Michael J. Large, Francesco J. DeMayo

Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA

INTRODUCTION

Driven by ovarian steroid hormones, the oviducts and uterine endometrium undergo a series of biochemical and histological changes to facilitate the establishment and maintenance of a pregnancy. An increase in cilia and secretory function in the fallopian tube epithelium occurs in response to estradiol production from the maturing ovarian follicles and enables pickup of the oocyte from the ovary, travel of sperm to the oocyte, an environment conducive for fertilization and early embryo development, and transportation of the fertilized embryo to the uterus. The rise in progesterone from the newly formed corpus luteum signals the regression and atrophy of the oviductal epithelium. Responding to these same signals of estradiol followed by progesterone, the endometrium undergoes a period of cellular proliferation followed by differentiation in preparation for embryo implantation. In the absence of a pregnancy, progesterone falls and much of the endometrium is shed. A rise in estradiol from the next cohort of developing follicles starts the cycle anew, with the oviduct and endometrium once again responding to these signals in a coordinated fashion in order to achieve pregnancy.

In this chapter, we will review these changes to the oviduct and endometrium throughout the menstrual cycle. We will trace the development of our understanding of fallopian tube and uterine biology from the early nonhuman histological studies through the latest genetic and molecular advances. In the second edition of this text (published in 1994),[1] histological analysis—most often in the nonhuman primate—dominated the description of changes to the oviduct and endometrium over the menstrual cycle, while the roles of the ovarian steroid hormones in regulating reproductive organ function were studied using binding and immunoassays to detail hormone receptor quantity and location in the various compartments over the course of the menstrual cycle. In the third edition (2006),[2] the authors explored in great depth the emerging gene-profiling experiments of the endometrium over the menstrual cycle. In the current edition, emphasis will be placed on studies in humans or involving human tissue, although we will explore in detail how modern transgenic studies, primarily in the mouse, have advanced our understanding of this dynamic system. We will review what is thought to underlie normal oviductal and endometrial function and explore some of what is known about their dysfunction in diseases such as endometriosis and endometrial hyperplasia and malignancy. Finally, with an eye to the future, we anticipate the ability to correct defects in tubal and endometrial function, whether to relieve symptoms, treat and prevent cancer, or improve outcomes through assisted reproduction.

ANATOMY, EMBRYOLOGY, AND HISTOLOGY: AN OVERVIEW

The paired oviducts, each approximately 13 cm in length, are contiguous with the endometrial cavity and terminate in communication with the peritoneal cavity. The oviducts are divided into four anatomic regions:

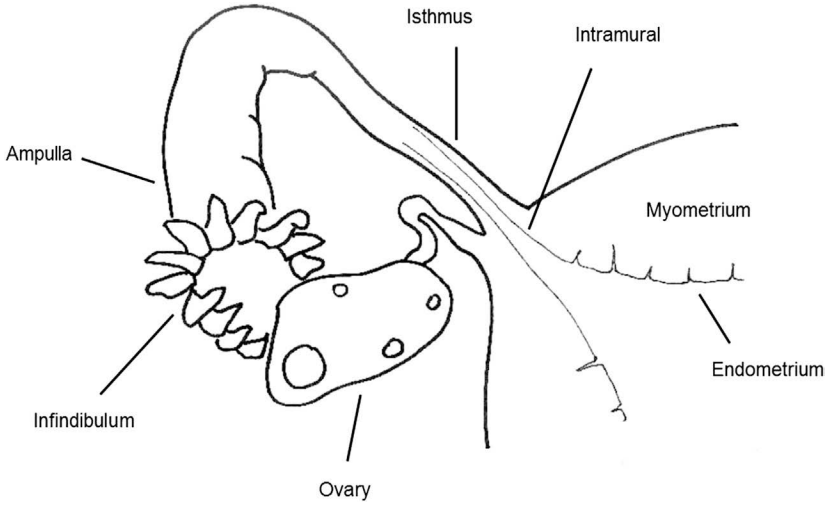

FIGURE 24.1 Anatomic regions of the human fallopian tube.

intramural, passing through the uterine wall; *isthmus*, the narrow proximal one-third of the tube; *ampulla*, the widening distal two-thirds of the tube; and *infundibulum*, the large terminus of the tube, open to the peritoneum and containing the tubal fimbriae (Figure 24.1).[2] In cross-section, one can appreciate the three distinct tubal layers of the inner *mucosa*, middle *muscularis*, and outer *serosa* (Figure 24.2), which are part of the visceral peritoneum that drapes over the pelvic organs and makes up the mesosalpinx. The mucosa is composed of longitudinal folds, which become more prominent and branch toward the infundibulum. The mucosa is lined by a single layer of epithelium of two cell types: ciliated and secretory (nonciliated). These epithelial cells are responsive to ovarian steroid hormones and, as such, undergo changes over the menstrual cycle that we can interpret in histological and biochemical terms. These cyclic changes will be addressed later in the chapter. Vascularized loose connective tissue makes up the lamina propria and supports the epithelium. The mucosa is made up of smooth muscle and connective tissue in an inner circumferential and outer longitudinal arrangement.

The uterus is pear shaped, with an average weight of approximately 50–100 g in the premenopausal adult, and is made up of the following regions: the *corpus* (the body), *fundus* (the top portion), and *isthmus* (the lower segment, contiguous with the cervix) (Figure 24.3, upper panel). The uterus can be divided into three distinct layers: an inner endometrium, myometrium, and outer serosa. The myometrium makes up the majority of the uterus and is composed mostly of smooth muscle along with vascular tissue and some supporting stroma. The outer serosa is contiguous with the visceral peritoneum, which drapes the uterus and oviducts in the pelvis. The endometrium is a complex collection of cell types and is lined by a single layer of columnar epithelium (luminal epithelium). This epithelium lines the uterine glands (glandular epithelium) as well. The glands are branched, tubular structures that extend through the stroma and can traverse the entire endometrial thickness to the myometrium underneath. The stroma is composed of connective tissue and extracellular matrix; and, as we will see, the various responses of the different uterine compartments, including the epithelium and myometrium, to circulating ovarian hormones are mostly coordinated through the stroma.

The human endometrium can be further divided into four zones that were originally used by Bartelmez (referenced in 2) to describe the endometrium of the rhesus macaque (Zone I, composed of the luminal epithelium and adjacent stroma, through Zone IV adjacent to the myometrium). More commonly, we can discuss the endometrium in reference to the "functionalis" (Zones I and II) and "basalis" (Zones III and IV) (Figure 24.3, lower panel). The functionalis is the portion of the endometrium that responds to the ovarian hormones, undergoes dramatic changes in cell appearance and function over the menstrual cycle, is the site of embryo implantation, and is shed each month in the absence of a pregnancy. The underlying basalis is not shed but participates in the regeneration of the functionalis after menses.

The anatomy of the uterus and fallopian tubes was first described by Johannes Müller in 1825.[3] The uterus and fallopian tubes originate from the Müllerian or paramesonephric ducts composed of coelemic epithelium, and their development occurs during weeks 9–14 of fetal life.[4] The formation of these ducts is a process of initiation, invagination, and elongation, the molecular cues for which have been shown to involve members of the LIM (**L**in-11, **I**slet-1, and **M**ec-3), WNT (**W**ingless and I**nt**egrase), and PAX (**Pa**ired bo**x**) protein families.[5–7] The cranial portions of the ducts, open to the peritoneum, become the oviducts, while the caudal portions of the ducts migrate medially and fuse to become the uterovaginal primordium. The lower portion of this primordium becomes the vagina and

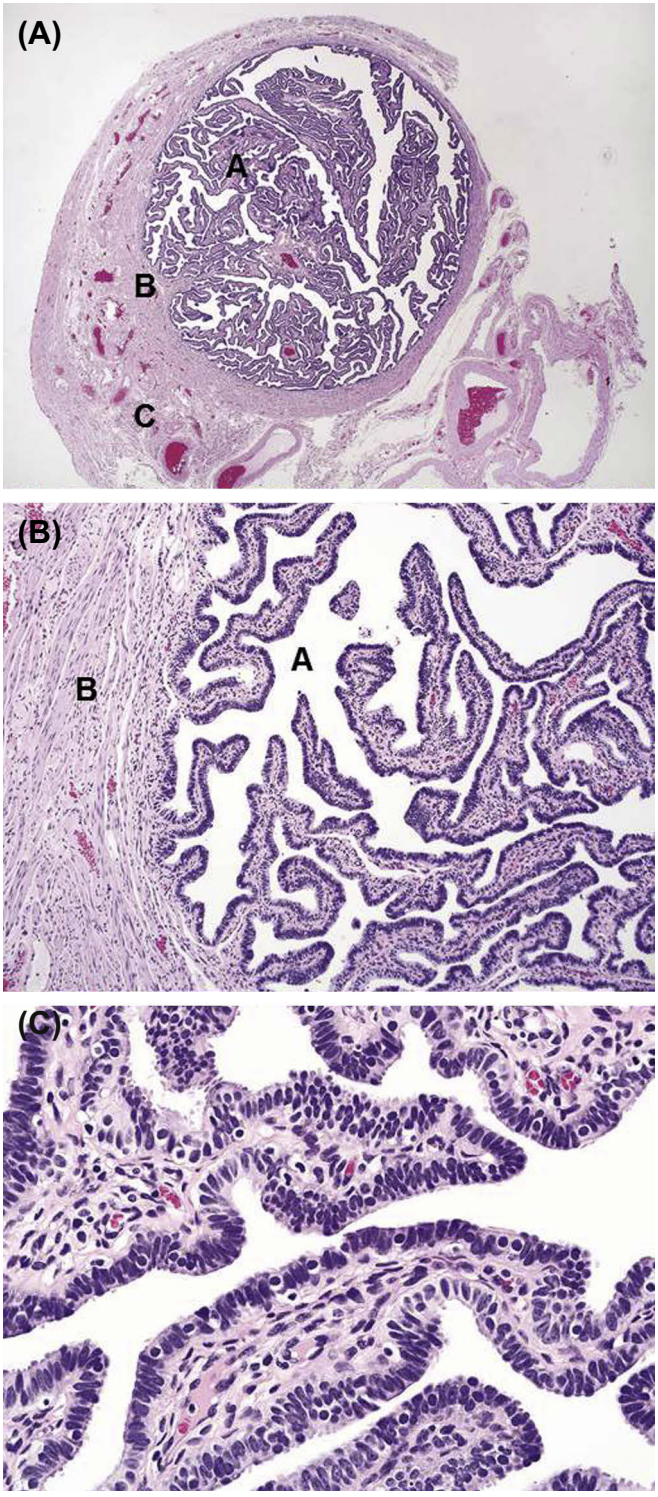

FIGURE 24.2 Cross-section of human fallopian tube, ampulla. This figure is reproduced in color in the color plate section. Inner mucosa (A) is arranged in longitudinal folds within the middle muscularis (B) and outer serosa (C). The mucosa is lined by a single layer of epithelium (lower panel) composed of ciliated and secretory (nonciliated) cell types. Hematoxylin and eosin (H & E) stain, magnification 20–400×. *Source: Images courtesy of Ramya Massand and Jason Moss.*

cervix, and the upper portion becomes the uterine glands and epithelium. The endometrial stroma derives from the adjacent mesenchyme.[2] After fusion of the two ducts to form the future uterus, there is regression in an area of the midline to create the uterine cavity. Failure to achieve proper paramesonephric duct formation, fusion, or regression leads to a spectrum of clinically relevant malformations of unicornuate uterus (hemi-uterus), uterus didelphys (double uterus), or uterine septum, respectively. Evolutionarily, the development of a single uterine cavity in humans can be compared to most nonprimate mammals, and even some primates, in which the uterus does not undergo extensive midline fusion and remodeling and thus remains didelphic.

By midgestation, smooth muscle is apparent in the future myometrium, and pouches (future glands) form from the epithelium into the underlying mesenchyme. By month 7 of gestation, glands are apparent and the endometrium responds to the steroid hormones produced by the placenta.[4] The endometrium is hypertrophic at birth and can even be shed as withdrawal from placental hormones occurs. At birth, the lower uterus and cervix make up two-thirds of the uterus, with the smaller fundus comprising the upper one-third. These proportions remain intact as the uterus grows through childhood in proportion to the rest of the body. At puberty, the endometrium and myometrium both respond to circulating ovarian steroid hormones. The uterus assumes the adult phenotype in which the corpus is larger than the cervix and the endometrium changes and is shed with each menstrual cycle.

OVIDUCT

For much of the past 450 years since Gabriel Fallopio first described the tube that now bears his name, the oviduct has been viewed as a passive conduit for the gametes. Modern investigation, however, describes a much more involved role for the oviduct in reproduction. The concept of the oviduct as an active participant in the establishment of a pregnancy likely arose with histological investigation of the nonhuman primate oviduct; much of this work was done by Brenner and colleagues and was discussed in detail in earlier editions of this text.[1,3] The tubal epithelium undergoes morphologic changes over the course of the menstrual cycle, including increases in cilia and cell height that peak at the time of ovulation. With the rise in progesterone following ovulation, the tubal epithelium loses cilia and atrophies. In many species, the utero-tubal junction is a barrier to limit the number of sperm gaining access to the oviduct. In humans, the tube may act as a sperm reservoir as it does in many other species and perhaps even actively coordinates sequential release of smaller numbers of sperm to continue the path to the oocyte,[8,9] while postovulatory oviductal fluid plays a role in sperm activation.[10] Oocyte pickup from the ovary and

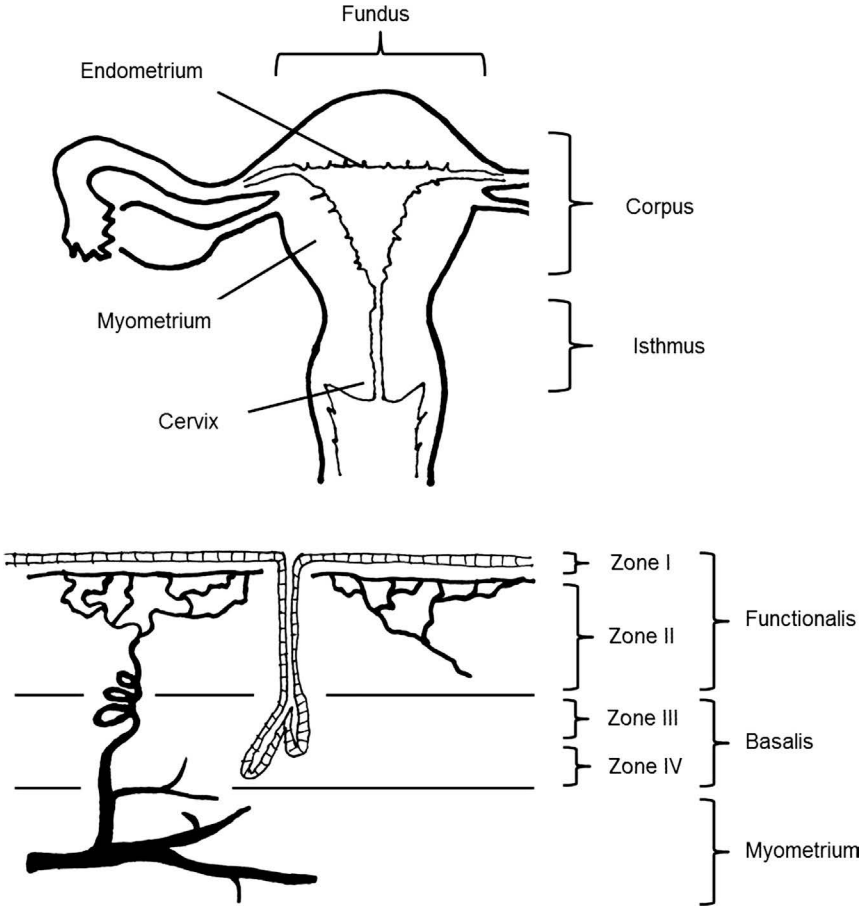

FIGURE 24.3 **Anatomic regions of the human uterus (upper). Cross-section of human endometrium (lower).**

transport of the embryo to the uterus depend on proper function of tubal cilia and smooth muscle in addition to important tubal interactions with the embryo. Additionally, co-culture of gametes and embryos with tubal epithelium has been shown to improve fertilization rates and certain developmental parameters of the embryo, while abnormalities in in vitro embryo development suggest an absence of exogenous components that would be encountered in vivo.[2,10] Taken together, these findings suggest that the structure of the oviduct and substances secreted by certain epithelial cells play important roles in gamete function. In this section, we will discuss what is known of the morphologic and biochemical changes to the oviduct over the course of the menstrual cycle. Central to these changes are the ovarian steroid hormones, which act directly on the oviduct and lead to communication between the cells and tissue types of the tube. Similar to the endometrium, we will see that the effect of the steroid hormones on the epithelium is dependent on signal transduction via the underlying stroma.

Oviduct Histology

The human oviduct is composed of smooth muscle lined internally by a single layer of epithelium. The epithelium is made up of three cell types: ciliated cells, secretory cells, and a third cell type of either an undifferentiated state or an altered, functionally depleted form of ciliated or secretory cells (intercalated or peg cells).[2,11] The ratio of ciliated to secretory cells varies by location through the tube, generally increasing from proximal to distal. The narrow isthmus contains the fewest ciliated cells, while, in the distal infundibulum, the majority of the cells are ciliated.[2,12,13] As early as 1928, researchers reported changes to the tubal epithelium over the menstrual cycle with enlarging cells and increasing cilia at midcycle.[2,14] The growth of these cells throughout the follicular phase was demonstrated to occur under the influence of estradiol while progesterone could be shown to inhibit it. Such hormonal control of the epithelium was supported by a series of clinical studies in women.[2] Cilia could be induced to grow in postmenopausal women with the addition of estrogen[15] or in patients immediately postpartum with the addition of a synthetic estrogen. Such changes could be abolished with the addition of progesterone.[16]

Much of our understanding of tubal histology arises from study of the nonhuman primate, a review of which can be found in great detail in earlier editions of this text.[2,3] These changes have been correlated with serum

estradiol and progesterone levels as well as with concurrent endometrial and ovarian histology. From their work in nonhuman primates, Brenner and colleagues described eight stages of the oviductal epithelium during the menstrual cycle in consideration of multiple morphologic characteristics, including the height of the cells, mitotic activity, the degree of ciliation, the appearance of glycogen and granules in the secretory cells, and the presence of macrophages.

Estradiol and Progesterone

The consistent morphologic changes to the oviduct over the menstrual cycle and the reproducibility of these findings with the administration of exogenous hormones suggest tight control by the ovarian steroid hormones estradiol and progesterone. Using autoradiographic techniques, studies in the 1970s and 1980s investigated the presence and binding capacities of estrogen receptor (ESR) and progesterone receptor (PGR) in the different regions of the oviduct, between nuclear and cytoplasmic fractions, and across the menstrual cycle. The presence of bound ESR and PGR was found to vary across tubal regions, with the highest binding in the ampulla.[17] For estradiol, greater nuclear binding was found as serum estradiol levels increased through the follicular phase of the cycle. Similarly, this nuclear binding decreased as serum progesterone levels rose after ovulation.[18] For progesterone, cytosolic fractions were always found to be greater than nuclear ones, and these findings were consistent across tubal regions. The ratio of nuclear to cytoplasmic binding, however, varied through the menstrual cycle, with an increasing ratio (relatively more nuclear PGR) mirroring serum progesterone levels in the luteal phase.[19]

Throughout the reproductive tract, estradiol stimulates the production of both ESR and PGR, a finding conserved across multiple species, including humans, nonhuman primates, chickens, and mice.[2] Receptor expression in both the cytosol and nucleus increases over the follicular phase and then decreases as progesterone levels rise after ovulation. These findings have been shown most convincingly in the nonhuman primate, where exogenously administered estradiol has been shown to upregulate ESR in the oviductal epithelium while treatment with progesterone decreased the receptor number. The receptor number increased again upon the withdrawal of progesterone. Furthermore, less binding of estradiol to its receptor was found in the presence of progesterone despite continued high levels of estradiol.[20] Measuring these receptors in naturally cycling animals confirmed this finding that progesterone suppresses the amount of ESR in the fallopian tube.[21]

Similar findings arose from advances in immunohistochemistry that enabled further examination of ESR and PGR in the oviduct through the menstrual cycle. In the luteal phase of human subjects, ESR and PGR were observed in both epithelial and stromal compartments of the oviduct, with higher PGR levels in the stroma of isthmic cells compared to other tubal regions. Upon administration of the antiprogestin mifepristone (RU486), PGR increased in both epithelial and stromal cells while ESR increased in the epithelial compartment.[22] Brenner and colleagues also showed increased nuclear ESR staining of the stromal, smooth muscle, and epithelial cells with administration of estradiol, a finding that was reversed with administration of progesterone. PGR increased in response to estradiol treatment in all of the cell types but was suppressed to a greater degree in the epithelium than in the stroma upon treatment with progesterone. The persistence of PGR in the stroma points to this compartment as central in the coordination of downstream responses in the oviduct to progesterone.

Regarding the two isoforms of the progesterone receptor, PGRA and PGRB, very little is known about the relative contributions of each in the oviductal response to progesterone. The two isoforms are encoded by the same gene under the control of different promoters and result in proteins of different size (PGRA, 94 kDa; and PGRB, 116 kDa), with PGRB containing an additional 164-amino-acid sequence at the N terminus.[23–26] Ratios of the different isoforms appear to vary among the different reproductive tissues and in relation to the context of hormonal environment and development.[27–29] For example, in the mouse, ablation of both PGR isoforms (knockout, or PRKO) leads to an infertile animal with multiple reproductive abnormalities, including failure to ovulate, implantation defects, uterine abnormalities, and behavioral disruption.[30,31] Knockout of only the A- or B-isoform has improved understanding of how each contributes to reproductive function, although this knowledge primarily involves ovarian and endometrial function. PGRA is required for both ovulation and the changes to the uterus required for implantation and pregnancy. When the A-isoform is knocked out, PGRB supports epithelial proliferation rather than limiting it.[30] Specific to the oviduct, little is known of the relative contribution of the two PGR isoforms to tubal function, although both are expressed.

The two estrogen receptors, alpha (ESR1) and beta (ESR2), have been detected in the epithelium of the oviduct but recent studies have shown differences in cellular location. In the human, ESR2 expression is mostly limited to the nuclei of the epithelium, with some immunoreactivity in the cytoplasm of these cells as well as in the nuclei of neighboring connective tissue cells. ESR1 was present in all of the oviductal compartments but always limited to the nuclei.[32] The role of each isoform in the function of estrogen in the oviduct remains largely unknown.

Oviductal Fluid and the Facilitation of Gamete Transport

The fluid of the tubal lumen is a product of epithelial secretory cells as well as transudate via the underlying vasculature. Oviductal fluid increases in amount and viscosity through the follicular phase of the cycle under the influence of ovarian estradiol, and bulk flow of the luminal fluid during this time is toward the abdominal cavity.[10] As has been shown in several species, the volume of fluid decreases around ovulation and the overall flow reverses, passing through a relaxed isthmus and into the uterus. The viscosity of the tubal fluid likely has implications for sperm movement, with entirely different patterns of flagellar beating noted using in vitro viscosity gradients and in the mouse oviduct in vivo.[33–35] Aquaporins may provide one means of such water regulation in the fallopian tube.[10,36] The composition of tubal fluid has also been shown to vary over the cycle as well as between regions of the oviduct. The regional differences in composition might be facilitated by macromolecules and the epithelial architecture of folds and grooves, which become more prominent through the follicular phase.[37]

The temporal differences in the consistency and composition of tubal fluid strongly suggest control by the ovarian steroid hormones, estrogen and progesterone; however, in the majority of cases, the mechanism of hormonal control is unknown. Oviductin, an oviduct-specific glycoprotein highly conserved among mammals, may also be regulated by luteinizing hormone (LH), the major ovulatory signal in these species. While oviductin production can be restored in ovariectomized mice with the addition of estrogen (and suppressed again with progesterone), LH has been shown to increase the half-life of the protein by decreasing its degradation.[38] Oviductin in humans has been correlated with serum estradiol and LH levels, and the expression has been shown to vary in different parts of the tube (it is higher in the ampulla and fimbriae), again suggesting both tight control by the ovarian steroid hormones and the different roles played by the various tubal regions.[39] Oviductin has been shown in humans to bind to the zona pellucida and sperm and can improve sperm binding to the zona.[40]

In humans, as in cows, sheep, rabbits, primates, dogs, and cats, semen is ejected into the anterior vagina during coitus. This stands in contrast to horses and many rodents in which semen is deposited directly into the uterus. Thus, in humans, sperm must first gain entry to the oviduct via the ostium at the utero-tubal junction. As it turns out, gaining access to the tube is not a trivial feat, and various knockout models in the mouse are infertile due to an inability of sperm to negotiate this first step. Interestingly, though several knockout models exist that show this same phenotype, the models share a commonality of lacking a particular protein, ADAM3 (a disintegrin and metallopeptidase domain 3), which is likely critical to facilitate entry into the tube.[9] Once in the isthmus, sperm bind to the ciliated epithelial cells, a process likely mediated by carbohydrate residues in the epithelial cells and lectin-like residues in the sperm head,[41] though the actual residues and proteins of this interaction vary among species. The isthmus serves as a reservoir for sperm with sequential release of small numbers of sperm, possibly limiting the number of sperm with access to the egg in the critical fertilization window and, as such, decreasing the incidence of polyspermy.[10] The release of sperm from the isthmus is temporally modulated and has been shown to increase in the periovulatory period.[42] These changes do not appear to be related to the number of carbohydrate-binding sites in the epithelium but are likely controlled by one or more of several other processes, such as sperm motility and binding. Sperm gain a hyperactivation status and thus may escape tubal binding. Oviductal fluid glycosidases and frucosidases have been shown to vary temporally through the cycle and may play a role in sperm release. Finally, evidence exists that a known spermadhesin, AWN (sperm-associated AWN protein), which exists in the sperm head and binds to carbohydrate residues in the oviduct, is actually secreted by oviductal epithelial cells in swine and thus may compete with sperm head binding to the epithelial cells.[43] Progressive waves of oviductal contraction also play a role in sperm transit through the tube. Such myometrial activity is modulated by a ratio of estradiol to progesterone, peaking in cyclic animals close to the time of ovulation.[10]

Capacitation is the process by which sperm acquire the ability to fertilize an egg, a process uncovered independently by Austin and Chang over 60 years ago.[44,45] Since capacitation occurs in the oviduct, the ability to achieve capacitation in vitro has been possible using media mimicking oviductal fluid. Such media require bicarbonate, calcium, energy sources, and serum albumin. Additionally, sperm gain a status of hyperactivation in the oviduct, and calcium flux is central to the acquisition of hyperactivation. Changes in sperm calcium levels have been observed with progesterone treatment, and changes in oviductal pH have been shown during peri-estrus.[9] Overall, increasing evidence suggests that changes in the oviduct specific to the time around ovulation are critical for sperm function.

The oviduct is also critical for regulating oocyte pickup and transport of the embryo to the uterus. Cilia covering the surface cells of the infundibulum beat in the direction of the ostium and induce a current of peritoneal fluid into the tube. Progesterone receptor has been localized in the lower half of motile cilia in oviductal epithelial cells and may regulate beat frequency.[46] Rhythmic contractions of the oviduct also play a role in

oocyte transport. Slow-wave impulses transmitted via interstitial cells of Cajal associated with the oviductal smooth muscle cells are not neuronally mediated, but rather originate from these cells of Cajal.[47] Passage of the oocyte–cumulus complex to the site of fertilization at the isthmic–ampulla junction is relatively rapid (9–15 min in rabbits and 30–45 min in pig), while a slow, controlled transit of the embryo to the uterus (2–7 days) follows fertilization.[10] Part of the regulation of this transit may involve the role of nitric oxide, known to affect oviductal motility and embryo transport.[48,49] Nitric oxide synthase has been shown to be upregulated by estradiol and suggests a mechanism by which ovarian steroid hormones regulate oviductal tone and thus gamete movement in the tube.[49,50]

Certainly, the fallopian tube will receive a great deal of attention in coming years as researchers seek to expand upon this understanding of the fallopian tube as an active contributor to reproduction. While we have an appreciation for tubal responsiveness to the ovarian steroid hormones, unraveling the estradiol and progesterone signaling pathways orchestrating tubal physiology will require a good deal more investigation. Furthermore, recent evidence that a great number of what previously were thought to be cancers of ovarian origin might originate from the fallopian tube will, no doubt, encourage immediate and accelerated research on this dynamic organ.[51–53]

ENDOMETRIUM

The human endometrium is a dynamic structure that cycles through periods of growth and differentiation to facilitate embryo implantation. In the absence of pregnancy, the endometrium breaks down and then regenerates in preparation for the next ovulation. The cues controlling this remarkable plasticity are estradiol and progesterone, which act both directly and through downstream signaling pathways to affect the changes in the endometrium required for implantation and pregnancy.

Much of our understanding of endometrial biology derives from a direct investigation of human endometrium and cell cultures obtained from endometrial biopsy specimens. Human cells, specifically the endometrial stromal cells, can be isolated, cultured, and studied in vitro. Upon treatment with a simple combination of hormones (cyclic adenosine monophosphate (cAMP), estradiol, and progesterone or another progestin such as medroxyprogesterone acetate) mimicking the in vivo environment following ovulation, these cells will undergo decidualization—the phenotypic and biochemical alteration heralded by the rise in luteal-phase progesterone that is required for the establishment and maintenance of a pregnancy. In this section, we will review the endometrium and the changes it undergoes through the menstrual cycle. Our grasp of this fascinating regenerative tissue arises from a combination of in vitro studies of human endometrium together with a system of powerful mouse genetics that has allowed molecular dissection of the various compartments of the endometrium and the molecular pathways underlying its complex function. Genome-wide approaches to characterize genetic transcript across the menstrual cycle and in disease states such as endometriosis have begun to reveal additional candidate genes involved in endometrial function.[54–58]

Histology, Structure, and Molecular Phenotype

Histology and Structure

Histological changes to the uterine endometrium over the menstrual cycle were reported over 100 years ago by Hitschmann and Adler,[2] findings that revolutionized the understanding of uterine biology, which until that point had been predicated on a theory that the physiological and pathological changes to the endometrium represented a spectrum of "chronic endometritis."[59] In the years following, studies in both humans and other primates began to explore the changes observed in this tissue over the menstrual cycle and correlate these findings with changes observed in the ovary. From this early work arose the central dogma of endometrial biology: the ovarian hormones, estradiol and progesterone, control the growth, differentiation, apoptosis, and functioning of the endometrium.[2,60,61] Noyes, Hertig, and Rock cataloged the histological stages of the endometrium based on an "ideal" 28-day cycle using nearly 8000 endometrial biopsies.[62] From this work and others, the human endometrium was described in its relation to the ovarian steroid hormones and the menstrual cycle.

The first half of the menstrual cycle is referred to as the follicular or proliferative phase, depending on whether the focus lies on the ovary or endometrium, respectively. During the proliferative phase, and under the influence of estradiol, the endometrium thickens from several millimeters to approximately 12–14 mm. High mitotic indices are apparent in the epithelium, stroma, and vascular epithelium as DNA synthesis increases, especially toward the end of the proliferative phase under the influence of the highest levels of circulating estradiol. Peak mitotic activity mirrors peak estradiol levels and maximum estrogen receptor expression around days 8–10 of the menstrual cycle.[63] The straight endometrial glands become larger and more tortuous, the vascular network expands, and the stroma proliferates (Figure 24.4).

During the luteal or secretory phase (again, ovarian or endometrial focus), the endometrium comes under the control of progesterone. For the first 36–48 h after the rise in serum progesterone, there is little observable

FIGURE 24.4 Human endometrium from proliferative (upper), early-secretory (middle), and late-secretory phases (lower). This figure is reproduced in color in the color plate section. Note the wide spacing between simple-appearing glands (proliferative), apically displaced nuclei in the glandular epithelium due to glycogen accumulation (middle), and tortuous glands with secretions and a decidualized stroma with abundant pale cytoplasm (lower). difference in the histology of the endometrium. After this point, however, dramatic changes ensue. Differences are first apparent in the epithelium, where glycogen begins to accumulate near the basalis and the nuclei begin to appear displaced upward by the glycogen granules.[2] By days 19–20 of a 28-day cycle, few vacuoles remain as the contents have been expelled into the glandular lumen. The amount of glandular fluid, a product of these epithelial cells and transudate from the endometrial vasculature, peaks at this time and is temporally aligned with embryo implantation. A defined "window of receptivity" exists in which the endometrium is capable of supporting an embryo, and it occurs 6–10 days after the LH surge.[64] Historically, timing of the implantation window was suggested by a classic 1956 study examining early-pregnancy specimens obtained at hysterectomy. In secretory-phase specimens, embryos found before cycle day 20 were free-floating, while those found after day 20 had attached or invaded the endometrium.[65] Later, the window of receptivity was found to coincide with the appearance of epithelial pinopodes, protrusions of the endometrial epithelium important for embryo attachment and water transport. The discrete implantation window is supported by clinical observations of high continuing pregnancy rates (84%) for embryos implanting postovulation days 8–10, versus low rates (18%) when implantation (as determined by chorionic gonadotropin detected in the urine) occurs more than 11 days after ovulation.[66] Similarly, in assisted reproductive cycles, pregnancy rates are 40.5% when embryo transfers are performed between cycle days 17 and 19, compared to 0% after day 20.[2,67]

By the onset of the implantation window, changes to the endometrial stroma are readily apparent, with increased mitoses, edema, and endothelial cell proliferation in the now-coiling spiral arterioles.[62] This edema and permeability precede the decidualization of the stroma in which the spindle-shaped stromal fibroblasts undergo transformation to a round, epithelial-like phenotype (Figure 24.5).[2,68] These cells are characterized classically by their appearance, the production of secreted products such as insulin-like growth factor binding protein 1 (IGFBP1) and prolactin (PRL), and characteristics of both epithelial cells and mesenchymal cells. Decidualized stromal cells have a lamin-rich basement membrane and intercellular adherens junctions (epithelial-like) but stain with immunohistochemical antigens that are classic for mesenchyme, such as vimentin and desmin, and not with certain antigens specific for epithelium, such as epithelial membrane antigens or cytokeratins.[2]

The decidualization of the stroma begins near the spiral arterioles and capillaries and then spreads, encompassing the entirety of the compartment before menses ensues. By the end of the implantation window, lymphocyte infiltration is visible in the stroma; and, immediately

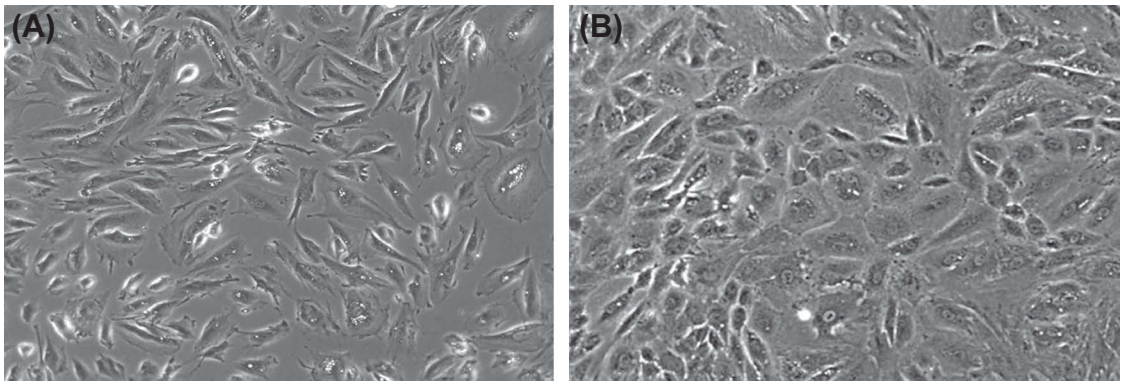

FIGURE 24.5 Human endometrial stromal cells in vitro before (A) and after 6 days of treatment with estradiol, medroxyprogesterone acetate, and cAMP (B). Note the plump, rounded cell morphology with enlarged nuclei in the decidualized cells.

preceding the menses, there is an influx of polymorphonuclear leukocytes (PMNs).[62] These immune cells are thought to be involved in establishing the protected relationship of the conceptus within the maternal immune system. The same cells likely also function to mediate the process of endometrial shedding that occurs in the absence of a pregnancy. In the absence of embryo implantation and the presence of human chorionic gonadotropin (hCG) from the trophoblast to maintain the corpus luteum, estradiol and progesterone levels fall. In this setting, the endometrium undergoes apoptosis, vascular basement membrane breakdown, bleeding, vasospasm, and desquamation, which result in the menses.[2] The vasomotor response to the fall in steroid hormones is dramatic and detailed in early studies of the nonhuman primate.[69,70] The spiral arteries lose height, blood flow in both the arterial and venous beds slows, and vasospasm of the spiral arterioles ensues in a rhythmic pattern of increasing intensity and duration, ultimately resulting in the blanching of the endometrium. Ischemia and capillary leak follow with leukocyte infiltration visible, first surrounding the vessels and then extending throughout the stroma. Prostaglandin (PGF2α, PGE2, and PGI2) production is maximal at the time of menstruation, and these factors are thought to underlie much of the vascular response of the spiral vessels. Enzymes (including matrix metalloproteinases (MMPs)) induced with the fall in progesterone and mediators of progesterone action (such as transforming growth factor beta (TGFβ)) catalyze the breakdown of transmembrane proteins and other components of the extracellular matrix. The cytokine tumor necrosis factor alpha (TNFα) also is thought to play a major role in menstruation through disruption of cell-to-cell communications and induction of apoptosis.[71] Vascular endothelial growth factors (VEGFs) have been implicated in both menstruation and the neovascularization of the proceeding cycle. Bleeding ensues as blood vessels are compromised and the surrounding tissue weakens, and the flow of menstrual blood is influenced by multiple factors, including clotting and fibrinolytic factors and the contraction of myofibroblasts surrounding the spiral arteries.[72] Ultimately, the shrinking functionalis splits from the underlying basalis and is shed. The proliferative phase begins again, the first few days of which are actually independent of the ovarian steroids as these levels are still low. Repopulation of the functionalis is thought to occur, in part, by stem cells from the basalis.[73] As estradiol levels rise, the proliferation and thickening of the endometrium follow once more.

Genomic Profiling of the Human Endometrium

Recent work has subjected the human endometrium to global gene expression profiling across the menstrual cycle.[54–58] Oligonucleotide microarrays and cDNA hybridization with polymerase chain reaction (PCR) techniques have been used to compare secretory endometrium to proliferative-phase endometrium. In addition, various points in the secretory endometrium phase (i.e., early versus mid versus late secretory) have been queried. Investigators have sought to describe the differentially regulated genes in terms of the functions of various gene groups through the menstrual phases, describing lists of genes consistent with much of what is known or suspected regarding the biology of the secretory endometrium. When comparing implantation window secretory endometrium to proliferative-phase endometrium, many of the differentially regulated genes are involved in cell cycle regulation, extracellular matrix synthesis, cell adhesion, immune modulation, and secretion.[55] Several studies have described large-scale gene expression profiles of human endometrium; however, significant variations exist in sampling, study design, and bioinformatics analysis, making comparisons difficult. Recently, work has been undertaken to compile data from these various studies,[74,75] including the creation of a database of nearly 20,000 genes expressed in the human endometrium, 179 of which have been consistently shown to exhibit differential regulation in the implantation window.[76]

Other studies have examined the promoter regions of these differentially regulated genes for the presence of progesterone response elements (PREs) or estrogen response elements (EREs) as evidence for direct regulation by the ovarian steroid hormone receptors.[55] The candidate genes uncovered through such expression profiling are currently under investigation to better understand their roles in both normal endometrial function and endometrial disease states, such as endometriosis, polyps, hyperplasia, and malignancy. Easy accessibility to such ever-increasing high-content data will help to facilitate the exploration of candidate genes and pathways involved in endometrial function and dysregulated under certain conditions or disease states. These gene lists will be supplemented by new techniques—for example, deep-sequencing transcriptome analysis (e.g., RNA sequencing)—which may overcome some intrinsic biases to array-based technologies and allow for the analysis of molecular isoforms in endometrial function.

Steroid Hormone Signaling and the Mediators of Compartmental Cross-Talk

The pattern of endometrial growth, differentiation, regression, and regeneration over the menstrual cycle is coordinated through actions of estradiol and progesterone. While these hormones act directly on the various compartments of the endometrium, strong evidence supports additional paracrine interactions between the epithelium and stroma to orchestrate proper functioning. Much of our understanding of this endometrial biology arises from studies using the transgenic mouse. While gene profiling has begun to detail regulatory pathways of the human endometrium at a transcriptional level during the menstrual cycle and in certain disease states, transgenic mouse models have been used to dissect these pathways at a functional level. Figure 24.6 outlines the regulation of endometrial function in the mouse in the peri-implantation period, briefly introduced here and discussed in greater detail later in the chapter. From day 0 to day 1.5 of the mouse estrous cycle, estrogen signaling predominates. Epithelial proliferation is driven indirectly via the paracrine action of growth factors produced under the control of stromal ESR, while estrogen regulation of target genes such as mucins and ion channels responsible for edema is regulated directly by epithelial ESR. At day 2.5 of pregnancy, the rise in progesterone coincident with luteal development acts predominantly through PGR in the uterine epithelium, inducing factors such as Indian hedgehog (IHH) that act in a paracrine fashion to prepare the underlying uterine stroma. As pregnancy progresses (Figure 24.6: Day 3.5), waning levels of PGR in the epithelium act to inhibit epithelial proliferation via the induction of Krüppel-like factor 15 (KLF15). Meanwhile, increasing levels of PGR in the stroma promote proliferation of said compartment while simultaneously inhibiting epithelial proliferation by inducing HAND2 (human heart– and neural crest derivatives–expressed 2). Embryo attachment is mediated both by leukemia inhibitory factor (LIF) and by sodium ion channels serving the dual purpose of luminal closing and signal transduction (Figure 24.6: Day 4.5). Implantation of the blastocyst triggers decidualization of the endometrial stroma, which is propagated through progesterone action and its downstream signaling paradigm (Figure 24.6: Decidua).

In the remainder of this section, we will review what is known of these complex signaling networks, both direct and cross-compartmental, that coordinate the changes of the endometrium over the menstrual cycle—changes that enable the establishment and maintenance of a pregnancy.

Estrogen Receptor Signaling

Estrogen receptor is critical for regulating the growth and integrity of the endometrium and for coordinating embryo receptivity. Acting via its receptors, estrogen regulates endometrial proliferation and inhibits apoptosis. In humans, lack of estrogen—such as that which occurs after menopause—leads to an absence of endometrial proliferation with resulting atrophy. On the other hand, estrogen-induced proliferation that goes unchecked by the differentiating effects of progesterone—as occurs in anovulatory states like polycystic ovary syndrome (PCOS)—increases the risk for endometrial hyperplasia and malignancy. The high levels of estradiol that result from the multifollicular development of ovarian hyperstimulation in assisted reproductive techniques (ARTs) for couples struggling with subfertility may have a detrimental effect on endometrial function, with resulting impacts on both the chance for and outcomes in a resulting pregnancy. Finally, the endometrium that exists *ex utero* in endometriosis is understood to display altered estrogen signaling, which likely contributes to its pathogenesis. Thus, understanding estrogen signaling—including its control over proliferation, implantation, and progesterone sensitivity—is critical as we strive to correct some of the most common and morbid diseases of the endometrium.

The estrogen receptor exists in two forms, alpha (ESR1) and beta (ESR2), transcribed from unique genes and each with different and specific roles in reproduction. Both ESR1 and ESR2 are expressed in the glandular epithelium and stroma of the human endometrium. Expression levels are high during the proliferative phase and decline during the secretory phase.[77,78] Studies in the mouse have determined that the alpha receptor is the critical estrogen receptor controlling estrogen action in the endometrium. In human endometriosis, however, the ratio of ESR1 to ESR2 has been shown to be altered,[79] a finding that might help to explain the particular growth characteristics, altered progesterone

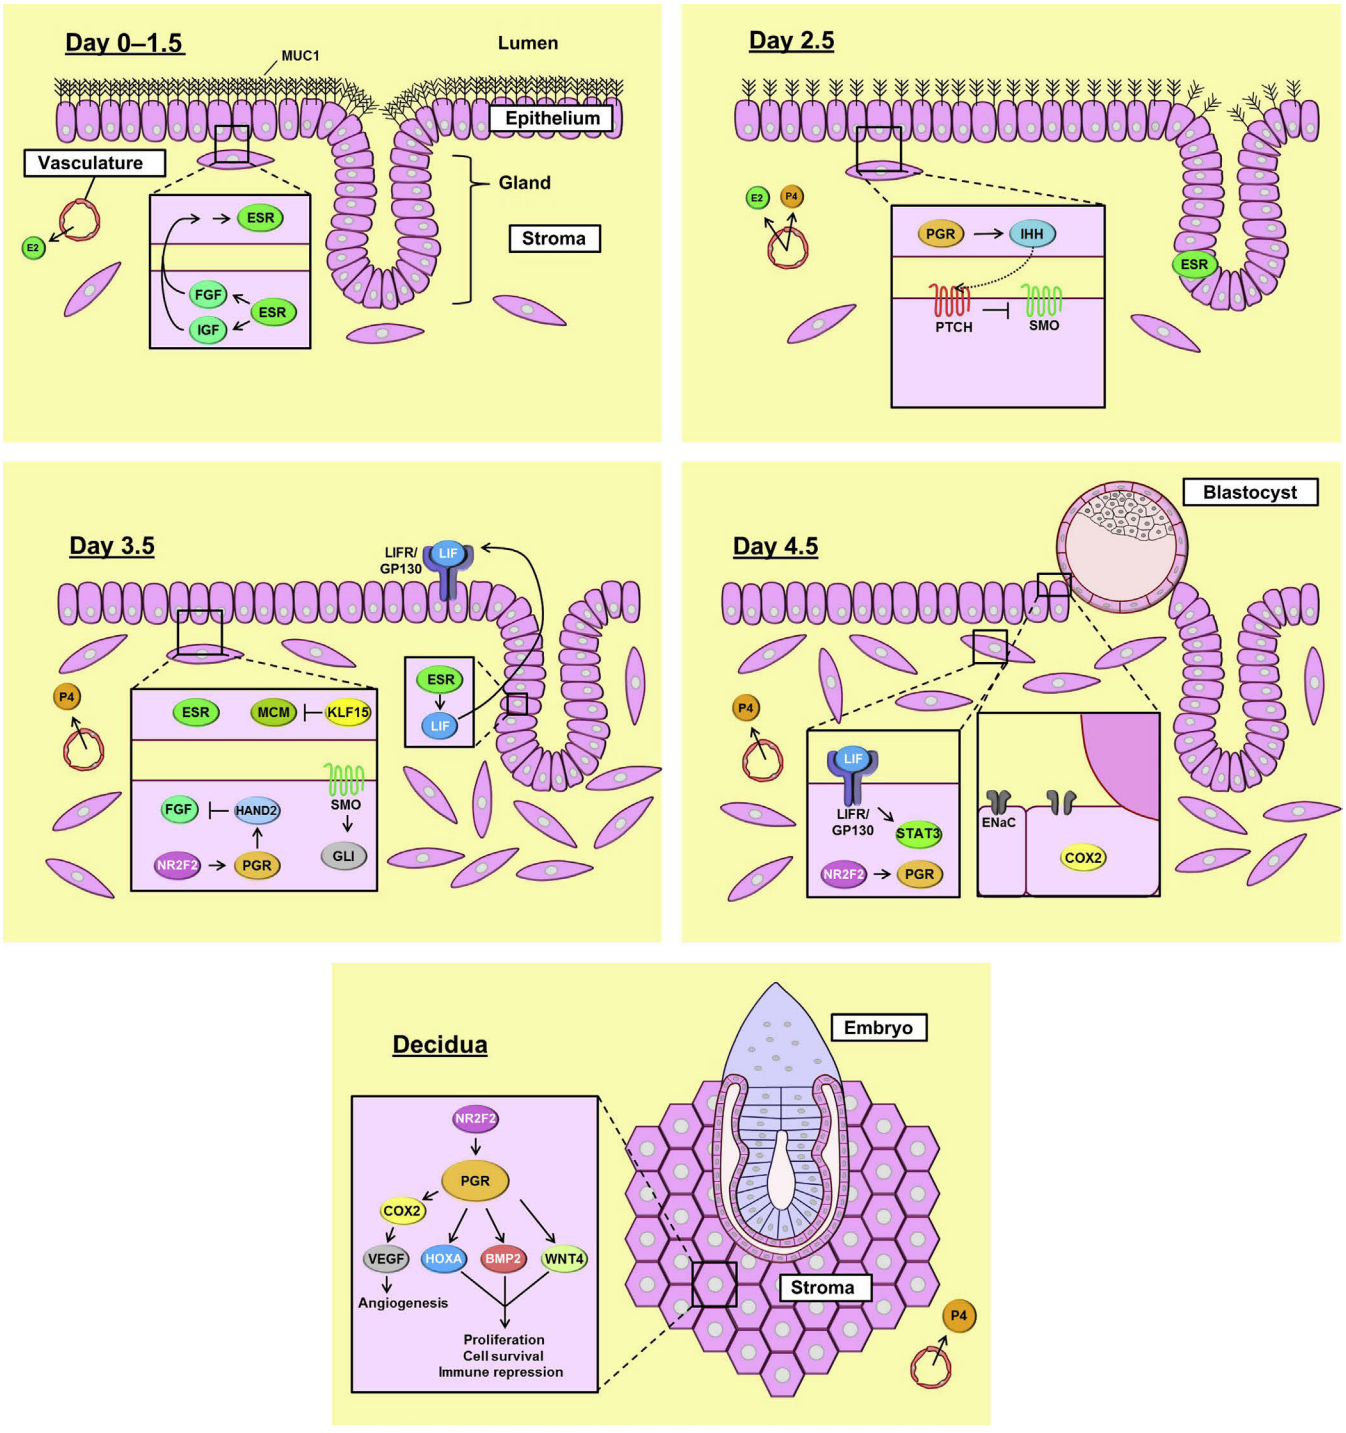

FIGURE 24.6 Estrogen and progesterone receptor signaling pathways in the murine endometrium. The early postovulatory phase (Days 0–1.5) is dominated by follicular estradiol (E2) acting via estrogen receptor (ESR) and driving epithelial proliferation (via stromal ESR and downstream growth factors) and the expression of epithelial ESR target genes such as *Muc1*. At Day 2.5, the epithelium is still proliferating, and progesterone receptor (PGR) is expressed in the uterine epithelium. Indian hedgehog (*Ihh*), a major PGR target gene, is expressed in the uterine epithelium but acts in paracrine fashion in the stroma, where it binds its receptor (PTCH), which then relieves smoothened (SMO) from repression. By Day 3.5, PGR, in part regulated by NR2F2 (COUP-TFII), is acting to inhibit proliferation of the epithelium, accomplished by both epithelial expression of KLF15 and stromal activation of HAND2, while inducing proliferation of the underlying stroma. *Lif*, an ESR target gene necessary for blastocyst implantation, is expressed in the glandular epithelium. LIF secreted from the glandular epithelium acts via its receptor, LIFR/GP130, in the luminal epithelium. With invasion of the blastocyst through the epithelium at Day 4.5, LIF expression shifts into stromal cells surrounding the implanting blastocyst and acts through the transcription factor, STAT3. COX2, a key enzyme in prostaglandin synthesis, is induced through a pathway involving the epithelial sodium channel, ENaC, and emerges as one of the first markers of stromal decidualization. In the stroma, expression of key regulators of decidualization increase robustly from basal levels observed at the time of implantation, concurrent with the wave of stromal cell differentiation (Decidua).

signaling, and inflammation that have been associated with endometriosis.

ESR1 has garnered the bulk of attention when studying the mouse uterus as *Esr2*-null mice demonstrate a very mild uterine phenotype compared to those lacking *Esr1*.[80,81] In the mouse, ESR1 exhibits a dynamic expression pattern in the various epithelial compartments, through the progression of pregnancy, and upon steroid treatment.[82–84] ESR1 is expressed in both the epithelium and stroma and promotes proliferation under the influence of estradiol, as has been discussed in this chapter. With ovulation and the rise in progesterone, PGR expression is induced in the luminal epithelium. Just prior to the window of receptivity, LIF is induced by estradiol in the glandular epithelium,[85,86] while PGR expression is extinguished in the epithelium.[83] Expression of LIF and downregulation of PGR in the epithelium are both critical for embryo implantation. Progesterone then acts via stromal PGR to regulate decidualization.

Steroid hormone control of ESR1 and PGR expression was shown using ovariectomized mice under the influence of exogenous steroids.[84] Without steroids, ESR1 was observed at high levels in both the epithelium and stroma while PGR expression was highest in the luminal and glandular epithelium. Upon administration of estradiol, ESR1 was upregulated in the luminal epithelium but inhibited within the stroma. PGR was observed in all compartments without hormone, but upon the administration of estrogen, PGR expression was lost in the luminal epithelium. Thus, estrogen was shown to drive PGR expression from the epithelium to the stroma while inducing expression of ESR1 in the epithelium.[82] Induction of ESR1 in the glandular epithelium was shown to be under the control of progesterone, and progesterone was shown to decrease the global expression of its own receptor.

Estrogen Receptor—Compartmental Cross-Talk

While estrogen and progesterone acting through their nuclear receptors can have a direct effect on the endometrial compartment in which the receptors are expressed, it is now clear that the action of these steroid hormones in regulating the function of the endometrium occurs via paracrine interactions between the epithelium and stroma. Endometrial epithelial cells do not respond to estrogen when cultured in vitro, which suggests the requirement of the underlying stroma to support their growth. Such epithelial–stromal interaction had previously been uncovered in the mouse mammary gland and testis where androgen action promoting development required androgen action through its receptor in the underlying stroma.[87–89] The generation of mutant mice with specific ablation of these steroid hormone receptors in either the whole uterus or specifically in the epithelium has confirmed the cell-specific roles of estrogen and progesterone in the uterus.

The paracrine regulation of the endometrial epithelium by estradiol was initially suggested by tissue reconstitution xenograft studies combining epithelial and stromal cells isolated from wild-type and *Esr1*-null mice.[90] These studies showed that estradiol could stimulate epithelial growth only when ESR1 was expressed in the underlying stroma, while ESR1 expression in the epithelium did not affect growth. A system of conditional knockout of *Esr1* only in the uterine epithelium confirmed this observation; while estradiol is indeed required for growth of the epithelium, its action does not occur directly through its receptor in the epithelium but rather through the ESR1-mediated production of growth factors such as insulin-like growth factor 1 (IGF1) and CCAT–enhancer binding protein beta (CEBPB) that originates in the stroma.[91]

Progesterone Receptor Signaling

PGR is likewise expressed in both uterine epithelium and stroma. Several studies have examined the presence of the progesterone receptor isoforms, PGRA and PGRB, in the various compartments of the human endometrium throughout the menstrual cycle. In the proliferative phase, PGRA and PGRB are present in both the glandular epithelium and stroma. PGR increases in both compartments throughout the proliferative phase, though PGRA is always present in greater quantity than PGRB. After ovulation, PGRA and PGRB are initially present in the glandular epithelium before levels of both isoforms decline. Levels of PGRB fall rapidly in the glandular epithelium but have been shown to rise again in the midsecretory phase. PGRA shows a more constant, steady decline in the epithelium throughout the secretory phase. In the stroma, PGRA and PGRB persist throughout the secretory phase.[27,92–94]

The relative importance of PGRA and PGRB in endometrial function has been elucidated through study of receptor-specific conditional knockout mice. Global knockout of *Pgr* (PRKO) in the mouse resulted in anovulation and an inability to respond to exogenous gonadotropins.[30] These mice were shown to be insensitive to the inhibitory effect of progesterone on estrogen-induced epithelial cell proliferation. A study in which chimeric uteri were created using the four possible combinations of wild-type and PRKO epithelium and stroma likewise confirmed the ability of progesterone to inhibit the proliferation of epithelial cells only when PGR was expressed in the stroma.[95] In other words, progesterone inhibited E2-induced DNA synthesis only in the two recombinants expressing PGR in the stroma (wild-type stroma combined with either wild-type or PRKO epithelium). However, a genetic model lacking *Pgr* in the adult epithelium demonstrated that epithelial PGR is also required to inhibit epithelial proliferation, the mechanisms of which will be discussed in this chapter.[96]

Using *Pgr-A* (PRAKO) and *Pgr-B* (PRBKO)-specific null mice, it was observed that PGRA is the obligatory receptor for fertility as these mice failed to ovulate normally and implantation–decidualization was prevented. These findings were not apparent in mice lacking *Pgr-B*.[97]

Other isoforms of the progesterone receptor likely exist (e.g., PGRC, PGRM, PGRS, and PGRT),[98] though clear roles for their function have not been shown. Some evidence exists that these isoforms may antagonize PGRA and PGRB by sequestering progesterone. In many mammals, progesterone levels fall immediately preceding parturition, supporting a role for progesterone in pregnancy maintenance. In humans, however, serum progesterone levels remain high through birth. Much effort is currently underway to characterize the changes to the uterus with the initiation of labor, with attention paid to reconciling differences between humans and other mammals regarding progesterone levels. Current theories include a role of PGRC in parturition,[99] isoform switching between PGRA and PGRB, and increased metabolism of progesterone,[100] among others.

In addition to acting via its nuclear receptors, progesterone can exert its effects via rapid cytoplasmic signaling. Classically, progesterone is understood to act via its nuclear receptors (as explained here). In this setting, ligand-bound progesterone receptor interacts directly with *cis*-acting progesterone response elements in the promoter regions of target genes.[101] PGRB can also interact with the Src tyrosine kinases at the plasma membrane, transducing a signal via the Ras–MAPK (mitogen-activated protein kinase) pathway.[102] These pathways of rapid cell signaling are important in proliferation, differentiation, angiogenesis, and decidualization.[103,104] Membrane-bound progesterone receptors distinct from the nuclear receptors have also been implicated in such rapid signaling involving calcium, MAPK cascades, and cAMP.[105,106]

Progesterone Receptor—Endometrial Compartment Cross-Talk

As with the estrogen receptors, PGR is involved in paracrine cross-talk between the stromal and epithelial compartments. While only a few studies using human tissue have investigated epithelium–stroma cross-talk in the endometrium, this work appears to support more extensive studies in the mouse. In vitro co-culture studies of human endometrium have shown that stromal cells play an important role in the epithelial response to estrogen and progesterone.[87,107,108] For example, epithelial proliferation was induced by estradiol and inhibited by medroxyprogesterone acetate only in the presence of stromal cells. Furthermore, PGR was not detected in the epithelium, suggesting that the action of progesterone to mediate epithelial function occurs via stromal PGR. IHH is expressed in the human endometrium and peaks during the secretory phase,[109] as is GLI family zinc finger 1 (GLI1), a downstream effector of IHH signaling. IHH has been shown to depend on the presence of progesterone,[110] and dysregulation of IHH has been shown in samples of endometriosis, a disease in which progesterone signaling is likely altered.[58]

Studies in the mouse using tissue recombination and compartmental-specific gene deletions have identified progesterone-regulated cross-talk both from epithelium to stroma and from stroma to epithelium. PGR cross-talk was initially studied by xenograft reconstitution experiments using various combinations of wild-type and PRKO epithelial and stromal cells. This analysis showed that PGR in the stroma was critical for regulation of epithelial-specific *Ihh* as well as the ability of progesterone to inhibit the epithelial cell proliferation induced by estradiol stimulation. Tissue reconstitution experiments indicated that stromal PGR is critical both for regulating progesterone-stimulated epithelial gene expression and for inhibiting estrogen-induced epithelial proliferation. However, unlike studies with ESR in which in vivo analysis or epithelial-specific ablation of *Esr* confirmed the importance of stromal ESR1 in the regulation of epithelial cell proliferation, in vivo conditional ablation of *Pgr* in the epithelium did not corroborate these stromal findings.[96]

Through studies of epithelial-specific ablation of *Pgr*, it was demonstrated that the progesterone-responsive gene *Ihh* could be directly regulated by epithelial PGR after progesterone stimulation. Also, this analysis demonstrated that epithelial PGR is directly responsible for the inhibition of estrogen-induced epithelial cell proliferation. Additionally, a microarray analysis of mouse endometrial epithelium during the window of receptivity[111] revealed induction of a transcription factor, KLF15, which was then shown, in the presence of progesterone, to inhibit epithelial proliferation by regulating minichromosome maintenance 2 (MCM2), an essential component in DNA synthesis initiation.[112] Understanding the discrepancy between the tissue recombination experiments and the in vivo compartmental-specific analysis can be accomplished by understanding the timing and nature of the paracrine cross-talk between these compartments.

During the preimplantation period in the mouse, PGR is expressed predominantly in the epithelial compartment of the endometrium, and this epithelial PGR is required for the inhibition of epithelial cell proliferation,[96] which likely occurs via KLF15. Interestingly, PGR transduces a signal from the epithelium to the stroma via the transmembrane receptor patched homolog 1 (PTCH1), which acts by inhibiting another transmembrane receptor, smoothened (SMO). Thus, binding of hedgehog to the PTCH1 receptor results in an active smoothened signal (Figure 24.6: Day 2.5). This signal activates transcription of the glioma-associated oncogene (*Gli*) family

of transcription factors and the orphan nuclear receptor chicken ovalbumin upstream transcription factor II (*Coup-TfII*), also known as nuclear receptor subfamily 2, group F, member 2 (*Nr2f2*).[113] IHH is expressed in the uterine epithelium just prior to the window of receptivity in the mouse, and the expression of NR2F2 target genes follows in the stroma.[114] These transcription factors have been shown to activate downstream targets of the hedgehog ligands by binding directly to response elements in the upstream promoters of the target genes.[82]

IHH and NR2F2 are fundamental to development, as the ablation of either gene in the mouse results in an embryonic lethal phenotype.[115,116] Mice heterozygous for *Nr2f2* have reproductive defects, including an inability to undergo the changes necessary for embryo implantation.[117] With such severe phenotypes in the global knockout of these genes, an understanding of the interplay between these factors has benefited from the use of conditional knockout studies in the mouse. Using a Cre recombinase system, selective knockout of these genes was possible in tissues expressing PGR (Pgr^{cre}). Both *Ihh* and *Nr2f2* conditional knockouts resulted in a similar phenotype in which embryos were unable to attach to the uterine lumen[118,119] and failed to undergo decidualization. The combined defects of attachment and decidualization again support the IHH–NR2F2 axis acting in both epithelial and stromal compartments to mediate proper endometrial function, and these factors have been shown to be important in the steroid hormone control of the endometrium. Estrogen promotes epithelial proliferation and the expression of factors on the epithelium, such as the large glycoprotein MUC1, during the proliferative phase of the cycle. Halting epithelial proliferation and downregulation of MUC1 after ovulation are critical steps in facilitating embryo attachment to the epithelium. Ablation of *Nr2f2* results in a failure to stop estrogen-related proliferation in the epithelium, and, similarly, MUC1 is not downregulated.[96] Furthermore, when these *Nr2f2*-ablated mice were treated with an ESR1 inhibitor, embryo attachment and decidualization were rescued.[120] The mechanism by which NR2F2 inhibits estrogen signaling may include HAND2, a PGR target shown to be important in downregulating the growth factor ligands that are critical for estrogen-driven epithelial proliferation.

The mechanism of progesterone inhibition of epithelial proliferation has been explained, at least in part, by studies investigating the role of HAND2. HAND2 is a basic helix–loop–helix transcription factor and a direct progesterone target that is upregulated in the stroma upon treatment with progesterone. In turn, HAND2 inhibits the expression of several fibroblast growth factor ligands, molecules that act as mediators to induce epithelial proliferation in response to estrogen.[121] This temporal progression of growth factor signaling indicates that PGR initially acts directly in the epithelial compartment to regulate gene expression and inhibit estrogen-induced cell proliferation. As pregnancy progresses and PGR is lost from the epithelium, stromal PGR then regulates epithelial cell function (Figure 24.6).

We have seen that dissemination of the progesterone signal to promote decidualization in the stroma and halt proliferation in the epithelium occurs via PGR through the aforementioned signaling pathways. Certainly, we have just begun to understand how progesterone acts to remodel the endometrium. Recent and current studies adopting a genome-wide assessment of progesterone binding and gene transcription will undoubtedly provide additional targets to investigate further both the mechanisms by which progesterone coordinates its effects on the endometrium and what, exactly, these changes entail. Excellent and detailed reviews of progesterone signaling and implantation are available for those interested in further information.[87,122]

Decidualization: Restructuring the Endometrium

While we have reviewed some of what is known regarding how steroid hormone signaling drives the endometrial transition, there is considerable information describing the changes of decidualization, even if the signaling pathways underlying these changes remain largely unknown. Ultimately, the function of the endometrium is singular: to serve as the interface between the mother and fetus. The endometrium allows attachment of the embryo and facilitates its invasion deeper into the lining. The highly invasive trophoblast is, at the same time, limited and nurtured by the endometrium. Again, while the signaling mechanisms remain, for the most part, poorly understood, it is clear that the rise in postovulatory progesterone initiates a cascade of events to allow the attachment and invasion of the embryo. Progesterone induces secretion in the endometrial glands and inhibits growth in the epithelium. Locally produced chemokines attract specialized uterine natural killer cells (uNKs, $CD56^{bright}$–$CD16^{-}$), which express immunomodulatory molecules and have been shown to play an important role in producing cytokines and angiogenic factors that reorganize the maternal spiral arteries.[123–125] Furthermore, progesterone has been shown to alter the contractile activity of junctional myocytes, a process likely important in allowing apposition of the blastocyst to the luminal epithelium.[123,126]

The most apparent—and thus the most studied—change to the human endometrium prompted by the rise in progesterone after ovulation is the structural and biochemical transformation of the endometrial stromal cells. Interestingly in humans, unlike in many mammals, decidualization occurs independent of pregnancy. The cues and functional ability to decidualize are inherent to

the cells themselves and depend on signaling that originated with progesterone from the corpus luteum.

Stromal Cell Decidualization

One reason why stromal cell decidualization is relatively well understood in comparison to changes involving other cell types (immune, vascular, etc.) occurring in the endometrium is the ability to isolate and grow these stromal cells in culture and then to recapitulate their transformation in vitro. The phenotypic and biochemical changes to stromal cells undergoing decidualization have been nicely reviewed.[123]

At a microscopic level, the elongated fibroblasts transform to plump, rounded cells (Figure 24.5). The nucleus becomes enlarged and rounded, and there is expansion of the rough endoplasmic reticulum and Golgi apparatus. Glycogen and lipid droplets accumulate. Processes appear on the cell surface and protrude into the extracellular matrix, impinging on neighboring cells. Extracellular matrix proteins such as type IV collagen, laminin, fibronectin, heparin sulfate proteoglycans, and decorin are produced. Part of the stromal cell transformation is acquisition of high secretory capacity, and secreted products from these cells (IGFBP1 and PRL) have become standard markers for the decidualization process. These cells also produce cytokines, growth factors, and signaling molecules thought to act in local autocrine or paracrine fashion—there is no evidence that these proteins are secreted into the circulation—to propagate the signals and processes of decidualization. Human endometrial stromal cells undergoing decidualization in vitro have been subjected to microarray and other transcriptome analyses that reveal enrichment pathways involved in cellular adhesion, organization of the cytoskeleton and extracellular matrix, signal transduction, cell cycle progression, and apoptosis, among others.[57,64,78,127,128] A major current goal is determining how these transcriptional networks translate into the biology of decidualization. This will be accomplished, no doubt, through continued study in humans (e.g., interrogation of biopsy specimens, and primary cell culture), other mammals (e.g., conditional knockout studies), and combinations of the two (e.g., human tissue xenografted into other animals).

Mediators and Products of Decidualized Cells

While endometrial stromal cells will respond in vitro to progesterone alone, the change is slow and not consistent with the temporal patterns in vivo. The addition of cAMP, however, drastically alters the rate of decidualization. Indeed, stromal cells will respond to cAMP alone, though this response is brief. The role of cAMP in the decidualization process has been explained as that of a progesterone sensitizer.[129] cAMP is stimulated by a variety of local and endocrine factors (prostaglandins, relaxin, and corticotropin-releasing hormone), and the production of cAMP is robust enough to be detected between proliferative and secretory cells. After pregnancy, the endometrium is exposed to vast amounts of hCG, which signals primarily through cAMP.[123] Exactly how cAMP and progesterone act in relation to one another is not well understood, though it is thought to involve recruitment of coregulators (see Chapter 9). cAMP has been shown to induce the transcription factors specificity protein 1 (SP1), Forkhead box O1 (FOXO1), signal transducer and activator of transcription 3 and 5 (STAT3/5), and CEBPβ (CCAAT/enhancer binding protein beta), all of which are known to function with progesterone receptor to affect decidualization.[129] Also, cAMP may be indirectly involved in the activity of PGR through alterations in enzymes that modify the attachment or removal of small ubiquitin modifier (SUMO)—a small peptide that changes nuclear localization patterns, associations, and activities of the transcription factors it binds. Thus, decreasing the amount of bound SUMO translates into a more active PGR.[130,131]

The prolactin secreted from the decidualized endometrium is structurally and functionally identical to prolactin from pituitary prolactin, though the pituitary prolactin secretagogues (dopamine, bromocriptine, and thyrotrophin-releasing hormone) have no effect on endometrial prolactin production. Prolactin from the endometrium can be stimulated by IGF1, relaxin, and insulin, each acting through its native receptor. A prolactin-releasing factor has been isolated from placenta, and an inhibitor of this releasing factor has been purified from decidua. Since prolactin can exert an overall inhibitory effect on decidualization, there may be a balance in the control of its production from the trophoblast and endometrium in early pregnancy.

Interestingly, certain factors at first expressed in the epithelial compartment during the proliferative phase of the menstrual cycle (superoxide dismutase 2 (SOD2), growth arrest and DNA-damage-inducible 45 (GADD45), CEBPβ, and FOXO1) are induced in the stroma during decidualization. Similarly, factors expressed in the decidualized stroma (prolactin, IGFBP1, and pregnancy-associated plasma protein A (PAPPA)) are eventually produced at high levels by the placenta during pregnancy.[123,132]

Since decidualization of the endometrial stroma in humans occurs in the absence of pregnancy and it is possible to recapitulate decidualization in vitro, investigators have begun to study the decidualization process in great detail, utilizing samples from human subjects. Clearly, however, study of a single cell type in the artificial in vitro environment cannot begin to explain the complexities of interactions between different cell types, compartments of the endometrium, or the endometrium and embryo. Here, too, additional animal model systems

have been used to understand this complex biology. For example, the cross-talk between epithelial and stromal compartments of the endometrium that has been shown to be critical to downregulation of estrogenic effects in the epithelium, as we saw in this chapter, is also important for promoting decidualization in the stroma. The conditional knockout mouse has enabled a better understanding of the mediators linking progesterone to the changes in the uterine stroma required to support a pregnancy.

Expression of key regulators of decidualization increases robustly from basal levels observed at the time of implantation (Figure 24.6: Decidua). COX2 (transcribed from the gene *Ptgs2*), a key regulator of prostaglandin synthesis, is one of the first markers observed. *Ptgs2*-null mice display multiple fertility defects, including impaired ovulation and fertilization as well as defective implantation and decidualization.[133] As COX2 is an early, rate-limiting step in the production of prostaglandins, it was not clear which prostaglandins were relevant to implantation and decidualization. Further work on COX2 revealed that COX2-derived prostacyclin (PGI_2) may be the primary prostaglandin involved in implantation and decidualization, and that the effects of PGI_2 are likely mediated through the nuclear receptor, peroxisome proliferator-activated receptor delta.[134]

Recently, regulation of COX2 has been shown to originate from blastocyst attachment to the endometrial epithelium. The process of blastocyst attachment has long been known to involve the movement of fluid out of the endometrial cavity, leading to a collapsed endometrium around the blastocyst.[135,136] Study of such fluid and electrolyte transport led to work on the voltage-gated sodium channel (the epithelial sodium channel, or ENaC), which now has been shown to be critical in transmitting a signal from the trophoblast to the endometrial stroma. Trypsin, a serine protease released from the trophoblast, leads to epithelial cell depolarization and the activation of L-type sodium channels. The resulting influx of calcium ions leads to the release of prostaglandin E2 (PGE_2) via COX2 upregulation that may occur via the cAMP-responsive transcription factor, cAMP response element-binding protein (CREB). This epithelial-derived PGE_2, triggered by the blastocyst, then functions in the stroma to regulate decidualization.[137] Further work is needed to better understand how interactions between the attaching blastocyst and endometrial epithelium affect the decidualization process and the requisite preparation of the stroma for embryo invasion.

The homeobox transcription factor, HOXA10, is also critical for decidualization of the endometrial stroma. *Hoxa* genes are essential in the mouse for endometrial development and implantation. *Hoxa10*-null mice display severely compromised decidualization,[138] and part of the effect of ablating *Hoxa10* involves altered function of cyclin D3 (CCND3), as replacement of cyclin D3 rescues much of decidualization and placentation, though the mice remain infertile.[139] In women with infertility, altered HOXA10 expression levels have been found in the endometrial stroma during the window of receptivity.[140]

Members of the bone morphogenetic protein (BMP) and wingless-related MMTV integration site (WNT) families are critical to these changes in early pregnancy.[82] BMP2, for example, is highly expressed in the stroma in the peri-implantation period and is thought to be involved with promoting decidualization after embryo implantation, a hypothesis supported by rescue of impaired decidualization in conditionally ablated *Bmp2* mice through the administration of recombinant BMP2.[141] WNT4 has been suggested to lie downstream of BMP2,[142] with this signaling axis originating via epithelial IHH and stromal NR2F2 (Figure 24.6: Decidua). Of note, BMP2 is also expressed at high levels in human endometrial stroma, suggesting a similar role in decidualization and conservation among species.[142]

Clearly, a better understanding of the complex biology of decidualization will come with continued investigation into multiple model systems, including cultures of human cells, transgenic mice, and combinations of the two.

Remodeling the Vasculature, Extracellular Matrix, and Immune System

Vascular remodeling is critical in a system such as the endometrium in which rapid, cyclic growth and regression occur, and the endometrium is a rich source of angiogenic factors in both pregnant and nonpregnant states. VEGFs, specific for endothelial growth, are expressed in the endometrium, with peak expression correlating to maximum angiogenesis during the secretory phase.[132] Certain members of the VEGF family are stimulated by estrogen in the proliferative phase and are sensitive—and upregulated—in the hypoxia that occurs with myometrial contraction and vascular interruption at the end of a menstrual cycle. Prompted by hypoxia and rising estradiol production from the new developing follicles, VEGFs once again promote the vascularization required to re-epithelialize and develop the endometrium. Angiopoietins and members of the fibroblast growth factor family are also involved in the growth of endothelial and endometrial stromal cells and act to maintain the endometrium by inhibiting apoptosis and stabilizing blood vessels. Further balance exists between potent vasoconstrictors, such as endothelin 1, and vasodilators such as nitric oxide and prostacyclins, though the exact control over these relationships remains poorly understood.

In the setting of an invading trophoblast, other local factors are involved in moderating the vasculature. Once the trophoblast has begun to invade the endometrium, spiral arterioles are plugged into the region surrounding

the embryo, creating a region with low oxygen tension that has been interpreted to be necessary for the continued growth and invasion of the pregnancy. This hypoxia comes at an expense, however, as the potential for damage from reactive oxygen species increases. Part of the decidualization process is an induction of both enzymes that neutralize reactive oxygen species (glutathione, monoamine oxidases, peroxidases, S-transferases, superoxide dismutases, and thioredoxin) and processes to repair the damage they cause (GADD45α).[123,143,144]

An additional requirement for trophoblast invasion is remodeling of the endometrial extracellular matrix. Extracellular matrix proteins are broken down by MMPs, a large family of proteolytic enzymes, several of which are expressed by the invading trophoblast. The action of MMPs is opposed by inhibitors of metalloproteinases (TIMPs), factors that are expressed by both the stromal cells and the trophoblast itself. Expression of TIMP3, for example, can be induced in stromal cells by embryo coculture.[145] The TGFβ family is also important in the regulation of MMPs. Multiple members of the TGFβ family are differentially regulated (most are downregulated) with decidualization and may be directly regulated by PGR. Interestingly, with the fall in progesterone at the end of the menstrual cycle, many of these factors have been shown to be upregulated and involved in the breakdown of the endometrium preceding menses. Thus, progesterone may play a direct role in the modulation of the TGFβ pathways, while additional fine-tuning occurs in the presence of the invading trophoblast. Similarly, plasmin and its various modulators play important roles in the structural reorganization of the stroma.

Immune factors also play an important role in the establishment and maintenance of pregnancy. Indeed, the invading trophoblast and embryo must be both tolerated by the maternal immune system and protected from pathogens. The specialized uterine natural killer (uNK) cells are recruited to the decidua by locally produced cytokines (CCL4 and CXCL9/10).[123] uNK cells express certain immunomodulatory molecules (galectin 1 and glycoledin A), which have been shown to inhibit T-cell activation, proliferation, and survival and attenuate the production of proinflammatory cytokines.[146] Other factors from the decidua have also been shown to modulate T-cell-mediated inflammation and are known to be involved in the control of apoptosis.

CONCLUSION

Originating from studies on the nonhuman primate and currently utilizing state-of-the-science techniques of genome-wide interrogation and transgenic animals, investigators have sought to understand the remarkable changes to the fallopian tube and endometrium over the menstrual cycle. By nature, in the case of the endometrium, rapid cycling of proliferation, differentiation, and regression requires a coordination of diverse cellular processes including cytoskeletal organization, cell cycle progression, cellular secretion, angiogenesis, and apoptosis. As the endometrium undergoes decidualization regardless of pregnancy in humans, the ultimate control of this process originates with the ovarian steroid hormones, estradiol and progesterone. Acting both directly and via multiple downstream signaling pathways, estradiol and progesterone coordinate the patterns of growth and differentiation that can be described histologically, genetically, and biochemically. When the regular, cyclic production of progesterone is lost—for example, with anovulatory conditions like PCOS—so too are lost the various stages of differentiation. Proliferation continues unchecked, and the risk of hyperplasia and malignancy increases. Endometriosis, a disease where endometrium exists outside the uterus, has been explained to a degree by progesterone resistance. The ectopic foci of endometrium contain glands and stroma, as with endometrium in its native state, but display altered patterns of gene expression and a defective decidual response to progesterone.[147] Critical to developing endometriosis therapies, however, is an understanding of the pathogenesis of the disease, knowledge that has remained largely elusive since Sampson described his hypothesis in the 1920s,[148] and whether differences in fundamental steroid hormone signaling underlie the ability for the endometrial tissue to persist and grow *ex utero*.

While evidence suggests that the endometrium is altered in hyperstimulated ART cycles, very limited data exist describing consistent—and thus fixable—defects in the receptive endometrium. While some advocate freezing all embryos of an in vitro fertilization cycle, with subsequent transfer of frozen-thawed embryos in subsequent hormonally prepared cycles meant to better recapitulate the endometrium of a natural cycle, the hyperstimulated endometrium remains receptive (even if altered), and most pregnancies still result from transfer of fresh embryos in the hyperstimulated cycle. Perhaps even more interesting, much attention is now focused on the earliest communication between the embryo and endometrium in the establishment of proper placentation and whether an abnormal endometrium might be responsible for outcomes such as growth restriction, preterm birth, and preeclampsia, which are associated with the patient's underlying infertility, the ART process itself, or both.

In the case of the fallopian tube, what was once considered a passive conduit for sperm and embryo transport is now better understood as a complex and dynamic system that actively participates in the movement of the gametes and contributes to the earliest steps of embryonic development. Dysfunction of the tube can prohibit

pregnancy altogether or result in life-threatening ectopic pregnancy. Recent work suggests that certain categories of malignancy whose origin has been thought to be the ovary may well originate from the fallopian tube.

The current application of genome-wide strategies to query the transcriptome and binding sites of the steroid hormone receptors across the human menstrual cycle and under specific treatment or disease states will, no doubt, provide new insights into the biology of the endometrium and fallopian tube. Powerful transgenic animal systems can be used to ablate or overexpress candidate genes in specific tissues or under certain conditions, thus fine-tuning our understanding of how these molecules regulate oviductal and endometrial function. Certainly, the development of new diagnostics and therapeutics for a host of endometrial and fallopian tube disorders will take advantage of our ever-sharper understanding of estrogen, progesterone, and the downstream molecular signaling underlying the cyclic physiology of these remarkable organs.

INTRODUCTION

The ovarian-derived sex steroid hormones dictate the uterine estrous or menstrual cycle in mammals and are therefore essential to the establishment and maintenance of pregnancy. The uterine response to the preovulatory rise in circulating estradiol (E2) is required to prepare the tissue for the forthcoming rise in progesterone (P) that accompanies ovulation and is critical to embryo implantation. This physiological coordination between the ovary and uterus is common to the large majority of mammals studied and the spectrum of actions and effects of the sex steroids in uterine tissue are mediated by their cognate NRs. Estrogen was first described almost 100 years ago as a substance that induced estrus. We now know from many studies over the past 50 plus years that its physiological activity is broader than simply inducing a secretory response in the reproductive tract—estrogen also affects multiple organs that previously were not considered estrogen responsive. The mechanistic theory for explaining the biological actions of steroid hormones came in 1960 when Elwood Jensen and colleagues first described the uptake and retention of labeled E2 in certain tissues that, because of this retention, became referred to as estrogen target tissues. The ovary and uterus were amongst the tissues showing this property. The hormone tissue retention concept was then shown to be reflective of other steroid hormones, exemplified by progesterone, glucocorticoid, and thyroid hormones. The Jensen and Gorski laboratories were then the first to show that the tissue retention of estrogen was due to the presence of specific proteins contained within those tissues, which became referred to as estrogen receptors (ER). Numerous research groups followed with studies showing that the receptor proteins were hormone specific and their presence was linked to some biological activity in certain tissues. Subsequent development some 20 years later of the first antibodies to the ER allowed for more direct detection and qualification of the protein levels in tissues under different physiological states or disease conditions. Although initially the dramatic physiological effects of estrogens on the mammalian uterus were appreciated and well described, later investigations began to elucidate the precise mechanisms and signaling pathways involved. Our understanding of steroid hormone action in the uterus has been greatly advanced by utilization of new technologies with the generation of knockout and knock-in models, including receptor or coactivator null, tissue and cell selective null, and mutant knock-in models in mice. These models are also used in combination with microarray, RNA-seq, and ChIP-seq methods that allow for comprehensive mapping of interaction of nuclear receptors (NRs) with chromatin and modulation of genomic response to steroids in uterine

tissues. Together, these models and techniques have led to better understanding of the molecular details of steroid receptor roles in biological processes.

Receptor-mediated actions of progestins, androgens, and estrogens are central to reproduction. Perhaps unique among the various categories of signaling pathways, the sex steroid hormones and their cognate receptors are surely mentioned, if not discussed in detail, in every chapter of this volume. The sex steroid hormones are integrated into every aspect of mammalian reproductive physiology in both sexes, including sexual maturation and development, gametogenesis, hypothalamic–pituitary control of gonadal function, sexual and maternal behavior, pregnancy, and lactation. Disruption of the signaling pathways for any one of the three gonadal steroids leads to reduced fecundity, if not infertility, due to aberrations in multiple organ systems. Therefore, a thorough understanding of the sex steroid receptors in terms of their expression in reproductive and endocrine tissues, their mechanism of action, their role in reproductive processes, and their interaction with nonsteroidal signaling pathways is instrumental to our ability to manage infertility and reproductive disease.

This chapter principally covers the signaling pathways for progestins, androgens, glucocorticoids, and estrogens, and the role of each in ovarian and uterine function in mammals. Because of the importance of the sex steroids and the likelihood that each is discussed in several other chapters of this volume, it is appropriate to first discuss the structure, mechanism of action, and signaling pathways for each of the sex steroid receptors. Sections then follow on the role of sex steroids in ovarian and uterine function. We chose to divide each of these sections according to the sex steroid receptors: the estrogen receptors (ERs), progesterone receptors (PRs), androgen receptors (ARs), and glucocorticoid receptors (GRs). The section Sex Steroid Receptors and Ovarian Function discusses what is currently known concerning each particular sex steroid signaling pathway in terms of its expression pattern and distribution within the ovary, and its intraovarian role in granulosa cell proliferation and differentiation, thecal cell function, and ovulation. Because a separate chapter (Chapter 23) is dedicated to the corpus luteum, the role of the sex steroid receptors in luteal function is not covered in detail. The section Sex Steroid Receptors in Uterine Function discusses what is currently known concerning each sex steroid signaling pathway in terms of its expression pattern and distribution within the uterus and its role in uterine cell proliferation and differentiation. New since the previous editions of this volume is the development of tissue selective null or "knock-in" mouse models for each of the sex steroids. The study of each of these models has already and will continue to make enormous contributions to our understanding of the reproductive role of each receptor signaling pathway in toto. Therefore, we include a detailed description of the ovarian and uterine phenotypes for each of these models in their respective sections.

THE STEROID RECEPTORS

The steroid receptors are part of the family of nuclear receptors (NRs) that is ubiquitous throughout the animal kingdom. The members of the NR family fulfill a plethora of functions and are integral to the development and maintenance of multiple physiological systems. Continued discovery of new NRs has led to a considerable expansion of the NR family and demanded a system of categorization. NRs have been assigned to three classes.[1–3] Class I includes the steroid receptors (ER, PR, AR, GR), which interact with high specificity to their steroid ligand as well as to DNA motifs comprised of inverted-repeat hexanucleotides separated by a 3-base pair (bp) spacer. The Nuclear Receptors Nomenclature Committee has developed an NR nomenclature scheme that is based largely on sequence homology and evolutionary comparisons and divides the over 60 NRs into seven subfamilies and a varied number of groups within each subfamily.[4] The ERs (ERα and ERβ) are the sole members of the NR3A subgroup, ERα and ERβ being NR3A1 and NR3A2, respectively.[4] The PR and AR are the third and fourth members of the NR3C subgroup that also includes the GR and the mineralocorticoid receptor.[4] The official gene names for these steroid receptors are *ESR1* and *ESR2* for ERα and ERβ, respectively, *PGR* for progesterone receptor, *AR* for androgen receptor, and *GCR* for glucocorticoid receptor. The general properties of the sex steroid receptor family and those mechanisms of receptor action that are most relevant to ovarian and reproductive tract function are outlined following.

Genes, mRNA, and Regulation

The genes encoding the sex steroid receptors exhibit a highly conserved structural organization. The human PR (*PGR* or *NR3C3*), AR (*AR* or *NR3C4*), ERα (*ESR1* or *NR3A1*), ERβ (*ESR2* or *NR3A2*), and GR (GCR or NR3C1) genes are each composed of eight coding exons, and vary in length from 40 kb (ERβ) to >140 kb (ERα).[5–8] In each case, the N-terminal domain (NTD) of the receptor is usually encoded by a single exon, the two zinc fingers of the DNA binding domain, each encoded by separate exons (2 and 3), and the ligand binding domain (LBD), encoded by exons 4–8 (Figure 25.1).

Estrogen Receptor

The human *ESR1* (ERα) cDNA was first cloned in 1985[9–11] and has since been isolated from numerous additional species.[12,13] A second ER gene, termed *ESR2* (ERβ), was discovered in 1996 in rat[14] and human[15] tissues and has since been cloned from many species.[13] Unlike the A and B forms of PR and AR, ERα and ERβ are not isoforms but rather distinct receptors encoded by two genes on different chromosomes. The ERα proteins are 595 and 599 amino acids in length in human and mice, respectively, with an approximate molecular weight of 66 kDa (Figure 25.1).[8,16–18] Multiple promoter and regulatory regions in the 5′-untranslated sequences of the human and rat *ESR1* gene have been described, yet all possess the same single open reading frame.[8] Numerous naturally occurring variants of the *ESR1* mRNA in normal and neoplastic tissues of several species have been described, but the existence of corresponding proteins remains controversial.[18]

The promoter region of the *ESR1* gene has been relatively well characterized and indicates a complex regulation of expression.[8,19–21] Cicatiello et al.[22] demonstrated that the proximal 0.4 kb of the mouse *Esr1* promoter is sufficient to provide for widespread but specific expression of a reporter construct in vivo. Regulatory elements that may provide for AP-1, Sp1, and ER autoregulation of the human *ESR1* promoter have been described.[23,24] Decreased *ESR1* expression is linked to receptor-mediated actions of vitamin D[25] and increased intracellular cAMP or mitogen-activated protein kinase activity.[23] Increased methylation of the *ESR1* promoter is implicated in reducing ER levels, especially in tumorigenic tissues.[23]

The *ESR2* genes of multiple species yield numerous transcripts that range from 1 to >9 kb in length, in contrast to the single predominant transcript of ~7 kb transcribed from the *ESR1* gene.[18] Initial descriptions of human and rodent ERβ projected a protein of 485 amino acids. However, it is now apparent that translation of the *ESR2* mRNA initiates upstream of these original open reading frames and yields a receptor of 549 amino acids in rodents and 530 amino acids in humans, each with an approximate molecular weight of 60–63 kDa (Figure 25.1).[8] Therefore, ERβ is slightly smaller than ERα, and most of this difference lies within the N-terminus. A number of

FIGURE 25.1 The steroid family of receptors and endogenous ligands. (A) Schematic illustration of the structural organization of the sex steroid nuclear receptors. The more highly conserved C and E domains are depicted as *open boxes* and the less well-conserved A/B, D, and F domains as *filled bars*. The F domain is unique to the estrogen receptors (ER). The functions of the modular domains are indicated as are the two known transcriptional activation function domains, AF-1 and AF-2 (as well as AF-3 found only in PRB). The AF-1 domain is harbored in the A/B region and exhibits constitutive activity in vitro, whereas the AF-2 domain lies with the ligand binding (E) domain and is critical to ligand-induced receptor activation. Both domains synergize during ligand-activated receptor actions. NLS, nuclear localization signal. (B) Comparison of the human steroid receptors, the androgen receptor (AR), estrogen receptors α (ERα) and β (ERβ), progesterone receptor B (PRB) and A (PRA) and the glucocorticoid receptor (GR). The amino acids that compose each domain of the human forms are indicated. For PRA, the numbers refer to the amino acid residues in reference to PRB.

variant transcripts of the *ESR2* gene have been described; however, unlike ERα, there is growing evidence that some of these variants may coexist with the wild-type (WT) receptor form in certain tissues (Figure 25.2). Portions of the mouse *Esr2* gene have been characterized and possess potential binding sites for numerous transcription factors[8,26] and the initiation of transcription from at least two distinct untranslated exons.[27]

Progesterone Receptor

Two distinct promoters in the *PGR* gene provide for the generation of two major PR isoforms, PRB (114 kDa) and PRA (94 kDa), in most species except rabbit, which possess PRB only. The two PR forms are identical in all regions except the NTD, which is truncated by 128–164 amino acids in PRA, depending on the species (Figure 25.1). Both PR isoforms are expressed at relatively equal levels in tissues, although differences in the ratio have been noted in certain tissues. A third isoform, termed PR-C, an N-terminally truncated form that lacks the full A/B domain and first zinc finger of the C domain, has been described, but its expression as a protein is controversial.[29,30] The level of PR expression is modulated by ER-mediated effects of E2 in certain but not all tissues, and this is especially true in the female reproductive tract.[31–34] Several naturally existing *PGR* variant transcripts harboring exon deletions or distinct 5′-untranslated sequences have been described but are not well characterized in terms of protein expression or functionality.[27,30,35]

Androgen Receptor

The *AR* gene is located on the X chromosome, and therefore genetic males possess only a single copy.[7,36,37] Two distinct start sites in the *AR* gene are used to produce two isoforms, AR-B (110 kDa) and AR-A (87 kDa), which differ only in the N-terminus (Figure 25.1).[12,38] However, in contrast to the PR, the two known AR isoforms exhibit only subtle functional differences. A unique feature of the *AR* gene relative to

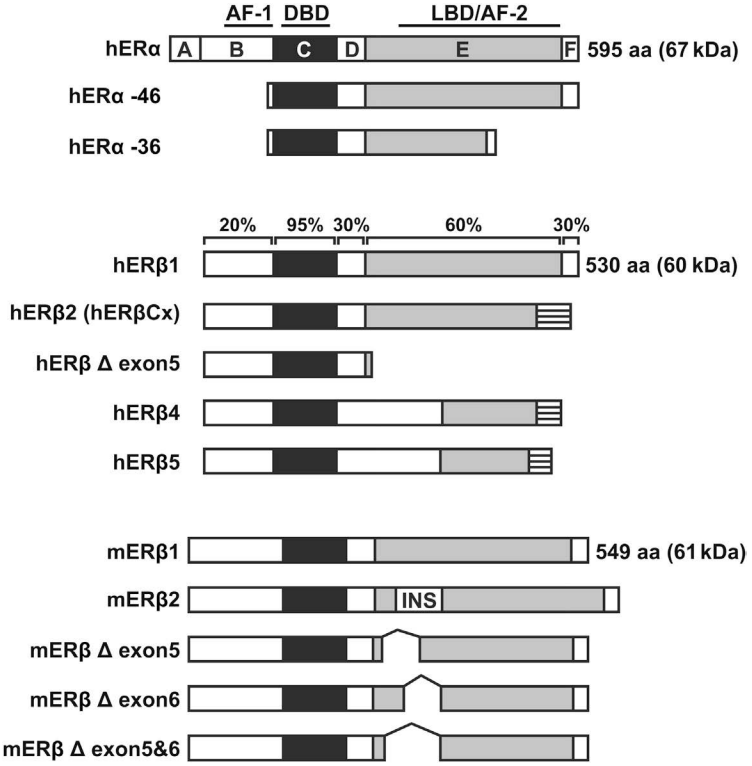

FIGURE 25.2 Human (h) and mouse (m) estrogen receptor variant transcripts. ERs are shown, with the general modular structure of steroid hormone receptors illustrating the N-terminal (A/B) domain, DNA binding (C) domain, hinge (D) region, ligand binding (E) domain, and C-terminal (F) domain (see Figure 25.1 for details). *Top*: hERα full-length and truncated variants (hERα-46 and hERα-36), lacking N-terminal AF-1. *Bottom*: Full-length hERβ (or ERβ1) with % sequences similarity in comparison to ERα indicated above it. Reported hERβ isoforms are shown beneath. hERβ2 is also called ERβCx, and encodes an alternate C-terminal region, depicted by the striped fill, also seen in hERβ4 and 5. hERβcx is unable to bind E2 but acts as a dominant negative receptor when heterodimerized with ERα in vitro.[28] hERβΔexon5 is produced by deletion of exon 5, and produced a truncated protein due to a frame shift leading to translational termination, and has been found in other mammals.[18,28] mERβ2 contains a 54-bp insert (INS) that codes for an additional 18 amino acids in the ligand binding (E) domain and has only been found in rodents. mERβ2 exhibits an approximate 35-fold decreased affinity for E2 relative to WT mERβ and a significantly reduced transactivational activity in vitro.[18] mERβΔexon5, mERβΔexon6, and mERβΔexon5&6 lack parts of the LBD. *Source: Redrawn with permission based on a figure from Ref. 18.*

its sex steroid receptor counterparts is the presence of polymorphic repeats of glutamine and glycine in the NTD, the former of which has been linked to certain chronic diseases and cancer in humans.[39] There are binding sites for a wide array of transcription factors in the *AR* promoter, including Sp1, cAMP-response element binding (CREB) protein, and c-*myc*, suggesting complex tissue-specific regulation. Direct androgen-mediated autoregulation of *AR* expression has also been shown.[39]

Glucocorticoid Receptor

Although not historically recognized for its roles in uterus and ovary, GR is ubiquitously expressed, and more recent studies have demonstrated important interactions between GR and sex steroid receptor mediated signaling.[40,41] GR isoforms, are produced by alternate splicing leading to different c-terminal amino acids. GRα is the primary isoform, whereas GRβ is unable to bind GR ligands and can behave as a dominant negative inhibitor of GRα activity.[42]

Receptor Structure

Common to all members of the NR family is a modular structure of domains, each of which harbors an autonomous function that is critical to total receptor action.[1,2,12,43–47] The sex steroid receptors are composed of five functional modules, an N-terminal domain (NTD) or A/B domain, the DNA binding (C) domain, a hinge (D) region, and an LBD (E) (Figure 25.1). The ERs also possess a unique C-terminal F domain of unknown function. Our understanding of the NR functional domains and their importance to overall receptor activity is largely derived from the in vitro study of artificially generated mutant receptors and more recently from X-ray crystallography studies.

NTD or A/B Domain

The NTD or A/B domains of the NR family members greatly vary in length and share little homology among the steroid receptors, although some structural features are conserved (Figure 25.1). Crystallography studies of the steroid receptor NTD have been largely unsuccessful because this portion of the receptor fluctuates in aqueous solutions. However, evidence suggests that intramolecular interactions between the A/B and other receptor domains are likely to induce a more structured NTD.[1,37,45] Current models of NR signaling incorporate the flexibility of intrinsically disordered (ID) regions of the receptor, including the NTD, into a mechanism of allosteric interaction and coordination of ligands, DNA motifs, and NR domain functions.[1,45,48] The NTD of each of the sex steroid receptors harbors the transcriptional activation function-1 (AF-1) domain and provides for cell and promoter-specific activity of the receptor as well as a site for interaction with co-receptor proteins (Table 25.1). The AF-1 domain alone can confer constitutive transcriptional (i.e., ligand-independent) activity when linked to a heterologous NR DNA binding domain in vitro, but this function is largely overcome in the context of the whole receptor.[12] Posttranslational modifications to the A/B domain can dramatically affect the overall behavior of the receptor and are thought to be an important mechanism for the modulation of AF-1 functions.[17] Phosphorylation of the A/B domain is the most well-characterized posttranslational modification and occurs in all three sex steroid receptors via the actions of multiple intracellular signaling pathways, including mitogen-activated protein kinase pathways,[49] the cAMP/protein kinase A (PKA) pathway, and cyclin-dependent kinases.[12,37,39,43,50]

The extended N-terminal sequences that are unique to PRB (Figure 25.1) provide a third transcriptional AF-3 domain in this isoform that is lacking in PRA. This may allow for PRB-specific expression of certain P regulated

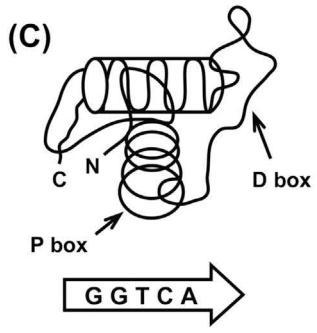

FIGURE 25.3 The nuclear receptor response elements and primary structure of the DNA binding domain. *Top*: Shown is the canonical core hormone response element (HRE) for the estrogen receptors (ERE) and glucocorticoid receptors (GRE). These sequences are located in the regulatory regions of sex steroid target genes and provide a site for receptor binding and transactivational activity. A full HRE consists of two core palindromic sequences arranged as an inverted repeat, always separated by three bp (denoted by XXX). Note that a change from GT to AA at positions two and three of the core sequence modifies the ERE to a GRE. *Bottom* (A) The DNA binding domain (C) of the sex steroid receptors is highly conserved and composed of two zinc fingers and a C-terminal extension (CTE). The ERα DBD is shown. Each zinc finger is composed of four conserved cysteine residues that coordinate to chelate a single zinc ion. Helix 1 of the first zinc finger contains the P-box residues involved in the discrimination of the HRE. Residues in the second zinc finger (helix 2) form the D box that provides a dimerization interface. The CTE is critical

genes.[29,50,60] In general, PRB is a stronger activator of transcription versus PRA when acting on a hormone response element (HRE)–driven gene construct in vitro.[60] Furthermore, antagonist-bound PRB acts as a strong transcriptional activator in certain cell and promoter contexts, whereas antagonist-bound PRA is inactive.[29]

The NTD of the AR is especially autologous in vitro and is likely more important to overall AR transactivation than the C-terminal AF-2 domain (described later).[1,37–39] Furthermore, the first 30 residues of the AR NTD are highly conserved and important for interactions with the LBD that provide for agonist-induced stabilization of the receptor.[37] Unique to the AR among the sex steroid receptors are a series of amino acid repeat sequences in the NTD, most notably the polymorphic tracts of glutamine and glycine, of which certain lengths are thought to be linked to various human diseases or cancer.[37,38]

The greatest structural disparities between ERα and ERβ lie within the A/B domain, which is approximately 30 amino acids shorter in ERβ and exhibits only >20% homology.[8,61,62] This divergence likely accounts for the many functional differences that have been revealed from comparative studies of the two ER forms.[8,17,18,62] In general, ERβ tends to be a less effective transcriptional activator compared with ERα when acting in a classic estrogen response element (ERE)–driven mechanism in vitro.[18] An ERα/ERβ chimera in which the A/B domain of ERβ has been replaced with that of ERα is able to activate transcription much better than the native ERβ.[61] Furthermore, certain antagonists (e.g., tamoxifen) that exhibit some agonist-like properties through AF-1 when bound to ERα exhibit no such activity with ERβ.[61,63]

DNA Binding or C Domain

The C domain of the NR family members is that portion of the receptor that specifically functions to recognize and bind to the *cis*-acting enhancer sequences, or HREs, that are located within the regulatory regions of target genes (Figure 25.3). It is the most highly conserved (55–80%) region among the NR family members.[2,46,64] The C domains of ERα and ERβ are practically identical (>95% homology) in most species and are therefore expected to exhibit a similar affinity for the same HREs.[62] The functionality of the C domain is provided by a motif of two zinc fingers, each composed of four cysteine residues that chelate a single Zn^2 ion, and are always encoded by separate exons within the gene (Figure 25.3). Crystallography studies indicate a highly conserved structure consisting of dual α-helices positioned perpendicular to each other[1,45,46] (Figure 25.3). Amino acids in the C-terminal "knuckle" of the first zinc finger form the "P box" (proximal box) of the DNA binding domain and confer sequence specificity to the receptor; hence, the proximal zinc finger is often referred as forming the "recognition helix" (Figure 25.3).[64] Amino acids at the N-terminal "knuckle" of the second zinc finger form the "D-box" (distal box) and are more specifically involved in differentiating the "spacer" sequence within the HRE as well as providing an interface for receptor dimerization (Figure 25.3).

The consensus HREs that sex steroid receptors bind are composed of two 6-bp palindromic sequences arranged as an inverted repeat and always separated by a 3-bp spacer (Figure 25.3). Because the P-box residues are identical among the AR, PR, and GR, these receptors bind a common consensus HRE consisting of two 6-bp palindromic half-sites (5′-PuG[G/A]ACA) arranged as an inverted repeat and always separated by a 3-bp spacer (Figure 25.3). The consensus ERE bears the same arrangement but is composed of a unique palindromic half-site (5′-PuGGTCA) (Figure 25.3). The inverted-repeat arrangement of the palindromic sequences is unique to sex steroid receptor HREs and dictates that the receptors homodimerize in a "head-to-head" position when bound to DNA. Evidence indicates that the AR can uniquely dimerize in a "head-to-tail" fashion on an HRE of the monomer 5′-GGTTCT. More recent structural analysis has revealed the importance of the 10-30 amino acid carboxy terminal extension (CTE) of the DBD in DNA interaction.[1,45,46,48] Although this region is variable between steroid receptors, it is crucial for DNA binding, particularly for sequence selectivity of DNA binding, by extending the interaction surfaces between the receptor and the DNA.

Hinge Region or D Domain

Historically, the D domain was thought to primarily serve to connect the more highly conserved C and E domains of the receptor.[12] The previously described CTE extends into the hinge region, which also harbors a nuclear localization signal, and influences cellular compartmentalization of receptors, as well as sites of posttranslation modifications.[48] Current mechanisms suggest this nonconserved and intrinsically disordered (ID) domain is important for intramolecular allosteric

for monomeric DNA binding. Diagram includes amino acids found in ERα. (B) Amino acid sequences in the vicinity of the P box and CTE regions of the steroid receptors are compared. The underlined residues in the P-box sequences are critical for HRE selectivity. Amino acid substitutions made within the P box to create the NERKI and the EAAE DNA binding–deficient ERα mouse lines are also shown. The EAAE mutations also includes an amino acid change in the "tip" of the first finger that isn't in the P box. (C) Shown is a ribbon diagram of the DNA binding (C) domain illustrating the putative arrangement of helix 1 and helix 2 crossing at right angles to form the core of the DNA binding domain that recognizes a hemi-site of the response element. *Source: (A) reproduced with permission from Ref. 43 and (C) reproduced with permission from Ref. 65.*

interactions involving the N-terminal and ligand binding domain (LBD)[48] (described earlier in the section NTD or A/B Domain). This type of flexible structural interaction works to allow rapid response to diverse modulators governing changes in biological environments.[48]

LBD or E Domain

The LBD or E domain of the steroid receptors is a highly structured multifunctional region that primarily serves to specifically bind ligand and provide for hormone-dependent transcriptional activity.[12] An AF-2 domain located in the C-terminus of the E domain mediates this latter function. The AF-2 domain is subject to posttranslational modifications[12] and is an especially strong activator of transcription in the ER and PR but is markedly weaker in the AR, where it is more involved in interactions with residues in the NTD.[37,38] Also harbored within the E domain is a strong receptor dimerization interface, sites for interaction with heat shock proteins, and nuclear localization signals.[12,48] Although there is minimal homology in the primary sequence of the LBD for the sex steroid receptors, comparative studies of the crystal structures of liganded and unliganded LBDs indicate a highly conserved structural arrangement. These structural studies indicate that the LBD is composed of 11 α-helices (H1, and H3–H12) arranged in a three-layer α-helical sandwich to create a hydrophobic ligand binding pocket near the C-terminus of the receptor.[48] The resulting shape and volume of the ligand binding pocket is larger than necessary to accommodate the corresponding ligand, suggesting that key interactions between the ligand and specific receptor residues are more critical to conferring ligand specificity.[61] Receptor binding to an agonist ligand leads to rearrangement of the LBD such that H11 is repositioned and H12 swings back toward the core of domain to form a "lid" over the binding pocket. This agonist-induced repositioning of H12 leads to the formation of a hydrophobic cleft, or "NR box", by helices 3, 4, and 5 on the receptor surface, constituting the AF-2, which serves to recruit co-activators (Table 25.1) to the receptor complex. In contrast, receptor antagonists are unable to induce a similar repositioning of H12, leading to a receptor formation that is incompatible with co-activator recruitment and is therefore less likely to activate transcription. The LBDs of PRB and PRA are identical and provide for high affinity binding to P.[12,50] The LBD of the AR in humans, rats, and mice is identical and provides for high affinity binding of two endogenous androgens, T and 5α-hydroxyT (DHT), the latter of which binds with much greater affinity.[38,66] Numerous high affinity synthetic ligands for PR and AR have been developed, including the agonists R5020 and R1181, respectively (Table 25.2).[12] The LBDs of ERα and ERβ exhibit less than 60% homology but bind the endogenous ligand, E2, with similar affinity (ERα, 0.1 nM; ERβ, 0.4 nM).[8,12,17] Both ER forms also bind the synthetic estrogen diethylstilbestrol (DES) with relatively equal affinity.[67] However, given the divergence in homology, it is not surprising that ERα and ERβ exhibit measurable differences in their affinity for other endogenous steroids and xenoestrogens.[8,17] Natural and synthetic steroidal and nonsteroidal ER agonists and antagonists have been described, some of which show specificity for one or the other ER subtype (Table 25.2), illustrating differences between the LBDs of ERα and ERβ, and provide for powerful pharmacological tools to discern the overall function of each ER (Table 25.2). The most widely used ER subtype selective ligands currently in use are propylpyrazole (PPT), an ERα selective agonist, and diarylpropionitrate (DPN), an agonist showing preference, but not exclusive selectivity, towards ERβ.[8]

F Domain

Among the sex steroid receptors, only ERs possess a well-defined F domain (Figure 25.1). This region is relatively unstructured and harbors little known function, although some data indicate a role in co-activator recruitment, dimerization, and receptor stability.[61,62,68–70]

Co-Regulatory Complexes

All steroid receptors interact with co-regulatory molecules, co-activators, and co-repressors.[51,71] The primary co-activator interaction for steroid receptors (SR) is with p160/SRC (steroid receptor co-activator) 1, 2, and 3.[52,72,73] SRC1 (NCOA1), SRC2 (GRIP1, TIF2), and SRC3 (pCIP, RAC3, ACTR, TRAM, A1B1) interact with helix 12 of SRs via "LXXLL" motifs in their nuclear receptor interacting domain, which are leucine rich regions with "X" designating any amino acid.[52] SRCs also contain activation domains that recruit secondary molecules such as p300, and a bHLH-PAS motif within the N-terminal region, which can interact with other transcription factors.[52] The elegant complexity of co-activator composition and function has been increasingly revealed. Steroid receptors and SRCs function as a nexus interacting with massive multimeric complexes, such as the SWI/SNF chromatin remodeler, mediator complex, or proteasomes (Table 25.1).[73] These interactions facilitate coordination of the specific functions necessary to allow appropriate gene and cell selective access to chromatin, via modifications of histones or members of co-regulatory complexes.[74] In this way, co-activators dynamically mediate and coordinate processes necessary to accomplish transcription, including initiation, elongation, termination, and clearing or turnover of the transcriptional modulators.

Receptor Mechanisms of Action

Our understanding of the mechanisms by which steroid hormones and their cognate intracellular receptors influence cell function and behavior has expanded

profoundly since 1988 when Clark and Markaverich reviewed the field for the inaugural edition of this volume. Much of that earlier chapter remains contemporary in reference to general receptor biochemistry and ligand-dependent activation, which is now referred to as the "classical" or ligand-dependent direct-DNA binding model of receptor function (Figure 25.4). In the years since, numerous discoveries have been made that illuminate the complexity of sex steroid receptor signaling in cells and tissues, such as the discovery of additional receptor forms and variants (e.g., ERβ) and high-resolution crystallography of receptor domains. The entrée into the "omics" era has facilitated massive expansion of study of transcriptional regulation and chromatin remodeling. In addition, several alternative receptor signaling mechanisms that diverge from the classic model have become apparent, including "tethering" of the sex steroid receptor to heterologous DNA-bound transcription factors to provide for steroid regulation of genes that lack HRE sequences within their promoter (Figure 25.4); plasma membrane steroid signaling, often referred to as "nongenomic" steroid actions; and ligand-independent "cross talk" with intracellular and second messenger systems that provide for sex steroid receptor activation in the absence of the cognate steroid ligand (Figure 25.4). The existence of multiple receptor-mediated signaling pathways likely accounts for the refined control and plasticity of tissue responses to sex steroids. These modes of sex steroid receptor action as currently understood are discussed following.

Ligand-Dependent Actions: Direct or Classical

The classic model of steroid receptor action states that the receptor resides in the nucleus or cytoplasm but is sequestered in a multiprotein inhibitory complex in the absence of hormone (Figure 25.4). The lipophilic steroid ligands are able to freely diffuse across the plasma and nuclear membranes and bind their cognate receptor. The binding of ligand results in a

conformational change in the receptor, transforming it to an "activated" state that is now available for homodimerization, increased phosphorylation, and binding to an HRE within target gene promoters, and interaction with chromatin and transcriptional mediators. NRs seem to be preferentially recruited to open regions of chromatin.[75] Studies using MCF7 breast cancer cells indicate that FoxA1 acts as a pioneering factor, providing accessible regions in the chromatin that recruit ERα.[76–79] The ligand-HRE-bound receptor complex then engages co-activator molecules as described before,[52] leading to modulation of transcription rates of responding genes. This classic steroid receptor mechanism is dependent on the functions of both AF-1 and AF-2 domains of the receptor, which synergize via the recruitment of co-activator proteins, most notably the p160 family members.[52] Depending on the cell and target gene promoter context, the DNA-bound receptor complex may positively or negatively affect expression of the downstream target gene. Initially, study of NR-mediated gene regulation was carried out on a gene-by-gene basis using a handful of known hormone regulated transcripts, such as the ER target genes PS2, lactotransferrin, and PR or the AR target gene prostate specific antigen. Now, after numerous comprehensive analyses of hormonally regulated transcriptional profiles, using microarray and more recently RNA-seq, thousands of NR targets have been found in various cell lines and tissues.

In general, PRB can better or uniquely activate transcription versus PRA when acting on progesterone response element–regulated genes in various cell types in vitro due to the presence of a third AF-3 in the NTD of PRB.[50,60] Furthermore, PRA can repress the transcriptional activities of PRB in certain cell and promoter contexts,[50] suggesting that PRA may modulate P responsiveness in certain tissues. Interestingly, PRA can also repress the actions of other heterologous NRs, including the AR, ER, and GR.[12,50,60] The variant, PR-C, is primarily cytosolic and lacks the A/B domain and the 5′ portion of the C domain, and has been shown to bind P and enhance the actions of PRB and PRA,[80] but the presence of encoded protein and a potential biological role remains controversial.[30,81] Some evidence for a role in P signal dampening during labor has been described for PR-C.[82] When acting via a classic ERE-driven mechanism in vitro, ERα homodimers and ERα/ERβ heterodimers tend to be stronger activators of transcription compared with ERβ homodimers.[18,61] Corroborating in vivo evidence of differential regulation and heterodimer formation by the ER subtypes has been difficult to generate. However, a microarray study by Lindberg et al.[83] using bone tissue from ovariectomized mice found that ERβ generally inhibits ERα-mediated gene expression, but in the absence of ERα, ERβ can partially provide some E2-stimulated gene expression. No evidence for ERα or ERβ preferential regulation of specific transcripts or promoters has been forthcoming; rather, it seems the

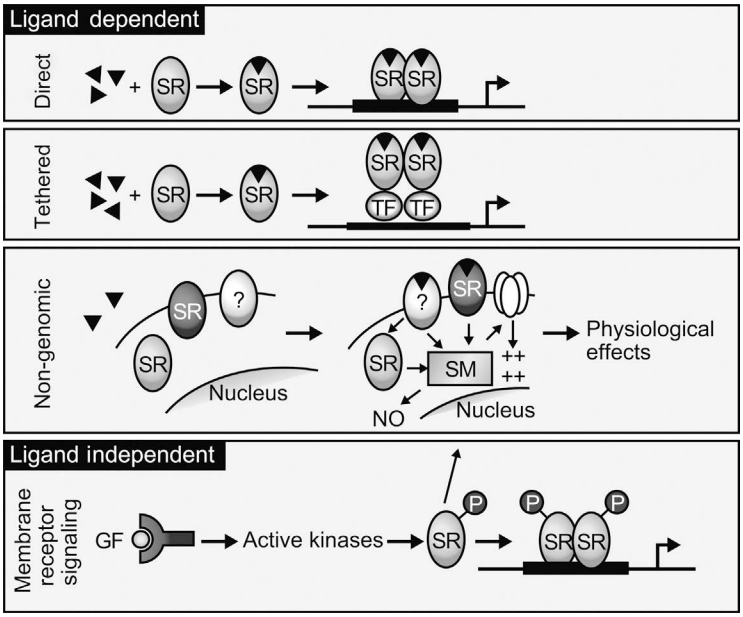

FIGURE 25.4 Ligand-dependent and ligand-independent nuclear receptor mechanisms. The direct "classic" model of sex steroid receptor (SR) action involves direct interaction between SR bound to hormone (triangles) and HRE; the tethered pathway utilizes indirect "tethering" of SR to genes via interactions with other transcription factors (TF). "Nongenomic" signaling is initiated by membrane-localized receptors modulating extranuclear second messenger (SM) signaling pathways. Ligand-independent responses occur as a result of transduction of membrane receptor signaling, such as growth factors, to nuclear SR. *Source: Adapted with permission from Ref. 18.*

important factor is which receptors are expressed in a responding tissue.

Indirect/Tethered Actions (HRE Independent)

Ligand-activated steroid receptors can stimulate the expression of genes that lack a conspicuous HRE within their promoter. This has been especially demonstrated for ERα[84–86] but is also known to occur for PR.[87] This mechanism of HRE-independent steroid receptor activation is postulated to involve a "tethering" of the ligand-activated receptor to transcription factors that are directly bound to DNA via their respective response elements (Figure 25.4), This mechanism involves a mediator component (e.g., p160) between ER and AP-1 versus direct interaction.[85] Interestingly, ERβ is unable to enhance the actions of a DNA-bound AP-1 complex when bound to E2 but can do so in the presence of certain selective estrogen receptor modulators (SERMs) such as tamoxifen, raloxifene, and ICI 164,384.[18] A similar HRE-independent mechanism of sex steroid receptor regulation has been documented for genes that possess a GC-rich region or Sp1 binding site within the promoter, upon which the actions of a bound Sp1 complex can be enhanced by ERα.[84] These mechanisms have primarily been demonstrated using in vitro cell culture models.

Nongenomic Actions

All models of sex steroid receptor action described thus far influence cellular phenotypes by acting in the nucleus and modulating target gene expression. The required gene transcription and mRNA translation is a relatively slow process; microarray studies demonstrate that initial transcriptional responses occur beginning about 60 min after administering hormones. Therefore, the numerous examples described to date in which steroids affect cellular dynamics within seconds to minutes of exposure have remained difficult to explain within the context of the previous models. Rapid cellular changes such as increased intracellular calcium or cAMP or activation of kinase signaling cascades have been attributed to sex steroid exposure of varied cell types and tissues.[88,89] Because these steroid effects do not involve direct steroid receptor activation of gene transcription, they are often collectively referred to as representing "nongenomic" pathways of steroid action. Indeed, several of the documented effects lack a conspicuous nuclear component or have even been demonstrated to occur in enucleated cells, yet others can ultimately affect gene expression. Therefore, rather than nongenomic, some have proposed these types of steroid actions to be loosely categorized as plasma membrane–associated steroid signaling events. Although there are numerous examples of putative membrane-associated steroid signaling effects in reproductive tissues and processes, a thorough description of these mechanisms is beyond the scope of this chapter.

An obstacle to our better understanding of membrane-associated effects of steroids is the lack of data on the nature of the cell-surface steroid "receptors". Questions remain concerning whether the membrane-associated receptors are identical or variant forms of the sex steroid NR or instead distinct receptors altogether. P is known to rapidly induce maturation in *Xenopus* oocytes that are arrested in the G2 phase of meiosis I,[90] without requiring protein synthesis. Most evidence indicates this process begins at plasma membrane progesterone binding sites that are unique from the classic nuclear forms of PR, called progesterone receptor membrane component 1 (PGRMC1),[91] although cDNA homologs of the PR were cloned from *Xenopus* and found to be associated with P-induced oocyte maturation.[89] In other studies, P is able to inhibit apoptosis of rat granulosa cells in vitro via a membrane-bound receptor that is immunoreactive to antisera directed against the LBD of the classic PR.[89]

Rapid effects of E2 have been described in a vast array of tissues, including a rapid activation of endothelial nitric oxide synthase in endothelial cells, potentiation of currents induced by the ion channel agonist kainite in hippocampal neurons, and influx of calcium in uterine endometrial cells.[88,90] The evidence of an association between ERα and plasma membrane–bound components has increased, supporting the view that this mechanism may indeed account for certain rapid effects of E2.[92,93] In this sense, the various nongenomic actions of E2 are often categorized according to their susceptibility to inhibition by classical ER antagonists (e.g., ICI type compounds).[92] E2-induced activation of membrane ion channels, endothelial nitric oxide synthase, and mitogen-activated protein kinase kinase are all inhibited by ER antagonists and therefore likely involve membrane-associated ERα or ERβ.[92] In contrast, examples of E2-induced PKA and protein kinase C (PKC) activation are not inhibited by ICI compounds and are therefore not likely to involve the nuclear ER form.[92] A recent study utilized a mutated form of the mouse ERα engineered to remain sequestered outside the nucleus (ERαH2NES), regardless of estrogen ligand. This form of ER did not mediate transcriptional responses but maintained estrogen-induced MAPK phosphorylation.[94] Targeting steroid receptors to the membrane involves palmitoylation, which is facilitated by HSP27.[88] The palmitoylation promotes interaction with caveolin-1, which then results in localization of the receptor in membrane caveolin rafts. Another potential mediator of rapid membrane localized hormone response is the G protein-coupled receptor GPER (originally referred to as GPR30), which is activated by E2.[95] GPER-null mice lack reproductive phenotypes,[96] although effects on the degrees of uterine responses elicited by E2 have been observed with G15, a GPER selective antagonist, suggesting a potential role for GPER in modulating

ERα-mediated outcomes.[97] A multiprotein complex of extracellular signal–related kinases, the inner plasma membrane component of tyrosine kinase receptors (c-Src), and the nuclear sex steroid receptors[92,98–101] has also been described as a mediator of rapid response to E. A different mechanism speculates that androgens or E2 may act as extracellular signaling hormones via binding to sex hormone binding globulin that is already bound to the cell membrane via a G protein–coupled-like sex hormone binding globulin cell-surface receptor.[102]

Ligand-Independent Actions: Membrane Receptor Cross Talk

We now have ample evidence that the sex steroid receptors can be activated via intracellular second messenger and signaling pathways, allowing for the induction of sex steroid target genes in the absence of steroid ligand, or the enhancement of steroid hormone signaling (Figure 25.4).[29,103–105] Polypeptide growth factors are able to activate ERα-mediated gene expression via mitogen-activated protein kinase activation of ERα in the absence of E2 (Figure 25.4). Similarly, interleukin-6 stimulation of cells leads to increased AR-mediated gene expression,[38,106] and cyclin-dependent kinases have been shown to activate PR-regulated gene expression.[29] The intracellular signaling molecule cAMP, a common second messenger of G protein–coupled receptors and an activator of the PKA pathway, can stimulate increased PR-, AR-, and ER-mediated transcription of target genes in the absence of steroid ligand.[29,103] A well-characterized example of ligand-independent cAMP activation of PR occurs after dopamine stimulation of dopaminergic neurons[107] and is the mechanism by which sexual behavior is induced in female rodents. Likewise, growth factors are able to mimic the effects of E2 in the rodent uterus via E2 independent activation of ERα.[109,110] Most interesting are recent studies indicating that the MAP kinase protein ERK is co-recruited to chromatin with ERα.[111] Ligand-independent activation of sex steroid receptors is believed to rely largely on cellular kinase pathways that alter the phosphorylation state of the receptor and/or its associated proteins (e.g., co-activators, heat shock proteins) (Figure 25.4). As in the classic ligand-dependent mechanism described earlier, specific receptor domains are critical to ligand-independent activation as well. ER activation by peptide growth factor–signaling pathways appears to be more dependent on AF-1 functions, whereas the effects of increased intracellular cAMP are postulated to depend on the AF-2 domain and do not require a functional AF-1.[103]

Receptor Antagonists

Structural analyses of the sex steroid receptors provide insight into the agonist/antagonist actions of endogenous or synthetic ligands (Table 25.2). Certain ligands possess "mixed" agonist/antagonist activity that is dependent on the receptor, cell, and promoter context, leading to the more descriptive terms of SERMs, selective PR modulator, and selective AR modulator. As described in the subsection Receptor Mechanisms of Action of the section Steroid Receptors, sex steroid receptor agonists interact with the LBD to generate an ordered array of 11 α-helices that is most conducive to receptor interaction with co-activator proteins and/or promotes disassociation of co-repressor proteins. In turn, antagonist ligands generally fail to generate the necessary changes in receptor structure that induce full transcriptional activity.[48,112–114]

Antiprogestins have a number of applications in reproductive medicine, including use as contraceptives due to their ability to prevent implantation or ovulation.[115] The currently available PR antagonists are all competitive inhibitors of P binding to the PR LBD.[115] Type I antiprogestins, such as ZK 98299 (onapristone), bind PR but fail to induce receptor phosphorylation and induce weak receptor binding to HREs.[115,116] In contrast, type II antiprogestins, such as RU 486 (mifepristone, Table 25.2), bind PR and promote receptor phosphorylation, homodimerization, and binding of the receptor complex to an HRE, but are unable to activate transcription.[50] Crystallography data indicate that RU 486 binding to PR induces an arrangement of helix 12 that is not conducive to binding of steroid receptor co-activators and may even promote recruitment of co-repressors such as NCoR.[50] Type II antiprogestins do possess some PR agonist activity when acting in the context of the cAMP/PKA signaling pathway in certain cell types.[50]

The field of antiestrogens and SERMS has been an area of intense research because the potential clinical applications include treatments for fertility, cardiovascular disease, osteoporosis, cognitive function, postmenopausal symptoms, and breast and gynecological cancers.[18] The best-characterized antiestrogens are competitive inhibitors of E2 binding to ER and have been classified into two major groups. The type I class of ER antagonists includes the triphenylethlylene compounds, tamoxifen (Table 25.2), hydroxy-tamoxifen, and raloxifene and are characterized by mixed agonist/antagonist activity depending on the receptor, cell, and promoter context.[18] Upon binding the ER, these compounds selectively inhibit AF-2 function but leave AF-1–mediated receptor functions intact, thus explaining the selective agonist activity. In contrast, the type II compounds are considered pure antagonists, the most well characterized being ICI 182,780 (Table 25.2), which is a 7α-substituted derivative of E2. This compound binds the ER but possesses extended side chains that prevent co-activator association with the NR box of helix 12 and may even promote interaction with co-repressors as well as increased receptor degradation,[18] resulting in

decreased ER protein. Compounds of this type have now been designated as selective estrogen receptor degraders (SERDs). ER-selective nonsteroidal ligands exploit differences between the LBDs of ERα and ERβ and provide powerful pharmacological tools to discern the overall function of each ER (Table 25.2).

Clinical use of antiandrogens has focused largely on the treatment of prostate cancer.[38,117] The best-characterized AR antagonists include the steroidal compound cyproterone acetate (Table 25.2) and nonsteroidal compounds hydroxyflutamide (Table 25.2), casodex, and nilutamide. Hydroxyflutamide is considered a pure AR antagonist that competitively binds AR and reduces AR transcriptional activity by preventing interaction with co-activators.[117,118]

SEX STEROID RECEPTORS IN UTERINE FUNCTION

Estrogen Receptor Signaling in Uterine Function

The ovarian-derived sex steroid hormones dictate the uterine estrous or menstrual cycle in mammals and are therefore essential to the establishment and maintenance of pregnancy. The uterine response to the preovulatory rise in circulating E2 is required to prepare the tissue for the forthcoming rise in P that accompanies ovulation and is critical to embryo implantation. This physiological coordination between the ovary and uterus is common to the large majority of mammals studied, and the spectrum of actions and effects of the sex steroids in uterine tissue are mediated by their cognate NRs. Estrogen was first described almost 100 years ago as a substance that induced estrus.[119] Although initially the dramatic physiological effects of estrogens on the mammalian uterus have been appreciated and well described, later investigations begun to elucidate the precise mechanisms and signaling pathways involved in estrogen responses. Our understanding of steroid hormone action in the uterus has been greatly advanced by utilization of new technologies with the generation of knockout and knock-in models, including receptor or co-activator null, tissue and cell selective null, and mutant knock-in models in mice. These models are also used in combination with microarray, RNA-seq, and ChIP-seq methods that allow for comprehensive mapping of interaction of NRs with chromatin and modulation of genomic response to steroids in uterine tissues. Together, these models and techniques have led to better understanding of the molecular details of steroid receptor roles in biological processes. The following sections discuss what is currently known and hypothesized about sex steroid receptor actions in the mammalian uterus.

ER Expression in the Uterus

RODENTS

ERα is present in the female reproductive tract of rodents throughout late fetal and neonatal development, puberty, and adulthood.[120,121] In mice, ERα transcript has been detected in the blastocyst, but immunoreactivity first appears in the mesenchymal cells of the fetal uterus as early as gestational day 15,[120,121] whereas epithelial expression is delayed until the late fetal period but increases substantially on postnatal day 4 and peaks on day 16.[122,123] The level of ERα transcripts in the murine uterus during neonatal development closely mirrors the patterns indicated by earlier immunohistochemical studies.[124] There is reportedly no ERβ immunoreactivity in the neonatal mouse uterus, although transcripts are detected at a modest level.[124] In adult mice, ERα transcripts and immunoreactivity are quite high in uterine epithelial cells before ovulation[125] but decrease during pregnancy, whereas expression in the stroma continues.[126] In contrast, ERβ expression is relatively low in uteri of virgin and pregnant mice.[124,127,128] Adult rats exhibit a similar uterine ER expression pattern such that ERα transcripts and immunoreactivity are easily detectable in the epithelium, stoma, and myometrium, and levels peak during the proestrous period of increased circulating E2 levels.[129] The evidence of ERβ expression in the rat uterus is conflicting; whereas ERβ expression has been reported to be in approximately 40% of rat uterine epithelial and stromal cells regardless of the estrous cycle stage,[129] others report a total lack of detectable ERβ.[130] These observations are plagued by the inconsistent quality of antibodies against ERβ. In ovariectomized mice, ERα and ERβ proteins were detected in the epithelial, stromal, and myometrial cells,[131–133] indicating that removal of ovarian hormones alters the ER expression pattern. Although ERβ protein is present in the mouse uterus, there is overwhelming functional evidence that ERα is responsible for mediating the many effects of estrogens in the uterus. As described following, only ERα-null female mice exhibit a severely attenuated response to acute and chronic estrogen (e.g., E2 or DES) treatment in terms of uterine growth and altered gene expression, as well as exhibit impaired embryo implantation.[110,134,135] Furthermore, categorical studies have shown that the toxic effects of neonatal estrogen exposure in the neonatal female mouse uterus are clearly mediated by ERα.[136,137]

DOMESTIC ANIMALS

In the neonatal ovine uterus, ERα mRNA and protein levels are highest in the developing glandular structures; detectable but lower in the luminal epithelia, stroma, and vascular endothelial cells; and absent in the myometrium.[138,139] In the adult ewe, ERα expression is detected

in all uterine cell types and is highest on day 1 of the 16- to 18-day cycle, concurrent with peak plasma E2 levels.[138,140] During days 1–6, when P levels rise and E2 declines, ERα expression decreases accordingly and does not begin to rise again until the end of the cycle nears on days 11–15.[138,140] A similar pattern of uterine ERα expression is reported during the 21-day bovine cycle.[141] In situ hybridization and immunohistochemical analyses indicate maximum ERα levels on days 1–3, especially in the glandular and stromal cells; these levels generally decrease by day 6, although cells comprising the deep glands maintain ERα expression.[142] The observed cyclical changes in ERα expression in ovine and bovine uteri are consistent with steroid regulation of receptor levels. Indeed, E2 treatment of ovariectomized cows leads to increased ERα expression in the glands, stroma, and luminal epithelia, whereas P alone or in combination with E2 elicits a decrease in ERα levels.[142]

PRIMATES

Early investigations in human uterine tissue found that levels of ER immunoreactivity or high-affinity E2 binding vary during the menstrual cycle such that peak expression occurs in the mid- to late proliferative phase and then decreases at ovulation and commencement of the secretory phase.[143–145] This peak in uterine ER levels at the time of rising plasma E2 levels is similar to several other species and suggests that expression is autoregulated. However, maintenance of uterine ER expression in postmenopausal women suggests that nonsteroidal regulatory factors are also involved.[145] The ovulatory decline in ERα levels among all uterine cell types is concurrent with the rise in circulating P levels and suggests that PR-mediated P actions may act to downregulate ER expression. Such PR-mediated decrease in ERα has been reported in experimental systems as well.[146] A distinct gradient of ER levels among the functional components of the human uterus was also reported such that levels are highest in the fundus and progressively decrease in those tissues closer to the cervix.[147,148]

The discovery of ERβ forced a reevaluation of uterine ER expression because the early studies discussed previously did not use methods that adequately distinguished between the two ER forms. More recent studies definitively show that ERα is the predominant form in the human uterus and accounts for the increased receptor levels that occur during the proliferative phase.[149] ERα transcripts and protein are especially high in glandular epithelial and stromal cells during the proliferative phase and exhibit a dramatic decrease among uterine tissues upon entering the secretory phase of the cycle.[149] The levels of ERα transcripts and immunoreactivity in the uterine myometrium are much lower and exhibit little change during the menstrual cycle.[149] Still, comparatively higher ERα levels are described in the subendometrial myometrium during the proliferative phase and are postulated to be involved in uterine peristaltic activity.[149]

ERβ expression in the human uterus is much lower relative to ERα but is generally present in the same cell types and exhibits comparative changes during the menstrual cycle.[149,150] There is one report of increased ERβ immunoreactivity in the uterine stroma during the secretory phase.[150] ERβ immunoreactivity is especially detectable in vascular smooth muscle cells and increases therein during the secretory phase, suggesting a role for this receptor form in vascularization.[150] The human-specific ERβ isoform, ERβcx, also called ERβ2 (Figure 25.2), is also detected in the uterus and is present along with full-length ERβ (ERβ1) in the functional and basal layer endometrial glands.[151] Interestingly, ERβcx immunoreactivity decreases in the basal layer glandular cells during the mid-secretory phase, whereas little change occurs in the level of full-length ERβ,[151] suggesting that differential expression of ERβ isoforms over the course of the menstrual cycle may modify the cellular responses to E2.

Nonhuman primates exhibit uterine ER expression patterns similar to those described in humans. ERα immunoreactivity in baboon uteri is highest in endometrial glandular, stroma, and myometrial smooth muscle cells during the proliferative phase and decreases in all cell types upon commencement of the secretory phase.[152] A similar ERα expression pattern in epithelial, stromal, and myometrial cells is reported in the cynomolgus monkey uterus.[153] ERα immunoreactivity is also reported in the vasculature, including the spinal arteries, of the baboon uterus.[152] Ovariectomy followed by exogenous E2 or E2 plus P treatments in baboons leads to changes in uterine ER expression that mirror the menstrual cycle, supporting the direct role of ovarian steroids in the regulation of uterine ER levels.[152] Considerable levels of ERβ transcripts are also detected in the epithelial, stromal, and myometrial cells of cynomolgus monkey uteri.[154] In contrast, ERβ immunoreactivity is reportedly low in normal uterine tissue from baboons, although higher levels are observed in diseased glands associated with endometriosis.[155]

Uterine Phenotypes in Mouse Models of Disrupted Estrogen Signaling

The murine models of disrupted estrogen signaling have proven invaluable to experimental investigation of estrogen actions in the uterus and the contribution of each ER form to these functions (Table 25.3). In addition to the ER-null models are two independently derived lines of mice that lack the capacity to synthesize E2 due to disruption of the *Cyp19* gene.[131,156] Following, we will describe how these different mouse models have helped to delineate the role of ER in the uterus.

TABLE 25.3 Uterine Phenotypes in Mice Null or Mutated for Sex Steroid Receptors and Signaling

Mutated or Null for Sex Steroid Receptors and Signaling	Uterine Phenotypes	References
Esr1$^{-/-}$ (homozygous null alleles for ERα: αERKO and Ex3αERKO)	Normal uterine development but exhibits hypoplastic uteri Insensitive to the proliferative and differentiating effects of endogenous growth factors and exogenous E2 Implantation defect *Exhibit decidualization Infertile	135,157–161
NERKI$^{+/-}$ (one mutated allele of two-point mutation in ERα DBD and one WT allele)	Normal uterine development but exhibits hyperplastic uteri Hypersensitive to estrogen Infertile	132
KIKO (ER$^{AA/-}$) (one mutated allele of two-point mutation in DNA binding domain of ERα and one ERαKO allele)	Normal uterine development Insensitive to the proliferative effects of exogenous E2 treatment Infertile	162,163
ERα$^{EAAE/EAAE}$ (homozygous animal of 4-point mutation of DBD ERα)	Normal uterine development but exhibits hypoplastic uteri Loss of E2-induced uterine transcripts Infertile	164
ERαAF-1^0 (deletion of amino acids 2–128 on ERα)	Normal uterine development and architecture Blunted E2 response Infertile	165,166
ERαAF-2^0 (deletion of amino acids 543–549 on ERα)	Normal uterine development but exhibits hypoplastic uteri Insensitive to E2 treatment Infertile	167
ENERKI (ERα^{G525L}) (homozygous animal of 1-point mutation in LBD of ERα)	Normal uterine development but exhibits hypoplastic uteri Insensitive to E2 treatment IGF1 induced slight uterine epithelial proliferation compared to control littermates (nonhomogenous pattern) Infertile	168
AF2ER$^{KI/KI}$ (homozygous knock-in of 2-point mutation in LBD of ERα)	Normal uterine development but exhibits hypoplastic uteri Insensitive to E2 treatment ER antagonists and partial agonist (ICI 182,780 and TAM) induced uterine epithelial proliferation Growth factor did not induce the uterine epithelial cell proliferation Infertile	169
Wnt7a^{Cre+};*Esr1*$^{f/f}$ (uterine epithelial cell–specific deletion of ERα)	Normal uterine development Sensitive to E2- and growth factor–induced epithelial cell proliferation Selective loss of E2-target gene response Implantation defect Infertile	170
Esr2$^{-/-}$ (homozygous null alleles for ERβ: βERKO, Ex3βERKO, and **ERβ$_{ST}^{L-/L-}$)	Exhibit grossly normal uterine development and function Sensitive to E2 treatment Some *Esr2*$^{-/-}$ lines reported elevated uterine epithelial proliferation after E treatment compared to WT Some are completely sterile (due to ovarian phenotype)	158,171–173
αβERKO (homozygous null for both ERα and ERβ)	Normal uterine development but exhibit hypoplastic uteri, similar to those of Esr1$^{-/-}$ Insensitive to E2 Infertile	158,174
Cyp19a1$^{-/-}$ (homozygous null aromatase: ArKO)	Normal uterine development but exhibits hypoplastic uteri Sensitive to E2-induced epithelial cell proliferation Infertile	131,156,175
Pgr$^{-/-}$ (homozygous null alleles for PRA and PRB: PRKO)	Exhibit grossly normal uterine development Implantation and decidualization defects Exhibit epithelial hyperplasia in response to E2 Loss of P-induced proliferative switch in uterine epithelial and stromal cells Infertile	176–178

(Continued)

TABLE 25.3 Uterine Phenotypes in Mice Null or Mutated for Sex Steroid Receptors and Signaling—cont'd

Mutated or Null for Sex Steroid Receptors and Signaling	Uterine Phenotypes	References
Wnt7a^{Cre+};*Pgr*$^{f/-}$(uterine epithelial cell–specific deletion of PR)	Normal uterine development Loss of P-induced uterine epithelial P target gene transcription Abnormal proliferative switch of uterine epithelial and stromal cells Implantation and decidualization defect Infertile	179
PRKO and *PR*$^{d/d}$ (homozygous null alleles for PR)	Normal uterine development Abnormal epithelial proliferation in response to P Implantation and decidualization defect Infertile	176
PRA$^{-/-}$ (homozygous null alleles for PRA: PRAKO)	Normal uterine development Resemble PRKO phenotypes Infertile	180
PRB$^{-/-}$ (homozygous null alleles for PRB: PRBKO)	Normal uterine development Normal implantation and decidualization responses Do not exhibit epithelial hyperplasia in response to E2 Normal fertility	181,182
AR$^{-/-}$ (homozygous null alleles for AR: ARKO)	Normal uterine development, function, and maintenance of pregnancy Slightly longer uterine horns compared to controls Slightly reduced uterine circumference Reduced uterine hypertrophic response to gonadotropins Increase placenta size (placentamegaly) Subfertile	183,184
AR$^{-/-}$ in-frame deletion of exon 3, loss of DNA binding activity	No overt uterine phenotype Subfertile	185
SPARKI (homozygous knock-in of mutated DBD of AR)	Normal female fertility, no uterine phenotype reported	186

** Ex3αERKO females have a similar uterine phenotype to the original αERKO except for exhibiting a decidualization defect, which may be due to the splice variants in the original αERKO that retains ER activities.*
*** ERβ$_{ST}^{L-/L-}$ females are the only line of ERβ knockout animals that are reported to be completely sterile.*

MICE LACKING ERα

Unlike the AR, which is mutated in the naturally occurring Tfm rat and mouse, no known mutations of the ERα have been reported, thus the deletion of ERα was thought to be lethal. Similarly, only one male patient and one female patient with ERα mutation have been discovered.[187,188] The male patient's mutation results in severe truncation of the ERα protein due to a stop codon in the A/B domain. The female patient has a point mutation in her ERα LBD that decreases activity by reducing E binding more than 200-fold. ERα-null mice were the first experimentally generated steroid-receptor-null animal, reported in 1993, and preceded the discovery of ERβ in 1996. There are currently numerous reported lines of ERα-null mice and additional lines of mice with mutations in functional domains of ERα. Three separate lines of ERα-null mice were generated: the αERKO, first described by Lubahn et al. in 1993,[157] the ERαKO (or Ex3αERKO), described by Dupont et al. in 2000[158] and by Hewitt in 2010,[159] and ERα$^{-/-}$, described by Antonson et al. in 2012.[160] Homologous recombination was employed to either disrupt (αERKO) or completely excise (ERαKO and ERα$^{-/-}$) exon 3[158,160] of the murine *Esr1* (ERα) gene. The uterine estrogenic response in αERKO females differs from the latter two lines, as αERKO animals have a low level of truncated ERα protein produced from a splice variant, which preserves some residual biological functions,[189] but all ERα-null female mice are infertile. Recently, an ERα-null rat has been derived using zinc finger nuclease (ZFN) genome editing. All phenotypes examined thus far were previously seen in the ERα-null mice, including infertility due to hypoplastic uteri, polycystic ovaries, and ovulation defects.[190] Interestingly, the recently described female patient with homozygous ERα mutation also has cystic ovaries and a small uterus despite elevated circulating E.[188]

MICE LACKING ERβ

The first description of ERβ-null mice followed the discovery of ERβ by only two years. Prior to generation of the ERβ-null model, very little was known as to the role of ERβ in biological processes, making it difficult to predict possible phenotypes. Therefore, the ERβ-null mice have served a tremendous role in providing insight

into the importance of the newly discovered ER form to female fertility, and studies to date indicate ERβ plays a particularly important role in ovarian function. Four different lines of ERβ-null mice have been described. The βERKO was first described by Krege et al. in 1998,[171] and the ERβKO, or Ex3βERKO, was described by Dupont et al. in 2000.[158] Homologous recombination was employed in both lines to disrupt exon 3[158] of the murine *Esr2* (ERβ) gene. As described to date, the reproductive, endocrine, and ovarian phenotypes of both lines are indistinguishable, with both exhibiting female subfertility. Then, in 2002, Shughrue et al. reported the third line of ERβKO animals, however, no uterine or ovarian phenotypes were reported.[191] Recently, $ERβKO_{ST}^{L-/L-}$ animals, which contain *LoxP* sites flanking exon 3 of *Esr2*, were generated using the *Cre/loxP* recombination system.[172] Interestingly, female mice from this recently described $ERβKO_{ST}^{L-/L-}$ colony were reported to be sterile due to an ovarian defect.

MICE LACKING ER α AND β

Much insight into the physiological roles of E2 has been gained from the study of mice lacking one or the other known ER forms. Still, conclusions drawn from these models are confounded by possible compensatory mechanisms provided by the opposite ER in each respective ERKO model. Furthermore, mice lacking only one ER form will lose possible ERα/ERβ heterodimer-mediated actions.[192,193] Therefore, compound ER-null mice (i.e., αβERKO) represent an opportunity to elucidate potential compensatory and cooperative actions of ERα and ERβ. The two reported lines of compound ER-null mice are the αβERKO, described by Couse et al. in 1999,[174] and the ERαβKO, described by Dupont et al. in 2000.[158] Both were generated by crossbreeding animals heterozygous for the respective individual ER-null mice and, as described to date, exhibit comparable reproductive, endocrine, and ovarian phenotypes as discussed in the subsection Mice Lacking ER α and β within the section Ovarian Phenotypes in Mouse Models of Disrupted Estrogen Signaling of this chapter. Shughrue et al. generated an additional ERαβKO line in 2002, however, their reproductive function was not described, as the study focused on ER-mediated estrogen responses in the brain.[191]

MICE LACKING CYP19

Estrogens are produced by aromatase cytochrome P450, the product of *Cyp19* gene. Female mice with disruption of circulating estrogen production exhibit altered female reproduction.[131,156,175] There are three animal models of Cyp19-null (called ArKO). Fisher et al. reported the first mouse line in 1998, which disrupted exon 9 of *Cyp19* gene, as the region is a highly conserved region among all aromatase.[156] Later, in 1998, Honda et al. reported a mouse line with targeted disruption of exons 1 and 2 of the *Cyp19* gene.[175] Toda et al. generated the most recent mouse line of Cyp19-null in 2001 with a targeted disruption of exon 9 of the *Cyp19* gene.[131] These ArKO female phenotypes are indistinguishable.[131,156,175] Briefly, these mice are infertile due to ovarian dysfunction marked by cystic follicles and a failure to respond to exogenous gonadotropins. This phenotype is described in detail in the subsection Mice lacking Cyp19 within the section Ovarian Phenotypes in Mouse Models of Disrupted Estrogen Signaling of this chapter.

UTERINE PHENOTYPES IN GLOBAL ER- OR CYP19-NULL MICE

Females within each respective model exhibit a similar phenotypic syndrome. Female mice lacking ERα or aromatase are infertile due to dysfunction of numerous physiological systems, including the ovary (see the section Estrogen Receptor Signaling in Ovarian Function) and uterus, whereas ERβ-null females exhibit reduced or lost fecundity that is largely attributable to ovarian dysfunction. A level of caution is warranted when making phenotypic comparisons between the ER-null and Cyp19-null models because sensitivity to maternally derived estrogens may provide a more normal developmental environment during gestation in Cyp19-null mice, and sensitivity to dietary estrogens during adulthood is able to abate several phenotypes in Cyp19-null mice.[194] The reported uterine phenotypes are summarized in Table 25.3.

All lines of ER-null females exhibit uteri that possess the expected tissue compartments, myometrium, endometrial stroma, and epithelium[134,159,174] (Figure 25.5). However, in females lacking functional ERα or Cyp19, uteri are overtly hypoplastic and exhibit severely reduced weights relative to WT littermates,[131,134,156,195] whereas ERβ-null females possess uteri that are grossly normal and responsive to ovarian-derived steroids[134] (Figure 25.5). The uterine endometrium of ERα-null females is severely hypotrophic, poorly organized, and possesses a paucity of glandular structures (Figure 25.5(B)).[159,196] The luminal and glandular epithelial cells in ERα-null uteri are severely immature with fewer glands and consistently exhibit a cuboidal morphology, versus the tall columnar morphology and basal location of the nucleus of an "estrogenized" epithelium in WT uteri (Figure 25.5(B)). Therefore, fetal, neonatal, and perinatal development of the female reproductive tract in mice is largely independent of ERα- and ERβ-mediated actions, but estrogen responsiveness and sexual maturation of the adult uterus are ablated after the loss of functional ERα. The totality of the ERα-null phenotype and lack of any overt uterine abnormalities in ERβ-null females suggest that ERβ has little function in mediating estrogen actions in the uterus. Moreover, ERαβ-null also demonstrated a similar uterine phenotype as ERα-null (Figure 25.5).[197]

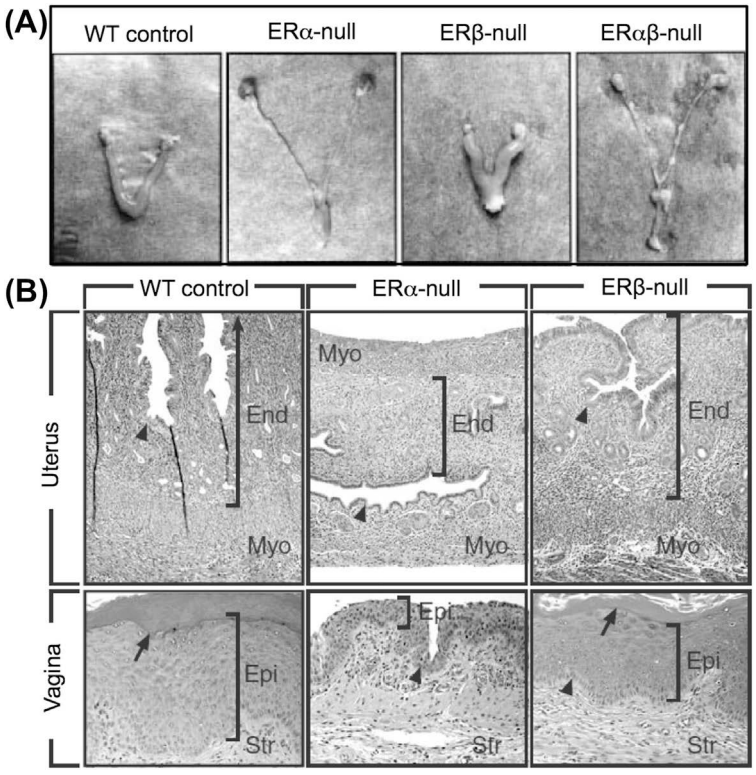

FIGURE 25.5 Gross uterine morphology of adult female estrogen receptor knockout mouse models. (A) Female reproductive phenotype of wild-type (WT) control, ERα-null, ERβ-null, and ERαβ-null. (B) Histology of uterine and vaginal tissue of WT, ERα-null and ERβ-null females. *Top*: Uterine cross-sections from representative adult WT, ERα-null and ERβ-null adult females illustrating the presence of a normal uterine architecture in all. The WT uterine section illustrates a normal myometrium (Myo), endometrial stroma (End), and columnar luminal epithelium (arrowhead). The ERα-null uterine section illustrates the characteristic hypoplasia of each anatomical compartment, a slightly disorganized endometrial stroma, and cuboidal luminal (arrowhead) and glandular epithelium. The ERβ-null uterine section is indistinguishable from that of the WT. *Bottom*: Vaginal cross-sections from tissue adult WT, ERα-null, and ERβ-null female mice. The WT and ERβ-null vaginal tissues illustrate a normal stroma (Str) and hypertrophied epithelium (Epi) showing estrogen-induced stratification and cornification (arrow). In contrast, the ERα-null vaginal tissue indicates complete estrogen insensitivity, as illustrated by a thin epithelium (Epi) and total lack of cornification. *Source: Reproduced with permission from Refs 197 and 134.*

Weihua et al. reported that ERβ-null females exhibited a slightly aberrant uterine growth response after estrogen replacement; however, the uterine bioassay was conducted in immature intact, not ovariectomized adult, animals.[133] In addition, Wada-Hiraike et al. showed that in immature females, loss of ERβ leads to increased uterine epithelial proliferation induced by E2 compared to WT uteri.[173] Although ERβ-null females are subfertile, when pregnancies are established they are sustained to term,[171] indicating uterine competence. More recent findings suggest that loss of ERβ leads to complete sterility due to a defect in ovarian function,[158,172] described in more detail in the subsection Mice Lacking ERβ of the section Ovarian Phenotypes in Mouse Models of Disrupted Estrogen Signaling of this chapter.

MICE WITH UTERINE-SPECIFIC DELETION OF ERα

Currently, only a single mouse model with tissue-specific deletion of ERα in the uterus has been published. Our laboratory has described selective deletion of ERα, using the *Cre/loxP* recombination system, by crossing *Wnt7a*$^{Cre+}$[198] with *Esr1*$^{f/f}$ animals[159] to generate mice with deletion of ERα in uterine epithelial cells (*Wnt7a*$^{Cre+}$;*Esr1*$^{f/f}$). The expression of ERα in the uterine luminal and glandular epithelium of these animals was ablated, while the ERα expression in the stromal cells and other uterine cells remains intact.[170] The epithelial ERα was ablated not only in the uterus in this mouse line[170] but also in the oviduct (unpublished data). As expected, based on findings in the global ERα knockouts, loss of uterine epithelial ERα has no effect on female reproductive tract development. Uterine histological analysis showed a similar uterine morphology as wild-type control.[170] The *Wnt7a*$^{Cre+}$;*Esr1*$^{f/f}$ uteri are sensitive to 24 h treatment of E2, as the uterine epithelial proliferation is preserved (Figure 25.6). However, *Wnt7a*$^{Cre+}$;*Esr1*$^{f/f}$ uteri lack a complete uterine response to E2, apparent following a 3-day uterine bioassay, which demonstrated a blunted growth response and increased apoptotic activity in *Wnt7a*$^{Cre+}$;*Esr1*$^{f/f}$ compared to the

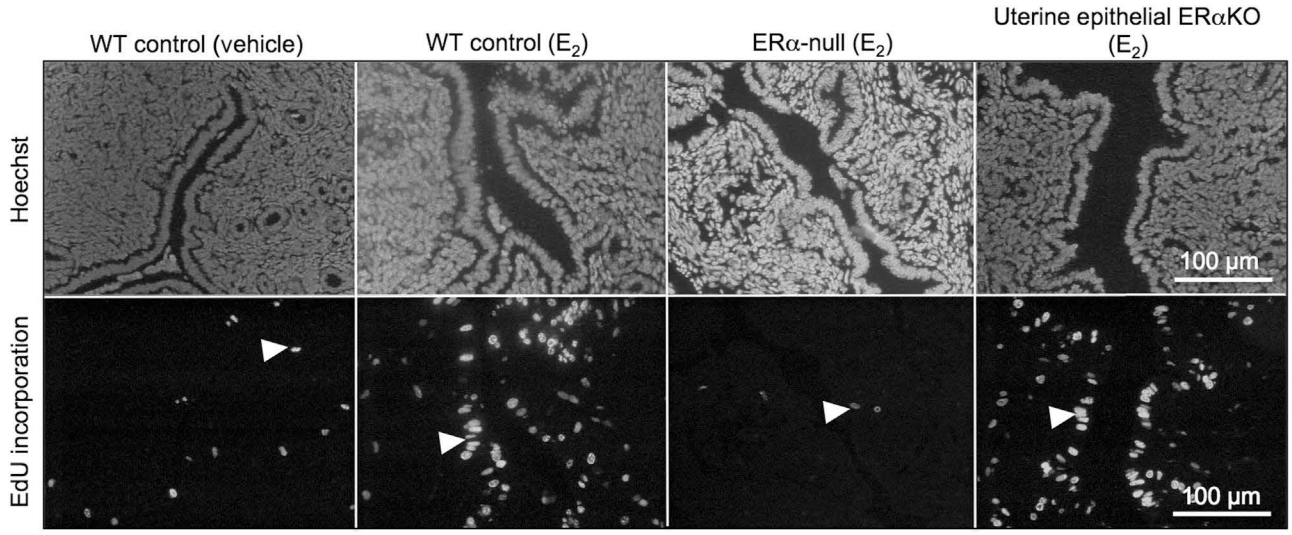

FIGURE 25.6 Estrogen-induced epithelial DNA synthesis in the uterus of adult ovariectomized mice is ERα dependent but occurs independent of epithelial ERα. Shown are cross-sections of uterine tissues from ovariectomized WT control, ERα-null, or uterine epithelial ERαKO mice treated for 24 h with vehicle or E2. DNA synthesis as indicated by nuclear EdU incorporation is detected in the luminal epithelia (arrowheads) of vehicle-treated WT uteri, and this is dramatically increased after E2 treatment of WT or epithelial ERαKO uteri. In contrast, ERα-null uteri exhibit a basal level of DNA synthesis that is unchanged after E2 treatment, indicating that E2-induced proliferation of the uterine epithelium is dependent on functional ERα (Scale bar = 100 μM). Hoeschst was used as a counterstain to visualize the tissue. *Source: Adapted with permission from Ref. 170*

control uteri. Additionally, a lack of ERα expression in the uterine epithelial cells contributes to complete infertility, partly due to an implantation defect.[170] This suggests that uterine epithelial ERα is dispensable for early uterine proliferative responses but crucial for complete biological responses induced by E2, as well as for embryo implantation.

MICE WITH MUTATED DNA BINDING DOMAINS OF ERα

The generation of mouse lines with mutation in the specific domains of ERα allows us to dissect the biological functionality of individual domains of the receptor in vivo. To date, there are two mouse lines with mutations that are designed to disrupt the DNA binding function of the ERα that have been "knocked-in" (KI) at the ERα gene locus. The first line was generated by replacing critical P-box amino acids E207 and G208 with alanines (Figure 25.3(B)). This line was named "Nongenomic ER knock-in" (NERKI), as these mutations were intended to restrict ERα signaling to the nongenomic and tethered mechanisms (Figure 25.4). Female NERKI$^{+/-}$ animals that have one mutated allele and one WT allele[132] were infertile, exhibiting a highly novel hyperplastic uterine phenotype, so NERKI$^{+/-}$ males were crossed with ERα-null heterozygous (WT/KO) females to produce mice with one NERKI mutated allele and one deleted *Esr1* allele, called ERα KIKO or ERα$^{AA/-}$ as described by O'Brien et al. in 2006.[162] The second line of DNA binding domain knock-in animals possessed mutation of four amino acids in the first zinc finger of the *Esr1* gene, substituting Y at position 201 with E, and in the critical P box (Figure 25.3(B)), K at position 210 with A, K at position 214 with A, and R at position 215 with E (Figure 25.3(B)) as described by Ahlbory-Dieker et al. in 2009 (called ERα$^{EAAE/EAAE}$).[164]

The NERKI$^{+/-}$ females have normal uterine development but exhibit hyperplastic uteri and are hypersensitive to estrogen.[132] This suggests that disruption of the ERα binding to ERE while maintaining the presence of a normal WT allele leads to an aberrant overstimulated uterine response to estrogen. Interestingly, these NERKI$^{+/-}$ are infertile and exhibit a uterine abnormality of enlarged hyperplastic endometrial glands despite possessing normal levels of circulating sex steroids.[132]

ERα$^{AA/-}$ females have normal uterine development. Initially, O'Brien et al. reported that ERα$^{AA/-}$ females, with mutation of the DNA binding domain, maintained proliferative responses—induced by E2.[162] However, in subsequent studies, no uterine proliferation was observed.[163,199] Ahlbory-Dieker et al. showed that, unlike the NERKI$^{+/-}$, females heterozygous for the ERα^{EAAE} mutation are fertile. The homozygous ERα$^{EAAE/EAAE}$ females have normal reproductive tract development, but uteri are severely hypoplastic (Figure 25.7(A)), similar to global ERα-null uteri. Additionally, ERα$^{EAAE/EAAE}$ uteri do not respond to E treatment, as the estrogen-regulated genes (such as *Pgr*, *Cdkn1a*, and *Igf1*) failed to be upregulated in ERα$^{EAAE/EAAE}$ compared to control uteri. The females from these two mouse lines with point mutations in the DNA binding domain of ERα are infertile. Thus the physiological function of the DNA binding domain of ERα is crucial for female reproduction.

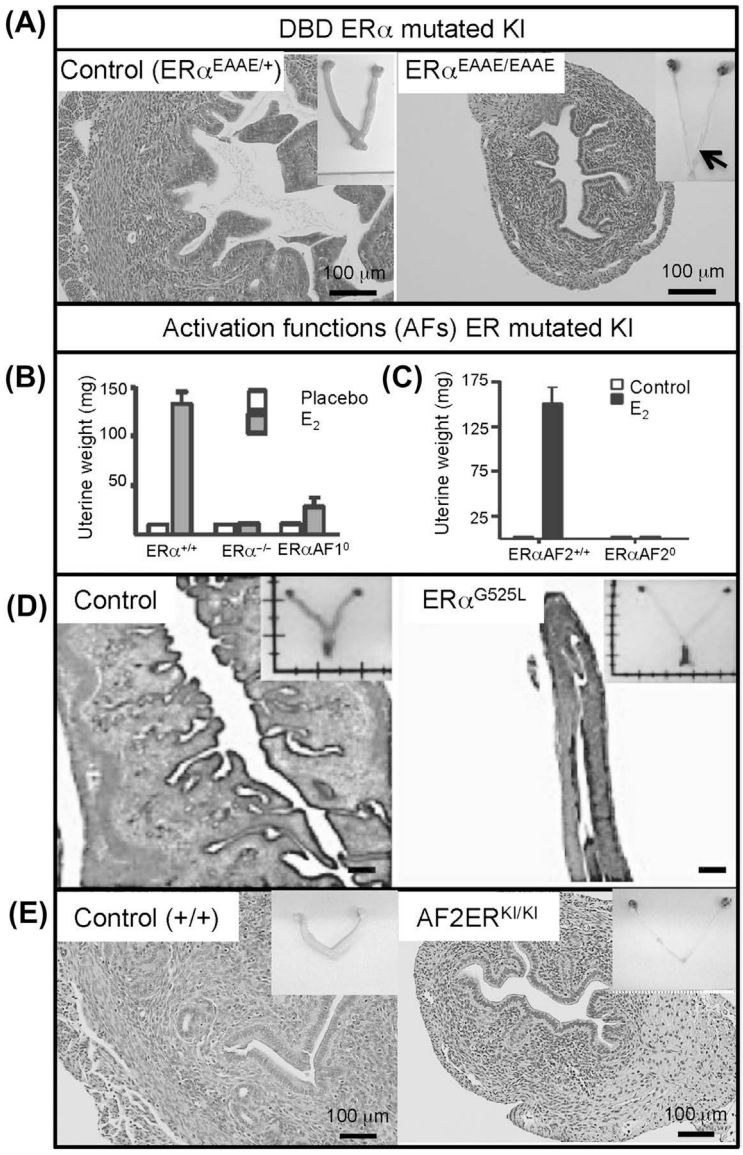

FIGURE 25.7 Gross uterine morphology and histological analysis of mice with knock-in of mutated ERα. (A) Female homozygous ERα$^{EAAE/EAAE}$ mice develop hypoplastic uteri (indicated by arrow) compared to heterozygous control (ERα$^{EAAE/+}$). (B) Uterine weight of ERα$^{+/+}$, ERα$^{-/-}$, and ERαAF-1^0 or (C) ERαAF-2$^{+/+}$ and ERαAF-2^0 mice treated with placebo control or E2 (80 μg/kg per day for 2 weeks). (D) Adult reproductive tract histology from WT control and ERα^{G525L} mice. H&E staining demonstrated that ERα^{G525L} animals exhibit hypoplastic uteri compared to WT control uteri. Insets depict gross reproductive tract morphology. Scale bar = 100 μm. (E) H&E staining of uterine tissues from WT control (+/+) and AF2ER$^{KI/KI}$ mice. Insets depict gross reproductive tract morphology. Scale bar: 100 μm. *Source: Reproduced and modified with permission from Refs. 164,165,167–169.*

MICE WITH MUTATED AF-1 OR AF-2 DOMAINS OF ERα

As discussed in the section Receptor Structure, AF-1 and AF-2 are important for ER transcriptional activity (Figure 25.1). A single mouse line with amino acids 2–128 deleted from exon 1 of *Esr1*, which removes the AF domain, called ERαAF-1^0, was described by Billon-Gales et al. in 2009.[165] There are three reported mouse lines with mutation in AF-2 domain of ERα. In the first line, the animals have a single point mutation in ERα of G at position 525 to L in the ligand binding domain (LBD), and this model was described by Sinkevicius et al. in 2008 (called "Estrogen-nonresponsive ERα Knock-in or ENERKI" or ERα^{G525L}).[168] Billon-Gales et al. generated a second line of LBD mutation animals in 2011, with amino acids 543–549 deleted from the LBD of ERα, removing helix 12 and thus AF-2 functionality (called ERαAF-2^0).[167] One month after the second line was published, Arao et al. reported the third line of animals with mutations within LDB of ERα[169] with two point mutations of L at position 543 and 544 to A (called AF2ER$^{KI/KI}$ animals). All females from the ERαAF-1^0, ERα^{G525L}, ERαAF-2^0, and AF2ER$^{KI/KI}$ mouse lines are sterile.[165,167–169]

ERαAF-1^0 females exhibited minimal uterine wet weight gain compared to ER$^{+/+}$ uteri after treatment with E2 pellets for two consecutive weeks (Figure 25.7(B)), while ERαAF-2^0 females did not respond (Figure 25.7(C)).[165–167] This indicates that the ERαAF-2 functional domain contributes to minimal uterine weight increase induced by E2 in the absence of AF-1. Both lines of AF-2-mutated animals (ERα^{G525L} and AF2ER$^{KI/KI}$) display severely hypoplastic uteri (Figure 25.7(D,E)) and lack uterine growth response to E2 treatment.[167–169] Interestingly, uterine wet weight can be increased by using the synthetic ERα agonist PPT (Table 25.2) in ERα^{G525L}

or by using the ER antagonists ICI 182,780 or tamoxifen (Table 25.2) in AF2ER$^{KI/KI}$ females.[168,169] The ability of the antagonists to mediate responses seems to be due to a unique conformation of the LBD of the AF2ER that leads to AF-1-dependent transcriptional activity.[169,200] Arao et al. also demonstrated that the uterine response to ICI or tamoxifen includes increased DNA synthesis in the uterine epithelial cells of AF2ER$^{KI/KI}$. The growth factor IGF1 (insulin-like growth factor 1) induced minimal uterine epithelial proliferation in ERα^{G525L} and was ineffective in AF2ER$^{KI/KI}$ uteri.[168,169] Together, these findings indicated that both AF-1 and AF-2 activation domains of ERα contribute to a normal regulation of uterine growth and reproductive functions. As the AF domains mediate ER-co-regulator interaction (Table 25.1), this emphasizes the importance of effective ERα co-activator protein recruitment for successful uterine E2 response. Similarly, mice lacking sufficient SRC-1 co-activator (*Src1*$^{-/-}$) exhibit measurably diminished uterine response to E2.[201]

Uterine Phenotypes in Mouse Models with Mutations in Transcriptional Proteins that Affect ER Function

MICE WITH UTERINE-SPECIFIC DELETION OF COUP-TFII

Chicken ovalbumin upstream promoter transcription factor II (COUP-TFII), encoded from the *Nr2f2* gene, is a transcription factor, belonging to nuclear receptor superfamily. COUP-TFII is expressed in uterine stromal cells and is crucial for female reproduction.[202–204] The tissue-specific deletion of COUP-TFII (*COUP-TFII*$^{d/d}$) in the uterus using *Pgr*$^{Cre+}$ crossed with *COUP-TFII*$^{f/f}$ animals demonstrated that *COUP-TFII*$^{d/d}$ females exhibited normal uterine development but were completely infertile, in part, due to lack of implantation.[202] Kurihara et al. also showed an enhanced estrogenic response in the epithelial cells of *COUP-TFII*$^{d/d}$ uteri, as E-responsive genes lactotransferrin (*Ltf*) and mucin 1 (*Muc1*) were elevated during the receptive window, which suggested that COUP-TFII modulates uterine epithelial ERα activity during pregnancy.[202] Inhibition of ERα activity using ER antagonist (ICI 182,789) partially rescued implantation in *COUP-TFII*$^{d/d}$ females and corrected the expression level of *Ltf* and *Muc1*.[203] These results suggest COUP-TFII plays an essential role in regulating uterine ERα activity during early pregnancy in rodents.

MICE WITH UTERINE-SPECIFIC DELETION OF REA

Repressor of estrogen receptor activity (REA) is an ER co-regulator that represses ER activity both in vitro and in vivo.[205–209] In Chinese hamster ovarian (CHO) cells, REA is shown to be a direct co-regulator of ERα and ERβ, but not PR or RAR.[205] In 2005, Park et al. generated a mouse line with a targeted deletion of REA exon sequence encoding amino acids 12–201 (heterozygous REA or REA$^{+/-}$).[208] Gross uterine morphology of REA$^{+/-}$ appeared normal compared to control littermates. However, the REA$^{+/-}$ females exhibited hypersensitivity to E2 treatment, as uterine weight and luminal epithelial cell height and proliferation were increased compared to E2-treated control uteri. In addition, E2-induced uterine genes (such as *C3* and *Ltf*) were also elevated in E2-treated REA$^{+/-}$ compared to E2-treated control uteri.[208]

Due to the embryonic lethality of REA$^{-/-}$,[208] uterine deletion of REA was generated using *Pgr*$^{Cre+}$ crossed with *REA*$^{f/f}$, producing *REA*$^{f/d}$ (heterozygous deletion) and *REA*$^{d/d}$ (homozygous deletion) animal models. Uterine epithelial cell hyperproliferation after E2 treatment was seen in *REA*$^{f/d}$, similar to the E2 response of REA$^{+/-}$ uteri.[207] The enhanced uterine weight increase by E2 in *REA*$^{f/d}$ females is in part due to increased levels of the aquaporin water transport gene (*Aqp4*). The levels of *Aqp3* and *Aqp5* induced by E2 treatment were similar between control and REA$^{f/d}$ uteri, but higher levels of *Aqp4* were reached in *REA*$^{f/d}$ than control uteri after E treatment.[207] *REA*$^{f/d}$ females were subfertile, while *REA*$^{d/d}$ females were completely infertile. No ovulation defect was found in *REA*$^{d/d}$ females, rather *REA*$^{d/d}$ females showed altered uterine growth and maturation, as well as implantation, decidualization, and placentation defects.[207] Aberrant apoptosis is observed in *REA*$^{d/d}$ uteri, as reflected by drastic increases in both TUNEL and active caspase-3 levels in *REA*$^{d/d}$ uteri compared to wild-type uteri.[207] These findings suggest that REA regulates proper ER responsiveness in vivo and is crucial for ER-mediated female uterine function.

MICE WITH UTERINE-SPECIFIC DELETION OF MSX1 AND MSX2

Mammalian homeobox genes, *Msx1* and *Msx2*, are crucial for organogenesis and embryo development. Nallasamy et al. reported that the selective ablation of either *Msx1* (*Pgr*$^{Cre+}$;*Msx1*$^{f/f}$, called *Msx1*$^{d/d}$) or *Msx2* (*Pgr*$^{Cre+}$;*Msx2*$^{f/f}$, called *Msx2*$^{d/d}$) in the uterus lead to subfertility in females, however, deletion of both *Msx1* and *Msx2* in the uterus (*Msx1*$^{d/d}$*Msx2*$^{d/d}$), resulted in complete infertility.[210] This indicates that *Msx1* and *Msx2* functions can partially compensate for each other. The female infertility in *Msx1*$^{d/d}$*Msx2*$^{d/d}$ females is in part due to an implantation defect.[210] Deletion of *Msx1* and *Msx2* in the uterus causes uterine hypersensitivity to estrogen due to an increase in uterine ERα activity. Increased ER phosphorylation in uterine epithelial and subepithelial stromal cells, resulting from high fibroblast growth factor (FGF) expression, were observed.[210] Female mice with uterine *Msx1* and *Msx2* deletion exhibited not only an altered ERα activity but also showed aberrant expression of Wnt/β-catenin signaling molecules.[210] This indicates that homeobox genes *Msx1* and *Msx2* in the uterus are mediators of physiological ERα activity, which subsequently play pivotal roles in establishing successful pregnancy.

MICE WITH UTERINE-SPECIFIC DELETION OF NCOA6

Nuclear receptor co-activator-6 (NCOA-6) is an ERα co-activator. Kawagoe et al. reported that NCOA-6 regulates uterine ER activity by using selective deletion of *Ncoa6* in the uterus (Pgr^{Cre+};$Ncoa6^{f/f}$, called $Ncoa6^{d/d}$).[211] Ovulation, fertilization rates, and blastocyst development are all normal in $Ncoa6^{d/d}$ females; however, embryo implantation fails. The implantation defect is in part due to an increased level of the ERα co-activator, SRC3, in the uterine epithelial cells of $Ncoa6^{d/d}$, which causes elevated uterine epithelial ERα activity compared to wild-type uteri. Moreover, a diminished PR activity, particularly during the implantation period, was observed. Implantation was partially rescued and the level of MUC1 was corrected in uterine luminal epithelia by treating $Ncoa6^{d/d}$ females with the ER antagonist ICI 182 780.[211] These findings suggest that loss of uterine NCOA-6 causes implantation failure due to an aberrant ER-estrogen hypersensitivity.

MICE WITH UTERINE-SPECIFIC DELETION OF MIG6

Mitogen-inducible gene 6 (Mig-6, encoded from the *Errfi1* gene) is a downstream target of P-PR and SRC1 action in the uterus.[108] However, uterine-specific deletion of Mig-6 ($Mig\text{-}6^{d/d}$ or Pgr^{Cre+};$Mig\text{-}6^{f/f}$) demonstrated altered ERα signaling resulting in uterine hyperplasia.[108] $Mig\text{-}6^{d/d}$ uteri are enlarged, with weights approximately 3-fold more than wild-type ($Mig\text{-}6^{f/f}$) uteri. Immunohistochemical analysis demonstrated that $Mig\text{-}6^{d/d}$ uteri exhibit hyperproliferation of the endometrium, with increased phospho-H3 staining, as a result of increased ERα expression and phosphorylation.[108] The ERα targeted genes, lactoferrin (*Ltf*), chloride channel calcium–activated 3 (*Clca3*), and complement component 3 (*C3*) were also elevated in $Mig\text{-}6^{d/d}$ uteri in the presence of both E and P, however, the PR-targeted genes amphiregulin (*Areg*) and follistatin (*Fst*) remained comparable to wild-type uteri. Ovariectomized $Mig\text{-}6^{d/d}$ females that were treated with E for 3 months exhibited endometrial cancer. However, co-treatment with E and P attenuated the pathology in the uterus of E treated $Mig\text{-}6^{d/d}$, although the uterine hyperplasia was still observed in $Mig\text{-}6^{d/d}$ females. Additionally, the expression level of MIG-6 in women with endometrioid carcinoma was elevated compared to normal endometrium.[108] These findings together suggest that Mig-6, as a tumor suppressor in both rodents and human, plays a crucial role in uterine growth in response to E in part by mediating the protective action of P.[108]

MICE WITH UTERINE-SPECIFIC DELETION OF HAND2

Heart and neural crest derivatives expressed 2 (Hand2) is regulated by P in the uterus, as protein expression of HAND2 is induced in the uterine stromal cells after P treatment.[212] PRKO uteri showed loss of Hand2 expression, indicating the direct regulation of Hand2 by PR.[212] Selective ablation of Hand2 in the uterus ($Hand2^{d/d}$) using the Pgr^{Cre+};$Hand2^{f/f}$ animal model demonstrated an elevated uterine ER activity.[212] Loss of uterine Hand2 expression in the stromal cells leads to aberrant fibroblast growth factor receptor (FGFR) signaling, which subsequently induced ERK signaling and ERα activity in the uterine epithelium (Figure 25.8), resulting in complete infertility. The infertility in $Hand2^{d/d}$ females is in part due to an implantation defect as a result of enhanced uterine epithelial ERα

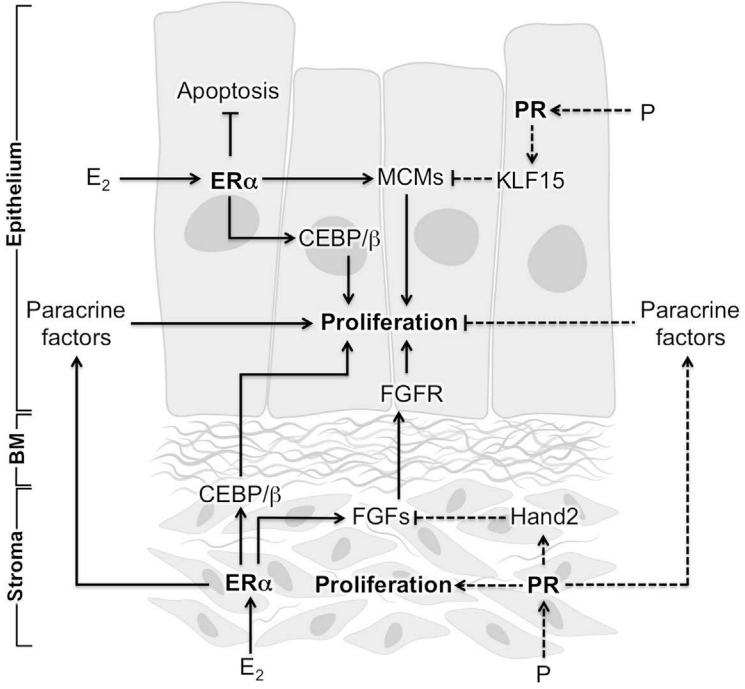

FIGURE 25.8 Schematic representation of paracrine and autocrine mechanisms of uterine proliferation in response to hormones. E2 stimulation of proliferation of the uterine epithelium requires the presence of functional ERα in the underlying stroma independent from epithelium, indicating that E2/ERα actions in the stroma induce the secretion of paracrine factors that then act on the epithelium to stimulate proliferation. Progesterone (P) acts through epithelial and stromal PRs to inhibit the proliferative response of the epithelium to E, while inducing proliferation of the underlying stroma. BM, basement membrane. (For detail see text.)

activity during the implantation period.[212] This suggests that *Hand2* expression in the uterus, orchestrated by an action of PR, mediates a proper physiological ERα activity (Figure 25.8) in response to ovarian hormones, leading to successful pregnancy establishment.

Vaginal and Cervical Phenotypes in Mouse Models of Disrupted Estrogen Signaling

The vaginal mucosa is composed of an epithelium and underlying stroma, possesses significant levels of ER,[213] and is highly sensitive to estrogens.[214] Endogenous or exogenous estrogens induce stromal differentiation, epithelial proliferation, and epithelial keratin synthesis to produce the stratified layer of cornified cells that lines the vaginal lumen.[214–216] These changes in the vaginal mucosa are used experimentally to estimate the level of circulating gonadal steroids and approximate the estrous cycle stage. Despite exposure to elevated endogenous E2 levels, the vaginal tissue of ERα-null females lacks any indications of estrogenization (Figure 25.5(B)).[134] Exogenous administration of E2 or DES also elicits no discernible vaginal response in ERα-null females.[196] In contrast, the vaginal mucosa of ERβ-null females undergoes the normal cyclic changes as dictated by ovarian sex steroids (Figure 25.5(B)). An effect on the vaginal mucosa similar to that observed in ERα-null females is produced in rodents after prolonged ovariectomy or exposure to ER antagonists.[217–219] Therefore, estrogenization of the vaginal mucosa in rodents, which is critical to mating, is ERα dependent. Using a human papilloma virus (HPV) transgenic model of cervical cancer, Chung et al. demonstrated that estrogen promotes development of HPV-induced cervical cancer through ERα, as αERKO HPV–transgenic animals were protected from developing disease.[220,221]

Progesterone Receptor Expression in the Uterus

In the murine uterus, PR transcript and protein levels are low on days 1–2 of pregnancy with the highest expression occurring in the epithelia and subepithelial stroma.[126] PR levels rise in these same tissues on days 3 and 4 of pregnancy, leading up to implantation.[126,222] Receptor-mediated E2 actions are a primary regulator of PR expression in the rodent uterus, but these actions are complex and specific to the different uterine compartments. Ovariectomy leads to increased PR levels in the uterine luminal epithelium that can be reduced upon exogenous E2 treatments, indicating E2 acts to repress PR expression in this uterine compartment.[128,223] Recombination experiments of stromal and epithelial tissues similar to those described earlier, as well as studies using epithelial selective ERα deletion, indicate this to be a paracrine-mediated effect that requires functional ERα in the stroma.[125,170] Simultaneous with causing decreased PR expression in the epithelium, E2 treatments lead to increased PR levels in the uterine stroma of ovariectomized mice.[128,223] This is an ERα dependent regulation, as PR is found only in epithelial cells, regardless of E2 treatment in αERKO. Additionally, epithelial ERα is dispensable for this response as increased PR expression in the stromal cells is preserved in the absence of epithelial ERα.[170] These observations have been largely confirmed in studies using a PR-lacZ reporter mouse that represents *Pgr* gene promoter activity as β-galactosidase activity in situ.[224] In these studies, β-galactosidase activity representative of PR expression is observed in luminal and glandular epithelium after ovariectomy and decreased after estrogen treatment.[224] P treatments also lead to decreased PR-lacZ expression in all cell types.[224]

In the adult ovine and bovine uterus, PR expression is highest during the early proliferative phase and present in all uterine cell types but is most abundant in the stroma and myometrium.[138,140–142] PR levels decline as the cycle progresses to the secretory phase, initially in the stroma and myometrial cells.[138,140–142]

In the human uterus, PR immunoreactivity is increased in all cell types during the proliferative phase but measurably lower than ER levels.[143,145] During the secretory phase, PR levels are maintained in the stroma and myometrium but decrease in the glandular epithelium such that levels are eventually undetectable.[143,145] Studies using PR isoform selective antibodies have shown that the decrease in PR levels that occurs in the glandular epithelium during the mid-secretory phase is largely representative of PRA, leading to an increased PRB/PRA ratio in these cells.[225] In stroma, where fewer cells expressed PR relative to glandular epithelium, PRA is more abundant.[225] During the late secretory phase, PRA levels in the stroma decrease but remain detectable, whereas stromal PRB expression decreases occur earlier and are significantly diminished by the late secretory phase.[225] The predominance of PRA in the glandular epithelium during the early secretory phase may serve to inhibit further estrogen-mediated proliferation, as the uteri in PRA-null mice exhibit an exaggerated proliferative response to estrogens.[181] As P levels rise during the mid-secretory phase, PRB is concentrated in nuclear foci, suggesting active transcriptional activity.[226] A similar finding of focal-concentrated PRB is reported in endometrial cancer cells in postmenopausal women, suggesting that inappropriate PRB activity may be associated with uterine cancer.[226] The pattern of PR expression in uteri of nonhuman primates is similar to that described in humans. In female baboons, PR levels are increased during the proliferative phase and then decrease accordingly during the secretory phase.[152]

Uterine Phenotypes in Mouse Models with Disrupted Progesterone Signaling

MICE LACKING PR

There are several reported lines of PR-null mice. Mice lacking both nuclear PR isoforms (PRKO) were first

described by Lydon et al. in 1995 and were generated via targeted disruption of exon 1 of the murine *Pgr* gene.[176] In 2006, Hashimoto-Partyka et al. generated the PR ($Pgr^{f/f}$)-targeted mutation in exon 1 of PR using *EIIa*-Cre promoter, which expressed Cre recombinase in the preimplantation embryo in order to create a deletion of exon 1 and loss of PR protein.[177] In 2010, Fernandez-Valdivia et al. described a mouse line that had a deletion of PR exon 2 and loss of PR protein using $Pgr^{f/f}$ and *ZP3*-Cre promoter expressing mice (called $PR^{d/d}$).[178]

Mice lacking only PRA (PRAKO)[180] or PRB (PRBKO)[182,227] were generated via a *Cre/loxP*-based gene targeting strategy that mutated the respective start codons for each isoform while preserving the translational reading frame of the other. Comparative studies in all models have greatly furthered our understanding of the divergent functions for the two PR isoforms. Recently, Franco et al. generated an epithelial cell specific deletion of both PRA and PRB in the uterus (called *Wnt7a-Cre*$^{+}PR^{f/-}$) using *Wnt7a*-Cre expressing promoter crossed with $Pgr^{f/-}$ animals.[179]

PR-null mice exhibit normally developed uteri that possess the expected uterine architecture (Table 25.3).[181,182] During the secretory phase of the murine estrous cycle, decreasing circulating levels of E2 concurrent with rising P cause a shift in uterine proliferation from the epithelial to stroma cells.[228] Estrogen, through ERα, is known to stimulate uterine epithelial cell proliferation in adult mouse uteri,[125,159,229] and P exhibits the antiproliferative effect on the action of E2 (Figure 25.8).[230,231] Therefore, PR-mediated P actions negatively modulate E2-induced proliferation of the uterine epithelium.[228] In addition, ovariectomized PR-null females treated with daily injections of E2 and P for 3 weeks exhibit abnormally large fluid-filled uteri that are characterized by a thickened uterine wall due to extensive extracellular edema, hyperproliferation of the glandular epithelia resulting in a disordered cellular arrangement, and acute inflammation of the endometrium.[176] The hyperestrogenic response in PR-null uteri is similar to that observed in ovariectomized mice after prolonged exposure to unopposed estrogens[229] and provides strong support of the modulatory actions of PR in the uterus.[176] Similar experiments in isoform-specific PR-null mice indicate this phenotype is reproduced in PRA-null mice only, whereas PRB-null mice exhibit a normal uterine response, indicating that PRA is primarily responsible for negatively modulating the uterine response to E2.[180–182]

Uterine Phenotypes in Mouse Model with Mutations in Transcriptional Proteins That Mediate PR Function

MICE WITH UTERINE-SPECIFIC DELETION OF P160 (SRCs)

The SRCs mediate P-dependent action in the uterus.[232] Immunohistochemical analysis in the uteri of pregnant mice demonstrated the spatiotemporal expression pattern of SRC1 and SRC2 in the luminal epithelial, stromal as well as secondary decidual zone. The uterine expression pattern of SRC1 and SRC2 was similar to the pattern of PR expression during pregnancy.[232] In uteri from ovariectomized animals, the majority of SRC1 and SRC2 was expressed in the luminal and glandular epithelium, much like PR expression.[232] Both E and P, either alone or administered together, increased the expression of SRC1 and SRC2 in the uterine stromal cells.[232]

There are several reports describing SRC-null mice and resulting effects on female reproductive functions.[201,232–234] Global disruption of the *Src1* gene demonstrated that both males and females were fertile, however, females exhibited a blunted response to ovarian hormones.[201] Treatment of $Src1^{-/-}$ females with E2 for 3 consecutive days resulted in less uterine weight increase than in WT, similarly, artificial induction of decidualization resulted in less stromal differentiation of $Src1^{-/-}$ uteri.[201] Due to a lethality of *Src2* global knockout,[235] uterine-specific SRC2 deletion ($Src2^{d/d}$) was generated using Pgr^{Cre+} crossed with $Src2^{f/f}$ animals.[233] $Src2^{d/d}$ females were infertile, in part, due to an implantation and decidualization defect.[232,233,236] E2-induced uterine epithelial cell proliferation was preserved in $Src2^{d/d}$ uteri.[233] The decidualization markers such as *Bmp2*, *Ptgs2* (Cox-2), and *Fst* were significantly decreased in $Src2^{d/d}$ when compared to wild-type uteri.[233] A complete absence of decidual response was observed in $Src2^{d/d}$ uteri in a $Src1^{-/-}$ background.[233] However, $Src3^{-/-}$ females had no overt uterine phenotype.[232] These findings indicate that of the three SRCs, SRC2 is most crucial for P-dependent uterine function.

MICE WITH UTERINE-SPECIFIC DELETION OF COUP-TFII

COUP-TFII regulates uterine ER function during early pregnancy as mentioned earlier. Additionally, the $COUP\text{-}TFII^{d/d}$ animal model also demonstrated that COUP-TFII is a downstream effector for PR-mediated decidualization.[202] Loss of uterine COUP-TFII resulted in a defect in decidualization, as reflected by lack of expression of decidual cell markers (WNT4 and BMP2).[203] Treatment of $COUP\text{-}TFII^{d/d}$ females with ICI 182,780 restores the expression of WNT4 and BMP2 in the decidual cells.[203] Together, the findings from uterine-specific deletion of COUP-TFII suggest that COUP-TFII regulates P signaling during implantation and decidualization by controlling uterine ER activity.

MICE WITH UTERINE-SPECIFIC DELETION OF REA

As discussed earlier, REA is crucial for uterine responses to ovarian hormones and establishment of pregnancy. Using $REA^{d/d}$ animals also demonstrated that loss of uterine REA led to aberrant PR function, which resulted in a decidualization defect.[207] The decidual cell

markers, *Wnt4* and *Bmp2*, were not increased in $REA^{d/d}$ uteri after artificial decidualization. The defect in decidualization is due to loss of PR expression after uterine REA ablation.[207] These findings indicate that uterine REA expression is not only crucial for ER activity but also for PR function to establish and maintain pregnancy.

MICE WITH UTERINE-SPECIFIC DELETION OF FKBPs

FK506 Binding Proteins 4 (FKBP4; encoded by *Fkbp52* gene) and 5 (FKBP5; encoded by *Fkbp51* gene) are immunophilin family co-chaperones that interact with PR in the absence of the ligands.[237] *Fkbp4* is expressed in the luminal and glandular epithelial cells during implantation, whereas a minimal level was detected in the uterine stromal cells, similar to PR expression.[237] During the decidual response, *Fkbp4* was highly expressed in both primary and secondary decidual zones. Although the expression of *Fkbp5* also showed a similar pattern, the level of expression was much lower than that of *Fkbp4*.[237] The global knockout of FKBP5 was fertile and showed no impairment of uterine functions.[237,238] However, the global knockout of FKBP4 caused complete female infertility,[237,238] due to implantation and decidualization defects,[237,238] suggesting that FKBP4 not only binds to PR but is crucial for PR action during pregnancy.

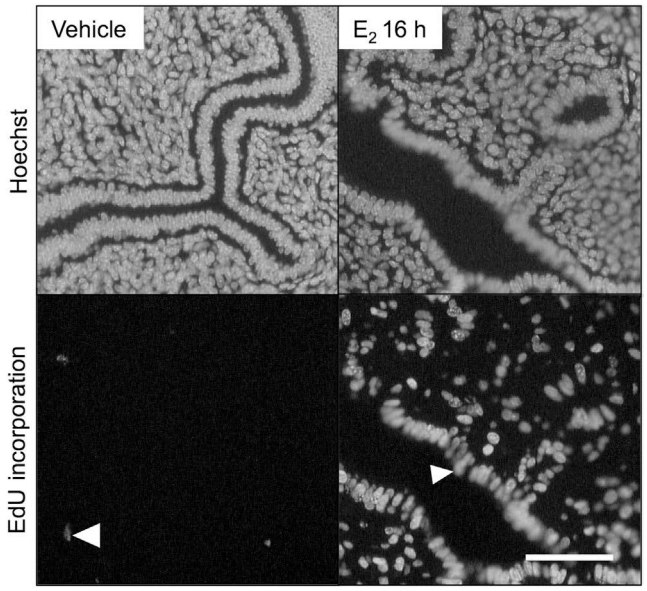

FIGURE 25.9 Estrogenic response in immature uteri in mice (21-day-old). DNA synthesis as indicated by nuclear EdU incorporation is detected in vehicle-treated uterine epithelial cells (arrowhead). However, DNA synthesis is dramatically increased in the luminal and glandular epithelia as well as stromal cells in the uteri 16 h after E2 treatment. Hoescht was used as a counterstain to visualize the tissue. Scale bar = 100 μm. Arrowhead indicates EdU positive epithelial cell.

Uterine Response to Estradiol and Progesterone

Changes in Physiology

Estrogens stimulate a complex process of epithelial proliferation and differentiation in the sexually mature uterus that leads to the formation of a multilayered secretory endometrium. This effect is critical to provide a suitable intrauterine environment for the establishment and maintenance of pregnancy. Early studies in neonatal and prepubertal rodents found that both the uterine stroma and epithelium proliferate in response to estrogens (Figure 25.9);[239] however, estrogen-induced mitogenesis in uteri of sexually mature rodents is limited to the epithelium.[229] Therefore, sexual maturation of the rodent uterus is not simply marked by the presence of ER or an estrogen response but is rather the acquired capacity to undergo synchronized phases of proliferation and differentiation as dictated by the ovarian-derived sex steroids. The lack of estrogen-induced uterine epithelial proliferation in ERα-null uteri indicates the essential role of ERα in this process (Figure 25.6). Although ERα is present in both epithelial and stromal compartments, tissue recombination studies and study of the uterine epithelial-specific ERα null indicate the proliferative epithelial response to estrogens is indirect and dependent on stromal ERα actions (Figure 25.6 and a working model in Figure 25.8).[170,240]

Treatment of ovariectomized mice with estrogens (e.g., E2 or DES) has long served as an experimental model to mimic the uterine events that occur during the estrous phase of the rodent cycle or immediately after the preovulatory E2 surge. Morphological and biochemical changes occur in the rodent uterus after estrogen stimulation following an established biphasic temporal pattern[241,242] (Table 25.4). Estrogen-stimulated changes in the rodent uterus that occur early, within the first 6 h after treatment, include increases in nuclear ER occupancy, water imbibition, vascular permeability and hyperemia, prostaglandin release, glucose metabolism, eosinophil infiltration, gene expression (e.g., c-*fos*), and lipid and protein synthesis (Table 25.4). Recent ERα ChIP-Seq profiles from uterine tissues showed that the receptor preoccupies chromatin sites and that E2 treatment increases ERα recruitment.[243] These processes are then accompanied by a delayed response that peaks after 24–72 h and includes dramatic increases in RNA and DNA synthesis, epithelial proliferation, and differentiation toward a more columnar secretory phenotype, dramatic increases in uterine weight, and continued gene expression (e.g., lactotransferrin) (Table 25.4). Ovariectomized mice exhibit a three- to four-fold increase in uterine weight after three daily treatments with E2 or DES, whereas no such response is observed in the uteri of ERα-null females.[157,159,244] The early phase effects of water imbibition and hyperemia as well as the late-phase effects of increased DNA synthesis and epithelial proliferation are absent in ERα-null uteri[159,189,196] (Figure 25.6). Interestingly, females that are heterozygous for the *Esr1* gene

TABLE 25.4 Biphasic Response of the Rodent Uterus to Estrogens

EARLY UTEROTROPIC RESPONSES (WITHIN 6 H)
Nuclear localization of estrogen receptor/recruitment to chromatin
Activation of receptor-tyrosine kinase pathways
Changes in gene expression (induction/repression of "early" genes)
Increased vascular permeability
Increased protein synthesis
Water imbibition
Hyperemia
Eosinophil infiltration
Albumin accumulation
Increased electrolytes
Lysozyme labilization
Increased cyclic nucleotides, prostaglandins, and associated enzyme activity
Increased glucose metabolism and associated enzyme activity
Calcium influx
Increased lipid synthesis
LATE UTEROTROPIC RESPONSES (WITHIN 24 H)
Second peak of nuclear localization of estrogen receptor
Changes in gene expression (induction/repression of "late" genes)
Increased protein synthesis
Increased DNA synthesis
Epithelial proliferation in "waves"
Cellular hypertrophy
Overall increase in uterine dry weight

disruption possess approximately one-half the normal level of ERα in the uterus, but their response to estrogen treatment is comparable with wild-type females. The total lack of response to estrogens in ERα-null uteri as well as a lack of late biological response in epithelial ERα knockout uteri provide strong evidence that ERα is required to mediate the full biochemical and biological uterine response to estrogens.[159,170]

Molecular Mechanisms of Estrogen-Induced Uterine Proliferation

Numerous studies have elucidated the molecular mechanisms of E2-induced uterine epithelial cell proliferative responses in animal models. For example, the transcription factor CCAAT enhancer binding protein beta (C/EBPβ) is involved in hormone-induced uterine proliferation.[245] Maximum uterine expression of C/EBPβ is induced 1 h after E2 treatment in both epithelial and stromal cells.[245,246] ICI 182,786 (ER antagonist) strongly inhibited E2-induced *Cebpb* transcript in the uterus, suggesting an ER-dependent expression of C/EBPβ.[247] In addition, loss of epithelial ERα in the uterus did not alter E2-induced *Cebpb* expression, indicating that *Cebpb* expression is independent of epithelial ER.[170] This points to the action of estrogen through ERα as the major mediator of C/EBPβ expression in the uterus. Indeed, the deletion of C/EBPβ (C/EBPβ$^{-/-}$) leads to a lack of the E-induced uterine proliferative response[245] as reflected by the absence of mitotic activity, S-phase activity, and an increase in apoptotic activity in the uterine epithelial cells.[246] In addition to a blunted uterine growth response to hormones, the C/EBPβ$^{-/-}$ females also exhibit complete infertility[247] due to implantation and decidualization defects.[245]

Pan et al. demonstrated that the uterine expression of minichromosome maintenance proteins (MCMs), a complex required for DNA synthesis initiation, is induced after E2 treatment, specifically MCM2 and MCM3[248] (Figure 25.8). MCM2 activity is crucial and required for DNA synthesis in the uterine epithelial cells.[249] The DNA replication of uterine epithelial cells induced by E2 is attenuated by P action, which will be discussed further in a later section.

Estrogen–Growth Factor Cross Talk in the Uterus

The autocrine and paracrine actions of polypeptide growth factors are an integral component of the uterine response to estrogens. The uterine response to E2 is modulated by stromal factors, such as IGF1, that are induced by E2 and then impact epithelial responses.[250] *Igf1* transcript is increased with concomitant decrease of *Igfbp3*[242] and activation of the IGF1 receptor and downstream effectors following E2 treatment.[251] *Igf1* transcript is increased in both stromal and epithelial compartments of the uterus by E2, with greater signal apparent in the stroma (Figure 25.10(A)).[252] Igf1 has been demonstrated to play an essential role in the uterine growth response, as *Igf1* null mice lack a full uterine proliferative response, and more specifically, lack G2/M progression of the epithelial cells following E2 stimulation.[253] Additionally, transgenic mice overexpressing *Igfbp1*, which sequesters, and therefore decreases, the amount of available IGF1, have an attenuated uterine response to E2.[254] Uterine response is restored by transplanting Igf1KO uterine tissue into a WT host,[255] which demonstrated the paracrine effect of the host Igf1. Further, E2 treatment results in the activation of downstream mediators of Igf1 signaling, including the Igf1 receptor, IRS1,[251] AKT, and inhibition of GSK3β,[252] leading to nuclear translocation of CCND1 and epithelial proliferation. Additionally, picropodophyllin (PPP), an IGF1R inhibitor, blunted the proliferative effect of E2. This effect of PPP on E2-stimulated uterine proliferation could be reversed, however, by

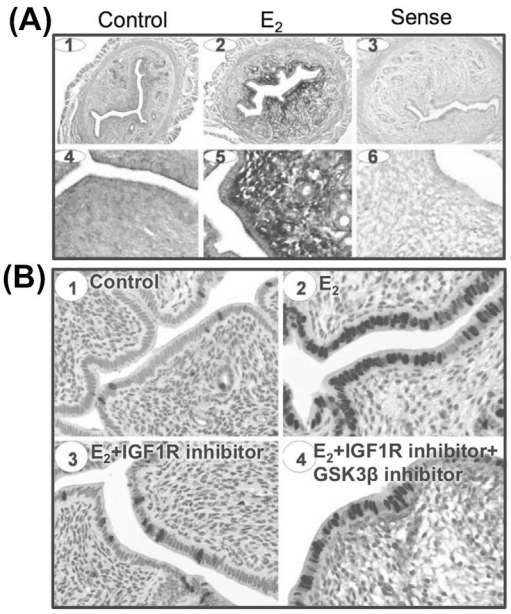

FIGURE 25.10 E2 treatment stimulates uterine epithelial proliferation through IGF1 signaling. (A) In situ hybridization of transverse sections of uteri of control (1 and 4) and E2-treated (2, 3, 5, and 6) mice probed by using antisense (1, 2, 4, and 5) or sense (3 and 6) probes. Dark precipitate represents the hybridization signal and indicates an upregulation of *Igf1* after E2 treatment principally in the stroma but also in the luminal and glandular epithelium. (Magnification: 1–3, 10×; 4–6, 40×.) (B) E2 signals through IGF1 and GSK3*β* to induce DNA synthesis in the uterine epithelium. BrdU incorporation in uterine section from ovariectomized mice 15 h after the following treatments: (1) control, (2) E2 (subcutaneous, s.c.), (3) E2 (s.c.) + PPP (picropodophyllin; IGF1R inhibitor) given intraluminally, and (4) E2 (s.c.) + PPP + SB415286 (GSK3*β* inhibitor) given intraluminally. *Source: Reproduced and modified with permission from Ref. 252. Copyright (2007) National Academy of Sciences, USA.*

co-treatment with PPP and the GSK3β inhibitor, SB415286 (Figure 25.10(B)).[252] These findings elegantly illustrate a direct role for IGF1R-initiated signaling through AKT and GSK3β on uterine response to E2.

In addition, IGF1 or EGF treatment of ovariectomized wild-type mice elicits a pattern of global gene expression similar to that induced by E2, although some estrogen-specific genes are revealed.[256] IGF1 treatment was shown to increase the expression of an ERE-driven luciferase reporter gene in transgenic mice, providing the first in vivo evidence of E2-independent ER activation by growth factor.[257] ER-null mice provide an excellent in vivo model for the study of ER–growth factor "cross talk" mechanisms in the uterus. ERα-null uteri express wild-type levels of functional EGFR but are unresponsive to the mitogenic actions of EGF, confirming the interaction of these two signaling systems.[258] However, not all EGF responses are lacking in the uteri of αERKO females, as upregulation of the c-*fos* gene by this growth factor remains intact. Similar studies have demonstrated that the uterine response to IGF1 is compromised in ERα-null females.[259] Cunha and colleagues[125,250,255] used the ERα-null mice in a series of tissue recombination experiments to further demonstrate interaction between ER and growth factor signaling in the murine reproductive tract. In these studies, uterine stoma and epithelium are enzymatically disassociated from prepubertal mice and recombined with corresponding tissue from animals of different treatments or genotypes. The resulting chimeric stromal-epithelial unit is then implanted under the kidney capsule of an ovariectomized nude mouse that is then treated with various hormonal combinations. A caveat to these studies is that neonatal tissues are used and may not accurately reflect the uterine physiology of sexually mature females. Nonetheless, these methods have been effectively used to demonstrate that estrogen-induced proliferation of uterine and vaginal epithelium requires functional ERα in the underlying stroma only,[250] whereas estrogen-induced increases in secretory products (e.g., LTF, complement C3, keratins) in the uterine or vaginal epithelium requires functional ERα in both uterine compartments. These findings have now been confirmed in sexually mature intact uterine tissue using uterine epithelial cell–selective ERα-null mice.[170] In addition, treatment of uterine epithelial ERα-null females with IGF1 or EGF mimics the uterine epithelial cell DNA synthesis stimulated by E2 (Figure 25.11). These studies strongly support a paracrine mechanism of estrogen-mediated epithelial proliferation that requires ERα in the stroma (working model in Figures 25.8 and 25.11). Interestingly, microarray studies indicate that the growth factor–induced genomic response is intact in ERα-null uteri, although epithelial proliferation is absent,[256] suggesting a greater complexity to the estrogen–growth factor signaling "cross talk" than was originally perceived. GF signaling is thought to mainly utilize AF-1 via MAPK phosphorylation sites in the N-terminus. Thus is was expected that IGF1 or EGF treatment of AF2ER$^{KI/KI}$ mice would lead to uterine growth, however, no response was seen,[169] indicating functional AF-2 is also involved in this mechanism.

Antiproliferative Functions of PR in the Endometrium

Tong and Pollard demonstrated that P inhibits E-induced uterine proliferation via the inhibition of DNA synthesis and PCNA expression (a component of DNA polymerase gamma, which is required for S-phase entry).[228] Additionally, Ray and Pollard demonstrated that Krupple-like transcription factor 4 (KLF4) expression is induced whereas KLF15 is suppressed by E2 treatment in the uterine epithelial cells.[249] Conversely, co-treatment with P and E decreased KLF4 expression and increased KLF15 in the uterus.[249] In addition, overexpression of uterine KLF15 using an adenovirus leads to a lack of E2-induced uterine epithelial proliferative

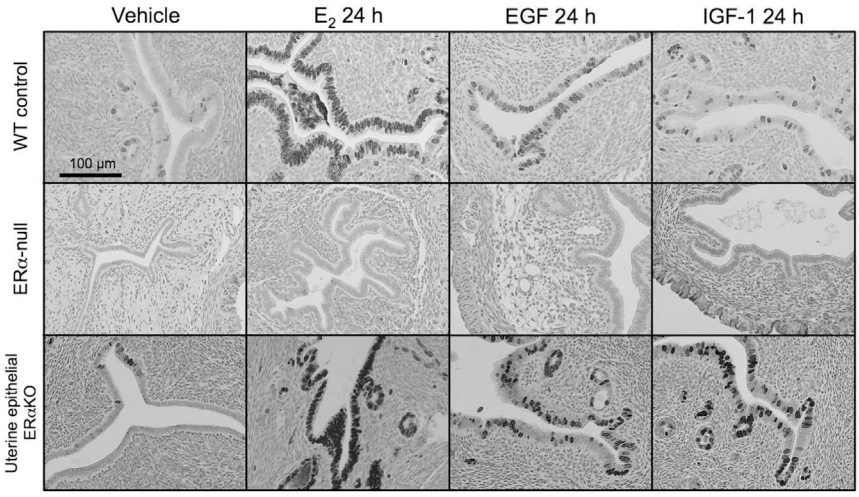

FIGURE 25.11 Growth factors are able to mimic the proliferative effects of E2 in the mouse uterus. Shown are uterine cross-sections from ovariectomized WT, ERα-null, and uterine epithelial ERα-knockout (uterine epithelial ERαKO) mice treated for 24 h with vehicle, E2, epidermal growth factor (EGF), or insulin-like growth factor 1 (IGF1). Uterine tissue was then subjected to immunohistochemistry for the antigen Ki67, a marker of cell proliferation. As expected, E2 treatment induces a dramatic increase in Ki67 immunoreactivity in uterine luminal and glandular epithelium, and EGF and IGF1 mimic this effect in the absence of endogenous E2. *Source: Reproduced and modified with permission from Refs 159,170.*

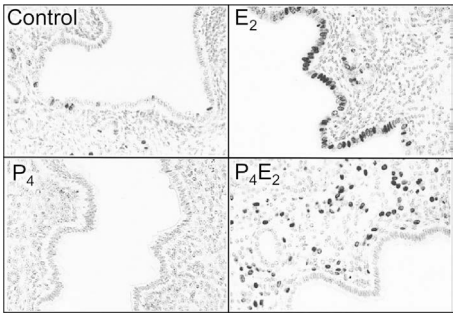

FIGURE 25.12 Progesterone inhibits E2-induced uterine epithelial cell proliferation and stimulates stromal cell proliferation. BrdU incorporation in the uterine tissues from ovariectomized mice treated with control (no treatment), E2 (15 h), P (daily for 4 days), and PE2 (P for 4 days and E2 on the fourth day for 15 h). *Source: Reproduced and modified with permission from Ref. 228.*

response due to the loss of MCM2 expression,[249] demonstrating that KLF15, through the action of P, inhibits E2-induced uterine epithelial DNA synthesis by inhibition of MCM2 expression. Moreover, P also diminished E2 induction of Cyclin D1 nuclear translocalization and expression of Cyclin A, which consequently decreased the phosphorylation of pRb and p107.[228,260,261] Together, these findings described the mechanism by which P inhibits cell cycle activity induced by E2 in the uterine cells (see Figure 25.8).

P not only inhibits the uterine epithelial proliferation but also contributes to an induction of stromal cell proliferation in the presence of E2. Recombination experiments using uterine tissues from PR-null mice demonstrate that the antiproliferative functions of P in the uterine epithelium are paracrine mediated and require PRA in the stroma[125,262] (Figure 25.12). However, selective deletion of PR in the uterine epithelial cells (*Wnt7a-Cre*$^{+}$*;PR*$^{f/-}$ animal model) demonstrated that epithelial PR expression is dispensable for E2-induced uterine weight increase and induction of stromal cell proliferation but required for the P-mediated inhibition of epithelial cell proliferative response induced by E2.[179,228] *Wnt7a-Cre*$^{+}$*PR*$^{f/-}$ animals exhibit an aberrant uterine expression of MCM3 and Cyclin D1,[179] which are important mediators of E2-induced uterine epithelial proliferative responses.

Moreover, P treatment also inhibits the pro-inflammatory activity induced by estrogen.[263] The inflammatory response observed in PR-null uteri after prolonged estrogen/P treatment is extensive and consists of "marked" infiltration of polymorphonuclear leukocytes into the endometrial stroma, mucosal epithelium, and uterine luminal fluid.[176] In vitro studies have shown that P inhibits the expression of chemotactic cytokines for neutrophil and lymphocyte infiltration[264,265] and may reduce prostaglandin E levels in uterine decidual and chorionic tissue during early pregnancy.[266] Therefore, PR-mediated P actions may be critical to suppressing the uterine inflammatory response that may accompany embryo implantation.[176,267] The uterine levels of macrophages, neutrophils, and *Ltf* are increased in both WT and PRKO uteri after unopposed E treatment. The pro-inflammatory activity is decreased by co-treatment of E with P in WT, but not in PRKO uteri,[223,263] thus PR function is crucial to control uterine inflammatory response during the ovarian cycle.

Roles of PR in the Rodent Uterus during Pregnancy

PR-mediated P actions in the uterus are critical to preparing the uterine endometrium for pregnancy. Embryo implantation is a highly complex process that requires synchronized cooperation between the blastocyst and uterine endometrium (see Chapter 38). Circulating E2 levels peak at ovulation and elicit a cascade of proliferation and differentiation in the luminal and glandular epithelium of the uterus, including induction of PR expression in the endometrial stroma and myometrium.[223] Postovulatory increases in circulating P then

cause decidualization, a complex process that involves massive proliferation and differentiation of the endometrial stroma along with localized increases in vascular permeability and edema.[34,268,269] This process involves the synthesis and interaction of numerous hormones and signaling pathways, including prolactin, cytokines, prostaglandins, and extracellular matrix components.[268,269] The result is a remarkable swelling of the uterine stroma that is thought to be necessary for implantation by forcing the uterus to close down on the blastocyst.[268,269] The final stage of apposition is a grasping of the blastocyst and ultimate attachment to the uterine wall, a process thought to be dependent on secondary rises in ovarian-derived E2.[268,269] Therefore, preparation of the uterus for blastocyst implantation is dependent on the multifunctional and sometimes opposing effects of E2 and P. In addition, PR-null models suggest that PRA is crucial not only for implantation but also the decidualization process as female mice lacking only PRA fail to exhibit a uterine decidual response, illustrating the importance of PRA for establishing successful pregnancy.[176,178,180] Recently, Franco et al. demonstrated that the epithelial PR is responsible for establishing successful pregnancy as the deletion of uterine epithelial PR contributes to an impaired embryo attachment, implantation, and decidual response.[179] Details of implantation and decidualization mechanisms are discussed in Chapter 38.

Maintenance of Progesterone Action in the Absence of ER

The *Pgr* gene is a well-described target of estrogen-induced expression via the classic model of ER action, especially in the uterus.[32,33] The lack of E2-induced increases in *Pgr* expression in ERα-null uteri confirms the regulatory dependence on ERα action.[189] Therefore, it was hypothesized that disruption of the ERα gene may subsequently result in abnormally low levels of PR in ERα-null uteri and thereby render this tissue refractory to P as well. However, assays for *Pgr* expression and P binding in ERα-null uteri indicate PR levels are only reduced by approximately half.[110,161,189] Furthermore, a greater proportion of PR is nuclear localized in ERα-null uteri (≈25%) relative to wild-type (≈5%).[161] Western blots indicate no difference in the relative levels of PRA and PRB between genotypes, with PRA consistently present in greater amounts in both.[161] Therefore, a loss of ERα action in the uterus has not led to a complete lack of PR or to altered and preferential transcription from one of the two *Pgr* gene promoters. Furthermore, several P-dependent actions are preserved in ERα-null uteri, including P-induced expression of amphiregulin and calcitonin and the uterine decidual response,[161] but not embryo attachment or implanation.[135]

The postovulatory nadir in circulating E2 levels has long been known to be critical to uterine decidualization in mice.[270] Studies have shown that the ER antagonist ICI 182,780 prevents artificially induced uterine decidualization in wild-type mice, indicating involvement of ER signaling.[161] Therefore, it is surprising that ERα-null mice exhibit a uterine response when exposed to an artificial model of hormonal and mechanical induction of uterine decidualization.[161,271] However, this may partly be due to the residual ERα protein produced by the splice variant found in the uterus of the αERKO line made by targeted disruption.[189] Nevertheless, these findings suggest that an altered "organization" of the uterine tissue or compensatory pathways might provide for hormonally driven uterine decidualization in ERα-null mice. Alternatively, some genes detected at the time of implantation, including the gap junction protein connexin 26[272] and the cytokine leukemia inhibitory factor,[135] are regulated by dual pathways. One involves estrogen-stimulated ERα, and the ability to induce via this mechanism is lost in the αERKO. The second pathway is initiated by decidualization-associated signals and is ERα independent and retained in the αERKO. This indicates a redundancy of regulatory mechanisms that allows retention of gene regulation in the αERKO and accounts for the ERα-independent uterine decidualization response observed in ERα-null mice. Recent studies demonstrated that de novo E2 synthesis occurs locally during decidualization, especially on day 6 and 7 of pregnancy in mice,[273] indicating an important role for local E2 synthesis for establishment of successful pregnancy.

Androgen Receptor Signaling in Uterine Function

AR Expression in the Uterus

AR is present in uterine tissues of multiple species,[130,274–278] although the function of androgen signaling in the uterus remains unclear. In rodents, ARs are present in all uterine cell types but most highly expressed in the myometrium, where expression may be positively regulated by estrogens.[276,279] In humans, ARs are also detected in the myometrial and endometrial uterine tissues, and levels increase during the proliferative phase.[280]

MICE LACKING AR

There are several reported lines of AR-null as well as mice with knock-in of mutated forms of AR (reviewed in Refs 281,282). *Tfm* mice were first described in 1970 and are a naturally existing androgen-resistant mutant[283] with an inactivating mutation of the *Ar* gene.[284,285] Comparable inactivation mutations of the *AR* gene and resulting phenotypes are well described in rats and humans.[286] Because the *Ar* gene is located on the X chromosome and *Tfm* males are infertile, it is impossible to breed for XX female mice that are homozygous for the

mutation. Lyon and Glenister overcame this challenge more than 30 years ago by utilizing embryo aggregation to generate a limited number of *Tfm* chimeric males that were fertile and carried germ cells harboring the *Ar* mutation.[287] More recently, AR-null female mice were generated via a *Cre/loxP* targeting scheme that allows for tissue and temporal specific disruption of the *Ar* gene and therefore the generation of fertile male carriers of the targeted *Ar* allele.[185,288–290] Exon 2 of the murine *Ar* gene was targeted for deletion in nearly all lines that have been described in the literature.[183,184,289,290] Additionally, one line of mice with in-frame deletion of exon 3 of the *Ar* gene has been generated, however, the uterine phenotype of this line was has not been described.[185] The exon 2 AR-null females have normal uterine development, although the uterine circumference is smaller than that of wild-type uteri (Table 25.3).[183,184] Hu et al. demonstrated that the AR-null uteri had increased uterine horn length, but smaller uterine diameter, as a result of decreased endometrial and myometrial areas during diestrus, when compared to wild-type uteri.[183,184] These AR-null females were subfertile, due to impaired folliculogenesis (discussed later in the section Ovarian Phenotypes in Mouse Models of Disrupted Androgen Signaling). Still, studies to date indicate that AR-null females exhibit reproductive phenotypes that are quite similar to those originally described in *Tfm/Tfm* females.

Recently, a mouse line was developed in which mutation of the AR DNA binding domain alters the ability of AR to bind to selective androgen response elements. This mouse line was generated by Schauwaers et al. with a targeted mutation of 12 amino acids in the second zinc-finger of the DNA binding domain at the exon 3 of AR (called SPARKI).[186] The heterozygous or homozygous SPARKI females do not have an overt phenotype and have normal fertility,[186] indicating selective AR DNA binding is not critical for female reproductive organ development and function.

Treatment of hypophysectomized rats with DHT is known to cause increased uterine weight in rodents, indicating that ligand-dependent AR actions can affect uterine responses.[291] Several studies also showed that DHT induced uterine weight increase in αERKO animals.[292,293] Upregulation of AR expression is observed in αERKO uteri after DHT treatment, suggesting that DHT exerts its action in the uterus through AR in the absence of ERα.[292] In addition, AR agonists increased myometrial thickness in the uteri of ovariectomized rats but inhibited estrogen-induced epithelial proliferation.[264] Similar observations were made in female mice, which exhibited not only uterine epithelial cell proliferation but also myometrial smooth muscle cell proliferation after DHT treatment.[294] AR-null female mice exhibit relatively normal uteri that are somewhat hypoplastic, although this phenotype may be more representative of decreased E2 synthesis in the ovaries rather than a role for AR in maintaining uterine weight (Table 25.3).[183] Furthermore, AR-null females are able to establish and maintain pregnancies to term.[183] Microarray studies have indicated that DHT leads to a pattern of uterine gene regulation that is remarkably similar to that elicited by estrogens but less robust,[292,293] with 86% of the DHT response consisting of a subset of estrogen responses. The fold response of the overlapping genes was in general more robust after estrogen treatment versus DHT. Thus, despite differences in biological outcomes, the global genomic patterns elicited by estrogens and nonaromatizable androgens largely overlap. Genes noted included those involved in metabolism, tissue growth and remodeling, transcription, protein synthesis and processing, and signal transduction.[293] Suppression of AR expression in human endometrial stromal cells (HESCs) using siRNA led to a decrease in decidual cell proliferation and differentiation.[295] These findings suggest that AR plays a minimal role for uterine growth and differentiation but is not essential for uterine development.

Glucocorticoid Receptor Signaling in Uterine Function

GR Expression in the Uterus

The uterus is not considered a classic target tissue of glucocorticoid action, although GRs are present throughout the cell types of the rodent uterus, including uterine natural killer cells (uNK cells).[40,296]

MICE LACKING GR

Homozygous GR-null animals generated via homologous recombination in embryonic stem cells die at birth due to respiratory failure.[297] Therefore, the generation of tissue-specific GR deletion in female reproductive tissues is crucial for studying the role of GR in reproductive functions.

Uterine Functions of GR

The limited experimental data available indicate that GR-mediated glucocorticoid actions are present in the uterus.[40] Treatment with the GR agonist, dexamethasone, did not increase the weight of immature rat uterus compared to E.[40,298] However, dexamethasone inhibits the uterine weight increase induced by estrogen in the rodent uteri.[40,298,299] Surprisingly, stimulation of the GR signaling pathway by dexamethasone treatment in immature rats elicits a pattern of gene expression that is remarkably similar to, but not as robust as, estrogen.[40] However, the molecular mechanism by which dexamethasone inhibits uterotropic action of estrogen remains unclear. A recent study reported that E-induced human uterine leiomyoma cell proliferation is suppressed by GR activation.[41] Gilz (glucocorticoid-induced

leucine zipper) is crucial for immune-related function of glucocorticoid activity.[300] Whirledge and Cidlowski also demonstrated that E suppressed *Gilz* gene expression induced by dexamethasone in human uterine epithelial (ECC1) cells.[300] This suggests that estrogen and glucocorticoid exert interplay between immune-responsive functions in the uterus.

GR activity not only exhibits inhibitory effects on estrogenic action in the uterus, but may also play important roles in the decidual response, as it is known that GR is expressed in uterine natural killer (uNK) cells,[296] and that the uNK cells play important roles for establishment and maintenance of successful pregnancy (reviewed in Ref. 301). However, the role of GR in uNK cell activity in the uterus remains unclear.

MicroRNAs in Uterine Reproductive Functions

MicroRNA (miRNA) are very small RNA molecules (18–24 nt) that are transcribed as larger primary RNAs (priRNA), either within introns of encoding transcripts or from miRNA encoding promoters. priRNA is processed to a shorter stem and loop pre-miRNA form by the activity of the DGCR8/DROSHA microprocessor complex. The pre-miRNA is then exported from the nucleus by exportin 5, to the cytoplasm where DICER cleaves the loop, leaving miRNA, which then functions to interact with mRNA, targeting it for degradation or repressing translation.[302,303] miRNA is particularly critical to female reproductive tract function, as mouse models with deletion of DICER in these tissues lose fertility. Estrogen has been demonstrated to regulate levels of miRNA in uterine tissue.[304,305]

The biological roles of Dicer are crucial for a normal development of limbs,[306] muscle,[307] and lung.[308] In addition, recent findings demonstrated that expression of Dicer is not only critical for female germ line biological functions[309] but also for embryo implantation.[310] Although miRNAs are expressed in the female reproductive tract, their precise physiological function remains unclear. To study the role of dicer and miRNAs during female reproduction, several studies used *Dicer1*$^{fl/fl}$ crossed with *Amhr2*$^{Cre/+}$ animals to generate a specific deletion of dicer in the mesenchymal layer of female reproductive tract (called *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$).[311–313] Female mice with a lack of Dicer1 expression in the mesenchyme exhibit a complete infertility.[311–313] Loss of Dicer1 has no effect on uterine development as the uterine epithelial cells, glands, stroma, and myometrium are present in *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females.[311,313] Uterine horns of *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females are shorter and hypoplastic when compared to control (*Dicer1*$^{fl/fl}$) uteri.[311,313] Additionally, the *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ uteri respond normally to an artificial decidual stimulation.[312] An ovarian defect was observed as increased apoptosis within the granulosa cells of *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ compared to wild-type ovaries.[312] Moreover, *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females exhibit an aberrant oviductal morphology with enlarged and fluid-filled cystic oviducts.[311–313] No embryos were found in *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ uteri, but were discovered to be retained within the oviduct.[312,313] The oviducts from *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females have an augmented inflammatory response seen as an increase in recruitment of lymphocytes and macrophages into the oviductal tissues.[313] Moreover, *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females are also defective in embryo transport as transferred blue beads were mostly retained in the *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ oviduct, whereas in WT females the beads moved through the oviduct and were found to be in the uterine lumen.[313] A lack of a proper embryo transport in *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ appears to be due to a uterotubal junction defect, resulting in retrograde uterine flow into the oviduct.[313] Additionally, the expression of Wnt/β-catenin signaling molecules was altered in the *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ oviduct.[311,313] A recent finding from a uterine-specific Dicer deletion using *Pgr*$^{Cre/+}$ and *Dicer*$^{fl/fl}$ animals demonstrated that the females are infertile.[314] Loss of uterine dicer leads to uterine developmental defects, including absence of glandular epithelium and increased apoptosis in the stromal cells.[314] Stromal cell proliferation could not be induced in *Dicer1*$^{fl/fl}$;*Pgr*$^{Cre/+}$ uteri treated with estrogen and P.[314] A decidualization defect was also found in *Dicer1*$^{fl/fl}$;*Pgr*$^{Cre/+}$, indicating loss of uterine response to P.[314] Additionally, loss of uterine dicer expression also leads to a dysregulation in Wnt/β-catenin signaling molecules, similar to the findings reported in *Dicer1*$^{fl/fl}$;*Amhr2*$^{Cre/+}$ females. These findings together suggest that miRNAs, produced by Dicer processing, play pivotal roles in female reproductive functions needed for establishing successful pregnancy.

Changes in Uterine Gene Expression

The dramatic physiological changes that occur in the uterus in response to steroid hormones are presumably the ultimate effects of equally dramatic changes in gene expression among the uterine cells. It is unlikely that the E2–ER complex is directly involved in mediating the whole genomic response in the uterus but more plausibly serves to stimulate a cascade of downstream signaling pathways that act to amplify the estrogen action. However, early investigations of the genomic response to estrogens in the rodent uterus discovered a handful of genes that are directly regulated via the classic ER mode of action, including *Pgr* and *Ltf*. The uteri of ERα-null females fail to exhibit estrogen-induced increases in *Pgr* and *Ltf* expression,[174] indicating the importance of ERα to this response. Furthermore, estrogen-stimulated increases in PR in the rodent uterus are localized to

the stromal and myometrial compartments, whereas increased *Ltf* is limited to luminal and glandular epithelium,[223] indicating that ERα functions are critical to induced gene expression in multiple uterine cell types. Further complexity of estrogen action in the uterus is illustrated by the simultaneous induction of PR expression in the myometrium and stroma while eliciting a decrease in PR levels in the luminal epithelium.[223] Similarly, the c-*fos* gene is rapidly induced by estrogen in the uterus, and this is ERα dependent.[159,242]

Microarray analysis of gene expression has significantly advanced understanding of genomic response of the rodent uterus to E2. Numerous studies have used microarray techniques to map the global gene expression patterns after estrogen exposure in the uterus and largely demonstrate that the biphasic uterine response to estrogens, so well characterized by physiological indicators discussed earlier (Table 25.4), is mirrored by the global changes in gene expression (Figure 25.13).[242,256,315–320] The clearly defined patterns of early and late response genes found in mouse uterine tissues are completely lacking in ERα-null uteri.[159,242] The identified genes fall into functional groupings, including signal transduction, gene transcription, metabolism, protein synthesis and processing, immune function, and cell cycle. Surprisingly, the expression levels of a striking number of genes are repressed by estrogen in the mouse uterus, and these effects were either absent in ERα-null uteri or relieved by co-treatment with ER antagonists, indicating that ERα is also actively involved in this process.[159,242] Comparative gene array analyses have also been conducted on human endometrial tissues during the proliferative and secretory phases of the menstrual cycle and have revealed gene expression patterns that are similar to those described in rodents.[321–325]

Microarray analyses have also been used to map the uterine response to P and have identified numerous target genes, including those involved in immune function, metabolism, growth factor regulation, signal transduction, and extra- and intracellular structure.[326–328] These observations have identified numerous signals and mechanisms important for normal uterine function and involved in uterine cancer (Table 25.5).[34]

Microarray approaches have been utilized to investigate the molecular responses to xenoestrogens, such as the industrial chemical bisphenol A (BPA) and the pesticide metabolite 2,2-bis(p-Hydroxyphenyl)-1,1,1-trichloroethane (HPTE). Microarray transcript profiles reveal that both xenoestrogens induce responses that are highly correlated to E2 response early (2 h), but less correlated later (24 h), similar to a pattern seen with a weak estrogen such as estriol.[336] Accordingly, BPA and HPTE, like estriol, are unable to induce uterine growth to the same degree as E2.[336]

White and black boxes highlight transcripts that typify early and late phases, respectively.

Whole transcriptome analyses are now routinely incorporated into studies of disruptions in signaling pathways underlying uterine phenotypes of mouse models such as those described in Table 25.3. Thus, microarray comparisons have now become just one of many tools employed for investigation of uterine functions. The data are routinely deposited in the publically accessible site GEO (Gene Expression Omnibus; http://www.ncbi.nlm.nih.gov/geo/). Table 25.5 lists examples of steroid-regulated uterine transcripts discovered in microarray studies.

Chip-seq

More recently, technologies to facilitate evaluation of sites of transcription factor interaction with chromatin (by enriching a DNA binding protein, such as ERα, that has been cross-linked in situ to chromatin, with immunoprecipitation [chromatin immunoprecipitation or ChIP], followed by hybridizing the associated DNA to a chip tiled with promoter region sequences [ChIP-Chip] or by "next generation" massively parallel sequencing [ChIP-seq]) have been developed and widely utilized to study sites of nuclear receptor interaction (Figure 25.14).[75,337–341] Initial studies focused on ERα binding in MCF7 breast cancer cells, and several similar studies followed, which are summarized and compared in several review articles,[97,342–345] and reported that most sites were distal from transcriptional start sites (TSS) or were in intronic regions, rather than adjacent to TSS, as models of NR regulation of target transcripts had hypothesized. These comprehensive maps of *cis*-acting transcriptional regulators have been dubbed "cistromes". The initial ERα cistrome–associated sequences were evaluated for enrichment of transcription factor motifs, and confirmed binding to the experimentally defined "ERE" sequence. In the case of the MCF7 cells, enrichment of motifs for forkhead binding factors (Fox) was apparent. Owing to the abundant expression of the FoxA1 member of the Fox family, a potential role for FoxA1 in estrogen response was pursued with an arsenal of bioinformatic, Next Gen sequencing, and biological studies that demonstrated the ability of FoxA1 to "pioneer", and thus make accessible, regions of the chromatin that were subsequently targeted by ERα.[76]

Most ERα cistromes reported have utilized in vitro cultured cell models, although ERα profiles from mouse liver tissue have been obtained.[346] A ChIP-seq study by Hewitt et al. examining ERα binding sites in mouse uterine tissue indicated that, much like the MCF7 breast cancer study, most ERα sites were not proximal to TSS.[243] Subsequent comprehensive ChIP-Chip or ChIP-seq studies have been published for the PR in mouse uterus,[347] and T47D breast cancer and leiomyoma cells[348] and for the AR in mouse epididymis[349] skeletal muscle myoblasts,[350] ZR-75-1 breast cancer cells[351] and LnCAP prostate cancer cells.[352] GR binding has been evaluated in mouse liver tissue,[353] mouse epithelial cells,[354] and A549 lung cancer cells.[355] We have learned that NRs bind to thousands of sites within the cellular chromatin, and that not all potential HREs in every cell demonstrate cognate NR binding. Rather, it is apparent that chromatin exhibits "pre-opened" regions destined to recruit NR.[356] For ER in MCF7, FoxA1 establishes ER and AR accessible regions; for other cells or other NRs this function might be mediated by other "pioneers", such as AP1 for GR.[354] The accessible chromatin regions are co-localized within nuclear "hubs" that seem to optimize frequency of interaction with NR.[356] ChIP-seq is also used to locate other molecules involved in chromatin remodeling and transcriptional regulation, and to examine activating or repressive histone modifications or "marks". These maps of relative locations and dynamics of NR and chromatin components greatly enhance our understanding of hormone response mechanisms.[339–342,345]

SEX STEROID RECEPTORS AND OVARIAN FUNCTION

The functions of the sex steroids and their cognate receptors in ovarian function are especially complex and multifaceted. P, T, and E2 are all synthesized and secreted by the ovary during folliculogenesis and act via both extraovarian (i.e., endocrine) and intraovarian (i.e., para-/autocrine) pathways to profoundly influence all aspects of ovarian function. The endocrine actions of the sex steroids in the hypothalamic–pituitary axis are critical to the regulation of gonadotropin secretion and the ovarian cycle and are described in more detail in other chapters of this book. In turn, our appreciation of the extent and importance of the para-/autocrine actions of sex steroids within the ovary has increased substantially over the past years. Herein, we specifically review the literature concerning the expression of the sex steroid receptors (Table 25.6) in the mammalian ovary and employ the described null and mutated mouse models that have been developed as a platform to focus on recent revelations concerning the intraovarian roles of steroid signaling in ovarian function. A caveat to experimental testing of steroid action and steroid receptor studies in a tissue such as the ovary is that the organ is also producing the steroid being studied. Androgen, estrogen, and progesterone are all synthesized by the ovary; therefore, removal and replacement studies to analyze response are impossible. Thus use of mutant or null mice allows evaluation of the phenotype reflecting loss of functional interactions between steroids and their receptors.

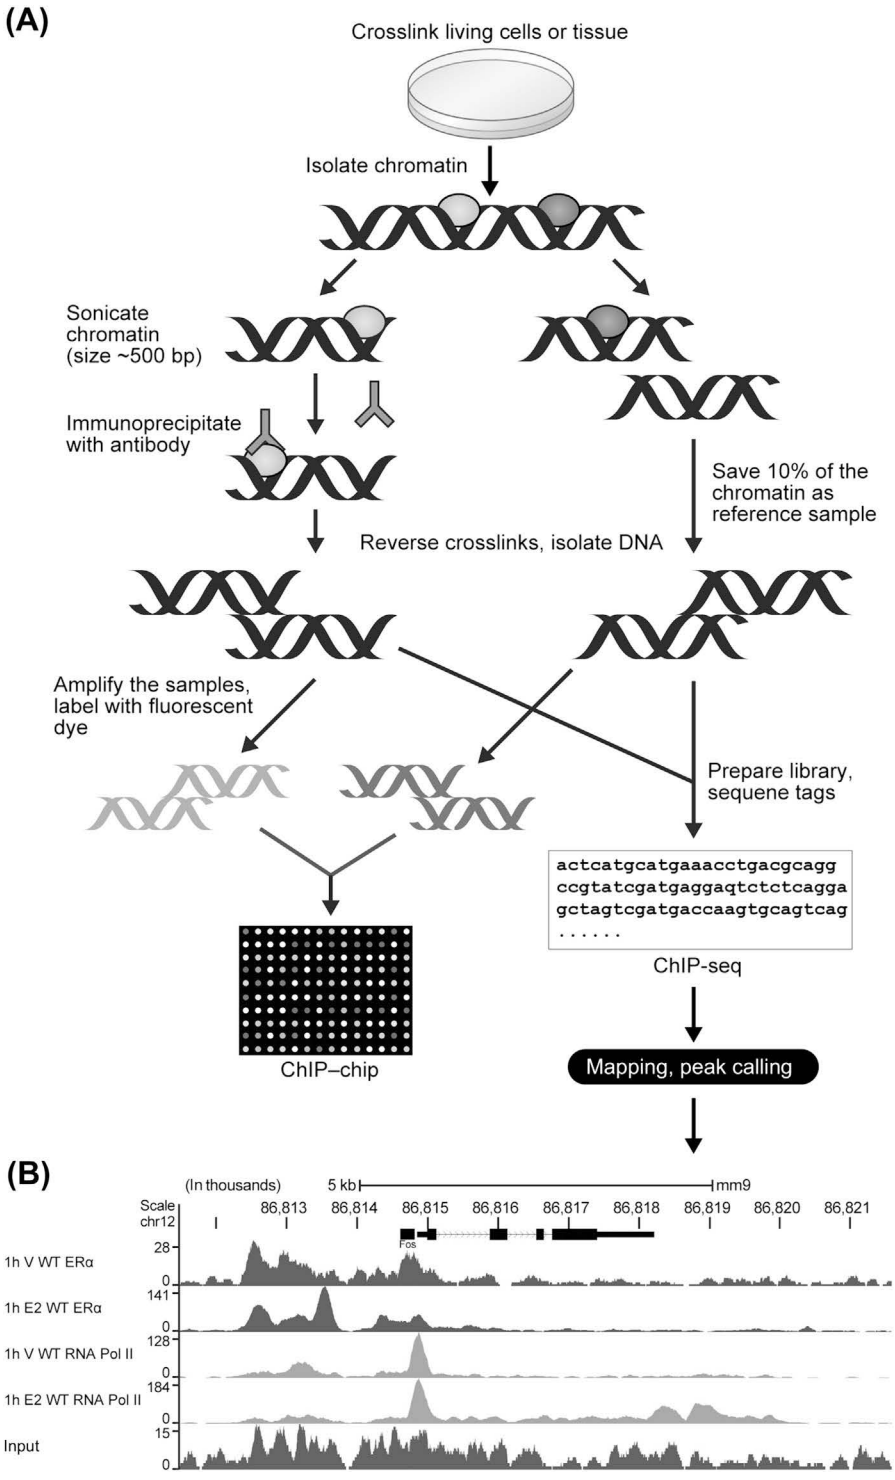

FIGURE 25.14 (A) Schematic *(Source: Modified with permission from Ref. 337)*, shows method to evaluate the "cistrome" of a steroid receptor or other chromatin interacting factors using ChIP–Chip or ChIP-seq. Cells or tissues are treated with a chemical, often formaldehyde, to cross-link DNA binding proteins to DNA. Then, chromatin (DNA and attached proteins) is isolated and fragmented with sonication or another method to break the chromatin into small pieces (approx. 500 bp). The protein of interest is immunoprecipitated with an antibody to enrich DNA fragments bound to the protein. Cross-linking is reversed to allow the enriched DNA to be purified. For ChIP–chip, DNA is amplified and labeled and hybridized to a chip spotted with promoter regions. For ChIP-seq, the DNA is sequenced using massively parallel (Deep) sequencing. The sequence "reads" are mapped onto known genomic regions, resulting in peaks indicating regions of binding of the immunoprecipitated DNA binding protein. Both methods are normalized in comparison to "input" chromatin that has not been immunoprecipitated. (B) A screenshot showing an example from ERα and RNA polymerase II cistromes in the vicinity of the Fos transcript from a mouse uterine dataset[243] is shown.

Estrogen Receptor Signaling in Ovarian Function

Estrogen Receptor Expression in the Ovary

There is a plethora of evidence for ER expression in somatic cell types of the mammalian ovary, and numerous reviews describe the importance of ERα and ERβ in ovarian function. As early as 1969, Stumpf demonstrated the specific uptake of [^{3}H]-E2 in rat ovaries using dry-mount autoradiography.[357] Richards later demonstrated that the predominance of high-affinity E2 binding sites in the rat ovary is found in the granulosa cell component and that these levels are regulated by estrogen and gonadotropins.[358,359] Successful cloning of the individual ER genes from multiple species and continued development of better ER-specific immunoglobulin allow for more detailed characterization of ERα and ERβ expression and regulation in the mammalian ovary. It should be pointed out that immunodetection and expression patterns of steroid receptors are dependent on the quality of the antibodies used. Such antibodies often vary between studies of ovarian tissue as described following and may explain both species and tissue differences.

ER expression patterns are well conserved among mammalian species, although distinct differences are apparent in late stage follicles. A high level of ERβ expression in granulosa cells of growing follicles is conserved among rodents, large animals, and primates. ERα expression is exclusive to thecal/interstitial cells in the stroma of the ovary in rats and mice (Table 25.6, mice) but this compartmental expression pattern does not hold true in hamsters, domestic animals, monkeys, or humans (Figure 25.15). In fact, current data indicate that granulosa cells of preovulatory follicles in large animals and primates express comparable levels of both ERα and ERβ, and, in humans, ERα may predominate.[360] Similarly, thecal cells in large animal and human ovaries possess both ER forms. These data force us to consider a greater potential role for ERα/ERβ heterodimers in the ovaries of large animals and primates that may not occur in rodents. The more restricted expression pattern of ERα and ERβ in rodent ovaries does not exclude possible cooperative action between the two receptors, as suggested by the unique ovarian phenotypes in compound ER-null mice compared to each single knockout ovarian phenotype (Table 25.7).[158,174] Although much has been learned concerning ER localization, it remains difficult to delineate which of the incongruent findings among species are truly representative of divergent expression patterns or are more attributable to disparities in techniques and immunoreagents. This is further confounded by evidence that levels of ER mRNA do not always correspond with the levels of immunoreactive protein within the ovarian compartments.[360] The following section reviews the literature concerning the expression patterns of ERα and ERβ in the ovaries of rodents, domestic animals, and primates, and the changes in expression patterns that occur during folliculogenesis. Altered expression has been implicated in diseases affecting ovarian function (including polycystic ovarian syndrome and ovarian cancer); however, this will not be addressed.

Estrogen Receptor α

RODENTS

ERα is localized to the ovarian interstitial/stroma, thecal cells of growing follicles, and surface epithelium in rat[129,130,274,366–372] and mouse[124,373] ovaries. This expression pattern is not evident in hamsters[374] where both receptors are detectable to varied degrees throughout the different somatic cell types of the ovary. In the fetal rat, ERα expression is detectable shortly after the first indications of gonadal differentiation.[375] Postnatal rat and mouse ovaries exhibit ERα mRNA shortly after birth, but levels remain relatively constant; whereas ERβ levels rise substantially during this period.[124,376] Immunoreactivity for ERα in neonatal rat ovaries indicates ERα expression is limited to thecal/interstitial cells and the ovarian surface epithelia and absent in granulosa cells and oocytes.[366,375] A similar pattern of ERα expression occurs in fetal hamster ovaries, which exhibit immunoreactivity as early as gestational day 14 and significant increases thereafter during the neonatal period.[377] Yang et al. report that a noticeable increase in ERα immunoreactivity occurs in the granulosa cells and oocytes of primordial follicles during neonatal days 8–15.[377]

In adult rats and mice, ERα expression continues to be exclusively localized to thecal cells of growing follicles, interstitial/stromal cells, and the ovarian surface epithelium[129,130,367,369,370,372,378,379] (Figure 25.15). Electrophoresis mobility shift assays (EMSA) of nuclear extracts from rat granulosa cells indicate that virtually all of the

TABLE 25.7 Ovarian Phenotypes in E Signaling Mutant and Null Mouse Models

Mutated or Null for Sex Steroid Signaling	Ovarian Phenotypes	Hormone Levels	References
Esr1$^{-/-}$ (homozygous null alleles for ERα animal)	Anovulatory and infertile Hemorrhagic and cystic pathology No CLs present in ovarian sections Increased expression of steroidogenic enzymes Reduced response or failure to respond to exogenous gonadotropins	Elevated T, E2 and LH Normal FSH & P	157–160
NERKI$^{+/-}$ (one mutated allele with 2-point mutation in DNA binding zinc finger of ERα and one WT allele)	Anovulatory and infertile No plugs observed in NERKI females after superovulation and natural mating Superovulation was able to partially restore ovulation in NERKI mice, however also increased hemorrhagic follicles in the ovaries	Normal LH, FSH and E2 Reduced P	132
KIKO (ER$^{AA/-}$) (one mutated allele of 2-point mutation in DNA binding domain of ERα and one ERαKO allele)	Anovulatory and infertile No CLs present in ovarian sections	Normal E2 and P	162
ENERKI (ERα^{G525L}) (homozygous animal of 1-point mutation in LBD of ERα)	Anovulatory Hemorrhagic and cystic ovarian pathology Increased number of atretic antral follicles and no CLs Hyperplastic theca cells in response to LH (data not shown)	Elevated serum E2, T and LH Normal FSH	168
ERα$^{EAAE/EAAE}$ (homozygous animal of 4-point mutation of DBD ERα)	Infertile Hemorrhagic ovaries	Not reported	164
AF2ER$^{KI/KI}$ (homozygous animal of 2-point mutation in LBD of ERα)	Anovulatory and infertile Hemorrhagic and cystic ovarian pathology No CLs present	Elevated serum LH and E2	169
Cyp17cre;ERα$^{flox/flox}$ (Theca cell specific ERα knockout)	Fertility normal in young mice, but 6 month old animals have reduced fertility and longer estrous cycle	Elevated T at both 2 & 6 months Normal FSH Decreased LH at 2 months with further decrease at 6 months	361,362
Esr2$^{-/-}$ (homozygous null alleles for ERβ: βERKO, Ex3βERKO, and **ERβ$_{ST}^{L-/L-}$)	Subfertile although some lines are infertile Reduced (or lack of) response to exogenous gonadotropins Approximately 1/5 the number of large preovulatory follicles after superovulation compared to WT mice Lack of COC expansion	Normal LH and FSH	158,171–173,363
ERαAF-1^0	Ovarian phenotype not reported	Unknown	165
ERαAF-2^0	Ovarian phenotype not reported	Unknown	167
αβERKO	Anovulatory and infertile No CLs and few large follicles Ovarian transdifferentiation to Sertoli-like cells that express Sox9 Altered expression of steroidogenic enzymes	Elevated LH and T Normal FSH and P	158,174
Cyp19a1$^{-/-}$	Anovulatory and infertile Hemorrhagic and cystic pathology No CLs present in ovarian sections Poor response to exogenous gonadotropins, although treatment with E2 in addition to gonadotropins improves ovulatory response Ovarian transdifferentiation to Sertoli-like cells that express *Sox9*	No E2 Elevated LH, FSH and T	131,156,175,194,364,365

***ERβ$_{ST}^{L-/L-}$ females are the only line of ERβ knockout animals that are sterile.*

specific ERE-bound complexes are supershifted by anti-ERβ but not anti-ERα immunoglobulin, providing further support that rat granulosa cells possess very little ERα.[367,371] Western blot analyses of whole cell or nuclear extracts from isolated rat granulosa cells do indicate a low level of ERα protein of 61 kDa,[371] and use of laser capture microdissection (LCM) shows some expression of ERα mRNA in granulosa cells (Figure 25.15).[363] Unlike ERβ, ERα expression remains relatively constant throughout the rat estrous cycle.[380] Furthermore, no change in ERα levels is detected in granulosa cells cultured in FSH/T over a period of 72 h; however, a 24-h treatment with forskolin induces a marked increase in ERα immunoreactivity in the nuclei.[371]

ERα localization in the adult hamster ovary is somewhat divergent from that in rats and mice. Yang et al. report moderate clear ERα immunoreactivity in thecal/interstitial cells, but also appreciable immunoreactive granulosa cells of small preantral follicles.[374] In the granulosa cells of antral follicles, ERα immunoreactivity is strongest among those in proximity to the forming antrum.[374] FSH treatment (twice a day for 2 consecutive days) or a single injection of E2 elicits a significant induction of ERα expression in both thecal and granulosa cells in hypophysectomized hamsters.[374] Still, Western blot analyses of whole ovarian homogenates from hamsters indicate an ERβ:ERα ratio of 14:1 during the follicular phase, indicating that ERβ predominates. However, the rapid decline in ERβ and concurrent increase in ERα that occurs just prior to and shortly after the gonadotropin surge adjusts this ratio to 2:1, suggesting that ERβ plays a more predominant role in follicular growth and ERα is more important during luteinization[374] in the hamster ovary.

DOMESTIC ANIMALS

In fetal bovine ovaries, ERα was shown to be localized in all cell types involved with follicle development, including granulosa cells, oocytes, and epithelial cells throughout development, with expression becoming

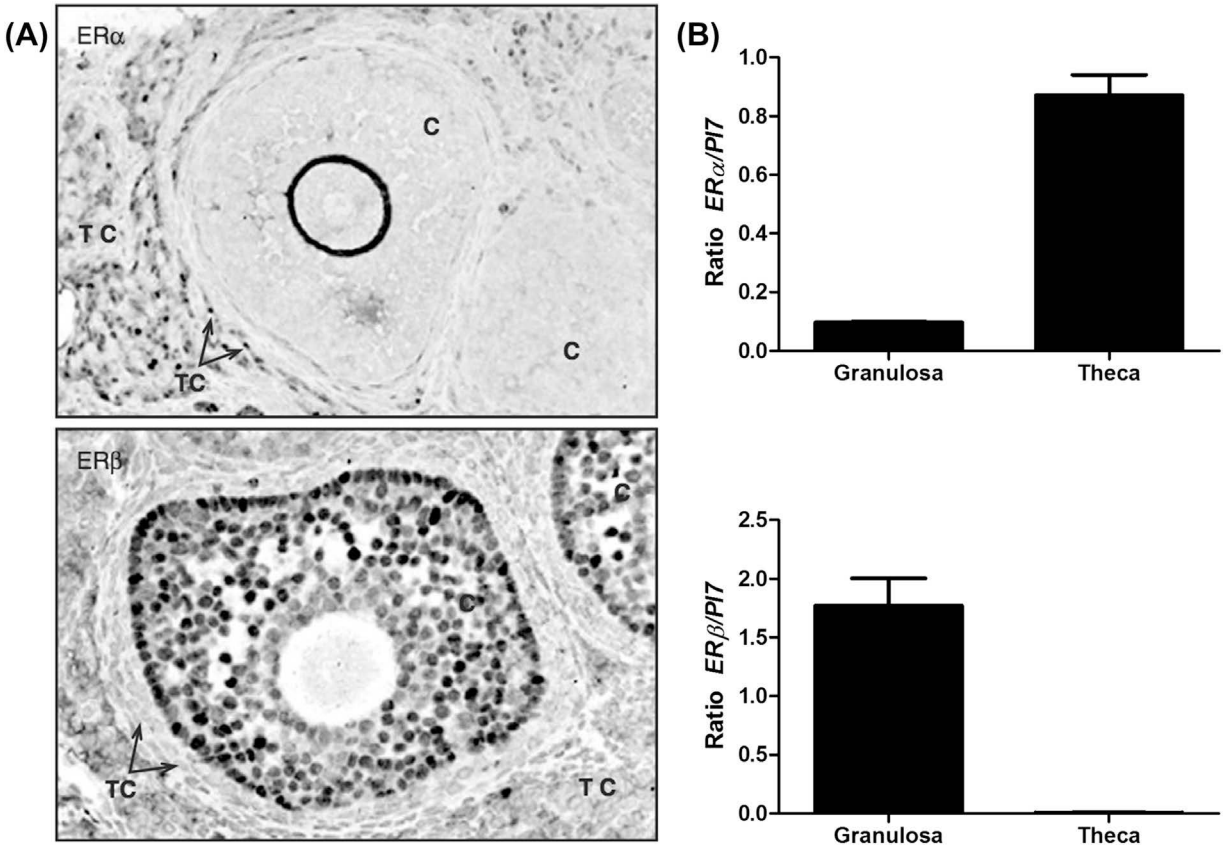

FIGURE 25.15 (A) Immunohistochemistry for ERα and ERβ in adult mouse ovary. Immunohistochemistry for ERα (*top*) indicates specific nuclear immunoreactivity in thecal/interstitial cells and thecal cells (TC) in and around a preantral follicle. Granulosa cells lack any measurable immunoreactivity for ERα. The staining around the outer surface of the oocyte is nonspecific and not representative of ERα immunoreactivity. Immunohistochemistry for ERβ (*bottom*) indicates specific nuclear immunoreactivity in the granulosa cells (GC) throughout a preantral follicle. Thecal cells (TC) lack any measurable immunoreactivity for ERβ, but the surrounding thecal/interstitial cells exhibit some cytoplasmic staining. Immunohistochemistry was done by Dr. Madhabananda Sar (see Ref. 366 for protocol). (B) Pure populations of granulosa and theca cells were isolated from large preovulatory follicles using laser capture microdissection (LCM), and RNA was reverse transcribed and real time PCR was performed using primers specific for ERα and ERβ.

more localized to thecal and some stromal cells during the later stages of development.[381] In adult bovine ovaries, ERα immunoreactivity is relatively high in thecal cells of secondary and tertiary follicles, substantially weaker in granulosa cells of tertiary follicles, and totally absent in primordial, primary, and secondary follicles.[382] In agreement, Barisha et al. found ERα transcripts are detectable in both granulosa and thecal cell fractions, but levels are substantially higher in the latter cell type.[383] Furthermore, thecal ERα expression appears to be differentially regulated as it is almost four-fold higher in follicles of 20–180 mm versus those <0.5 mm, whereas ERβ expression in thecal cells remains constant among follicles of different sizes.[383] ERα expression in granulosa cells, although much lower relative to theca, also increased with advanced follicle size.[383] In porcine ovaries, ERα immunoreactivity is detected in both theca interna and granulosa cells, but only in large follicles; and even then ERα immunoreactivity is considerably moderate relative to ERβ.[384] In ovine ovaries, ERα mRNA and immunoreactivity is detected in both cell types but predominates in granulosa cells and is particularly high in cumulus oophorus cells of small antral follicles.[385]

PRIMATES

The first reported study of ERα immunoreactivity rhesus or cynomolgus monkey ovaries found that ERα was undetectable in all ovarian cell types except the surface epithelia, regardless of menstrual stage.[386] However, a later study in baboon ovaries using the same antibody found nuclear ERα immunoreactivity in 30–40% of the granulosa cells of healthy antral follicles, and detectable but less intense staining in granulosa cells of preantral follicles.[387] This same study found the stroma, interstitial, and thecal cells to be largely unlabeled.[387] Pau et al. produced similar findings of ERα expression in the granulosa cells of rhesus monkey ovaries by in situ hybridization.[388]

High-affinity E2 binding sites in normal human ovarian tissue were first described several decades ago,[389–391] but these techniques were not able to differentiate between the two ER forms. Iwai et al. used anti-ERα antisera similar to that in the nonhuman primate studies to demonstrate immunoreactivity in the granulosa cells of antral and preovulatory follicles in human ovary but a total absence in primordial, preantral follicles, atretic follicles, and thecal/interstitial cells.[392] Pelletier and El-Alfy[393] used a different antihuman ERα antisera and reported results that are in contrast to those of Iwai et al.,[392] i.e., a total lack of ERα immunoreactivity in granulosa cells but clear nuclear staining of theca interna cells, interstitial gland cells, and ovarian surface epithelia. A possible explanation for this discrepancy may be a lack of large antral follicles in samples evaluated by Pelleteir and El-Alfy since both studies agree that ERα is not detectable in the granulosa cells of less mature follicles. In support of this explanation is a report by Taylor and Al-Azzawi in which ERα immunoreactivity is illustrated in the granulosa cells of what is clearly a large antral follicle when using antisera raised against the bovine ERα.[394] Indeed, Saunders et al. described ERα immunoreactivity that is limited to granulosa cells of large antral follicles and undetectable in smaller follicles in the human ovary.[395] Also, in agreement with Pelletier and El-Alfy,[393] Saunders et al. found ERα immunoreactivity in thecal cells of preantral and antral follicles, and ovarian surface epithelia.[395]

ERα transcripts are detectable in human nonluteinized granulosa cells[396] and granulosa-luteal cells collected at the time of oocyte retrieval during in vitro fertilization (IVF) procedures.[396,397] In fact, Jakimiuk et al. found ERα mRNA and protein levels are two- to four-fold higher in granulosa versus thecal cells of small antral follicles in human ovaries.[360] Furthermore, ERα protein levels remain elevated in granulosa cells but decrease in thecal cells of dominant follicles.[360] In luteinized human granulosa cells, Chiang et al. found ERα levels to remain relatively constant over a period of 10 days in culture but always much lower than ERα mRNA levels.[398] Recent reports in human ovarian samples collected during elective hysterectomy demonstrate that ERα is expressed in granulosa cells of antral follicles, with weak to no positive immunohistochemical staining in luteinized granulosa cells[399] supporting previous data.

Estrogen Receptor β

In the nonpregnant ovaries of most mammalian species, ERβ is clearly the predominant ER form and is most often exclusively localized to granulosa cells of follicles from the primary to preovulatory stage. This expression pattern is documented in the ovaries of rats,[14,130,366,367,370–372,380,400–402] mice,[124,373,379,402] hamsters,[374] cows,[383,403,404] sheep,[405,406] pigs,[402,407] nonhuman primates,[274,388] and humans.[393,394,402,408,409]

RODENTS

In developing rat ovaries, ERβ expression is detectable shortly after the first indications of gonadal differentiation on gestational day 14, and levels increase thereafter during prenatal development.[375] A second, more robust increase in ERβ expression occurs during days 10–15 of neonatal development in rat ovaries,[376] and immunoreactivity is largely localized to granulosa cells of growing follicles and notably absent in primordial follicles and oocytes.[366,375] Developing mouse ovaries exhibit a comparable pattern ERβ expression.[124] In contrast, ERα is limited to thecal and interstitial cells[366,375] and exhibits little change in levels with increased age[124,376] in developing rat and mouse ovaries. The hamster ovary exhibits a fairly similar ontogeny as ERβ is detectable as early

as gestational day 13 and increases thereafter to peak on postnatal day 10, throughout which ERβ immunoreactivity is predominantly localized to granulosa cells but detectable in some interstitial cells and oocytes.[377]

In the ovaries of prepubertal and adult rats and mice, ERβ immunoreactivity is nearly exclusive to the nuclei of granulosa cells of healthy follicles at all advanced stages of folliculogenesis[124,129,130,366–370,374,402] and is notably decreased or absent in atretic follicles[129,366] (Figure 25.15). Primordial follicles, thecal cells, oocytes, ovarian surface epithelium, and luteal cells lack ERβ immunoreactivity in adult rat and mouse ovaries,[129,130,366–369,374,402] although some cytoplasmic staining in the latter cell type is reported when using certain antisera.[129,366] Granulosa cell specific expression of ERβ in the rat ovary was reproduced using three separate anti-rat ERβ antisera, two raised against residues 467–485 and a third raised against residues 54–71.[369] Furthermore, independent studies using in situ hybridization produced results congruent with the immunohistochemical findings of strict localization of ERβ mRNA to granulosa cells of healthy growing follicles,[14,129,375,401] although Bao et al. reported scattered but specific hybridization for ERβ mRNA in thecal cells of healthy medium and large follicles in the rat ovary.[400]

A study by Saunders et al.[370] stands in contrast to those just discussed. In this study, strong nuclear immunoreactivity is described throughout the different somatic cell types of the rat ovary, including thecal, interstitial, and luteal cells, as well granulosa cells of maturing follicles when using an anti-rat ERβ antisera raised against residues 196–213. Yang et al. reported similar findings of ERβ immunoreactivity in thecal/interstitial cell preparations from hamster ovary using different ERβ-specific antisera.[374] Still, the results of Saunders et al. are problematic because they include reports of substantial ERβ immunoreactivity in certain reproductive tissues of the rat, such as the oviduct and uterus,[370] that are otherwise thought to possess relatively low or null levels of ERβ mRNA and immunoreactivity. Two obvious differences between the immunohistochemical study of Saunders et al.[370] and others are the aforementioned use of different antisera as well as different tissue fixative.

The previous discrepant findings notwithstanding, ERβ is clearly the predominant ER form present in granulosa cells of healthy growing follicle in the rodent ovaries. Recent isolation of pure granulosa and theca cells from mouse ovaries using laser capture microdissection demonstrates that ERβ mRNA expression is solely in granulosa cells (Figure 25.15). Any specific distribution of ERβ throughout the subpopulations of granulosa cells of growing follicles has been difficult to ascertain. In general, ERβ immunoreactivity is continuous and strong among the mural cells and relatively uniform among those layers closer to the antrum and oocyte.[366,367,369] However, not all granulosa cells of healthy growing follicles in the rodent ovary express ERβ, as negative cells are randomly distributed throughout the follicle.[366,367]

Data from Western blots of nuclear extracts from whole ovaries or isolated granulosa cells support the immunohistochemical data that ERβ is the predominant receptor form in rodent granulosa cells.[367,371] Electrophoresis mobility shift assays in which whole cell extracts from ovaries or isolated granulosa cells of rats provide further evidence of the predominance of ERβ.[367,371,410] Sharma et al. found that antisera raised against residues 54–71 of rat ERβ produces the optimum results on Western blot and detects four immunoreactive bands of 58/52 to 46/44 kDa in size, the 58 kDa protein presumably being full-length ERβ (ERβ1 in Figure 25.2).[371] Antisera raised against the AF-2 (residues 182–485) domain of rat ERβ detects a single specific protein of 60 kDa in whole-cell extracts from both rat and mouse ovaries that comigrates with the putative full-length ERβ.[367] Choi et al.[402] and Hiroi et al.[368] produced comparable findings of immunoreactive proteins at 60 and 55 kDa in rat and mouse ovarian extracts when using either a monoclonal antibody mapped to residues 272–285 of human ERβ or antisera raised against C-terminal residues 467–485 of rat ERβ, respectively. In the hamster, a single ERβ-immunoreactive protein of 54 kDa is detected.[374] To date, ERβ antibodies are not as specific as those manufactured for ERα, and produce bands in the ERβ-null tissues similar to those observed in WT tissues (unpublished data from Korach laboratory) such that further characterization of ERβ localization is challenging.

Several different ERβ isoforms are present in rodent ovaries, notably ERβ2 (Figure 25.2), ERβ-Δ3, and ERβ2-Δ3, the latter being a compound form of the two former variants. ERβ-Δ3 is an exon 3 deletion that results in a receptor lacking the C-terminal zinc-finger of the DNA binding domain and therefore unable to bind an ERE.[193] ERβ2 is an especially interesting variant because it possesses an insert of 18 amino acids in the N-terminal region of the LBD (Figure 25.2) that causes a 35-fold reduction in affinity for E2 and a 1000-fold decrease in E2-induced transactivational activity in vitro.[193] This isoform is not found in human ovary (Figure 25.2). Pettersson et al.[193] speculate that ERβ2 may be especially attuned to mediating E2 actions within healthy growing follicles where intrafollicular E2 levels greatly exceed that required to activate wild-type ER forms. Differential RT-PCR indicates a 1:1 ratio of ERβ1:ERβ2 mRNA in the ovary of adult[371,410,411] and neonatal rats,[323] while transcripts encoding ERβ1-Δ3 or ERβ2-Δ3 variants are detectable but at substantially lower levels.[410,411] Pettersen et al. demonstrated that FLAG-tagged clones of ERβ1 and ERβ2 expressed in 293T cells co-migrate at approximately 60 kDa,[411] suggesting that resolution of the two isoforms by Western blot may be difficult. However, several studies illustrate

two distinct ERβ-specific bands appear on Western blots from rat[367,368,371,410] and mouse[402] ovarian extracts. Furthermore, O'Brien et al. fractionated rat granulosa cell preparations in a 7.5% SDS-PAGE from which immunoreactive protein bands presumed to be ERβ1 (60 kDa) and ERβ2 (62 kDa) were resolved; they further remarked that an equal ratio of ERβ1:ERβ2 transcripts does not correlate to actual protein amount by Western blot, as much greater amounts of ERβ1 protein are present.[410] In retrospect, previous [^{3}H]-E2 binding data also supports a predominance of ERβ1 versus ERβ2 in rat granulosa cells. Because recombinant ERβ1 and ERβ2 differentially bind E2 with affinities of 0.14 and 5.1 nM, respectively,[411] one would expect differentiation of the two forms when assessed by Scatchard plot analysis. Therefore, the earlier studies using [^{3}H]-E2[412] and more recent studies using [^{125}I]-17α-iodovinyl-11β-methoxyE2[367] that report a single, saturable, high-affinity binding factor with a $K_d = 0.4$ nM in rat ovarian or granulosa cell extracts are congruent with ERβ1 as the predominant form present. Similar data of a single E2 binding component with a $K_d = 1$–1.4 nM in hamster ovaries is also reported.[413,414]

The majority of studies on the regulation of β expression during folliculogenesis focus on the rat ovary. While some report high but relatively constant levels of ERβ mRNA leading up to proestrus,[380] more detailed studies indicate a substantial increase in ERβ expression that peaks in medium sized (275–450 mm) follicles possessing clearly defined antrum.[400] Most studies agree on the precipitous decline in ERβ levels that occur shortly after the ovulatory gonadotropin surge and the low levels that remain during estrus in rats[380] and hamsters[374] (Figure 25.16). In retrospect, it is evident that the decreasing effect of the gonadotropin surge on ERβ levels was first indicated by Richards in 1975, in which a 75% decrease in high-affinity E2 binding sites in granulosa cells of hypophysectomized, FSH/E2-primed rats was found to occur following a single LH treatment.[358] This effect of LH on ERβ expression has been reproduced in vivo in gonadotropin-primed rats[367,380] and mice[415] in which a single hCG injection led to a rapid decrease in ERβ mRNA and protein levels of more than 50% within 6–9 h (Figure 25.16). Similarly, granulosa cells isolated from pregnant mares serum gonadotropin (PMSG)-stimulated rats and exposed to hCG in vitro exhibit a comparable loss of ERβ protein when assessed by western blot[367] or EMSA.[371]

Therefore, induction of the LH-signaling pathway in differentiated granulosa cells is the primary stimulus for rapidly decreased ERβ expression. Evidence of a direct role of LH comes from findings that only preovulatory follicles that co-express LH receptor exhibit a decline in ERβ expression; while smaller, LH-receptor negative follicles maintain ERβ expression as late as 24 h post-hCG exposure.[367,380] The inhibitory effect of LH on ERβ

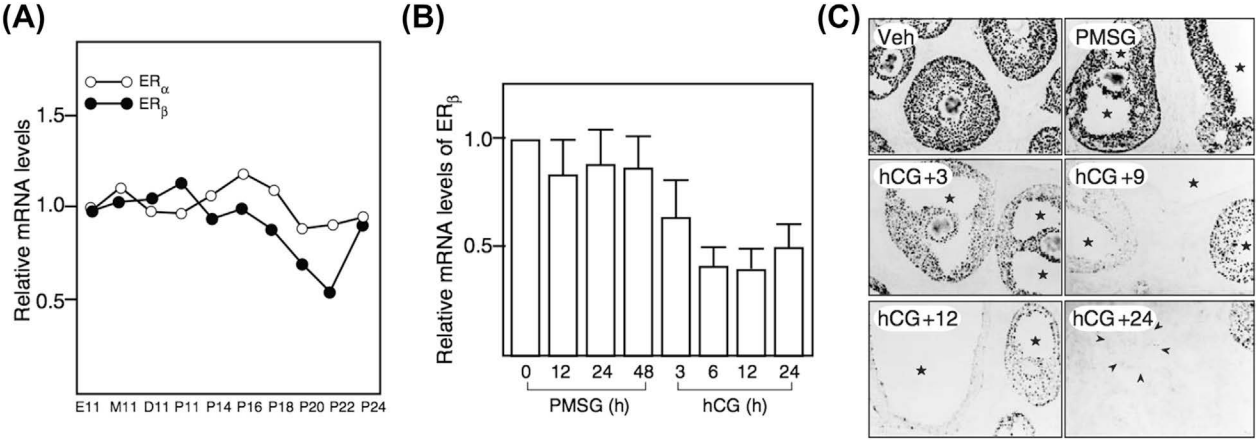

FIGURE 25.16 Regulation of ERβ expression in adult rat ovaries during the estrous cycle or after exogenous gonadotropin treatments. (A) Quantification of gene expression from Northern blot analysis (not shown) for ERα and ERβ in adult rat ovaries during the estrous cycle. Band intensities were measured on a phosphorimager and normalized to an S16 internal control for each time point. mRNA levels are shown relative to the level at E1100 (set to 1.0). Sera from animals were used to determine LH concentrations; the onset of the LH surge was observed at 1600 h of proestrous, and the peak was observed at 1800 h of proestrous. Annotation at bottom indicates the estrous cycle stage and hour of tissue collection: E, estrous; M, metestrous; D, diestrous; P, proestrous. *(Source: Reproduced with permission from Ref. 380.)* (B) Reverse transcriptase polymerase chain reaction was used to quantify ERβ mRNA levels in the ovaries of immature rats after treatment with PMSG alone or PMSG for 48 h followed by hCG. The ratio of ERβ/S16 of control rats with no hormonal treatment was set to 1.0. Shown are the mean ± SE ($n = 4$). *(Source: Reproduced with permission from Ref. 380)* (C) ERβ immunoreactivity in rat ovaries treated with vehicle (Veh), PMSG for 48 h, or PMSG for 48 h followed by hCG. ERβ immunoreactivity is detected in granulosa cells of small and large antral follicles in Veh PMSG animals. Stars indicate the location of antra in antral follicles. PMSG-treated rats were injected with an ovulatory dose of hCG and ovaries isolated after 3, 9, 12, or 24 h. The expression of ERβ protein in granulosa cells 9 h after hCG is reduced in large antral follicles (*left*), greatly reduced in preovulatory follicles (*center*), but does not change in small antral follicles (*right*). Similar expression is observed 12 h after hCG administration. One day (24 h) after hCG treatment, ERβ expression is not detected in corpora lutea (*small arrowheads*) but is highly expressed in preantral (*right*) and small antral follicles. Magnification 250×. *Source: Reproduced with permission from Ref. 367.*

expression can be reproduced by exposing differentiated granulosa cells to either forskolin or TPA,[380,410] activators of the protein kinase-A and protein kinase-C pathways, respectively, and thought to mimic the effects of LH stimulation.[416] Furthermore, forskolin or TPA treatment reproduce the same temporal pattern of decreased ERβ expression that follows LH or hCG exposure,[417] suggesting a common mechanism. Guo et al. demonstrated both activators and mimics of the LH-signaling pathway elicit the rapid decline in granulosa cell ERβ levels by decreasing the stability of ERβ transcripts rather than via a repression of gene expression.[417]

In contrast to the peri-ovulatory decrease in ERβ expression that occurs, there is little known about the positive regulation of ERβ expression in rat granulosa cells. Induction of folliculogenesis by PMSG or FSH in hypophysectomized rats leads to a significant rise in E2 binding among granulosa cells, presumably representative of ERβ,[358,418] but this is likely due more to an increased number of granulosa cell population rather than direct gonadotropin-stimulated ERβ expression. The presence of ERβ in the granulosa cells of primary follicles, considered to be insensitive to direct gonadotropin stimulation, supports a minor role for FSH in ERβ expression.[366,375] Furthermore, ERβ levels exhibit little change in immature rat or mouse ovaries 48 h after a single injection with PMSG,[367,380,415] and no reports exist of altered ERβ expression in the ovaries of mice null for FSH signaling.[419–421] Sharma et al. found that ERβ protein levels in gonadotropin-primed rat granulosa cells evaluated are highest if assessed after isolation and decrease steadily to undetectable levels within 72 h in culture, even in the presence of FSH and T.[371] However, this pattern was not totally reproduced at the level of ERβ mRNA, which drops by only 55% when cultured for the first 24 h in the absence of hormones but stabilizes upon the addition of FSH and T,[371] suggesting that FSH may be more important to the maintenance rather than stimulation of granulosa cell ERβ expression. In contrast to the previous findings, preovulatory rat granulosa cells allowed to lose ERβ expression following long-term (6 day) culture exhibit a significant rise in levels 48 h after exposure to forskolin, a direct PKA activator and thought to mimic FSH signaling.[371] Interestingly, FSH may have a greater positive influence on ERβ expression in the hamster ovary where a substantial increase in expression in preantral and antral follicles is observed in hypophysectomized females following 1–2 days of treatment with ovine FSH;[374] and ovaries of neonatal hamsters in which prenatal FSH action is inhibited exhibit significant decreases in ERβ expression.[377]

The existing evidence of E2 regulation of ERβ expression is conflicting. Treatment of hypophysectomized rats with E2 for 3–4 days results in steady and dramatic increases in E2 binding sites in granulosa cells,[358,422] but once again this is more likely due to an increased granulosa cell population. However, Tonetta et al. demonstrated that FSH-induced increases in E2 binding sites in granulosa cells of hypophysectomized rats are blocked by co-administration of an ER antagonist, suggesting an autoregulatory element for ER expression.[418] In contrast, Kim and Greenwald found little change in the number of E2 binding sites in hamster ovaries following E2 or DES treatment, although animals were exposed for only 1–2 days, and therefore significant gains in granulosa cell number may not have been achieved.[413] Drummond et al. reported that 1–4 days of treatment with DES has no discernible effect on the levels of ERβ1 or ERβ2 transcripts in immature rat ovaries.[376] Yang et al. found that hypophysectomized hamsters exhibit an almost six-fold increase in ERβ expression as detected by immunohistochemistry 24 h after a single injection of 0.1 mg E2-valerate.[374] Furthermore, rat granulosa cells isolated from E2-primed versus untreated animals exhibit a four- to six-fold higher basal estrogenic activity on an ERE-luciferase reporter construct, suggesting that individual cellular levels of ERβ are increased by E2 treatment.[371] Also, isolated rat granulosa cells exhibit an increased nuclear intensity for ERβ immunoreactivity 1.5 h after E2 exposure that is maintained for 24 h but totally lost by 48 h.[371] Still, the failure of granulosa cells to totally sustain ERβ expression when maintained in FSH and T, and therefore capable of synthesizing endogenous E2, is puzzling. It is plausible that E2 regulation of ERβ expression in granulosa cells may require the actions of ERα in thecal cells, which cannot be mimicked when granulosa cells are isolated in culture. Preservation of ERβ expression in preantral follicles of ERα-null ovaries argues against this hypothesis.[127,373] Recent work in KGN cells suggest that GIOT-4, a cofactor regulated by FSH, may act to increase ERβ expression as well as work in combination with ERβ to regulate target genes in follicles.[423] Although this work was done primarily in KGN ovarian cells, it was also reported that GIOT-4 and ERβ are co-localized in growing follicles providing support for the co-regulation. The expression of GIOT-4 has not been examined in in vitro–cultured granulosa cells. Therefore, although the signaling factors that may be most important to inducing ERβ expression remain unknown, it is clear that the level of ERβ is highly dependent upon the state of granulosa cell differentiation as cells from primary, growing, and preovulatory follicles exhibit divergent expression patterns and mechanisms of regulation.

DOMESTIC ANIMALS

Descriptions of ERβ expression in the ovaries of domestic animals are limited but generally indicate patterns that are congruent with rodent ovaries. In the fetal bovine ovary, ERβ is localized in the cell types associated with follicle growth, predominantly in pregranulosa

and granulosa cells. In early development, epithelial cells show expression; however, this becomes punctate as follicles begin to develop.[381] In adult bovine ovaries, Rosenfeld et al. found that ERβ mRNA and immunoreactivity is restricted to granulosa cells of small and large antral follicles with no detectable levels in thecal cells.[403] A follow-up study further demonstrated substantial ERβ immunoreactivity in cumulus oophorus and antral granulosa cells relative to mural granulosa, as well as mentioned significant ERβ expression in oocytes,[404] the latter finding being common only to hamsters.[374,377] In contrast to the immunohistochemical data, Walther et al.[424] and Berisha et al.[383] found ERβ transcripts are detectable in both granulosa and thecal cells. In ovine ovaries, ERβ is highly expressed in granulosa cells of growing follicles,[405,406] and levels exhibit little change over the course of the estrous cycle.[406] However, Jansen et al. report via in situ hybridization that ERβ mRNA is greatest in follicles ≤3 mm and declines in larger follicles during the early follicular phase.[405] Both reports describe low but detectable ERβ expression in thecal cells of growing follicles in the sheep ovary[405,406] as well as in ovarian surface epithelia.[406] In porcine ovaries, ERβ is almost equally expressed among the granulosa and theca interna of medium and large follicles, as well appreciable detection in the oocyte and ovarian surface epithelia.[384] Like the rodent, atretic follicles in porcine ovaries exhibit reduced ERβ expression.[384] LaVoie et al. found that ERβ mRNA levels in whole ovarian lysates exhibit little change during the porcine estrous cycle and are relatively equal when comparing follicles of 1–5 mm in size.[407]

An interesting commonality among bovine, ovine, and porcine ovaries is the presence of a truncated ERβ isoform lacking most of the ligand binding domain, termed ERβΔLBD in the cow[424] and ERβ-Δ5 in sheep and pig[406,407] (Figure 25.2). In all three species, ERβ-Δ5 is a deletion of exon 5 and encodes a receptor isoform that is truncated 15 residues into the LBD and terminates with four to nine heterologous residues depending on the species.[406,407,424] LaVoie et al.[407] and Choi et al.[402] produced Western blot evidence that ERβ-Δ5 may indeed be translated as a 35 kDa protein in porcine ovaries. Given that ERβ-Δ5 lacks the LBD, it predictably exhibits little estrogen-induced transactivational activity when overexpressed in vitro but does possess measurable ligand-independent transactivational activity that is three-fold lower than full-length ERβ, suggesting preservation of AF-1 functions.[407] ERβ-Δ5 is also able to reduce the in vitro activity of full-length ERβ by approximately 40% when present in excess.[407,424] Thus ERβ-Δ5 might modulate ERβ activity in an environment of high hormone concentrations, such as is found with estrogens in granulosa cells.

PRIMATES

In ovaries of known fertile cynomolgus monkeys, Pelletier et al. localized ERβ expression via in situ hybridization to granulosa cells of follicles at all different stages of development, as well as substantial labeling in theca interna and ovarian surface epithelia.[154] Similar findings are described by Pau et al.[388] in granulosa cells of large follicles in rhesus monkey ovary. In the baboon ovary, Pepe et al. found ERβ immunoreactivity is abundant in granulosa cells of follicles at all stages, including large antral follicles but notably lacking in thecal cells.[425] Western blots of baboon ovarian homogenates indicate two specific ERβ protein bands at 55 and 63 kDa.[425] An extensive immunohistochemical study in marmoset ovaries using antisera raised against human ERβ found extensive immunoreactivity in granulosa cells of primary through to mid- and late follicular stage follicles, including those with a large antrum, but a clear lack of staining in atretic follicles.[395] No specific pattern of ERβ immunoreactivity was apparent among subpopulations of granulosa cells within any one follicle.[395] In contrast to baboon ovaries but in agreement with cynomolgus monkey ovaries, thecal cells of large growing follicles as well as the ovarian surface epithelia in marmoset ovaries possess appreciable levels of ERβ immunoreactivity.[395]

High-affinity E2 binding sites in normal human ovarian tissue were described several decades ago.[389–391] Al-Timimi et al. found 45 of 89 normal ovaries from premenopausal women to possess detectable E2 binding sites; whereas all of the ($n = 10$) postmenopausal ovaries assayed were devoid of detectable binding.[390] Vierikko et al. reported high-affinity E2 binding in a similar percentage of premenopausal ovaries but did find 67% of postmenopausal samples were also positive, although the levels of E2 binding in both are notably lower than that for P.[391] The advent of better reagents has allowed for differentiation of the two ER forms within human ovaries. ERβ expression was first detected in human ovary by Northern blot analysis.[15,408,426,427] Follow-up studies using RNase-protection assays or RT-PCR indicate a relatively equal ratio of ERα:ERβ transcripts in mixed-cell homogenates from ovaries of pre-and postmenopausal women but exclusively ERβ transcripts in luteinized granulosa cells isolated from women undergoing IVF.[408,427] Hillier et al. report equal levels of ERα and ERβ mRNA in both nonluteinized and luteinized granulosa cells from normal human ovaries, although levels of both ER forms are reduced in the latter.[396] Another study comparing ERβ mRNA and protein levels within isolated thecal and granulosa cells of small antral follicles found mRNA levels are two-fold higher in thecal cells but protein levels are similar in both cell types.[360]

Three reports describing immunohistochemical localization of ERβ in human ovaries produced comparable findings of specific immunoreactivity among granulosa cells of follicles from primary to late antral stage, and specific, but considerably lower, levels in thecal cells of preantral and antral follicles.[393–395] Furthermore, all three demonstrate substantial ERβ immunoreactivity in human ovarian surface epithelia.[393–395] Hillier et al. also found

ERβ transcripts are detectable in primary cultures of human ovarian surface epithelial cells;[396] however, similar evaluations in cell lines derived from human ovarian surface epithelium indicate no detectable ERβ mRNA.[427]

There is currently little known about ERβ regulation in human ovaries. Jakimiuk et al. found ERβ expression is significantly decreased in thecal and granulosa cells of dominant follicles relative to those at earlier stages, yet ERβ protein levels did not mirror this difference.[360] In primary cultures of human granulosa–luteal cells, ERβ is more highly expressed relative to ERα and levels of the former increase 1.6-fold over a 10-day period during which spontaneous luteinization is believed to occur, while ERα levels remain constant throughout.[398] Treatment of human granulosa-luteal cells maintained in culture for 7 days with hCG reduces ERβ and ERα expression by almost 50% within 24 h, and this effect is mimicked by activators of protein kinase A (forskolin) or protein kinase C (TPA).[398] Recent examination of human ovaries found that ERβ1 and ERβ2 are expressed in granulosa-luteal cells as well as endothelial cells at all stages of the luteal phase. This study also used in vitro luteinized granulosa cells, treated with hCG or E2. Treatment of the luteinized granulosa cells with hCG reduced expression of ERα, ERβ1, and ERβ2 by approximately 50%, while treatment with E2 reduced expression of ERα and ERβ1 with no significant change in ERβ2,[399] suggesting that human granulosa cells may respond to LH by reducing ERβ in a manner similar to that found in rodent ovaries.

Studies to date indicate that human tissues express a unique C-terminal variant of ERβ termed $ERβ_{cx}$[426] or human ERβ2[409,428] (Figure 25.2). $ERβ_{cx}$ is a 495–amino acid–long receptor form in which the 61 C-terminal residues are replaced by a heterologous string of 26 amino acids encoded by an alternative downstream exon.[426,428] Transcripts encoding $ERβ_{cx}$ are detectable in multiple human tissues but most especially in ovary, testis, thymus, and spleen and are often at levels equal to or greater than wild-type ERβ.[426,428] Immunohistochemistry employing $ERβ_{cx}$-specific antisera indicate the variant is nuclear localized in granulosa cells of early follicles.[409] The physiological function of $ERβ_{cx}$ remains unclear. It is unable to bind E2, but in vitro studies indicate the isoform may preferentially heterodimerize with ERα and act as a dominant negative modulator of ERα action. Rodents also possess an ERβ variant (ERβ2) that poorly binds E2, but this receptor form does not inhibit wild-type ERα or ERβ activity.[193] Furthermore, categorical studies have shown that the rodent ERβ2 variant is not detected in human tissues.[409,429]

Ovarian Phenotypes in Mouse Models of Disrupted Estrogen Signaling

MICE LACKING ERα

Several lines of ERα-null mice have been characterized as listed in Table 25.7. Neonatal and prepubertal ERα-null mice exhibit relatively normal ovaries except for signs of premature folliculogenesis as indicated by the sporadic presence of large antral follicles.[158,373] Adult ERα-null females are anovulatory and hence infertile, and exhibit ovaries that possess normal pre- and small antral-stage follicles, multiple hemorrhagic cysts, absence of corpora lutea, reduced number of interstitial glandular cells,

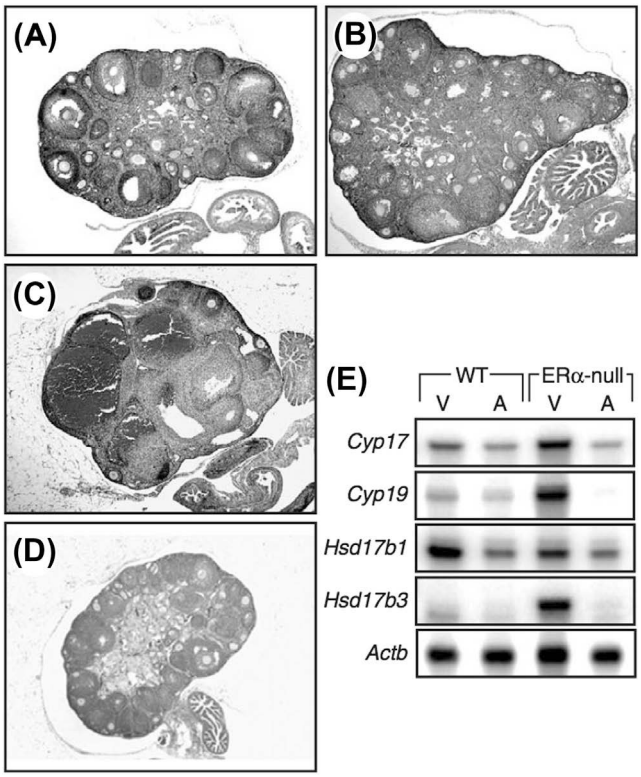

FIGURE 25.17 Ovarian phenotypes in ER-null mice. (A–C) Shown are cross-sections from representative adult ovaries of wild-type (A), ERβ-null (B), and ERα-null (C) female mice. Wild-type and ERβ-null ovaries each exhibit all stages of folliculogenesis except corpora lutea, although large antral follicles are sparse in the ERβ-null ovary. In contrast, ERα-null ovaries are characterized by several large, hemorrhagic, and cystic follicles; a sparse number of follicles at the early stages of proliferation; and a lack of corpora lutea. (D) Cross-section of a representative ERα-null ovary after prolonged treatment with a GnRH antagonist. Circulating LH levels were reduced in ERβ-null females by treatment with a GnRH antagonist (60 μg Antide) every 48 h from the age of 28–53 days. Ovaries were collected within 24 h of the final treatment. The characteristic ovarian phenotypes of ERα-null mice (shown in C) are prevented by reducing circulating LH levels, indicating these more dramatic phenotypes are secondary to the loss of ERα actions in the hypothalamic pituitary axis that are necessary to maintain proper LH levels and not due to the loss of ERα within the ovary. *(Source: Reproduced from Ref. 415.)* (E) Ribonuclease protection assays for the steroidogenic enzymes in adult wild-type (WT) and ERα-null ovaries treated either with vehicle (V) or a GnRH antagonist (A) every 48 h for 12 days (as described above). ERα-null ovaries exhibit increased expression of *Cyp17* and *Cyp19*, both of which are reduced to normal after reduction of gonadotropin levels. ERα-null ovaries also uniquely express *Hsd17b3*, a Leydig cell–specific enzyme, and this expression is dependent on gonadotropin stimulation as it is ablated after the reduction of circulating LH levels with GnRH-antagonist treatments. All samples are normalized to β-actin (*Actb*) mRNA levels. *Source: Reproduced with permission from Ref. 431.*

and mast cell infiltration in the interstitium[134,158,373,430] (Figure 25.17) (Table 25.7). The cystic and hemorrhagic follicles likely originate from antral follicles that fail to ovulate due to acyclicity (i.e., lack of an LH surge) and therefore become atretic and accumulate within the ovary. They are characterized by a mural granulosa cell layer of one to several cells thick surrounding an enormous fluid-filled antrum containing blood and immune cells; a degenerating ovum if visible at all; elevated FSH-receptor and LH-receptor expression in the granulosa cell layer, and a hypertrophied theca (Figure 25.17) that also exhibits elevated LH-receptor levels.[373,415] Therefore, ERα is not required for the recruitment and early growth of follicles or the induction of gonadotropin receptors in thecal and granulosa cells, but is vital to the later stages of folliculogenesis in the mouse ovary.[158,373]

ERα-null (αERKO) females exhibit a severely disrupted reproductive hormonal milieu, which in toto represents the cause and effect of the overt ovarian phenotypes[415,431] (Table 25.7). Plasma LH level in αERKO females is elevated three to eight-fold relative to their wild-type littermates, while FSH levels remain normal.[431] This is interesting in light of the fact that ovariectomy of normal WT mice leads to elevation of circulating FSH and suggests that the αERKO differs from ovariectomized WT females. Therefore the ovarian phenotypes of thecal hypertrophy,[373] elevated steroidogenic enzyme expression, and increased sex steroid synthesis in αERKO females are congruent with hypergonadotropic-hypergonadism.[431] A synopsis of evidence that supports acyclicity and chronically elevated LH as a primary cause of the other ovarian phenotypes in ERα-null females includes: (1) the cystic and hemorrhagic follicles appear after the onset of puberty (approximately 40 days of age),[373] (2) the cystic follicles and elevated steroidogenesis (Figure 25.17) are prevented when plasma LH levels are reduced to normal via treatments with a GnRH antagonist,[415,432] (3) transgenic mice possessing elevated LH but functional ERα exhibit a comparable ovarian phenotype[433–435] that is rescued by periodic ovulatory doses of exogenous hCG to induce luteinization,[436,437] and (4) immature αERKO females successfully ovulate, albeit with a reduced number of oocytes compared to wild-type mice, and form some corpora lutea when treated with exogenous gonadotropins prior to the onset of the cystic phenotype.[415,430,432] Others propose that aberrantly high intraovarian histamine levels due to infiltration of mast cells in the interstitium may also contribute to cyst formation in ERα-null ovaries.[158] Therefore, the previous findings indicate that a primary role of ERα in murine ovarian function may be extraovarian, i.e., as an essential mediator of the endocrine actions of E2 in the hypothalamic–pituitary axis that are critical to gonadotropin regulation. Indeed, prolonged treatment of female rodents with antiestrogens that cross the blood–brain barrier (e.g., ZM-189,154, EM-800) and produce an αERKO-like gonadotropin profile lead to a similar ovarian phenotype; whereas treatments with tamoxifen, a receptor antagonist that does not alter gonadotropin secretion generates no such effects in the ovary.[217–219]

A prominent phenotype in αERKO ovaries that may be indicative of an intraovarian role for ERα is their elevated capacity to synthesize androgens.[431] Relative to their wild-type littermates, αERKO females possess plasma levels of androstenedione and T that are increased 3 and 40-fold, respectively.[431] Indeed, LH is the primary stimulus of thecal cell androgen synthesis and plasma LH and thecal cell LH-receptor levels are both significantly increased in αERKO females (as discussed previously). Therefore, it is not totally unexpected that αERKO ovaries exhibit increased expression of the enzymes necessary for androgen synthesis, most notably a remarkable increase of *Cyp17* expression,[431] the enzyme necessary for the final step of androstenedione synthesis (Figure 25.17). However, the elevated plasma androgens found in αERKO females is likely not due solely to LH-mediated hyperstimulation of the theca. E2 from granulosa cells is proposed to mediate an intraovarian short feedback loop upon thecal cells to negatively modulate androgen synthesis during the later stages of folliculogenesis by primarily targeting CYP17 activity.[438] Given that ERα is the dominant ER form expressed in rodent thecal cells, the elevated *Cyp17* expression found in αERKO ovaries suggests ERα mediates this effect of E2 on androgen synthesis. Additional support for a specific ERα-mediated effect on thecal cell steroidogenesis comes from our findings that chronically elevated LH in wild-type and ERβ-null females leads to a much more moderate increase in *Cyp17* expression and androgen synthesis relative to αERKO females.[439] Furthermore, individually cultured ERα-null follicles in vitro secrete substantially more androgens relative to similarly propagated wild-type follicles even though the level of gonadotropin stimulation is held constant.[440] Therefore, it may be concluded that ERα is paramount to maintaining proper androgen synthesis in rodent females via: (1) endocrine actions in the hypothalamic–pituitary axis that negatively modulate LH secretion, and (2) intraovarian actions on thecal cells to negatively modulate *Cyp17* expression.

The granulosa cell–specific enzymes necessary for E2 synthesis, *Cyp19* and *Hsd17b1*, are also expressed at elevated levels in αERKO ovaries.[431] As a result, plasma E2 levels are typically increased almost 10-fold relative to wild-type littermates.[431] It is likely that the plasma androstenedione levels discussed earlier would be even greater in αERKO females if ovarian aromatase activity was not also equally elevated and providing for efficient conversion.[431] Although these findings in αERKO females suggest that ERα may also negatively modulate

E2 synthesis in granulosa cells, there is little precedent for this hypothesis. The chronically elevated plasma LH in αERKO females is also not likely to positively influence granulosa cell E2 synthesis as most evidence indicates that LH stimulation of granulosa cells leads to decreased aromatase activity.[441–443] Furthermore, individually cultured ERα-null follicles in vitro continue to exhibit heightened E2 synthesis relative to similarly propagated wild-type follicles in an environment of controlled FSH and LH stimulation.[440] Instead, increased aromatase activity in ERα-null ovaries is likely due to the positive actions of estrogens on FSH-induced granulosa cell steroidogenesis[442,444–447] which are presumably mediated by ERβ and therefore remain intact in ERα-null ovaries. Androgens have also been shown to augment FSH induction of E2 synthesis[442,448,449] and therefore the elevated androstenedione and T levels characteristic of αERKO females may also contribute to increased E2 synthesis in granulosa cells.

The several attempts to induce ovulation of ERα-null females collectively indicate an age-dependent effect of the loss of ERα. Schomberg et al. report that 4-month-old αERKO females do not successfully ovulate following exogenous treatments with PMSG and hCG, although this conclusion was based solely on the absence of corpora lutea rather than actual oocyte numbers.[373] Two later studies focused on younger αERKO females (3–5 weeks) and produced comparable results of successful ovulation (oocytes in the oviduct) and formation of functional corpora lutea, although the oocyte yield was reduced compared to age-matched wild-type females.[415,430] Oocytes harvested from ERα-null females successfully undergo in vitro fertilization, indicating that ERα may not be important to oocyte function.[415] In contrast, Dupont et al. report that the other line of ERα-null females (ERαKO) fail to ovulate or exhibit corpora lutea following exogenous gonadotropin treatments even at 21–25 days of age.[158] Studies in immature αERKO females of pure C57BL6 background (versus the mixed background of earlier studies) found that these mice can elicit a response to gonadotropin-induced ovulation.[432] This discrepancy in in vivo ovulatory success between the αERKO and ERαKO mice may be due to differences in genetic strain, the considerable disparity in the doses of gonadotropin used, or the small sample size in the Dupont et al. ($n = 3$). In further support of a minor role for ERα in ovulation, Emmen et al. demonstrated that individual ERα-null follicles propagated and induced to ovulate in vitro behave no differently than similarly cultured wild-type follicles.[440]

The discrepancies in the ovulatory response described herein may also be due to the splice variant of ERα expressed in the αERKO that was able to respond to exogenous gonadotropins (albeit reduced number [~15 oocytes] compared to wild-type [~41 oocytes]).[415] These mice were found to have expressed a splice variant in some tissues, and to circumvent this, a new ERα-null mouse model was made by *Cre/loxP*-mediated recombination (Ex3αERKO).[159] The ovarian phenotype and hormonal milieu of these mice is similar to that observed in the αERKO mice,[134,157] however the ability of these animals to respond to exogenous gonadotropins has not been fully studied to date. Preliminary data suggest reduced response to exogenous gonadotropins, as less than 50% ovulate and those that do respond ovulate a significantly lower number of oocytes (preliminary data Korach laboratory); however, further work is necessary to confirm this finding and fully characterize the ovulatory response of the Ex3αERKO mice.

Recently, a woman with homozygous mutation of ERα leading to severe E resistance was reported.[188] It is interesting to note that, similar to the ERα null mouse lines, she had cystic ovaries and elevated E, but unlike the mouse models, her LH and T levels were normal or nominally elevated. This is perplexing in light of the mechanisms discussed previously proposing the key role of LH elevation in causing the hemorrhagic cystic ovarian phenotype, and suggests notable interspecies differences in the mechanisms underlying these processes.

MICE WITH OVARIAN-SPECIFIC DELETION OF ERα

In rodent species, ERα is expressed predominately in theca cells, while ERβ is expressed in granulosa cells. Global loss of ERα in mice leads to a severe ovarian phenotype with large hemorrhagic and cystic phenotype due increased serum LH from loss of negative feedback in the hypothalamic–pituitary axis. While examination of ovarian function in these global ERα-null mice has provided important data on the necessity of ERα for ovarian function, the models make it difficult to delineate the importance of ERα specifically in the theca cells of the ovary. To circumvent this, Bridges et al. generated a mouse model with *Cre-recombinase* under control of the *Cyp17* promoter so that it is expressed specifically in thecal cells in the female mouse, and when crossed with a $ERα^{f/f}$ mouse deletes expression of ERα in thecal cells in the ovary.[361] Further characterization of this mouse and ovarian function in the absence of ERα demonstrated that these mice prematurely lose fertility.[362]

Theca cell–specific ERα knockout (thEsr1KO) mice did not have an altered estrous cycle, fertility as measured by the number of offspring born, or ovarian response to exogenous gonadotropins (superovulation) in animals aged 2 months; however, these measures were significantly reduced in thEsr1KO females at 6 months of age (Table 25.7).[362] In response to exogenous gonadotropins the thEsr1KO animals release similar numbers of oocytes to WT at 2 months of age (27 in WT versus 22 in thEsr1KO); however, by 6 months there are significant reductions in oocytes released (22 in WT versus 6 in

thEsr1KO) and the ovaries show an increase in the number of cystic/hemorrhagic follicles.[362] Additionally, the oocytes collected from the thEsr1KO ampulla appeared to be more degenerated than WT oocytes, however, further studies are required to examine the viability of oocytes collected from thEsr1KO mice. The age-related reduction in fertility coincides with an increase in the length of estrous cycle these animals have at 6 months of age,[362] demonstrating that ERα is important for maintenance of fertility, but its expression in thecal cells is dispensable for normal ovarian response in younger mice.

Global ERα-null mice have increased serum LH, which contributes to the cystic and hemorrhagic phenotype presumably due to loss of negative feedback in the hypothalamic–pituitary axis. Loss of ERα specifically in the theca cell layer leads to a reduction of serum LH in mice at 2 months of age, and a further reduction at 6 months.[362] This reduction in LH in the thEsr1KO animals was not due to reduced gonadotropes in the anterior pituitary, as there was actually an increase in the number of gonadotrope cells. Moreover, no difference is seen in the amount of LH stored in these cells as examined by immunofluorescence.[362] This confirms that the excess LH in the global ERα-null models is due to loss of ER in the hypothalamic–pituitary axis, and suggests that ERα expression in the ovary may be important for positive feedback and/or normal LH secretory patterns, although this needs to be tested experimentally.

Previous work has suggested that androgen synthesis is negatively regulated by estrogen through paracrine signaling actions, which can be examined in the thEsr1KO mouse model. Examination of serum hormone levels at both 2 and 6 months shows that T is increased,[362] confirming that ERα is necessary for maintenance of normal T levels. Examination of the expression of several steroidogenic enzymes found that *Cyp17* expression was increased at both 2 and 6 months following PMSG and hCG stimulation, while *Cyp19* expression was not significantly different between WT and thEsr1KO animals.[362] While expression of *Cyp17* is increased, the protein concentration of CYP17 was also increased in thEsr1KO ovaries in both aged animals and younger mice. CYP17 levels were also examined via immunohistochemistry during diestrus, when CYP17 activity and expression should be minimal, and increased CYP17 was observed in interstitial cells in the thEsr1KO ovary compared to wild-type ovaries.[362] The collective data support the notion that ERα signaling is necessary to support proper androgen synthesis in the ovary.

MICE WITH MUTATED DNA BINDING DOMAINS OF ERα

As discussed earlier in this chapter, the ERs may act as transcription factors on certain genes in the absence of a classical ERE within the regulatory sequences. This alternative mechanism of ER action, often referred to as "tethering", is thought to occur via interaction with transcription factors that are in fact bound directly to DNA (Figure 25.4). To develop an in vivo model for the study of ERα signaling via ERE-independent pathways, Jakacka et al. generated mice that possess a mutant form of the zinc-finger of the ERα DBD.[132] Because this mutation was incorporated into the endogenous *Esr1* gene (i.e., a "knock-in"), transcriptional expression of the mutant ERα is presumably no different than that of an undisrupted *Esr1* gene. Female animals that are heterozygous for the ERα mutation, termed NERKI$^{+/-}$ or ERα$^{AA/+}$ mice, are infertile and exhibit distinct ovarian phenotypes characterized by follicles of all stages of growth but no corpora lutea and lipid-filled cells throughout the stroma (Table 25.7).[132] The latter phenotype is similar to that of female mice lacking functional steroid acute regulatory protein (STAR) and correlates with reduced *StAR* expression in NERKI$^{+/-}$ ovaries.[132] Upon stimulation with exogenous gonadotropins, NERKI$^{+/-}$ ovaries exhibit multiple large hemorrhagic follicles similar to those found in ERα-null ovaries.[132] NERKI$^{+/-}$ females exhibit normal plasma gonadotropin and E2 levels and proper expression of steroidogenic enzymes in the ovary.[132] Still, induced ovulation in NERKI$^{+/-}$ females is only partially successful in causing some oocytes to be released and the formation of corpora lutea, as several preovulatory follicles fail to rupture and become hemorrhagic.[132]

Without further data it is difficult to determine the exact cause of the NERKI$^{+/-}$ ovarian phenotypes. Jakacka et al. postulate that the mutant ERα may act as a dominant-negative form of ER, however, the mutant ERα does not exhibit this property in vitro.[132] Furthermore, prolactin (*Prl*) is a known ERE-regulated gene and exhibits no change in expression in NERKI$^{+/-}$ females.[132] An imbalance between ERE-dependent and -independent pathways or tissue-specific inhibitory effects of the mutant ERα may also explain some of the resulting phenotypes.[132]

To further explore the role of the DNA binding domain in ERα function in the ovary, both the ER$^{AA/-}$ (also called "KIKO") and ER^{EAAE} mouse models (described in the section Mice with Mutated DNA Binding Domains of ERα) were developed,[162,168] both expressing only ERα that is unable to bind directly to ERE DNA motifs. KIKO were found to be anovulatory and infertile (Table 25.7).[162] Further characterization of the ovaries of these mice found follicles at most stages of development, however, there was a lack of corpora lutea in the ovary sections. The lack of corpora lutea and an estrous cycle in these mice suggests that they do not ovulate, however, the ability of these mice to respond to exogenous gonadotropins was not examined. These animals have some of the ovarian phenotypes identified in the NERKI$^{+/-}$,

demonstrating that the DNA binding activity of ERα is important for normal ovarian function. $ER\alpha^{EAAE/EAAE}$ females are infertile and have a hemorrhagic and cystic ovarian pathology (Table 25.7)[164] similar to the ovarian phenotypes observed in the other models that carry a mutation in the DNA binding domain. While further characterization of the ovarian phenotype in these animals is necessary to determine the exact cause of the ovarian phenotypes, the data to date suggest that DNA binding is an essential activity of ERα in normal ovarian function.

The KIKO animals have normal levels of E2 and P (Table 25.7),[162] and hormone levels were not examined in the $ER\alpha^{EAAE/EAAE}$ mouse model although ovarian phenotypes were similar between the two mouse models,[164] suggesting that regulation of serum steroid levels are not dependent on ERα DNA binding activities. Furthermore, the role of the DNA binding domain in ERα in tissues other than the ovary (such as the pituitary) could contribute to some of the observed phenotypes. Tissue-specific knock-in mutations to examine the role of direct DNA binding of ERα in ovarian function experiments could provide more mechanistic properties of the role of ERα, however, these experiments have not been done to date.

MICE WITH MUTATED AF-1 OR AF-2 DOMAINS OF ERα

While the models presented to date discuss the role of the DNA binding domain of ERα, there are other important domains of the nuclear receptor that may also contribute to the role of ERα in the ovary. To examine this, two different mouse models were developed with mutations in the ligand binding domain of ERα. In the first model, a single point mutation was made in the LBD (Figure 25.1) where a leucine was substituted in place of residue 525 where normally a glycine resides. This mutation alters the binding pocket, preventing normal ligand binding due to the increased side chain present in leucine compared to the single methyl group present in glycine. The knock-in mouse model $ER\alpha^{G525L}$, hereafter referred to as ENERKI, is anovulatory with a hemorrhagic and cystic ovarian pathology (Table 25.7).[168] The animals were found to have an increased number of atretic antral follicles, which presumably became the hemorrhagic/cystic follicles observed due to lack of rupture. Furthermore, these animals did not have any corpora lutea present, similar to the ERα suggesting that they do not ovulate,[168] demonstrating the importance of ligand binding ERα for normal ovarian function.

The AF-1 and AF-2 domains of ERα are important for ER function as demonstrated in vitro reporter assays. Mouse models were developed with each AF domain deleted, and uterine function was determined as described earlier in this chapter; however, the ovarian phenotype or hormone levels of these mice were not reported (Table 25.7).[165,167] To examine the importance of the AF-2 domain, a knock-in mutation in the AF-2 domain of ERα was made such that E2 is no longer able to transactivate E-dependent transcription.[169] This two-point mutation in the AF-2 domain was introduced into a knock-in mouse referred to as $AF2ER^{KI/KI}$. The mice are anovulatory and infertile (Table 25.7),[169] similar to the global αERKO knockout mouse models developed to date.[134,157,159] The ovaries of these mice also resemble the ovaries in ERα-null mouse models, in that they are hemorrhagic and cystic and lack presence of corpora lutea.[169] Furthermore, the endocrine milieu of these mice is similar to the global ERα-null animals; the $AF2ER^{KI/KI}$ mice have elevated serum LH and E2 (Table 25.7)[169] presumably due to lack of negative feedback in the hypothalamic–pituitary axis. The ovarian functions of other mice with AF-1 or AF-2 disruptions ($ER\alpha AF\text{-}1^0$ and $ER\alpha AF\text{-}2^0$) were not reported (Table 25.7). These models suggest that the ligand binding domain of ERα is required for normal ovarian function; however, the results differ slightly from the tissue-specific ERα knockout mouse described earlier. Therefore, further work using a tissue-specific knock-in mouse model would be useful in determining the mechanistic role of the different domains of ERα in the ovary.

MICE LACKING ERβ

Several facets of ovarian physiology thought to be dependent on the paracrine actions of E2 are clearly maintained in ERα-null and ERα-mutated ovaries, including granulosa cell proliferation, LH-receptor and aromatase expression, antrum formation, and the attenuation of atresia. The preservation of these estrogen actions in ERα-null ovaries strongly suggests their dependence on ERβ, which continues to be expressed in αERKO granulosa cells.[373,431] Neonatal ovaries from ERβ-null mice exhibit no gross abnormalities,[134,158,171,450] however, there are some differences in the expression of extracellular matrix proteins at this time of development.[451] Adult ERβ-null ovaries possess all stages of folliculogenesis,[158,171,440,450] a slight but perceptible increase in atretic follicles,[171,440,450] and a paucity of corpora lutea[171,440] (Table 25.7; Figure 25.17). Cheng et al. found that among 5-month-old ERβ-null females, less than 30% exhibit corpora lutea compared to 100% incidence in wild-type littermates.[450] Furthermore, when corpora lutea are present in ERβ-null ovaries, there are rarely more than two versus upwards of seven in wild-type females.[450] Continuous mating studies with ERβ-null females indicate a severe impairment in fecundity, but there is discernible variability in this phenotype among age-matched animals.[158,171] Consistent among βERKO pregnancies is reduced litter size of approximately one-third relative to wild-type.[158,171]

However, whereas some βERKO females exhibit the expected number of pregnancies over a 4 month period, others become pregnant only once while still others exhibit total infertility.[171,172] This variability in fecundity among ERβ-null females remains puzzling but is reported in both independently generated lines.[158,171] Given that the ERβ-null lines represent distinct targeting schemes for the *Esr2* gene on different genetic backgrounds, the observed variability in fertility is likely related to the loss of ERβ functions. A similar variability in oocyte yield is found when immature ERβ-null females are induced to ovulate by exogenous gonadotropin treatments.[158,171,172,432] A third ERβ-null mouse model was recently developed in which all mice were found to be infertile and unable to respond to exogenous gonadotropins.[172] These animals also had a significant reduction in the number of corpora lutea present in the ovaries of the ERβ-null mice.[172] While subfertile versus infertile phenotypes are observed in the different ERβ-null mouse lines, it should be noted that although some mice did produce pups and respond to exogenous gonadotropins, the number was significantly lower than that observed in WT mice, demonstrating the importance of ERβ in normal ovarian function. Therefore, the observed sub/infertility in ERβ-null females appears to originate from disrupted ovarian function that is best characterized to date as infrequent and inefficient spontaneous ovulation. A lack of evidence indicating embryo resorption during gestation in mated βERKO females[171] rules out an extraovarian contribution, although such phenotypes have not been categorically studied.

Histological evaluation of ERβ-null ovaries following induced ovulation reveals multiple preovulatory follicles possessing underdeveloped antra and minimal cumulus expansion.[158,171,172,432] Krege et al.[171] report obvious corpora lutea in immature βERKO ovaries 20 h after hCG treatment, but Dupont et al. remark that no luteal cells were observed in similarly treated ERβKO ovaries that did not ovulate.[158] However, immature βERKO females do indeed exhibit functional corpora lutea following induced ovulation, as indicated by histological evaluation of the ovaries and a substantial rise in plasma P levels following induced ovulation.[432] Luteinization and increased P synthesis is also observed when individually propagated ERβ-null follicles are exposed to an hCG bolus in vitro.[440] Furthermore, luteinization occurs in unruptured preovulatory follicles both in vivo and in vitro,[134,171,440] resulting in "trapped" oocytes similar to those observed in other null mouse models.[176,452]

ERβ-null females exhibit a relatively normal reproductive endocrine milieu.[431] Basal gonadotropin levels are within the range of control values,[431] although one report remarks that plasma LH levels are slightly increased in βERKO females.[453] This notwithstanding, ERβ-null females clearly do not exhibit the ovarian phenotypes that are associated with chronically elevated LH.[415,435] Therefore, ERα is clearly the principal receptor involved in mediating the negative feedback effects of E2 on gonadotropin secretion from the hypothalamic–pituitary axis. Sex steroid hormone levels in ERβ-null females are also comparable to wild-type littermates.[431] Additionally, the overtly estrogenized uterine and vaginal tissues observed in ERβ-null females indicate sufficient ovarian estrogen synthesis in the absence of functional ERβ.[134] This preservation of normal E2 levels in βERKO females is surprising given the evidence that estrogens are necessary to maximize FSH stimulation of aromatase activity in granulosa cells.[442,444–447]

Recent studies into the role of ERβ in normal ovulatory function have found that ERβ is necessary in granulosa cells for normal response to both gonadotropins FSH and LH. Granulosa cells isolated from ERβ-null ovaries and grown in culture had reduced levels of cAMP in response to FSH stimulation compared to granulosa cells isolated from WT ovaries.[454] The reduced signaling response to FSH was also observed in granulosa cells from in vitro–stimulated ovaries, and whole follicles grown in vitro.[454,455] The reduced cAMP accumulation after FSH stimulation coincided with a reduction of LH-receptor (officially *Lhcgr*) mRNA accumulation.[455] This suggests that granulosa cells in ERβ-null ovaries are unable to stimulate increased LH-receptor expression, which could contribute to the inability of these cells to respond to LH intracellular signaling components[363,455] and ultimately ovulate. Still, βERKO females clearly do not exhibit a normal ovarian cycle, as evidenced by vaginal smears indicating animals in persistent estrous and the paucity of corpora lutea in the ovary. This suggests the βERKO female mounts a preovulatory rise in E2 that is insufficient to induce the gonadotropin surge from the hypothalamic–pituitary axis, and/or a diminished ability of the βERKO ovary to respond to the LH surge. As mentioned before, androgens also augment FSH-induction of E2 synthesis[442,448,449] and provide for compensatory actions in ERβ-null granulosa cells.

MICE LACKING ER α AND β

Congruent with the loss of ERα, αβERKO females are infertile and do not spontaneously ovulate.[158,174] Adult αβERKO ovaries possess structures appropriate to the normal ovary, including primordial and growing follicles, although the latter possess an underdeveloped antrum, reduced granulosa number and a thin poorly structured theca (Table 25.7).[158,174] Cystic follicles that are somewhat characteristic of those found in ERα-null ovaries are also present but are not as large or as hemorrhagic in αβERKO ovaries and are more apt to exhibit only a thin layer of granulosa cells.[158,174] We have used mice with chronically elevated expression of LH from a transgene (α-LHβCTP mice) to show that the formation

of hemorrhagic and cystic follicles in the mouse ovary are due to ovarian acyclicity compounded by chronically elevated plasma LH in the presence of normal FSH levels.[435,437] The occurrence of hemorrhagic follicles in α-LHβCTP transgenic ERα-null mice and the absence of hemorrhagic follicles in α-LHβCTP transgenic ERβ-null mice[439] demonstrates a role of ERβ in development of the cysts. Therefore, the absence of hemorrhagic and cystic follicles in αβERKO ovaries indicates an important intraovarian role for ERβ in this pathology. A recent compound αβERKO mouse model that does not express the splice variant for ERα[159] has elevated plasma LH and hemorrhagic and cystic ovarian phenotype observed in the ERα-null mice.[456] The discrepancy observed in these mice suggests that the presence of the splice variant, genetic background, or mode of knockout in the mouse models may contribute to the ovarian pathology observed. Further studies are necessary to determine the role of ERα or ERβ in development of hemorrhagic follicles within the ovary.

A most remarkable feature of adult αβERKO ovaries is the presence of seminiferous tubule-like structures that often occupy large portions of the gonad but are conspicuously absent in ERα- or ERβ-null ovaries[158,174] (Figure 25.18). Morphological observations indicate these structures are the "ghosts" of atretic follicles as they possess an intact basal lamina, partial layers of granulosa cells, and an invariably degenerating oocyte[174] (Figure 25.18). Furthermore, these structures are postpubertal as Couse et al. report no such structures in αβERKO ovaries at 10 days of age[174] and Dupont et al. concur in another line of ERαβKO ovary as late as 23 days of age.[158] The defining characteristic of the "ghost" follicles that led to their initial description as testis-like seminiferous tubules is the overt presence of Sertoli-like cells in the lumen (Table 25.7 and Figure 25.18).[158,174] Several morphological features of these cells in both αβERKO and ERαβKO ovaries are strongly indicative of a Sertoli cell phenotype (Figure 25.18), including: (1) alignment with the basal lamina of the follicle wall, (2) a tripartite nucleolus, (3) numerous veil-like cytoplasmic processes extending inward toward the lumen, (4) ectoplasmic specializations that are unique to Sertoli cells in prepubertal testis, and (5) immunoreactivity for Müllerian-inhibiting substance and sulfated glycoprotein-2.

Granulosa and Sertoli cells fulfill analogous gametogenic roles as "nurse" cells in the ovary and testis, respectively, and are postulated to derive from a common embryological precursor cell during early gonadal

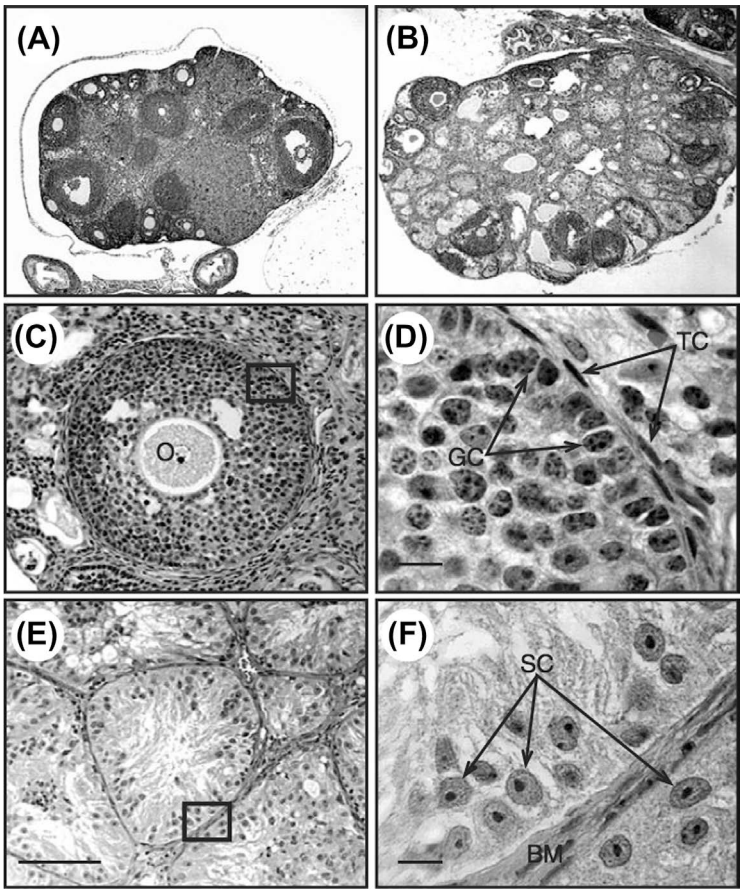

FIGURE 25.18 Ovarian phenotype in adult mice lacking both ERα and ERβ. (A, B) Low-power magnification of representative adult wild-type (A) and ERαβ–null (B) ovaries. The wild-type ovary exhibits all stages of folliculogenesis, including a preovulatory follicle (*right*) and corpus luteum (*right, bottom*). The ERαβ-null ovary exhibits a few relatively healthy maturing follicles but is overwhelmed by multiple "sex-reversed" follicles. (C–F) High-power magnification of representative follicles from adult ERαβ-null ovaries (C, 66×; D, 330×). A healthy follicle shows a single oocyte (O), several layers of granulosa cells (GC), an intact basal lamina, and thecal cells (TC) (E, 66×; F, 330×). A representative "sex-reversed" follicle in which there is no longer evidence of an oocyte and the somatic cells have undergone redifferentiation to a Sertoli-like cell (SC) phenotype. Preservation of the basement membrane (BM) of the follicles provides for the "tubular" appearance that assimilates testicular cords. The Sertoli-like cells (SC) possess the characteristic tripartite nucleolus and veil-like cytoplasmic extensions (F). Scale bars: E ×100 μm; D, F ×10 μm. *Source: Reproduced with permission from Ref. 174.*

differentiation.[457] Thus, the origin of the Sertoli-like cells in αβERKO ovaries remains a perplexing question. Do they originate from a bi-potent precursor population present in the αβERKO ovary at birth, or are they the result of granulosa cell transdifferentiation following oocyte death and follicle atresia? A report of extra-follicular Sertoli cells in the ERαβKO ovary[158,458] supports the existence of an embryological precursor cell population, yet similar interstitial cell populations are not found in ovaries from the other αβERKO.[174] In turn, the following findings that are common to both lines support a pathway of granulosa cell transdifferentiation: (1) the Sertoli-like cells are not apparent prior to 30 days of age, (2) the spherical shape of the "tubules" suggested by two-dimensional histology suggests they originate from a once-healthy follicle in which only the basement membrane remains, and (3) the appearance of Sertoli cells is strongly correlated with oocyte death and follicle atresia.[158,174] Furthermore, *Sox9* is highly expressed in both αβERKO and ERαβKO ovaries[174] and localized to the Sertoli-like cells.[458] SOX9 is an *Sry*-related transcription factor that is critical to normal Sertoli cell differentiation during testis development in rodents and humans.[459,460] Transgenic overexpression of *Sox9* leads to phenotypic male gonadal development in XX mice and therefore acts "downstream" of the Y-linked male-determining gene, *Sry*.[461,462] In strong favor of a pathway of granulosa cell transdifferentiation, *Sox9* expression in ERαβKO ovaries is restricted to the granulosa cells of atretic follicles and precedes the overt appearance of Sertoli-like cells but is not detectable in the granulosa cells of primordial follicles.[458] Furthermore, those cells expressing *Sox9* are initially present with the confines of the follicle "ghosts" and appear in the intrafollicular spaces of the ovary only after the phenotype has progressed to an advanced stage,[458] supporting a follicular (i.e., granulosa) origin.

Similar phenotypes of "sex-reversal" are reported in fetal rodent ovaries following: (1) transplantation of the fetal ovary to an adult host,[463,464] (2) in vitro exposure to purified Müllerian inhibiting substance (MIS),[465] (3) transgenic MIS overexpression in vivo,[453] (4) transgenic *Sox9* overexpression in vivo,[461,462] and (5) following targeted disruption of the *Wnt4* gene in mice.[466] Although the αβERKO ovarian phenotype shares a number of morphological similarities with the previous findings, including aberrant expression of the MIS, SGP-2 and *Sox9* genes, a remarkable distinction in the αβERKO ovary is the postnatal onset of the phenotype. The previous descriptions of ovarian sex reversal are reported to occur or even require *fetal* ovarian tissue.[465,467] Therefore, the observed "sex-reversal" adult αβERKO ovaries is the first to be described in the postnatal mouse gonad, indicating that the potential of female ovarian somatic cells to redifferentiate into Sertoli-like cells may be present throughout life in the mouse. Recently, postnatal reprogramming of ovaries to testis with cells that are positive for SOX9 expression and cells resembling Sertoli cells was reported in adult mice lacking FOXL2.[468] This provided a second postnatal model for this ovarian transdifferentiation, and suggested that FOXL2 is an important transcription factor necessary for granulosa cell differentiation and ovarian function. Interestingly, the Ex3αβERKO mouse model shows loss of *Foxl2*/FOXL2 expression followed by increased *Sox9*/SOX9 expression and appearance of Sertoli-like cells in the ovary of adult mice.[456,469]

A causal link between the loss of all ER function and postnatal morphological ovarian sex reversal is unclear. Dupont et al. report that female mice possessing only one functional ERα allele but lacking functional ERβ also exhibit the αβERKO ovarian phenotype, suggesting a gene-dosage effect for ERα.[158] The majority of documented cases of similar phenotypes in the mammalian ovary are preceded by massive germ cell loss.[470] The remarkable oocyte attrition that occurs in the αβERKO ovaries suggests a similar mechanism occurs in this model; yet it remains unclear if the progressive loss of germ cells in αβERKO ovaries illustrates the loss of critical intraovarian estrogen signaling that is perhaps dependent upon ERα/ERβ cooperation. A role of direct estrogen/ER actions in gonadal differentiation is supported by reports of sex reversal in turtles and whiptail lizards following developmental exposure to aromatase inhibitors.[471,472] The mouse *Sox9* promoter lacks an obvious ERE but does possess two consensus binding sites for GATA-1,[460] a transcription factor expressed in Sertoli cells during differentiation of mouse testis but repressed by germ cells in adult testis.[473] Furthermore, ERα can repress the transcriptional activities of GATA-1,[474] suggesting that aberrant *Sox9* expression leading to Sertoli-cell differentiation in αβERKO ovaries may be due to increased GATA-1 activity following the loss of ERα and other potential oocyte-derived inhibitory factors. As a similar phenotype is observed in FOXL2 knockout ovaries, it has been hypothesized that *Foxl2*/FOXL2 is regulated by ERE-dependent transcription,[468] and loss of this regulation contributes to the Sertoli-cell phenotype in the ovaries of knockout mice. This does not account for the lack of transdifferentiation during ovarian development or in neonatal animals,[158,174,468] which suggests that this "sex-reversal" or transdifferentiation phenotype is a complex trait that requires aberrant regulation/expression of multiple genes. Current studies are underway with the Ex3αβERKO mouse model to look at ovarian gene expression and identify possible candidate genes that may contribute to the granulosa cell transdifferentiation observed.[456,469]

Female αβERKO animals exhibit a gonadotropin profile that is similar to αERKO females, although plasma LH levels are noticeably higher. Therefore, the hormonal

milieu in αβERKO females may impact the ovarian "sex reversal" observed.[174,431] Still, transgenic mice possessing chronically elevated plasma LH also display a progressive loss of oocytes but lack any evidence of ovarian "sex reversal".[435,439,475] Interestingly, αβERKO ovaries do not exhibit αERKO-like increases in ovarian aromatase or E2 synthesis.[431] This finding provides further support that elevated LH and precursor substrates, combined with the positive actions of ERβ, lead to enhanced E2 synthesis in ERα-null ovaries—a scenario that would be disrupted in αβERKO ovaries. The dramatic loss of germ cells in the αβERKO ovary may also impact gonadotropin responsiveness of granulosa cells as oocyte-derived factors are known to positively influence steroidogenesis;[476] further studies are necessary to determine how germ cell loss contributes to the observed phenotype.

MICE LACKING CYP19

In the ovary, CYP19, or aromatase, is expressed exclusively in the granulosa cells (Table 25.6). Initial reports of Cyp19-null ovaries indicated no phenotypic difference from WT, suggesting estrogen-independent signaling mechanisms were involved in eliminating the phenotypes of the ERKO mice.[477] It was not until Cyp19-null mice were fed a soy-free diet that phenotypes appeared. These observations were some of the first to directly demonstrate dietary estrogen contamination in feed. Therefore, to study the phenotypes associated with loss of estrogens, Cyp19 null are kept on soy-free diets. Under these conditions, Cyp19-null mice have ovaries with all stages of folliculogenesis, including multiple large antral follicles but no corpora lutea at 10–14 weeks of age (Table 25.7).[131,156,364] At 21 weeks of age, Cyp19-null ovaries continue to exhibit all stages of folliculogenesis, but larger follicles possess a reduced number of granulosa cells and become enlarged, cystic, and hemorrhagic, similar to ERα-null follicles.[364] By 1 year of age, Cyp19-null ovaries are characterized by a paucity of normal follicles, an increased number of cystic and hemorrhagic follicles, significant collagen deposition, and massive macrophage infiltration into the interstitium (Table 25.7).[364] Several findings indicate infertility among Cyp19-null females due to an inability to spontaneously ovulate, including: (1) absence of corpora lutea at all ages,[131,156,364] (2) lack of pregnancies during continuous mating,[131] and (3) total failure to ovulate following exogenous gonadotropin treatments.[131] Recently, it has been demonstrated that co-treatment of Cyp19-null mice with E2 and PMSG followed by hCG can rescue the anovulatory phenotype,[365] demonstrating the necessity of E2 signaling in addition to the gonadotropins for normal ovulatory function.

Surprisingly, initial descriptions of the ovarian phenotypes in Cyp19-null females did not include remarks of Sertoli-like cells similar to those found in αβERKO females. However, Britt et al. later demonstrated that mutant females maintained on a diet free of phytoestrogens exhibit a clearly exacerbated ovarian phenotype by 6 weeks of age that included hemorrhagic and cystic follicles, seminiferous tubule–like structures possessing Sertoli-like cells, and an almost 40-fold increase in *Sox9* expression.[194] By 16 weeks of age, the tubule-like structures and Sertoli cells occupy up to 80% of the ovary and are strikingly similar to those found in αβERKO ovaries in both morphology and gene expression.[194] Additional supporting evidence of Sertoli-like cells in Cyp19-null ovaries is documentation of Sertoli cell-specific ectoplasmic specializations and immunoreactivity for Espin, an important component of Sertoli cell junctions in testis.[194] Recent microarray analysis has identified 450 genes that are differentially expressed in Cyp19-null ovaries compared to wild-type ovaries, with 291 showing increased expression and 159 showing reduced expression.[478] Several of these genes have been implicated in testis development, however, further studies and confirmation are necessary to determine potential candidates that may contribute to ovarian transdifferentiation. Interestingly, a similar phenotype of "sex reversal" has not been described in the ovaries of a second line of Cyp19-null females.[131]

As expected, the reproductive hormonal milieu in female Cyp19-null mice is severely disrupted. Plasma E2 levels[131] and ovarian aromatase activity[156] are below the level of detection, supporting the existence of a single aromatase-encoding gene in mice. In turn, plasma T levels in Cyp19-null females are 10-fold that found in wild-type littermates.[131,156] Increased plasma androgens in Cyp19-null females are likely the combined effect of an accumulation of androgen precursors that occurs in the absence of aromatization to E2, and increased synthesis due to hyperstimulation of the ovarian theca by five-fold increased plasma LH.[156,364] Thus, increased plasma LH and androgens are characteristic of mice lacking ERα-mediated estrogen actions following the loss of receptor (ERα-null animals) or ligand (Cyp19-null animals). However, one striking difference between Cyp19-null and ERα-null females is the four- to six-fold increase in plasma FSH that is unique to the former.[364] Interestingly, Cyp19-null females exhibit the above abnormal hormone milieu regardless of phytoestrogen content in the diet,[194] suggesting that dietary phytoestrogens may attenuate some but not all of the effects that follow the loss of endogenous E2 synthesis.

Studies have indeed shown that Cyp19-null mice still possess functional ER signaling.[479] Tonic E2 replacement therapy in Cyp19-null females over a period of 21 days leads to restored gonadotropin homeostasis, improved follicular development in the ovary, a reduced presence of Sertoli-like cells and *Sox9* expression, and restoration of ovulation and corpora lutea formation.[479,480] In

a similar study, Toda et al. report that E2 administration to Cyp19-null females every fourth day for 4 weeks also ameliorates the ovarian phenotypes but did not restore ovulation.[131] Ovulation was partially restored when the mice were treated with E2 in addition to exogenous gonadotropins,[365] although oocyte numbers were still significantly lower than those observed in WT mice. Furthermore, treatment of the Cyp19-null mice with a GnRH antagonist and E2 replacement was able to restore normal gonadotropin levels, while treatment with an antiandrogen had no effect. This demonstrates that loss of E2 in these animals contributes to the ovarian phenotype observed and also indicates that an indirect effect from excess androgens does not directly contribute to the excess gonadotropins, hemorrhagic follicles, or Sertoli-like cells present in the Cyp19-null mice.[481]

Intraovarian Roles of Estradiol in Ovarian Function

The importance of the extraovarian or endocrine roles of estrogen signaling in ovarian function has long been recognized and is the precedent for steroid-based oral contraceptives.[482,483] In contrast, the significance of estrogen signaling within the ovary is not well understood due to the inherent difficulties associated with the study of a particular hormone's action within the very tissue from which it is synthesized and secreted. Past in vivo investigations employing ER antagonists[217–219,484] or aromatase inhibitors[484–486] to inhibit hormone receptor actions within the ovary have provided informative but often equivocal findings[217–219] due to the following limitations: (1) the enormous levels of endogenous E2 in the ovary are difficult to overcome by pharmacological administration of a receptor antagonist, (2) the enormous levels of aromatase activity in the ovary are difficult to overcome by pharmacological administration of an enzyme inhibitor, (3) the effects of a pharmacological ER antagonist due to actions directly in the ovary versus actions in the hypothalamus or pituitary are difficult to discern, (4) the well-characterized agonists (e.g., E2 and DES) comparably activate both ERα and ERβ, (5) early antagonists were not selective for the two known ERs, and (6) the two ERs may respond differently to agonist or antagonist ligands. The generation of ER and Cyp19-null mice, and development of improved ER-selective ligands or SERMs[61,487,488] have contributed to better understanding over the years.

The abundance of data on the localization of ERα and ERβ within rodent follicles allows for a simplified model of estrogen actions within the ovary. For example, given that ERα predominates in thecal cells, does it mediate the inhibitory effects of E2 on LH-stimulated androgen synthesis? In turn, as ERβ clearly is the predominant receptor in granulosa cells, is it responsible for mediating the known estrogen augmentation of FSH actions? This section employs the contributions from studies of the pertinent null- or mutated-mouse models as a platform to discuss the current view on intraovarian estrogen/ER signaling.

GRANULOSA CELL PROLIFERATION

A number of studies in immature hypophysectomized rodents have demonstrated that DES or E2 treatments over 2–4 days leads to a marked increase in ovarian weight[489] a significant rise in the number of medium-sized preantral follicles and increased DNA synthesis in both thecal and granulosa cells,[422,490–492] indicating a direct and gonadotropin-independent effect of E2 on the ovary. Similar data have been reported following DES treatment of intact immature rats.[493] However, there is equally convincing data that sequential treatment of immature hypophysectomized rodents with DES followed by FSH results in a synergistic response in terms of increased ovarian weight and DNA synthesis, and elicits several major indices of granulosa cell differentiation, i.e., antrum formation and acquisition of LH-receptor expression, that are not observed with either hormone alone.[359,490,491,494] Furthermore, co-administration of an antiestrogen (*cis*-clomiphene) inhibits FSH-induced increases in ovarian weight and follicular growth in hypophysectomized rats, suggesting that ER-mediated effects are necessary for a full response to gonadotropin.[495] The synergistic actions of E2 on FSH-induced granulosa cell proliferation have been replicated in vitro,[496] although others report that FSH-mediated growth of isolated murine follicles is not affected by anti-E2 antisera or ER antagonist (ICI 182,780).[497] The capacity of E2 to enhance the granulosa cell response to FSH is not believed to rely on estrogen-induced increases in FSH-receptor levels, although some evidence indicates such an effect may play a greater role in mice versus rats.[359,492,494] These differences will be easier to study with the recently described ERα-null rat,[190] which can be used to compare the roles of ERα in rat versus mouse ovarian functions. Still, pretreatment of hypophysectomized rats with antiestrogen (CI628) inhibits FSH-induced increases in granulosa cell FSH receptor levels.[418]

It is generally agreed that the synergistic response of granulosa cells to estrogens and discovery of ERβ and its substantial expression in the granulosa cells of growing follicles and absence in atretic or luteinized follicles strongly suggests that the trophic actions of estrogens are direct and ERβ mediated. Supporting data of a greater importance of ERβ versus ERα in estrogen-induced granulosa cell proliferation comes from a report of Hegele-Hartung et al. in which the ERβ-selective agonist 8-vinylestra-1,3,5-(10)-triene-3,17β-diol induces increased ovarian weight and granulosa cell proliferation to levels comparable to that elicited by

17β-E2 in hypophysectomized rats; whereas the ERα-selective agonist 3,17-dihydroxy-19-nor-17α-pregna-1,3,5 (10)-triene-21,16α-lactone has little effect.[488] However, although these data indicate that E2/ERβ actions may indeed enhance FSH-induced granulosa cell proliferation, several findings question the overall importance of this intraovarian role. First, ERβ-null ovaries exhibit a relatively normal number of growing preantral follicles with no obvious reduction in the granulosa cell population.[158,171,498] Furthermore, immature ERβ-null females treated with PMSG exhibit the expected increase in the number of small and large preantral follicles.[158,440] In addition, granulosa cell tumors, due to the loss of inhibin-α (*Inha*) in mice continue to proliferate regardless of the presence or absence of functional ERβ.[499] It is possible that ERα may provide some compensatory actions as ERβ-null follicles show increased expression of ERα mRNA.[455] Furthermore, Cyp19-null mice are presumably devoid of E2-dependent ER action but exhibit ovaries possessing all stages of follicle growth, each with a normal complement of granulosa cells.[364] Therefore, the data suggest that although estrogen-induced granulosa cell proliferation is likely mediated by ERβ, it is not obligatory to gonadotropin-induced follicle growth in rodent ovaries.

ERβ may facilitate gonadotropin-induced granulosa cell proliferation through the induction of cyclin-D2 (*Ccnd2*), which enhances progression of the cell cycle from the G_0 to S phase. Targeted disruption of the *Ccnd2* in mice indicates this cyclin protein is obligatory to granulosa cell proliferation as Ccnd2-null ovaries lack follicles beyond the small preantral stage.[500] Furthermore, the arrest in folliculogenesis observed in Ccnd2-null mice is not rescued by exogenous FSH treatment in vivo or in vitro, indicating the critical downstream role of cyclin-D2 in gonadotropin-mediated granulosa cell proliferation.[500] In rats, *Ccnd2* expression is localized to the granulosa cells of early growing follicles and is significantly induced by PMSG or FSH treatments.[501] However, E2 also induces *Ccnd2* expression in rat granulosa cells, and although the response is less rapid relative to that elicited by FSH, the overall induction by E2 is higher and better sustained over 24 h.[501] Furthermore, E2 elicits a concomitant decrease in the expression of *Cdkn1b* (p27), a cyclin-dependent kinase inhibitor.[501] E2 induction of *Ccnd2* in undifferentiated rat granulosa cells in vitro is inhibited by the ER antagonist ICI 164,384, indicating this to be an ER-mediated event, presumably ERβ.[501] Therefore, parallel pathways of FSH and E2 converge to induce and maintain *Ccnd2* expression in granulosa cells, thereby forcing cell cycle progression and subsequent proliferation.[501] Interestingly, adult ERβ-null ovaries possess normal granulosa cell expression of *Ccnd2*[450] as well as exhibit the expected induction following PMSG exposure,[432] further supporting the hypothesis that FSH and E2 work in parallel. Therefore, these observations and the absence of any gross deficiency in granulosa cells in ERβ-null ovaries suggests that FSH may play a greater role in inducing *Ccnd2* expression and granulosa cell proliferation. Interestingly, E2 specifically induces *Ccnd2* expression in keratinocytes via the cAMP/PKA signaling pathway that leads to activation of CREB,[502] the same intracellular pathway employed by FSH signaling in granulosa cells. These findings suggest that E2 may also function within the FSH signaling pathway to induce *Ccnd2* in granulosa cells.

A second mechanism by which E2 may amplify FSH-induced granulosa cell proliferation is via interactions with the ovarian IGF1 axis. Like Ccnd2-null mice, Igf1-null mice exhibit a total failure of follicles to progress beyond the small preantral stage.[503,504] This arrest in folliculogenesis in Igf1-null ovaries is primarily due to a >50% reduction in FSH receptor levels in the granulosa cells, severely hampering their response to FSH.[504] However, Kadakia et al. demonstrated that Igf1-null granulosa cells are also refractory to E2-induced proliferation and exhibit a 50% lower rate of DNA synthesis and decreased *Ccnd2* induction following E2 treatment in vivo.[505] The poor response of Igf1-null granulosa cells to E2 may be due to a likewise reduction in ERβ levels as IGF1 is reportedly necessary for the maintenance of ERβ expression in granulosa cells in vitro.[506] There are currently no reports describing the levels of ERβ expression in the ovaries of Igf1–null mice. Interestingly, Richards et al. demonstrated that E2 significantly upregulates the expression of several components of the IGF1 signaling pathway in rat granulosa cells, including the IGF1 receptor-β subunit, the glucose transporter, Glut-1, and the forkhead family member, FKHR (Foxo1).[506] These findings suggest that E2 may enhance IGF1 actions in granulosa cells by regulating targets important for cellular energy flow, glucose metabolism, and cell survival.[506] In summary, IGF1 actions are clearly necessary to provide for sufficient FSH signaling in granulosa cells, which in turn, is necessary for the induction of aromatase activity and E2 synthesis, thereby providing ligand for ERβ to enhance the effects of IGF1, hence forming an autocrine regulatory pathway to promote granulosa cell proliferation.[506] The extent to which these findings may translate to the human ovary remains to be determined since IGFII, rather than IGF1, is the predominant and gonadotropin-regulated IGF form in the human ovary.[507]

The previous discussion provides a compelling argument that the mitogenic actions of E2 on granulosa cells are direct and ERβ mediated. However, thecal cell ER actions may also be involved. For example, ERα in the thecal cells may respond to granulosa cell–derived E2 by inducing the synthesis and secretion of a paracrine-acting growth factor(s) that then becomes the principal stimulus for granulosa cell proliferation. Indeed, Dorrington and

colleagues have proposed that thecal-derived transforming growth factor-β (TGFβ) is estrogen induced and stimulates granulosa cell proliferation.[508,509] Similar examples of growth factor–mediated cooperative actions between theca and granulosa cells are postulated to regulate follicle steroid production.[510,511] Still, ERα-null follicles do not exhibit any gross deficits in granulosa cell number and possess a normal number of preovulatory follicles following gonadotropin stimulation.[415] ERα-null follicles in vitro show normal growth, however, they do not reach the same size as wild-type follicles.[440] It is plausible that a dramatic effect on granulosa cell proliferation may only become apparent following the loss of both putative estrogen pathways, i.e., the direct (ERβ-mediated) and indirect (ERα-mediated) actions—hence explaining the unique somatic cell phenotypes observed in the ovaries of compound ER-null[158,174] and older Cyp19-null mice[364] on a soy-free diet in absence of estrogen ligand.

GRANULOSA CELL DIFFERENTIATION

The process of granulosa cell differentiation that occurs during progression from a preantral to preovulatory follicle has been an area of intense research. Fully differentiated preovulatory follicles in mammalian ovaries are distinctly characterized by: (1) a large fluid-filled antrum, (2) acquisition of LH responsiveness, (3) significant increases in aromatase (CYP19) activity, and (4) increased inhibin synthesis. Although FSH is the primary stimulus for both granulosa cell proliferation and differentiation, these two processes appear to be independent as the undersized follicles in Ccnd2-null ovaries still develop an antrum, possess sufficient aromatase activity, and are responsive to exogenous LH stimulation.[502] Therefore, granulosa cell proliferation and differentiation are separate gonadotropin-induced events during folliculogenesis.

The absolute requirement of FSH signaling in the process of granulosa cell differentiation is illustrated by the lack of antral follicles, aromatase and E2 synthesis, and granulosa cell LH receptor in mice null for FSH action.[420,512,513] Igf1-null follicles exhibit a similar failure to differentiate; this is postulated to be due to a lack of sufficient FSH-receptor expression.[503] However, numerous studies in rat ovaries have demonstrated that FSH induction of antrum formation,[490] aromatase expression and activity,[442,444–447] and LH-receptor expression[484,514,515] require E2 for maximum effect. FSH acts via a classic heterotrimeric G protein–coupled receptor pathway that may activate multiple intracellular second messenger systems, the most well characterized being activation of adenylyl cyclase, which leads to intracellular accumulation of adenosine 3′,5′-monophosphate (cAMP) and activation of protein kinase A (PKA).[416,494] The long-recognized synergism between E2 and FSH on granulosa cell differentiation is believed to be due to the capacity of E2 to both amplify the level of FSH-stimulated intracellular cAMP[359,441,494,515,516] and augment the downstream actions of cAMP itself.[494,515] The mechanisms involved remain poorly understood and are unlikely to involve estrogen-induced increases of FSH receptor levels but appear more likely to rely on E2's capacity to positively modulate the granulosa cell adenylyl cyclase system.[441,494]

ER-mediated estrogen activation of the adenylyl cyclase system and subsequent cAMP-regulated gene expression has been demonstrated in uterine and breast cancer cells.[517] Furthermore, in vitro and in vivo studies indicate that ERα or ERβ can activate ERE-dependent gene transcription via the cAMP/PKA signaling pathway in the absence of E2.[93,103,518] This pathway involves the CREB protein,[519] which is also known to be critical to FSH induction of gene expression.[442,520,521] Therefore, given the existing evidence that E2 is required to maximize the FSH response, combined with the known cooperative activity between the ER and PKA signaling pathways, it may be reasonable to expect that a loss of ER action in the ovary would cause severe deficits in granulosa cell differentiation. Indeed, the ovarian phenotypes in ERβ-null females in terms of antrum formation, aromatase expression, and LH responsiveness collectively represent an attenuated response to FSH-induced granulosa cell differentiation in the absence of ERβ. Additionally, ERβ-null granulosa cells and follicles have a reduced response to FSH marked by reduced cAMP accumulation in vivo and in vitro.[454,455] The reduction in cAMP can be overcome when cells are stimulated with forskolin to activate cAMP accumulation,[455] demonstrating that altered cAMP/PKA signaling contributes to the reduced granulosa cell differentiation observed in ERβ-null ovaries and suggests that maximal activation requires cross talk between FSH and ER-mediated signaling pathways. Possible downstream mediators were recently identified in a microarray study,[363] providing key targets to further study in the future.

ANTRUM FORMATION

Goldenberg et al. first demonstrated that both FSH and estrogen are required for full antrum formation in preovulatory follicles of hypophysectomized rat ovaries.[490] Wang and Greenwald produced similar data in hypophysectomized mice, reporting that FSH plus E2 leads to an average of >70 large antral follicles per ovary versus an average of six or none when treated with FSH or E2 alone, respectively.[492] The requirement of FSH plus E2 for antrum formation holds true when rat preantral follicles are grown in vitro.[522] Others have shown that exposure to aromatase inhibitors during gonadotropin-induced folliculogenesis also reduces the number of healthy antral follicles in rats,[485,486] although contradictory findings are reported when follicles are

similarly exposed in vitro.[523] Independent evaluations of ovaries from three separate lines of ERβ-null mice indicate a paucity of follicles with fully developed antra, even following standard gonadotropin stimulation.[158,172,440] These data strongly suggest that the vital role of E2 in FSH-induced antrum formation is mediated by ERβ. A role for ERα in antrum formation cannot be excluded but is unlikely given the hallmark phenotype in ERα-null ovaries is the invariable presence of severely oversized antral follicles, lending to their description as "cystic".[157–159,373,415] Furthermore, a role of aberrant LH action cannot be discounted, as mice overexpressing a mutant LH receptor have large cystic and hemorrhagic follicles similar to those observed in ERα-null mice.[524] While it is possible to hypothesize that ERβ may contribute to the formation of exaggerated antrum due to hyperstimulation of the receptor, the data supporting this idea are not clear. For example, mice that lack both ER forms (αβERKO),[158,171] or transgenic βERKO females that have elevated LH,[439] do not have large cystic follicles, although a new line of compound αβERKO mice (Ex3αβERKO) do have large cystic follicles[456] as do the Cyp19-null mice.[480] This contradictory data suggests that the mechanism behind antrum formation may not be due solely to overstimulation of ERβ, and multiple mechanisms may exist. Furthermore, mice lacking ERα specifically in the theca cells develop cystic follicles as they age in response to excess gonadotropins, which is not observed in younger mice,[362] suggesting a more complex mechanism contributes to antrum formation.

As mentioned, FSH alone will induce the formation of small antra in growing follicles whereas E2 has no such effect in vivo and in vitro, but both hormones are required for full antrum development.[490,492,522] Compared to the total failure of antrum formation among follicles in the murine models of disrupted FSH signaling,[420,503,512,513,525] similarly sized follicles in ERβ-null ovaries exhibit an initiation of antrum formation but fail to develop to a full preovulatory stage.[158] Quantitative analyses of immature ERβ-null ovaries 48 h after PMSG stimulation indicate an increased number of small antral follicles but fewer large (preovulatory) follicles relative to wild-type females, suggesting an arrest in antrum formation.[440] Likewise, a large percentage of ERβ-null follicles fail to reach maximum size when grown in culture with FSH and E2.[440] These follicles also fail to accumulate maximal cAMP levels after FSH stimulation,[455] suggesting that multiple signaling pathways may contribute to antrum formation. These data support the role of FSH actions in the initiation of antrum formation, but in the absence of ERβ-mediated E2 augmentation, maximum antrum development is prohibited.

Because so little is known about the physiology of antrum formation, the role of ERβ-mediated estrogen actions is speculative. It has long been proposed that antrum development follows gonadotropin-stimulated increases in granulosa cell proteoglycan secretion, which act to increase osmotic pressure within the follicle and cause the influx of water from the ovarian vasculature.[526,527] McConnell et al. report that water movement into mouse follicles in vitro occurs via a transcellular pathway and is likely mediated by aquaporins-7, -8, or -9 on the surface of granulosa cells.[528] Although there is currently no evidence of estrogen regulation of aquaporin expression in the ovary, E2 is known to influence fluid transport in the uterus via regulation of aquaporins -1,[332] -2, and -3,[529] and 5 and 8.[242,530] Furthermore, ERα is principally involved in the regulation of Na^+ and water transport across the efferent ductules in the rodent testis,[531] suggesting ERα may play a similar role in follicles. Antrum formation may not rely totally on hydromechanical mechanisms but is likely to require cell–cell interactions among the granulosa cell layer. Gore-Langton and Daniel demonstrated in vitro that rat preantral follicles lacking an intact basement membrane and therefore unable to provide a sealed environment exhibit a reorganization of granulosa cells that is unmistakably antrum-like in response to FSH plus E2, supporting a role for cell–cell interaction during antrum formation.[522] A lack of antral follicles in the ovaries of mice lacking the gap junction component connexin-37 (*Cx37*) further supports a need for cell–cell interactions among granulosa cells.[532] E2 is known to dramatically increase the number of gap junctions between granulosa cells[533] as well as regulate ovarian expression of certain component proteins.[534–536] Additionally, the extracellular matrix may be important to antrum formation. Mice lacking ERβ exhibit altered expression of several extracellular matrix proteins, including increased expression of Collagen 11a1 and Nidogen 2 at both the mRNA and protein level in both prepubertal and adult ovaries,[451,500] which may alter the follicle composition and contribute to loss of antrum in these mice. Future studies of a potential regulatory role for E2 in the expression of the aquaporins, connexin, and extracellular matrix proteins may reveal a precise role for ERβ in antrum formation.

AROMATASE AND ESTRADIOL SYNTHESIS

Acquisition of aromatase activity and E2 synthesis is a hallmark of healthy preovulatory follicles in mammalian ovaries. In monotocous species, including women, 90% of the circulating E2 is estimated to originate from the dominant follicle in the ovary. Aromatase (*CYP19*) expression in rat, mouse, bovine, marmoset, and human ovaries, via activation of the gonad-specific promoter II,[537] is exclusive to and highest in the granulosa cells of fully differentiated healthy follicles (Table 25.6).[400,538–540] Likewise, E2 levels are consistently highest in the follicular fluid of healthy preovulatory, and substantially

lower in overtly atretic, follicles. The endocrine actions of ovarian-derived E2 are critical to preparing the female reproductive tract for a forthcoming pregnancy and priming the hypothalamic–pituitary axis for generation of the gonadotropin surge. However, there is equally abundant evidence that E2 acts in a paracrine or autocrine manner to augment FSH stimulation of aromatase activity in granulosa cells and thereby positively influences its own rate of synthesis (Figure 25.19). This pattern of *CYP19* expression described herein strongly resembles the profile of ERβ during folliculogenesis, suggesting that the E2-induced enhancement of aromatase activity in granulosa cells is ERβ mediated.[440]

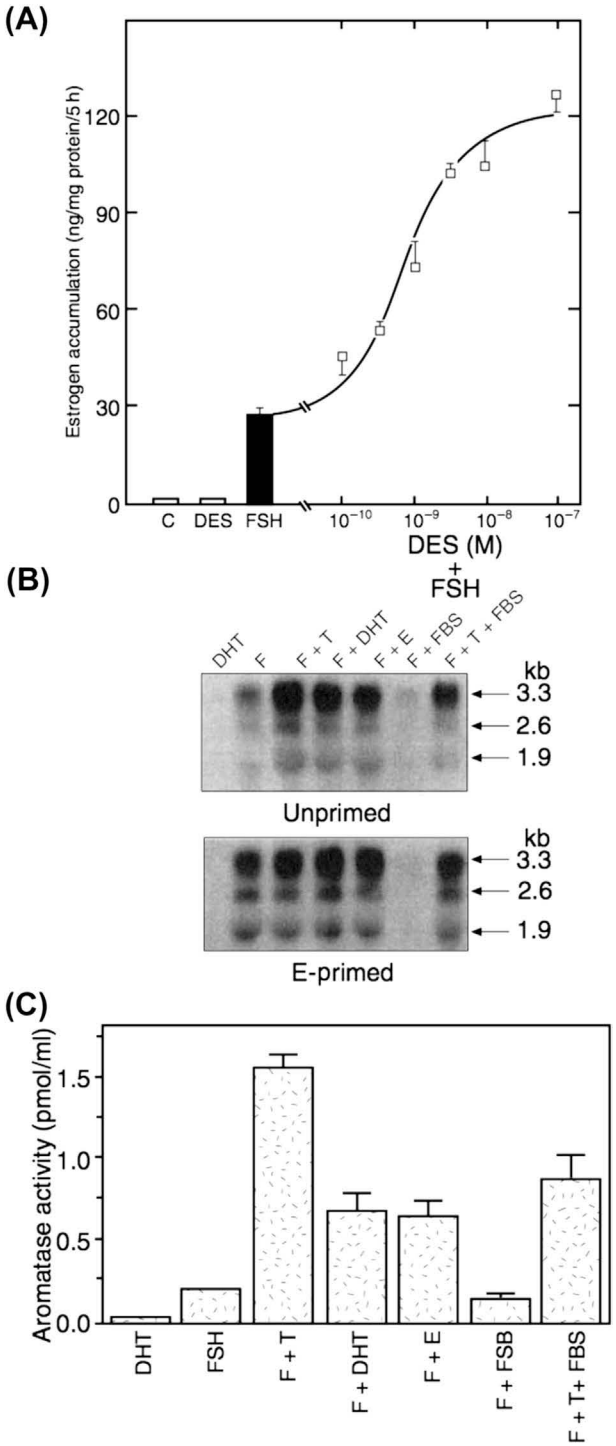

FIGURE 25.19 Synergistic action of sex steroids and FSH in the induction of *Cyp19* expression and aromatase activity in rodent granulosa cells. (A) Shown is the effect of in vitro treatment with the synthetic estrogen DES on FSH-induced aromatase activity in granulosa cells isolated from immature hypophysectomized rats. Granulosa cells were cultured for 3 days in the presence or absence of FSH (10 ng/ml) with or without increasing concentrations of DES. Three days later, the cells were washed with medium and reincubated for a 5-h test interval in medium supplemented with androstenedione. The accumulation of estrogen (as measured by radioimmunoassay) during this test period is taken as a measure of the level of aromatase activity. C, controls. *(Source: Reproduced with permission from Ref. [445].)* (B, C) Shown is the effect of FSH and sex steroids on *Cyp19* expression and aromatase activity in cultured granulosa cells. Granulosa cells were isolated from 26-day-old rats that had been untreated (unprimed) or treated with E2 (1.5 mg/day) for 3 days (E-primed). Cells were incubated in serum-free medium with 5α-dihydroT (DHT) at 20 nM, FSH (50 ng/ml), or FSH in combination with DHT (20 nM), T (20 nM), or E2 (20 nM). Cells were also incubated in medium containing 5% fetal bovine serum (FBS), with FSH alone (50 ng/ml), or in combination with T (20 nM). After 48 h in culture, cells were collected for RNA extraction and evaluation of *Cyp19* expression by Northern Blot analysis (B) or for measurement of aromatase activity (C). *Source: Reproduced with permission from Ref. [442].*

FSH is clearly the principal stimulus for the acquisition of aromatase activity in granulosa cells. Once again, female mice lacking FSH (*Fshb*-null mice)[419,541] or FSH receptor (*Fshr*-null mice)[421,513] exhibit phenotypes that are consistent with a severe reduction in circulating estrogens, including uterine hypoplasia and elevated plasma levels of LH. Furthermore, the ovaries of *Fshb*-null mice exhibit a six-fold reduction in *Cyp19* transcripts,[419] although these data are not corroborated in *Fshr*-null mice.[421] FSH regulation of *Cyp19* expression in granulosa cells is believed to require the actions of multiple transcriptions factors, including steroidogenic factor-1 (SF-1) and β-catenin,[542] CREB protein, GATA-4 and CBP, the former three of which possess cognate response elements within the rodent and human *CYP19* promoter II.[441,520,521,543]

The mechanism by which E2 augments FSH stimulation of aromatase activity or *Cyp19* expression in granulosa cells is unclear but shown to occur in isolated granulosa cell cultures,[442,444–447] ruling out the influence of a thecal cell–derived factor and supporting a direct role for ERβ. Coadministration of FSH and an ER antagonist (tamoxifen) to granulosa cells either in vivo or in vitro inhibits the expected induction of aromatase activity;[544] although others report conflicting data using a different antagonist (ICI 182,780) in whole follicle culture experiments.[497] More recently, Emmen et al.[440] and Rodriguez et al. found that ERβ-null follicles grown in vitro do indeed secrete significantly less E2 relative to wild-type follicles.[455] The absence of a consensus ERE within the rat or human *Cyp19* promoter II makes it unlikely that the effect of E2 is via a direct ERβ mechanism (Figure 25.4). However, ERβ may interact with the cAMP/PKA pathway, SF-1, CREB, GATA-4, CBP, or other unknown transcription factors that act to promote *Cyp19* expression. Indeed, ERβ has been shown to associate with both CREB[519] and CBP[545,546] in heterologous in vitro systems. The ERs are also known to influence GATA-directed gene expression via direct interactions with multiple members of the GATA family of transcription factors.[474,547] Therefore, there is ample evidence to support ER interaction with the multitude of transcription factors known to influence *Cyp19* expression, but the exact nature by which ERβ is involved requires further study.

ACQUISITION OF LUTEINIZING HORMONE RECEPTOR

In contrast to the constitutive expression of LH receptor in thecal cells, granulosa cells express LH receptor only in follicles in the late preovulatory stage. This limited expression of LH receptor to the granulosa cells of healthy preovulatory follicles provides for an intraovarian mechanism that ensures only those follicles that are suitable for ovulation acquire the capacity to respond to the LH surge. As with the other markers of follicle differentiation discussed previously, FSH is the primary stimulus of LH-receptor (*Lhcgr*) expression in preovulatory granulosa cells. However, FSH exposure alone leads to a minimal increase of LH-receptor levels in the ovaries of hypophysectomized rats, and then only after 4 days of treatment; whereas pretreatment of animals with E2 for 4 days prior to FSH exposure leads to an enormous induction of LH-receptor levels that are limited to the granulosa cells of preovulatory follicles (Figure 25.20).[359] This requirement for FSH plus E2 and the temporal pattern of LH-receptor expression has been reproduced in rat granulosa cells in vitro, with maximum levels reached after 48–72 h.[515,548,549] *Lhcgr* mRNA levels mirror the LH-receptor protein levels and exhibit a comparable FSH/E2 regulation in rat granulosa cells.[550] Further confirmation that estrogens are required to augment FSH-induced LH-receptor expression in granulosa cells comes from studies that have collectively shown the following: (1) only estrogens (e.g., E2, diethylstilbestrol) or substrates for aromatization (e.g., androstenedione, T, estrone) are effective,[515,548,549] (2) nonaromatizable androgens (e.g., DHT) and P have little effect (Figure 25.20),[515,549] (3) co-treatment with aromatase inhibitors, ER antagonists, or 17β-E2-specific antisera block FSH induction of LH receptor[484,514,548] and hCG-induced ovulation,[485] and (4) *Lhcgr* levels are decreased five-fold in the ovaries of Cyp19-null mice.[479] The poor ovulatory response of ERβ-null ovaries to an ovulatory dose of the LH analog, hCG,[171,432] strongly suggests that ERβ mediates the synergistic actions of E2 during FSH induction of the *Lhcgr* gene in granulosa cells.[134,171] In contrast, the granulosa cells of large antral follicles in ERα-null ovaries exhibit abnormally high levels of LH receptor, even after becoming enlarged and cystic.[134,373]

The complexity of the *Lhcgr* promoter is illustrated by the differential regulation between thecal and preovulatory granulosa cells. Not surprisingly, FSH induction of LH-receptor expression in granulosa cells occurs via the cAMP/PKA pathway.[551–554] However, the proximal promoter of the *Lhcgr* gene in both humans and rats lacks a consensus cAMP response element (CRE) similar to those that confer FSH regulation of the *Cyp19* promoter II.[555,556] Studies indicate that a GC-rich region possessing a cluster of Sp1 binding sites and an ERE half site contributes to FSH and 8-bromo-cAMP induction of the rat *Lhcgr* promoter in vitro.[557–559] Furthermore, multiple nonconsensus cAMP-response elements within this GC-rich region of the rat *Lhcgr* promoter provide a platform for assembling an undefined complex of nuclear proteins from granulosa cell extracts that confer cAMP induction.[556,560] With such limited data concerning *Lhcgr* regulation, it is difficult to speculate where the actions of ERβ may impact LH responsiveness in granulosa cells. ERβ-null granulosa cells have reduced cAMP accumulation after FSH signaling and also show reduced *Lhcgr* accumulation compared to wild-type granulosa cells.[454]

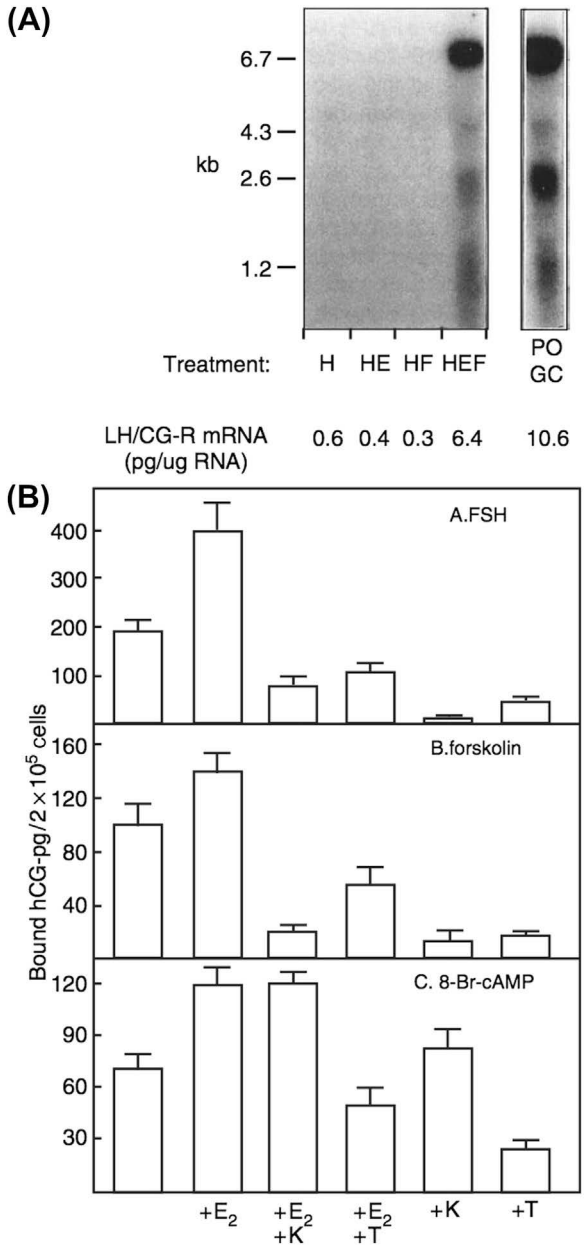

FIGURE 25.20 Synergistic action of E2 and FSH in the induction of LH receptor in rodent granulosa cells. (A) Induction of *Lhcgr* (LH/CG-R) mRNA in granulosa cells of hypophysectomized rats after treatment with FSH and/or E2. Animals were untreated (H) or injected with 1.5 mg E2/day for 3 days (HE), 1 mg FSH twice daily for 2 days (HF), or a sequential combination of E then FSH (HEF). Animals were euthanized after treatment and granulosa cells isolated from the ovaries for total RNA extraction. *Top*: Northern blot of 20 µg RNA/lane probed for *Lhcgr* (LH/CG-R) mRNA. (PO GC: pro-ovulatory granulosa cell RNA) *(Source: Reproduced with permission from Ref.* 550.*)* (B) Effect of antiestrogens on the induction of LH-receptor levels by FSH, forskolin, or 8-bromo-cAMP. Granulosa cells were isolated from immature rats implanted with DES pellets for 4 days. 2×10^5 cells were cultured for 48 h with FSH (100 ng), forskolin (10 µM), or 8-bromo-cAMP (5 nM), with or without E2, 10^{-8} M in the absence or presence of antiestrogens, keoxifene (K, 1 µM), or tamoxifen (T, 1 µM). Media were then removed and cells were analyzed for LH-receptor content by radiolabeled binding assay. The *first bar* on the left side of the figure is FSH (A), forskolin (B), or 8-bromo-cAMP (C) alone. Control cells bound less than 10 pg hCG/2×10^5 cells, and the data are not shown. *Source: Reproduced with permission from Ref.* 514.

The reduced expression suggests it may be downstream of cAMP, and in vitro follicle culture studies found increased *Lhcgr* expression when follicles were treated with forskolin to induce cAMP accumulation.[455]

As discussed before, E2 enhances the level and action of FSH-stimulated increases in intracellular cAMP to maximize *Cyp19* expression, and it is likely that a similar mechanism is employed for induction of LH-receptor levels. However, there are notable differences in the E2/FSH regulation of *Cyp19* versus *Lhcgr* expression. FSH induction of *Lhcgr* expression in preovulatory granulosa cells is augmented by estrogens only,[515,548,549] whereas nonaromatizable androgens or estrogens act through their respective receptor pathways to enhance FSH induction of *Cyp19* expression.[442] This divergence in regulation is critical since androgen augmentation of FSH on *Cyp19* expression allows for FSH/AR-mediated initiation of E2 synthesis in preantral follicles shortly after thecal cells begin synthesizing aromatizable precursors; whereas the specificity for ER/E2 actions in the FSH induction of the *Lhcgr* gene provides that LH receptors are acquired only by those follicles that have sufficient E2 synthesis, and are hence healthy and suitable for ovulation. Secondly, Farookhi and Desjardins[549] demonstrated that FSH induction of *Lhcgr* but not *Cyp19* expression is lost when estrogen-pretreated granulosa cells are dispersed in culture by EGTA-disruption of cell–cell contacts.[549] A requirement for intact cell–cell contacts for E2/FSH-mediated *Lhcgr* expression may ensure that atretic follicles, which often exhibit a fragmented and less compact granulosa cell population, do not acquire the capacity to respond to an LH surge and ovulate an unhealthy oocyte.

ESTRADIOL MEDIATED NEGATIVE FEEDBACK ON THECAL CELL FUNCTION

Like granulosa cells, follicular thecal cells also undergo a process of differentiation during progression from a preantral to preovulatory follicle.[561] Fully differentiated thecal cells are best characterized by their unique capacity to convert cholesterol to C_{19} steroids, primarily androstenedione.[561] A principal element of the *two-cell, two-gonadotropin* paradigm of steroidogenesis in maturing follicles (Figure 25.21) is that thecal cells exclusively possess the 17β-hydroxylase:$C_{17,20}$-lyase activity necessary for synthesizing androgens, forcing the granulosa cell layer to be dependent upon the theca as a source of aromatizable precursors.[562] Thecal cell synthesis of androstenedione is considered the rate-limiting step in E2 production by preovulatory follicles and involves the sequential enzymatic actions of $P450_{scc}$ (CYP11), $P450_{17\alpha/17,20\text{-lyase}}$ (CYP17) and Δ^5-3β-hydroxysteroid dehydrogenase (3β-HSD 1).[562] It is generally accepted that LH regulates thecal cell steroidogenesis via the induction of CYP17 and CYP11 activity,[561] while 3β-HSD 1 is constitutive.[562] The requirement of LH stimulation to induce CYP17 activity in thecal cells

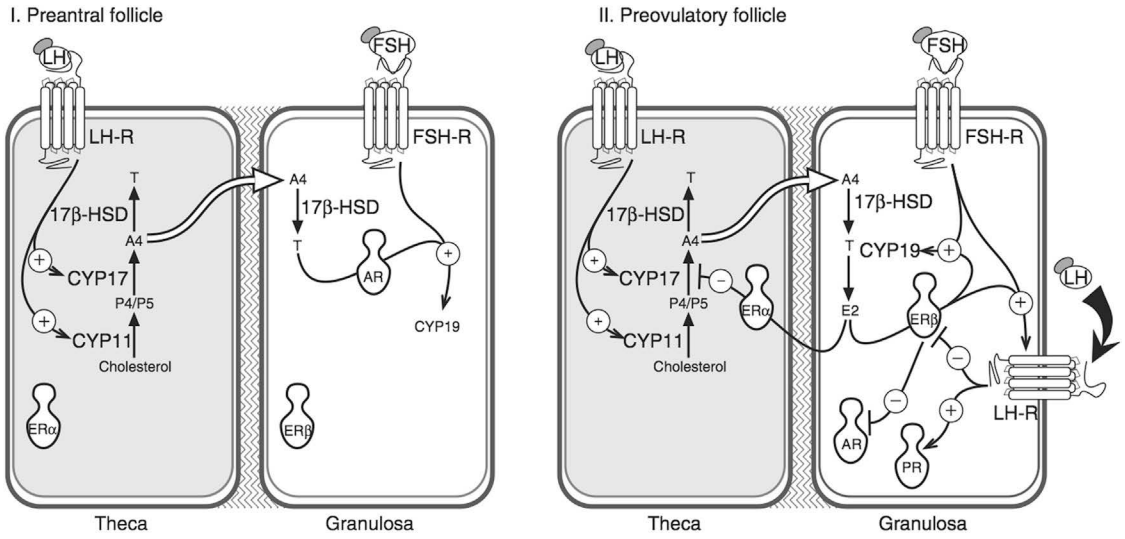

FIGURE 25.21 Model of sex steroid receptor actions in the ovary during follicular differentiation. The process of follicle differentiation from preantral to preovulatory follicle is marked in granulosa cells by the induction of aromatase (CYP19) activity for the synthesis of E2 and LH-receptor (LH-R) expression. This process is principally dependent on stimulation of thecal cells by LH and granulosa cells by FSH. However, there is substantial evidence of a modulatory role for the sex steroid receptors in this process. The above model illustrates the putative expression pattern and actions of the sex steroid receptors during follicle differentiation. Some aspects of the above model are supported by experimental data, whereas others are more speculation at this time (see text for details). (I) Preantral Follicle: In undifferentiated preantral follicles, LH stimulation of thecal cells (which constitutively express LH-R) leads to de novo synthesis of androstenedione (A4) and T. A4 and T diffuse across the basement membrane of the follicle and into the granulosa cells. A4 may be converted to T in granulosa cells. Thecal-cell derived or locally synthesized T activates the androgen receptor (AR), and this action synergizes with FSH to induce aromatase (CYP19) expression in the granulosa cells. The induction of E2 synthesis commences the process of follicle differentiation. (II) Preovulatory Follicle: Increasing E2 synthesis in the granulosa cells leads to activation of ERβ and induces differentiation by synergizing with FSH to further increase CYP19 expression and E2 synthesis and induce LH-R expression in the granulosa cells. Ligand-dependent ERβ actions may also lead to decreased AR expression, allowing the role of A4 and T to shift from that of a ligand for AR-mediated actions to that as substrates for E2 synthesis. Increasing E2 levels eventually activate ERα in thecal cells to reduce further androgen synthesis by decreasing CYP17 activity, forming a negative feedback loop to ensure the proper estrogen-to-androgen ratio in the follicle. LH Surge: Climaxing E2 levels in the circulation facilitate the release of the LH surge from the pituitary, which stimulates ovulation and terminal differentiation of the granulosa cells. Only those follicles that possess properly differentiated granulosa cells (i.e., have acquired sufficient LH-R) are able to respond to the LH surge, which causes a dramatic rise in PR expression that occurs in the preovulatory granulosa cells within hours of the LH surge, whereas ERβ and CYP19 levels are both dramatically decreased.

is effectively illustrated by the 12-fold reduction in *Cyp17* expression in ovaries of LH-receptor (*Lhcgr*)-null mice,[563] as well as the five-fold increase in expression in the ovaries of transgenic mice that possess chronically elevated LH levels.[439] Likewise, chronically elevated plasma LH leads to a comparable increase in *Cyp17* expression and androstenedione synthesis in both ERα-null and ERβ-null ovaries and cultured follicles, indicating that neither ER is obligatory to the positive regulation of thecal cell steroidogenesis.[431,439,564]

Therefore, androgens are necessary to serve as both a stimulus of and substrate for aromatase activity in granulosa cells. However, a proper androgen:estrogen ratio is critical as an intrafollicular milieu of increased androgens is strongly associated with atresia.[565] It is generally believed that an intraovarian mechanism exists to negatively modulate thecal cell androgen synthesis so that levels do not surpass the aromatase capacity of the granulosa cell layer. Indeed, defects in this intraovarian mechanism are postulated to be an underlying cause of the excess thecal cell androgen synthesis that is a hallmark of polycystic ovarian syndrome (PCOS) in women. There is ample evidence that granulosa cell–derived E2 may mediate a feedback loop on thecal cells to decrease further androgen synthesis in thecal cells,[566] however, the mechanism remains unclear. Magoffin posed the question several years ago as to whether E2 inhibition of androgen synthesis occurs at the level of steroidogenic enzyme expression or via direct inhibition of enzymatic activity.[561] Indeed, estrogens have been shown to inhibit CYP17 activity in both thecal and Leydig cell preparations while having no effect on activities of the upstream steroidogenic enzymes.[566–571] Early studies found that E2 can compete with androstenedione for CYP17 enzymatic activity;[568] however, this effect could not be reproduced in ovarian lysates in vitro.[572] Additional studies in dispersed rat ovarian cells found that E2 has no effect on the number of LH receptors or level of hCG-stimulated cAMP synthesis, further supporting a direct E2 inhibition of CYP17 activity as a mechanism for regulating androgen synthesis.[570] However, other evidence supports a role for ER-mediated regulation of *Cyp17* expression at the transcriptional level, including demonstrations that an antiestrogen blocks the expected drop in CYP17

activity that occurs just prior to ovulation in rats,[573] and that E2 significantly reduces *Cyp17* expression in the testes of rats[574] and fish.[575] Our findings that ERα-null ovaries exhibit increased *Cyp17* expression and enzymatic activity despite a milieu of significantly elevated E2 also supports a mechanism of ERα-mediated suppression of *Cyp17* transcription in thecal cells versus direct inhibition of CYP17 activity.[431] Furthermore, Taniguchi demonstrated that in vitro–cultured ERα-null follicles have increased *Cyp17* expression similar to that observed in WT follicles cultured in the presence of an aromatase inhibitor.[564] Treatment of ERα-null follicles with E2 or an ERα-specific agonist as well as an aromatase inhibitor reduced *Cyp17* expression to that observed in wild-type vehicle treated follicles.[564] Therefore, the excess androgen synthesis observed in ERα-null ovaries is due to the loss of ERα-mediated suppression of *Cyp17* expression, indicating the existence of intraovarian feedback actions of E2 that are mediated by ERα and critical to maintaining homeostasis of androgen levels in the female mouse.

OVULATION

E2 clearly facilitates the acquisition of several gonadotropin-dependent effects during folliculogenesis, including: (1) the proper cellular organization of the follicle, e.g., antrum and cumulus oocyte complex; (2) the necessary enzymatic activity, e.g., E2 synthesis; and (3) the essential receptor signaling pathways; e.g., LH receptor. All of these characteristics define a healthy differentiated follicle and are necessary for a proper response to the gonadotropin surge and expulsion of a competent oocyte. However, a need for estrogen signaling in the ovulating follicle or following the postgonadotropin surge remains unclear. Selvaraj et al.[485] found that coadministration of immature rats with PMSG and an aromatase inhibitor (Fadrazole) leads to a reduced number of healthy antral follicles that culminates with a severely reduced ovulatory response to a bolus of hCG. These data support the intrafollicular role of E2 in preparing competent preovulatory follicles for ovulation. However, in an additional experiment, Selvaraj et al. once again treated immature rats with PMSG but delayed administration of the aromatase inhibitor by 40 h such that exposure occurred just 6 h prior to hCG induced ovulation.[485] These animals exhibit an equally poor response in terms of follicular rupture and recoverable oocytes from the oviduct; and this effect is abated by coadministration of E2 just prior to induced ovulation. These data in turn suggest that E2 does facilitate the ovulatory process. However, inhibition of E2 synthesis is known to cause severe intraovarian[485] and intrafollicular[523] accumulations of P and androgens that could also lead to a poor ovulatory response. In contrast to the above in vivo findings, Hu et al. reports that isolated mouse follicles grown exposed to an aromatase inhibitor in vitro exhibit a normal ovulatory response to hCG, including mucification of the cumulus–oocyte complex.[523] Furthermore, detrimental effects of aromatase inhibition such as those reported in the rat ovary are not observed in similarly treated hamsters, rabbits, or monkeys.[486]

Multiple investigations of the ovulatory capacity of ER-null and CYP19-null mice have been conducted. As described before, ERα-null females are anovulatory throughout life and gonadotropin-induced ovulation is unsuccessful in ERα-null females at 4 months of age when the ovarian cystic phenotype is advanced.[373] However, immature (≤28 days of age) ERα-null (αERKO) females do respond to induced ovulation and yield recoverable oocytes in the oviduct at an average yield of 14.5 oocytes/ERα-null female versus 40.6 oocytes/wild-type female.[415] Similar data has been reported in ERα-null females as old as 5 weeks of age.[415,430] Interestingly, Dupont et al. report that immature females from their ERα-null (ERαKO) line exhibit a total failure to ovulate in response to exogenous gonadotropin treatments, although this study involved only three females.[158] Preliminary studies suggest Ex3αERKO mice[159] have a significantly reduced ovulation response, where less than 50% of mice ovulate in response to exogenous gonadotropins, with few oocytes produced from those that do ovulate (Korach laboratory, unpublished data). These observations suggest that the response observed previously[415] was possibly due to the presence of residual ERα splice variant expressed in the αERKO mice,[159,189] thus further studies are underway to confirm these preliminary studies.

The cause of the reduced ovulatory response to exogenous gonadotropins in ERα-null females is unclear and suggests a facilitatory role for ERα in follicular rupture. However, the expected induction of several genes that are critical to follicle rupture, such as P receptor, prostaglandin-synthase-2,[576] occurs in gonadotropin-primed ERα-null ovaries shortly after hCG treatment.[415,432] Furthermore, ERα-null ovaries form functional corpora lutea following induced ovulation, indicating that granulosa cells of ERα-null preovulatory follicles possess the capacity to respond to LH. Therefore, the reduced ovulatory response in ERα-null ovaries is more likely attributable to premature increases in endogenous plasma LH[415] and subsequent ovarian androgen synthesis.[415,430] Although immature ERα-null ovaries do not yet manifest the overt morphological effects of LH-hyperstimulation, e.g., cystic follicles, they do exhibit elevated LH-receptor levels.[415] Cumulative damage in the ovary from chronic LH hyperstimulation likely causes the age-related reduction in gonadotropin-induced ovulatory capacity in ERα-null females discussed previously. Indeed, Armstrong and colleagues demonstrated in rats that treatment with PMSG preparations possessing increased LH activity lead to a reduced ovulatory response to subsequent hCG stimulation[577,578] and that this effect is likely due to inappropriately high stimulation of androgen synthesis during follicle maturation.[578] Studies showing ERα-null follicles allowed to differentiate in vitro under controlled hormonal

stimulation exhibit a rate of hCG-induced rupture that is comparable to similarly cultured wild-type follicles further indicating that any role for ERα in the ovulatory process is minimal.[440] The ERα was found to be necessary for ovulatory response in aging animals, as thEsr1KO mice had normal ovulatory response at 2 months that was severely dampened by the time the mice were 6 months old.[362] The premature loss of fertility in these mice suggests that ERα is important for normal ovulatory function; however, the precise mechanism has yet to be elucidated.

The loss of functional ERβ clearly leads to ovarian defects that are inhibitory to ovulation. Both lines of ERβ-null females exhibit severely reduced fertility due to ovarian defects; however, unlike ERα-null females, ERβ-null animals do spontaneously ovulate.[158,171] Krege et al. found that immature ERβ-null (βERKO) females exhibit a severely reduced oocyte yield of 6 oocytes/female versus 34 oocytes/female among age-matched wild-types following gonadotropin-induced ovulation.[171] Dupont et al. report a similar average yield in immature ERβKO females (17.6 versus 37 oocytes/female), even when excluding those females that do not ovulate at all.[158] A third line of ERβ-null mice was found to be unresponsive to exogenous gonadotropins, and no animals were able to ovulate ($n=19$).[172] Collectively, even though some animals are able to respond with some oocytes ovulated, the models demonstrate the necessity of ERβ for optimal ovulatory response.

Immature ERβ-null ovaries collected 20 h after hCG-induced ovulation reveal multiple preovulatory follicles that retain their oocyte and fail to undergo expansion of the cumulus–oocyte complex.[158,171,432] Furthermore, hCG induction of prostaglandin-synthase 2 and PR, two events that are critical to follicular rupture, are significantly compromised in immature βERKO ovaries.[432] ERβ-null follicles induced to ovulate in vitro exhibit an equally poor rate of rupture and gene induction following hCG exposure.[440] The sum of in vivo and in vitro data from ERβ-null mice strongly indicates an inability to fully respond to an endogenous LH surge or an exogenous bolus of hCG. This is likely due to insufficient acquisition of LH-receptor expression among granulosa cells of ERβ-null preovulatory follicles.[432,440,455] Indeed, Clemens et al. found that the ER-antagonist ICI 164,384 inhibits FSH-induced differentiation of rat granulosa cells in vitro, as illustrated by a severely compromised induction of PR expression following stimulation of the cAMP/PKA signaling pathway.[579] However, if exposure to the ER antagonist is delayed until the time of ovulatory stimulation, little effect is observed,[579] further supporting a role for ERβ in granulosa cell differentiation and LH-receptor expression rather than during ovulation. ERβ-null follicles cultured in vitro also have a reduced ovulatory response and reduced cAMP accumulations after FSH stimulation.[455] Interestingly, treatment of these follicles with forskolin to increase cAMP levels was able to increase the ovulation of these follicles in vitro,[455] suggesting that ERβ is necessary for maximal ovulatory response downstream of gonadotropins, although ERβ is not directly contributing to follicle rupture.

Evidence of any cooperative action between ERα and ERβ in ovulation may be derived from studies of the compound ER-null and CYP19-null mice. The single report of induced ovulation in immature ERα/ERβ-null (ERαβKO) females describes a total failure of ovulation.[158] Not surprisingly, ovaries from these females exhibited underdeveloped preovulatory follicles that failed to exhibit cumulus–oocyte complex expansion or luteinization,[158] indicating an attenuated response to hCG similar to that in ERβ-null ovaries. Investigations in both lines of Cyp19-null females produced comparable results of a total failure to ovulate and luteinize.[131,580] Interestingly, Huynh et al. remarked that cumulus–oocyte complexes lacking oocytes were recovered from the oviducts of 4-week-old Cyp19-null females following induced ovulation, indicating that some elements of follicle rupture may occur after degradation of the oocyte.[580] The more severe ovulatory phenotypes in compound ER-null and Cyp19-null females suggest that the intraovarian functions of both ERα and ERβ are necessary for ovulation but not necessarily for the process of follicular rupture. Recent studies in Cyp19-null mice suggest that treatment with E2 as well as exogenous gonadotropins could stimulate some ovulation,[365] suggesting the importance of the steroid and gonadotropin hormones in regulating ovulation.

ERα MEDIATED REPRESSION OF LEYDIG CELL DEVELOPMENT IN THE OVARY

As discussed in earlier sections, female mice lacking ERα action due either to the loss of receptor (αERKO, thEsr1KO, and αβERKO) or ligand (Cyp19-null) exhibit abnormally high levels of plasma T. For example, the average plasma T level in adult αERKO and αβERKO females is 5.5 ng/ml and 2.1 ng/ml, respectively, versus 0.14 ng/ml in wild-type females.[431] In females of the two existing Cyp19-null lines, Fisher et al. report average plasma T levels in mutant females to be 2.3 ng/ml versus 0.24 ng/ml in wild-type;[156] while Toda et al. report 1.4 ng/ml in the mutant females versus 0.13 ng/ml in wild-type.[131] These levels of plasma T in ERα-null and Cyp19-null females surpass the lower limits characteristic of normal male mice (2–10 ng/ml)[131,156,581] and are obviously very uncharacteristic of normal females. The mouse ovary possesses the enzymatic machinery necessary for T synthesis, although it is not a major product. The *two-cell, two-gonadotropin* paradigm of ovarian steroidogenesis (Figure 25.21) postulates that thecal cell–derived androstenedione serves as a substrate for two sequential reactions in granulosa cells, CYP19-mediated aromatization to estrone followed by a reduction to E2 by 17β-hydroxysteroid dehydrogenase type I

(*HSD17β1*).[561] The murine form of 17β-HSD 1 is reported to efficiently reduce androstenedione to T as well as estrone to E2; whereas the human form may not possess this activity.[582] Therefore, the accumulation of androstenedione that occurs in ERα-null and Cyp19-null ovaries due to LH hyperstimulation of the theca in both, and the absence of aromatization in the latter,[156,431] provides for sufficient substrate for 17β-HSD 1 conversion to T. However, further investigations have discovered that ERα-null[431] and Cyp19-null[479] ovaries uniquely possess substantial levels of 17β-hydroxysteroid dehydrogenase type III (*Hsd17b3*), a Leydig cell–specific enzyme in testes that specifically functions to reduce androstenedione to T.[583–587] Remarkably, the level of *Hsd17b3* expression in αERKO, αβERKO,[431] and Cyp19-null[479] ovaries is comparable to that found in testes of wild-type males. Therefore, the abnormally high capacity of ERα-null and Cyp19-null ovaries to synthesize T may be attributed to the accumulation of androstenedione and its conversion to T by 17β-HSD 3 rather than 17β-HSD 1.

Hsd17b3 expression in Leydig cells is primarily LH regulated.[585] The ectopic expression in ERα-null ovaries is also dependent on LH hyperstimulation as expression is eradicated following prolonged treatment of animals with a GnRH antagonist.[431] In ERα-null females, *Hsd17b3* expression is limited to the ovarian interstitium and possibly the theca.[588] However, it is unclear whether these cells are Leydig-like and suggestive of an "organizational" defect in ERα-null ovaries or are thecal/interstitial type cells within which the loss of ERα leads to loss of *Hsd17b3* repression, i.e., an "activational" defect. Evidence to support the latter hypothesis includes: (1) testes from ERα-null males also exhibit elevated *Hsd17b3* expression and T synthesis,[589] (2) female mice possessing chronically elevated LH but intact ERα signaling do not exhibit ovarian *Hsd17b3* expression,[439] and (3) prolonged E2 therapy in Cyp19-null females eradicates *Hsd17b3* expression.[479] In turn, there exists supporting evidence for the former hypothesis that a defect during ovarian differentiation may occur in the absence of ERα. Thecal and Leydig cells are believed to derive from a common bi-potent embryological precursor cell during gonadal differentiation. In Cyp19-null ovaries, Britt et al. have described the presence of cells resembling the mature Leydig cells of testes, in that they possess a tubulovesicular arrangement of mitochondrial cristae, an annular nucleolus, and an abundance of smooth endoplasmic reticulum in whorl-like formations.[194] These Leydig cell–like ultrastructural features were also observed in ERα-null ovaries.[588] These Leydig-like cells in Cyp19-null ovaries are located in the interstitial regions and often proximal to the basement membrane of atretic follicles that exhibit Sertoli-like cells in the follicle lumen.[194] Indeed, E2 is a potent inhibitor of Leydig cell proliferation in vitro and in vivo,[590] and E2 replacement in Cyp19-null females reduces the presence of Leydig-like cells in the ovaries.[479] Therefore, ERα may be critical to promoting thecal cell differentiation and inhibiting the Leydig cell phenotype during ovarian differentiation. A similar phenotype of Leydig cell differentiation, *Hsd17b3* expression, and "masculinization" of the ovary and reproductive tract is reported in female mice lacking *Wnt4* function.[466]

DISRUPTED ESTROGEN SIGNALING IN HUMANS

There is one case of a human female that is autosomal recessive for an inactivating mutation of the *ESR1* (ERα) but no patients with *ESR2* (ERβ) mutation reported. There are cases of human females that are autosomal recessive for inactivating mutations of the *CYP19* gene and therefore lack the ability to synthesize E2.[591–597] The CYP19 mutated females present with androgen-induced pseudohermaphrodism at birth,[591–593] and amenarche, polycystic ovaries, and an absence of female secondary sex characteristics at puberty.[591,593,594] Three reports describe elevated plasma FSH and LH levels, leading to hypergonadism that manifests as increased plasma androgens and virulization.[591,593,594] The female with Esr1 mutation has polycystic ovaries and elevated E2. The ovarian pathology exhibited is somewhat similar to that observed in ERα-null females and compatible with a diagnosis of PCOS.[593] To date there are no indications of "sex reversal" in terms of male cell types or gene expression in the ovaries of CYP19-null human females. Estrogen and P replacement effectively alleviates all of the above phenotypes.[591,593,594]

Polymorphisms of the human *ESR1* gene have been linked to breast cancer, cardiovascular disease, osteoporosis cognitive function, and multiple reproductive anomalies.[598–603] A polymorphic $(TA)_n$ repeat within the *ESR1* promoter region has been linked to premature ovarian failure[604] but has no effect on plasma levels of E2, sex-hormone binding globulin (SHBG), T, or FSH in premenopausal women during the follicular phase.[605] Two *PvuII* single nucleotide polymorphisms (SNP) in the *ERS1* gene have been described to date. The first of these is a glutamine-to-glycine transformation at amino acid 400[606] and has received little investigative attention. The second is an anonymous SNP located in intron 1, 400 bp upstream of exon 2,[607] and is found in approximately 30% of women.[608–612] Although the intronic *ESR1 PvuII* SNP does not affect ERα receptor levels,[607] it may be associated with: (1) poor performance in women undergoing in vitro fertilization,[608,612] (2) increased plasma E2 and androstenedione levels,[610,612] and (3) late onset of menarche and/or menopause.[609,611,613,614] Two SNP of the *ESR2* gene have been described to date, an *RsaI* SNP leads to a silent nucleotide change in exon 5, and an *AluI* SNP occurs in the 3′-untranslated region of exon 8.[615] Sundarrajan et al. found that Chinese women that are homozygous for either the *RsaI* or *AluI* SNP of the *ESR2* gene are more

prone to exhibit ovulatory defects, menstrual disorders, and elevated LH; while women that are homozygous for both exhibit more severe idiopathic ovulatory defects.[616]

Progesterone Receptor Signaling in Ovarian Function

PR Expression in the Ovary

The first report of saturable, high-affinity P binding sites in the rat ovary is that of Schreiber and colleagues in 1979[617,618] and has since been followed by similar descriptions in human[389–391,619] and cow[619,620] ovaries. Later immunohistochemical studies primarily localized ovarian PR expression to the theca of large preovulatory follicles, the surface epithelia, and stromal/interstitium, and found this expression pattern is well conserved among species, including mice,[621,622] pig,[623] monkeys,[386,624] and humans.[392,625,626] Numerous studies in species ranging from rodents to large domestic animals and primates agree that granulosa cells possess minimal PR expression throughout folliculogenesis except for the period 2–4 h after the preovulatory gonadotropin surge, whereupon an enormous induction of PR expression occurs in preovulatory granulosa cells and peaks just prior to follicle rupture[386,392,415,621–624,627–630] (Figure 25.22). This dramatic increase in PR expression in the granulosa cells of ovulatory follicles is absolutely essential to follicle rupture.[182,631] This induction of PR expression in ovulating follicles is quite transient and lasts less than 12 h in rodent ovaries[415,621,628] but is maintained throughout luteinization and corpus luteum formation in porcine[623] and primate[386,392,624] ovaries.

The regulation of ovarian PR expression prior to the preovulatory surge is poorly characterized. PMSG treatment of immature rats leads to a four-fold increase in cytosolic P binding sites[632] and a modest two-fold increase in *Pgr* mRNA levels[628] after 48 h, indicating that FSH or subsequent E2 signaling may stimulate these basal levels of PR expression. In contrast, the mechanisms underlying the dramatic induction of PR expression in preovulatory granulosa following the gonadotropin surge are relatively well characterized. Over the course of the estrous cycle in rats, *Pgr* mRNA levels are increased >30-fold during a 4 h period (1800–2200 h) on the evening of proestrus and then return to baseline shortly after (2400 h).[628] The increased expression is almost exclusive to the mural granulosa cells of healthy preovulatory follicles in rats,[628,633] indicating that only fully differentiated granulosa cells possess the capacity for such rapid induction of the *Pgr* gene (Figure 25.22). Although PR expression climaxes within hours after plasma E2 and LH levels climax, the following evidence indicates LH is most directly involved: (1) expression peaks just 2 h after plasma LH levels climax versus >8 h after peak plasma E2 levels,[628] (2) hCG treatment 48 h after PMSG exposure leads to a comparable increase in PR expression, whereas PMSG and concomitant increases in E2 have a minimal effect,[415,621,628] (3) treatment of hypophysectomized or immature rats, or differentiated rat granulosa cells with E2 has no marked effect on ovarian PR expression,[422,634] (4) inhibition of the LH surge by pentobarbital abates the increase in PR expression despite having no effect on the rise in plasma E2 levels,[628] (5) LH but not E2 elicits a dramatic PR induction in differentiated granulosa cells from rat[634,635] or porcine[629] ovaries in vitro, (6) an ER antagonist (ICI 164,384) does not inhibit forskolin-induced PR expression in differentiated rat granulosa cells,[579] (7) the putative ERE-like region of the rat *Pgr* promoter does not bind ERα or ERβ in ovarian extracts,[579] and (8) ER (mainly ERβ) levels are rapidly decreasing at the time of rising PR expression in preovulatory granulosa cells.[367,371,380,415]

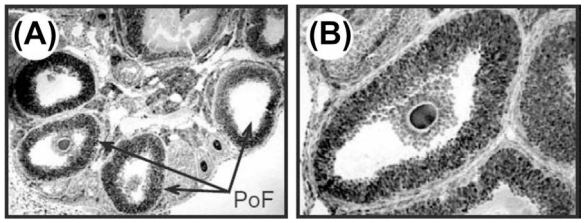

FIGURE 25.22 Regulation of PR expression in mouse ovaries and granulosa cells during gonadotropin-induced ovulation. (A, B) Immunohistochemistry for PR in the ovary of a PMSG-primed mouse 4 h after hCG treatment, illustrating the dramatic induction of PR immunoreactivity in the granulosa cells of preovulatory follicles (POF) but not surrounding preantral follicles. (B, higher magnification of A.)

The above data provide a convincing argument that the rapid and transient induction of PR expression in preovulatory granulosa cells is directly mediated by the LH surge. Clearly only granulosa cells of preovulatory follicles in vivo or fully differentiated granulosa cells in vitro possess the capacity to respond to the LH surge and increase PR expression, presumably due to their unique acquisition of LH receptor.[579,634] Indeed, granulosa cells isolated from estrogen-primed immature rats require a 48-h exposure to physiological concentrations of FSH and T to acquire LH induction of PR expression.[579] LH-mediated induction of the intracellular cAMP/protein kinase-A pathway is likely the principal stimulus for increased PR expression in preovulatory granulosa cells as large doses of FSH, forskolin, or $(Bu)_2$cAMP also elicit a comparable response in rat ovaries in vivo[634] and differentiated rat[634,635] or porcine[629] granulosa cells in vitro. However, GnRH, PMA, or EGF exposure of differentiated rat granulosa cells in vitro elicits a comparable induction and temporal pattern of PR expression, suggesting that stimulation of protein kinase C or tyrosine kinase signaling cascades may also be involved.[635] In fact, Sriraman et al. report that forskolin and PMA synergize to induce increased PR expression in undifferentiated

primary rat granulosa cells.[636] However, studies in fully differentiated rat granulosa cells demonstrate that forskolin-induction of PR expression is fully blocked by co-treatment with a PKA inhibitor (H89) but only minimally affected by a PKC inhibitor (Cal-C),[579] indicating a greater importance for the former signaling pathway.

The mechanisms by which LH activation of the PKA pathway leads to increased PR expression in preovulatory granulosa cells remain unclear. The *Pgr* promoter is complex, consisting of distal and proximal regions and able to give rise to multiple transcripts.[31,33] Initial studies concluded that an estrogen-response element-like region (ERE3) within the proximal rat *Pgr* promoter is important to LH induction,[579] but later studies that better modeled the structure of the rat *Pgr* promoter indicated these sequences are dispensable.[636] Sriraman et al.[636] demonstrated that two Sp1/Sp3 binding sites within the proximal promoter of the mouse *Pgr* gene bind Sp1/Sp3 and are essential to forskolin/PMA-induced expression. Furthermore, LH induction of *Pgr* also involves MAPK activation as mice lacking ERK1/2 in granulosa cells do not induce expression of *Pgr* in response to an hCG ovulatory signal.[637] While these mice show reduced expression, the direct targets of ERK1/2 remain unknown at this time. Recent evidence in porcine granulosa suggests that androgens may regulate *Pgr* expression, where treatment with either T or an AR antagonist alone reduces *Pgr* expression, while co-treatment leads to increased *Pgr* expression.[638] Further characterization into the molecular mechanisms involved in this regulation is necessary. Therefore, unlike the uterus where *Pgr* is estrogen regulated, estrogen does not have the same effect on ovarian *Pgr*.

Differential expression of the two PR isoforms, PRA and PRB, among thecal and granulosa cells further illustrates the complexity of PR expression in the ovary. Western blot analyses following LH induction indicate a PRA:PRB ratio of 3:1 in differentiated granulosa cells from rats[635] and 2:1 ratio in whole ovaries from mice.[621] In rat ovaries, PRA immunoreactivity is restricted to the thecal cells of preantral and antral follicles prior to the gonadotropin surge; whereas PRB immunoreactivity is detected in both thecal and mural granulosa cells throughout the stages of folliculogenesis and shows less variation over the course of the estrous cycle.[622] The enormous induction of PR expression that occurs in preovulatory granulosa cells on the evening of proestrus is primarily representative of PRA, resulting in a 2:1 ratio of PRA:PRB in these cells.[622] In turn, the more moderate LH-induced increases in PR expression in thecal cells is predominantly PRB.[622] During the metestrous stage and rising P synthesis that follow ovulation, PRB is the sole isoform in thecal cells of preantral and antral follicles.[622] The differential expression of PRA and PRB suggests that specific roles exist for each isoform.

To examine this possibility, Sriraman et al. recently examined genes that were induced by PRA or PRB in granulosa cells in vitro. In the absence of P ligand, PRA regulated 41 genes, while PRB only showed differential expression of seven genes compared to control cells.[639] When the granulosa cells were treated with a PR ligand in vitro, PRA-transduced cells showed an increase in 42 genes, while PRB-transduced cells only showed 27 transcripts that were differentially expressed, while only three transcripts were shared between the two PR isoforms.[639] The differential expression of genes in granulosa cells transduced with either PR isoform supports the hypothesis that specific roles exist for each isoform and provide target genes for future study.

Ovarian Phenotypes in Mouse Models of Disrupted Progesterone Signaling

Several mouse lines have been developed that are null for both PR forms and exhibit grossly normal ovaries but are anovulatory and therefore infertile[176–178] (Table 25.8). Furthermore, gonadotropin-induced ovulation of PR-null females is unable to rescue the anovulatory phenotype as no oocytes could be recovered following treatment.[176,178]

TABLE 25.8 Ovarian Phenotypes in PR-Null Mouse Models

Mutated or Null for Sex Steroid Signaling	Ovarian Phenotypes	Hormone Levels	References
$Pgr^{-/-}$ (homozygous null alleles for PRA and PRB: PRKO)	Anovulatory and infertile Failure to respond to superovulation—large follicles present in ovary with trapped oocytes No follicle rupture No CL	Elevated LH Normal FSH	176–178
$PRA^{-/-}$ (homozygous null alleles for PRA: PRAKO)	Anovulatory and infertile Reduced to no response to superovulation Large follicles present with trapped oocytes similar to PRKO No follicle rupture	Not reported	180
$PRB^{-/-}$ (homozygous null alleles for PRB: PRBKO)	Fertile Ovaries appear normal Respond to superovulation similar to wild-type	Not reported	182,227

Instead, PR-null ovaries following induced ovulation exhibit multiple large, preovulatory follicles, each possessing a healthy, competent oocyte but a total failure to rupture[176,178] (Figure 25.23). The follicular cells of the unruptured preovulatory follicles undergo luteinization and form functional corpora lutea within the expected time frame, suggesting that some elements of an LH response are intact[177,178,182,633] (Figure 25.23). Similar experiments in isoform-specific PR-null females indicate a more severe phenotype following the loss of PRA relative to PRB, as females lacking PRA ovulate an average of 9 oocytes/female versus 32 oocytes/female among wild-type littermates; whereas PRB females exhibit no deficits in oocyte yield.[180,182,227] This finding that the PRA isoform is more critical to ovulation[180] is congruent with the above studies of Gava et al. that demonstrate this isoform is much more dramatically induced by the LH surge in preovulatory granulosa cells. This also supports the finding that PRA in the presence of ligand regulates more genes in granulosa cells in vitro compared to cells expressing PRB.[639] Still, the absolute failure of ovulation even after gonadotropin induction in females lacking both PR forms indicates a level of cooperation between PRA and PRB that is vital to follicular rupture.[180] Recently, a mouse model was developed to use for tissue-specific deletion of PR,[177] however to date only global knockout models have been published that show a similar phenotype as previously reported.[176,178]

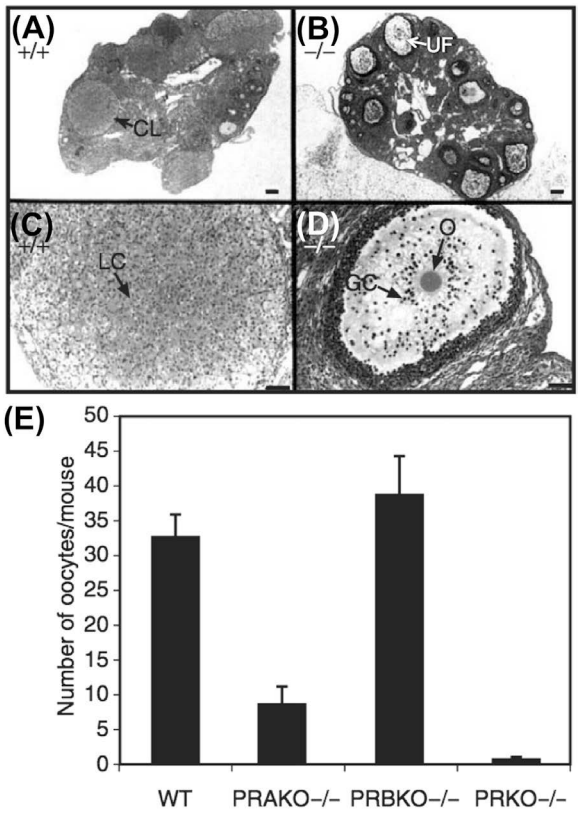

FIGURE 25.23 Ovarian response to gonadotropin-induced ovulation in PR-null mice. (A) Transverse section of a typical ovary isolated from a 6-week-old wild-type mouse (+/+) treated with an intraperitoneal injection of 5 IU of PMSG, followed 48 h later with 5 IU of hCG, and killed 24 h later. Note the presence of numerous corpora lutea (CL). Scale bar = 100 µm. (B) A representative cross-section of an ovary from an age-matched PR-null (−/−) female that was hormonally treated exactly as the wild-type described above. Note the unusual presence of several unruptured follicles (UF) as indicated. Scale bar = 100 µm. (C) High magnification of a corpus luteum in the wild-type ovary, exhibiting the characteristic hypertrophied luteal cells (LC). Scale bar = 50 µm. (D) High magnification of an unruptured follicle present in a PR-null ovary, exhibiting an intact oocyte (O) with a zona pellucida and granulosa cells (GC) that have undergone cumulus expansion. Note the lack of luteinization among the GCs in the PR-null follicle compared to those in the wild-type (C). Scale bar = 50 µm. *(Source: (A–D) reproduced with permission from Ref. 176.)* (E) Average number of oocytes (±SEM) released per mouse after gonadotropin-induced ovulation in wild-type (WT), PRA-null (PRAKO−/−), PRB-null (PRBKO−/−), and PR-null (PRKO−/−) mice; $n = 8$ per test group. *Source: Reproduced with permission from Ref. 182.*

Intraovarian Role of Progesterone in Ovarian Function

FOLLICLE GROWTH AND DIFFERENTIATION

Although immunohistochemical studies indicate that both PR isoforms are expressed at basal levels throughout thecal and granulosa cells,[622] there is little evidence that P action profoundly influences follicle growth and differentiation in the rodent ovary. Administration of P or synthetic progestins to immature or hypophysectomized rats has no obvious effect in the ovary in terms of estrogen receptor levels[358,422] or gonadotropin/estrogen-induced follicle growth and maturation.[358,640] In addition, P has no measurable influence on FSH-induced granulosa cell proliferation[496] or growth and differentiation of whole follicles[497] in vitro. Perhaps most indicative of a minor role for P signaling during folliculogenesis prior to ovulation is the lack of any overt phenotype in follicle growth, maturation, or steroidogenesis in the ovaries of PR-null mice (Table 25.8).[176–178,641] Indeed, Robker et al. demonstrated that the expected FSH- or PMSG-induced increases in *Cyp19* and *Lhcgr* expression in mature follicles occurs in PR-null ovaries.[633]

OVULATION

PR expression in the ovary is relatively low throughout folliculogenesis except during the 4–6 h period immediately after the ovulatory gonadotropin surge, during which an enormous induction of PR expression occurs in granulosa cells of ovulating follicles[628,634,635] and is synchronized with an equally acute increase in ovarian P synthesis. These phenomena alone are indicative of an important role for PR-mediated P signaling during ovulation. Experimental evidence of a critical role for PR in ovulation comes from studies in which ovulation is blocked when peri-ovulatory ovaries or follicles are exposed to: (1) anti-P antisera,[642] (2) inhibitors of P synthesis,[643–645] or (3) PR antagonists.[621,646,647] Finally, the

anovulatory phenotype of PR-null mice discussed before provides definitive evidence that PR actions are required in the mammalian ovary during the period just prior to ovulation.[176–178,180] PR-null females exhibit multiple large, preovulatory but unruptured follicles following induced ovulation.[176] Therefore, follicle growth and differentiation are unaffected by the loss of PR functions as PR-null follicles exhibit fully formed antra and increased *Cyp19* and *Lhcgr* expression following FSH or PMSG treatment.[176,633] Furthermore, although follicle rupture is impaired, PR-null ovaries exhibit several indications that other LH- or hCG-induced responses are intact, including: (1) rapidly decreased *Cyp19* expression,[633] (2) dramatic induction of *Ptgs2* expression,[633] (3) expansion of the cumulus–oocyte complex,[176] and (4) luteinization and formation of functional corpora lutea.[182,633] These findings in PR-null females are congruent with earlier studies using P synthesis inhibitors[645,648] or PR antagonists,[646] which also report that ovulatory levels of prostaglandins and steroids are largely unaffected by inhibition of P signaling.

The previous data clearly indicate that PR actions are highly specific and critical for follicle rupture. Studies have discovered that PR-null ovaries fail to exhibit LH-induced expression of several proteases, including ADAMTS-1, ADAM8, and cathepsin-L, which are postulated to be involved in degradation of the follicle wall and extracellular matrix that is necessary for oocyte extrusion (Figure 25.24). ADAMTS-1 (*Adamts1*) and ADAM8 are members of the A disintegrin and metalloproteinase family of proteases and are dramatically increased in granulosa cells of preovulatory follicles 12 h after hCG treatment, after peak PR expression and coinciding with a period of follicular rupture.[644,649] A similar pattern of peri-ovulatory ADAMTS-1 expression is documented in preovulatory follicles of porcine,[650] equine,[630] and primate[651] ovaries. Cathepsin-L (*Ctsl*) is also significantly increased following hCG exposure in granulosa cells of preovulatory follicles and also peaks 12 h after treatment.[633,652] PR-null females,[633] as well as wild-type female rats exposed to a P synthesis inhibitor near the time of hCG treatment[644,653] fail to exhibit hCG-stimulated increases in *Adamts-1* expression, indicating this effect of LH is primarily dependent on PR-mediated P action. ADAMTS-1-null female mice exhibit a severely compromised ovulation and a phenotype of large, preovulatory but unruptured, follicles following gonadotropin-induced ovulation.[654,655]

Interestingly, PRA-null mice exhibit a severe ovulatory phenotype similar to total PR-null females but possess normal LH-stimulated induction of *Adamts-1* and *Ctsl* during induced ovulation,[182] suggesting possible compensatory actions by PRB but also questioning the importance of ADAMTS-1 and cathepsin-L to follicle rupture. ADAM8 was recently shown to be regulated specifically by PRA in reporter assays, while PRB was unable to regulate the promoter of ADAM8 in vitro.[649] This could explain why PRA-null mice show LH-stimulated induction of *Adamts-1* and *Ctsl* yet are unable to ovulate, although further studies are needed to confirm this.

Several other genes have been identified downstream of PR and suggested to be important in follicle rupture and ultimately ovulation. Since ovulation is discussed more fully in another chapter (Chapter 22) of this volume, we will not provide in-depth description, although

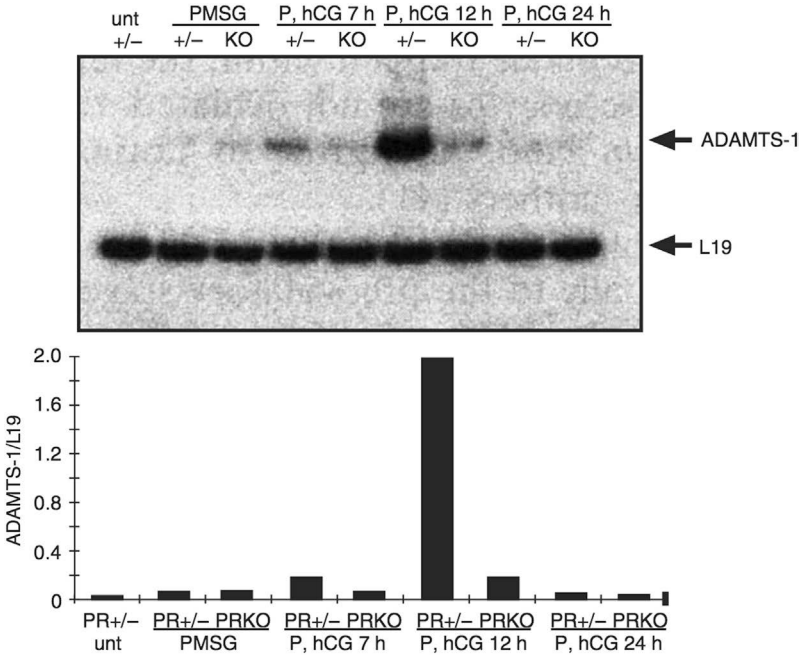

FIGURE 25.24 Ovarian expression of ADAMTS-1 in PR-null ovaries during gonadotropin-induced ovulation. Immature heterozygous (PR+/–) and homozygous PR-null (PRKO) mice were left untreated or injected with PMSG and euthanized 46 h later, or were treated with PMSG for 46 h followed by hCG and euthanized 7, 12, and 24 h later. Reverse transcriptase polymerase chain reaction analysis of total RNA from whole ovaries indicates that ADAMTS-1 expression is dramatically increased by hCG in PMSG-primed mice, but this induction is lacking in PR-null ovaries, indicating dependence on PR function. ADAMTS-1 expression was normalized to expression of ribosomal protein L19. *Source: Reproduced with permission from Ref. 633.*

we will briefly describe what is known to date. These include SNAP25, synaptosomal-associated protein 25, an LH-regulated gene that has decreased expression in PR-null mice but not *Ptgs2* mice.[656] Furthermore, *Snap25* was PR regulated in in vitro reporter assays, and the PR antagonist RU486 was able to inhibit this regulation. SNAP25 acts to alter cytokine and chemokine secretion in granulosa cells, which may act to facilitate follicle rupture.[656] Endothelin 2 (*Edn2*) was identified to be an LH-regulated gene with undetectable levels in PR-null mice that plays a role in follicle rupture.[657,658] Recent studies have shown that *Edn2* is regulated by PRA,[639] and studies in rats have shown that it acts to stimulate smooth muscle contraction and follicle constriction.[659] EDN2 provides the mechanical actions that help to facilitate follicle rupture and successful ovulation. This is supported by its regulation specifically by PRA, which is essential for ovulation, whereas loss of PRB doesn't reduce ovulatory response as described previously.

Numerous transcription factors have also been identified as PR targets, and knockout mouse models have demonstrated that these factors are necessary for ovulation in mice. Hypoxia inducible factor 1 (*Hif1*) is induced by FSH in rat granulosa cells cultured in vitro,[660,661] and have also been found to be regulated by PR.[662] Furthermore, the expression of several HIF family members, including *Hif1a*, *Hif2a*, and *Hif1b*, are reduced in PR-null ovaries[662,663] suggesting an important role in follicle rupture. To further explore this possibility, pharmacological inhibitor of HIF activity was shown to block ovulation and inhibit follicle rupture,[662] demonstrating the importance of HIF activity in regulating ovulation. Another nuclear receptor, PPARG, is also necessary for follicle rupture as demonstrated by targeted deletion in granulosa cells in mice that had no response to exogenous gonadotropins.[664] The action of PPARG was found to be mediated by several PR target genes, including *Il6* and *Edn2*,[664] demonstrating that several targets are regulated downstream of PR and LH signaling to coordinate follicle rupture and ovulation.

Androgen Receptor Signaling in Ovarian Function

AR Expression in the Ovary

AR expression has been documented in the ovaries of multiple species, including mouse,[373,450] rat,[130,665–668] pig,[669,670] sheep,[671] cow,[672] monkey,[274,395,673–675] and human.[395,625,676–679] The ovarian pattern of *AR* expression is well conserved among species, with levels being detectable throughout the stages of folliculogenesis except primordial follicles, with the highest expression in the granulosa cells of small preantral follicles, detectable expression in thecal/interstitial cells, and little to no expression in luteal cells (Table 25.6).

In the ovaries of multiple species, *Ar/AR* expression among growing follicles is inversely correlated with the extent of granulosa cell differentiation (Figure 25.25). A mechanism to decrease AR levels during follicle maturation is consistent with the need to reduce sensitivity to intrafollicular androgens, which rise to levels sufficient for aromatization to E2, as activating AR ligands are detrimental to the health of preovulatory follicles.[680] In the ovaries of gonadotropin-stimulated rats, Testsuka and Hillier found that large antral follicles (>400 μm) exhibit a 2.75-fold higher level of *Cyp19* expression relative to small follicles (<200 μm) but a 51% decrease in *Ar* expression.[665] In rat ovaries, *Ar* expression is first apparent in early postnatal development in follicles of the preantral stage.[681] In adult ovaries, decreasing AR immunoreactivity occurs during follicle differentiation; a decrease is first apparent in mural granulosa cells and then progresses in those cells closest to the antrum.[667] Interestingly, cells composing the cumulus–oocyte complex of preovulatory follicles are believed to be the last to differentiate[682] and maintain *Ar* expression throughout.[667] This gradient of AR expression suggests that AR signaling correlates with the differentiation state of granulosa cells and follicle development.

In primate and human ovaries, *AR* expression is also highest in the granulosa cells of small growing follicles, yet evidence of an inverse correlation with follicle differentiation is conflicting.[625,674,675,678,684] Hillier et al. found AR immunoreactivity in the marmoset ovary is most abundant in granulosa cells of healthy pre- to small antral follicles and low or absent in preovulatory follicles of late follicular stage.[674] In contrast, minimal differences in granulosa cell *AR* expression between preantral and large antral follicles are reported in rhesus monkey ovaries.[675] Furthermore, healthy follicles at late stages of maturation in human ovaries are described to possess significant AR immunoreactivity.[625,678,679] A recent report has suggested that AR expression is highest in small antral follicles and decreases as the follicle matures,[685] suggesting that message levels may not correspond with AR protein levels in human follicles.

The regulatory factors for *AR* expression in the ovary are poorly understood. Small preantral follicles in rats maintain high AR levels after hypophysectomy indicating that gonadotropins are not required to induce *AR* expression.[668] In fact, most evidence indicates that FSH or PMSG-induced differentiation of granulosa cells is the primary cause of reduced *AR* expression; Campo et al. demonstrated that PMSG treatment of rats leads to the replacement of high-affinity, low-capacity androgen binding sites by nonsaturable, low-affinity binding sites in the ovary.[686] Similarly, immature rats treated with recombinant FSH over 48 h exhibit a 65% reduction in ovarian *Ar* mRNA levels and a further decrease when LH is included.[668] However, neither FSH nor (BR)-cAMP

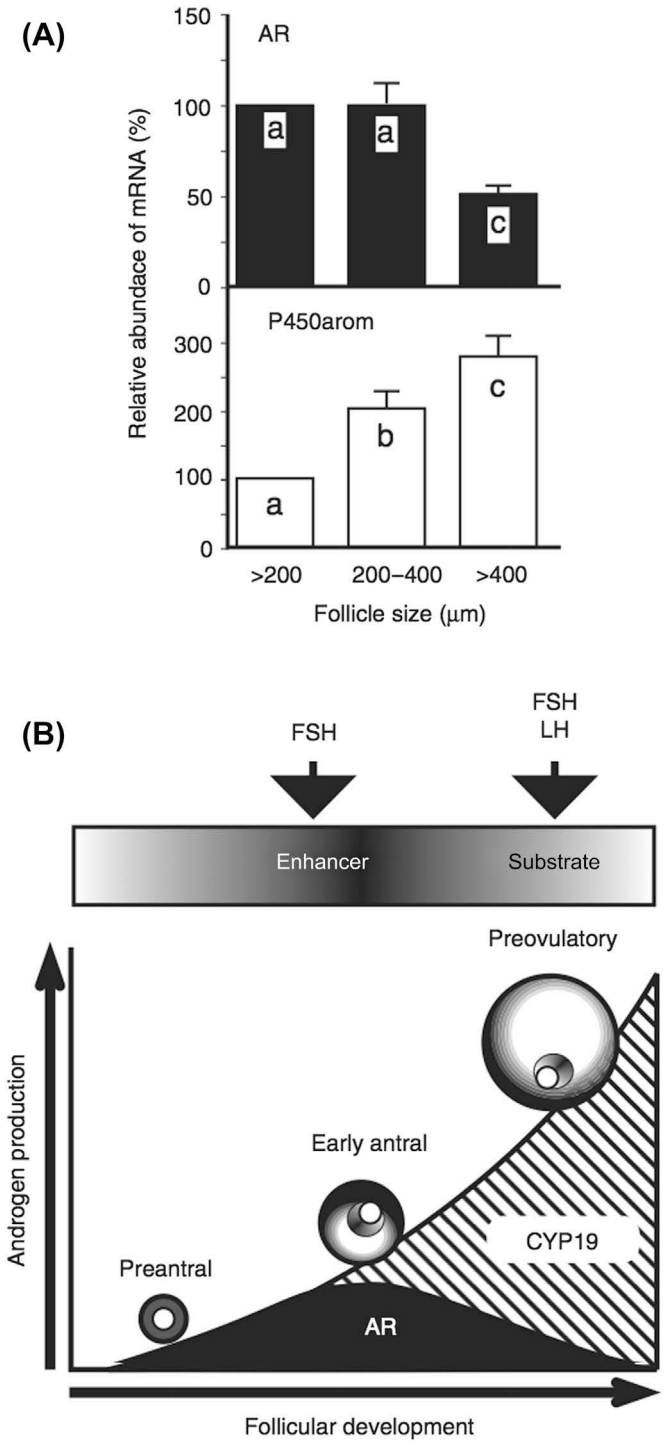

FIGURE 25.25 Relationship between expression of androgen receptor and aromatase (CYP19) during folliculogenesis. (A) Expression of androgen receptor (*Ar*) and aromatase (*Cyp19*) expression in granulosa cells of small (~200 μm), medium (200–400 μm), and large (>400 μm) follicles from immature rats after treatment with PMSG. Expression was quantified by RNase-protection assay and normalized to 18S rRNA (not shown); data are expressed as percentage of control values (SEM of three separate trials, each consisting of 8–10 animals). a, b: $P < 0.05$; a, c: $P < 0.01$ (by ANOVA with the Newman–Keuls test). *(Source: Reproduced with permission from Ref. 491.)* (B) Hypothetical model of androgen utilization during folliculogenesis. As follicular development progresses, thecal androgen production gradually increases. During the early stages of follicular differentiation, androgens act via androgen receptor (AR) to enhance FSH-induced differentiation, including the stimulation of *Cyp19* expression. During the final stages of follicular development, androgens primarily serve as a substrate for CYP19-mediated E2 synthesis under stimulation by FSH and LH. This differential regulation of AR and CYP19 may be important in shifting androgen utilization from action to metabolism, thereby ensuring a healthy transition of a follicle from the early maturation to full maturation stage. *Source: Reproduced with permission from Ref. 683.*

affect *Ar* mRNA levels in cultured rat granulosa cells in vitro.[665] This suggests that a paracrine interaction with theca and/or stromal cells is necessary for reduced *Ar* expression observed in granulosa cells. Interestingly, DHT also elicits a 20% reduction in *Ar* expression in rat granulosa cells in vitro that is prevented by co-treatment with FSH.[665] In contrast, T reportedly has little effect on *AR* expression in rhesus monkey ovaries.[675] There is increasing evidence that E2 may play a role in decreasing granulosa cell AR levels during follicle differentiation. Like DHT, E2 exposure of rat granulosa cells also leads to a 20% reduction in *Ar* transcripts, but this effect is unabated by FSH.[665] Furthermore, granulosa cells retrieved from untreated hypophysectomized rats respond well to DHT plus FSH and exhibit increased *Cyp19* expression accordingly; but the effect of DHT is

lost in granulosa cells isolated from E2-primed hypophysectomized rats, suggesting that estrogen pretreatment decreases *AR* expression.[442] Indeed, mature follicles in ERβ-null ovaries are reported to possess aberrantly high *AR* expression relative to similarly staged follicles in wild-type ovaries,[450] supporting the idea that ER may act to decrease *Ar* expression. While the hormonal regulation of Ar expression is unclear, recent reports suggest that a member of the orphan nuclear receptor family, *Nur77*, is required for maximal *Ar* expression in murine ovaries. *Nur77* regulates several steroidogenic enzymes in the ovary, including those involved in androgen synthesis,[687] and recent reports demonstrate 20% reduction in Ar expression in the granulosa cells from *Nur77*-null mice.[688] Dia and colleagues were able to show that NUR77 bound directly to the promoter regulatory region of the Ar gene in mouse granulosa cells, providing insight into one of the transcriptional factors necessary for maximal AR expression in the ovary.[688]

Ovarian Phenotypes in Mouse Models of Disrupted Androgen Signaling

MICE LACKING AR

Tfm mice were first described in 1970 and are a naturally existing androgen-resistant mutant[283] due to an inactivating mutation of the *Ar* gene.[284,285] With the advent of gene targeting techniques, comparable inactivation mutations of the *AR* gene and resulting phenotypes have been described in rats and humans.[286] *Tfm*/*Tfm* female mice are fertile but exhibit a noticeably shortened reproductive life span that becomes apparent after approximately four litters compared to control (*Tfm*/X or X/X) females; however, individual litter sizes were not different.[287] Histological evaluation of ovaries from the *Tfm/Tfm* breeding females indicated a sparse number of healthy follicles and a hypertrophied interstitium, both illustrative of premature ovarian failure (POF).[287] The difficulties in generating *Tfm/Tfm* female mice limited more extensive studies.

Several global AR-null mouse models have been generated via a *Cre/loxP* targeting scheme that allows for tissue and temporal specific disruption of the *Ar* gene and therefore the generation of fertile male carriers of the targeted *Ar* allele[183,185,288,290] (Table 25.9). In one study, global AR-null females made through deletion of exon 1 exhibit normal fecundity only during the first 12 weeks of continuous breeding, after which they produce a reduced number of litters per female (2.3 versus 3.3 in wild-type) and less offspring per litter (4.5 versus 9.8 in wild-type), while others become totally infertile.[183] The POF observed in AR-null females is remarkably similar to that described before in *Tfm*/*Tfm* females.[287] Adult AR-null females possess ovaries exhibiting a normal number of growing and antral follicles but notably fewer corpora lutea[183] and reduced circulating P (Table 25.9),[689] suggesting that folliculogenesis is preserved but ovulation and luteinization are disrupted. Gonadotropin-induced ovulation of immature AR-null females leads to a severely reduced ovulatory yield and oocytes that often exhibit a less condensed cumulus–oocyte complex.[183] This latter finding is especially interesting in light of the preserved *Ar* expression in the cumulus oophorus cells of preovulatory follicles. Additional evidence that AR-null ovaries fail to fully respond to an ovulatory dose of hCG is an inadequate induction of *Pgr*, hyaluronyl synthetase-2 (*Has2*), and tumor necrosis factor-α-stimulated gene 6 (*Tnfaip6*),[183] all factors that are critical to expansion of the cumulus–oocyte complex and follicle rupture. Furthermore, granulosa cells of ovulatory follicles in AR-null ovaries fail to terminally differentiate and luteinize following hCG-induced ovulation, as indicated by decreased expression of cyclin-dependent kinase inhibitor 1A (*Cdkn1a*) and cytochrome $P450_{scc}$ (*Cyp11*).[183] These animals were generated by targeted deletion of exon 2 and demonstrate that AR signaling is important for normal ovarian function and to prevent POF in rodents.

A second global knockout mouse model was developed by Shiina et al., where AR was deleted through *Cre/loxP* mediated removal of exon 1.[690] This animal model is similar to that described before in that the female mice show an age-dependent decrease in fecundity, however, these mice also have a decrease in number of offspring per litter in animals aged 8 weeks old (4.5 versus 8.3 in wild-type). At 8 weeks of age, these mice also have decreased number of CL and an increased number of unhealthy and atretic follicles.[690] Knockout of AR in exon 1 also causes a POF phenotype where the number of offspring decreases over time concomitant with a decrease in the number of healthy follicles, suggesting defects in folliculogenesis. By 32 weeks of age, 40% of knockout females are infertile, similar to that observed in *Tfm*/*Tfm* females and the exon 2–deleted AR-null mice,[183,283] and at 40 weeks of age all of the mice are infertile.[690] No difference was observed in genes involved in steroidogenesis within the ovary, and serum hormone levels for E2, P, and T are within normal rages similar to WT controls, providing evidence that AR is not necessary for normal steroidogenesis in the ovary (Table 25.9)[690] in contrast to reduced P observed in the exon 2–deleted AR-null female.[689] Microarray analysis was done on ovaries from these animals to find potentially altered transcriptional networks that might contribute to the POF phenotype. Several genes implicated in oocyte-granulosa cell communication were found to be increased,[690] including kit ligand (*Kitl*). Kitl is a downstream target of AR as demonstrated by induction of *Kitl* expression following DHT treatment, while co-treatment with DHT and the antiandrogen flutamide attenuated the increased *Kitl* expression.[690] This report suggests that AR signaling has

TABLE 25.9 Ovarian Phenotypes in AR-Mutant or Null Mouse Models

Mutated or Null for Sex Steroid Signaling	Ovarian Phenotypes	Hormone Levels	References
Tfm/Tfm mice	Fertile but have a reduced number of pups/litter as they age Shorted reproductive life span	Not reported	283
$AR^{-/-}$ (exon 2)	Reduced fertility and a shortened reproductive life span Adults exhibit grossly normal ovaries with reduced number of CL Abnormal estrous cycle Immature females have reduced response to gonadotropin-induced ovulation	Reduced P Other hormones not reported	183,290
$AR^{-/-}$ (exon 1)	Reduced fertility and POF phenotype where animals have a shortened reproductive life span Increased number of atretic follicles and reduced number of CL Altered ovarian gene expression in immature and adult animals	Normal serum E2, P, T, LH, and FSH	690
$AR^{-/-}$ (inframe deletion of exon 3, loss of DNA binding activity)	Delayed production of first litter Decreased pups/litter and reduced number of CL $AR^{+/-}$ animals had age-dependent reduction in pups/litter Increased number of unhealthy antral follicles Normal response to exogenous gonadotropins, but a reduced number of oocytes ovulated during natural mating	Normal serum E2, T, LH and FSH Increased intraovarian T in 10–12 week old mice	185
$AMH^{Cre+}Ar^{f/+};Ar^{f/f}$ (exon 3 floxed, loss of DNA binding activity in large preantral to antral follicles)	Subfertile due to reduced number of litters and age dependent decrease in total number of pups born Decreased fertility over time with a cumulative decrease in pups born per dam 3-month-old animals have increased large preantral and antral follicle numbers 6-month-old animals have increased length of estrous cycle Reduced cumulus expansion and oocyte/embryo viability	Normal serum LH and FSH	691
$Amhr2^{Cre+};Ar^{f/f}$ (exon 2 floxed) GCARcKO	Reduced fertility Altered follicle progression and development 8–9 week mice: normal estrous cycle, reduced pups/litter, reduced number of oocytes from natural mating, however, no differences observed when treated with exogenous gonadotropins 24 weeks: increased length of estrous cycle, reduced number of pups born per dam, reduced number of oocytes from natural mating and treatment with endogenous gonadotropins	Not reported	692
$Gdf9^{Cre+};Ar^{f/f}$ (exon 2 floxed, oocyte specific loss of AR)	Normal female phenotype except androgens were unable to promote oocyte maturation in vitro	Not reported	692
SPARKI (homozygous KI of mutated DBD of AR)	Normal female phenotype	Not reported	186

an important role in the oocyte-granulosa cell regulatory loop,[690] although future work is needed to identify potential mechanisms of action.

These knockout mouse models demonstrated an important role for AR in normal ovarian function and suggest that loss of AR contributes to POF (Table 25.9). Both AR-null models lack all AR protein due to a truncated message and premature stop codon. A third AR-null mouse model was developed by Walters et al. where an in-frame deletion of exon 3 was made that led to production of an AR protein lacking the second zinc finger and is therefore truncated and unable to bind DNA.[185] Mutations in this region of the AR gene have been identified in human patients with androgen insensitivity syndrome (AIS), demonstrating the importance of binding DNA to AR activities in normal physiological state.[693–695] This mouse model allows for analysis of the direct effects of classical genomic AR signaling in the ovary compared to the AR-null models that lack all AR protein. Deletion of the DNA binding domain in female mice led to a subfertile phenotype where the females homozygous for the deletion had less offspring per litter compared to both heterozygous and WT females.[185] Interestingly, the AR(exon 3)-null females had reduced numbers of CL similar to other AR-null mice,[290,690] demonstrating the importance for intact AR signaling for this process.

Furthermore, these mice also had an age-dependent reduction in fecundity similar to the other AR-null models,[183,690] and females heterozygous for the AR(exon3) deletion also showed an age-dependent reduction in offspring born at 6 months of age, suggesting a dosage effect.[185] An increase was observed in the number of unhealthy antral follicles, although AR(exon3)-null mice did not have significant changes in overall follicle development even in animals aged 10 months[185] in contradiction to reports in AR-null ovaries with reduced follicle numbers.[183] While these models have indicated some differences in the role of AR in normal folliculogenesis, all demonstrate an increase in the number of atretic follicles, demonstrating the importance of AR signaling in maintaining ovarian health over time. AR-null mice have reduced response to gonadotropin-induced ovulation,[183] and examination of the AR(exon3)-null animals found that they respond to exogenous gonadotropin stimulation with similar numbers of oocytes ovulated; however, a decrease was observed in oocytes ovulated when examined after natural mating.[185] This suggests that AR is necessary for normal ovulatory response; however, excess gonadotropins are able to override this defect in the presence of a truncated AR protein (lacking the entire DNA binding domain) compared to ovaries that are void of all AR protein. Mutation of the DNA binding domain that alters the ability of AR to bind to selective androgen response elements in the SPARKI mouse model presented by Schauwaers et al. did not lead to a female reproductive defect, suggesting that the ovary does not require selective AR binding to response elements as compared to the male SPARKI mice that have a reproductive phenotype and will not be further discussed herein.[186]

The identification of genes necessary for oocyte-granulosa communication in the ovary as being AR targets[690] provides a possible mechanism that is aberrant in AR-null ovaries, but further studies are necessary to confirm this difference and explore the pathways involved. Loss of the DNA binding domain in AR did not affect circulating hormone levels, as the mice had normal serum levels of E2, T, LH, and FSH; however, an increase in intraovarian T levels was observed in mice aged 10–12 weeks,[185] suggesting alterations in the steroid environment locally may have paracrine effects on ovarian function that was not measured in other AR-null models.[183,690]

MICE WITH OVARIAN-SPECIFIC DELETION OF AR

The global AR knockout mouse models described herein have offered many insights into the important role of AR in female reproduction, specifically in the ovary. However, these models lack AR in all tissues, including all parts of the hypothalamic–pituitary–gonadal axis, which could contribute to the ovarian phenotype observed. To circumvent this, two conditional knockout mouse models have been developed to remove AR specifically in granulosa cells of the ovary.[691,692] These models provide a unique way to explore the role(s) of AR in female fertility and ovarian function.

Sen and Hammes used *Amhr2*-cre to delete exon 2 of AR in the ovary and found that the animals had reduced numbers of offspring born to young dams (2.8 pups in KO versus 7 in WT mice),[692] similar to that observed in the global knockout animals.[183,290] In these granulosa cell AR conditional knockout (GCARcKO) animals, altered follicle progression was observed in animals aged 9 weeks as well as in animals aged 24 weeks (Table 25.9),[692] supporting observations in global knockout animals,[183,290] where numbers of corpora lutea were reduced and atretic follicles were increased. These patterns persisted in older animals, which also showed an increased length of estrous cycle at 24 weeks of age compared to mice aged 9 weeks old that had a normal estrous cycle.

Several other differences were observed in animals at the two ages examined (9 weeks versus 24 weeks), including differences in ovulation. Mice aged 9 weeks had a reduced number of oocytes ovulated during natural mating, but treatment with exogenous gonadotropins was able to circumvent this defect and cause normal numbers of oocytes to be ovulated from these animals. As the animals aged, however, the ability of exogenous gonadotropins to override this defect was lost, and reduced oocyte numbers were observed from natural mating and superovulation paradigms.[692] Failure of the ovary to respond to exogenous gonadotropins concurrent with a reduction in the total number of offspring born over a long-term fertility study (19 in KO versus 119 in WT mice) supports the POF phenotype observed in the global AR-knockout models.[183,185,290]

The GCARcKO presented by Sen and Hammes was made using the *Amhr2*-cre mouse, which has been found to be active in tissues other than granulosa cells including the pituitary,[696] which may complicate the findings. While reduced expression of *Ar* was not reported in the hypothalamus or the pituitary,[692] the heterogeneous population of cells present could mask a reduction in gonadotrope cells that are required for normal female fertility. To eliminate this possibility and explore the classical role of AR in large preantral to antral follicles, Walters et al. used the *Amh*-cre mouse model to delete exon 3 in the ovary.[691] *Amh* is the ligand for *Amhr2* and is expressed specifically in large preantral to antral follicles during folliculogenesis demonstrated by crossing the Amh-cre mouse to R26R (ROSA) reporter mice.[691] This mouse expresses β-galactosidase activity where *Cre recombinase* is expressed, and the X-Gal blue stain can be used to localize cells expressing the β-gal indicator within tissues. The *Amh*-cre mouse was crossed with exon3 floxed AR mouse that creates a truncated protein lacking the DNA binding domain.[185] The use of this

mouse model allowed *Ar*/AR to be deleted in a temporal pattern and to examine whether DNA binding activities are necessary during this stage of folliculogenesis for normal ovarian function.

The *AMH*$^{Cre+}$*Ar(exon3)*$^{f/f}$ females are subfertile, and while the number of offspring born per litter was not significantly altered, an age-dependent decrease in the total number of pups born was observed[185] similar to the POF phenotype observed in other AR-null models (Table 25.9).[183,185,283,690,692] This provides evidence that AR binding to direct AR target genes in large preantral follicles is necessary for normal ovarian function over time. The *AMH*$^{Cre+}$*Ar(exon3)*$^{f/f}$ females also have an increased length of estrous cycle at the age of 6 months that is not observed in younger mice,[691] supporting the POF phenotype observed and the importance of AR in maintaining normal ovarian health. Altered follicle progression was observed in these mice, and at 3 months of age fewer large preantral and small antral follicles were observed; however, this difference was not noted in older animals.[691] While no difference is observed in follicle progression during folliculogenesis in *AMH*$^{Cre+}$*Ar(exon3)*$^{f/f}$ females aged 6 months, a significant increase in unhealthy follicles was observed,[691] supporting the notation that AR signaling is necessary for normal ovarian health and prevention of POF in the ovary.

Communication between granulosa cells and the oocyte are necessary for oocyte health and viability, and disruption of this communication can lead to infertility. Animals lacking functional AR protein have altered expression of several genes implicated in this communication network, including the AR-dependent gene *Kitl*.[690] Pharmacological studies have suggested that T can induce mouse[697,698] and porcine[389,699,700] oocyte maturation presumably through classical AR signaling in vitro. To directly examine the role of AR expression in oocytes, a conditional knockout mouse model was developed using an oocyte-selective *Gdf9*-cre crossed with exon 2–floxed AR.[692] These mice had normal fertility and no overt ovarian phenotype compared to WT controls, demonstrating that AR expression within oocytes is not necessary for female fertility, while granulosa cell specific expression of the AR nuclear receptor is necessary in vivo.[692] Interestingly, when oocytes were removed from immature unprimed females and grown in vitro, DHT was unable to induce oocyte maturation in the absence of AR expression in oocytes.[692] However, P-mediated oocyte maturation was not affected by the loss of AR in vitro, demonstrating that these oocytes could still mature, albeit not through an androgen-mediated mechanism. This suggests that AR expression in oocytes is necessary for in vitro maturation in the absence of granulosa cells, while in vivo expression of AR in the granulosa cells is sufficient for oocyte maturation, possibly due to P-mediated mechanisms.

Loss of AR in granulosa cells contributes to altered ovarian function including a POF phenotype and loss of ability of the ovary to ovulate oocytes through both natural mating or superovulation depending on the age the animals were tested.[183,185,692] While differences were observed depending on the AR-null mouse model examined and the ovulation paradigm presented, the data provide evidence that AR is necessary for normal ovulatory function of the ovary. Interestingly, a decrease was observed in the number of oocytes naturally ovulated by one granulosa cell–specific AR-null model,[692] while no differences were observed in a second model (Table 25.9).[691] These differences may be due to the timing of AR deletion or the different flox animals used (i.e., exon 2 versus exon 3). Further study was done on oocytes ovulated from natural mating in the *AMH*$^{Cre+}$*Ar(exon3)*$^{f/f}$ females to see if these oocytes could be fertilized and progress through early embryo development in vitro.[691] While the number of oocytes ovulated was not different, the number of fertilized oocytes was reduced (38.6% in KO versus 94.5% in WT), as was the number of the embryos able to process to the two-cell stage of embryo development (35.7% in KO versus 89.5% in WT).[691] This supports the necessity of AR expression in granulosa cells to promote oocyte maturation and development, and indicates that DHT-mediated oocyte maturation could be mediated through expression of AR in granulosa cells. It also provides insight into the inability of some oocytes to respond to in vitro fertilization, which has implications in human health in cases where some women fail to respond to assisted reproductive technologies. The variety of AR-null mouse models to date provides evidence of the importance of AR signaling in normal ovarian development, female fertility, and follicle health.

Intraovarian Role of Androgen in Ovarian Function

The intraovarian roles of androgens can be categorized into three distinct functions: (1) as substrates for E2 synthesis, (2) as an enhancer of follicle differentiation, and (3) as a stage-specific inhibitor of follicle growth.[683] The role of thecal-derived androgens, most notably androstenedione, as substrates for E2 synthesis in granulosa cells is obviously critical given the profound importance of the latter hormone to reproductive function. While ovarian steroidogenesis is essential for function of the ovary and female fertility, this topic will not be covered here; instead we focus on the additional intraovarian actions of androgens, which include their role as activating ligands for AR-mediated effects.

GRANULOSA CELL PROLIFERATION

The follicular response to androgens is dependent upon the stage of growth and differentiation. In preantral,

undifferentiated follicles that are unable to synthesize E2, androgens promote gonadotropin-induced granulosa cell proliferation and maturation. In large, differentiated follicles that have acquired aromatase activity, E2 assumes the role of enhancing FSH-induced granulosa cell proliferation and differentiation, and androgens in excess of that required for conversion to E2 are detrimental to follicle health, leading to atresia. This paradox of androgen action during follicle growth and differentiation explains the contradictory results when comparing experimental studies.

Several studies in hypophysectomized rats have shown that coadministration of T inhibits estrogen or gonadotropin-induced granulosa cell proliferation and increased ovarian weight, and promotes degeneration in more mature follicles.[422,489,701–703] In contrast, Armstrong and Papkoff found aromatizable androgens (e.g., T or androstenedione) enhance the promotional effects of FSH in the ovaries of hypophysectomized rats but that the nonaromatizable androgen DHT is inhibitory.[291] Similar treatment with hCG instead of T has a comparable effect on gonadotropin or E2-induced follicle growth in hypophysectomized rats, but is prevented by AR-antagonists, indicating the detrimental effects of hCG are due to stimulation of thecal cell androgen synthesis.[702,704,705] However, Bley et al. found that granulosa cells from preantral follicles of estrogen-primed rats proliferate at comparable rates in response to FSH plus E2 or DHT in vitro[496] and that the promotional effects of the latter steroid are blocked by the antiandrogen hydroxyflutamide.[496] Investigations toward the mechanism by which androgens inhibit granulosa cell proliferation indicate that DHT exposure to estrogen-primed rats prior to granulosa cell isolation causes a blunted response to forskolin-induced cyclin-D2 (*Ccnd2*) expression in vitro, leading to cell-cycle arrest and reduced proliferation.[706] DHT is able to exert its inhibitory effect on *Ccnd2* expression through AMP-activated protein kinase (AMPK) activation, which in turn inhibits phosphorylation of MAPK and ultimately impacts granulosa cell proliferation downstream of FSH.[707,708] AMPK has a role in inhibiting cell proliferation, and pharmacological activation of the kinase can lead to cell cycle arrest, while blocking AMPK activity prior to treatment with DHT was able to overcome the inhibitory effect normally observed,[708] providing insights into the mechanism of action of DHT inhibition on cell cycle progression in estrogen-primed rat granulosa cells. This work also highlights how androgens are able to be stimulatory during early stages of folliculogenesis and then inhibitory during the latter stages when estrogen signaling is the main driver of follicle development.

The stage-specific effects of androgens during folliculogenesis described herein may be more apparent in rat ovaries relative to other species. In hypophysectomized mice, Wang and Greenwald found that T or DHT, in combination with FSH, induces greater levels of DNA synthesis in antral follicles than FSH alone; a similar response is not observed in small- and medium-sized follicles.[492] In preantral mouse follicles grown in vitro, antiandrogen antisera reduce FSH-stimulated growth and DNA synthesis; however, these data must be interpreted with caution since antiandrogen antisera may also remove androgens from the pool of substrates for E2 synthesis. Additional evidence that androgens may promote granulosa cell proliferation in mice comes from the findings of Burns et al. that the AR-antagonist flutamide reduces the growth rate of granulosa cell tumors in animals lacking functional inhibins.[499] In vitro follicle culture studies demonstrated the importance of AR signaling in folliculogenesis, where treating follicles with antiandrogenic compounds reduced follicle growth during the preantral stage of folliculogenesis,[709] demonstrating the importance of androgens in early follicle growth.

In cumulus cells of large antral follicles from porcine ovaries, DHT augments FSH or IGF1-induced proliferation, and this effect is inhibited by flutamide.[710] Rhesus monkey ovaries exhibit a strong correlation ($r = 0.91$) between *AR* expression and cell proliferation[675] and exhibit an increased number of follicles of all stages except large antral following T or DHT treatments.[711] Yang and Fortune reported that T was able to stimulate early follicle maturation in bovine follicles.[712] The collective data support the notion that androgens are important in granulosa cell proliferation during early stages, but at latter stages the effect appears to be species dependent.

GRANULOSA CELL DIFFERENTIATION

Fully differentiated preovulatory follicles in mammalian ovaries are distinctly characterized by a large fluid-filled antrum, significantly increased aromatase (CYP19) activity, and acquisition of LH responsiveness. The absolute requirement of FSH signaling in this process is illustrated by the absence of all three phenotypes in mice null for FSH action.[420,512,513] E2 is also required for full FSH-induced follicle differentiation. However, there is substantial evidence that androgens may be equally efficient as E2 in augmenting certain responses to FSH, most especially the induction of aromatase activity and antrum formation.[683] Both T and DHT enhance FSH induction of aromatase activity in hypophysectomized rat ovaries or isolated granulosa cells in vitro in a dose-dependent fashion.[291,713] Furthermore, pharmacological inhibition of ovarian androgen synthesis in rats simultaneously reduces aromatase activity that can be restored by exogenous T.[714]

Fitzpatrick et al. found that T, and DHT to a lesser extent, significantly enhances FSH induction of *Cyp19* expression and aromatase activity in granulosa cells from

untreated hypophysectomized rats[442] (Figure 25.19). This finding was supported by work done in in vitro cultured granulosa cells isolated from rats where T was able to increase Cyp19 and P450scc expression. This regulation was found to be dependent on liver receptor homolog-1 (*Lrh1*) expression that is induced by T and not DHT through AR binding to *Lrh1* promoter regulatory region[715] and provides evidence that T, and not DHT, affects the expression of genes necessary for estrogen production during folliculogenes. Furthermore, *Lrh1* expression is also induced by FSH in granulosa cells,[715] providing a potential mechanism of action for synergy necessary for differentiation of granulosa cells in the ovary.

Interestingly, this effect is lost in granulosa cells isolated from estrogen-primed hypophysectomized rats,[442] supporting the hypothesis that early growing follicles are more sensitive to androgen action and that estrogens downregulate *AR* expression as part of the process of follicle differentiation. Similar data has been produced in mice. For example, AR antagonists are able to inhibit FSH-induced E2 synthesis in individually cultured murine follicles if included at the beginning of the culture period prior to any indications of differentiation.[716] Similarly, E2 output by large antral murine follicles in vitro is unaffected by DHT.[492] In marmoset ovaries, granulosa cells isolated from small (0.5–1 mm) follicles are highly responsive to the enhancing effects of T or DHT on FSH-induced aromatase activity, but this response is lost in granulosa cells from larger (>2 mm) follicles whereupon DHT exposure becomes inhibitory.[717,718] In contrast, 3 or 10 days of T treatment in rhesus monkeys has no effect on ovarian *CYP19* expression.[684]

The majority of data indicate that healthy preantral follicles are responsive to T and require the steroid for the initiation of *Cyp19* expression by FSH in granulosa cells. Since androgen synthesis in thecal cells precedes the acquisition of aromatase activity in the accompanying granulosa cells, this mechanism of androgen/FSH synergism allows for more efficient induction of *Cyp19* expression than would occur with FSH alone. Once the granulosa cells acquire sufficient aromatase activity, thecal-derived androgens become more important as substrates and ER-mediated E2 actions continue the role of synergizing with FSH to promote follicle differentiation (Figure 25.25). Hence, the hallmark of a healthy preovulatory follicle in rodent ovaries may be the presence of substantial aromatase activity and E2 output, and decreased *AR* expression and androgen sensitivity.

The mechanism by which androgens augment FSH action on granulosa cells is unclear but may differ from that hypothesized for E2. Whereas ER-mediated E2 actions are believed to enhance the amount and effectiveness of FSH-stimulated intracellular cAMP without obvious changes in FSH-receptor levels, evidence suggests that androgens may act at a site prior to adenylyl cyclase. For example, neither T nor DHT synergize with $(Bu)_2$-cAMP to induce aromatase activity in rat granulosa cells[719] whereas E2 does.[442,720] Instead, AR-mediated androgen actions may largely act by increasing the level of FSH receptor in granulosa cells of preantral follicles. T can also restore the losses in FSH receptor and responsiveness that occur in rat granulosa cells cultured without gonadotropins, and this effect is inhibited by AR antagonists.[719] Evidence that androgens increase granulosa FSH-receptor levels comes from reports that ovaries of 10-day-old and prepubertal AR-null females exhibit significantly reduced *Fshr* mRNA levels, even 48 h after PMSG treatment in the latter age group.[183] Similarly, Weil et al. found that 3 or 10 days of T treatment in adult rhesus monkeys increases FSH-receptor expression in follicles of all stages except primary.[684] In human small antral follicles cultured in vitro, a positive correlation was observed in AR expression, androgen concentrations in follicular fluid, and FSHR expression[721] in small follicles demonstrating an association with AR and androgens in immature granulosa cells, and suggests that in human ovaries this association is important for normal follicle development.

AR-mediated androgen actions may also be involved in antrum formation. Murray et al. found DHT potentiates suboptimal doses of FSH to stimulate increased follicle diameter of murine follicles in culture, and this promotional effect is inhibited by AR antagonist.[716] T or DHT are also reported to be almost as effective as E2 in augmenting FSH-induced increases in the number of antral follicles in the ovaries of hypophysectomized mice.[492] However, the ovaries of global AR-null mice do not show differences in the number of antral follicles,[183,185,690] while in the granulosa-specific AR-null mice a reduction in the number of antral follicles was observed at all ages,[692] or only in younger mice (3 months).[691] The conflicting reports of antral formation in AR-null mice demonstrate the complexity of this developmental process in the ovary. Therefore, FSH-dependent antrum formation may be enhanced by either receptor-mediated androgen or estrogen actions, congruent with the process being part of the transition period during which follicles become less sensitive to androgens and more dependent on estrogens.

Not all FSH-dependent processes during follicle differentiation are enhanced by androgens. LH-receptor expression and LH responsiveness by granulosa cells occurs only in preovulatory follicles during the final stages of folliculogenesis, just prior to the LH surge. Unlike the above processes of follicle differentiation, FSH stimulation of LH-receptor expression in preovulatory granulosa cells is facilitated by estrogen or aromatizable androgens only[515,548,549] while DHT has no effect or may even be inhibitory.[515,549] These data

are consistent with the mutually exclusive pattern of AR and LH receptor in preovulatory follicles of rodent ovaries, as *AR* expression is limited to the cumulus cells[667] while LH receptor is predominantly localized to mural and antral granulosa cells.[722–724] In addition, in vivo studies demonstrating that AR antagonists have no effect on LH-receptor expression in the ovaries of FSH-stimulated, DES-primed hypophysectomized rats suggest that AR-mediated actions are not required to promote or maintain LH-receptor expression in preovulatory follicles.[725] The specific requirement of ER-mediated E2 actions to augment FSH-stimulated LH-receptor expression in preovulatory granulosa cells provides a mechanism by which only those follicles that acquire sufficient aromatase activity and are suitable to ovulate acquire the capacity to respond to the LH surge.

THECAL CELL STEROIDOGENESIS

There are few studies on the role of androgen signaling in thecal cell function and steroidogenesis despite these cells being the primary source of androgen synthesis. Several nonsteroidal paracrine factors are known to modulate thecal cell steroidogenesis and have been more thoroughly studied.[476,566] The limited available evidence suggests that AR-mediated androgen actions may negatively regulate thecal cell steroidogenesis, thereby forming an autocrine regulatory feedback loop. Mahesh and colleagues have shown in enriched thecal/interstitial cell cultures from rats that AR activation by nonaromatizable agonists attenuates hCG or hCG/IFG-1–stimulated increases in androstenedione synthesis by 32% and 40%, respectively, via selective inhibition of *Cyp17* expression.[726] Similar experiments demonstrated that AR-antagonists enhance hCG-induced androstenedione synthesis, further indicating a receptor-mediated effect of androgens on thecal cell steroidogenesis.[726] The majority of recent studies published to date focus on the transcriptional regulation of genes involved in androgen biosynthesis in theca cells,[687,688] but not on the autocrine action of the synthesized androgen(s) within the cells. In fact, a recent review entitled "Theca: The forgotten cell of the ovarian follicle" described the various factors that are known to regulate steroidogenesis and androgen production,[727] which also highlights the need for more focused experiments looking at theca cell functions of AR. The use of conditional knockout mouse models to explore the role of AR specifically in theca cells could also shine light on this important question. Therefore, ER-mediated E2 actions (see the section Estrogen Receptor Signaling in Ovarian Function) and AR-mediated androgen actions may both contribute to maintaining homeostasis of androgen synthesis in the thecal cells of developing follicles.

OVULATION

Over the past decade there have been few studies aimed at determining a role for androgen signaling in follicle rupture and ovulation, the majority of these from the AR-null mouse models (Table 25.9). This is especially surprising since Mori et al. demonstrated in 1977 that inhibition of androgen action at the time of ovulation is detrimental to follicle rupture in the rat.[728] These studies employed anti-T and anti-P antisera during induced ovulation in immature or hypophysectomized rats to demonstrate that: (1) acute treatment with anti-T antisera at the time or shortly after hCG-induced ovulation leads to a dose-dependent reduction in the number of ovulated oocytes, and (2) inhibition of ovulation by acute treatment with an anti-P antisera at the time of hCG treatment is rescued by concurrent treatment with T or DHT but not E2.[728] In a similar study, Peluso et al. demonstrated that treatment of immature rats with the AR antagonists, cyproterone acetate or flutamide, 3 h prior to hCG-induced ovulation drastically reduces the number of ovulated oocytes and prevents expansion of the cumulus–oocyte complex.[729] Similar findings are reported in mice.[730] The development of AR-null mouse models has provided some insight into the role of androgen signaling in ovulation. An ovulatory defect in AR-null mice is suggested by the presence of a normal number of preovulatory follicles but few corpora lutea in the ovaries,[183] as well as reduced circulating P levels.[689] Furthermore, gonadotropin-induced ovulation of immature AR-null females indicates a severely reduced response in terms of recoverable oocytes in the oviducts, and may be attributable to their failure to exhibit hCG-induced expression of P receptor, hyaluronyl synthetase-2, and tumor necrosis factor-α-stimulated gene 6.[183] Reduced ovulatory rates were also observed in another AR-null mouse model lacking the DNA binding domain after normal mating,[185] however ovulation rates after treatment with exogenous gonadotropins were normal. A similar finding was observed in granulosa cell–specific AR-null mouse model where oocytes collected after natural mating are reduced but animals respond to exogenous gonadotropins. Interestingly, when these animals were 6 months of age, they didn't ovulate at all.[692] These mouse models suggest that AR plays a role in normal ovulation, but stimulation with excess gonadotropins can overcome these deficiencies only in young mice. Further work to study the role of androgen signaling in other mammalian species including primates and humans could provide insight into possible fertility treatments.

FOLLICLE ATRESIA

Follicle atresia in the mammalian ovary has been thoroughly described in several reviews.[565,680,731] Follicular atresia is a complex hormonally driven process

involving both putative "survival" factors, e.g., insulin-like growth factor-1, epidermal growth factor, basic fibroblast growth factor, E2, and activin; and putative atretogenic factors, e.g., tumor necrosis factor-α, GnRH, and androgens.[565,680,731] The respective action of each of these factors on atresia is dependent on the follicular stage,[731] for example, epidermal growth factor and basic fibroblast growth factor begin to act early on primordial stage follicles, whereas insulin-like growth factor-1 affects early antral follicles.

Circumstantial evidence of the actions of androgen includes the numerous observations that atretic follicles consistently exhibit an increased androgen:estrogen ratio within the intrafollicular fluid.[565] Supporting experimental evidence includes reports that low doses of hCG (to induce endogenous androgen production), T, or DHT following 4 days of E2 treatment in hypophysectomized rats lead to increased numbers of atretic follicles within 24 h.[705,732] The detrimental effects of hCG or exogenous androgens are inhibited by co-treatment with anti-T antisera or AR antagonists, indicating the involvement of androgen receptor in this process.[705,732] Interestingly, large (>150 μm) follicles are more susceptible to the atretogenic effects of androgens than small (<150 μm) follicles, indicating that androgens are largely atretogenic in late-stage follicles.[705,732] In similar experiments on hypophysectomized rats, Billig et al. demonstrated that the follicular atresia that follows the withdrawal of 2 days of continuous estrogen (DES) treatment is enhanced by subsequent T exposure but prevented by E2.[733] Conversely, Flaws et al. show follicular atresia induced by the endocrine-disrupting chemical methoxychlor.[734]

Additionally, AR-null mouse models also have increased atretic follicles,[183,185,690] demonstrating that AR signaling plays a role in follicle atresia; however, further studies are needed to understand the mechanism.

Glucocorticoid Receptor Signaling in Ovarian Function

While the ovary is not considered a classic target tissue of glucocorticoids, altered glucocorticoid production can affect reproduction and fertility throughout the HPG axis. Within the ovary, glucocorticoid signaling through GR can modulate steroidogenesis/gametogenesis and will briefly be discussed here. GR is expressed in the rat ovary, and examination of whole ovary expression shows that levels do not change upon treatment with exogenous gonadotropins.[735] Further examination of GR expression in isolated granulosa cells shows no significant alterations in expression within these cells, although GR expression appears to be elevated in corpora lutea.[735]

Glucocorticoid signaling in the ovary acts to inhibit LH action and steroid biosynthesis during folliculogenesis.[736] Treatment of granulosa cells with cortisol or dexamethasone was able to inhibit FSH-stimulated increases in aromatase activity in vitro, while P production was increased compared to control-treated cells. This finding suggests that GR signaling may affect steroidogenesis of the ovarian steroids in a differential manner.[737] Furthermore, this finding suggests that GR signaling in the ovary is important for P function and ovulation. Dexamethasone was also found to stimulate FSH-mediated increases in P production in porcine granulosa cells,[738] suggesting a key role for GR signaling during late stages of ovulation and for corpora lutea function.

The expression of GR in granulosa cells does not change significantly during early follicle development; however, the treatment of cells with agonist shows differential activity depending on the stage of differentiation of the cells. To circumvent the action of glucocorticoids, expression of two metabolizing enzymes has been found to have stage-specific expression in the ovary.[736] The expression of the type I and type II 11β-hydroxysteroid dehydrogenase (11HSD 1 and 11HSD 2) modulates the action of glucocorticoids by regulating their concentrations within tissues.[739] This is important in the ovary during folliculogenesis since glucocorticoids are not synthesized within the tissue itself. During FSH-stimulated follicle growth, *11Hsd1* is expressed and acts to suppress glucocorticoid action, then as the granulosa cells become luteinized after LH stimulation, *11Hsd2* expression is increased.[735,740] This acts to increase the action of glucocorticoid action on the ovary during luteinization and formation of the corpora lutea, which also shows an increase in GR expression, demonstrating the importance of GR signaling during this process. Interestingly, expression of *11Hsd2* is reduced during luteal regression,[741] demonstrating the importance of GR activity specifically in the corpora lutea. The evidence to date suggests that GR signaling is important in ovarian function, although further work is needed to define the precise activity and necessity of this signaling mechanism specifically in the ovary.

SUMMARY

The salient aspects of the previous discussion are summarized in a model of sex steroid and steroid receptor action during folliculogenesis. Although certain postulated mechanisms and pathways portrayed in this model are supported by substantial evidence, other aspects are much more speculative and remain to be demonstrated. Regardless, the evidence is solid that the receptor-mediated steroid pathways exist in the ovary and their intraovarian functions are critical to female fertility.

CONCLUSION

Within this fairly extensive review we have endeavored to describe as comprehensively as possible what is currently known regarding the important functions of estrogen, progesterone, androgen, and glucocorticoid receptors in ovarian and uterine tissues. Clearly, an abundance of data has been obtained that has greatly advanced our understanding of the roles of these receptors since early descriptions more than five decades ago. Nevertheless, many open questions remain for further elaboration. At the level of the steroid receptors themselves, questions remain regarding how the receptors mediate the spectrum of responses, and what roles tissue and gene specificity of distinct activation domains on the receptors play. Additionally, better understanding of the interactions of receptors with chromatin, which are often quite far from regulated transcripts, and how the interactions lead to changes in transcription, are challenging questions to approach. We can hope to learn more about temporal patterns of changes in the organization of nuclear structures initiated by steroid receptors. At the whole animal level, what remains is to piece together advances gleaned from diverse models and methods into a comprehensive description of the coordinated signaling between receptors for different steroids in cells and tissues that culminate in an optimal environment for fertilization, implantation, gestation, and parturition.

Color Plates

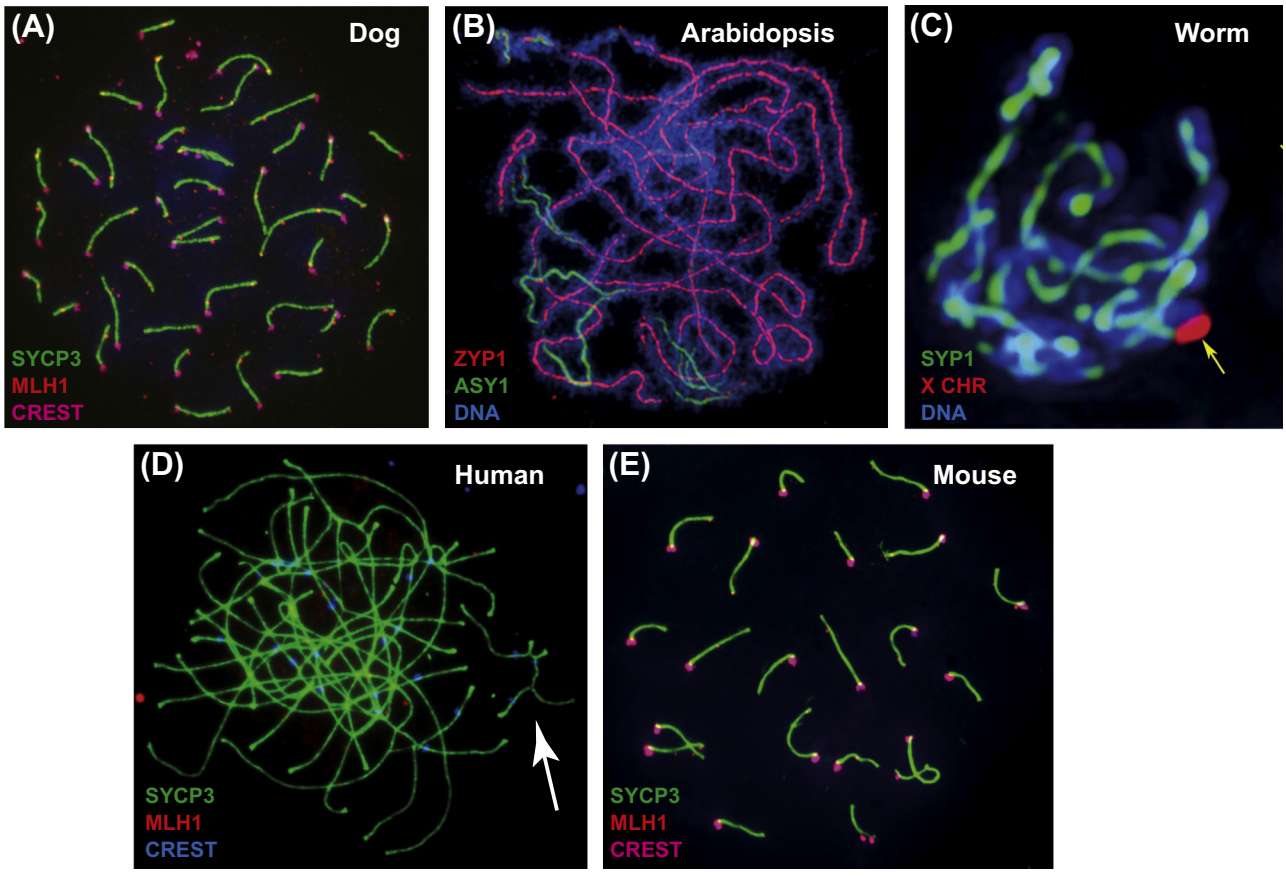

FIGURE 1.2 Comparative meiosis across eukaryotic species. (A) Pachytene cell from an adult dog testis stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, pink). (B) Immunolocalization of the *Arabidopsis* synaptonemal complex transverses filament protein ZYP1 (red), polymerizing between the homologous chromosome axes marked by ASY1 (green) and the DNA loops (blue) in a late-zygotene nucleus. The ASY1 signal (green) is reduced in synapsed regions (red), and an interlock is being resolved. (C) A *C. elegans* pachytene nucleus immunostained to show that the synaptonemal complex (green) is normal and that the pairing center ends of the X chromosome are fully paired (red); *(Source: Adapted from Saito et al., PLoS Genet, 2009.)* (D) A trisomic human embryonic oocyte at the pachytene stage stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, blue). The three copies of chromosome 21 can be seen attempting to pair (arrow). (E) Mouse pachytene cell stained immunostained with SYCP3 (green), MLH1 (red), and cREST (centromere, pink).

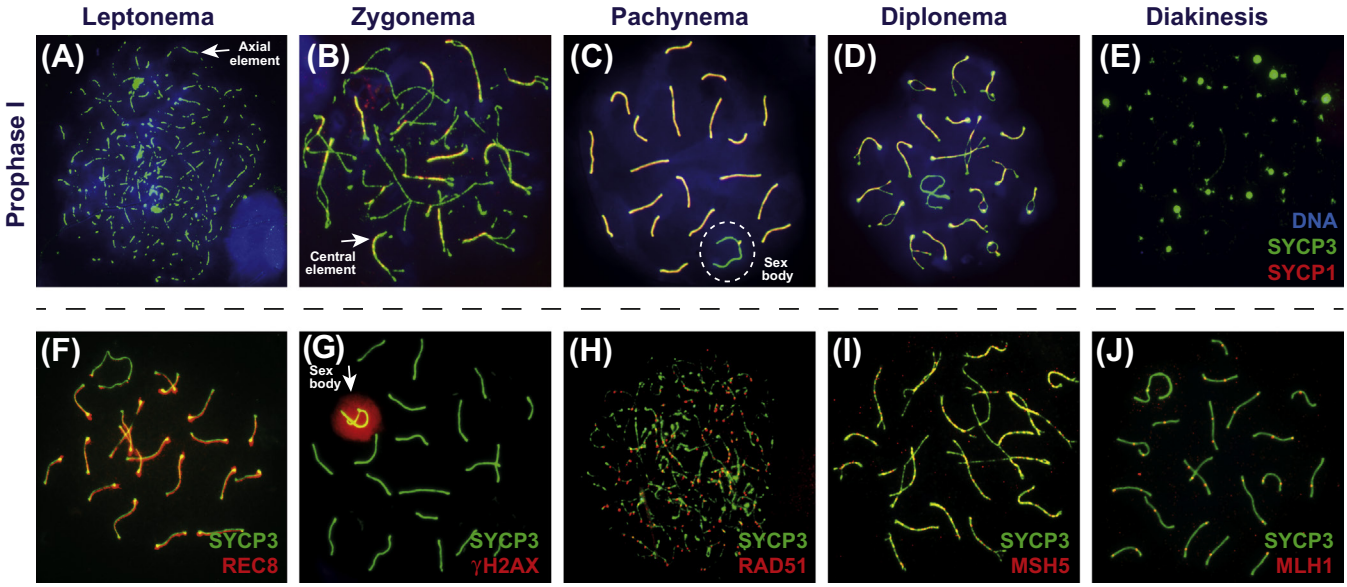

FIGURE 1.7 Immunofluorescent analysis of meiotic prophase I events in mouse spermatocytes. (A–E) Synaptic events in the five substages of prophase I, visualized by staining with antibodies against axial–lateral element protein SYCP3 (green) and central element protein SYCP1 (red), where the overlay between the two appears in yellow. (F–J) Immunolocalization of SYCP3 (green) with key meiotic markers during prophase I; (F) REC8, (G) λH2AX, (H) RAD51, (I) MSH5, and (J) MLH1 all in red, and SYCP3 in green.

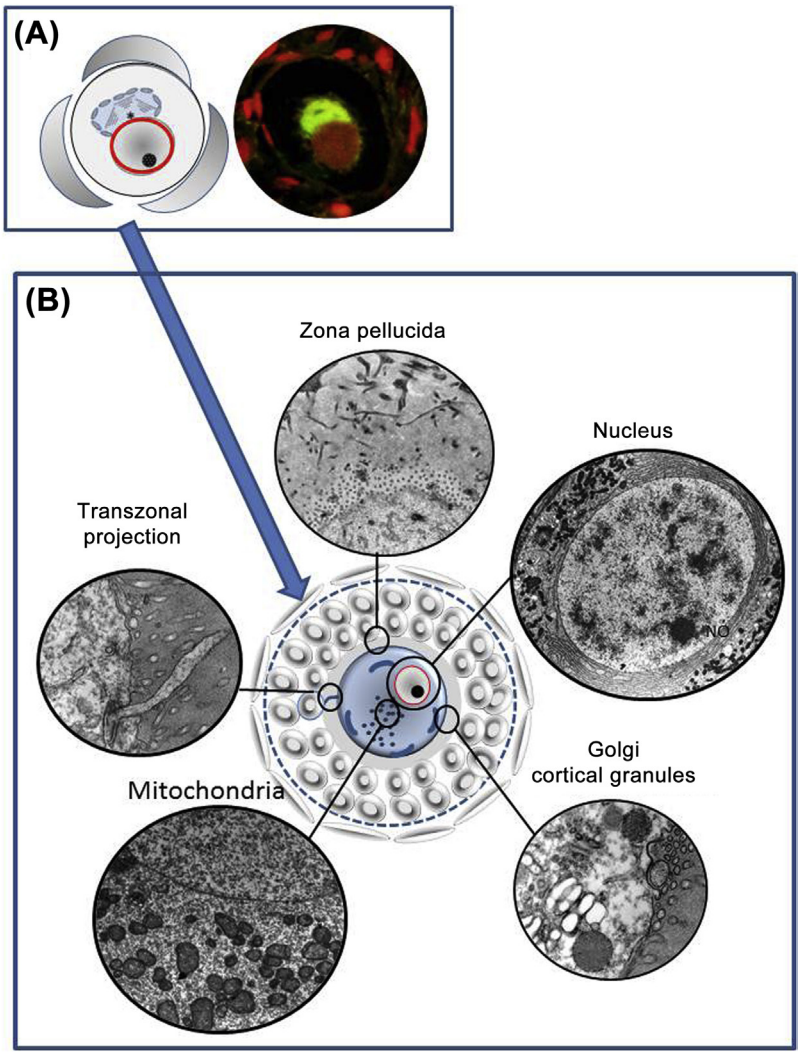

FIGURE 2.1 **Structure of the mammalian oocyte.** (A) depicts the general organization of organelles in a primordial follicle; schematic (left) denotes centrally positioned nucleus and aggregation of organelles known as Balbiani's body (asterisk). Right is an immunofluorescence micrograph illustrating the concentration of the germ cell–specific marker VASA within Balbiani's body (green) located next to the oocyte nucleus (red). *(Image courtesy of Professor Alfredo Vitullo)*. Upon activation, oocytes enter the growth phase of oogenesis (B). (B) summarizes the major ultrastructural features of a growing oocyte within a preantral follicle noting the assembly of the extracellular coat or zona pellucida, the enlarged nucleus or germinal vesicle with prominent nucleoli (NO), subcortical Golgi complexes with associated cortical granules, abundant perinuclear mitochondria, and the elaboration of microvilli on the oocyte plasma membrane interacting with somatic cell projections known as transzonal processes.

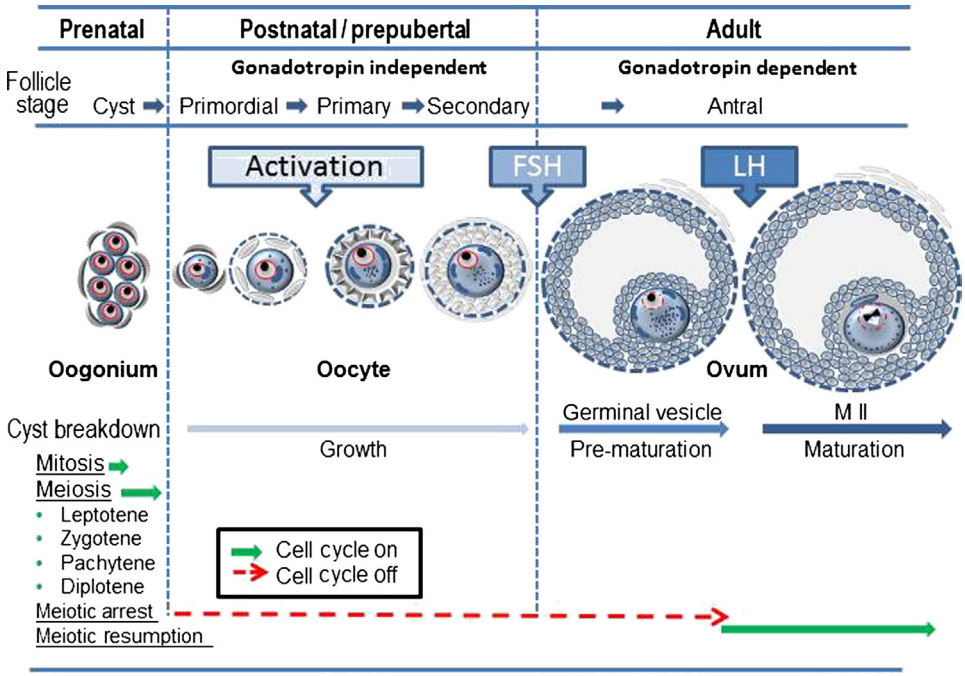

FIGURE 2.2 Stages of oogenesis defined on the basis of the oocyte cell cycle state as it occurs in the mouse. Mitotic proliferation of oogonia occurs in the prenatal gonad and is accompanied by entry into meiotic prophase as follicle formation and cyst breakdown take place. The cell cycle is then turned off for the duration of the growth phase of oogenesis that occurs during the preantral stages of follicle development. While FSH is required to advance follicle development, the oocytes remain in meiotic arrest with a germinal vesicle in the prematuration stage. In response to the LH surge, meiotic arrest is released and the oocyte proceeds through maturation being ovulated at the metaphase two stage of meiosis, which is maintained until the fertilization signal elicits completion of meiosis two. Note that in general the growth phase of oogenesis occurs independent of gonadotropin stimulation, whereas the prematuration and maturation phases require gonadotropin stimulation.

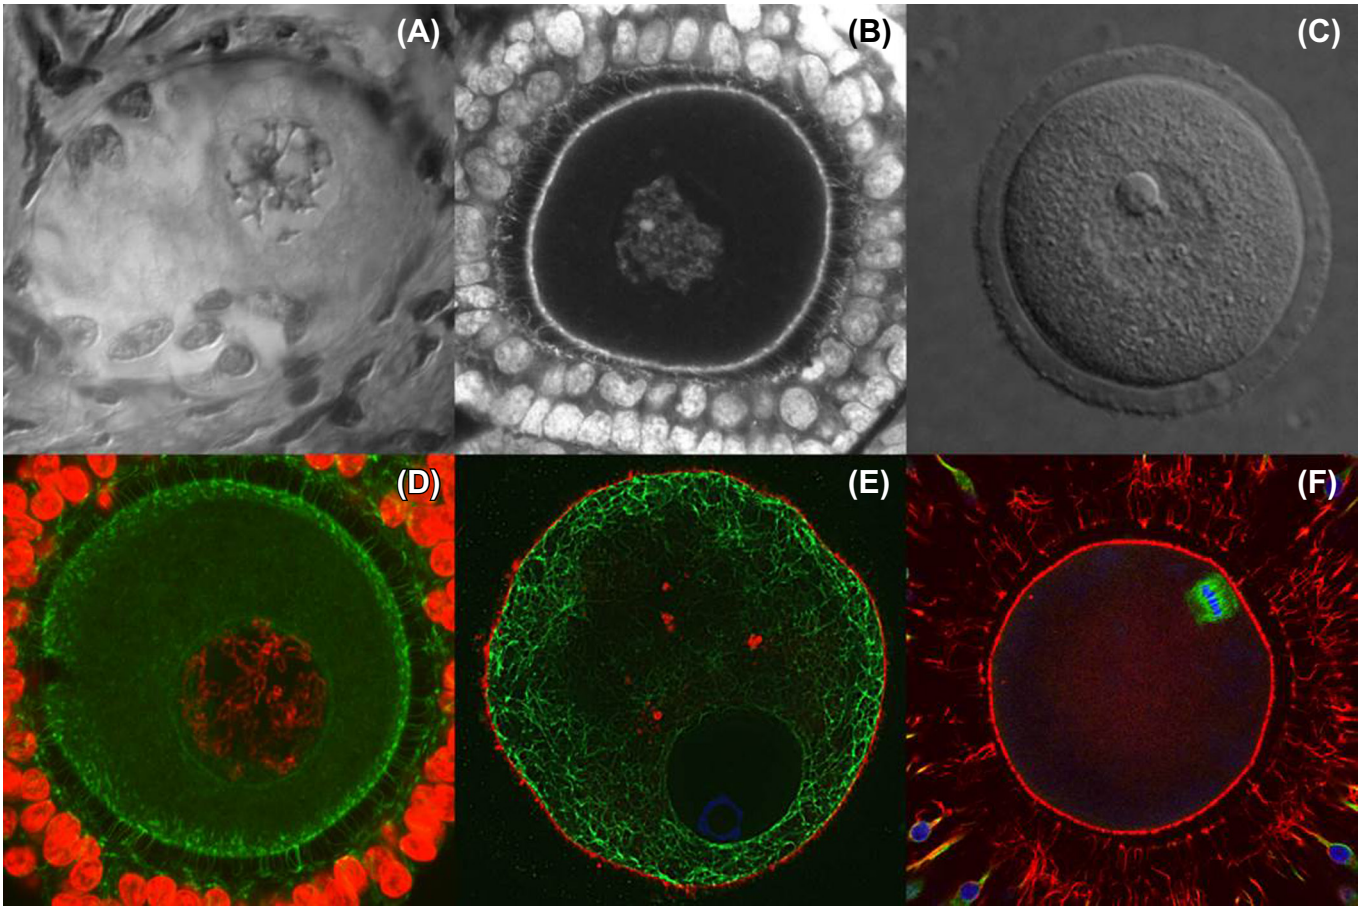

FIGURE 2.3 **Prominent morphological features of the mammalian ovum at various stages of oogenesis in various species.** (A) depicts a resting primordial oocyte within the bovine ovary in which the germinal vesicle chromatin assumes a distinctly fibrillar pattern of organization. (B) represents a primary growing oocyte from the mouse containing a centrally positioned germinal vesicle and illustrating the prominent actin-rich cortex and numerous transzonal projections emanating from surrounding granulosa cells. (C) demonstrates the appearance of a full-grown immature mouse oocyte following isolation from the ovary; note the prominent eccentrically positioned nucleolus within the GV and the cell free zona pellucida. (D) depicts a full-grown immature bovine oocyte isolated from a Graafian follicle; note the clear organization of bivalents in the GV and the presence of numerous foci at the oocyte cell surface, which represent terminal connections with corona TZPs (preparation labels f-actin using rhodamine phalloidin). (E) illustrates an immature GV-stage human oocyte that has been labeled for chromatin and microtubules (fibrillar structures); note that the chromatin is aggregated around the nucleolus of the GV and that a dense network of cytoplasmic microtubules is present in the outer regions of ooplasm. (F) illustrates a mature metaphase two arrested oocyte from a horse following controlled ovarian hyperstimulation; this preparation has been dual-labeled for tubulin (green) that highlights the cortical anchored meiotic spindle and f-actin (red) that labels the prominent corona cell projections or TZPs that appear detached from the oolemma.

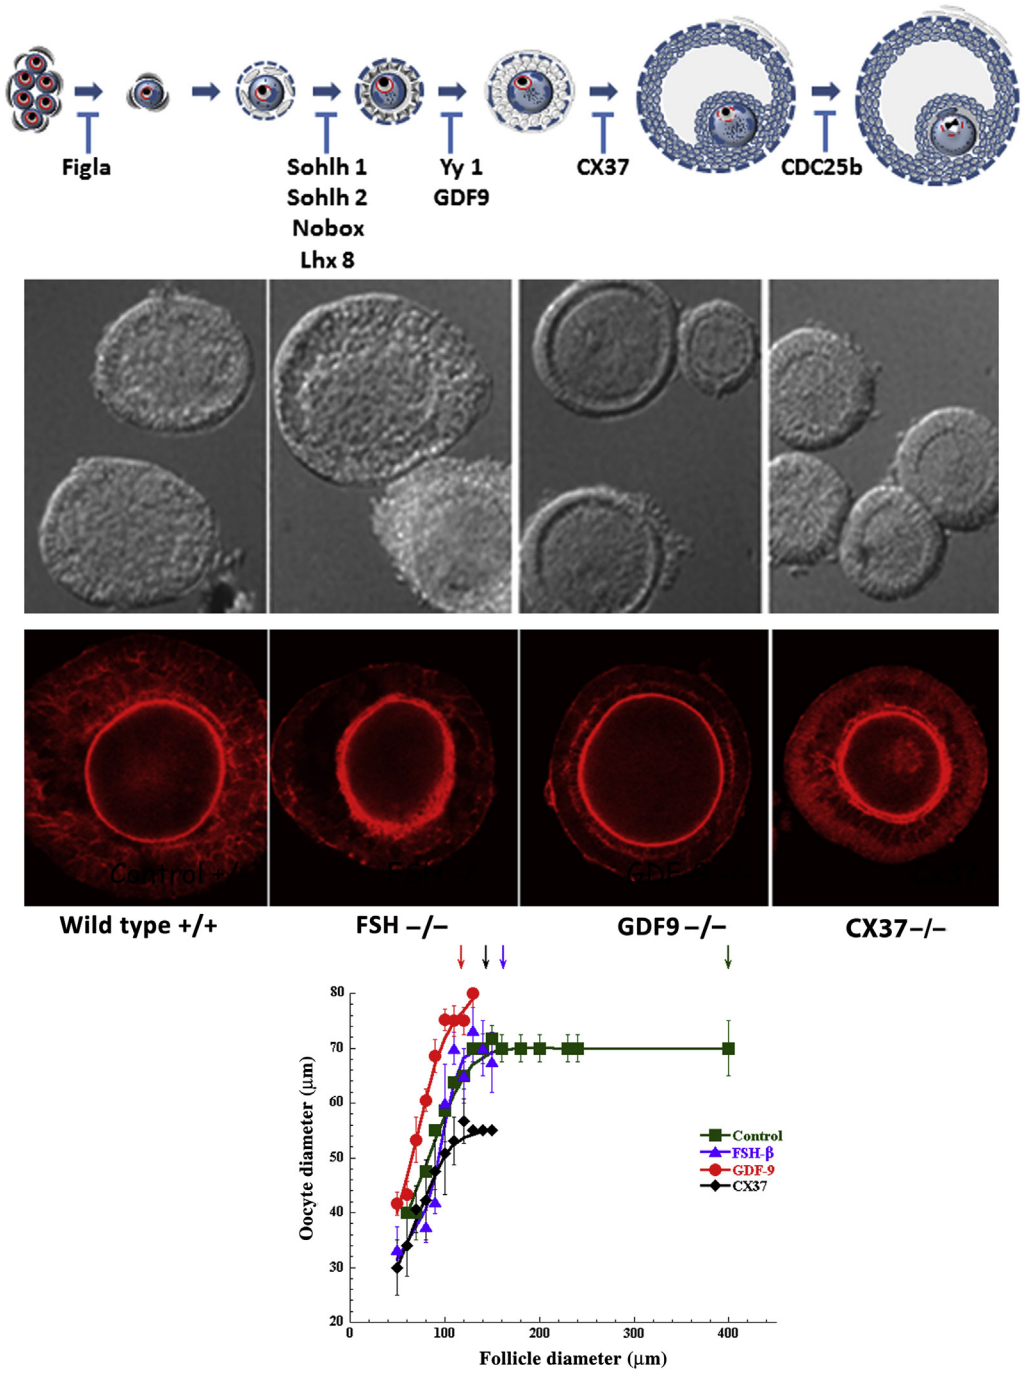

FIGURE 2.10 Mouse knockout phenotypes with distinct defects during the growth phase of oogenesis. Schematic at top shows effects of targeted gene deletion on stage of follicle development. Images show phenotype of wild type (left), GDF9, FSH beta, and CXN 37 in sequence that in the top panel show living follicles, and in the lower panel, the organization of granulosa cell–oocyte interface. Graph (bottom) plots the relationship between follicle and oocyte growth for the same four groups.

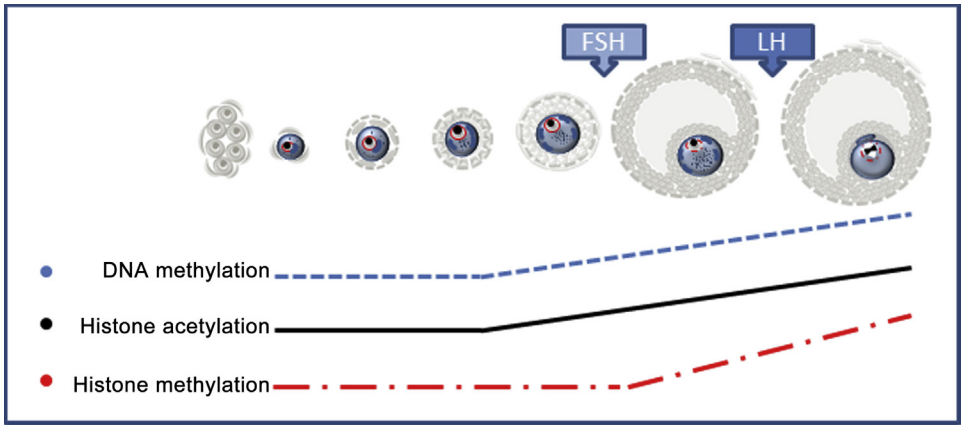

FIGURE 2.11 Epigenetic modifications of chromatin during the course of oogenesis. Genes subject to imprinting show progressive signs of DNA methylation beginning during the growth phase of oogenesis and ending at some point in the preovulatory follicle. Histone acetylation in developing oocytes follows a similar time course as DNA methylation, whereas histone methylation is reported to occur following the growth phase. Data are based primarily on studies in the mouse.

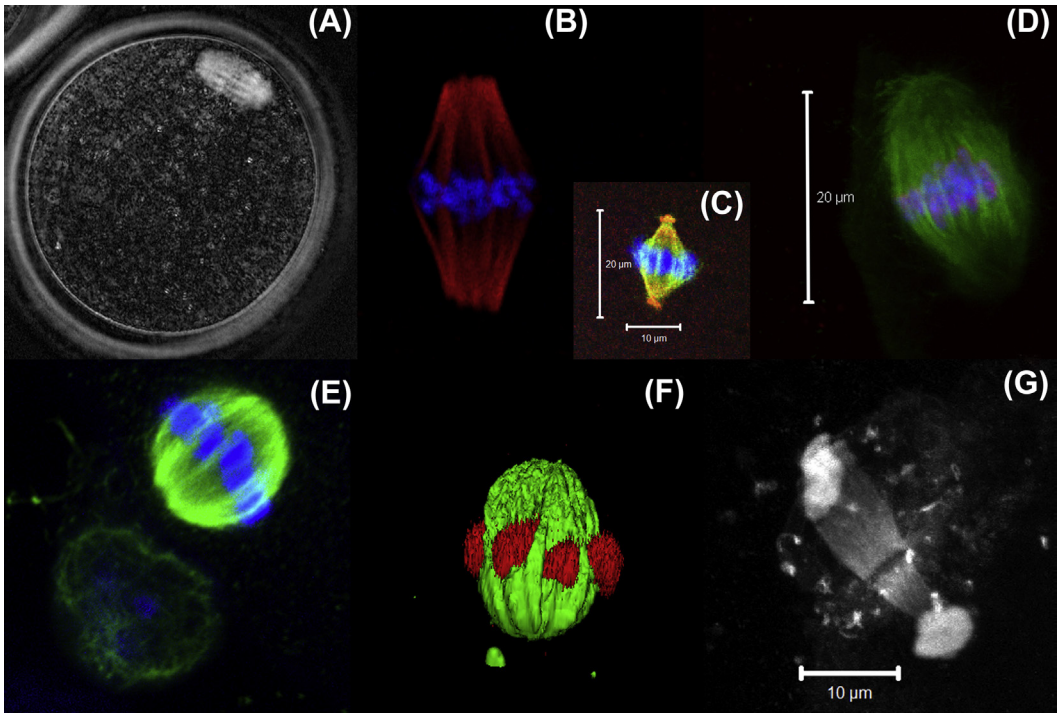

FIGURE 2.15 Meiotic spindles of mammalian oocytes. (A), (B), and (C) depict metaphase two–stage mouse oocytes under polyscope in a living oocyte (A), and after confocal immunofluorescence of tubulin (B, red; C, green); chromosomes aligned on the metaphase plate are rendered blue, and in (C), the poles of the spindle from a naturally ovulated oocyte show gamma-tubulin in red. (D) illustrates kinetochore microtubules as green stripes in a metaphase one horse oocyte that has been stained for chromosomes (blue) and phosphohistone H3 (red). (E), (F), and (G) are human oocytes at metaphase two (E and F, with the latter rendered as a three-dimensional projection); and (G) illustrates a projection of telophase one at the time of polar body extrusion.

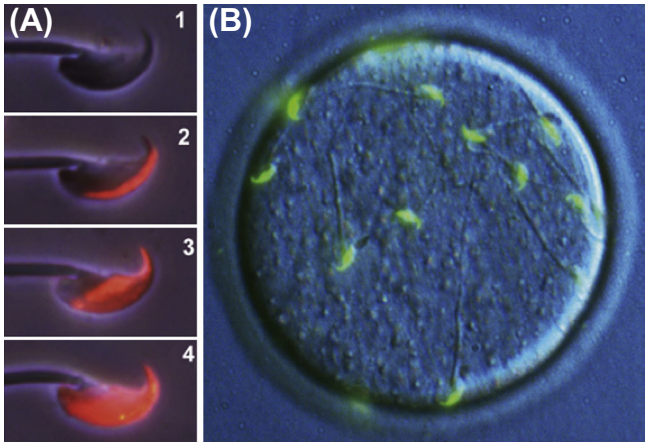

FIGURE 4.7 Gamete fusion-related factor IZUMO1 and localization in sperm. (A) IZUMO1 is an acrosomal membrane protein that is not exposed before the completion of an acrosome reaction (1). Acrosome-reacted sperm can be classified into three major groups by their IZUMO1-staining pattern: acrosomal cap (2), equatorial (3), and whole-head (4). (B) Accumulation of many sperm in the perivitelline space of the eggs recovered from females mated with *Izumo1*$^{-/-}$ males. Sperm in the perivitelline space were labeled with acrosome-reacted sperm-specific monoclonal antibody MN9. *Figure reprinted from Ref. 273 with permission from the* Asian Journal of Andrology. *Courtesy of Dr Masaru Okabe.*

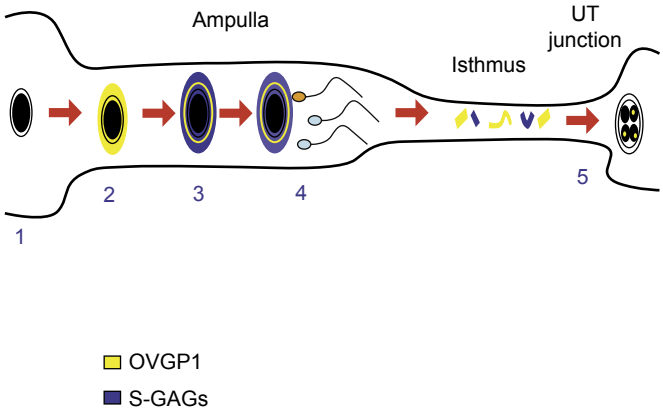

FIGURE 4.8 Depiction of the proposed role of oviductal contents in preventing polyspermy in ungulates. After the egg is shed into the ampulla following ovulation (1), oviduct-specific glycoprotein (OVGP1) surrounds it in a "shell" that renders the zona pellucida (ZP) resistant to proteolysis (2). Other oviduct molecules such as heparin-like glycosaminoglycans (S-GAGs) are thought to aid and strengthen the binding of OVGP1 to the ZP (3), modifying interaction with spermatozoa (4). As the zygote advances to the uterus, the aforementioned factors are shed or absorbed into the egg (5). *Figure reprinted and legend adapted from Ref. 375 with permission from John Wiley & Sons. Courtesy of Dr Pilar Coy.*

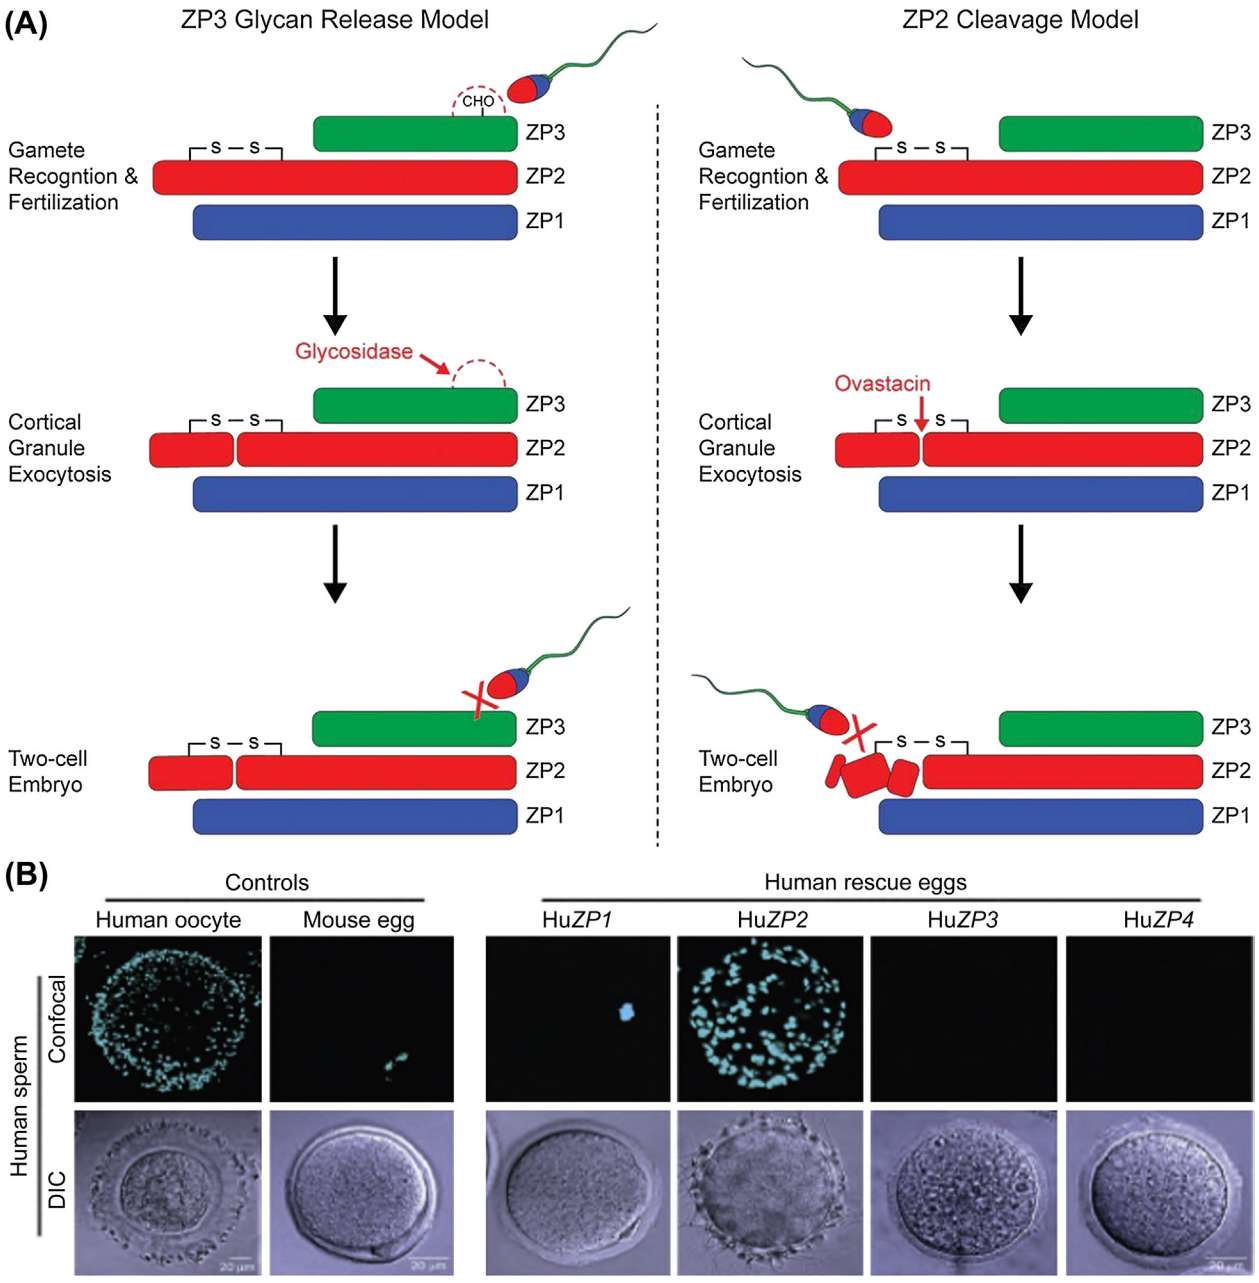

FIGURE 4.9 Models of zona pellucida block to polyspermy. (A) A specific glycan-release model (left panel) proposes that *O*-glycans on ZP3 Ser^{332} and Ser^{334} or possible others act as ligands for a sperm surface receptor. Following fertilization, cortical granules would release a glycosidase that would remove the *O*-glycans and account for the inability of sperm to bind to two-cell embryos. The ZP2 cleavage model (right panel) proposes that sperm bind to an N-terminal domain of ZP2. Following fertilization, ovastacin, a cortical granule metalloendoprotease, is exocytosed and the proteolytic destruction of the ZP2 docking site prevents sperm from binding to two-cell embryos. (B) Human sperm bind to mouse eggs from transgenic strains expressing human ZP2, but not other human ZP proteins, in the ZP. Confocal and differential interference contrast images of capacitated human sperm binding to the ZP of mice expressing human ZP1, human ZP2, human ZP3, or human ZP4, in the absence of the corresponding mouse protein. Human oocytes and mouse eggs served as positive and negative controls, respectively. Specific references and experimental details can be found in the text. *Figure reprinted from Ref. 229 with permission from Oxford Journals. Courtesy of Dr Jurien Dean.*

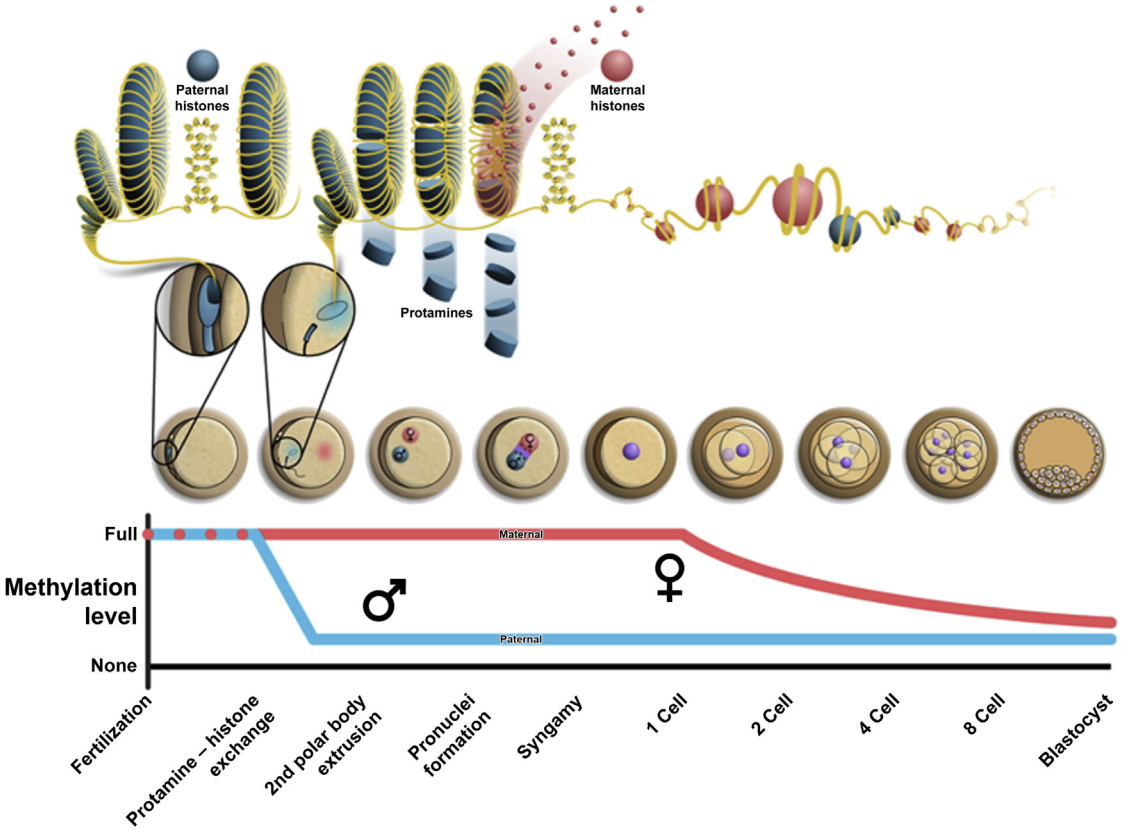

FIGURE 4.13 Reorganization of the male chromatin after fertilization and alterations to the epigenome postfertilization. The top panel illustrates the chromatin structure of the mature sperm immediately following fertilization (highly protaminated with some retention of paternally derived histones). Soon after sperm entry, the protamine to histone transition takes place where maternally derived histones replace protamines resulting in the decondensation of the sperm head. The middle panel illustrates the various stages of early embryonic development. The bottom panel shows the methylation changes that occur over time in the maternal and paternal pronucleus, where the paternal pronucleus undergoes active demethylation and the maternal DNA is demethylated passively in a replication-dependent manner. The approximate chronology of major events in the early embryo is outlined along the bottom of the figure and correlates to the illustrations of embryos above. *Figure reprinted from Ref. 444 with permission from Frontiers. Courtesy of Dr Douglas Carrell.*

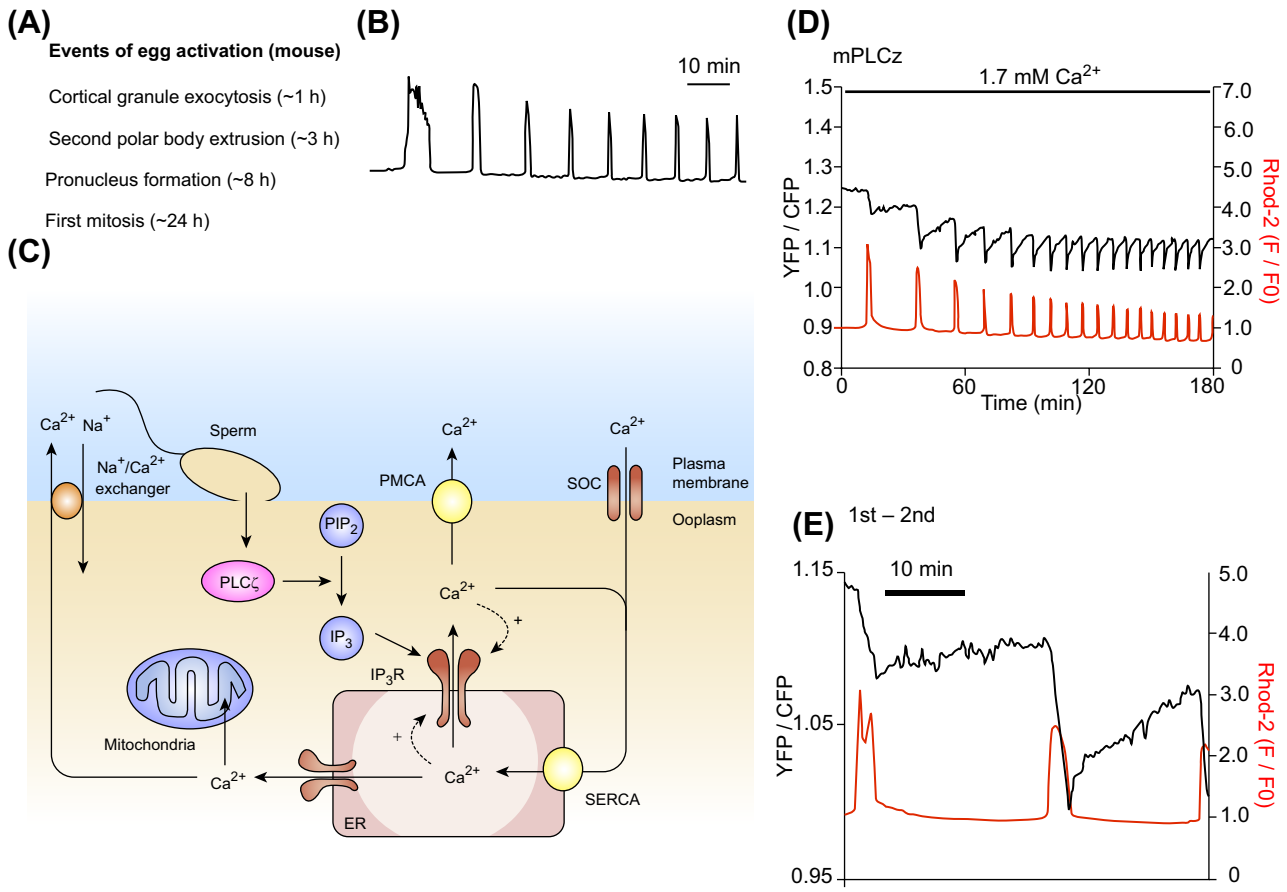

FIGURE 4.14 **Temporal course of activation events in mouse eggs with a characteristic Ca^{2+} response and candidate molecules involved in the initiation oscillations and in Ca^{2+} homeostasis.** (A) Main cellular events of egg activation after sperm entry and approximate time in hours (h) required for their completion. (B) A typical pattern of $Ca^{2+}{}_i$ oscillations associated with fertilization or with injection of PLCζ cRNA. Note that recordings were terminated prematurely. (C) Upon fusion, the sperm is thought to deliver phospholipase C (PLC) ζ, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol 1,4,5-trisphospahte (IP_3) and diacylglycerol (DAG). IP_3 binds its receptor, IP_3R1, causing Ca^{2+} release out of the endoplasmic reticulum (ER). Following Ca^{2+} release, basal $Ca^{2+}{}_i$ levels are regulated by the combined action of the sarcoendoplasmic reticulum Ca^{2+} ATPase (SERCA), plasma membrane Ca^{2+} pump (PMCA), Na/Ca^{2+} exchanger, and mitochondria. Store operated Ca^{2+} channels (SOC) or other Ca^{2+} channels are proposed to mediate Ca^{2+} influx, which is required to fill the ER and maintain oscillations. Broken lines suggest feedback action of Ca^{2+} on IP_3R1. *(Adapted from Ref. 507 with permission of CSHLP.)* (D) $Ca^{2+}{}_{ER}$ and $Ca^{2+}{}_i$ undergo simultaneous but opposite changes in concentration during oscillations in mouse MII eggs. $Ca^{2+}{}_i$ responses were induced by injection of 0.05 µg/µl mouse PLCζ cRNA into MII eggs. In vitro transcribed D1ER cRNA was injected into eggs 5 h before the initiation of $Ca^{2+}{}_i$ measurements. The emission ratio of D1ER (YFP/CFP) was used to estimate relative changes in $[Ca^{2+}]_{ER}$ (left axis, black trace). $[Ca^{2+}]_i$ (right axis, red trace) was recorded using Rhod-2. (E) The first and second $Ca^{2+}{}_i$ rises do elicit significant refilling of the ER, but subsequent rises, especially after ~ the sixth rise (D). *Adapted from Ref. 508 with permission from The Company of Biologists.*

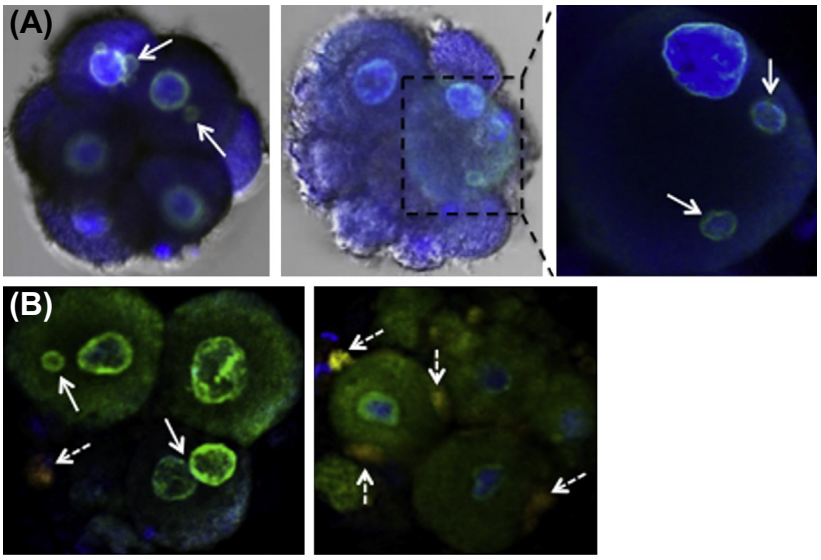

FIGURE 6.4 Detection of embryonic micronuclei in cleavage-stage human embryos. (A) Expression of the nuclear envelope marker, LAMIN-B1 (green), in 4′,6-diamidino-2-phenylindole (DAPI)-stained (blue) cleavage-stage human embryos visualized by immunofluorescent confocal microscopy and differential interference contrast (DIC) imaging at 20× (left and middle) and 40× (right) reveals the presence of several embryonic micronuclei (indicated by white solid arrows) distinct from primary nuclei in human blastomeres. (B) Similarly evaluated additional cleavage-stage human embryos with low (left) and high (right) fragmentation also immunostained for centromere protein E (CENP-E; orange) in the absence of DIC imaging identifies multiple missing chromosomes in cellular fragments (indicated by white dashed arrows) adjacent to blastomeres at this stage of development. *Source: Adapted from Ref. 16.*

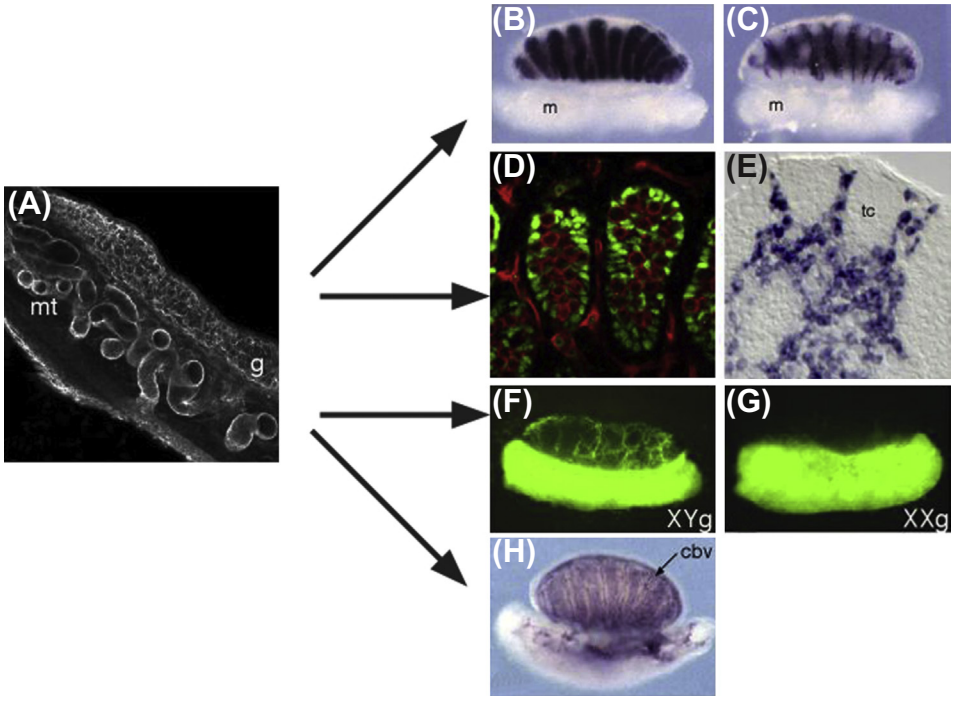

FIGURE 7.6 Differentiation of the embryonic testis from a bipotential precursor. (A) Confocal image of a gonad and mesonephros stained with an antibody to laminin at a stage before morphological changes take place (E11.5). (B–H) Morphology of the embryonic testis. (B, C) The Sertoli and Leydig cells of the E13.5 gonad are marked by whole-mount in situ hybridization for the expression of the Sertoli cell marker AMH (B) and the Leydig cell marker *Cyp11a1* (C). The structure of the testicular cords is seen in the confocal image of an E12.5 gonad that was stained with an antibody against SOX9 in green (D). Germ cells are found within the testicular cords as marked by the antibody stain for PECAM in red (D). In the interstitium, epithelial cells, as marked by the antibody stain for PECAM in red (D), and Leydig cells, as marked by the section of the whole mount in situ hybridization on a gonad from a E14 embryo for the expression of *Cyp11a1* (E), are found. (F, G) Mesonephric cell migration is observed in the XY (F) but not the XX (G) gonad, as shown by organ culture samples where the mesonephros but not the gonad is derived from transgenic mice that express GFP ubiquitously. (H) The formation of male-specific vasculature as shown by a whole-mount antibody stain to PECAM, which marks endothelial cells, of gonad and mesonephros from an E14 embryo. mt, mesonephric tubules; g, gonad; m, mesonephros; tc, testis cord; cbv, coelomic blood vessel. *Source: Adapted from Ref. 252; confocal image (D) courtesy of Blanche Capel.*

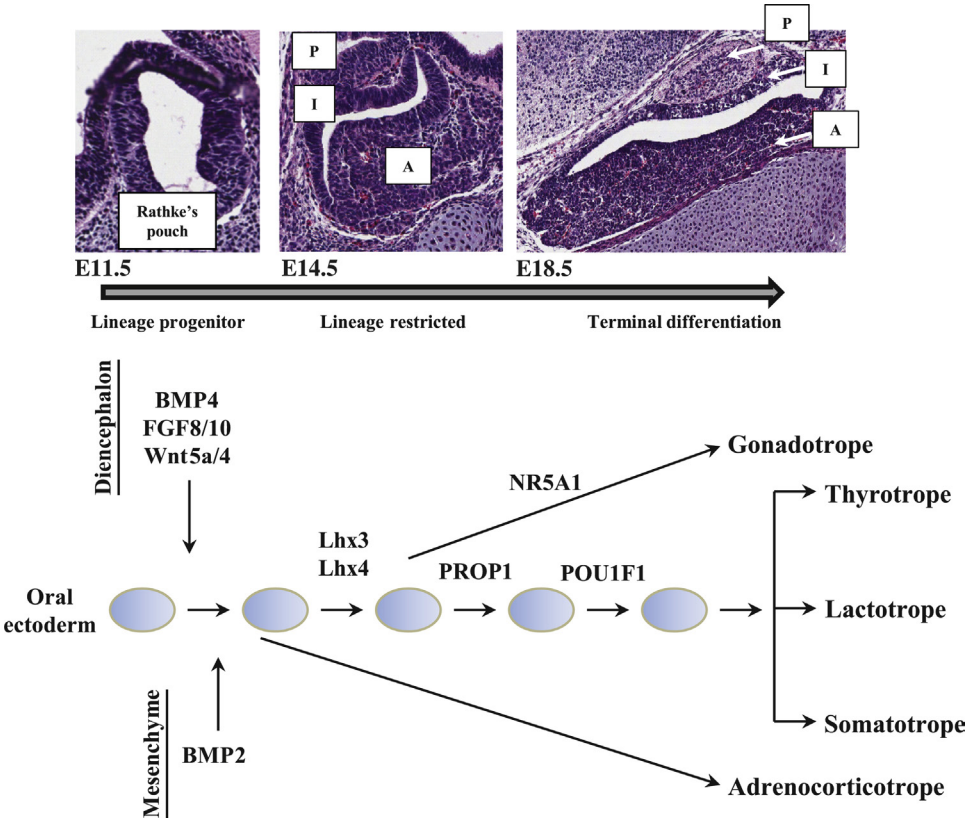

FIGURE 10.1 **Pituitary development.** The pituitary gland emerges from important interactions between the oral and neural ectoderm (diencephalon). Early expansion of the oral ectoderm appears to be functionally related to paracrine signals (such as bone morphogenic proteins (BMPs) and fibroblast growth factors (FGFs)) originating from the neural ectoderm and affecting proliferation and early differentiation of the oral ectoderm. The resulting expansion of tissue forms Rathke's pouch, the anlagen of the presumptive lineage progenitors of the anterior and intermediate lobes of the gland. In addition to signals emerging from the diencephalon, the surrounding mesenchyme provides additional paracrine signaling from BMPs, further restricting lineage identity. Differentiation of the five endocrine cell types within the anterior lobe of the pituitary is controlled by concise expression of a series of transcription factors that serve to restrict cell identity and drive terminal differentiation of the anterior pituitary. For specification of the gonadotrope cell lineage, early expression of Lhx3 (controlled by FGF signaling) and later expression of NR5A1 are central. Interestingly, Lhx3 and NR5A1 play central roles in the regulation of the four gonadotrope signature genes that define gonadotrope function in the adult animal. Sagittal tissue sections shown are from the mouse (unpublished data from M.S. Roberson and A.M. Navratil; e11.5 represents embryonic age in days post conception; P: posterior; I: intermediate; A: anterior).

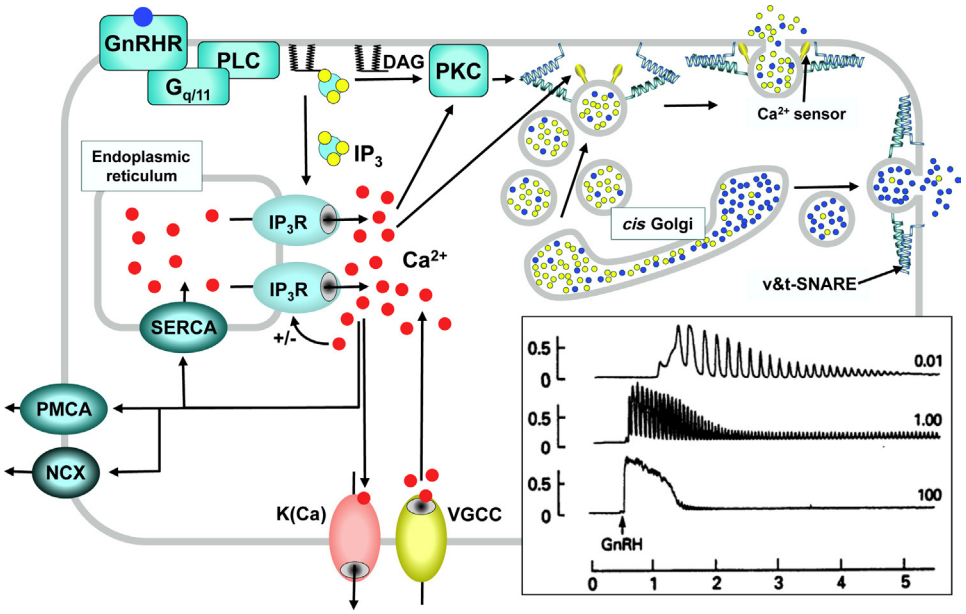

FIGURE 10.2 Acute effects of GnRH on Ca^{2+} and gonadotropin secretion. GnRH acts via Gq/11 coupled GPCRs to activate PLC, with consequent IP_3-mediated Ca^{2+} mobilization and Ca^{2+}–DAG-mediated activation of PKC. The interplay of Ca^{2+} mobilization from intracellular stores and Ca^{2+} entry across the plasma membrane increases $[Ca^{2+}]_i$. This response may be oscillatory or more sustained, often with a spike–plateau-type profile. The response elicited by GnRH varies according to cell type and stimulus intensity but is also variable from cell to cell, even within isogenic cell populations. The GnRHR-mediated increase in $[Ca^{2+}]_i$ drives the secretion of LH and FSH by regulated exocytosis, a process likely involving interaction of a vSNARE (i.e., synaptobrevin) and a t-SNARE (i.e., syntaxin) as well as regulation by a Ca^{2+} sensor (i.e., synaptotagmin). PKC can also stimulate gonadotropin secretion, acting as a positive modulator of Ca^{2+}-driven exocytosis. In addition to regulated exocytosis, gonadotropins may be secreted via the constitutive pathway. The proportion of FSH (blue circles) secreted constitutively is higher than that of LH (yellow circles), and this could reflect sorting into distinct secretory vesicles formed at the Golgi. This principle is illustrated here by the presence of a Ca^{2+} sensor on LH-enriched vesicles but not on FSH-enriched vesicles. The inset shows μM $[Ca^{2+}]_i$ in individual cells stimulated with the indicated concentration of GnRH (plotted against time in min) and is adapted from Ref. 258.

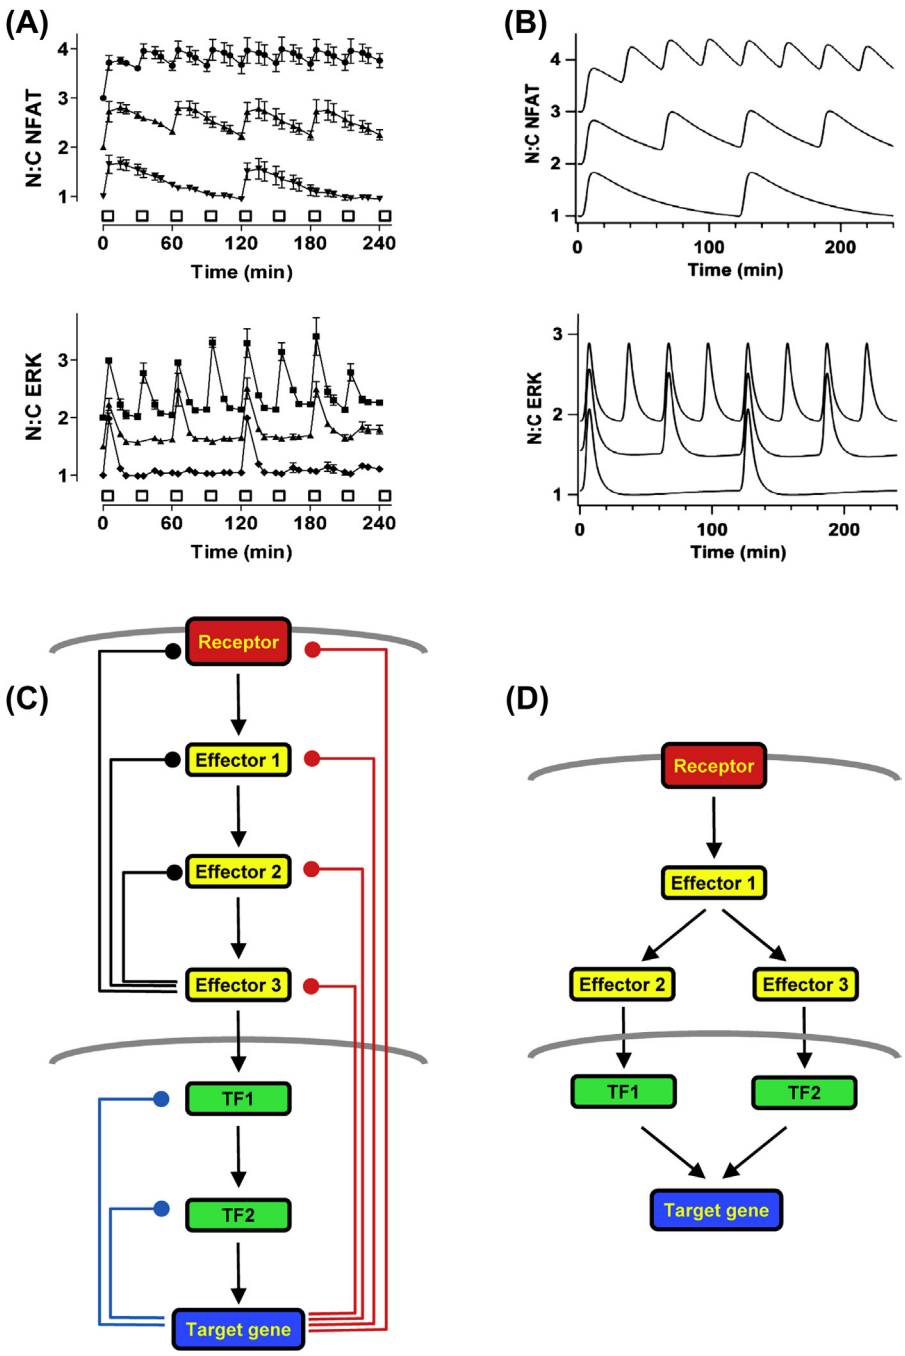

FIGURE 10.7 **GnRH pulse frequency decoding, part I.** Panel (A) shows the effects of pulsatile GnRH (1 nM pulses of 5 min duration and varied intervals) on the nuclear:cytoplasmic ratio (N:C) of NFAT2–EFP (upper chart) or ERK2–GFP (lower chart). In each case, the data are normalized to the prestimulation value and are offset on the vertical axis for clarity. Note that neither of the responses shows desensitization from pulse to pulse and that NFAT–EFP shows a cumulative sawtoothed response at the highest pulse frequency, whereas the ERK2–GFP response is not sawtoothed at any frequency (because it is rapidly reversed on removal of GnRH). Panel (B) shows data from an ordinary differential equation–based mathematical model that mirrors the empirical data for NFAT–EFP and ERK2–GFP translocation. Panel (C) shows a schematic signal transduction cascade in which a receptor in the plasma membrane causes sequential activation of three cytoplasmic proteins (effectors 1–3), and the last of these drives sequential activation of two transcription factors (TF1 and TF2) within the nucleus, which are upstream of a target gene. Also illustrated are multiple negative-feedback loops that could be restricted to the cytoplasm (black) or could involve transcription-dependent feedback to cytoplasmic proteins (red) or nuclear proteins (blue). Panel (D) shows a schematic network in which the receptor activates a bifurcating signal transduction pathway involving three cytoplasmic effectors and two nuclear transcription factors and where these transcription factors converge on the target gene. The empirical and modeled data in panels (A) and (B) suggest that the signal passing from the cytoplasm to the nucleus does not desensitize with pulsatile GnRH, arguing against the upstream negative-feedback pathways shown in black or red in panel (C). *Source: The data in panels (A) and (B) are adapted from Refs 618,620,621.*

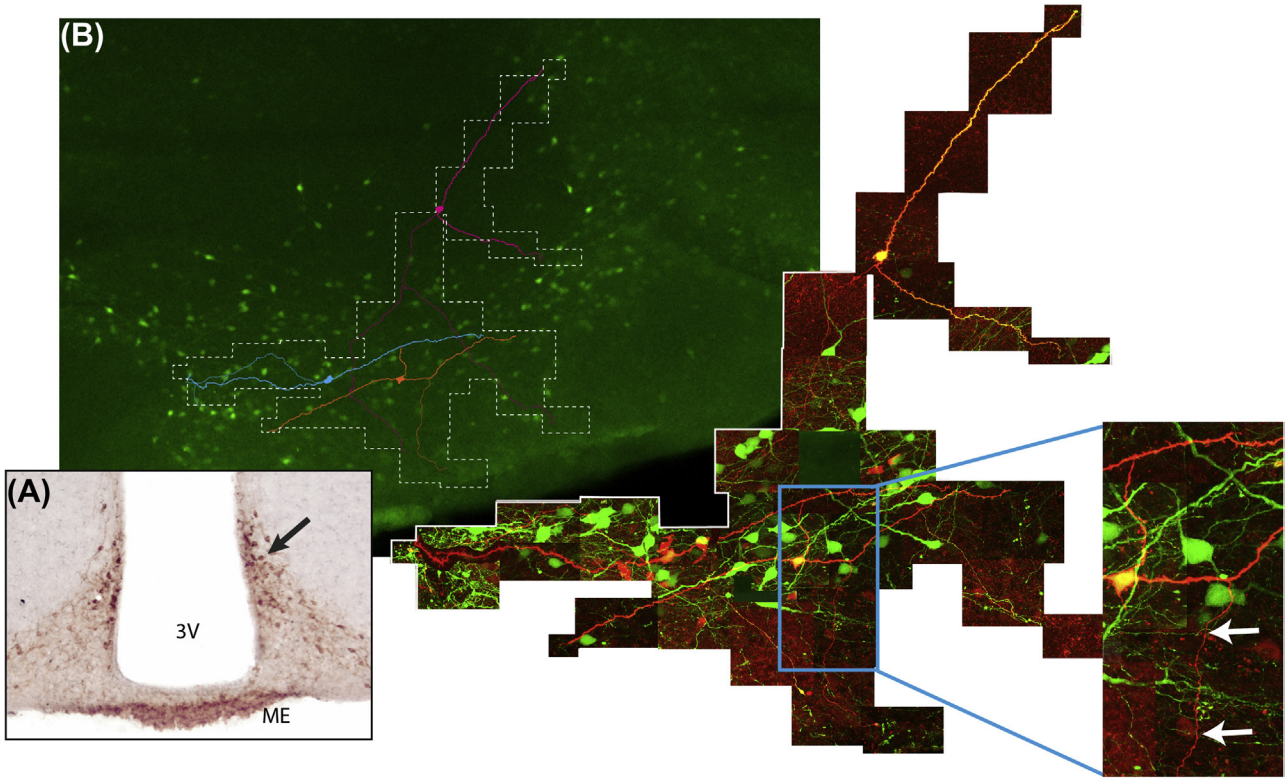

FIGURE 12.3 Neuroanatomy of the TIDA neurons. Panel A shows a coronal section through the mouse hypothalamus, with TIDA neurons identified by tyrosine hydroxylase (TH) immunoreactivity (3V: third ventricle; ME: median eminence). Note the cell bodies in the dorsomedial arcuate nucleus (arrow), as well as strong staining in the nerve terminals in the external zone of the median eminence. Panel B shows a low-power sagittal view of the hypothalamus from a mouse in which green fluorescent protein is expressed under the control of the TH promoter (green). These neurons were visualized in a brain slice, and then three individual TH-positive neurons were filled with neurobiotin (red; but pseudocolored pink, blue and orange in the low power view), allowing visualization of the full extent of the nerve processes. The montage (right) is constructed from multiple high-power views obtained using a laser confocal microscope, illustrating the dentritic tree of three filled cells extending a long distance throughout the nucleus. In the enlargement (right), note the major dendrites coming off the cell body, identified by a wide diameter and multiple spiny processes. The thin, smooth axon (arrow) arises off a primary dendrite and projects down toward the median eminence in the base of the hypothalamus. *Source: Images provided by Drs Michel Herde and Allan Herbison, based on work published in Ref. 86.*

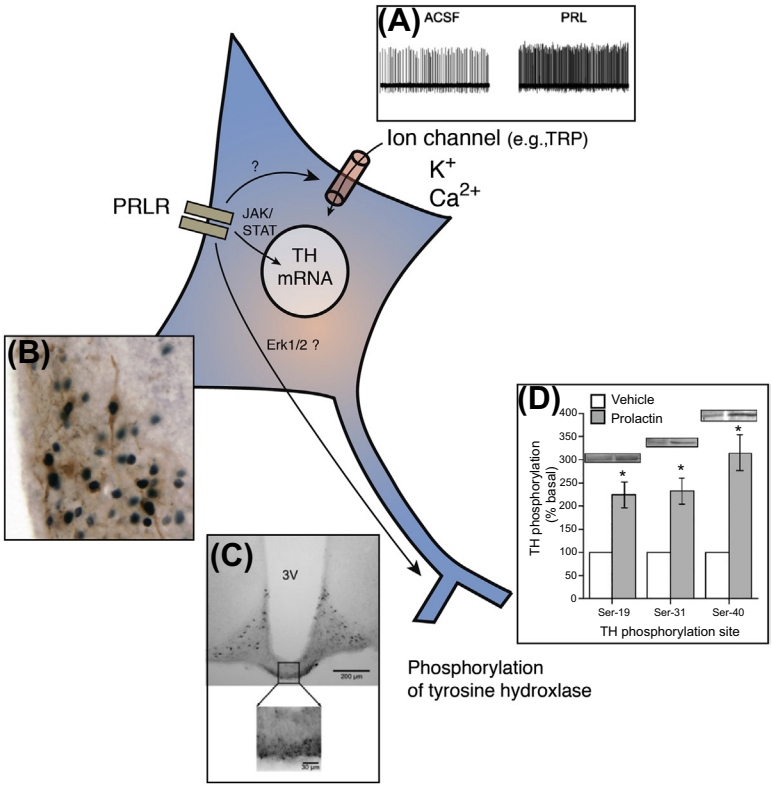

FIGURE 12.4 Diagrammatic representation of the multiple levels of prolactin feedback on NEDA neurons. Prolactin binds to prolactin receptors on NEDA neurons and then acutely (within 5 min) increases the firing rate of those neurons. Inset (A) shows prolactin-induced increase in the firing rate of a TIDA neuron.[92] Prolactin also increases the phosphorylation of STAT5 in TIDA neurons (approximately 15–20 min), inducing a transcriptional response. Inset (B) shows prolactin-induced STAT5 immunoreactivity (black) co-localized with immunoreactivity for tyrosine hydroxylase (TH) (brown), demonstrating direct prolactin action in these cells.[91] Finally, prolactin induces the phosphorylation of TH (approximately 15–30 min) both within the cell body and, more particularly, in the nerve terminals within the median eminence. Inset (C) shows prolactin-induced serine 40 phospho-TH immunoreactivity in the arcuate nucleus and median eminence (unpublished data); inset (D) shows prolactin-induced phosphorylation of TH at serines 19, 31, and 40 in mediobasal hypothalamic cultures.[102] ? indicates an uncertain mechanism; **P* <0.05.

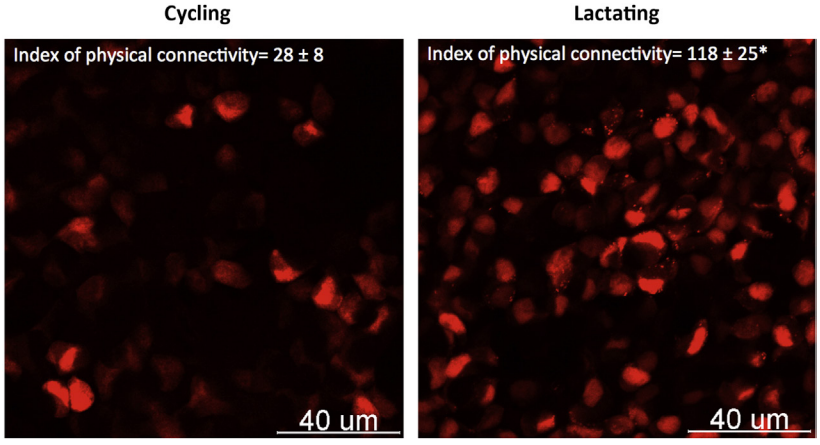

FIGURE 12.5 Biphoton imaging of pituitaries from virgin (left panel) and lactating (right panel) mice with transgenic expression of DsRedExpress fluorescent protein identifying lactotroph cells. In the virgin pituitary, lactotrophs are organized into a network of honeycomb-like structures. In the lactating pituitary, these honeycomb structures become more pronounced, and there is an overall increase in the proportion of lactotrophs with homotypic contacts. The "index of physical connectivity" is generated by three-dimensional reconstructions of the fluorescent label and reflects the degree of structural connections of lactotrophs with other lactotrophs. ? indicates an uncertain mechanism; **P* <0.05. *Source: Image courtesy of Chrystel Lafont, Taoufik El Yandouzi, and Patrice Mollard, Montpellier, France, based on work published in Refs 327,340.*

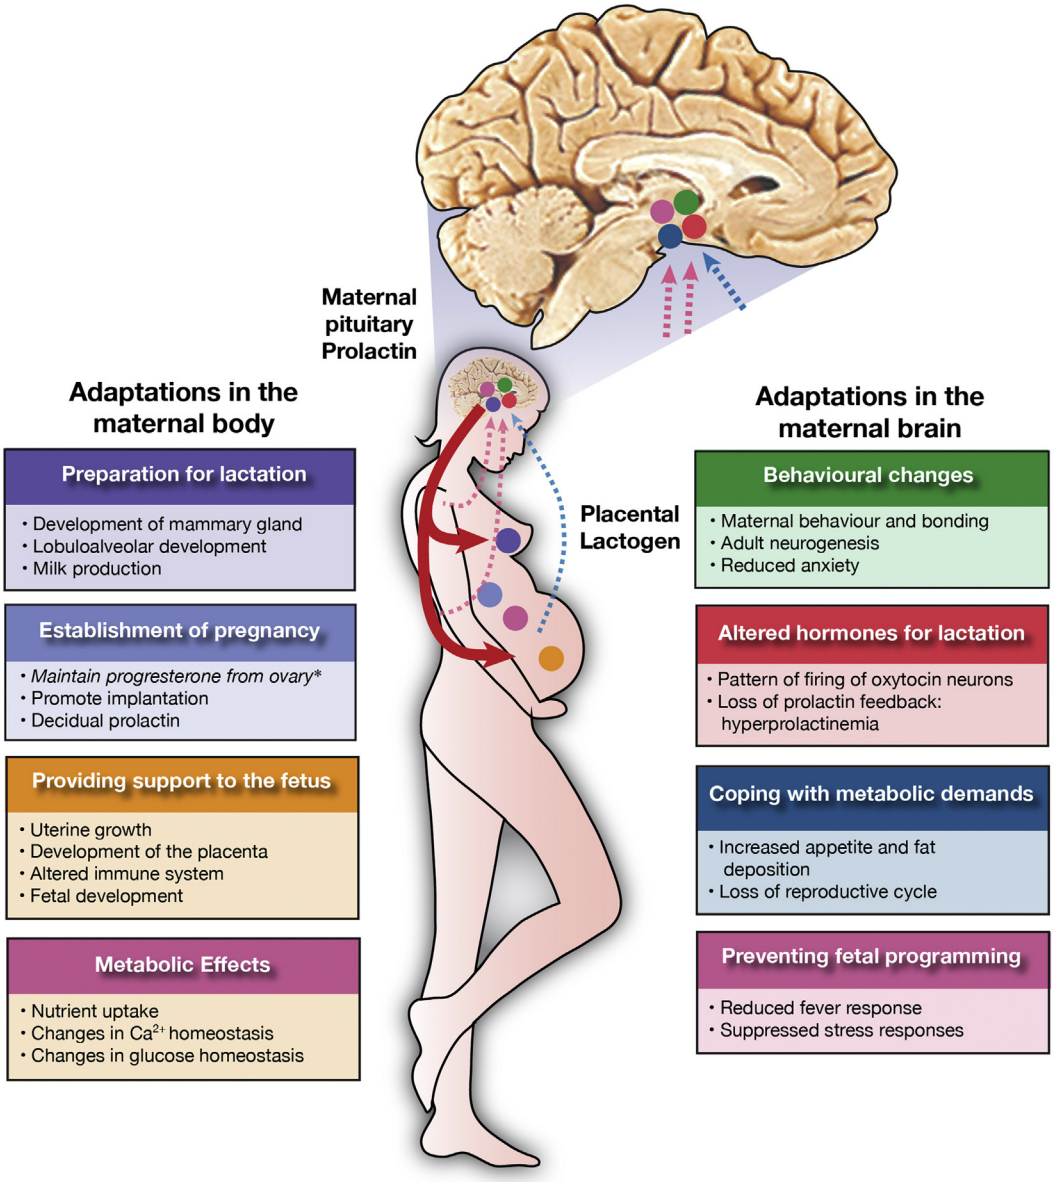

FIGURE 12.8 **Summary of adaptive responses in the pregnant female that may be induced or regulated by prolactin and/or placental lactogen.** Note that while this figure shows a human pregnancy, most of the data are based on experimental data from laboratory animals, and some have not yet been confirmed in women. *Those shown in italics are known to occur only in rodents.

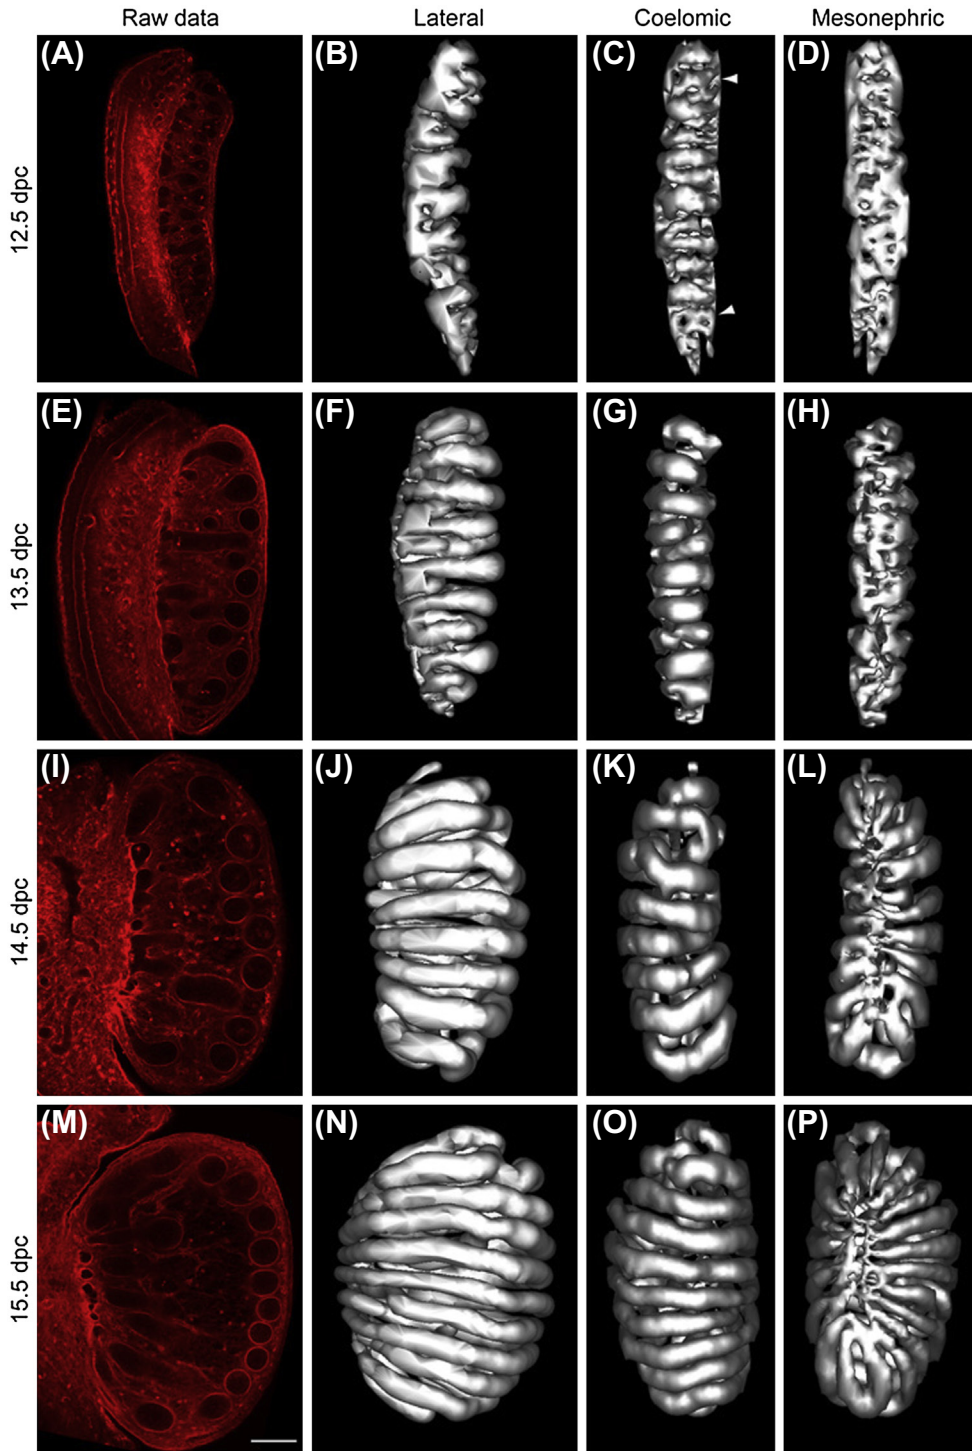

FIGURE 14.2 Modeling of testicular cord development in the mouse. This figure is taken from Ref. 9 and shows lateral (B, F, J, N), coelomic (C, G, K, O), and mesonephric (D, H, L, P) views of models generated from testis cord outlines prepared from whole mount testis. The left panel in each row (A, E, I, M) is a representative image from the data set used to compile the models. The results show that cords initially form as a network of irregular cell clusters that are subsequently remodeled to form regular parallel loops, joined by a flattened plexus at the mesonephric side. Branched, fused, and internalized cords are commonly observed. Parts A–D, E–H, I–L and M–P show models of testicular development at 12.5, 13.5, 14.5 and 15.5 dpc, respectively. Scale bar, 100 μm. *Source: Modified from Ref. 9.*

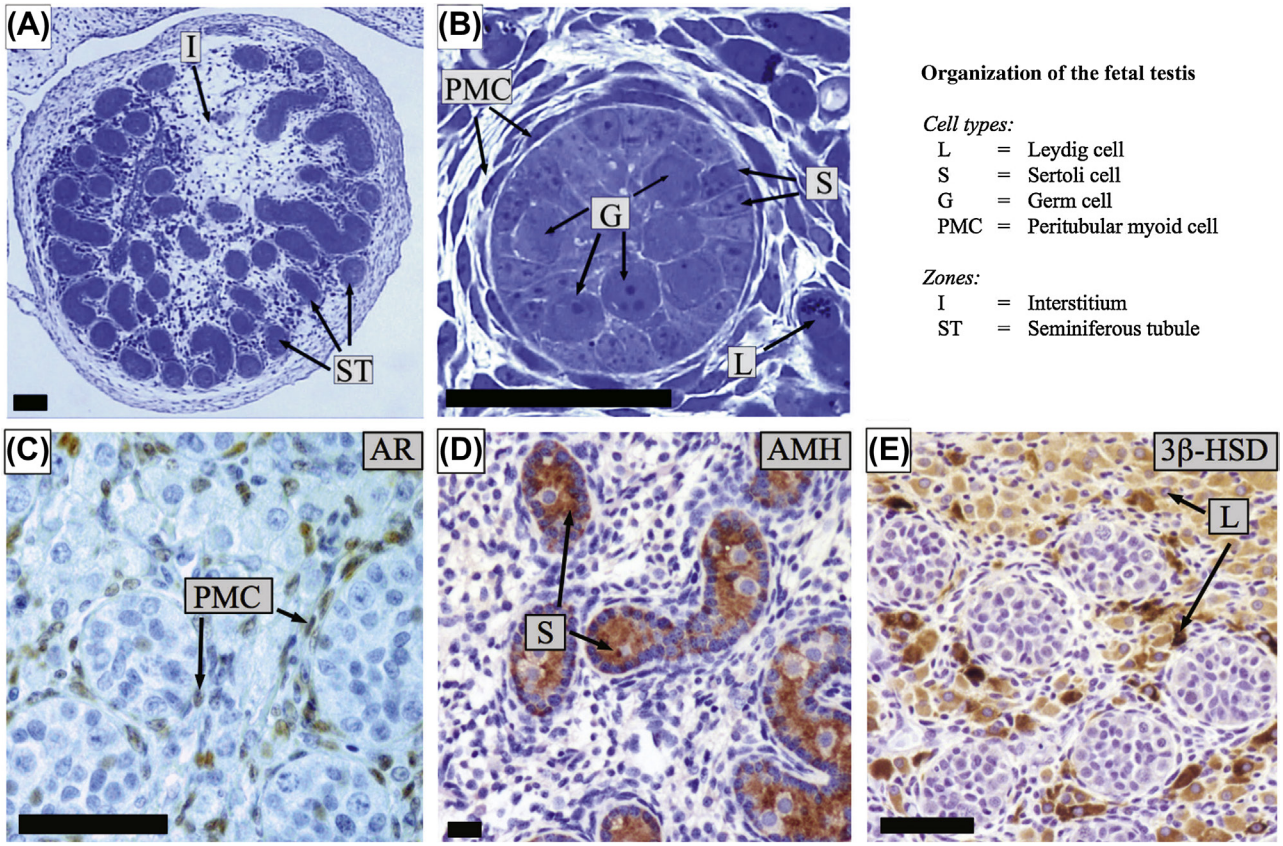

FIGURE 14.3 Histology of the fetal testis. (A) Fetal mouse: low magnification of a semi-thin section showing seminiferous tubules and interstitial tissue (I). (B) Fetal mouse: higher magnification of (A) showing gonocytes (G) in the central part of the sex cord with the Sertoli cells (S) around the periphery. The peritubular myoid cells (PMC) form a concentric layer around the cord, and Leydig cells (L) are present within the interstitium. (C) Fetal human: immunohistochemically labeled for the androgen receptor (AR), which is clearly expressed in PMC and in some interstitial cells. (D) Fetal sheep: immunohistochemically labeled for anti-Mullerian hormone (AMH), which is strongly expressed in fetal Sertoli cells. (E) Fetal human: immunohistochemically labeled for 3β-hydroxysteroid dehydrogenase (HSD3B), which is localized exclusively in the Leydig cells. In all photomicrographs, the bar represents 50 μm. *Source: Reproduced from Ref. 11. © Society for Reproduction and Fertility (2011). Reproduced by permission.*

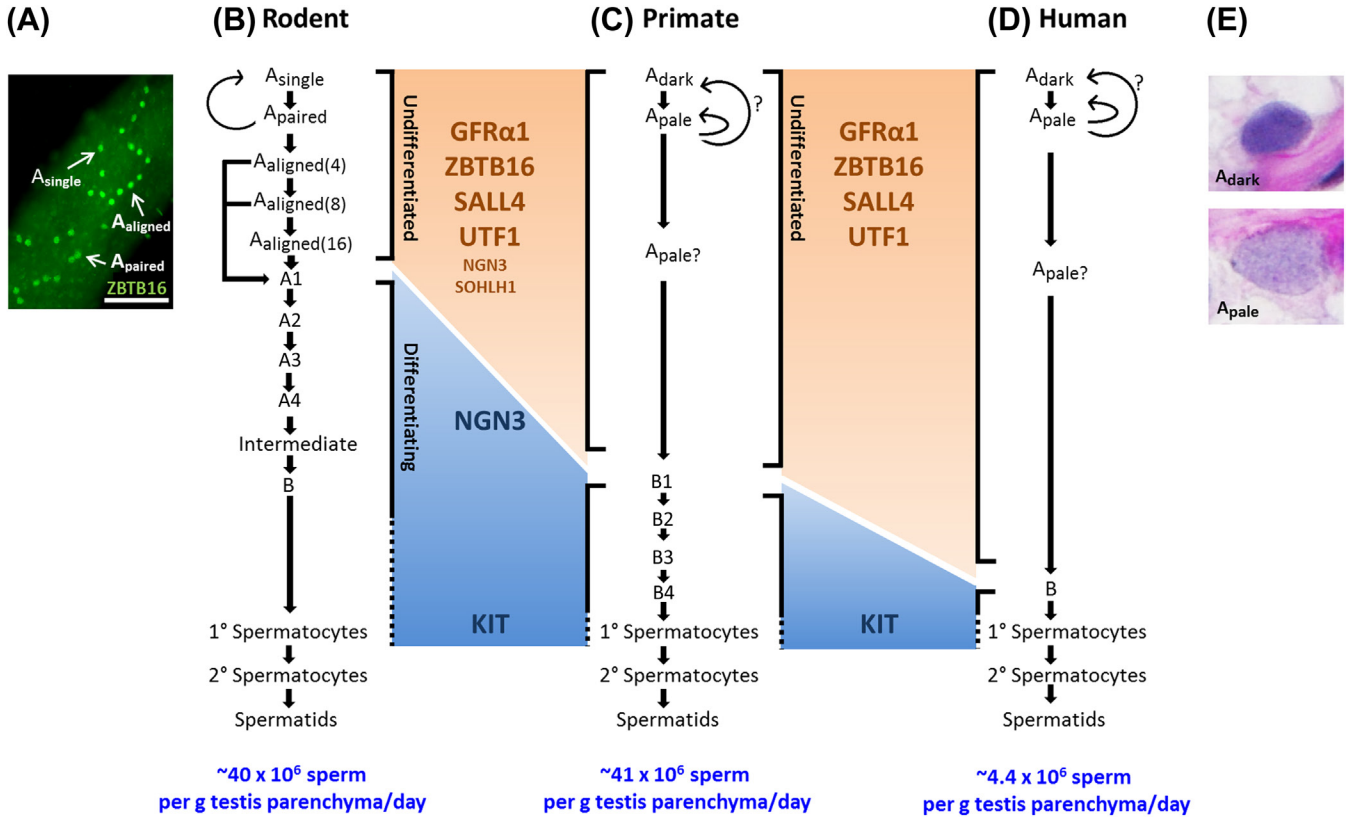

FIGURE 15.2 Current model of rodent, nonhuman primate, and human spermatogenesis. (A) Whole-mount immunohistochemistry staining for ZBTB16 in adult mouse seminiferous tubules. ZBTB16^{+} spermatogonia are identified as A_{single}, A_{paired} or $A_{aligned}$. Scale bar = 100 μm. (B) Rodent undifferentiated spermatogonia, including the SSC pool, is comprised of A_{single} and some A_{paired} spermatogonia and based on whole-mount staining analysis their phenotype is of GFRα1^{+}, ZBTB16^{+}, SALL4^{+}, UTF1^{+}, NGN3$^{+/-}$, and KIT^{-}. Transit amplifying progenitors include some A_{paired} spermatogonia and $A_{aligned}$ spermatogonia (chains of 4–16 cells), with a phenotype of GFRα1^{+}, ZBTB16^{+}, SALL4^{+}, UTF1^{+}, NGN3$^{+/-}$, and KIT$^{+/-}$. The differentiating spermatogonia that are made up of A1–A4, intermediate, and B spermatognia have a phenotype of GFRα1^{-}, ZBTB16^{-}, SALL4^{-}, UTF1^{-}, NGN3$^{+/-}$, and KIT^{+}. (C and D) In nonhuman primate and human testis, the undifferentiated spermatogonia are the type A spermatogonia that are designated A_{dark} and A_{pale} based on nuclear staining intensity with hematoxylin. The B spermatogonia are considered to be the differentiating spermatogonia and in nonhuman primates; they go through four divisions before producing primary spermatocytes, whereas in human there is only one division of B spermatogonia. (E) Sections of human testis stained using periodic acid-Shiff method and counterstained with hematoxylin to show nuclear morphology. ZBTB16, zinc finger and BTB domain containing 16; GFRα1, GDNF family receptor alpha-1; UTF1, undifferentiated embryonic cell transcription factor 1; SALL4, Sal-like 4; NGN3, neurogenin 3; SOHLH1, spermatogenesis and oogenesis specific helix-loop-helix 1. *Adapted from Ref. 75.*

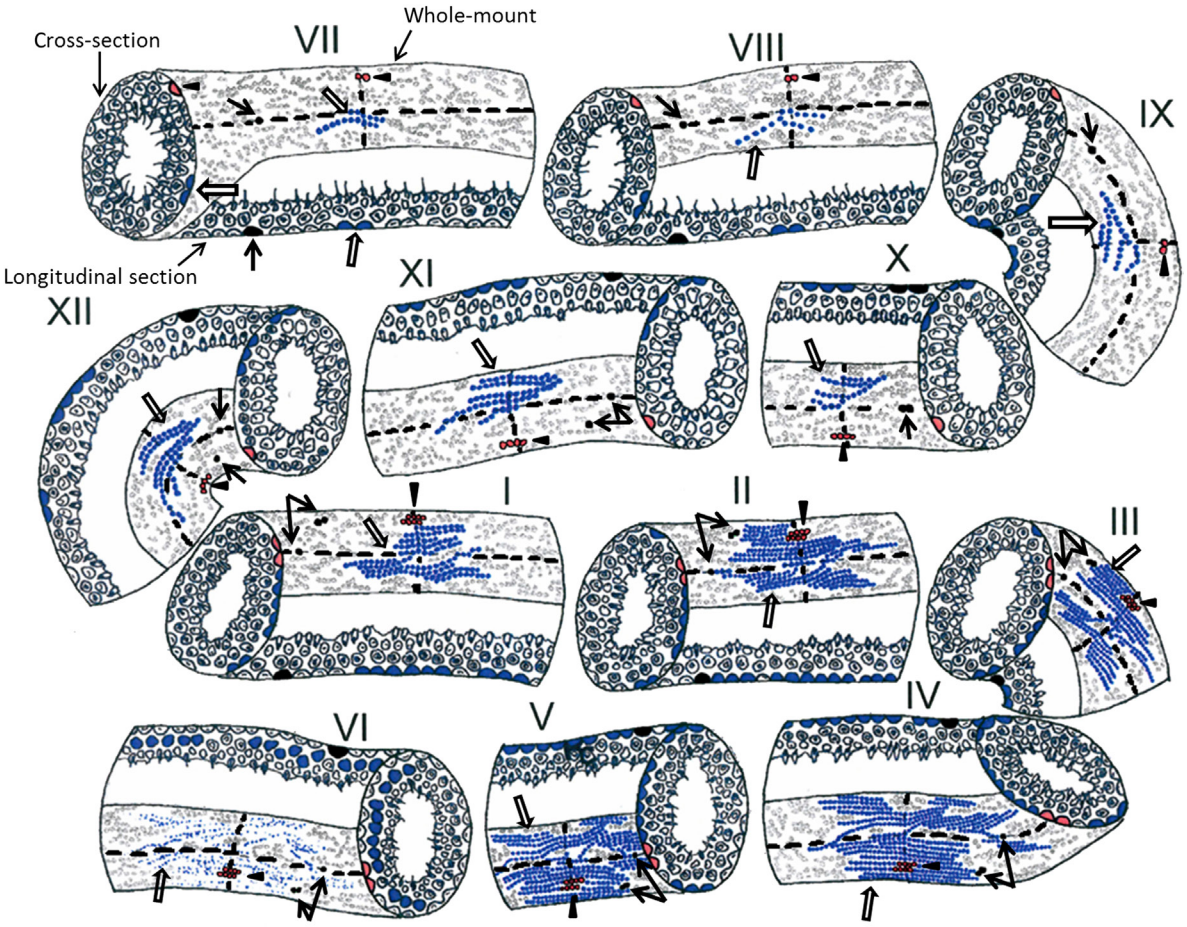

FIGURE 15.3 Schematic of mouse spermatogenic clone development by stage. The seminiferous epithelial cycle of the mouse contains 12 stages (I-XII). Each stage is shown in cross-sectional, longitudinal, and whole-mount perspectives (labeled in stage VII). Three putative spermatogonial clones are highlighted in blue (open arrow), red (arrowhead), and black (black arrow). These clones are only representative examples and do not imply A_{single} spermatogonia divide only in stages X and I. A_{single} and A_{paired} spermatogonia are present in all stages of the seminiferous epithelium and tend to divide more frequently in early and late stages than middle stages. The dotted lines in the whole-mount perspective indicate planes of the cross-section and longitudinal section views. Cells that lie on the focal plane in the whole mount appear in the corresponding cross-section and longitudinal section views; this is indicated by matching color or arrows (arrows shown for stage VII only). For example, in stage VII, the red cell (arrowhead) is in the vertical line and therefore appears in the cross-sectional view. A black cell (black arrow) is in the horizontal line, so it is observed in the longitudinal section view. The development of three putative clones (blue/open arrow, red/arrowhead and black/black arrow) through one cycle of the seminiferous epithelium is shown. Stage VII: $A_{al\text{-}16}$ (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage VIII: A1 (clone of 16) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage IX: A2 (clone of 32) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage X: A2 (clone of 32) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{pair} (black/black arrow); stage XI: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage XII: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage I: A4 (clone of 128) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage II: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage III: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage IV: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage V: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage VI: primary spermatocytes (lifting off the basement membrane) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow). *Reproduced with permission from Ref. 28.*

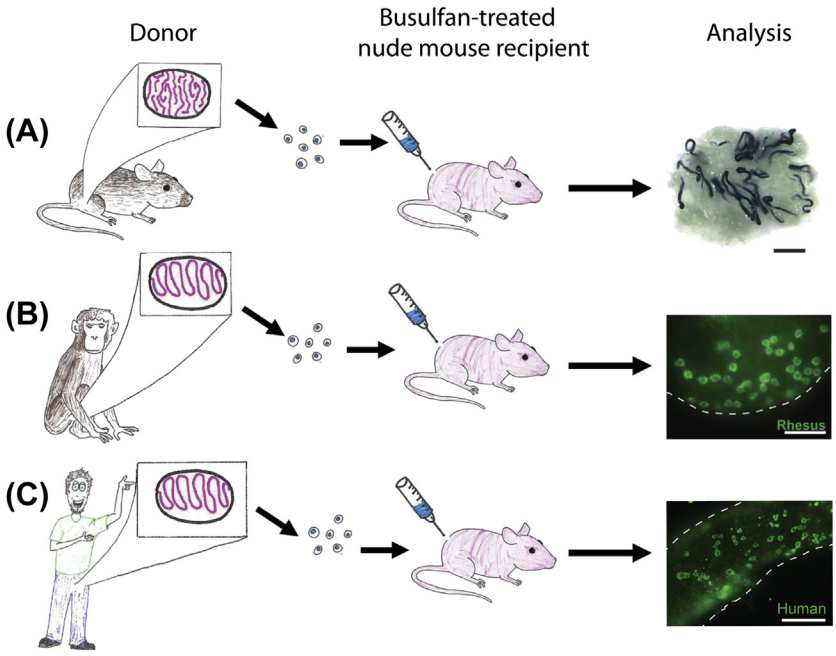

FIGURE 15.6 Spermatogonial stem cell (SSC) transplantation assay. The only way to definitively identify SSCs is to analyze SSC function. (A) In this case, a testicular cell suspension is produced from a *lacZ* donor mouse. The cells are injected into the testis of an infertile recipient mouse and the results are analyzed two to three months after transplantation for *lacZ* expressing donor spermatogenesis (dark colonies). Scale bar = 2 μm. (B, C) Xenotransplantation of nonhuman primate (B) and human (C) testicular cells into busulfan treated nude mouse can be used as an assay to identify SSCs by their ability to initiate the early steps of spermatogenesis in the mouse testis. The colonies of spermatogonia are identified by staining with anti-primate antibody that only recognizes primate cells. The colonies of SSCs are identified by the following criteria—they are located on the basement membrane of the seminiferous tubules, they have four or more cells, and the cells are within 100 μm of each other. Scale bars = 100 μm. In the B and C analysis panel, broken lines indicate the borders of seminiferous tubules.

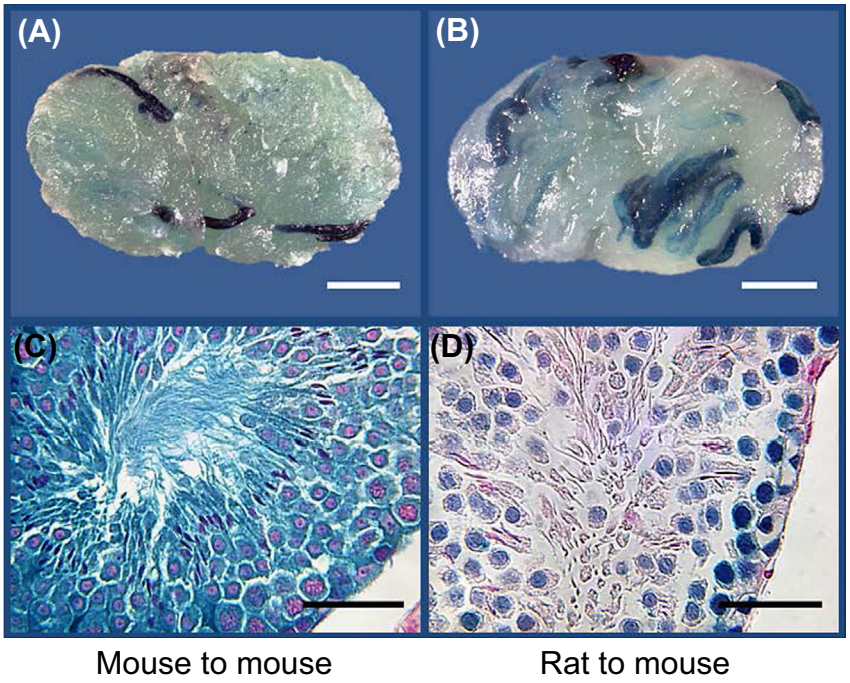

FIGURE 15.7 Macroscopic and histologic appearance of recipient testes transplanted with mouse and rat adult donor testis cells expressing *lacZ*. NCr nude (spontaneous mutant T cell deficient mice) recipient mouse testes were stained with X-gal 3 months after transplantation to visualize mouse (A and C) and rat (B and D) donor-derived spermatogenic colonies. Both mouse and rat donor testis cells generated complete spermatogenesis, characterized by multiple germ cell layers and mature spermatozoa, in recipient testes. Note that the lacZ stain is localized in the cytoplasm of ROSA26 mouse testis cells (C) and the nucleus of MT-lacZ rat testis cells (D). Nuclear fast red counterstain (C and D). Bar = 1 mm (A and B), 40 μm (C and D). *Reproduced with permission from Ref. 134.*

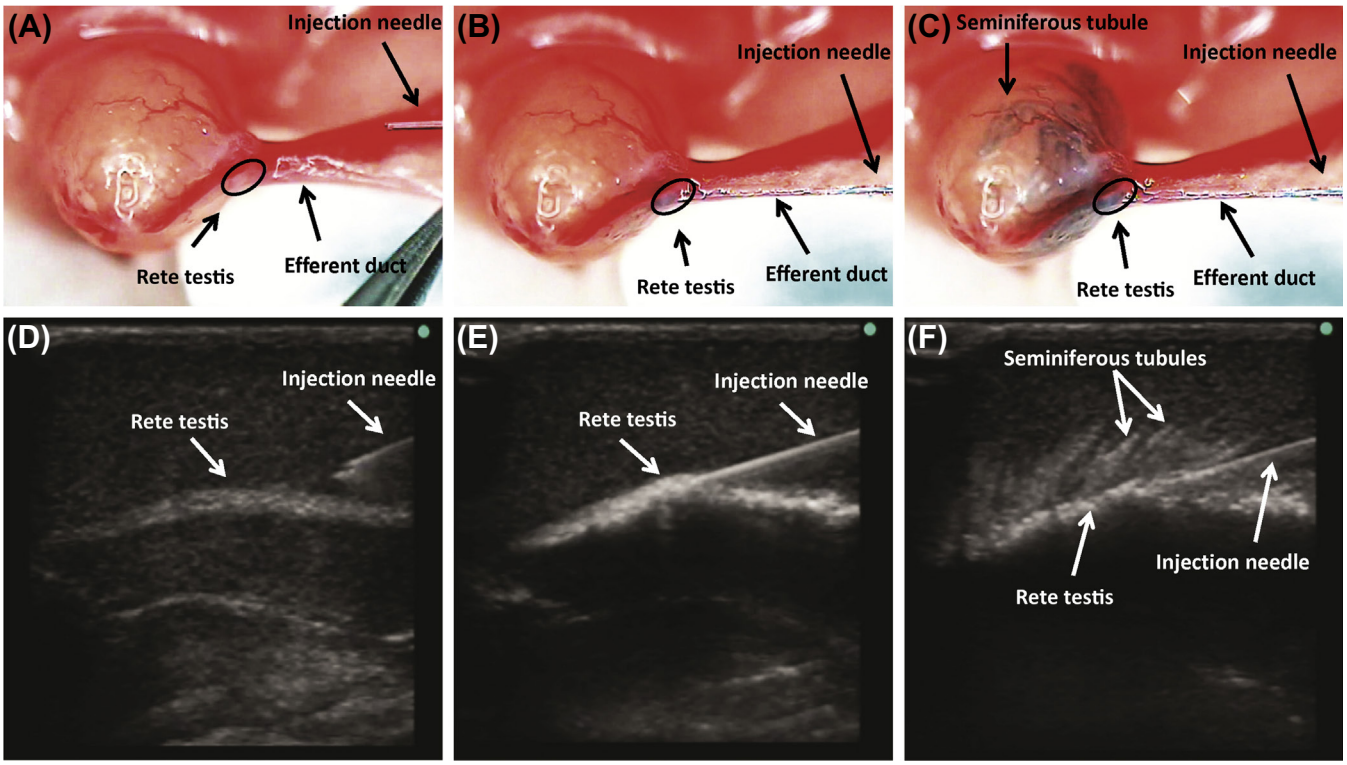

FIGURE 15.8 Testicular cell transplantation. (A–C) In rodents, the testicular cells are injected via the efferent ducts into the rete testis space, which can be visualized on the surface of the testis and is contiguous with all seminiferous tubules. (C) Trypan blue is injected with the testicular cells to visualize the filling of the seminiferous tubules. (D–F) Testis anatomy in large animals is different than rodents, with the rete testis being more centrally localized and therefore more difficult to visualize and access. Therefore, ultrasound is used to guide injections. (D) Rete testis (echo-dense structure) is visible on ultrasound. The injection needle is inserted under ultrasound guidance through the scrotal skin into the rete testis space, which is continuous with the seminiferous tubules. (E) Positive pressure is applied to the needle, so the cells are slowly injected into the rete testis and seminiferous tubules. (F) The filling of the seminiferous tubules is observed using microbubbles.

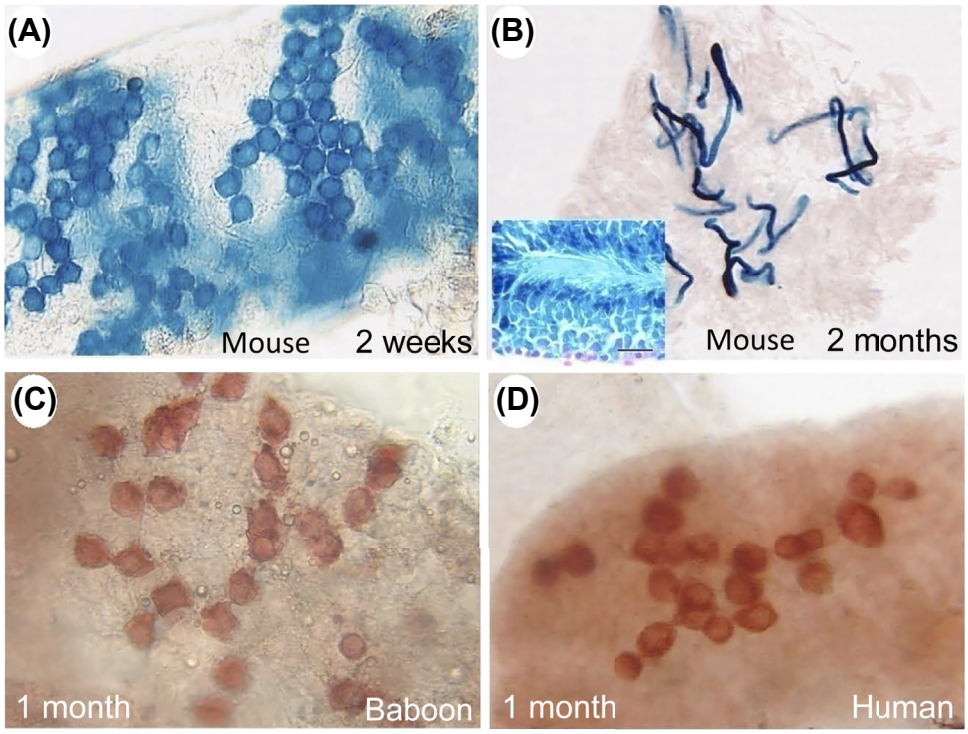

FIGURE 15.9 Colonization of recipient testis. (A) Two weeks after transplantation of transgenic mouse donor cells (stained blue) into a recipient mouse seminiferous tubules, small groups of cells can be seen at low magnification. (B) Two months after the transplantation of mouse donor cells, the blue areas are dark in the center, indicating multiple layers of germ cells and development of spermatogenesis. (B inset) Cross-section of a transplanted mouse seminiferous tubule 2 months after transplant. Scale bar = 30 μm. (C and D) Detection of baboon and human germ cells transplanted into the seminiferous tubules of recipient mouse, using an antibody raised against baboon testis cells. One month after the transplant, clusters of baboon (C) and human (D) germ cells are located on the basement membrane of mouse tubules and exhibit characteristics of undifferentiated spermatogonia. The clusters are similar to the ones seen in mouse 2 weeks after the transplant. *Modified with permission from Refs 104 and 149.*

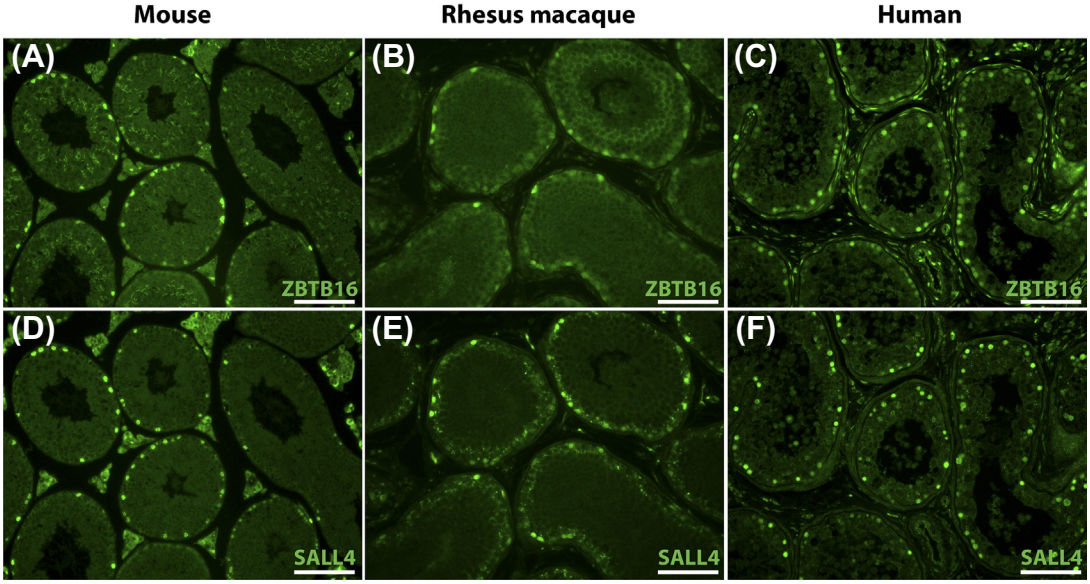

FIGURE 15.10 Conservation of stem and progenitor markers ZBTB16 and SALL4 from mouse to human. ZBTB16 (A–C) and SALL4 (D–F) staining in cross-sections of seminiferous tubules from mouse, rhesus macaque, and human testes shows expression of these transcription factors on the basement membrane of the tubule. Both ZBTB16 and SALL4 are conserved markers from mouse to rhesus macaque to human. Scale bar = 100 μm. ZBTB16, zinc finger, and BTB domain containing 16; SALL4, Sal-like 4.

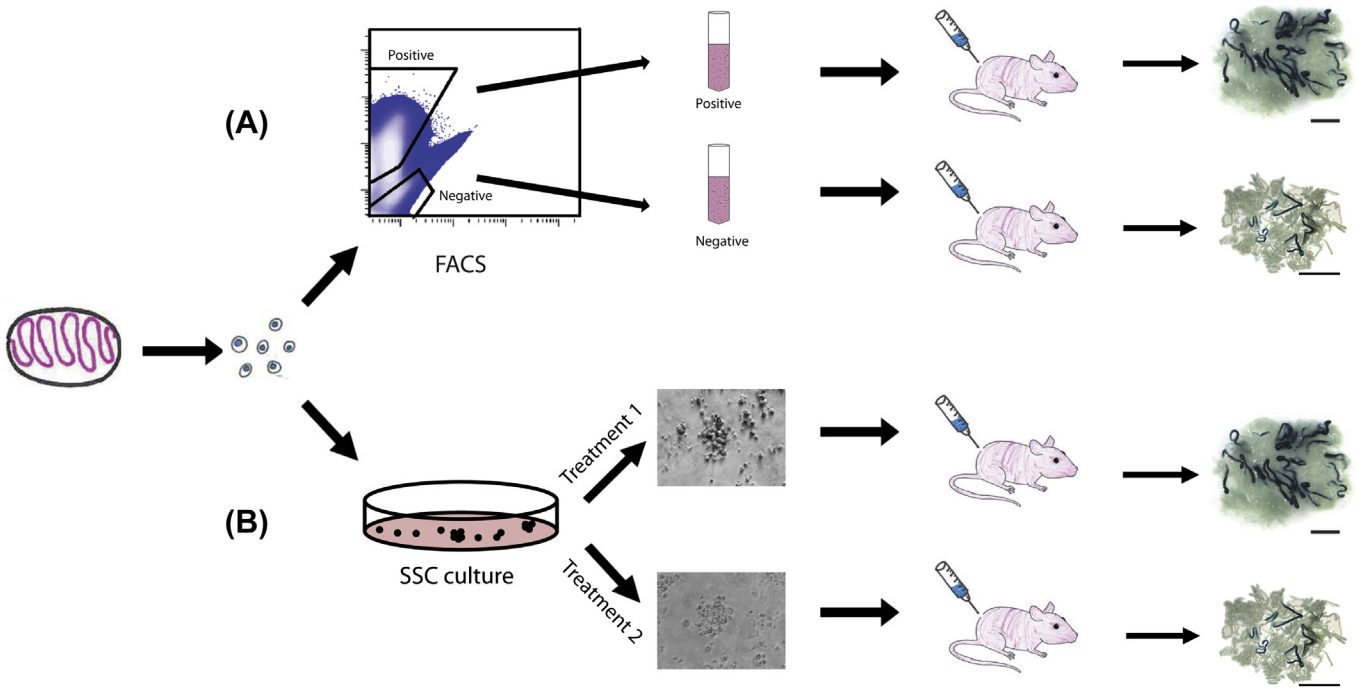

FIGURE 15.11 Experimental designs to study seprmatogonial stem cells. SSC transplantation is used to analyze the effectivness of (A) fluorecsence-activated cell sorting (FACS) for a cell-surface protein or (B) a treatment of SSC culture. (A) FACS is used to fractionate the testicular cell population stained with an antibody against a cell-surface protein, based on marker$^+$ and marker$^-$ status. The sorted fractions can then be transplanted into infertile nude mice to determine which fraction contains the SSCs. (B) SSC cultures are used to identify factors important for SSC self-renewal and maintenance or for SSC differentiation. For example, GDNF can be removed from the culture media to determine whether or not it has an effect on SSC self-renewal and/or maintenance. The cells cultured with or without GDNF are then transplanted into testis of infertile recipient mice and, 2 months later, the testis are analyzed for colony formation. FACS, fluorescence activated cell sorting; SSC, spermatogonial stem cell; GDNF, glial cell-derived neurotrophic factor.

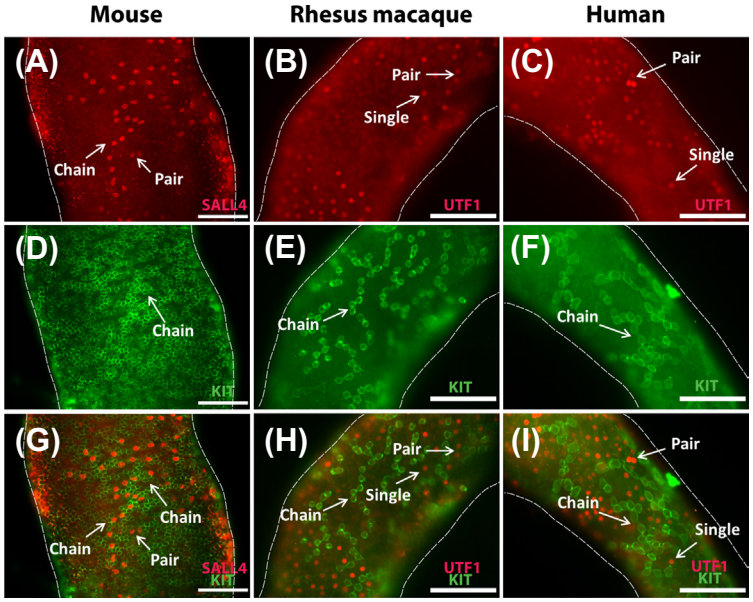

FIGURE 15.12 Whole-mount immunohistochemistry of seminiferous tubules from mouse, rhesus macaque, and human testes. Whole-mount immunofluorescence analysis of the undifferentiated spermatogonia marker, SALL4 (A), differentiating spermatogonia marker, KIT (D) and co-staining of SALL4 and KIT (G) in mouse. Whole-mount immunofluorescence analysis of undifferentiated spermatogonia marker UTF1 (B, C), differentiating spermatogonia marker KIT (E, F), and co-staining of UTF1 and KIT (H, I) in the rhesus macaque (B, E, H) and human (C, F, I). Arrows indicate spermatogonia arranged as single cells, pairs, and larger chains for each species. Scale bar = 100 μm. SALL4, Sal-like 4; UTF1, undifferentiated embryonic cell transcription factor 1.

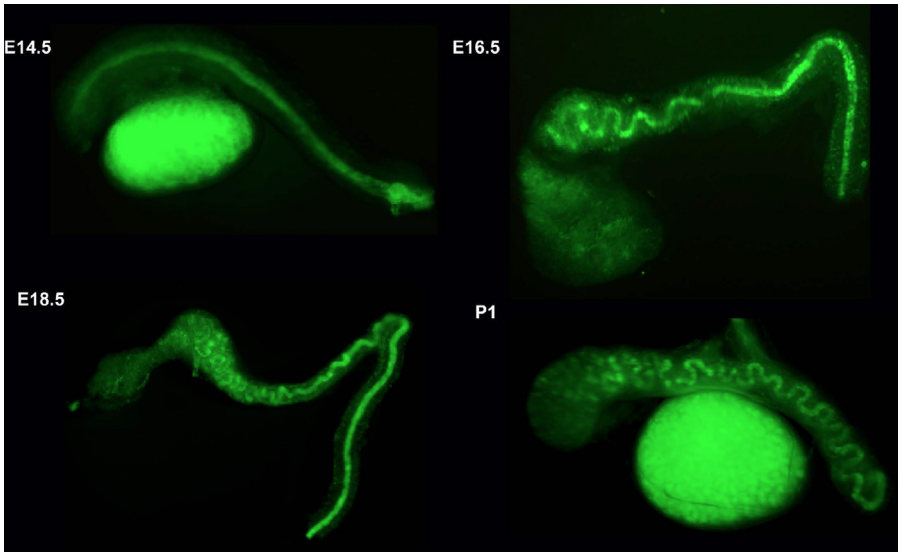

FIGURE 17.2 Wolffian ducts collected from hoxb7-gfp mice at different developmental stages, embryonic (E) days 14.5, 16.5, 18.5 and postnatal (P) day 1. Note how the coiling proceeds from proximal to distal with three-dimensional coiling beginning around 18.5. *Source: Image from Ref. 60.*

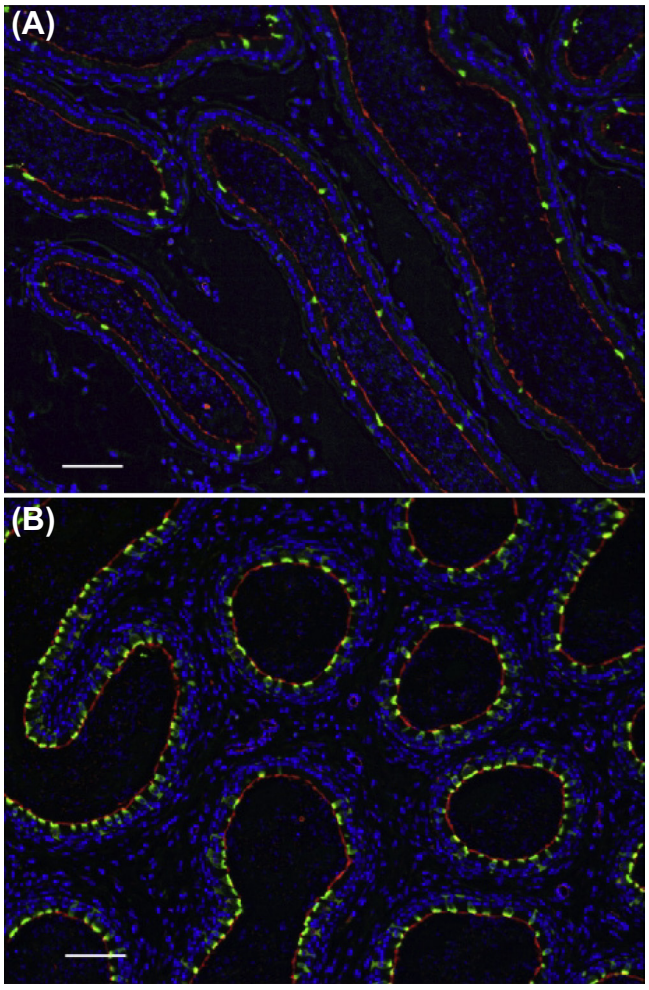

FIGURE 17.8 Relative numbers of clear cells in the rat caput (A) versus cauda (B) epididymidis. Rat epididymis was stained for the V-ATPase B1 subunit (green) to label clear cells, and NHERF1 (red). Nuclei and spermatozoa were stained with DAPI (blue). NHERF1 is located in the apical membrane of both principal cells and clear cells. Clear cells positive for the subunit B-1 or V-ATPase are much more numerous in the cauda (B) than in the caput (A) epididymidis. Scale bars, 50 μm. *Source: Reproduced with permission from Ref. 164.*

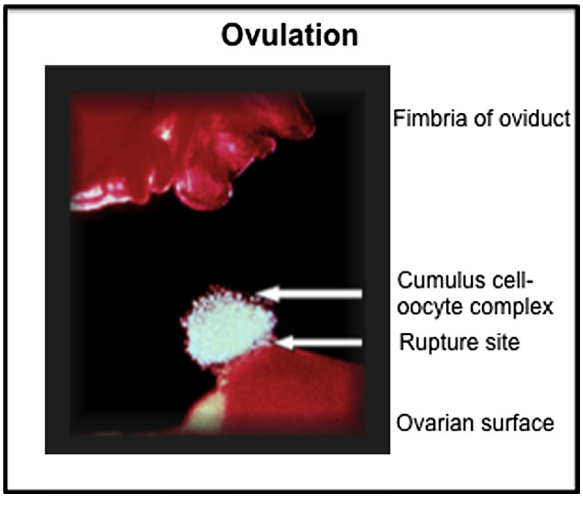

FIGURE 22.1 Moment of rupture of a rabbit follicle. Ovulation of a fertilizable oocyte involves disintegration of the ovarian surface epithelium and extrusion of the expanded cumulus cell–oocyte complex (COC) through the ovulation pore. This is followed by retrieval of the COC by the ciliated cells of the oviduct and its subsequent transport down the oviduct where fertilization occurs. (See text.) *Source: Ref. 3.*

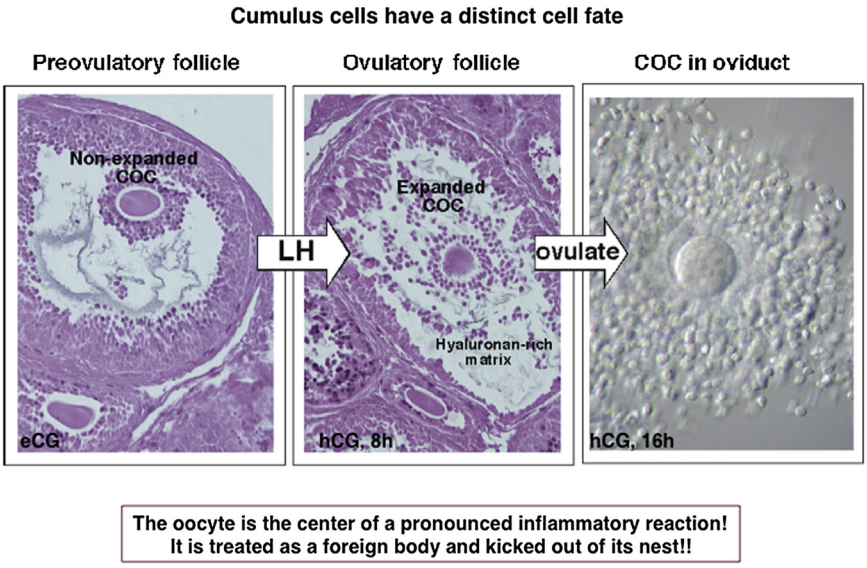

FIGURE 22.3 **The LH surge induces expansion of the cumulus cell-oocyte complex (COC).** Expansion is dependent on the biosynthesis of long polymers of hyaluronan by HAS2. The hyaluronan polymers are stabilized by specific hyaluronan-binding factors including the proteoglycan versican and inflammatory-related factors such as TNFAIP6, IαI, and PTX3. COC expansion is obligatory for release of the enclosed oocyte from the surface of the ovary into the oviduct. (See text.)

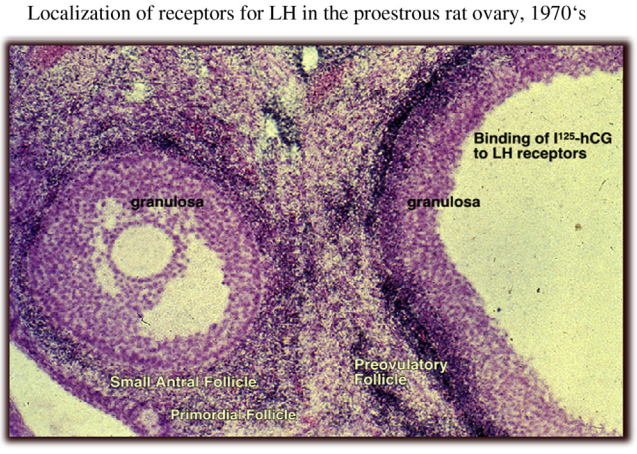

FIGURE 22.5 **Induction of LH receptors (LHR; LHCGR) in granulosa cells is the key distinguishing hallmark of preovulatory follicles.** The presence of LHR in granulosa cells of preovulatory follicles permits them (but not small follicles lacking LHR in granulosa cells) to respond to the LH surge and initiate the molecular programs required for ovulation, COC expansion, resumption of meiosis, and luteinization. This image shows the uptake of radiolabeled hCG (LH) into the theca cells and mural granulosa cells of a preovulatory follicle (right) but only in theca cells of small follicles (left). Primordial follicles do not exhibit detectable uptake of the hormone. Uptake reflects the presence of receptors.

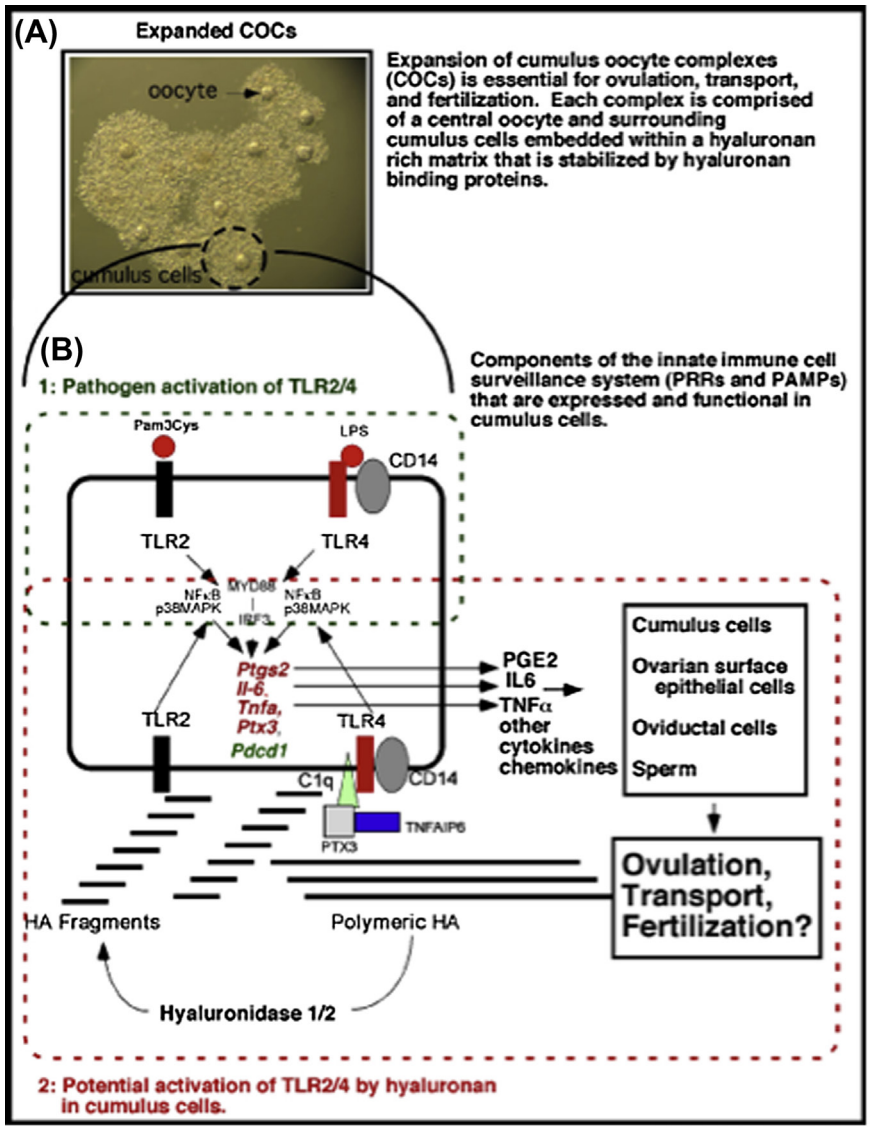

FIGURE 22.12 Schematic of TLR pathway activation and functions in cumulus cells during COC expansion, ovulation, transport and fertilization. (A) In response to the ovulatory surge of LH, cumulus cell–oocyte complexes (COCs) undergo expansion. This process requires the synthesis of a hyaluronan (HA)-rich matrix and factors that bind HA to stabilize the matrix. This process is critical for ovulation. (B) Cumulus cells express members of the Toll-like receptor (TLR) superfamily and can respond to specific ligands (1: pathogen-derived or 2: matrix-derived), leading to the induction of inflammation- and innate immune-related genes. These include: *Ptgs2, Il6, Tnfaip6, Tnfa*, and *Pdcd1*. Prostaglandins (PGE2) synthesized by PTGS2, IL6, and TNFα, as well as other cytokines and chemokines, are released from cumulus cells and can impact the function not only of the cumulus cells but also oviductal cells during transport and sperm during fertilization. The degradation of polymeric HA by hyaluronidases is presumed to lead to the generation of HA fragments that activate TLR2 and TLR4. *Source: Ref.160.*

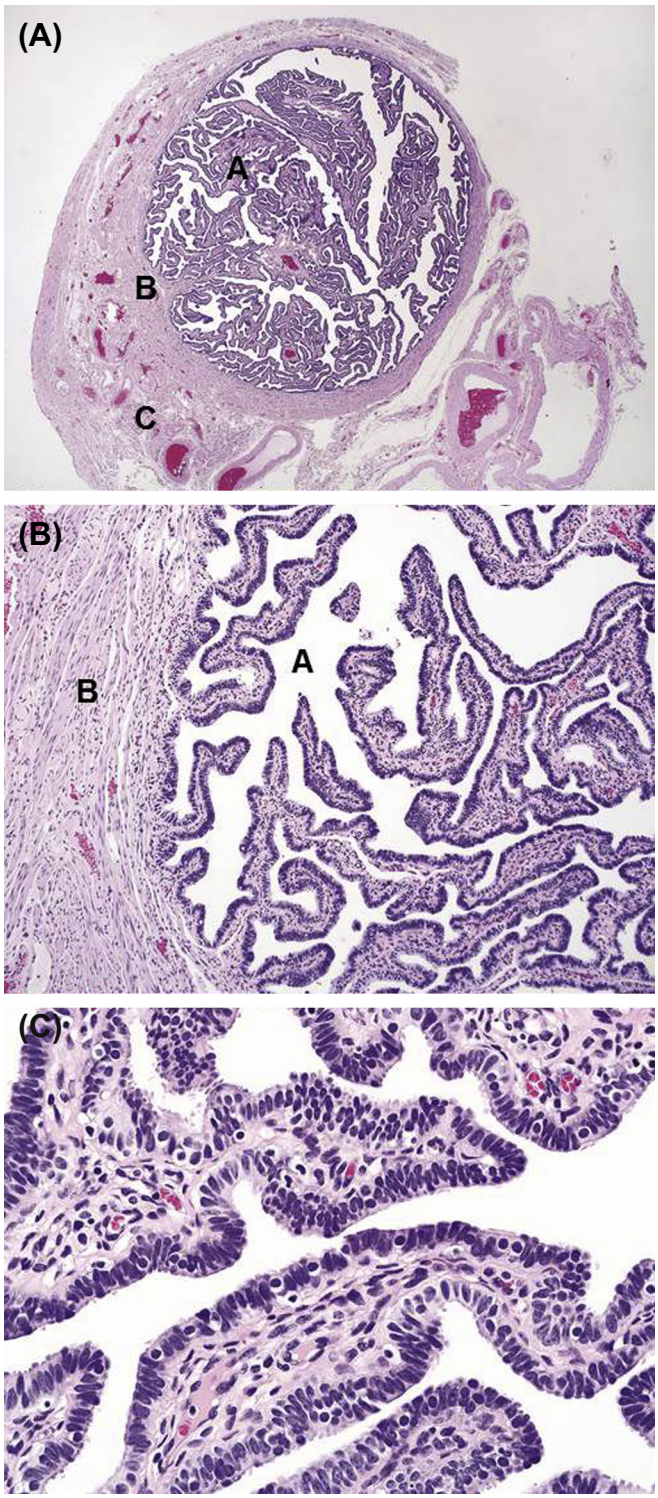

FIGURE 24.2 Cross-section of human fallopian tube, ampulla. Inner mucosa (A) is arranged in longitudinal folds within the middle muscularis (B) and outer serosa (C). The mucosa is lined by a single layer of epithelium (lower panel) composed of ciliated and secretory (nonciliated) cell types. Hematoxylin and eosin (H & E) stain, magnification 20–400×. *Source: Images courtesy of Ramya Massand and Jason Moss.*

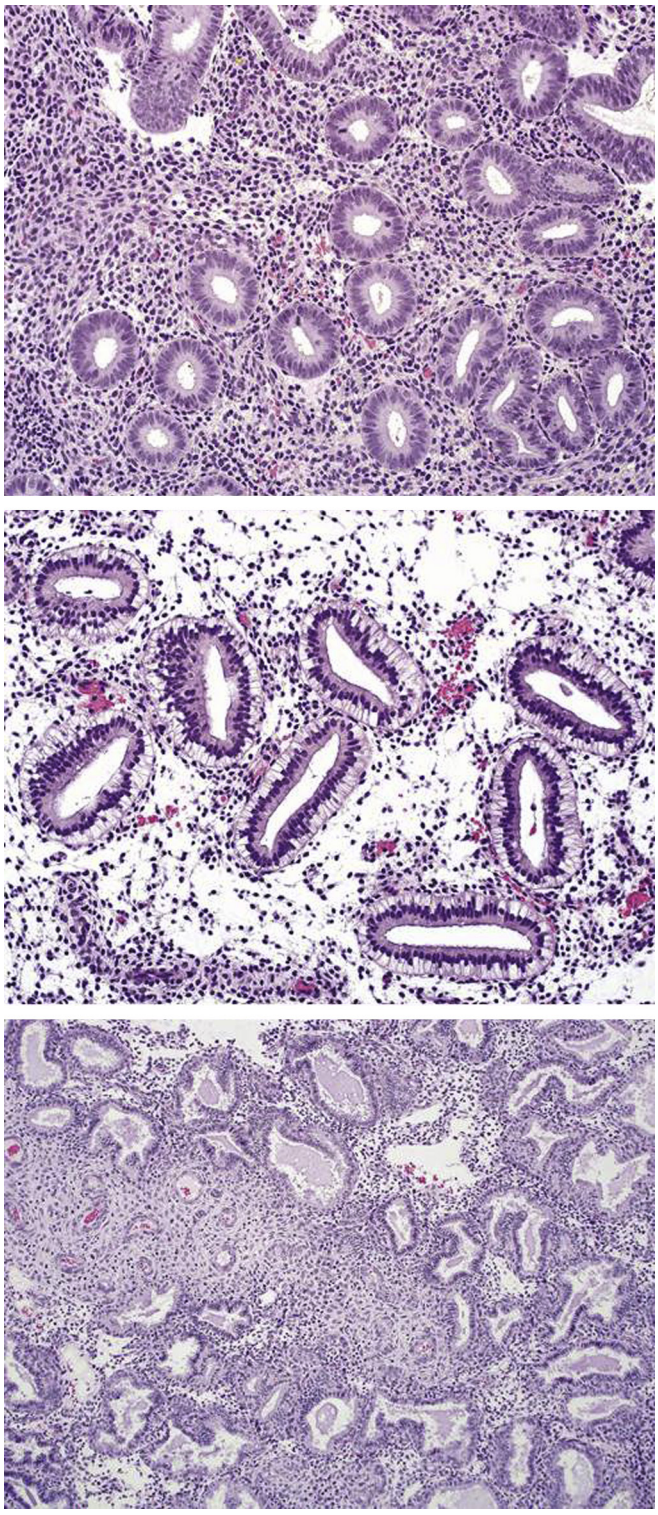

FIGURE 24.4 Human endometrium from proliferative (upper), early-secretory (middle), and late-secretory phases (lower). Note the wide spacing between simple-appearing glands (proliferative), apically displaced nuclei in the glandular epithelium due to glycogen accumulation (middle), and tortuous glands with secretions and a decidualized stroma with abundant pale cytoplasm (lower). H&E stain, magnification 100–200× (Images courtesy of Ramya Massand and Jason Moss).

Color Plates

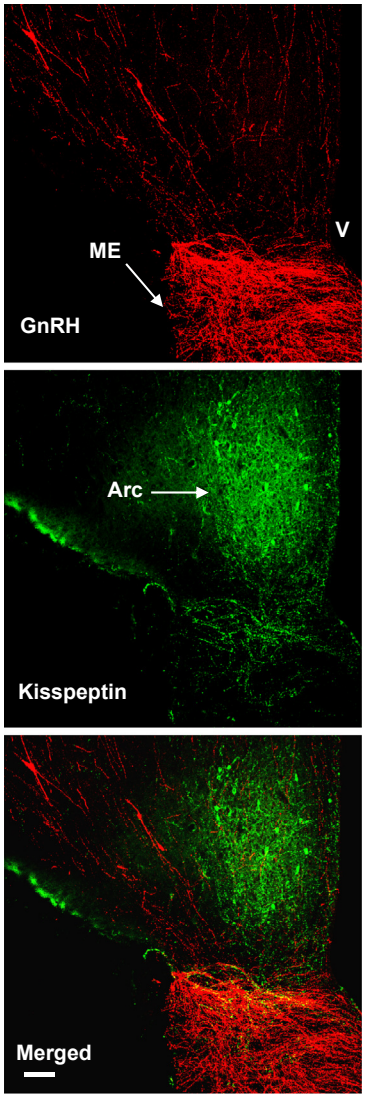

FIGURE 28.3 **A hemi-coronal section through the mediobasal hypothalamus of a castrated rhesus monkey at the level of the arcuate nucleus (Arc), the posited site of the gonadotropin-releasing hormone (GnRH) pulse generator.** The section was doubled labeled by immunofluorescence for GnRH and kisspeptin. Top panel, a confocal image of the distribution of GnRH cell bodies and fibers; middle panel, also a confocal image of the same section showing the corresponding distribution of kisspeptin cell bodies and fibers. The lower panel shows the merged image. Castration results in an upregulation of kisspeptin expression that is associated with robust GnRH pulse generator activity. Note that GnRH cell bodies at this level of the hypothalamus are found lateral to the kisspeptin perikarya in Arc: both sets of neurons send projections to the median eminence (ME) where they closely intermingle. The ependymal lining of the third ventricle (V) may be seen on the right-hand side of the section. Scale bar 100 μm. *Source: Rearranged from Ref. 57, with permission, Copyright 2008, The Endocrine Society.*

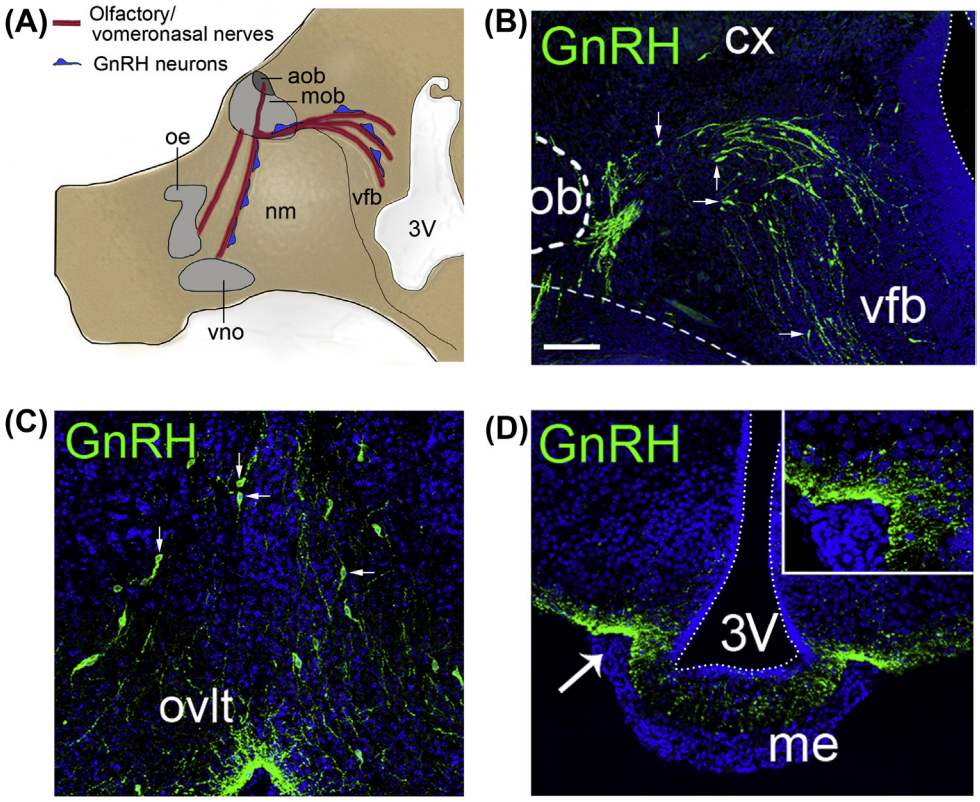

FIGURE 30.1 (A) Schematic representation of the head of a mouse embryo at E14.5, showing the scaffold of vomeronasal/terminal nerve fibers (thick lines) along which GnRH cells (neuron-like shapes) migrate from the nose to the brain. (B) Sagittal section of the rostral and ventral forebrain regions at E14.5, immunolabeled for GnRH. Arrows show GnRH neuronal cell bodies. (C, D) Coronal section of the preoptic region showing GnRH neuroendocrine cells (arrows, C) and their nerve terminals in the median eminence (me, D) in newborn (P0) mice. In D, the inset shows a higher magnification of the area identified by the arrow in the main panel. Abbreviations: oe, olfactory epithelium; vno, vomeronasal organ; nm, frontonasal mesenchyme; mob, main olfactory bulb; aob, accessory olfactory bulb; vfb, ventral forebrain; cx, cerebral cortex; ovlt, organum vasculosum of the lamina terminalis; 3V, third ventricle. Scale bar: 100 μm (50 μm in inset).

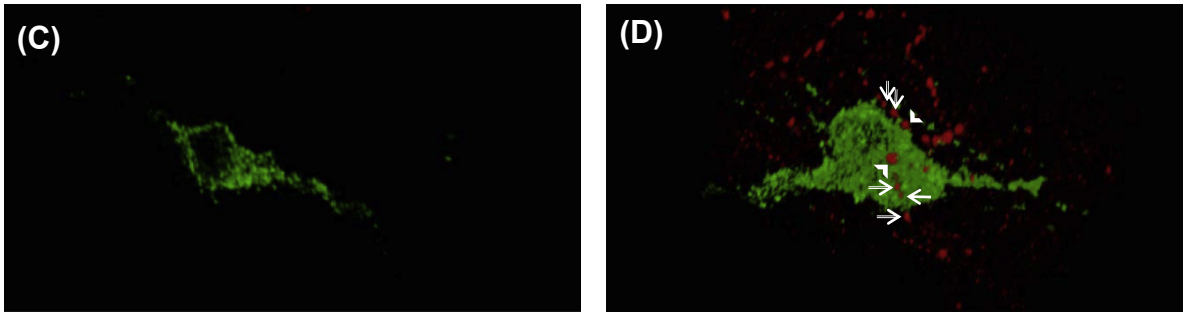

FIGURE 31.8 Changes in LH pulse frequency and kisspeptin during pubertal development. *Panel A*: LH pulse frequency in prepubertal and postpubertal female lambs that were either gonad-intact (Intact) or ovariectomized (OVX). Postpubertal intact lambs were in the early follicular phase. LH pulse frequency was higher in intact postpubertal female lambs than in intact prepubertal female lambs and rose following ovariectomy in the prepubertal, but not postpubertal, lambs. *Panel B*: Kisspeptin-immunopositive cell numbers were greater in postpubertal intact females than prepubertal intact females and increased with ovariectomy in the prepubertal, but not postpubertal, lambs. *Panels C and D*: GnRH neuron from a prepubertal female (panel C) and postpubertal female (panel D). Heavy arrows indicate point of contact between kisspeptin-containing varicosities and the GnRH neuron. Lighter arrows depict kisspeptin-positive nerve fibers. *Panels E and F*: The percentage of GnRH neurons exhibiting at least one kisspeptin close contact (panel E) was greater in intact postpubertal females than intact prepubertal females. This percentage increased with ovariectomy in the prepubertal, but not postpubertal, group. Numbers of contacts per GnRH neuron (panel F) did not differ among groups. *Redrawn from Ref. 72, with permission.*

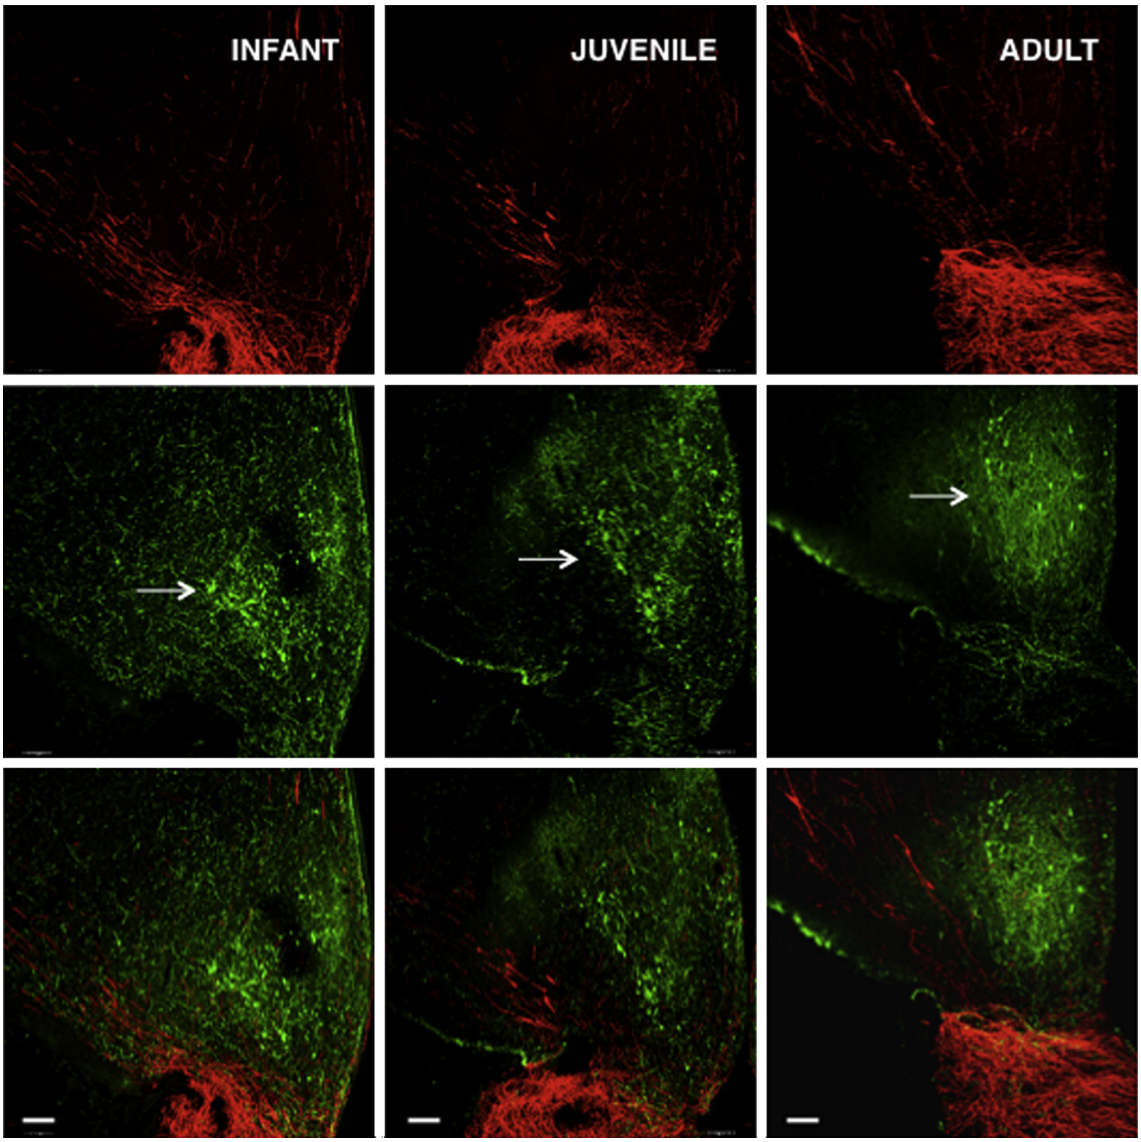

FIGURE 32.6 Confocal images illustrating developmental changes in GnRH (top panels) and kisspeptin (middle panels) neurons (immunopositive perikarya and fibers) in the MBH at the mid-tuberal level during postnatal development in the agonadal male rhesus monkey. The lower panels show the merged images. A hemi-hypothalamic section is shown for an infant (left-hand panels), juvenile (center panels), and adult (right-hand panels) animal; stages of postnatal development corresponding to the on-off-on pattern of GnRH pulse generator activity in primates. Note that kisspeptin immunoactivity is reduced in the juvenile MBH at a time when GnRH pulsatility is arrested but GnRH immunoactivity in the median eminence is maintained during this phase of development. In most cases the ependymal lining of the third ventricle is visible on the right-hand boundary of each hemi-section. *Arrow* indicates kisspeptin neurons in the arcuate nucleus. Scale bar, 100 μm. *Source: Parts of this montage have been reprinted with permission from Refs 170,266.*

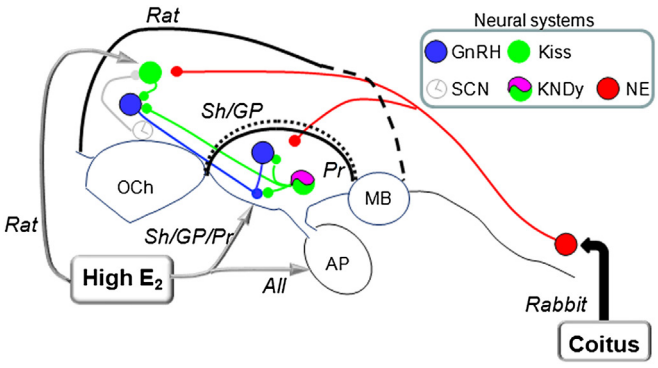

FIGURE 33.8 Schematic of parasagittal section of the hypothalamo–hypophysial unit illustrating the anatomical areas and neural systems participating in the preovulatory GnRH surge and sites of E_2 positive feedback in various species. All structures are required in rabbits; in other species, solid lines depict knife cuts that had no effect on the surge. Dotted lines are cuts that only decreased the amplitude of the LH surge, and the dashed line illustrates that NE input is normally required for the surge in rats but can be compensated for under some circumstances. See the text for more details. AP: anterior pituitary; GP: guinea pig; MB: mammillary body; OCh: optic chiasm; Pr: primate; Sh: sheep.

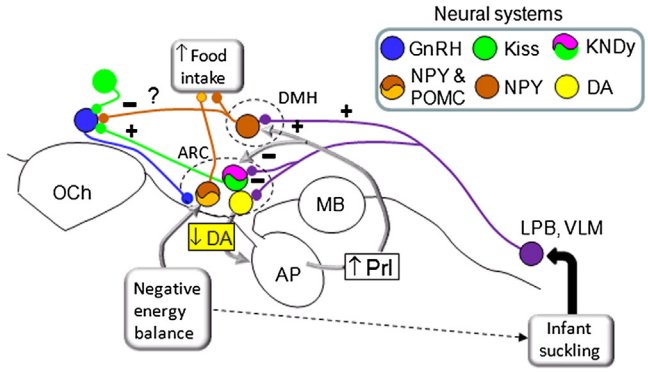

FIGURE 33.12 Neural systems stimulating food intake and inhibiting GnRH secretion during lactation in the rat. The suckling stimulus is transmitted to the hypothalamus via neurons in the lateral parabrachial nucleus (LPB) and ventrolateral medulla (VLM), inhibits DA release from tuberoinfundibular dopaminergic (TIDA) neurons and kisspeptin release from KNDy neurons, and stimulates NPY neural activity in the DMH. The fall in DA allows prolactin secretion to increase, which further inhibits KNDy kisspeptin and stimulates NPY from the DMH. The latter increases food intake, while the former inhibits GnRH secretion. At the same time, the negative energy balance in the mother induced by the demands of the offspring acts via the metabolic homeostatic circuitry in the ARC (increased NPY–AgRP and decreased POMC–CART), which also acts to stimulate food intake and may inhibit GnRH secretion. Note that this circuitry is depicted by a single neural element (NPY and POMC) for simplicity. Similarly, orexogenic neurons in the LHA and anorexogenic CRH neurons in the PVN are not illustrated.

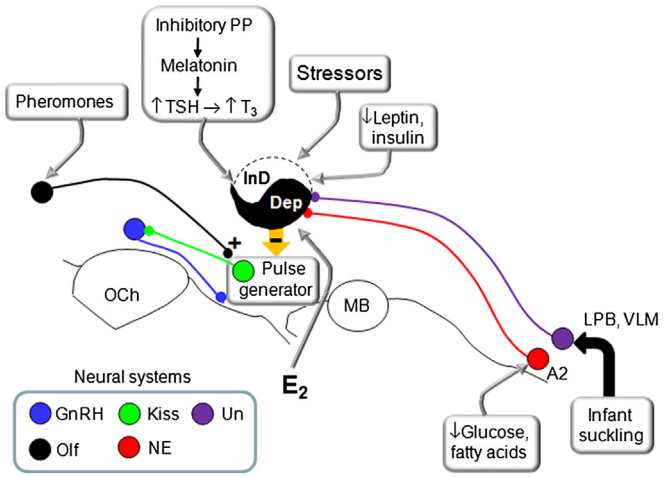

FIGURE 33.13 Schematic of parasagittal section of the hypothalamus illustrating mechanisms by which different external factors alter episodic GnRH secretion. Note that neural inputs are conceptual and do not represent monosynaptic pathways. See the text for more details. Dep: steroid-dependent mechanisms; InD: steroid-independent mechanisms; Kiss: kisspeptin; NE: norepinephrine; Olf: olfactory epithelium; Un: unknown neurotransmitter.

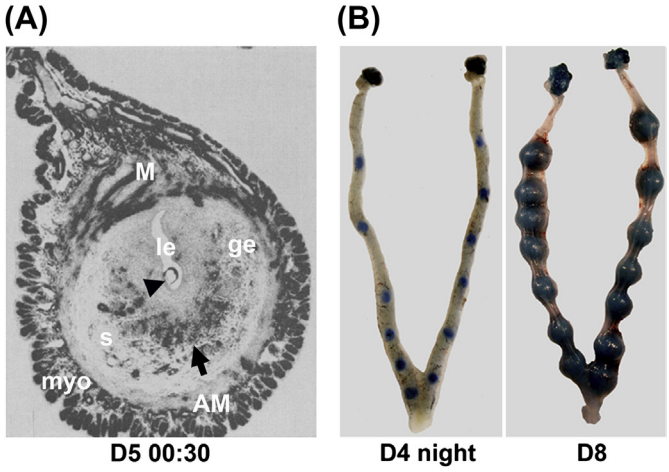

FIGURE 38.1 Increased endometrial vascular permeability upon attachment and implantation in the mouse. (A) Transverse section of uterus on day 5 (D5) early morning (00:30) of pregnancy showing implantation at the antimesometrial pole within a crypt (arrowhead). This section also shows weak alkaline phosphatase activity in the uterine stroma (black, arrow). Note the edema in the outer areas of the mucosa, contrasting with the closely packed cells around the uterine lumen (presumptive primary decidual zone). Le, luminal epithelium; ge, glandular epithelium; s, stroma; myo, myometrium; M, mesometrial pole; AM, antimesometrial pole. *(Source: Reprinted with permission from Ref. 2.)* (B) Increased vascular permeability at the sites of blastocyst attachment with the uterine luminal epithelium was detected after an intravenous injection of a blue dye (Chicago Blue B6) solution in mice at midnight of day 4 (D4) and day 8 (D8) of pregnancy. On day 4, distinct blue bands (dark bands in this picture) indicate that the attachment process has been initiated.

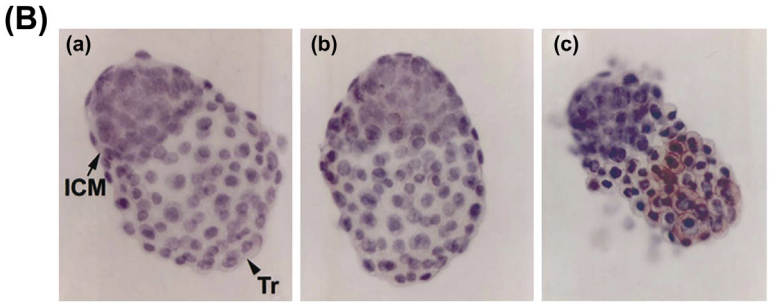

FIGURE 38.4 Molecular markers for blastocyst dormancy and activation. (B) Dormant blastocysts recovered from P_4-primed delayed-implanting mice on day 7 were cultured for 24 h in Whitten's medium, in the presence of (a) vehicle; (b) E_2; or (c) 4-OH-E_2. Blastocysts were processed for immunostaining and counterstained with hematoxylin. Red deposits indicate the sites of immunoreactive COX2. ICM, inner cell mass; Tr, trophectoderm. *Source: Reprinted with permission from Refs 67,137.*

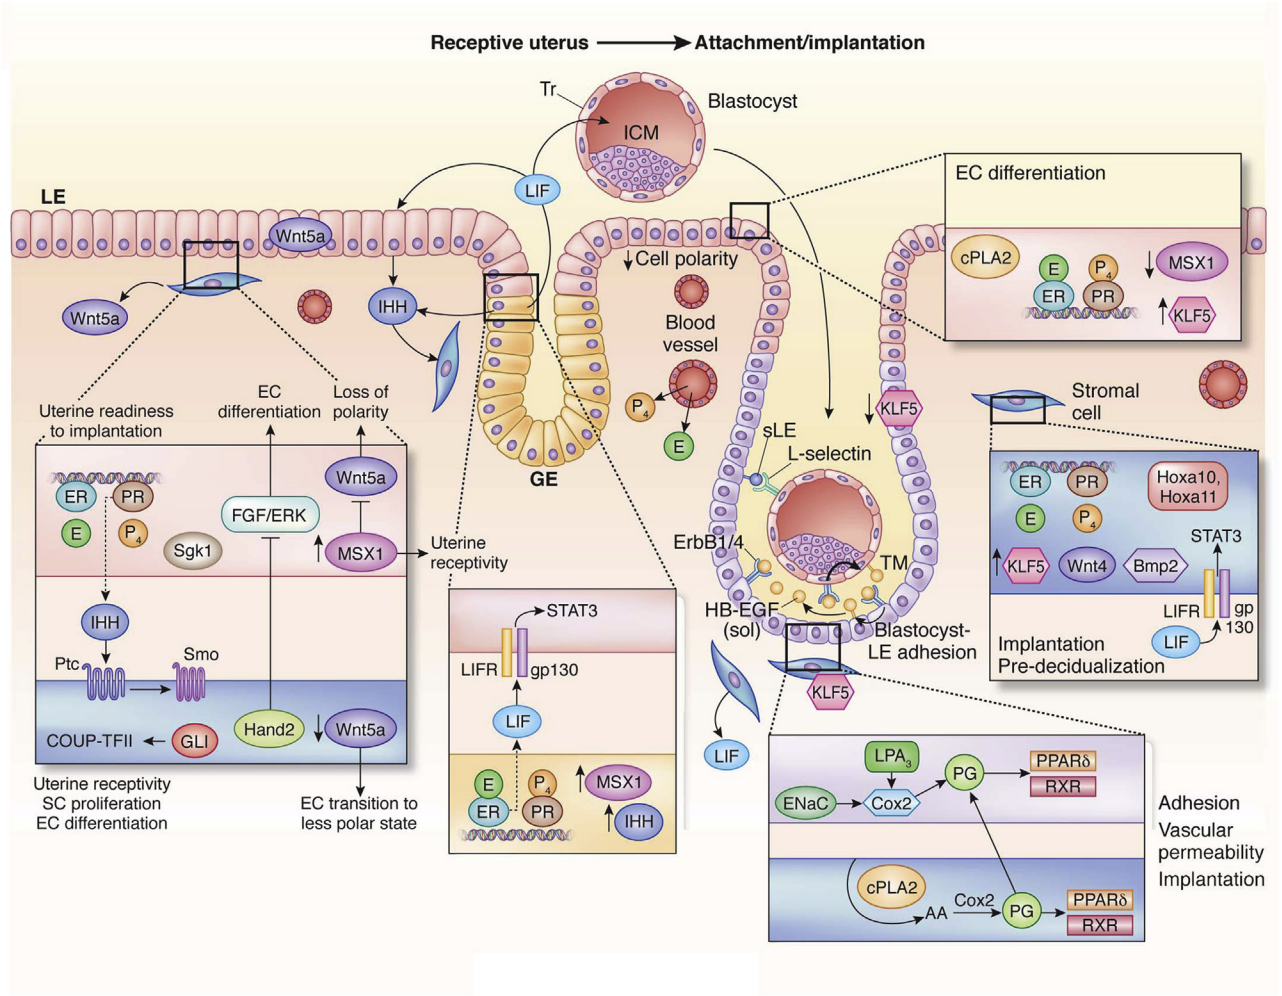

FIGURE 38.5 Signaling network for uterine receptivity and implantation. This is a hybrid cartoon, based on mouse and human studies, portraying compartment- and cell type–specific expression of molecules and their potential functions necessary for uterine receptivity, implantation, and decidualization. Interplay of ovarian P_4- and/or E_2-dependent and P_4- and/or E_2-independent factors in the pregnant uterus in specific compartments contributes to the success of implantation in a juxtacrine–paracrine–autocrine manner. During attachment, interactions between the blastocyst and luminal epithelium (LE) involve ErbB1/4 (blue) and both transmembrane (TM) and soluble (Sol) forms of HB-EGF, as well as L-selectin ligands (sLE) expressed by the luminal epithelium to L-selectin receptors on the blastocyst. The other key signaling pathways for uterine receptivity and implantation are also shown. AA, arachidonic acid; BMP2, bone morphogenetic protein 2; cPLA2α, cytosolic phospholipase A2α; COUP-TFII, chicken ovalbumin upstream promoter transcription factor 2; Cox2, cyclooxygenase 2; E, estrogens; EC, epithelial cell (luminal and glandular epithelia); ENaC, epithelium sodium channel; ER, estrogen receptor; ErbB1/4; epidermal growth factor receptor 1/4; ERK, extracellular signal–regulated kinase; FGF, fibroblast growth factor; GE, glandular epithelium; gp130, glycoprotein 130; Hand2, heart- and neural crest derivatives–expressed protein 2; HB-EGF, heparin-binding epidermal growth factor-like growth factor; Hoxa10/11, homeobox A10/11; ICM, inner cell mass; IHH, Indian hedgehog; KLF5, Kruppel-like factor 5; LIF, leukemia inhibitory factor; LIFR, LIF receptor; LPA3, lysophosphatidic acid receptor 3; MSX1, muscle segment homeobox 1; P_4, progesterone; PG, prostaglandin; PPAR-δ; peroxisome proliferator-activating receptor δ; PR, progesterone receptor; Ptc, Patched; RXR, retinoid X receptor; SC, stromal cell; SGK1, serum- and glucocorticoid-inducible kinase 1; Smo, Smoothened; STAT3, signal transducer and activator of transcription 3; Tr, trophectoderm; Wnt4/5a, Wingless-type MMTV integration site family members 4/5a. Compartment colors: blue, stroma; pink, luminal epithelium; orange, glandular epithelium; purple, epithelium at the attachment site. *Source: Reprinted with permission from Ref. 153.*

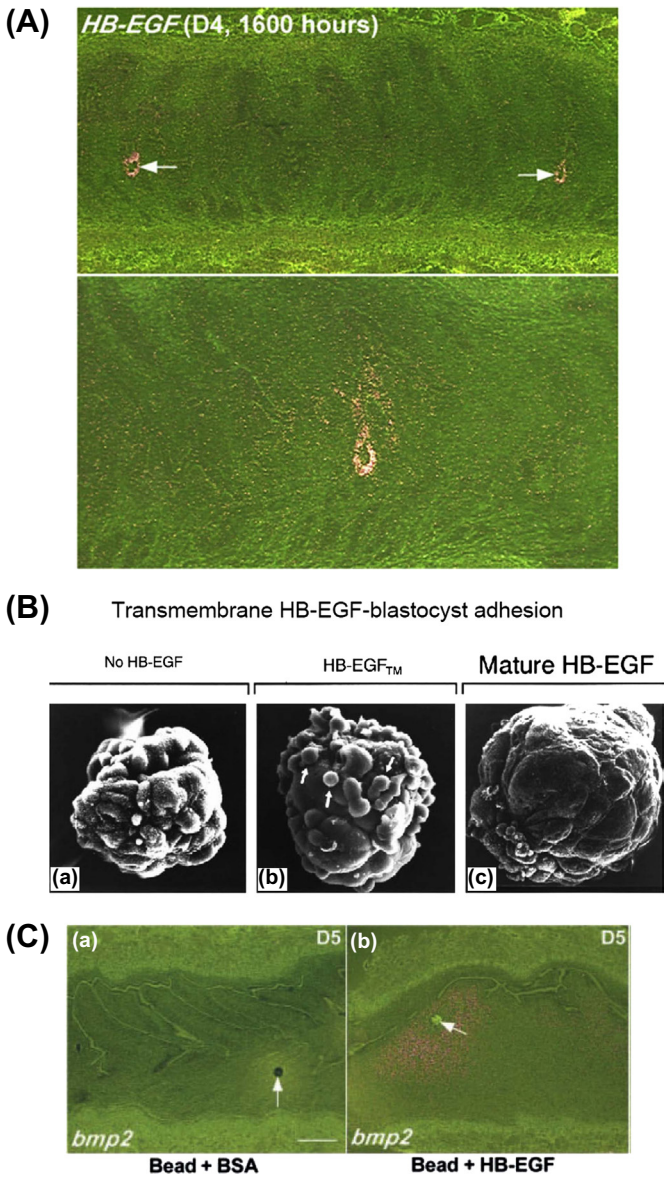

FIGURE 38.6 HB-EGF serves as a reciprocal mediator between the luminal epithelium and activated blastocyst during attachment reaction. (A) In situ hybridization of HB-EGF mRNA (dark-field) in the mouse uterus at 1600 h on day 4 of pregnancy. Note distinct hybridization signals in luminal epithelial cells surrounding two blastocysts in a longitudinal section. Arrows demarcate location of blastocysts. (B) Scanning electron microscopy of blastocysts co-cultured with 32D cells (a murine myeloid cell line). Zona-free day 4 (0900 h) mouse blastocysts were co-cultured with (a) parental 32D cells, (b) 32D cells displaying transmembrane form of HB-EGF^{TM}, or (c) 32D cells synthesizing soluble form of HB-EGF for 36 h. After extensive washing to remove loosely adhering cells, blastocysts were fixed and examined by scanning electron microscopy; magnification 800×. Arrows point to 32D cells. (C) *Bmp2* gene expression in response to beads preloaded with HB-EGF. Beads (7 beads/horn) preabsorbed either in BSA (control) or HB-EGF (100 ng/ml) were transferred into uterine lumens of day 4 pseudopregnant mice. Mice were killed on day 5 to examine *Bmp2* expression at the sites of beads. Arrows indicate the locations of the beads. Note localized stromal expression of *Bmp2* at the sites of beads preabsorbed with HB-EGF. Bar: 75 mm. *Source: Reprinted with permission from Refs 9,135,220.*

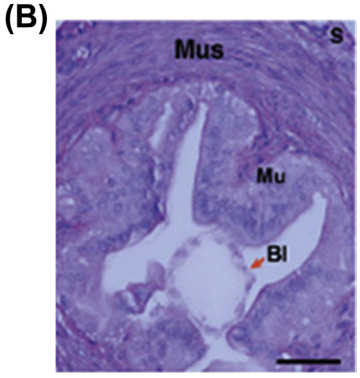

FIGURE 38.7 Impaired oviductal embryo transport causes pregnancy loss in *Cnr1*$^{-/-}$ but not *Cnr2*$^{-/-}$ mice. (B) A representative histological section of a day 7 pregnant *Cnr1*$^{-/-}$ oviduct showing an entrapped blastocyst (Bl, arrow) at the isthmus. Mus, muscularis; S, serosa; Mu, mucosa. Bar, 100 μm. *Source: Reprinted with permission from Ref. 394.*

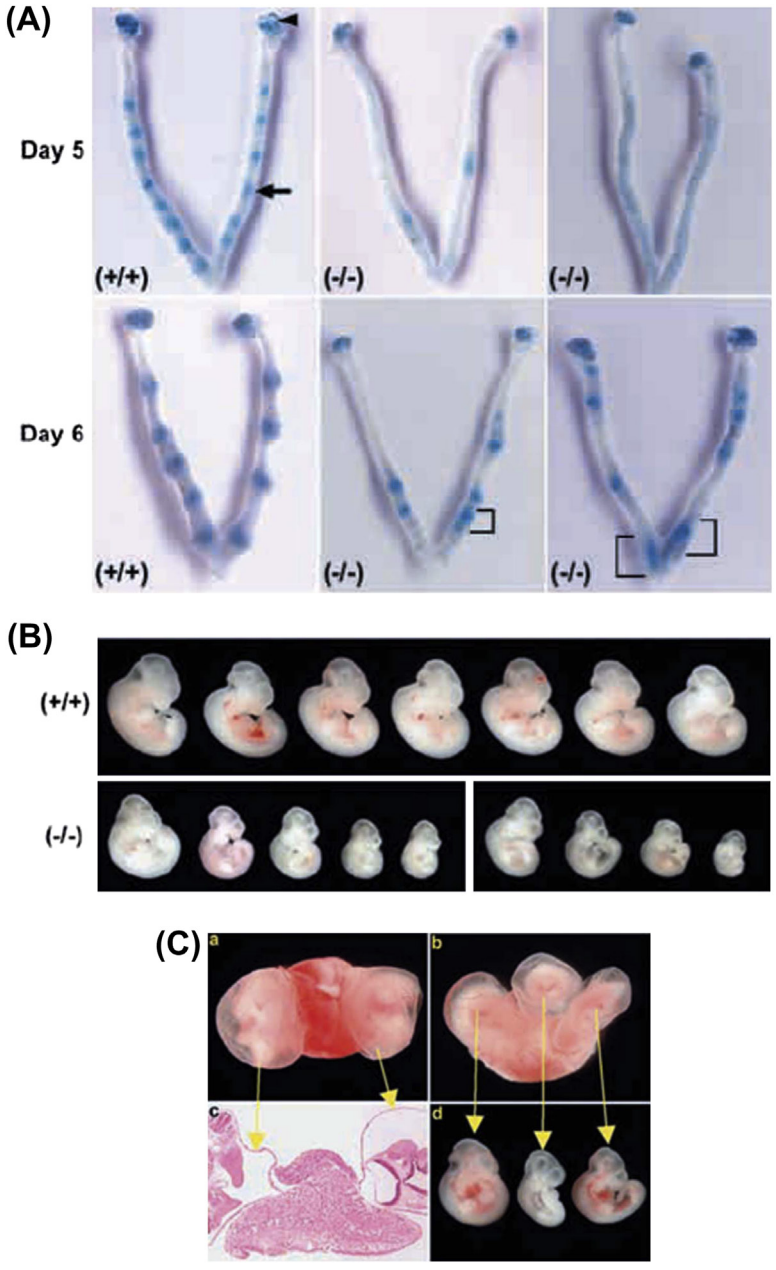

FIGURE 38.8 **Defective postimplantation development in *Pla2g4a*$^{-/-}$ mice.** (A) Representative photographs of uteri with implantation sites (blue bands) on days 5 and 6. Note very few or no implantation sites on day 5, but unevenly spaced implantation sites on day 6 in *Pla2g4a*$^{-/-}$ mice. Arrowhead and arrow indicate ovary and implantation site, respectively. Brackets indicate crowding of implantation sites. (B) Photographs of embryos isolated from implantation sites of one representative wild-type and two *Pla2g4a*$^{-/-}$ mice on day 12. Note retarded and asynchronous development of embryos in *Pla2g4a*$^{-/-}$ mice. (C) Representative photographs of conjoined embryos in a placenta (a, c) and three embryos in the same decidual envelope (b, d) from *Pla2g4a*$^{-/-}$ mice on day 12. (c) A histological section of (a) with two embryos; embryos shown in (d) are from (b). Yellow arrows indicate the source of the embryos from the decidual envelope. *Source: Reprinted with permission from Ref. 47.*

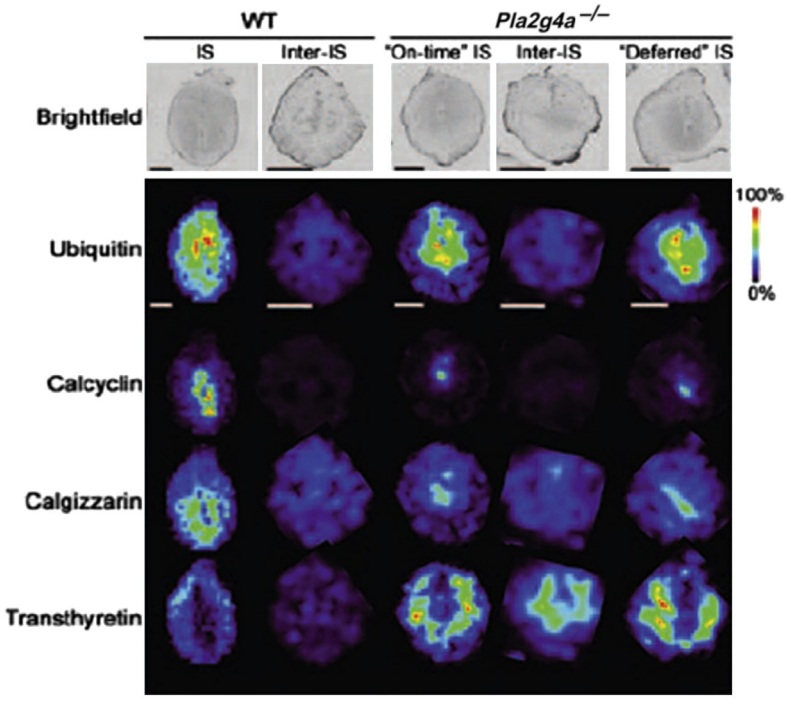

FIGURE 38.9 **Proteome profiles differ between WT and *Pla2g4a*$^{-/-}$ uteri on day 6 of pregnancy, regardless of implantation timing.** Optical images of a WT implantation site (IS) and interimplantation site (inter-IS) and *Pla2g4a*$^{-/-}$ deferred and on-time IS (*upper panel*). Bar, 670 μm. Ion intensity maps are shown below their respective bright-field images. *Source: Reprinted with permission from Ref. 480.*

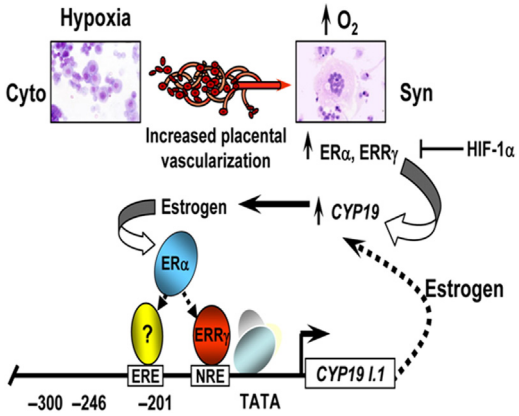

FIGURE 40.12 Model of hCYP19 regulation in human trophoblasts. Early in gestation, the placenta is relatively hypoxic; the elevated levels of HIF-1α inhibit ERRγ transcription via interaction with a response element (HRE) in the ERRγ promoter. This, together with hypoxia-mediated induction of basic helix–loop–helix factors ASCL2 and USF1/2, blocks syncytiotrophoblast differentiation and hCYP19 gene expression. After the ninth week of gestation, increased placental vascularization results in increased oxygen availability to the trophoblast cells. The consequent decrease in HIF-1α levels and the expression of other inhibitory transcription factors cause upregulation of ERRγ and induction of hCYP191.1 transcription. The increased estrogens produced, in turn, activate ERα, which may functionally interact with ERRγ and other activating transcription factors to further upregulate hCYP19 expression. *Source: Reprinted with permission from Ref. 360.*

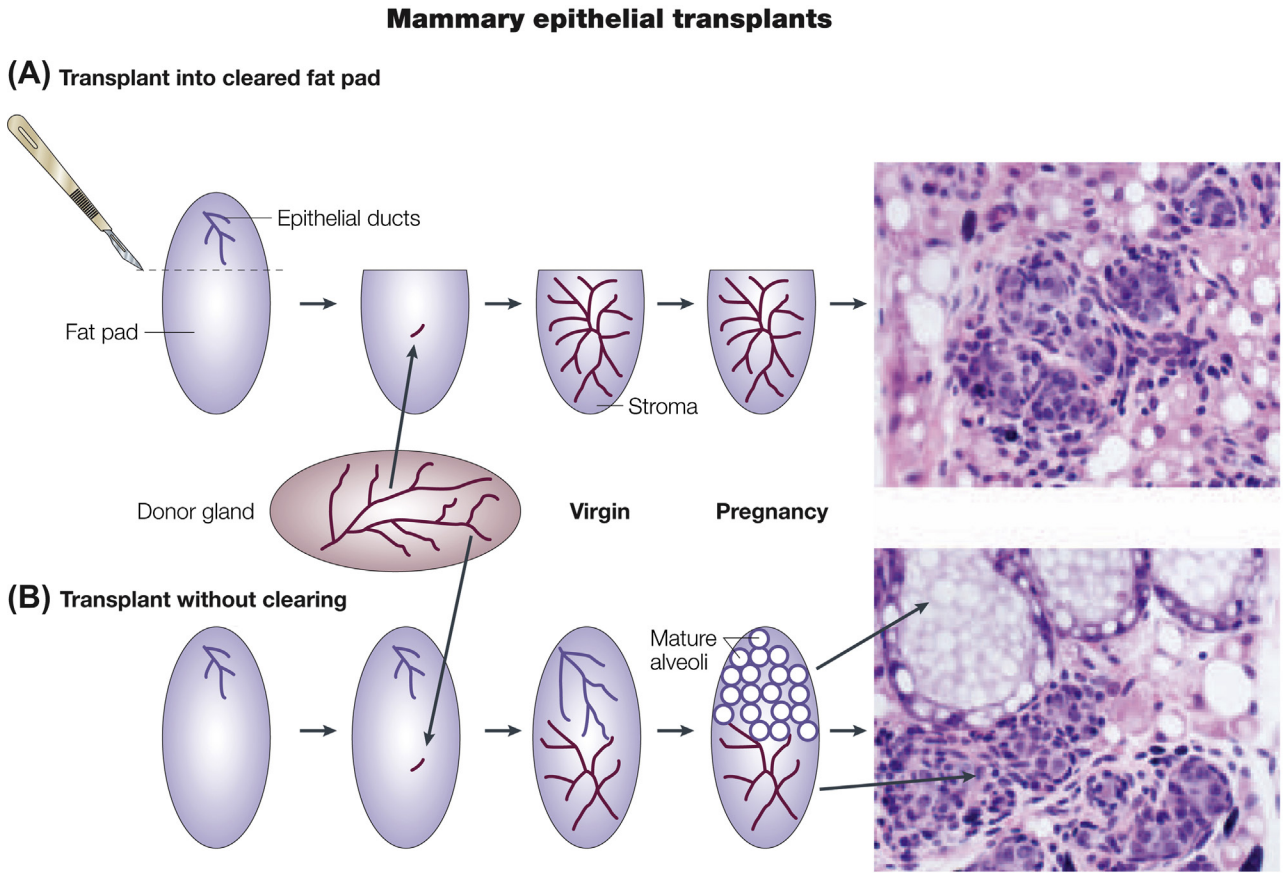

FIGURE 46.2 Use of mammary gland transplantation to assess developmental potential. (A) The area containing the ductal anlage (purple) in a 3-week-old mouse is surgically removed to generate a "cleared fat pad" into which donor tissue (dark pink) is transplanted. The development of the transplanted tissue is monitored at intervals posttransplant by either whole mount or standard histological analysis. (B) An alternative approach involves direct transplantation into a non-cleared mammary gland. Transplanted cells are frequently marked with either immune-fluorescent markers, genetic markers, or infected with viruses expressing detectable markers. *Source: Used by permission from Macmillan Publishing Company; Ref. 14.*

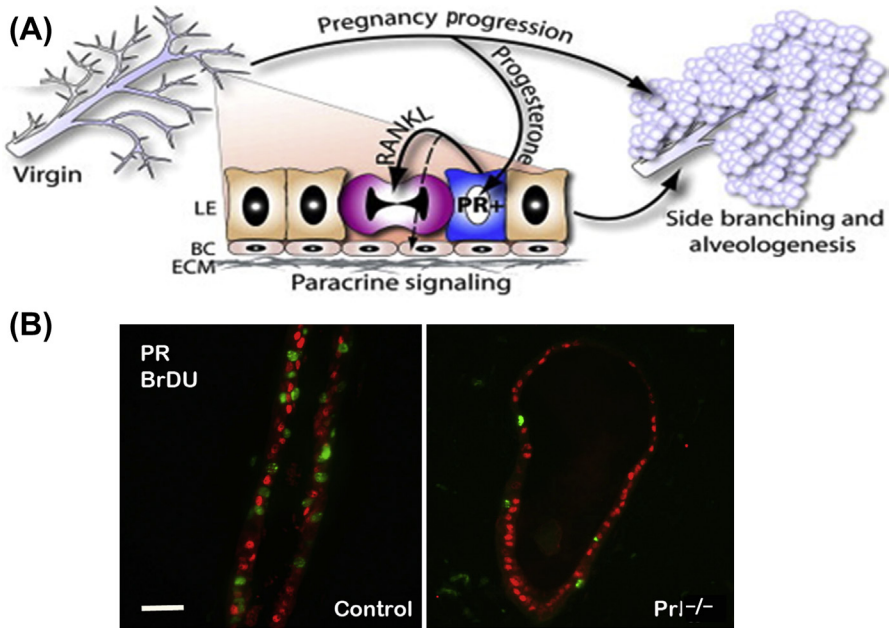

FIGURE 46.4 Role of paracrine signaling in alveologenesis. (A) As pregnancy progresses side branches develop at discreet intervals along the ducts; cells in these side branches proliferate to form alveoli. The progesterone receptor (PR) is expressed in a subset of alveolar cells that are stimulated by increasing P4 from the ovaries to secrete RANKL. This paracrine factor acts on neighboring cells to promote proliferation. (B) Expression of PR and proliferating cells after 2 days of treatment with E2 and P4 in wild-type (control) and PRL-null mice. Proliferating cells (BrDU labeled, green) and PR positive cells (red) are generally not coincident. Note that the number of proliferating cells is reduced in the absence of PRL. Scale bar, 50 μm. *Source: (A) Used by permission from Ref. 93. (B) Original figure from Ref. 64.*

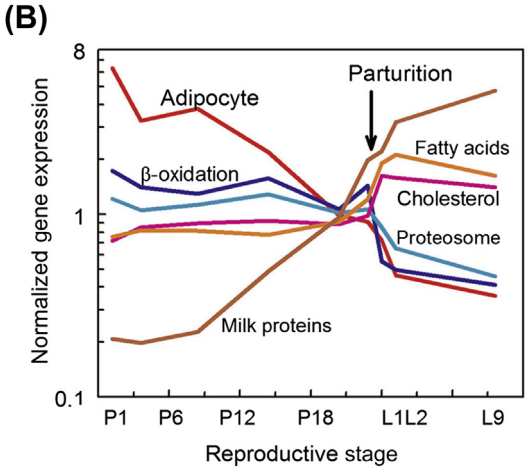

FIGURE 46.5 Changes in the differentiated activity of the mammary gland in pregnancy and lactation. (B) Changes in gene expression of different categories of genes in the mouse mammary gland from microarray studies. Expression of adipocyte-specific genes and collagens (not shown) decreases six- to eightfold during pregnancy and another twofold at parturition, whereas the genes for fatty acid degradation and many components of the proteosome are level during pregnancy and decrease about twofold at parturition. Milk protein genes, on average, increase about fivefold during pregnancy and another threefold around parturition, whereas the genes for fatty acid and cholesterol synthetic enzymes increase about twofold just after parturition. Normalized data for each class were averaged to produce the lines on this graph. *Source: (B) From Ref. 11.*

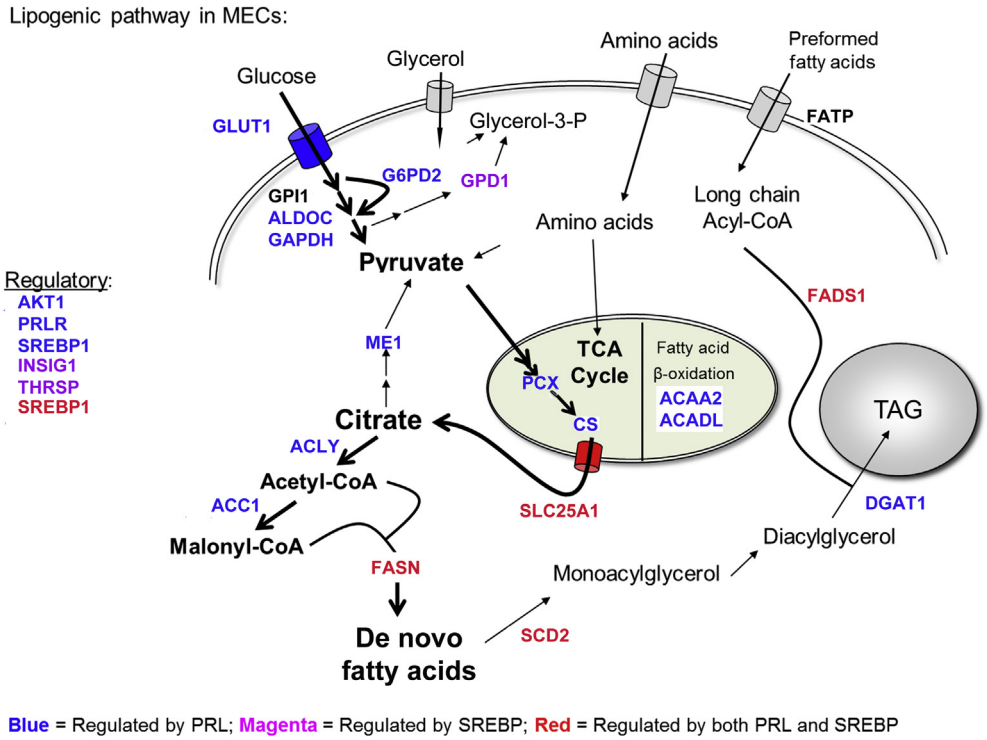

FIGURE 46.7 **Lipid synthesis pathways in mammary epithelial cells during lactation.** Substrates for lipid synthesis enter the cells via the glucose transporter (GLUT1), a glycerol transporter, as amino acids, or as preformed fatty acids via a fatty acid transport protein (FATP). Glycolysis leads to the production of both glycerol-3-phosphate and pyruvate from glucose. The genes for several enzymes in this pathway, fructose bis-phosphate aldolase (ALDOC) and glycerol-3-phosphate dehydrogenase (GAPDH), as well as glycose-6-phosphate dehydrogenase (G6PD2 in the mammary gland) are all upregulated by prolactin along with mitochondrial genes for pyruvate carboxylase (PCX) and citrate synthase (CS). Glycerol-3-phosphate is formed from dihydroxyacetone phosphate, a product of glycolysis, by glycerol-3-phosphate dehydrogenase (GPD1) to be used as a backbone for triacylglyceride (TAG) synthesis. GPD1 is regulated by SREBP. Amino acids are transformed into pyruvate and other substrates that enter the mitochondria to be transformed into citrate, which is exported via the tricarboxylic acid transporter, SLC25A1. Citrate is the major substrate for de novo synthesis of fatty acids in species other than ruminants, which utilize acetate for this purpose. Citrate is transformed into acetyl-CoA by ATP citrate lyase (ACLY), then to malonyl CoA by acetyl-CoA carboxylase (ACC1), and finally to saturated fatty acids with 8–16 carbons (C:8–C:16) by fatty acid synthase (FASN). Cytosolic malic enzyme (ME1) and the enzymes of the pentose phosphate shunt both provide the necessary reducing molecule NADPH that is required for activity of FASN. C:16 fatty acids can be desaturated by stearoyl-CoA desaturase (SCD2) prior to being esterified into monoacylglycerol, then diacylglycerol, and finally into triacylglycerols, with subsequent integration of the fatty acids derived from preformed sources. The final step in the TAG synthesis pathway is catalyzed by diglyceride acyltransferase (DGAT1). The TAG coalesce into lipid droplets. Both prolactin and SREBP have been shown to regulate the genes for FASN, SLC25A1, SCD2, and FADS1. *Source: Diagram derived from data in Refs 19,20.*

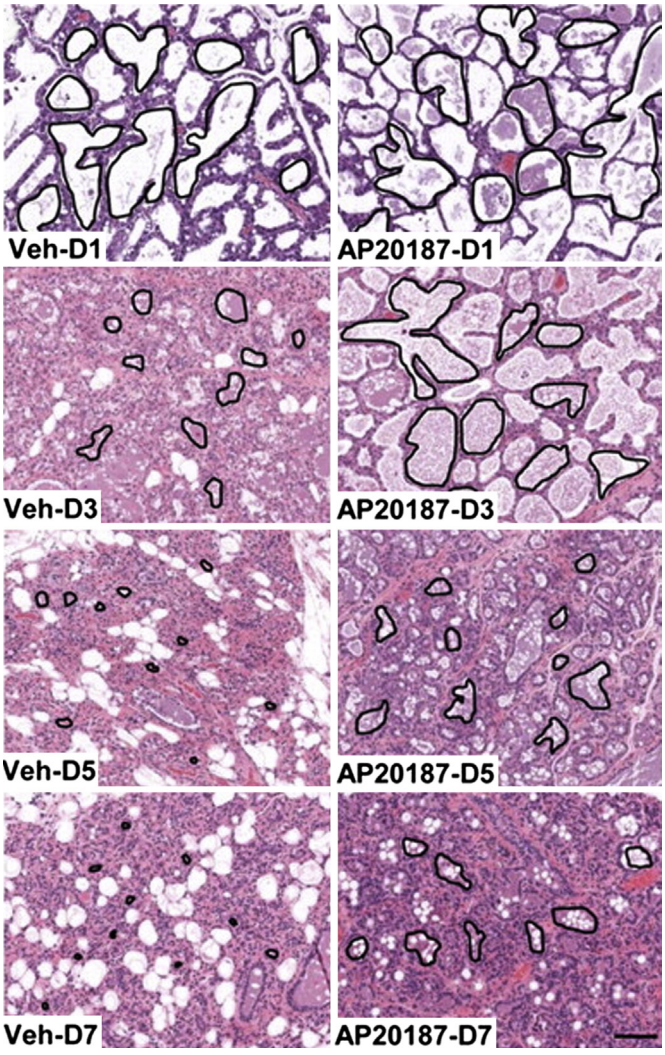

FIGURE 46.9 The role of macrophages in mouse mammary gland involution; histological analysis. Glands from Mafia mice were analyzed on days 1, 3, 5, and 7 after pup removal from a 10-day lactating mouse suckling five to six pups. Three days prior to pup withdrawal experimental dams were given a dose of AP20187, which depletes macrophages in this strain. Left-hand images, vehicle only (macrophages present); right-hand images, AP20187 (macrophages depleted). In both control and experimental mice marked luminal expansion is evident 1 day after removal of pups (some lumens outlined in black for illustration). In vehicle-only mice a marked decrease in lumen size by day three is observed as milk is resorbed. Very small lumens remain on day 7, however significant numbers of lipid filled adipocytes are evident between the alveoli starting on day three and increasing to day 7. These changes occur much more slowly in the glands of AP20197-treated mice, providing evidence that macrophages are required for several aspects of normal involution. *Source: Reproduced by permission from Ref. 183; link at Development:* dev.biologists.org.

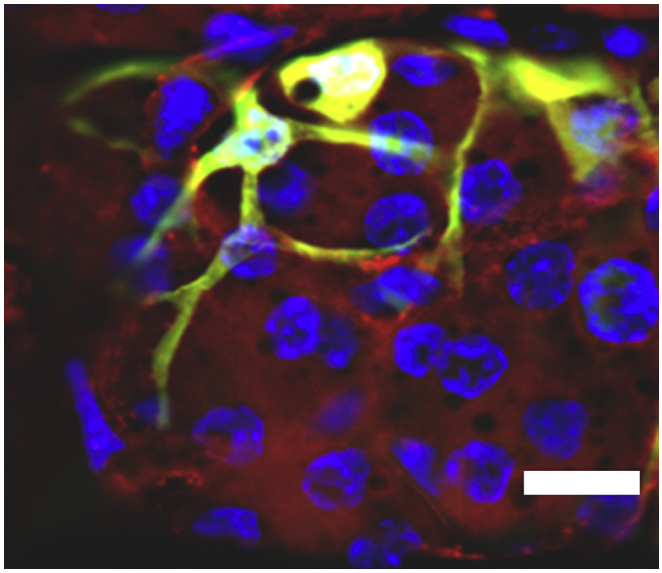

FIGURE 46.19 Myoepithelial cell in the mammary gland of a lactating mouse. The cell has been transduced with adenoviral GFP (yellow) showing processes embracing the luminal epithelial cells (red). Nuclei stained with DAPI (blue). Scale bar 10 μm. *Source: From Russell T, Fischer A, Beeman N, Freed E, Neville MC, Schaack J. Transduction of the mouse mammary epithelium with adenoviral vectors in vivo.* J Virol *2003;77(10):5801–09.* http://dx.doi.org/10.1128/JVI.77.10.5801–5809.2003, *© 2003, American Society for Microbiology.*

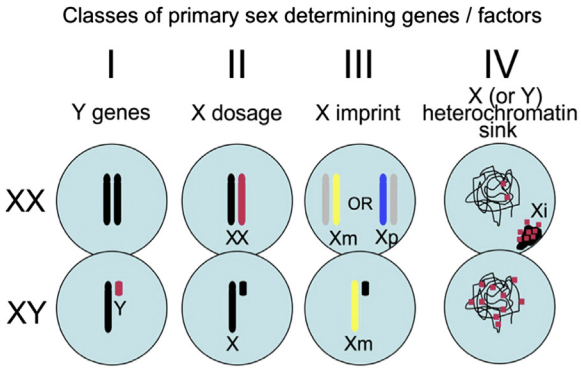

FIGURE 47.7 Four ways that sex chromosomes could affect gene expression. Four possible classes of primary sex-determining factors are recognized. Class I comprises Y genes that have a male-specific effect on one or more tissues. Class II is X genes that are expressed at a higher level in females than males by virtue of the 2:1 ratio in the number of X chromosomes. Class III is X genes that receive a parental imprint. The X chromosome receiving a maternal imprint (Xm, yellow) is active in half of XX cells and all of XY cells, whereas the X chromosome receiving a paternal imprint (Xp, blue) is active in half of XX cells and no XY cells. Class IV comprises proposed regions of the sex chromosome heterochromatin (the heterochromatic inactive X (Xi) is illustrated here) that act as sex-specific sinks for factors (red dots) that regulate the amount of euchromatin–heterochromatin at interphase and therefore affect gene expression throughout the genome. To date, specific members of only Class I have been identified (*Sry* and spermatogenesis genes). Although evidence indicates that the number of X chromosomes leads to some sex differences in phenotype, the specific genes or chromosome regions that explain these X effects have not been identified. Class IV is particularly speculative at present because it is based on a limited number of studies. Future studies are likely to expand the importance of Classes II–IV. *Source: Adapted with permission of Elsevier from Ref. 58.*

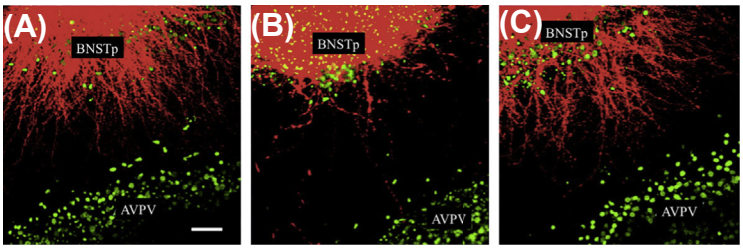

FIGURE 47.10 Target-dependent induction of neurite outgrowth in co-cultures of the principal nucleus of the bed nucleus of the stria terminalis (BNSTp) and anteroventral periventricular nucleus (AVPV). Confocal images of BNSTp-AVPV co-cultures show DiI labeling of neuritis (pseudo-colored red) that extend from the BSTp toward the AVPV. The BSTp explant was derived from a male rat on postnatal day 5 (PN5) and co-cultured with an AVPV explant (pseudo-colored green) derived from a PN9 (A) male, (B) female, or (C) androgenized female. A marked difference in the density of neurites between the co-cultures explants was observed, with many more neuritis seen when the AVPV explant was derived from a male (A) versus a female (B) rat. Treatment of neonatal female rats with testosterone during the first 9 days of life in vivo masculinized (i.e., increased) neurite outgrowth from BSTp explants (C), suggesting that the target-dependent formation of neuritis extending from the BSTp to AVPV is determined by exposure to sex steroid hormones during the neonatal period. Scale bar: 15 μm. *Source: Adapted with the permission from Ref. 217.*

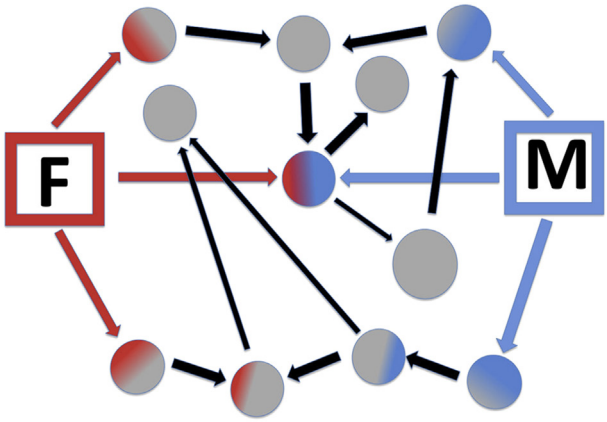

FIGURE 47.21 Schematic view of the sexome. Male- and female-biasing factors (chromosomes, hormonal profiles, etc.) are represented by the M and F boxes, respectively. These factors act on specific nodes in the gene network causing male and female bias in gene expression represented by differently colored shading. Sex bias can be propagated to other nodes, thereby increasing or decreasing gene expression and in some cases canceling out sex-biasing effects. Arnold and Lusis define the sexome as the total of all sex-biasing actions within the network.[404] Although they focus on sex bias in gene products,[404] the circles and arrows in this figure may just as well represent interactions between different organ systems. *Source: Adapted from Ref. 404.*

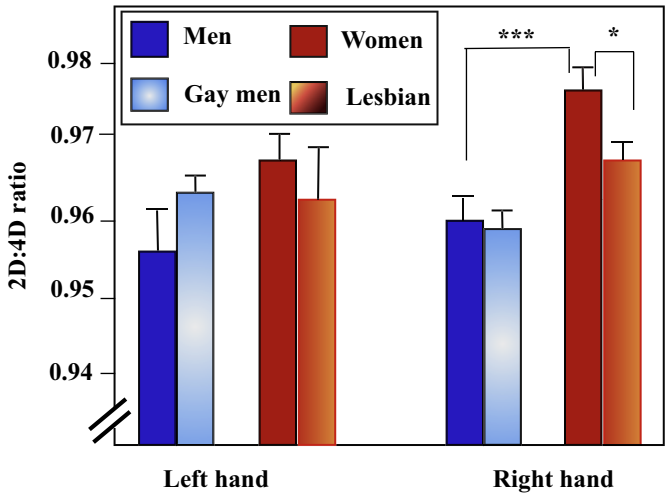

FIGURE 48.7 **Ratio of lengths of the index (2D) and ring finger (4D) as a function of sex and sexual orientation.** The 2D:4D ratio is greater in women than in men, probably due to in utero exposure to testosterone of male embryos. It is close to the male level in homosexual women, suggesting that they have been exposed to abnormally high levels of testosterone during a part of their embryonic life. For unknown reasons, these differences are more pronounced in the right hand. * = $p < 0.05$, *** = $p < 0.001$. *Source: Redrawn from Ref. 117.*

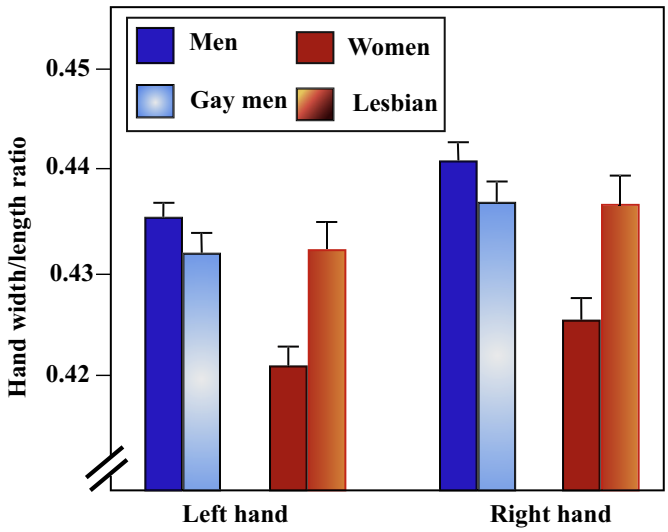

FIGURE 48.8 **Relationship between sex and sexual orientation and the ratio of width to length of the hand.** *Source: Redrawn from data in Ref. 123.*

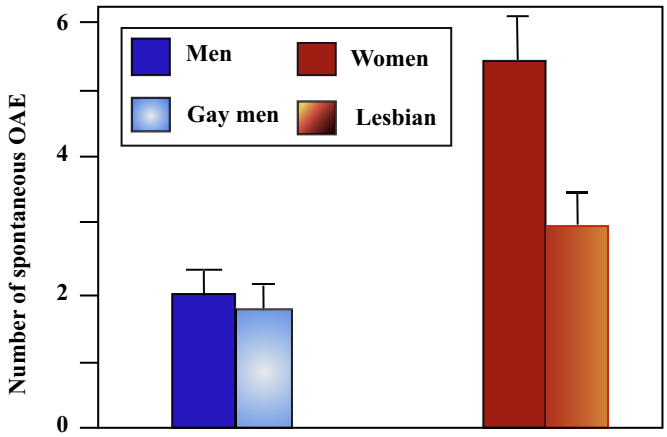

FIGURE 48.9 **Frequency of oto-acoustic emissions (OAE) evoked by click sounds measured in the right ear in men and women as a function of sexual orientation.** OAE are sexually differentiated and significantly masculinized in homosexual females. *Source: Redrawn from data in Refs 124,127.*

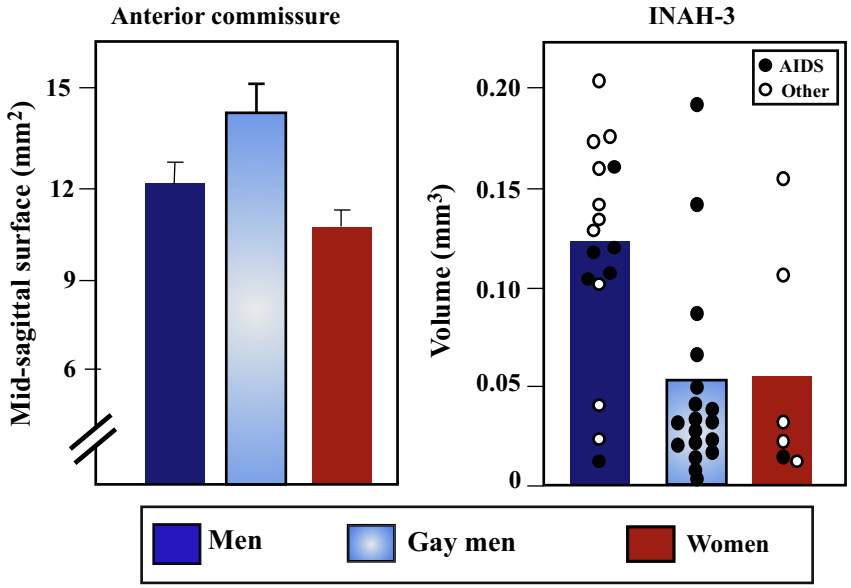

FIGURE 48.11 **Average size of the anterior commissure as estimated by its surface in the mid-sagittal plane (left) and volume of the 3rd interstitial nucleus of the anterior hypothalamus (INA-3) (right) in men, gay men, and women.** Data for the anterior commissure are presented as means ± SEM, whereas for INAH-3 the average value in each group, as well as all individual data points, are shown to clearly illustrate the partial overlap between groups despite the significant differences between men and women and between men and gay men. Individual data points are filled in subjects who died from AIDS and open in subjects who died from other causes. The smaller average size of INAH-3 in gay men cannot be accounted for by the fact that all subjects included in the study had died from AIDS since in the control group, the INAH-3 of men who died from AIDS is not smaller than in men who died from other causes. *Source: Redrawn from data in Refs 140,141.*

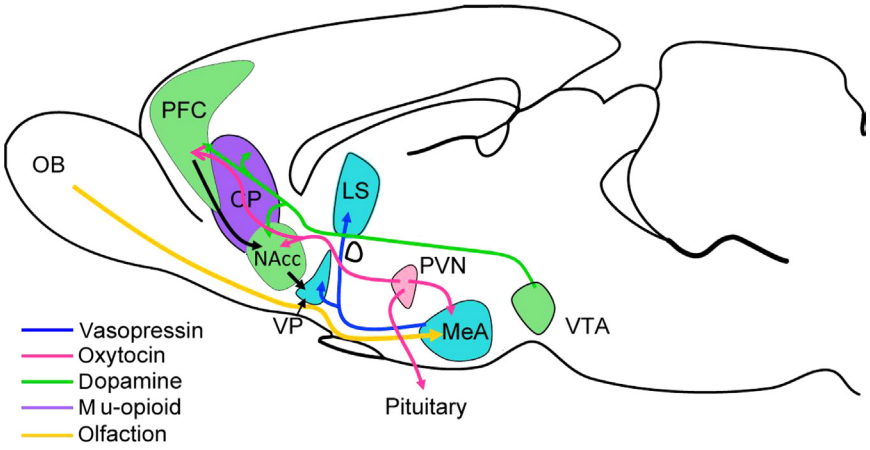

FIGURE 48.21 A schematic of the proposed neural circuitry of pair bond formation in prairie voles. Mating stimulates the release of oxytocin from neurons in the paraventricular nucleus of the hypothalamus (PVN) into the nucleus accumbens (NAcc) and prefrontal cortex (PFC) in females, and the release of vasopressin from neurons in the medial amygdala (MeA) into the ventral pallidum (VP) and lateral septum (LS) in males. Mating also stimulates the release of dopamine from neurons in the ventral tegmental area (VTA) into the NAcc and PFC. The MeA receives olfactory input from the partner and conveys the neural encoding of the olfactory signature of the partner to the striatum and LS. Mu-opioid receptors in the CP stimulate the rewarding aspects of mating. OT and AVP facilitate the processing of the olfactory signatures of the mate, and dopamine facilitates an association between the neural encoding of the social cues of the partner and the opioid-based reward and reinforcement. The actions of these neurochemicals in these circuits lead to a conditioned partner preference. *Source: Adapted from Refs 271,334.*

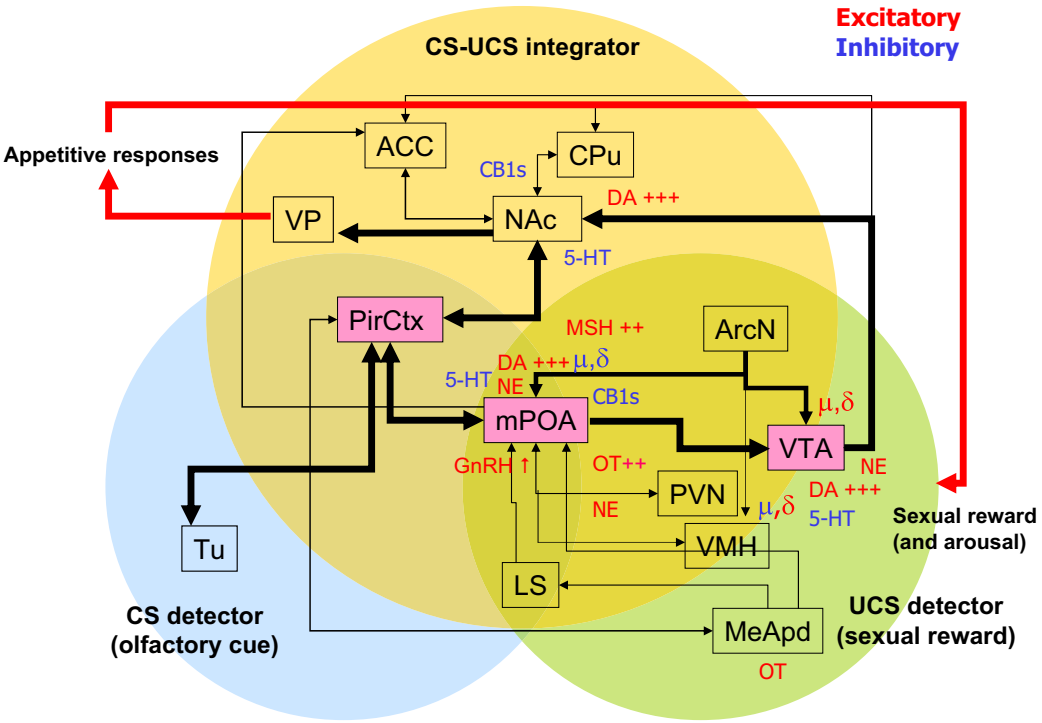

FIGURE 50.28 **Neural systems critical for the display of sexual behavior in the rat.** Appetitive behaviors made toward unconditioned or conditioned sexual incentive stimuli lead to sexual reward that is processed by three interactive systems. Two systems process olfactory stimuli and sexual reward relatively independently, whereas a third, mesolimbic DA system, acts to integrate both the conditioned olfactory cue and its rewarding sexual outcome. Three common regions, the piriform cortex, mPOA, and VTA, are activated in male and female rats by conditioned olfactory stimuli. Opioid actions in the VTA potentiate mesolimbic DA activation, whereas opioid actions in the mPOA inhibit sexual arousal and desire. Neurotransmitter systems or their receptors in red are excitatory for sexual motivation whereas those in blue are inhibitory. Black pathways signify major inputs and outputs of the system. Note that opioids can be excitatory in the VTA, inhibitory in the mPOA, or either in the VMH (depending on the receptor type). A similar system is activated in humans.[63] Abbreviations: ACC, anterior cingulate cortex; ArcN, arcuate nucleus of the hypothalamus; CB1, cannabinoid Type 1 receptor; CPu, caudate-putamen (striatum); DA, dopamine; δ, delta opioid receptors; GnRH, gonadotropin releasing hormone; LS, lateral septum; MeApd, posterior-dorsal nucleus of the medial amygdala; mPOA, medial preoptic area; MSH, melanocyte stimulating hormone; μ, mu opioid receptors; NAc, nucleus accumbens; NE, norepinephrine OT, oxytocin; PirCtx, piriform cortex; PVN, paraventricular nucleus of the hypothalamus; Tu, olfactory tubercle; VMH, ventromedial nucleus of the hypothalamus; VP, ventral pallidum; VTA, ventral tegmental area; 5-HT, serotonin. *Source: Adapted from Pfaus et al.*[683]

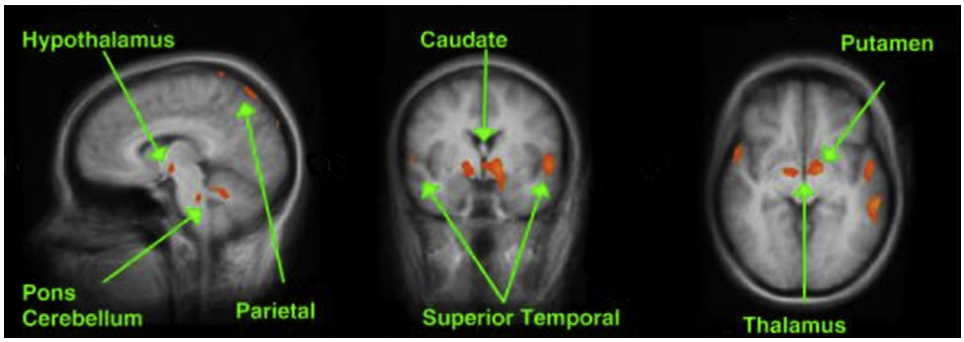

FIGURE 51.20 Sites of the maternal brain where fMRI activity was higher (indicated by red) in mothers who delivered vaginally compared to via Caesarean section while listening to their own infant crying. *Source: Modified from Swain et al., 2008.*[98]

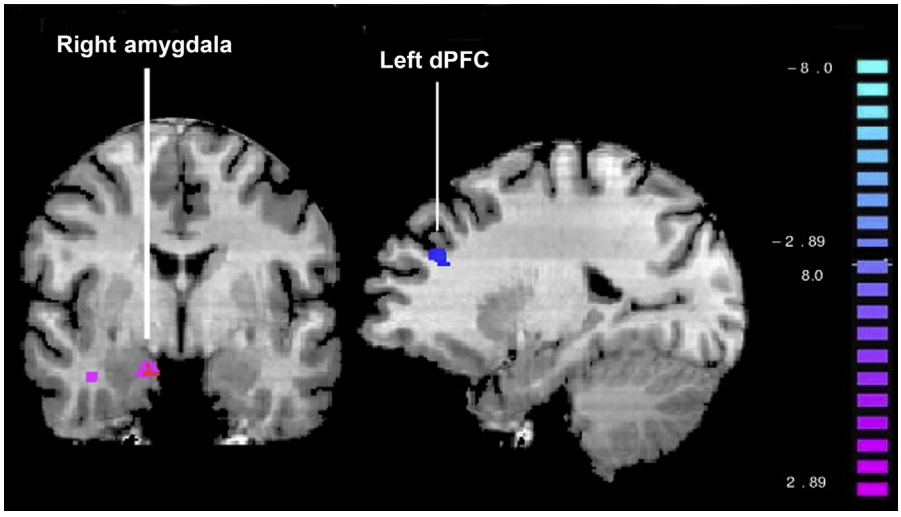

FIGURE 51.21 Sites in the parental brain where mothers (left) or fathers (right) showed greater fMRI activity in response to their own infant video compared to viewing an unfamiliar infant. Mothers showed greater activity in the right amygdala and temporal, occipital, and parietal cortices compared to fathers, while fathers had greater activity in the dorsal prefrontal cortex (dPFC). *Source: Modified from Atzil et al., 2012.*[711]
