epithelium.[565]

Withdrawal of androgen by orchidectomy induces a wave of apoptotic cell death in the epididymis beginning in the initial segment and moving over several days to the cauda epididymidis.[110,566,567] Apoptosis in the initial segment seems to be caused by withdrawal of androgen and of luminal components coming from the testis and be p53 independent.[568] Using the entire epididymis, BCL-2, an anti-apoptotic factor, was found to be suppressed by 36 h after orchidectomy; this was followed by the appearance of Fas and DNA fragmentation in the epididymal epithelium at 48 h post-orchidectomy.[569] Mutant mice null for *Fas* showed no epididymal regression or DNA fragmentation after orchidectomy.[570] These data suggest that the regression of the epididymal epithelium after orchidectomy may be regulated through the FAS pathway.

Several studies point to the rapid action of steroids, as opposed to the slower, nuclear-receptor mediated response. For estradiol, it is now well established that such a mechanism is an integral component of hormone action[571,572] and involves steroid action at the cell membrane resulting in the activation of a signal transduction pathway. For androgens, Walker and his colleagues have demonstrated that such a mechanism exists for Sertoli cells[573] (see also Chapter 16). It has also been shown that androgen action can be as rapid as 1 min after exposure to androgen in an epididymal principal cell line.[574] The relative role of this signaling mechanism, as opposed to the more traditional nuclear receptor mediated mechanism remains to be elucidated.

In addition to androgens, many other hormonal factors have been postulated to play a role in regulating epididymal function; these are listed in Table 4 (supplemental material at http://www.medicine.mcgill.ca/PhysiolReprodEpidi dymis/). Of special note however, is estradiol. It has been known for many years that the administration of estrogens could affect the male

reproductive system in general[575–579] and the epididymis in particular.[245,580] With the advent of aromatase specific inhibitors and null mutation mice for the two isoforms of the estrogen receptor (discussed below), it is now clear that estrogens act as regulators of some specific epididymal functions;[581] however, much remains to be done to resolve exactly what role this steroid family plays.

Testicular Factors

In addition to being dependent on the presence of circulating androgens (reviewed in Ref. 578), the epididymis is also dependent on the presence of luminal fluid factors originating from either the testis and/or the epididymis itself. Without testicular luminal fluid factors many cells within the initial segment undergo apoptosis within 24 h.[566,567,582] Therefore, it is not surprising that ligating the efferent ducts results in changes in morphology and gene expression in the initial segment.[48,145,583] From these studies, it has been postulated that a factor(s) originating from testis is/are responsible for maintaining the integrity and survival of cells within the initial segment. This type of paracrine secretion has been termed lumicrine because the processes regulated are occurring within a duct/tubal system.[583] A general scheme depicting how factors secreted directly into the epididymis via the efferent ducts can affect activities of cells in the initial segment and how such effects can cascade down the duct is depicted in Figure 17.14. Perhaps the first studies demonstrating lumicrine regulation in the male excurrent duct system was those by Skinner and Rowson in the 1960s.[585,586] These investigators showed that the ampulla of the vas deferens weighed less, contained less fructose and was smaller in diameter following unilateral vasectomy compared to the ampulla on the control intact side. Skinner and Rowson[586] suggested that vasectomy prevented luminal fluid testosterone from reaching the ampulla, and, to test this hypothesis, they perfused the vas deferens of an orchiectomized ram with testosterone. Their data showed that the ampulla of the perfused side weighed more, contained more fructose and citric acid compared to the nonperfused control side. Similarly,

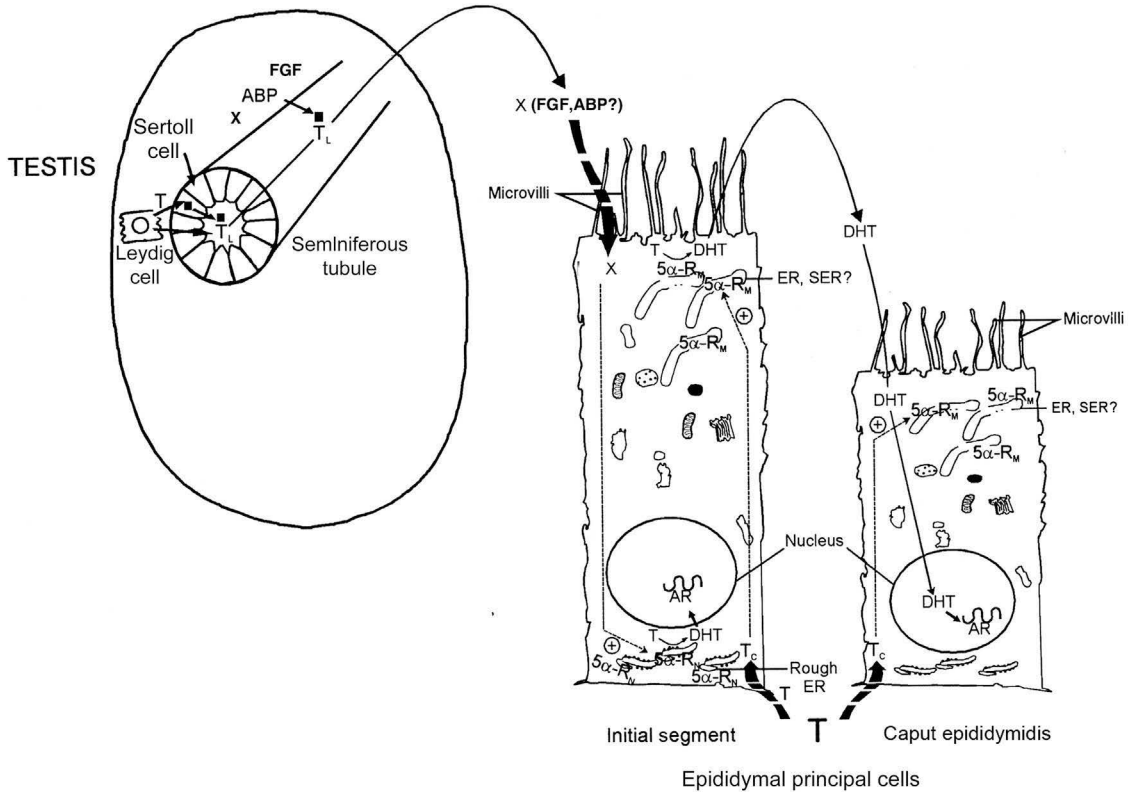

FIGURE 17.14 Proposed mechanism for the regulation of SRD5A and androgen action in the rat epididymis. Leydig cells synthesize testosterone (T), which stimulates the Sertoli cell to secrete ABP and other proteins into the lumen of the seminiferous tubule. In the initial segment of the epididymis, the paracrine/lumicrine regulator (e.g. FGF, ABP) is proposed to be the paracrine factor regulating the infranuclear localized steroid 5α-reductase enzyme (5α-R, SRD5A). In contrast, the apically localized 5α-reductase enzyme (microsomal 5α-reductase, 5α-R_M) found throughout the epididymis is under the control of circulating androgens. The synthesis of locally high concentrations of DHT in the initial segment of the epididymis provides an excellent mechanism for stimulating critically important androgen-dependent genes in this region of the epididymis and for providing the most active androgen to mediate androgen action in the rest of the tissue. ABP, androgen binding protein; 5α-R_N, nuclear SRD5A; 5α-R_M, microsomal SRD5A; ER, endoplasmic reticulum; SER, smooth endoplasmic reticulum; DHT, dihydrotestosterone; T, testosterone. *Source: Modified from Ref. 584.*

Abe et al.[79] show that ligation of the mouse corpus epididymidis results in abnormal differentiation of the principal cells downstream from the ligature. Hence, lumicrine regulation may not only occur between the testis and epididymis but also between regions of the epididymis including the vas deferens.

Although testicular luminal fluid steroids, androgens and estrogens, are the most obvious candidates for regulating initial segment function, several lines of evidence suggest that additional factors are important. Using a histological approach, Fawcett and Hoffer,[555] supported the idea that factors other than androgens are responsible for the maintenance of initial segment function because the morphology of the initial segment cells failed to return to normal following efferent duct ligation (EDL) and testosterone treatment. Likewise, Nicander and colleagues,[582] suggested that since the cells within the initial segment are highly mitotic, they are more dependent upon the presence of a mitogen(s) within testicular luminal fluid.

The first nonsteroidal molecule proposed to be a testicular factor acting on the epididymis was ABP.[533,587] This hypothesis stemmed from a series of studies demonstrating that the steroid 5α-reductase activity in the initial segment of the epididymis fell after EDL or unilateral orchidectomy; it could not be maintained by administration of testosterone, even at very high doses. Luminal fluid ABP was also proposed as the factor that enhances the function of ovine epididymal principal cells in culture,[588] appears to play a role in protein synthesis in the caput region,[589] and has the ability to bind and be internalized by epididymal principal cells.[590,591] However, although gamma-glutamyl transpeptidase mRNA IV (GGTIV) is also controlled in a lumicrine manner in the initial segment of the epididymis, ABP does not play a role in its expression.[592] Instead, fibroblast growth factors (FGFs) may be partly responsible for the regulation of expression of this gene.[592–594] It has been postulated that luminal fluid growth factors interact with their cognate receptors on the apical cell surface of initial segment cells whereupon a signal transduction pathway is initiated (e.g. MAPK, PI3 kinase); transcription factors are then activated, presumably by phosphorylation leading to transcription of target genes.[583,593] In support of this hypothesis soluble FGFs (2,4 and 8) have been identified in testicular luminal fluid, and FGFR-1 IIIc (both long and short forms) have been identified in the principal cells within the initial segment.[592,593] Further, the activity of the MAPK pathway and the expression of members of the PEA3 (ETV4) transcription factor family (ETV1, ETV4 and ETV5; ER81, PEA3, and ERM, respectively) are decreased following loss of testicular factors.[594–597] The cascade of signaling pathway events leading to initial segment cellular apoptosis following loss of lumicrine factors has been described.[596] From this study it appears that under normal physiological conditions, lumicrine factors maintain initial segment cell survival (prevent apoptosis) by maintaining the activation of the ERK pathway, suppressing stress-related signaling pathways and proapoptotic phosphatases and cell cycle inhibitors. Sipila and colleagues[598] also showed that etv4 mRNA expression was regulated by ERK signaling but not via protein kinase C, stress-activated p38, phosphoinositol 3-kinase nor p70 kinase cascades in an immortalized epididymal cell line. It is also very clear that the presence of the androgen receptor within the cells of the initial segment is vital for normal initial segment function.[94,599,600]

Another "factor" that has been postulated to regulate initial segment function is the presence of spermatozoa.[601] At first, cells seem to be an unusual "ligand", yet, upon closer inspection, there may be a sound basis for this hypothesis. Spermatozoa themselves may not be the "ligand", but it may be that the ligands that they carry and transport to the different epididymal regions that are important; many molecules are known to bind to spermatozoa and potentially shed in the epididymis. Interestingly, testicular spermatozoa stain positively for growth factor receptors;[602] it is tempting to speculate that upon entering the initial segment, growth factors dissociate from the sperm surface and are now available to stimulate their cognate receptors on the epididymal apical cell surface.

Lumicrine regulation is not necessarily restricted between the testis and the epididymis, but appears to operate along the entire length of the epididymis. An example is the potential function of BMP8A that is secreted by the initial segment and acts downstream in the cauda region.[603] Of further interest is that *RNase10*, which is highly expressed in the initial segment and under the regulation of lumicrine factors, is important for male fertility.[95]

MAJOR PROTEIN FAMILIES IN THE EPIDIDYMIS AND THEIR REGULATION

General Principles

The division of the epididymis into segments has more than anatomical implications. For many years, the differential expression of proteins and mRNA along the epididymis has become a hallmark of this tissue. Indeed, the large number of gene expression profiling studies,[71,432,475,604–616] proteomic analyses,[152,543,617–625] and microRNA and piRNA analyses[626–630] have all revealed that nearly all molecules have characteristic longitudinal expression profiles in the epididymis of all species examined. Data on the gene expression profiles of the different segments of the rat and mouse epididymis are available at http://mrgd.org/index.cgi. In addition, tables of some genes encoding distinct

classes of proteins (enzymes, signaling, DNA binding) that exhibit regionalized expression in the epididymis are provided in the supplemental material on this chapter's Website. Table 2 lists genes encoding secretory proteins which may perform direct or indirect roles in the sperm maturation process while Table 3 provides a list of genes that encode cellular proteins which likely perform regulatory functions (supplemental material at Website).

Although all of the above studies clearly demonstrate that there is a highly regionalized activation and deactivation of gene expression, the underlying mechanism(s) that allow for this regulation is unclear. Regionalized expression of transcription factors (see below) is beginning to provide some insight into this question; the relationship between the luminal, endocrine and cellular components that allow for such highly regionalized expression of genes, proteins and noncoding RNAs will require many more years to resolve.

Immunohistochemical staining of cross-sections of the epididymal epithelium for most proteins reveals a checkerboard pattern of expression. This characteristic pattern is usually seen when a given protein or mRNA is first expressed along the duct or when the expression terminates. The reason for this unique distribution of expression of genes and proteins in the epididymal epithelium is not clear. It can be assumed that adjacent principal cells either have different sensing mechanism for triggering the signal for expression of a given gene or protein, or, more likely, that principal cells function as a syncytium to coordinately optimize the level of expression of a given gene or protein. Three examples of this checkerboard pattern of expression are shown in Figure 17.15.

As one might expect based on their appearance and proposed functions, the different cells of the epididymal epithelium express different genes and proteins. Isolating each of the different cell types has been a challenge, but with the development of tools such as laser capture microscopy, it should become possible to resolve the profiles of genes and proteins expressed in each type of epithelial cell. Using immunohistochemistry, however, it has been possible to demonstrate that highly specific expression of certain proteins in principal, basal, clear, narrow and halo cells. In Figure 17.16, examples of the selective marking of each of these cell types is presented. More contemporary approaches now include labeling cells with an epithelial cell-specific promoter driving a reporter gene such as green fluorescent protein (GFP). The GFP-positive cells are then sorted, isolated and analyzed, e.g. Ref. 152. In order to provide potential tools to help identify cell types in vivo and in vitro, representative proteins expressed selectively in individual cell types of different regions of the epididymis are listed in Table 4 (supplemental material at Website); some of these proteins are secreted, while others are retained within the cell.

Functional Families

Ligands, Their Biosynthesis and Receptors

ANDROGEN RECEPTOR, ANDROGEN BINDING PROTEIN, AND STEROID 5α-REDUCTASES

The limiting factor in determining the action of testosterone on cells is not clear. The presence of both the

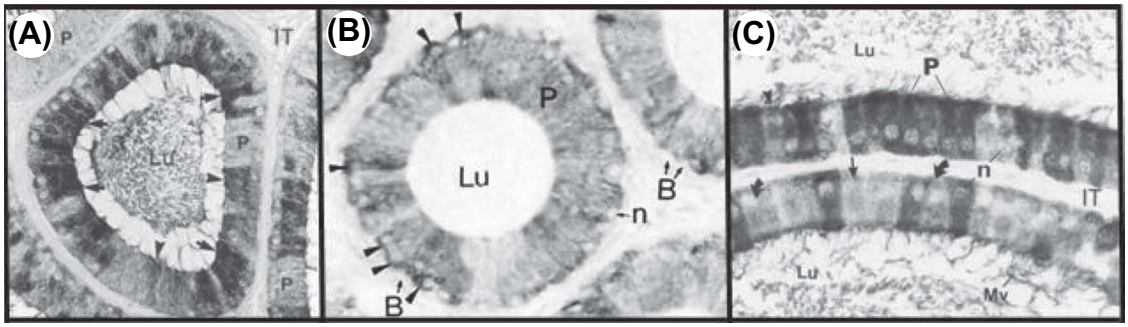

FIGURE 17.15 Representative examples of the checkerboard pattern of protein expression seen immunohistochemically along the epididymis. (A) High power light micrograph of tubules of the distal area of the initial segment immunostained with anti-immobilin. Although many principal cells are reactive, they show a variable staining pattern. Several principal cells are intensely stained throughout their cytoplasm (arrows), while others are moderately or weakly stained (arrowheads); a few are unreactive (P). The luminal content (Lu) is well stained. IT, intertubular space. ×350.[135] (B) High power light micrographs of the proximal initial segment of the epididymis stained for SDR5A. Epithelial principal cells (P), nuclei of principal cells (n), basal cells (B), and lumen of the duct (Lu) are shown. Intense staining in the infranuclear region of the principal cells is designated by the arrowheads. Magnification ×400.[452] (C) Higher power micrograph of portions of adjacent tubules of the caput epididymis immunostained with anti-SGP-2. Note intense immunoperoxidase staining reaction product over some epithelial principal cells (P). Other principal cells are moderately (arrowheads) or weakly (curved arrows) immunoreactive. A few principal cells are virtually unreactive (arrow). Note that the reaction product extends throughout the entire cell cytoplasm, i.e. basal, supranuclear and apical regions, leaving only the nucleus (n) unstained. The microvillar (Mv) border of the principal cells and sperm in the lumen (Lu) of the tubules are reactive. IT, intertubular space ×600.[632] *Source: Micrographs are modified from Refs 135,452,631.*

androgen receptor and an agonist are clearly necessary, but there are several lines of evidence that indicate that it is not primarily the absolute number of androgen receptors present but rather the amount of the ligand that is limiting. In addition, testosterone, a highly lipophilic molecule, is carried to sites distant from where it is made by binding proteins such as ABP. Testosterone can act directly on the androgen receptor in some tissues, such as muscle; in other tissues, such as some brain nuclei, testosterone needs to be aromatized to estradiol in order to mediate its action via the estrogen receptor; while still in other tissues, it is converted to a 5α reduced metabolite, DHT.[633] DHT binds to the androgen receptor with higher affinity than testosterone.[633–636] This latter mode is what occurs in many androgen dependent tissues such as the epididymis, prostate, seminal vesicles, and skin. The rate limiting step in the pathway leading from testosterone to its 5α-reduced metabolites is by steroid 5α-reductases (SRD5A1 and SRD5A2).

ANDROGEN RECEPTOR The first report that exogenously administered testosterone was converted to DHT and bound a cytosolic protein in the epididymis (the androgen receptor),[637] was nearly coincident with the discovery of a second androgen-binding component (androgen binding protein, ABP) in testis and epididymal cytoplasmic fractions.[638] Although both of these proteins bind androgen with high affinity, they are distinct molecules. For example, although they both have high affinity for DHT, the androgen receptor has a slow dissociation rate for DHT ($t_{½}$ 0 °C >4 days), while ABP dissociates at a much faster rate ($t_{½}$ 0 °C = 6 min). Androgen receptors have been found in the epididymis of all species examined to date (rat, rabbit, dog, ram, monkey, and human).[637,639–645] In all mammalian tissues, a single gene for the androgen receptor has been identified. In man, the gene spans approximately 90 kb, and it consists of eight exons on chromosome Xq12. The coded protein is approximately 110 kDa, and multiple transcripts are produced with variable lengths of a polymorphic region of CAG repeats in exon-1.[634,636,646,647] The gene contains two polymorphic trinucleotide repeat segments that encode polyglutamine and polyglycine tracts in the N-terminal transactivation domain of its protein; mutations in this gene can be associated with complete androgen insensitivity, but this depends on the severity of the mutation. Alternatively spliced variants encoding distinct isoforms have been described[647,648] but the consequences

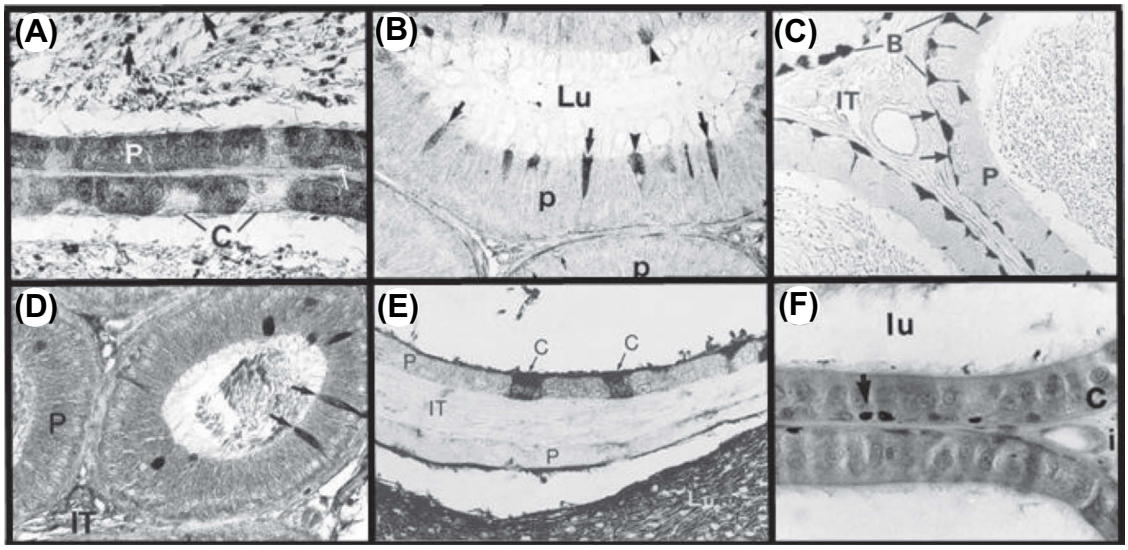

FIGURE 17.16 Cell specific expression of proteins along the rat epididymis. Examples of immunolocalization of proteins in each of the major cell types are presented. (A) Principal cells (junction of the caput-corpus of the epididymis) are immunostained for the glutathione S-transferase (GST) Yo subunit. The epithelial principal cells (P) are well stained, but basal (white arrow) and clear (C) cells are unreactive. Cytoplasmic droplets of spermatozoa (arrows) in the lumen are intensely reactive. ×365 [632]. (B) Apical cells (arrowheads) and narrow cells (large arrows) of the proximal initial segment of the epididymis are intensely reactive when immunostained with anti-Yo GST antibody, while principal cells (P) and basal cells (small arrows) are unreactive (Lu, lumen; ×320).[149] (C) Basal cells. The only cell type of the epithelium of the corpus epididymidis that is intensely reactive is the basal cell (B) when immunostained with antibodies to the Yf (Yp) subunit of GST. These cells often show slender processes (arrows) extending from the expanded main cell body along the basement membrane and, occasionally, toward the lumen (arrowheads). Principal cells (P) appear unreactive. Spermatozoa in the lumen are unreactive. IT, intertubular space. ×440.[167] (D) Narrow cells. Initial segment of epididymides immunostained with anti-carbonic anhydrase II antibody. Intense reaction is localized over narrow cells. P indicates principal cell; IT, intertubular space; and arrows, narrow cells (×350).[151] (E) Clear cells. Tubules of the distal area of the cauda epididymidis immunostained with anti-immobilin. Note that several epithelial clear cells (C) are intensely reactive throughout their cytoplasm, while other cells remain unreactive. IT, intertubular space; P, principal cells. X 375.[141] (F) Halo cells. Immunostaining with an antibody for helper T lymphocytes (CD4) in the cauda epididymidis. Arrow, CD4-positive cells; lu, lumen. X450.[175] *Micrographs are modified from Refs 141,149,151,167,175,632.*

for epididymal function of these alternate splicings have not been examined.

There are relatively small changes in the concentration of the mRNA for the androgen receptor along the epididymis.[584,649] When changes are noted, they often reflect a decline in the concentration of androgen receptors in the progression toward the distal end of the epididymis. For example, in the human, both the mRNA and protein for the androgen receptor are found throughout the entire tissue with high levels in the distal caput and proximal corpus, declining in the caudal region, including the vas deferens; interestingly the efferent ducts do not show any immunostaining while the vas deferens is only weakly positive.[641] An exception is the ram where androgen receptor concentrations are similar in the caput and cauda epididymidis but are less than 25% of these levels in the corpus epididymidis.[650] In both the rat and the goat, epithelial cells stain fairly evenly for androgen receptors throughout the duct.[651,652]

It is clear that principal cells stain heavily for androgen receptors, but the relative concentration of this receptor in basal, clear, narrow and apical cells is not known. However, the immunolocalization of androgen receptors in all epididymal epithelial cells has been reported for monkey, mouse, and goat,[645,653,654] while in the rat, it is apparent that clear cells do not stain for the androgen receptor.[558] Due to their origin in the immune system, and as one might anticipate, halo cells do not stain for the androgen receptor in any species examined. Peritubular cells occasionally display weak signals, while interstitial cells or blood vessels are consistently negative. When noted, the intracellular localization of the androgen receptor is distinctly nuclear.

Very few studies have focused directly on the mechanism of action of the androgen receptor in the epididymis; however, with the advent of several stable cell lines from this tissue,[598,655–658] some studies have been undertaken. Using the mouse PC-1 cell line, it was shown that DHT can cause a rapid response that is independent of the androgen receptor–DNA interactions and that this response is mediated by activation of the ERK pathway as early as 1 min after exposure to DHT;[574] interestingly, activation of the ERK pathway was blocked by hydroxyflutamide, indicating that early ERK activation was an androgen receptor-mediated response. Such a rapid action of androgen may ultimately act to modulate the transcription of genes regulated by AR in the nucleus.

The characteristics and mode of action of the androgen receptor as a transcription factor[552,633,636,659] in the epididymis seem to resemble those seen in other tissues. However, androgen signaling, although essential, is not sufficient for epididymis-specific gene expression since androgen receptor is expressed in many tissues. One mechanism proposed to explain the specificity of transcriptional responses to androgen is the tissue-specific combination of transcription factors binding to the promoter region of androgen regulated genes.[660] For example, the epididymal and prostatic lipocalin genes E-RABP and probasin are regulated by the androgen receptor. In the prostate, the transcription factor Foxα1 is required for probasin gene expression.[661] In the epididymis, Foxα2, but not Foxα1, is expressed, interacts with the androgen receptor and binds to the promoter of the E-RABP gene. Interestingly, overexpression of Foxα2 suppresses androgen activation of the E-RABP promoter, but increases activation of the prostate-specific promoter in an androgen independent manner.[662] Since Foxα1 and Foxα2 expression is restricted to the prostate and epididymis, respectively, it suggests that these transcription factors have distinct and different action on androgen receptor regulated genes in different male reproductive organs. It is tempting to speculate that these differential responses may have a role in the different response of these two organs to oncogenic transformation.

Little is known about the regulation of expression of the androgen receptor in the epididymis. In the goat, circulating androgens seem to be sufficient to regulate the expression of both androgen and estrogen receptors.[654] In the rat, androgen withdrawal achieved by suppression of LH by the administration of an GnRH antagonist results in a more extensive and rapid decline in androgen receptors in stromal than in epithelial cells; androgen replacement results in a complete restoration of androgen receptors, indicating that stromal cells are more sensitive than epithelial cells to the regulation of androgen receptor concentrations by androgen.[558]

ANDROGEN BINDING PROTEIN AND ITS RECEPTOR

Androgen binding protein (ABP) is one of the first proteins shown to be synthesized by Sertoli cells of the testis,[513] and has been found in several species, including the rat,[638,663] rabbit,[664] guinea pig,[665] ram,[639] monkey,[666] and human.[667] It is secreted in both the luminal and basal compartments of the seminiferous tubules, but the overwhelming majority, more than 80%, is directed toward the epididymis.[668] Plasma sex hormone-binding globulin (SHBG) shares the same amino acid sequence with ABP; these molecules differ only with respect to the types of oligosaccharides associated with them.[669] The biological significance of these differences is not clear in light of the fact that SHBG and a glycosylated mutant have similar binding characteristics to sex steroids.[670] ABP concentrations are highest in the caput and lowest in the cauda epididymal segments of most species examined, including primates; this distribution correlates well with DHT content.[139,671,672] ABP is synthesized and secreted by epididymal principal cells all along the epididymis,[673] but in several species it is also taken up into the epididymal principal cells of the initial segment and caput epididymidis,[663,674,675] through a

receptor-mediated process.[590,591,672,676,677] Testicular ABP production is regulated by androgens,[678] while that of the epididymis seems to be under the control of a testicular factor.[673]

Several functions have been ascribed to ABP. It has been proposed to act as a carrier of androgens to the epididymis.[679] Within the principal cells, testosterone is released from ABP and converted to the more potent androgen, DHT, by the enzyme SRD5A1 and 2. ABP has high affinity for 5α-DHT ($K_a = 1.25 \times 10^9$/M) and testosterone ($K_a = 0.5 \times 10^9$/M); rapid dissociation of testosterone from ABP (6 min) is consistent with a role for ABP as a carrier molecule for testosterone. In addition to its role as a carrier molecule, ABP has been suggested to be an androgen sink in the seminiferous tubules of the testis,[679] since the concentration of androgens in the seminiferous tubules needs to be higher than that in the peripheral circulation in order to maintain spermatogenesis[680–682] (see also Chapter 16). ABP has also been proposed to regulate the expression of SRD5A1.[452,533,588]

To unequivocally demonstrate a function for ABP in spermatogenesis or in the epididymis would require the development of a null mutation model; this has not yet been accomplished. However, mice overexpressing ABP,[683] show fertility defects stemming from spermatogenic dysfunction in the testis, which translates into reduced numbers of spermatozoa in the cauda epididymidis. Although in these transgenic lines, ABP protein levels are increased in the epididymis, the consequence of this on epididymal function is not evident.

Although it is clear that testicular ABP enters the principal cells of the proximal segments of the epididymis, the mechanism of internalization is still not fully understood. The presence of high affinity binding sites (K_a of 3.7/nM; 4.5×10^{11} sites/mg protein) on the apical surface of epididymal principal cells and the demonstration that the number of these receptors is fivefold lower in the cauda than in the caput of the epididymis have led to the proposal that ABP internalization is a receptor mediated process in both rats and monkeys.[591,672,676]

STEROID 5α-REDUCTASES The selective presence of radioactive DHT in epididymal cell nuclei after injection of radiolabeled testosterone,[684] and the demonstration using micropuncture studies that, beyond the efferent ducts, the predominant androgens in epididymal fluid are 5α-reduced metabolites of testosterone,[139] are two of the key findings establishing the central role of DHT, and hence steroid 5α-reductases, in mediating androgen action in the epididymis. The discovery that testosterone is rapidly converted by the epididymis to 5α-reduced products was first made almost simultaneously by two different groups.[685,686] The epididymis is one of the tissues with the highest level of activity anywhere in the body.[686]

In the mouse, rat, dog, monkey, and man, two 5α-reductase isozymes, with different tissue distributions, have been identified. SRD5A1 and SRD5A2 are the products of separate genes.[687,688] SRD5A1 is most abundantly expressed in the initial segment of the epididymis, with a positional gradient that is similar to the enzyme activity. Endocrine and developmental regulation of SRD5A1 show the following: (1) orchidectomy results in a decrease in type 1 mRNA levels in all epididymal segments; (2) after orchidectomy high-dose exogenous testosterone maintains SRD5A1 levels at control levels in all regions of the epididymis except the initial segment; (3) unilateral orchidectomy and efferent duct ligation cause a dramatic decrease in SRD5A1, selectively in the initial segment of the epididymis; and (4) only the type 1 transcript is developmentally regulated. Therefore, as for enzyme activity, the primary regulator of SRD5A1 expression in the initial segment is a lumicrine factor of testicular origin.[452,689]

Although several theories have been put forward regarding the relative role of these two isozymes,[690,691] little solid data exist to allow resolution of their relative roles. The consequence on reproduction in the mouse of a null mutation in *Srd5a1* is an effect on parturition,[692] but null mutations of either or both genes are compatible with male fertility.[690] However, no detailed studies on spermatozoa or on the epididymis of mice carrying null mutations for these genes have appeared. To understand the regulation of this enzyme activity in the epididymis, it is necessary to determine where and how the proteins are expressed, the translation, and, ultimately, the factors regulating transcription of the genes for this enzymatic activity.

5α-Reductase activity is expressed in a striking positional gradient as well as in different subcellular fractions in the adult rat epididymis.[587,693] The activity associated with the nuclear fraction is highest in the initial segment, where it is higher than in any other male reproductive tissue, and declines dramatically in more distal segments of the tissue. The hormonal regulation of epididymal 5α-reductase activity is complex.[452,689] This was the first enzyme shown to be regulated by testicular factors as well as by circulating testosterone, depending on which segment and subcellular fractions were examined. While nuclear fraction epididymal 5α-reductase activity is regulated in a lumicrine manner by a substance directly entering the epididymis via the efferent ducts, microsomal 5α-reductase activity is found throughout the epididymis but is present at a lower level and is regulated by circulating androgens.

The mRNA encoding SRD5A2 is found in high concentrations throughout the epididymis, with a somewhat elevated concentration in the caput epididymal segment.[452] Although in the epididymis SRD5A2 mRNA is present in abundance relative to that of SRD5A1, its

activity as a functional enzyme appears to be relatively poor. Unlike the developmental expression pattern of *Srd5a1*, characterized by dramatic increases occurring just before the first appearance of spermatozoa in the epididymis, *Srd5a2* expression does not show any significant developmental changes in any epididymal segment. Efferent duct ligation results in a dramatic decrease in *Srd5a1* expression in the initial segment, but causes a near doubling in that of *Srd5a2*. This differential regulation of the *Srd5a* transcripts within one tissue has not been observed in other rat tissues such as the prostate.[452]

In comparing the regulation of epididymal 5α-reductase enzyme activity and the expression of its mRNAs, it is apparent that a potential regulatory step is at the level of the protein itself. Post-transcriptional regulation has been proposed for several other epididymal proteins.[130,211,486,606,694–696] In the adult rat, SRD5A1 expression is intensely immunolocalized in discrete lobules of the proximal initial segment of the epididymis; a sharp decline in staining intensity occurs between the proximal initial segment and its adjacent region, followed by a progressive decrease in intensity beyond that point.[452] In all epididymal regions, SRD5A1 immunoreactive is localized specifically in the epithelial principal cells and is uniquely associated with membranous elements; the intracellular localization of the SRD5A1 changes as one moves down the epididymis. Savory et al.[697] have localized SRD5A1 to the nuclear envelope of both transfected COS cells and of rat liver. The infranuclear localized form of the SRD5A1 is regulated in a similar fashion to the *Srd5a1* and enzyme activity, that is, by a lumicrine factor of Sertoli cell origin.[452,698]

The genomic regulation of the expression of both 5α-reductase isozyme genes has also been investigated.[699,700] Characterization of the proximal promoter of *Srd5a1* displays all the features of a CpG island and has numerous Sp1 binding sites; it also has a bidirectional promoter activity in this region that is highest in the negative orientation. Promoter activity, in either orientation, is lost in Sp1 deficient cells and rescued following co-transfection with an Sp1 expression vector.[699] The *Srd5a2* promoter region has a noncanonical TATA box located upstream of the transcriptional start, has multiple Sp3 and Sp1 sites site, and is also GC rich.[700] The potential role of this GC-rich region is intriguing in light of the observation that the methylation pattern of the two genes appears to differ not only between each other but also between reproductive and non-reproductive tissues.[701] The genes for SRD5A1 and SRD5A2 are also differentially methylated in lymphocytes from normal and 5α-reductase deficient patients.[702] The methylation pattern of *SRD5A2* has been proposed as a marker for hepatocellular carcinoma,[703] but no studies on alterations of the methylation pattern of this gene in reproductive tissues have yet been reproted.

ESTROGEN RECEPTORS AND CYTOCHROME P450 AROMATASE

ESTROGEN RECEPTORS Starting in the 1970s, substantial evidence accumulated for the direct action of estrogens on androgen target tissues. Using binding studies, specific, high affinity cytosolic and nuclear estrogen binding proteins, presumably receptors, were identified in the epididymis by a number of investigators in mice,[704] rats,[705–707] guinea pigs,[708] rabbits,[709–712] dogs,[713] rams,[714] monkeys,[715,716] and men.[717] Through a comprehensive series of studies, Danzo's group established the presence of estrogen receptors in the rabbit epididymis and demonstrated both its developmental[718] and regional distribution;[708] however, enthusiasm for further studies on the estrogen receptor in the epididymis diminished when this same group demonstrated the presence of a protease, in the adult, that cleaves the DNA binding region of the estrogen receptor.[719]

The histolocalization of tritiated DHT and estradiol in the adult mouse epididymis revealed differential distribution of grains over nuclei in different segments of the excurrent duct system, as well as over different cell types.[704,719] These studies confirmed the earlier binding experiments and provided a more detailed localization of the putative receptors. Very strong labeling of the efferent ducts and initial segment of the epididymis was noted, with lesser binding in the more distal segments of the epididymis; nuclei of clear cells were more densely labeled with estradiol than with DHT, in sharp contrast to what was seen over nuclei of principal cells. Based on such data, and prior to the studies with null mutant mice, specific functions for estradiol in the epididymis were proposed.[48,570]

With the discovery of the existence of two estrogen receptors (ERα and ERβ, now referred to as ESR1 and ESR2), the availability of specific antibodies for these receptors as well as mice having null mutations for either or both receptors, our understanding of localization of estrogen receptors and their potential role(s) has grown rapidly.[581] ERα and ERβ are remarkably similar to one another in some respects(e.g. 95% identity in the DNA binding domain), but they have individual characteristics (e.g. less than 55% homology in the ligand binding domain), that clearly indicates functional differences.[720,721] The two isoreceptors have different binding affinity for estrogenic and antiestrogenic compounds,[722,723] different tissue distributions,[723] and different response elements.[724,725]

Although there are some conflicting data on the immunolocalization of ERα and ERβ along the efferent ducts and the epididymis presumably due to technical differences (e.g. antibody source, tissue preparation,[726,727]

and differences among species),[581] a general pattern is emerging. In the mouse, the epithelium of the efferent ducts shows strong ERα- and weaker ERβ -immunoreaction.[581,728,729] The initial segment of the epididymis shows some reactivity for ERα, primarily in narrow, apical and some basal cells;[653] in the caput, epididymidis, principal cells and clear cells stain positively, while in the distal regions only clear cells are immunoreactive. In the rat, ERα mRNA and protein are higher in the corpus region than in any other region of the rat epididymis.[581] In contrast, ERβ immunoreactivity is clearly observed all along the epididymis with more intense staining in the more distal regions (corpus and cauda).[581,729] The mRNA data are consistent with the observations made using immunohistochemistry.[581,726,730,731] In monkeys, baboons and men, both forms of the ER are present along the epididymis.[732–735] Interestingly, G protein–coupled estrogen receptor-1 (GPER, formerly known as GPR30) found on the cell membrane has also been found in the epididymis with the highest expression reproted for the corpus region.[581]

The first clear insight into the functional role of ERα in the efferent ducts and epididymis came through null mutation studies. The ERα receptor knockout mouse (αERKO) was developed by Lubahn et al.[736] and is infertile in spite of the presence, until puberty, of apparently normal seminiferous tubules; in the adult, testicular atrophy becomes evident.[737] Through an elegant series of studies, Hess's group,[738–740] has demonstrated that the cause of the infertility is atrophy of the seminiferous tubules due to increased back pressure resulting from the inability of the efferent ducts and initial segment of the epididymis to reabsorb the large volume of fluid secreted by the testis. This reabsorption process is under the control of estradiol, acting as a paracrine regulator of the efferent ducts. Further, it has been proposed that the action of estrogen on fluid reabsorption is mediated via the CFTR receptor.[741] The abnormal milieu created by the defect in fluid reabsorption contributes to abnormalities in sperm maturation and consequent infertility.[740] In contrast to the clear role of the ERα receptor, function for ERβ in the male reproductive tract awaits further investigation, as the ERβ knockout mouse is fertile and appears to have a normal testis and epididymis.[742]

CYTOCHROME P450 AROMATASE Cytochrome P450 aromatase (CYP19A1), localized to the smooth endoplasmic reticulum, is a terminal enzyme that irreversibly catalyzes the conversion of testosterone to estradiol. Both the absence of aromatase and an excess of estrogen result in male infertility.[743] There are several sources of estradiol in the adult male reproductive tract. In the testis of adults, both Leydig cells,[744,745] and germ cells[746] have been reported to actively synthesize estradiol. In germ cells, the enzyme is localized in the Golgi of round spermatids and throughout the cytoplasm of elongating and late spermatids.[581,743,747]

Early investigations of the presence of CYP19A1 in the epididymal epithelial cells indicated that this activity was absent;[748] however, no direct assessment of the enzyme was done in these studies. In several subsequent investigations, direct detection of the P450 aromatase mRNA, protein, and enzyme activity (formation of estradiol from testosterone), as well as the ability of specific aromatase inhibitors to inhibit estradiol formation, all led to the conclusion that epididymal principal cells, but not the smooth muscle cells surrounding the duct, have the ability to synthesize estradiol from testosterone in a number of species, including the rat,[749] monkey,[750] and man.[751]

In the epididymis, aromatization of the very high concentrations of testosterone to produce estradiol, could occur either in the luminal or the epithelial compartments. The presence of CYP19A1 in epididymal spermatozoa has been demonstrated in several species, including mouse, rat, bear, rooster, buffalo, and human.[746,752–756] The enzyme is localized to cytoplasmic droplets, and the staining becomes less intense as spermatozoa traverse the epididymis.[748]

RETINOIC ACID RECEPTORS

Retinoids, which include vitamin A, are highly potent molecules with pleiotropic action in a wide range of biological processes during development and in the adult.[757] For example, vitamin A deficiency (VAD) results in both keratinizing and non-keratinizing squamous metaplasia of numerous epithelia, including the epididymal epithelium.[758,759]

Given the importance of retinoids, it is not surprising that a complex system has evolved to control retinoic acid biosynthesis and metabolism.[760–762] Because retinoids are hydrophobic molecules insoluble in water, they require chaperones to ensure proper storage, transport, and uptake in the tissues. These chaperones, the retinoid binding proteins, are members of either a large superfamily of small intracellular proteins that includes numerous fatty acid binding proteins or another superfamily of secreted proteins, the lipocalins, which bind hydrophobic molecules. There are four intracellular retinoid binding proteins that are members of the fatty acid binding protein family (CRBP I and CRBP II: cellular retinol binding protein type I and type II; CRABP I and CRABP II: cellular retinoic acid binding protein type I and type II) and two extracellular retinoid binding proteins that are members of the lipocalin family (RBP: retinol binding proteins; E-RABP (LCN5): epididymal retinoic acid binding protein).

Within the nucleus, two classes of nuclear retinoic acid receptors named RAR and RXR have been identified and cloned. Each receptor class consists of three
