receptor subtypes, α, β, and γ, and their isoforms. RXRs form heterodimers with RARs that are thought to be the functional units transducing the retinoid signal. The binding of RARs/RXRs to retinoic acid response elements (RARE) modulates gene expression and is likely to be responsible for the observed biological effects of retinoids.[763]

Most of the components of the retinoid-signaling pathway have been identified in the epididymis. Retinoids were quantified in the rat epididymis by high performance liquid chromatography (HPLC) followed by derivation of the HPLC-purified retinoids to confirm their identities.[764] In the epididymal tissue, the major retinoids identified included retinol, retinyl ester, all-*trans* retinoic acid and 9-*cis*-retinoic acid. The concentration of retinol and retinyl esters decreased from the caput to the cauda epididymidis from 2.7 to 1.7 nmol/g of tissue and 6.2 to 1.4 nmol/g tissue, respectively. The active retinoids, all-*trans* retinoic acid and 9-*cis*-retinoic acid (9-*cis*-RA) showed an inverse gradient with lowest concentrations in the caput (RA: 13 pmol/g tissue; 9-*cis*-RA: 2.9 pmol/g tissue) and highest concentrations in the cauda epididymidis. Using a bioassay, levels of 7 pmol/g of tissue have been reported in the murine epididymis.[765]

The cellular retinol and retinoic acid binding proteins are also present in the epididymis, but their localization is regionalized. CRBP is most abundantly present in the columnar epithelial cells of the proximal caput epididymidis of the rat; this tissue has one of the highest CRBP expressions in the body.[766–768] The mouse has the highest concentrations of CRBP in the proximal caput epithelium, but also has significant levels in the epithelium throughout the epididymis. CRABP II is found in the epithelium of the cauda epididymidis co-expressed with CRBP in both the mouse and the rat, while CRABP I is present in the smooth muscle of the distal cauda epididymidis.[769]

The retinoid-signaling pathway in the epididymis includes the retinoic acid receptors and the RA carrier protein E-RABP, synthesized and secreted into the lumen in the distal caput and found in the lumen from the caput to the cauda epididymidis. In the rat epididymis, RAR α, β, and γ transcripts have been detected by RT-PCR.[770] In situ hybridization and immunolocalization revealed region specific patterns of RARα mRNA and protein expression.[771] The highest levels of RARα transcript and RARα immunostaining were seen in the proximal caput epididymidis. The levels of RARα transcripts and RARα protein staining were higher in the initial segment, proximal caput and distal cauda. The lowest levels were seen in distal caput, corpus, and proximal cauda epididymidis.

It is clear that a remarkable retinoid homeostasis system has evolved to permit the transport of these hydrophobic molecules, their metabolism, their extracellular and intracellular sequestration, and delivery to the nuclear chromatin for optimum retinoid signaling in the epididymis. However, knowledge of the pattern of expression of the various components of the retinoid biosynthesis and metabolism pathway, although suggestive, is not sufficient to deduce the precise role of these regulatory factors or the site of action of RA in the epididymis. VAD has pervasive effect, affecting many organs during pre- and postnatal development and in adult life. Reproduction is affected both at the level of the testis where spermatogenesis is arrested and at the level of the epididymis where the epithelium develops squamous metaplasia. Because of this dual effect, it is difficult to ascertain from studies of VAD the physiological role of retinoids in epididymal function.

Gene inactivation has produced surprising results. Null mutants for transthyretin, a protein carrier of thyroxine found in serum, has a virtual loss of serum RBP; yet, the mice seem normal.[772] The CRABP I and CRABP II null mutant mice also appear normal.[773,774] The double knockouts of CRABP I and CRABP II have a higher death rate at 6 weeks than the wild-type mice, but the survivors appear normal.[774] Although each retinoid binding protein separately appears to be dispensable, the lack of phenotype may simply reflect that redundant mechanisms are built in within the organism.

The functional redundancy is well illustrated in the case of the retinoic acid nuclear receptors where six RXR isoforms and six RAR isoforms have been identified.[775] Null mutations of RARβ, RARα1, RARβ2, or RARγ2 appear normal. Null mutations of all RARα isoforms or all RARγ isoforms display some of the defects of the postnatal VAD syndrome. Only double null mutants of the RAR subtypes (RARα/γ, RARα/β_2, RARα$_1$/β_2, RARβ$_2$/γ) reproduce most of the VAD syndrome. Null mutation of RXRα induces some abnormalities, but double inactivation of RXRα and RARβ or RARγ increases the severity of the RXR phenotype. It appears that even though the different receptor isoforms are not truly functionally equivalent, they can substitute for one another under certain conditions. This functional redundancy may not be surprising in any gene family that has been conserved throughout vertebrate evolution and that has evolved by duplications from an ancestral gene.

Notwithstanding, an epididymal phenotype has been observed in transgenic mice after disruption of the RAR gene. Expression of a dominant negative mutant of RARα induced loss of organization of the columnar epithelium lining the cauda epididymidis and its transformation by squamous metaplasia. The aberrant transformation resulted in blockage and/or rupture of the duct with concomitant inflammatory response and, ultimately, infertility.[776] The RARα null mutant mice display not only aspermatogenesis, but also vacuolization of the epididymal epithelium,[777] and the RARα/γ

double null mutant display either severe dysplasia or complete agenesis of the epididymis and the vas deferens.[778]

In summary, given the pathological changes seen in the epididymal epithelium in VAD, the epididymal phenotypes seen in RAR null mutant mice and the presence of most of the components of the retinoid-signaling pathway, it is highly likely that retinoids play a regulatory role in epididymal function. However, there have been no recent studies on the role of vitamin A on the epididymis to support this hypothesis. Interestingly, the role of vitamin A during spermatogenesis has been and continues to be explored.[779–781]

OXYTOCIN RECEPTORS

The first demonstration of the presence of oxytocin receptors in the epididymis was by Maggi et al.[273] Since then, several reports on the localization, distribution, regulation and potential functions of these receptors in a variety of species have appeared.[272,274–276]

Although in the marmoset monkey, the oxytocin receptor seems to be primarily expressed in peritubular cells of the epididymis, in human, macaques, and ram, its localization is apparent in the epididymal epithelium and varies along the duct.[272,275] The expression in principal cells is seen only in the initial segment of the epididymis of primates and has a checkerboard appearance; throughout the rest of the duct, it is confined to peritubular cells of the epididymis.[275] In the ram, however, oxytocin receptors are found in both principal and basal cells throughout the epididymal duct, while peritubular staining is seen only in the more distal segments.[276] Since principal cells express oxytocin,[272,274–276,782,783] then presumably this hormone acts as paracrine regulator of epididymal sperm transit.

Two functions have been ascribed to the oxytocin/oxytocin receptor system in the epididymis.[784,785] As discussed above, the first is that of promoting contractility of the duct, as demonstrated both in vitro[277,786] and in vivo,[275] thus promoting sperm transport through the epididymis.[289] In addition, estrogens regulate both oxytocin and endothelin-1 induced epididymal contractions, which in turn regulate the activity of RhoA/Rho-kinase signaling.[267,275] The second function of this system involves the promotion of the formation of DHT by stimulation of 5α-reductase activity in the initial segment of the epididymis.[784,785,787] This function is of particular interest, given the very high 5α-reductase enzymatic activity in this segment of the epididymis (see above) and the presence of oxytocin in the luminal fluid of the ram and the rat.[782,783] The mechanism for this type of stimulation is not clear but has been postulated to be mediated by phosphorylation and activation of existing 5α-reductase due to tyrosine kinase activation through a coupling to the oxytocin receptor via G_i signal transduction.[788]

GROWTH FACTOR RECEPTORS

Fibroblast growth factor receptors (FGFR), platelet derived growth factor receptors (PDGFR) and vascular endothelial growth factor receptors (VEGFR) have all been identified in the epididymis. Specifically for FGFR, two splice variants FGFR-1 IIIc (long and short forms) have been identified in the principal cells of the initial segment.[593] Although all four major splice variants of FGFR (1–4) are present in initial segment tissue, it is only the FGFR-I IIIc variants that are present in principal cells. The remaining splice variants are presumably localized to the endothelial and interstitial cells. FGFs 2, 4 and 8, present in rete testis and epididymal luminal fluid,[592,593] are potential ligands for the apically placed receptor.[593,594,596] Interestingly, overexpression of FGF8b in the epididymis caused epithelial and stromal hypercellularity eventually leading to malignant transformation of the stroma.[789]

PDGF α and β receptors and their ligands (PDGF A–D) have been localized in the rat and mouse epididymis.[790] In view of the specific localization of PDGF-A in the epithelium and the PDGF α–receptor in the mesenchyme, the authors suggested that the PDGF-A/α-receptor system may be involved in epithelial–mesenchymal interactions during epididymal development. In the adult epididymis, PDGF-A and B and α and β receptors were identified in the epithelium only. Interestingly, in PDGF-A null mutants an epididymal phenotype was not observed during development but epididymal epithelial disruption was observed at postnatal day 25.[790]

VEGF and its receptors are highly localized in both the testis and epididymis, with c-fms-like tyrosine kinase (FLT-1) and fetal liver kinase (designated as kinase insert domain-containing receptor, KDR); VEGF receptors are identified by immunohistochemistry in the ciliated cells of the efferent ducts and vascular endothelial cells of the human epididymis, respectively.[791] Flt-1 was also observed in the lymphatics. Further, addition of VEGF28 to epididymal tissue in culture resulted in endothelial fenestrations and opening of interendothelial junctions. Since the ligand, VEGF, was localized to the peritubular and ciliated cells of the efferent ducts, and to the peritubular and basal cells of the epididymis, it was suggested that VEGF may play a paracrine role in the permeability of blood vessels via KDR and lymphatics via flt-1.[791] Overexpression of VEGF in the testis and epididymis results in male infertility due to spermatogenic arrest and increased capillary density in the testis and epididymis.[792]

Epidermal growth factor receptor (EGFR) has also been identified in the epididymis[793,794] and may play a role in the paracrine regulation of cell function within

tubular segments,[111] facilitate early response signaling pathways activated by DHT[634] and regulate connexin 43 in the human epididymis.[795]

Although not specifically expressed in the epididymal epithelium, the hepatocyte growth factor receptor, c-met, is localized to epididymal spermatozoa, with the ligand, hepatocyte growth factor (HGF), being secreted into the lumen by the epididymal epithelium. The putative action of HGF is maintenance of sperm motility.[796] Interestingly, the hepatocyte growth factor-like protein (HGFL) receptor, *Ron* mRNA, which encodes for is a receptor tyrosine kinase, is expressed in the epididymal epithelium.[797] Additional growth factor binding proteins and growth factor receptors that are expressed in epididymal epithelial cells include: insulin-like growth factor binding protein-rP1/mac25(IGFBP7),[798] latent transforming growth factor beta binding protein 2,[799] EGFR,[799] and growth hormone receptor/binding protein.[800] Microarray analyses have also shown the expression of numerous growth factor genes in the epididymis of several species.[604–616]

C-ROS (ROS1)

C-ROS is an orphan tyrosine kinase receptor that has received considerable attention since it was shown that *c-Ros* null male mice were infertile.[55] The kinase and extracellular domains of the *c-Ros* gene show similarities to the *Drosophila sevenless* (*sev*) tyrosine kinase receptor gene[801] (see also Ref. 802 for more information of the evolution of *c-Ros*). The *sev* gene was originally discovered in a *Drosophila* mutant that failed to express the R7 photoreceptor cell in the ommatidium.[803,804] Further studies demonstrated that the adjacent R8 photoreceptor cell expressed *boss*, the ligand for *sev*. Interaction between these two cell types was crucial for the development of these photoreceptor cells. Following this cell interaction, a signal transduction cascade involving RAS and activation of downstream target genes was initiated in the R7 photoreceptor cell. Interestingly, ectopic expression of *boss* or of constitutively active forms of *sev* causes the formation of ectopic R7 cells.[805,806] The overall sequence homology between c-ROS and SEV is quite low, but there are some very interesting structural similarities between them. For example, (1) both genes encode a large extracellular domain and a kinase domain, (2) sequence homology extends into the putative extracellular ligand-binding domain, (3) there is a short insert of five to seven amino acids in the same position in the kinase domain of both genes that is not found in other receptor tyrosine kinases, (4) there are several common exon-intron junction points between the two genes, (5) the kinase domains of both genes are 70% homologous[801,807–810], and (6) particularly striking is the analysis of Springer,[811] who showed a colinearity and spacing of β-propeller and EGF-repeat structures in c-Ros and *sev*. Interaction of ligand with β-propellers has been shown for other proteins.[812] The ligand of SEV is bride of sevenless (BOSS),[806,813] a seven-transmembrane G-coupled protein kinase, which has signal transduction properties of its own. Presumably, a *boss* homolog exists in mammals if c-ROS has similar function to SEV.

Although *c-Ros* is expressed in several tissues throughout development, including the lung, kidney and epididymis, it remains highly expressed in the initial segment of the adult mouse epididymis[55,810] and along the human epididymis.[814] A clue as to the function of c-ROS came from *c-Ros* knockout mice: the animals displayed an underdeveloped initial segment and male infertility. The infertility phenotype was due to spermatozoa having an angulated flagellum at the end of the mid-piece;[815] it was suggested that this defect was due to the failure of spermatozoa to regulate their cell volume.[815] This infertility phenotype was also shown to be cell autonomous; the defect was due to the passage of normal spermatozoa through the underdeveloped initial segment, resulting in the sperm phenotype, and not because of some inherent defect in the spermatozoa themselves. Further, the infertility phenotype was observed whether either the kinase domain or the extracellular domain of c-Ros was lacking.[55]

Although the functional role of c-ROS is not known, it has been suggested that it plays a role in the regulation of cell volume.[520,816] Although c-ROS itself may not have a direct effect on cell volume regulation, gene expression profiling suggests that several osmolyte transporters are compromised in the initial segment of the *c-Ros* null animals.[615] Certainly, the changes in pH of epididymal luminal fluid in the *c-Ros* null animals could also contribute to the infertility phenotype.[520] Further, it appears that at least inositol and glutamate sperm concentrations are lower in the c-Ros mice compared to controls, even though there are no differences in luminal fluid concentrations of the two osmolytes between the two groups.[520] Whether the lower intracellular levels of these osmolytes in spermatozoa is the cause of the infertility phenotype remains to be determined. Adding to the complexity of the problem is that the infertility phenotype may be related to an underdeveloped initial segment rather than directly to c-ROS. Since the adult mouse initial segment still expresses *c-Ros*, the challenge will be to silence this gene in the adult and then examine the fertility phenotype. This experiment needs to be done especially if c-ROS and its downstream signaling pathways are to be considered as potential targets for the development of a male contraceptive. Adding to this importance is the finding that the adult human epididymis also expresses *c-Ros* throughout its length.[814]

In an attempt to identify downstream targets of c-ROS, Keilhack et al.[817] used a yeast two-hybrid assay and identified several proteins that associated with

the kinase domain of c-ROS. These included the phosphatase SHP-1, phospholipase Cγ, the SH2 domain of c-Abl, Grb2, the phosphoinositide-3 kinase subunit p85α and the SH2 domains of SHP-2. To demonstrate the potential importance of the SHP-1 phosphatase in male fertility, viable motheaten (me^v) mice were tested for fertility because these mice contain a mutation in the SH2 domain of SHP-1. The male mice were infertile. Hence, downstream targets of c-ROS are clearly excellent candidates for male contraceptive development. Although Keilhack et al.[817] indicated that the infertility phenotype of me^v mice is similar to that seen in the *c-Ros* knockout animals, the authors do not present convincing data that there is a reduction in epithelial cell height in the initial segment of the *Shp-1* knockout animals similar to that seen in the initial segment of *c-Ros* knockout mice. Their data suggests that the initial segment has developed normally in this knockout. Hence, although male infertility is observed in both the *c-Ros* and *Shp-1* knockouts, the mechanisms by which infertility is achieved in each case are probably different. At this time, c-Ros remains a viable epididymal target for the development of a male contraceptive.[818]

HE6/GPR64

The *He6* gene encodes a novel human epididymal protein that comprises a seven transmembrane component with a large extracellular domain and shows high homology to the secretin/PACAP superfamily of G-protein coupled receptors.[819] In view of the large ectodomain, HE6 has also been considered to be a member of the LNB-TM7 protein family B-GPCR-related TM7 receptors with long terminal extensions.[820] This large domain also contains a GPCR proteolysis site (GPS) and therefore HE6 may exist as a two-subunit receptor. *He6* is located on the human X-chromosome and both rat and mouse homologs of *He6* have been cloned.[819,820] Immunolocalization studies show human and mouse HE6 localize to the apical surface of human epididymal cells with staining being more pronounced in the efferent ducts-caput region compared to the distal epididymal regions. A mosaic pattern of staining was also observed, as is often seen with localization of other epididymal proteins. Mouse HE6 was localized to the apical cell surface but highly restricted to the initial segment region.[820] The function of HE6 is yet to be determined, although a knockout study suggests that the protein may be involved in fluid reabsorption in the efferent ducts.[821] Further, studies have shown that HE8 localizes to subcellular domains involved in the process of fluid reabsorption.[822] Studies have also revealed a number of potential downstream targets of HE6 including Adam 28, claudin-10, EAAC1 and a novel gene, *Me9*.[823] HE6 would probably not be a good epididymal contraceptive target because of the blocked efferent ducts observed in the *He6* mouse knockouts.

It is interesting to note that *He6/Gpr64* is over expressed in Ewing sarcomas and up-regulated in carcinomas of the kidney, lung and prostate.[824] Regulating the expression of this gene may be important in preventing the very rare cases of carcinomas of the epididymis.

MINERALOCORTICOID AND GLUCOCORTICOID RECEPTORS

Previous studies have shown that the rat epididymis responds to aldosterone and aldosterone antagonists[825–828] and there is evidence for the presence of aldosterone receptors in the epididymis.[829–831] Interestingly, aldosterone receptors were identified in clear cells[829] indicating that aldosterone may be regulating water transport specifically in this cell type. Glucocorticoid receptors have also been identified in the epididymis.[831–833] The exact role of glucocorticoids and their receptors in the epididymis is unclear but there is some evidence to suggest they may play a role in innate immunity[834] (see also Chapter 19).

OTHER RECEPTORS

In addition to those receptors discussed above, the epididymis also expresses orexin receptors,[835–837] the urokinase-type plasminogen activator receptor (u-PAR[838]), apolipoprotein (apo) E receptor-2 (apoER2[839]), adrenomedullin receptors,[840] purinergic receptors,[841] guanylyl cyclase C receptor,[842] melatonin receptor,[843–845] vitamin D receptor,[846,847] LXR and ABCA1 receptors.[848] Interestingly, FSH receptor was identified in the mouse and human epididymis.[849] The precise biological role(s) played by any of these receptors in the epididymis is not clear.

Transcription Factors

An understanding of transcriptional regulation of epididymal genes has been limited to a few genes.[144–146,850–854] However, in these studies, several key transcription factors have been identified that may play an important role in the tissue-specific, region-specific and/or cell-specific expression of epididymal genes.

ETV4 (PEA3) FAMILY

One of the first major epididymal transcription factors to be examined was polyomavirus enhancer activator 3 (PEA3), which is a member of the Ets transcription factor family. This family is characterized by an 85 amino acid ETS domain[855] that encodes for a helix-turn-helix DNA binding motif. It is also part of a subfamily, referred to as the PEA3 family, which comprise PEA3, ERM, and ER81.[856–861] The consensus site for PEA3 is 5′-AGGAAG-3′ with GGAA being the core binding motif for the *Ets* family. Xin et al.[856] were the first to show

expression of *Pea3* in the epididymis; Drevet et al.[862] clearly demonstrated a role for members of the PEA3 family in regulating GGT IV and GPX5 gene expression in the epididymis. Performing standard in vitro promoter analyses of both GGT IV and GPX5 revealed that PEA3 acts as both a repressor and an activator of transcription. This was confirmed by Kirby et al. (2004),[863] using a novel in vivo electroporation technique. There were differences in promoter activity between the in vivo and in vitro studies when the same constructs were used, highlighting the importance of performing such an analysis under as near physiological conditions as possible. The arrangement of PEA3 binding sites along the GGT IV promoter may be unique to this gene because of the absence of binding motifs, for example, AP-1, which are known to regulate the activity of PEA3 in many other gene promoters, such as urokinase plasminogen activator (uPA) and matrix metalloproteinase.[864,865]

There appears to be redundancy among the PEA3 family members, as SouthWestern analysis[595] showed that multiple proteins identified as PEA3, and possibly ERM and ER81, bound to *GGT IV* mRNA PEA3 binding motifs. Further, *Pea3* knockout mice had a normal epididymal phenotype, supporting the idea that ERM and ER81 may take over the functions of PEA3. However, *Pea3* knockout male mice are infertile, but their infertility is due to impotence and/or failure to ejaculate spermatozoa.[866] Interestingly, the promoters of several genes that are highly expressed in the initial segment, including 5α-reductase type 2,[700] have PEA3 family binding motifs and each gene, including PEA3 family members, is regulated specifically by testicular factors. It will be important to generate initial segment-specific *Pea3* family member knockouts to determine whether PEA3 family members play an important role in the function of the initial segment and thereby male fertility.

CCAAT/BINDING PROTEINβ (C/EBPβ)

C/EBPβ is a member of the CCAAT/binding proteins that regulate genes that have various functions including cell cycle control, fatty acid metabolism, cellular differentiation, growth, tumorigenesis and apoptosis.[867] This six-member transcription factor family is characterized by having a highly conserved basic-leucine zipper domain at the C-terminus that is involved in dimerization and DNA binding. Interestingly, although heterodimerization can occur, the heterodimer C/EBPβ-C/EBPζ does not bind to the standard C/EBP consensus sequence but binds to a subset of promoters in genes involved in cellular stress. Hence, this family of transcription factors can function as either repressors or enhancers depending upon the physiological state of the cell.[868]

C/EBPβ is expressed in the proximal regions of the mouse epididymis and plays a role in the regulation of expression of the *Cres* (cystatin-related epididymal spermatogenic) gene.[869] Two putative C/EBP DNA binding motifs were identified in the first 135 bp of the *Cres* promoter. Data from gel shift assays, in vitro and in vivo promoter analyses and analysis of C/EBPβ knockout mice suggest that expression and activation of C/EBP is necessary for complete activation of *Cres* in the proximal caput region.[863,869] Further analysis showed that although C/EBPβ was the predominant form expressed in the epididymis, C/EBP α and δ were also expressed but to a lesser degree. C/EBPε was not identified.[869] Since the expression of members of the *Cres* gene family is dependent on the presence of testicular luminal fluid factors,[870] it is assumed that C/EBP family members are also regulated in a similar manner. As members of C/EBP family play a role during cellular stress, it would be interesting to examine their potential role during apoptosis of the initial segment following loss of testicular factors.

HOMEODOMAIN-CONTAINING TRANSCRIPTION FACTORS

Several classes of homeodomain-containing proteins are expressed in the mammalian epididymis; these include hox, PEPP-family (PEM), Prd-class and Pou-class genes.[71,850,871] Homodomain containing proteins are transcription factors that contain a highly conserved 60 amino acid DNA binding domain composed of three alpha helices with the third helix interacting closely with DNA The major role of *hox* genes is in organ development and in the establishment of segment identity along the anterior–posterior body axis.[872,873] The epididymis is a highly segmented organ and therefore it is not surprising that many *hox* genes are expressed in the developing epididymis.[71,871,874–876] Since the epididymis forms later in development, it is the *5′hox* genes that appear to play a major role in epididymal development compared to the earlier expressed *3′ hox* genes. Interestingly, hox genes are also expressed in the adult epididymis;[876] their precise function in the adult warrants further study.

A first indication that *hox* genes were expressed in the epididymis and played a role in epididymal development came from an analysis of reproductive tissues from *hoxa10* and *hoxa11* knockout animals.[874,877] One of the most intriguing phenotypes to be produced from these null mutations was the homeotic transformation of the distal epididymal regions. *Hoxa11* was expressed in the initial segment and in the more distal epididymal regions,[876] therefore, the observation of a distal epididymal phenotype in the *hoxa11* knockout was not surprising. However, it is not clear if the epididymis developed appropriately in this mutant because the initial segments of these animals were not analyzed. The regulation of *hox* genes in the epididymis is poorly understood; however, it is known that in many tissues, co-factors must be involved in the transcriptional activation of genes by hox

transcription factors. Two examples include MEIS family members and PBX,[878] both of which contain a homeodomain, *Meis 1a* and *1b* are expressed in the mammalian epididymis.[876]

A homeobox cluster termed *Rhox* has been identified on the X-chromosome. Although the majority of the members of this family are expressed in the testis, several are also expressed in the epididymis in a region-specific manner.[854,879,880] A putative homeodomain transcription factor called PHTF1 has been identified in the principal cells of the initial segment and the caput epididymidis regions.[881] Although this protein contains domains that would suggest that the protein is a transcription factor, immunolocalization studies show it to be localized to the endoplasmic reticulum saccules applied to the trans face of the Golgi system.

One of the most well studied homeodomain-containing transcription factors is PEM (RHOX 5), a member of the PEPP homeobox subfamily. Rao and Wilkinson[850] suggested that the *Pepp* genes were derived from the *Drosophila aristaless* gene. Of the *Pepp* gene family members, only *Pem* was expressed in the epididymis as well as in the testis.[850] *Pem*, like *hoxa11*, was expressed throughout development and into adulthood[882,883] from a "male-specific" proximal promoter. The expression of *Pem* in the epididymis was species dependent. In the mouse *Pem* was found mainly in the caput, whereas in the rat it is expressed throughout the duct increasing from caput to cauda. However, *Pem* was not expressed in the initial segment of either the rat or mouse.[850] Further, expression of *Pem* was androgen-dependent.[882,884] The function of *Pem* is not known because *Pem* knockout animals did not display an epididymal phenotype.[885] However, sperm did not display normal forward motility and subfertility was observed.[854,880]

FOXI1

FOXI1 is a member of the forkhead transcription factor that comprises over 100 members[886] and is characterized by a 100-amino-acid winged helix domain. It is also a highly conserved family being originally identified in the fly, *Drosophilia melanogaster*, but also found from yeast to human. Of interest to the epididymis is that a null mutation of *Foxi1* in mice leads to male infertility.[887] FOXI1 binding sites are found on the promoter of the B1-subunit of the vacuolar H^+-ATPase proton pump, and is also important for the activation of carbonic anhydrase II and the chloride/bicarbonate transporter pendrin (SLC26A4).[887,888] Because these transporters play a key role in proton homeostasis in epididymal luminal fluid, then their disruption leads to changes in pH which in turn leads to changes in the luminal fluid microenvironment that are necessary for normal sperm maturation.

Other transcription factors that have been identified in the epididymis include: SP1 and SP3,[699,700,889] c-FOS,[145] TST-1,[890] EMX-2,[891] LBX-2,[892] PAX-2,[893] ZFY,[894] NOR-1[895] in addition to those identified in gene microarrays.

Transporters and Channels

WATER AND ION TRANSPORT

Although the efferent ducts serve as a conduit for spermatozoa from the testis to the epididymis a major function of the efferent ducts is the reabsorption of water. The major driving force for water movement across the efferent ducts and the cauda epididymidis is the Na^+-K^+ ATPase located on the basolateral membrane.[896,897] However, since the activity of the Na^+-K^+ ATPase in the efferent ducts is less than that found in the cauda of the epididymis, the paracellular pathway also plays a critical role in sodium and water movement,[479] across the epithelium of the efferent ducts.

The involvement of an apically placed Na^+-H^+ exchanger, which drives sodium out of the lumen with water following, was proposed by Wong et al.[482] since fluid absorption is amiloride-inhibitable, isosmotic and flow dependent. So far four Na^+-H^+ exchangers (NHE1-4) have been identified in several tissues and three of them have been found in the epididymis;[898–901] such transporters appear to play a role in sodium and bicarbonate reabsorption and proton secretion. NHE1 and NHE2 are expressed on the basolateral surface and apical surface, respectively, throughout the epididymal duct, except that NHE2 is not expressed in the initial segment. Cheng Chew et al.[899] suggested that NHE1 is involved in bicarbonate secretion whereas NHE2 may be involved in sodium reabsorption. Studies by Breton's group[902] and others,[898,901] have shown that the expression of NHE3 varies throughout the length of the epididymis and is localized to the apical surface of principal cells only. Important to bicarbonate reabsorption are the presence of apical and cytoplasmic carbonic anhydrases. NHE3 appears to participate in bicarbonate reabsorption, similar to its role in the renal proximal tubule. Through the activity of apically placed NHE3, protons are secreted and sodium is reabsorbed. Carbonic anhydrase IV, which is also apically positioned, then converts the luminal protons into water and carbon dioxide, allowing the carbon dioxide to enter the cells. Cytosolic carbonic anhydrase II catalyzes the production of new intracellular bicarbonate and generates a proton. The proton is recycled back into the lumen via NHE3. Intracellular bicarbonate is then transported out of the cell across the basolateral membrane via the bicarbonate exchanger (AE2),[903] or the electrogenic sodium-bicarbonate co-transporter, NBC1.[903] The driving force for this whole process is provided by the low intracellular sodium concentration that is achieved by the basolateral Na^+/K^+ ATPase. In addition, maintenance of a high potassium concentration by the Na^+/K^+ ATPase induces an intracellular negative potential of about −70 mV. This drives

bicarbonate across the basolateral membrane via the NBC1 transporter, which transports three molecules of bicarbonate for every sodium molecule, resulting in the net transfer of two negative charges.

A major player in hydrogen ion secretion is vacuolar type H^+ATPase (also known as the V-ATPase), which is highly expressed in apical/narrow cells in the proximal regions of the epididymis and in the clear cells throughout the epididymis.[151,902–906] Further, using a proton-selective electrode, Breton and colleagues,[905] showed that the epithelium of the vas deferens secreted protons and that this was inhibited by bafilomycin, an inhibitor of H^+ATPase. This study clearly demonstrated that acidification of the luminal fluid within the vas deferens was due to this transporter. An acidic pH in the lumen of the epididymis and proximal part of the vas deferens contributes to keeping sperm in a dormant state during their storage period.[164,907] The importance of an acidic luminal pH in the establishment of male fertility was illustrated by the generation of *Foxi1* KO mice, which have a higher luminal pH compared to wild type mice.[887] FOXI1 is a transcription factor that regulates key acid/base transporters in clear cells, including subunits of the H^+ATPase, CAII and the chloride/exchanger pendrin.[887,888] *Foxi1* KO males are infertile due to the inability of their sperm to move up the female tract to fertilize an egg. To maintain an acidic luminal fluid microenvironment, clear cells respond to a luminal increase in bicarbonate by increasing their rate of proton secretion.[162] This is achieved via the bicarbonate-sensitive soluble adenylyl cyclase, sAC, which is enriched in clear cells. A sAC-dependent increase in cAMP induces the apical membrane accumulation of the H+ATPase in these cells.[162] This effect requires the participation of protein kinase A.[908] H^+ATPase-dependent proton secretion is regulated via recycling of sub-apical vesicles to and from the plasma membrane.[164] This is reflected in part by a very high rate of endocytosis in clear cells.[156,157] Recycling of the H^+ATPase may involve unique clathrin- and caveolin-independent mechanisms, as well as members of the SNARE protein family.[909] Both actin[165,910] and microtubules are essential for V-ATPase recycling to occur.[184,483]

The aquaporins (AQP) play a major role in water transport across the epididymal epithelium and, of the 13 isoforms, AQP 1, 2, 3, 5, 7, 8, 9 and 11 have been identified throughout the epididymis including the efferent ducts and vas deferens,[911–918] but not necessarily in every region and epithelial cells.[914,919,920] For example, AQP1, which is highly expressed in the efferent duct epithelium, is present only in the vasculature and is absent from the epithelium in the epididymis. AQP9 is clearly the most abundant of all aquaporins in the epididymis epithelium, and it is located in the apical membrane of principal cells. However, AQP5 and AQP11 are also expressed apically in some principal cells. The significance of such "redundant" aquaporin expression in the same membrane domain of these cells remains obscure. Although very few functional studies have been done on the aquaporins, studies by Wong and colleagues,[917] have shown that CFTR potentiates water permeability of AQP9 in oocytes and in the rat epididymis. The role of CFTR as a regulator of AQP9 function was further confirmed using epididymal tubules perfused in vitro.[921] In this study, CFTR was shown to co-localize with AQP9 in the apical membrane of principal cells and inhibition of CFTR reduced the permeability of AQP9. In addition, both proteins co-immunoprecipitated in a complex that also contained the scaffolding protein NHERF1. It was proposed that the c-terminal SVIM motif of AQP9 binds to the PDZ domains on NHERF1, which serves as a mediator for the interaction between AQP9 and CFTR. CFTR is expressed in the rat and human epididymis.[164,921–924] Besides CFTR's known role as a cAMP-activated chloride channel, its role as a regulator of AQP9 may, therefore, have ramifications in males with cystic fibrosis.[917] Other chloride channels have received little attention. However, a previous study by Isnard-Bagnis et al.[163] showed that the epididymis expresses members of *Cic* gene family of chloride channels. Studies from this group suggest that CIC-3 may be involved in chloride transport by principal cells and CIC-5 might play a role in the acidification of H^+ATPase-containing vesicles in narrow and clear cells.

Although net water movement is from lumen to cell in the proximal regions of the epididymis, water is secreted in the distal epididymis and plays an important role in ion and water homeostasis. Chloride and bicarbonate are again responsible for driving water from the cell into the lumen. Wong et al.[482] have undertaken extensive investigations recognizing the importance of peptide hormones in this process. These investigators have presented a novel model to explain anion secretion by multiple peptide hormones. For example, angiotensin II, bradykinin, endothelin, and arginine vasopressin (AVP) interact with their cognate receptors on the basolateral membrane, which in turn activates phospholipase A2 (PLA2) on membrane phospholipids resulting in the release of arachidonic acid. Prostaglandins are subsequently produced through the actions of cyclooxygenase I (COX-1) and isomerases. This process occurs within the basal cells. Prostaglandins then diffuse out of the basal cells and interact with their receptors on the basolateral membranes of principal cells, which in turn will cause an increase in cAMP resulting in activation of the apically placed CFTR channel and chloride secretion.[482] With the identification of the family of TRP channels in the epididymis, Leung et al.[172] suggested

that TRP3 provides the increase in intracellular calcium levels, which translocates PLA2 from the cytosol to phospholipids membranes, where COX-1 has been identified (Figure 17.17).

In summary, water secretion in the distal epididymis is driven by chloride transport whereas fluid reabsorption in the proximal epididymis is principally driven by sodium transport. As suggested by Wong and colleagues,[482] secretion of water may play a role in fine tuning water movement across the epididymal epithelium. This may be particularly important because at this moment there have been very few hormones that appear to play a role in regulating water reabsorption. Interestingly, luminal bradykinin increases AQP9-dependent transport via activation of the calcium-signaling pathway.[925] The dual activation of CFTR and AQP9 by this hormone might provide a synergistic activation of chloride-dependent water transport in the epididymis. In addition, estrogen has been implicated as a major regulator of water reabsorption in the efferent ducts.[726,738,926] As discussed above, the efferent ducts in ERKO mice failed to reabsorb water sufficiently, resulting in the accumulation of fluid and spermatozoa, testicular blockage and atrophy. Later studies by Hess and others suggest that androgens may also play a role in the regulation of water reabsorption by the efferent ducts.[581] If hormones such as estrogen and androgen play a role in water reabsorption in the efferent ducts, it will be of interest to identify the downstream targets of androgens and estrogens in order to uncover the mechanisms by which hormones regulate water movement.

ORGANIC SOLUTE TRANSPORTERS

Few studies have focused on the physiology of organic solute transporters, although many have been identified in gene arrays.[433,475,607,611] This aspect of the review will only focus on those transporters that have been identified to function in the epididymis.

L-CARNITINE TRANSPORTERS In 1998, two independent laboratories reported the cloning of a high affinity L-carnitine transporter, OCTN2, isolated from human and rat small intestine cDNA libraries.[926,927] OCTN2 is a member of the organic cation transporter family. Thus far, only three members of this family, OCTN1 (SLC22A4), OCTN2 (SLC22A5) and OCTN3 (SLC22A21), have been shown to transport L-carnitine (reviewed in Ref. 928). OCTN2 transports L-carnitine against a concentration gradient in a sodium-dependent manner. In contrast, OCTN1 is a low-affinity, sodium independent carnitine transporter,[929,930] and OCTN3 is a high-affinity sodium independent carnitine transporter.[931,932]

The *Octn2* cDNA encodes a 557 amino acid protein with a predicted molecular mass of 63 kDa. Mutations in *Octn2* are responsible for primary carnitine deficiency, an autosomal recessive disorder characterized by cardiomyopathy and muscle weakness.[933–935] Hence, OCTN2 is a key protein involved in L-carnitine transport. OCTN2 is localized to the basolateral membranes of the rat epididymis in a region-specific manner, with highest mRNA and protein expression observed in epididymal regions involved in L-carnitine transport.[515] Therefore, OCTN2 is the prime candidate for transporting L-carnitine into epididymal cells.

The function of L-carnitine in the epididymis is unknown but the hypothesis that OCTN2 plays a role in the protection of osmotic stress in the epididymis is supported by an intriguing observation. Toshimori et al.[936] described an animal model for primary carnitine deficiency, the juvenile visceral steatosis (*jvs*) mouse. These mice exhibit symptoms similar to those of patients suffering from primary carnitine deficiency. Studies by Lu et al.[937] demonstrated that mutations in *Octn2* were responsible for the *jvs* phenotype, and complementation with human OCTN2, but not OCTN1, rescues the phenotype in the *jvs* mice.[938] Loss of OCTN2 results in the loss of integrity of the epididymal epithelium in *jvs* mice, especially within the corpus region, a site known to express high levels of OCTN2 and readily transport L-carnitine. Therefore, it would seem plausible that loss of epididymal epithelial integrity in *jvs* mice may be the result of osmotic stress. Further evidence to support this hypothesis comes from the studies of Cotton et al.[517] who showed that epididymal OCTN2 transcriptional activity is regulated by osmotic stress.

A putative protein that transports L-carnitine, CT2, from cells into the lumen has been identified.[412] Although initially thought to be a testis-specific transporter, immunohistochemical studies clearly demonstrate its presence on the apical surface of human epididymal cells.[516] The transporting characteristics and kinetics of CT2 are similar to those previously reported for an apical L-carnitine transporter in the rat;[939] we propose that they are, in fact, the same transporter. CT2 is a little unusual in that it can transport L-carnitine in either direction; transport is partially dependent upon the presence of sodium (in both directions), and the transporter has limited substrate specificity.[516] CT2 may have multiple functions despite its narrow substrate specificity. Certainly, from the distal caput to proximal cauda epididymidis, it functions to transport L-carnitine from cells into the lumen. However, it can also transport solutes from the lumen into cells,[939] suggesting that CT2 ensures that any L-carnitine that does enter the lumen proximal to the distal caput is rapidly removed and/or that it can transport other solutes yet to be identified.

TAURINE TRANSPORTERS Although not shown to specifically transport taurine into the epididymis, the taurine transporter TauT and the putative taurine channel phospholemman are expressed in the epididymis, with the more distal epididymal regions showing higher expression.[737] Although these studies were performed using the mouse epididymis, these data coincide nicely with the measurement of intraluminal concentrations of taurine in the rat epididymis; the values measured were: corpus (~6 mM) > cauda (~3 mM) > caput (~2 mM).[415]

GLUTAMATE TRANSPORTERS The expression of glutamate transporter *Eaac1* and the glutamate transporter-associated protein (*Gtrap)* have been identified in the epididymis.[940] Although the expression of both of these genes is high in the caput region where the highest concentration of glutamate is observed (~50 mM[523]), expression is also high in the distal epididymal regions. This would suggest that the protein is transporting glutamate into the lumen in the proximal epididymal region, that the protein is transporting glutamate out of the lumen in the distal epididymal regions because the intraluminal concentration of glutamate rapidly declines from the caput to cauda epididymidis,[523] and/or that the protein may be transporting other amino acids. Since many amino acid transporters are not specific for individual amino acids and some are bidirectional, then all three possibilities are plausible. Definitive functional studies are needed to confirm that either EAAC1 and/or GTRAP are responsible for the high intraluminal concentrations of glutamate. An alternative possibility for the high concentrations of glutamate is the metabolism of intraluminal glutathione by gamma-glutamyl transpeptidase.[941]

CE11/TSCOT/SLC46A2 A transporter called CE11 has been identified in the canine epididymis that has 12 transmembrane domains and functions as a co-transporter. The transporter has homology to the thymic stromal cotransporter (TSCOT; SLC46A2) with some similarity to a sugar transporter.[942] The transporter has been localized to the apical membranes of the canine epididymis and its function is not known.

ABC TRANSPORTERS ABC transporters (ATP-binding cassette) are a family of transporters that are responsible for the efflux of many xenobiotics and toxicants from cells and are expressed in a wide array of tissues.[943–945] ABCB1 is expressed in the clear cells of the epididymis, the epididymal endothelial cells and epididymal spermatozoa.[946] The exact role of this transporter is unclear, but its presence may be necessary for removal of xenobiotics for protection of the epididymal epithelium and spermatozoa.

Antimicrobial Peptides

Groups of epididymal proteins belonging to the defensin and defensin-like family and other proteins having antimicrobial properties were identified in the epididymis. The presence of antimicrobial peptides in both reproductive and non-reproductive tissues has long been acknowledged.[947–949] but recently several antimicrobial peptides have been shown to be epididymis specific. Some of these are members of the β-defensin family, beta-defensin-like peptides (e.g. bin1b, EP2 and HE2 variants), lactoferrin, cystatins, Eppin, and the cathelicidins (hCAP18, rCRAMP).[950–971]

The vertebrate defensin family of genes is comprised of two major groups, the alpha and beta defensins. The classic defensin motif consists of six cysteines linked by three intramolecular cysteine disulphide bonds, which differ in topology in the alpha and beta groups. Alpha defensins are produced mainly in neutrophils and Paneth cells, while the beta defensins are widely expressed in epithelial tissues, including those of the respiratory, gastrointestinal and reproductive systems and the skin. Defensins are synthesized as preproproteins that are subsequently cleaved to generate the active cationic peptides of approximately 3–5 kDa.[947,956] It has been suggested that, in the epididymis, a furin-like proprotein convertase is responsible for the cleavage.[957] The defensin genes are also clustered on certain chromosomes, chromosome 8 in human.[972,973] A study by Zaballos et al.[965] using the Celera mouse genome database found exons encoding 23 different β-defensins. Using a combination of RT-PCR and in situ hybridization, these workers found nine of

these genes to be highly specific for the epididymis and expressed in distinct epididymal regions. Gene microarrays have identified multiple defensins along different regions/segments of the epididymis.[608,611]

Members of the β-defensin and β-defensin-like family are expressed in the epididymal epithelium in a region-specific manner and appear to be secreted into the epididymal fluid as demonstrated by a variety of techniques including RT-PCR, in situ hybridization, western blot analysis and immunolocalization.[950,954,957–963,965–968,974,975] The androgen regulation of epididymal β-defensins is still unclear. The expression of *Bin1b* in the rat epididymis,[954] and *He2* expression in the non-human primate epididymis are androgen dependent.[950] Although rat β-*defensin1* is androgen-regulated in the initial segment and caput regions, this may not be the case in the more distal epididymal regions. To add to the complexity, *rat* β-*defensin1* expression in the initial segment/caput regions appears to respond slowly to androgen deprivation, suggesting that the action of androgens may be indirect.[960] *He2* expression in the human epididymis does not appear to be androgen regulated, but the subcellular distribution of the HE2 variants is androgen-regulated.[957] Expression of human β-*defensin 118* (previously called ESC42) in the non-human primate is primarily in the caput region and is androgen regulated. Hence, more studies are warranted to clearly define the androgen regulation of these genes.

Although one would suspect that members of the β-defensin family would be upregulated during inflammation, it turns out that, at least for rat β-*defensin-1*, this gene was not upregulated during inflammation of the epididymis induced by lipopolysaccharide from *Pseudomonas aeruginosa* or *Escherichia coli*.[960] Rat recombinant β-defensin 22, an epididymal-specific β-defensin, has been shown to have antimicrobial activity against *E. coli* and *Candida albicans*.[975] Similarly, rat epididymis-specific β-defensin 15[976] and BIN1b[977] have antimicrobial activity. An increase in resistance to infection was observed when *Bin1b* was overexpressed 50 times its normal level in the caput region of the mouse epididymis.[977] Further, these investigators showed a decrease in the levels of IL1α and IL1β in the caput region, suggesting a role for BIN1b in the regulation of inflammation.

Another β-defensin-related member that is beginning to receive considerable attention is SPAG11, which is found in the epididymis of several species.[978–981] The SPAG11B/D splice variant has been shown to bind to a tryptase alpha/beta1, a protein involved in inflammatory responses.[980]

The structure-function relationship of the defensins is complex. Outside of the defensin motif, their sequences vary greatly.[982] The antimicrobial activities of human β-defensin 3 (HBD3[983]) and HE2[957,967] are very much dependent on both charge and structure. In the case of HE2 expressed in the chimpanzee and in the human,[950,957] two major isoforms are found in the epididymis, HE2α1 and HE2β1, each related to the β-defensin gene family. HE2β1 clearly has the β-defensin motif and antibacterial activity, yet the processed form of HE2α1 does not have the β-defensin motif but does have antibacterial activity. This suggests that the human epididymis secretes a novel class of antimicrobial peptides.[957]

Cathelicidins are another group of antimicrobial peptides that has received attention recently. The human cathelicidin *hCap18* is expressed in the epididymis and associates with prostasomes (exosomes) in seminal fluid and with spermatozoa.[951,952,984] Although hCAP18 is processed in neutrophils by proteinase 3,[985] it is processed in seminal fluid by a prostate-derived protease, gastriscin, to generate a 38 amino acid antimicrobial peptide ALL-38. Presumably, this antimicrobial peptide plays an important role in preventing vaginal bacterial infections following intercourse and ejaculation. Cathelicidins have also been identified in other species, for example, rat and mouse cathelin-related antimicrobial peptide (CRAMP), and have been shown to have antimicrobial properties[887–989] Members of the family of lipocalins are actively synthesized and secreted by the epididymis of most mammals and have been proposed to play an active role in immune and inflammatory responses.[990,991]

In addition to their antimicrobial activity, several of these peptides have additional functions. For example, BIN1b[969,992] and β-defensin 15[976] appears to be involved with the acquisition of sperm motility in the epididymis and interfere with the ability of spermatozoa to fertilize an egg. It is intriguing that these peptides have evolved to have multiple functions in this tissue. Hence, future studies should help our understanding of how these peptides are indeed bifunctional, and of the mechanisms by which they promote sperm maturation and maintain antimicrobial activity.

Lipocalins

Several proteins binding and transporting small hydrophobic ligands and belonging to the lipocalin family have been identified in the epididymis. Some of these have been introduced earlier for their role in mediating retinoic action in epididymal epithelial cells. We will focus here on the secreted proteins that serve a carrier function.

EPIDIDYMAL RETINOIC ACID BINDING PROTEIN (E-RABP)

E-RABP is one of the major epididymal secreted proteins. It was first identified as one of the four prealbumin proteins migrating after polyacrylamide gel electrophoresis of rat and mouse epididymal cytosol,[993] and luminal fluid,[142,994] with an apparent molecular weight of 18,500. The mouse and rat proteins were subsequently

purified,[694,995] and the cDNA isolated.[694,996,997] In other studies, two retinoic acid binding activities were found after separation by ion exchange chromatography of rat and mouse caudal epididymal fluid.[998–1000] After purification and N-termini sequencing,[999,1001] these proteins were found to be identical to proteins identified by Brooks et al.[694] and Rankin et al.[1000] The predicted amino acid sequence, the ligand binding specificity, and the X-ray crystal structure showing that the protein has a β-barrel structure and a hydrophobic ligand pocket, indicated that E-RABP belonged to the lipocalin family of small extracellular hydrophobic binding proteins.[1002,1003]

E-Rabp is present as a single copy gene in both the rat and mouse. The gene structures are similar but not identical. The rat *E-Rabp* gene is unusual compared to other lipocalins in that it has eight exons instead of seven, the more usual number. The cDNA encodes a protein of 188 residues with alternative sites for signal sequence cleavage to give secreted proteins composed of 166 and 169 amino acid residues. In contrast, the murine gene has seven exons, as seen in other lipocalins.[1003] The cDNA encodes a protein of 185 residues, also with alternative sites for cleavage of the signal sequence to give secreted proteins of 163 and 166 residues. The exon/intron boundaries of the first seven exons are identical for rat and mouse and the first five exons are quite similar in size to the exons of other members of the lipocalin family. The murine gene is located within the [A3] region of chromosome 2. An analysis of the nucleotide sequence of the flanking regions of the *mE-Rabp* gene (*Lcn 5*) showed the presence of six new genes, *Lcn 8*, *Lcn 9*, *Lcn 10*, *Lcn 11*, *Lcn 12*, and *Lcn 13* that evolved by gene duplication. The new genes encode proteins of 175, 178, 182, 170, 193, and 176 amino acids, respectively, with a signal peptide of 16–21 amino acids, consistent with these proteins being secreted proteins.[1004,1005] Within this cluster of genes, *Lcn 5*, *Lcn 8*, *Lcn 9*, *Lcn 10*, *Lcn 12*, and *Lcn 13* are specifically expressed in the mouse epididymis. However, each gene has a distinct spatial expression within the epididymis and a different regulation. *Lcn 8* and *Lcn 9* are expressed in the initial segment only, *Lcn 5* is expressed in the distal caput only, while *Lcn 10* is expressed in the initial segment but also in the upper margin of the distal caput. The *Lcn 8*, *Lcn 9*, and *Lcn 13* genes are strictly dependent on testicular factors circulating within the luminal fluid. The *Lcn 5* and *Lcn 12* genes are dependent on androgens circulating in the serum, whereas *Lcn 10* gene expression is regulated both by circulating androgens and by testicular factors supplied from the luminal fluid.

A computational analysis of the human genome identified five putative genes (*E-Rabp* (*Lcn 5*), *Lcn 8*, *Lcn 9*, *Lcn 10*, and *Lcn 12*) encoding homologous lipocalins. These genes were localized on human chromosome 9q34.[1005,1006] The genomic organization, chromosomal arrangement, and orientation of these human genes were similar to those of the murine genes.

The cluster of lipocalin genes expressed specifically in the epididymis is localized within an area rich in lipocalin genes on mouse chromosome 2 and human chromosome 9.[1007] Interestingly, this epididymis-specific lipocalin cluster is flanked by other members of the lipocalin family, such as *Pgds*, and *Lcn 2*,[1005,1007] that are expressed in other tissues besides the epididymis.[1008,1009] This suggests that the epididymis-specific lipocalin cluster may contain a locus control region that enhances lipocalin gene expression only in the epididymis, while genes flanking either side of this epididymal gene cluster show expression in other tissues besides the epididymis.

More recently, a new member of the lipocalin family, *rLcn9*, has been cloned from the rat epididymis,[1010] mouse epididymal lipocalin promoters have been further characterized[852] as well as distinct epididymal lipocalins, for example Lcn6 and 12.[1011–1013]

LIPOCALIN TYPE PROSTAGLANDIN D SYNTHASE

Prostaglandin D Ssynthase (PGDS), formerly identified as β-trace, was first shown to be localized in the central nervous system and secreted in cerebrospinal fluid.[1014–1019] PGDS is also localized in the male genital tract where it constitutes one of the major secreted epididymal proteins in many mammals: mouse,[1020–1022] rat,[1008,1021–1023] hamster,[1021] ram, stallion,[1024,1025] bull,[1026] monkey,[1027] and man.[1028] The cDNA for PGDS was first isolated from a rat brain library,[1029] and subsequently from many species, including man and zebrafish.[1024,1026,1030–1035] The cDNA for L-PGDS encodes a protein of 180–190 amino acid residues with a signal peptide of about 20 amino acids removed in the mature protein and 2 N-glycosylation sites. The tertiary structure of the rat and mouse recombinant proteins identified PGDS as a lipocalin.[1027,1036] The gene organization is similar to that of other lipocalins in terms of number and size of exons and phase of splicing introns.[1037–1039]

Within the epididymis, PGDS distribution varies among species. In the mouse, *Pgds* mRNA is not detected in the initial segment, but is expressed in all the other regions of the epididymis,[793] while in the rat,[1008,1040] ram, stallion,[1024] and bull[1041] there is a higher expression of *Pgds* mRNA in the caput than in the cauda epididymidis. In rodents, the secreted protein accumulates in the caudal fluid of mouse, rat, and hamster,[1021,1026] while in ram and stallion the highest concentration of the protein is found in the fluid of the proximal epididymis.[1024]

PGDS expression is regulated by androgens, increasing in parallel with endogenous androgen levels during sexual maturation, decreasing after castration, and being restored with exogenous androgens.[1008,1022,1024,1040]

LIPOCALIN 2 (LCN 2)

Lipocalin 2, also known as NGAL, uterocalin, *neu*-related lipocalin, and 24p3, was originally identified as a component of neutrophil granules, but is also expressed

in epithelia in response to inflammatory signals.[1042] It is present in epididymal fluid, although it is not one of its major components. This protein is expressed in various organs but, within the male reproductive tract, is restricted to the epididymis.[1009] LCN 2 is a 25 kDa protein originally purified from human neutrophils.[1043] It is a 178 amino acid protein with glycosylation sites and a 20 amino acid signal peptide.[1044–1047] X-ray crystallography revealed that the protein has the typical lipocalin structure, but the calyx is shallower and broader than in other lipocalins.[1048] Within the epididymis, LCN 2 is expressed in the caput,[1009] under androgen regulation;[1004] the protein accumulates in the caudal fluid.[1009] Interestingly, and unlike E-RABP, sequential washing of spermatozoa with low salt and high salt left a substantial amount of LCN2 immunoreactivity in the Triton X-100 and the SDS sperm extract, suggesting that LCN 2 is bound to spermatozoa.[1009]

LIPOCALIN FUNCTION

Lipocalins form an ancient family of proteins widely distributed among species with the phylogenetic tree rooted in bacteria.[1049] *L-pgds* gene is found in fish, amphibians, and many mammalian species,[1027] and is believed to be the ancestral gene of the epididymal lipocalin cluster,[1005] while the *E-rabp* gene is found in reptiles,[1050] and mammals, including man.[1005] Genes preserved in different lineages are likely to possess important biological functions that are conserved from reptiles to primates. In addition, gene duplication provides genetic redundancy and improves the fitness of the organism.[1051] However, gene duplication also allows adaptation and functional innovation.[1052,1053] Species comparison, even over short evolutionary distances, reveals dramatic expansions and contractions of gene families.[1054–1058] It is all the more remarkable that the organization of the lipocalin gene cluster is conserved in mouse and man with similar gene number, order, and orientation.[1005] This implies that functional constraints have maintained the integrity of the cluster since their last common ancestor 75 million years ago.

The basic function of lipocalins, determined by X-ray crystallography, is to bind small hydrophobic ligands. The folding of the protein into a barrel structure with a deep calyx is well suited for this function. As extracellular secreted proteins, lipocalins function as carriers for these ligands, and their biological properties depend on their respective ligand. However, endogenous ligands are known for only a few lipocalins because the methods of isolation used disrupt the complexes. The endogenous ligands of LCN 1 (tear lipocalin) belong to a class of lipophilic molecules such as fatty acid, phospholipid, glycolipid, and cholesterol.[1059] By scavenging these molecules, LCN 1 may act as a general protection factor for epithelial surfaces. In vitro LCN 1 also binds retinol.[1060] In addition, LCN1 binds to microbial siderophores with high affinities and inhibits quite effectively bacterial and fungal growth under iron limiting conditions. Therefore, as discussed above, LCN 1 appears to be part of the complex defense system involved in protection against harmful molecules and microbial and fungal infections.[1061] LCN 2 is the only known endogenous ligand of the lipocalins cluster on human chromosome 9. Its ligand is a breakdown product of enterobactin, a siderophore that is used by bacteria for uptake of the essential nutrient iron.[1062] This is consistent with the potent antimicrobial action of LCN 2.[1063] LCN 2 is also upregulated in response to inflammatory stimuli.[1064,1065] This suggests that LCN 2 may have a role in the innate immune response to bacterial challenges in the epididymis. Mouse LCN 2 has also been reported to deliver ferric iron to spermatozoa through internalization,[1066] and to enhance sperm motility through an elevation in intracellular pH and an increase of intracellular cAMP accumulation.[1067] LCN 2 may have a dual function role in the epididymis.

Ligand affinity of the other lipocalins has been determined in vitro. L-PGDS binds all-trans or 9-*cis* retinoic acid and all-*trans* or 13-*cis* retinaldehyde, but not all-*trans* retinol.[1068] Also, it binds thyroid hormone, biliverdin, and bilirubin.[1069] However, similar to BIN1b and Eppin, discussed above, PGDS is a dual function protein. Within the cell, it acts as an enzyme producing PGD_2, a potent endogenous somnogen and pain modulator as well as anti-inflammatory agent, and after secretion, it functions as a lipophilic ligand carrier. This dual function may reflect subfunctionalization within the lipocalin cluster. After inactivation of the PGDS gene, the main abnormalities that occur are in the regulation of sleep and pain responses, but no obvious phenotype was reported in the male genital tract, reflecting perhaps a built-in redundancy in the lipocalin cluster.[1070] Nevertheless, PGDS has been reported to be a biochemical marker of sperm quality in human semen,[1071] and to be correlated with fertility in bulls.[1026] Another study failed to find the correlation statistically significant, although the lowest PGDS contents were found in rams and bulls with the lowest fertility and the highest content in animals with normal or high fertility.[1021] This suggests that PGDS affects male fertility, but its role is either not essential or can be compensated by other lipocalins in the cluster.

It is likely that retinoic acid is the endogenous ligand for E-RABP, which binds in vitro all-*trans* and 9-*cis* retinoic acid, but not retinol. E-RABP inactivation produced a phenotype similar to that seen in transgenic mice expressing a dominant negative mutation of retinoic acid receptor α, albeit with a lower severity and penetrance.[776] The transgenic mice expressing the dominant negative RARα were either infertile or had reduced fertility. The epithelium of the cauda epididymidis had undergone squamous metaplasia with tubule rupture, sperm leakage into the connective tissue, and inflammatory reaction. This indicates that interaction of retinoic acid with its receptor

is essential for the maintenance of the epithelium of the cauda epididymidis. These observations are consistent with E-RABP functioning as an intraluminal carrier protein delivering retinoic acid to the epithelium of the cauda, and the fact that the epithelium of the cauda epididymidis is most affected in VAD.[1072]

In summary, gene duplication of a PGDS-like lipocalin gave rise to a new epididymal lipocalin family as amniotes appeared during evolution. Internal fertilization is a common feature of amniotes and this process leads to complex and changing environmental conditions for male gametes. Gene duplication which led to an epididymal lipocalin gene cluster may have allowed an early adaptive response to a new environment; its conservation through 250 million years strongly suggests that the epididymal lipocalins have important functions.

Lipocalins on mouse chromosome 2 and human chromosome 9 are involved in immunoregulation, anti-inflammatory, and antibacterial responses.[990] As discussed above, the epididymis has a complex host defense system involving, in particular, the defensins. It is likely that the lipocalins of the epididymal cluster are part of this network, either by their antimicrobial action, as LCN 2, or by preserving the integrity of the luminal compartment of the epididymis as E-RABP (LCN 5).

CYSTATIN-RELATED EPIDIDYMAL SPERMATOGENIC (CRES) PROTEIN

CRES (*Cst8*) belongs to the cystatin family of proteins, albeit within its own subgroup because it does not contain the consensus sites for cysteine protease inhibition.[1073,1074] This protein has received considerable interest because of its putative antimicrobial role.[1075] Mice with a CRES null mutation have reduced fertility;[1076] this was due to the failure of spermatozoa to undergo capacitation. Addition of dibutyryl cAMP and 3-isobutyl-1-methyxanthine to the spermatozoa from *Cres* mutant mice reversed the defect. Further, CRES appears to play an important role in the formation of amyloid. The precise function(s) of these aggregations of amyloid, which are found within the epididymal luminal fluid, is/are unknown but Cornwall et al.[1074,1077] suggest roles in cell–cell communication, mediation of protein–protein interactions, delivery of proteins to the maturing spermatozoa and/or acting to remove secreted proteins from the lumen.

AGING

Effects of Aging on the Appearance of the Epididymal Epithelium

As discussed above, numerous studies have focused on the structure, function, and regulation of the epididymis during pre- and postnatal development and in the adult, yet very few investigations have been undertaken of the effects of senescence on epididymal structure and function. In the aging rabbit, Cran and Jones[1078] showed that there was an absence of spermatozoa in the epididymal lumen, an accumulation of lipofuscin pigmented bodies in principal and basal cells, cytoplasmic vacuoles in the distal segments, and intranuclear inclusions. In the cat epididymis during aging, Elcock and Schoning,[1079] observed occasional intraepithelial cysts and hyperplasia of the epithelium, as well as eosinophilic to amphophilic round cytoplasmic bodies in interstitial cells, and proteinaceous luminal debris. In the hamster, Calvo et al.[1080] found that the cauda epididymidis was particularly affected by aging; the epididymis of aged hamsters presented involutive changes including a decrease in tubular diameter in the cauda region. Principal cell ultrastructure showed the appearance of damaged mitochondria and bundles of filaments. The presence of large electron-dense vacuoles in some clear cells was unusual. Decreases in sperm concentration and an apparent decrease in motility were noted also. Decreased epididymal sperm counts, brown patches or lipofuscin, arteriosclerosis, lymphocyte infiltration, and the emergence of sperm autoantibodies have been reported in other apecies: rat,[1081,1082] monkey,[1083] and human.[1084,1085]

Results from many of these studies are difficult to interpret because separating direct from indirect effects can be challenging. Determining whether the age-dependent effects observed are due to aging of the tissue per se or to other conditions, such as decreased androgen prodcution, arthroscleroses or carcinoma in other tissues (e.g. pituitary) that impinge on the epididymis renders data interpretation difficult at best. The Brown Norway rat has been established as a valuable model for the study of the aging male reproductive system.[144,1086–1090] This strain of rat has a long life span, does not exhibit many of the age-related pathologies found in other rat strains, such as pituitary and Leydig cell tumors, does not become obese, and is the first rat strain to have had its genome sequenced;[1086,1087,1091] similar to humans, aging of the male leads to dramatic changes in the seminiferous epithelium and to decreases in spermatogenesis and steroidogenesis,[1091–1095] with no decrease in the concentrations of gonadotropins.

Using the Brown Norway rat as a model to study aging of the epididymis, several clear observations have emerged.[153,175,212] Although the luminal diameter and epithelial height were not affected by age, there was a marked progressive increase in the thickness of the basement membrane during aging. In young rats, the relative contribution of clear cells increased in the distal segments, resulting in a relative decrease in the numbers of principal cells, while halo cells were rare. With increasing age, there was a decrease in the proportion of principal cells and basal cells in

all segments of the epididymis, of narrow cells in the initial segment, and of clear cells in the corpus epididymidis. This decrease was accompanied by a proportional striking increase in the number of halo cells in each segment.[153]

Several dramatic changes occur along the epididymis in specific cellular structures during aging.[153] In the initial segment, basal cells emitted an extensive network of pseudopods extending downward toward the basement membrane, and the number and size of halo cells increased progressively during aging; whether aging results in an altered pattern of dendritic cells[176] has not been determined. In the caput epididymidis, principal and basal cells did not appear to change while clear cells changed dramatically; they appeared swollen and bulged into the lumen; their nuclei were irregularly shaped and displaced to the upper half of the cell; lysosomes, enlarged and dense, were often fused with lipid droplets; and the presence of lipofuscin became evident. In the corpus epididymidis, a remarkable increase in the size and number of lysosomes was seen in principal cells. The emergence of a localized region with large vacuoles reflected the major effect of age in the proximal distal corpus/proximal cauda epididymidis. Although some principal cells in old animals had a normal morphology, many others contained extremely large vacuoles. Endosomes and lysosomes often appeared to be emptying their contents within the large vacuoles, and debris from spermatozoa was found in giant vacuoles. Serial sections of these vacuoles revealed that entire spermatozoa were found in the vacuoles, thus leading to the hypothesis that mechanisms controlling intracellular trafficking are impaired as animals age.[153]

With increasing age, there was a dramatic increase in the number of halo cells (composed of monocytes, helper T lymphocytes, and cytotoxic T lymphocytes) throughout the epididymis in a segment specific manner.[175] There is a segment specific recruitment of cytotoxic T lymphocytes and monocytes-macrophages in the epididymal epithelium of aged rats whose epididymal lumen contain few spermatozoa. Thus, accumulation of damaged epithelial cells and antigens of germ cell origin, leaking through a dysfunctional blood–epididymis barrier, may contribute to the active recruitment of immune cells with age.[212] This age-dependent increase in the number of halo cells in the epididymis, in conjunction with the fact that the blood–epididymis barrier should protect from immunological attack, led to investigation of whether there are changes in the structure and function of this barrier with age in the Brown Norway rat model.[212] Based on changes in the distribution of several immunocytochemical markers of this barrier (occludin, ZO-1, and E-cadherin), as well as in lanthanum nitrate permeability, a clear breakdown of the barrier during aging was shown to occur selectively in the corpus epididymidis.

Molecular and Functional Effects of Aging in the Epididymis

Using both gene expression profiling (cDNA microarrays) and Northern blot analysis, segment specific changes have been found to occur along the epididymis during aging.[604,1095] The overwhelming effect was a decrease in gene expression during aging. In the initial segment, corpus and cauda epididymidis, more genes decreased in expression with age than did not change. Interestingly, the magnitude of the decreases in expression was considerably larger in the corpus and cauda epididymidis, where expression of 83% and 62%, respectively, of the genes decreased by greater than 50% with age. This is in contrast to the initial segment where only 31% of the genes expressed decreased by at least 50%; the caput epididymidis was the only segment in which the expression of a large proportion of the genes did not change with age. No transript showed increased expression with age in any of the four segments of the tissue; however, the expression of four transcripts was increased in a segment-specific manner.[604] These studies were done prior to the availability of rat whole transcriptome analysis or deep sequencing and should be revisitied with more in depth transcript analysis.

Nonetheless, changes in the expression of specific genes/gene families are of particular interest. The expression of the mRNAs for SRD5A (particularly the type 1 isozyme) is among the first to decline during aging, while the message for the androgen receptor is not affected.[1095] Changes in the expression of components of intracellular degradation pathways (i.e. proteasome components) are most dramatic in the distal epididymis. While in the initial segment and caput epididymidis, either no change or small decreases (less than 33%) are seen with age, in the corpus and cauda epididymidis essentially all proteasome components show remarkable decreases in intensity of expression (greater than 67%). Cathepsins, a family of cysteine proteases implicated in proteolytic processes, are abundantly expressed in the epididymis.[611,1095–1097] Of the six cathepsin transcripts detected in the epididymis, the relative intensity of cathepsin K was affected by age to the greatest extent in the initial segment, while that of cathepsin H and B decreased most in the more distal segments of the epididymis; cathepsin E transcripts decreased to below the level of detection in all regions of aged epididymides. Oxidative stress related genes, such as copper-zinc superoxide dismutase (Cu-Zn SOD1), showed a small decrease with age in the initial segment, but a very large decrease in the corpus epididymidis. The relative intensity of expression of

glutathione synthetase decreased dramatically with age in the initial segment, corpus and cauda epididymides, while epididymal secretory glutathione peroxidase (GPX5) showed the largest decrease in relative intensity in the initial segment and GPX4 showed the largest decrease in relative intensity in the cauda epididymidis.[604] The changes seen with age for many of these transcripts are consistent with what has been observed by others on the effects of aging in various tissues in a wide spectrum of animals from flies[1098] to mice (muscle[1099] and brain[1100]).

Mechanism(s) Underlying Aging of the Epididymis

Numerous hypotheses have been put forward regarding the underlying cause(s) of aging. These include the specific gene theory,[1101] such as the klotho gene,[1102] the telomere theory,[1103] altered gene expression due either to mutations[1104] or altered DNA methylation status,[1105] the network or immune theory of aging,[1106] and the free radical (oxidative stress) theory.[1107] However, there is no consensus regarding any one hypothesis, and too few studies have been done on the epididymis to demonstrate the primary role of any one or any combination of these theories. There is a significant recruitment of immune cells into the epididymis as animals age, and this recruitment is greatest in parts of the tissue exhibiting greatest damage.[175,212] Although it is possible that this immune response is a cause of the epithelial damage, it is perhaps more likely that the damaged tissue and ruptured blood–epididymis barrier are the attractants of immune cells. It was also shown that the amount of apoptosis seen in epididymides was higher in aged than in young mice, and that this increased rate of apoptosis could be prevented by the administration of testosterone.[1108]

There are several lines of suggestive evidence that point to the association of oxidative stress with changes induced by aging in the epididymis. These include region-specific accumulation of lipofuscin,[1109] changes in the distribution of glutathione S-transferases,[1110] formation of intracellular vacuoles,[153] and altered expression of genes associated with oxidative stress.[604] Therefore, it is reasonable to speculate that oxidative stress is a key factor in mediating the dramatic response of the epididymis to age. Knockout of *Nrf2* (nuclear factor-erythroid 2-related factor 2), the factor that regulates basal and inducible transcription of key genes for protection against ROS, results in an age-dependent decrease in sperm motility, further supporting the likely role of oxidative stress damage to the epididymis during aging.[1111] However, we still know little about whether there are changes with age in the ability of the epididymis to respond to stress or altered endocrine environments.

In addition, two issues have been addressed with respect to the effects of advancing age on epididymal functions: the first relates to tissue weight, sperm number, and the effect of sexual experience on sperm number in this tissue,[1112] and the second to the effects of testosterone administration on sperm number and sperm maturation status ("sperm profile").[1081] Sexual experience in rats was shown to lead to an increase in epididymal sperm counts, which peaked at 9 months but returned to within 5% of that at 3 months when animals were 24 months old. Only the weight of the epididymides increased between 3 and 24 months, reaching a value at 24 months that was 28% greater than that of the 3 month old animals. However, sexually inexperienced rats had a 31% decrease in epididymal spermatozoa between the ages of three and 24 months, while epididymal weight still increased by 25%.[1112] The lack of correlation between epididymal weight and epididymal sperm content is completely unexpected and provides an important clue to potential histological changes taking place within the tissue. The administration of exogenous testosterone could not prevent the decrease in sperm number, but did prevent the changes seen in sperm profile, suggesting that the epididymis of aged animals retains its ability to respond to endocrine manipulations.[1081]

Changes in Spermatozoa during Aging

Several clinical studies, as well as studies using models of animal aging, indicate that there are significant changes that occur in spermatozoa as males enter advanced age and that such changes have consequences for the progeny.[1113–1118] Determining whether these changes are due to alteration taking place in the testis or the epididymis is challenging. The existence of a paternal age effect on semen parameters, fertility, and anomalies in children demonstrates that the quality of spermatozoa and the genetic integrity of otherwise apparently healthy spermatozoa are not immune to the effects of paternal age.

Although genetic changes in spermatozoa during aging, such as non-dysjunction and autosomal dominant disorders that exhibit paternal age effects, such as Down's[1119] and Klinefelter syndromes[1120] and achondroplasia,[1121] are clearly of testicular origin, others, such as changes in the DNA methylation pattern (epigenetic changes),[1122] altered sperm motility and retention of cytoplasmic droplets are more likely to have an origin in the epididymis. Using the Brown Norway rat as a model for male reproductive aging, it was shown that there is a marked increase with age in the number of abnormal flagellar midpieces of spermatozoa, that the percentage of motile spermatozoa was significantly decreased in the cauda epididymidis of old rats, and that the proportion of spermatozoa that retained their

cytoplasmic droplet was markedly elevated.[1123] Furthermore, the extent of chromatin breaks is associated with advancing age and the ability to mount a response to oxidative stress decline with age.[1124–1126] Although it is now clear that germ stem cell number and quality decline with age[1127,1128] and that there are changes in the transcriptome of spermatognia and more advanced germ cells as a function of paternal aging,[1128,1129] it is likely that altered epididymal epithelial functions contribute to changes seen in ejaculated or cauda epididymal spermatozoa.

Another mechanism that may allow for sperm quality control has been observed to act at the level of the epididymis and involves the cell surface ubiquitination and subsequent phagocytosis of abnormal spermatozoa.[425] However, large-scale phagocytosis of spermatozoa by the epididymal epithelium is not observed in young or old animals.[426] The intriguing possibility that principal cells secrete into the lumen the appropriate components of the ubiquitin-proteasome pathway necessary to ubiquinate damaged sperm has been put forward.[1130] The mechanism(s) that would be used by the epididymis to identify such damaged sperm and its possible change in sensitivity with advancing age remain(s) to be determined.

The multiple effects of aging on progeny outcome, sperm morphology, the acquisition of and motility all indicate that the quality of spermatozoa is affected by aging.

THE EPIDIDYMIS AS TARGET FOR XENOBIOTICS

Xenobiotics that have been shown to act on the epididymis can be broadly divided into two major, somewhat overlapping, categories. The first consists of those chemicals for which the epididymis is the explicit target; a number of compounds that have the potential to act as part of a male contraceptive formulation fall into this group. The second is made up of therapeutic agents or known toxicants that are targeted principally at other organs but also act, as a side effect, on the epididymis. For some of these compounds, their effects on the epididymis are at the level of the epididymal epithelium, for others effects have been demonstrated on sperm traversing the epididymis, and for others still the site of action is mixed or not resolved. Various aspects of the action of drugs on the epididymis have been thoroughly reviewed.[818,1131–1136]

Demonstrating the direct action of chemicals on the epididymis is challenging because if, subsequent to administration or exposure to a chemical, there is an effect on the epididymal epithelium or on epididymal spermatozoa, it becomes essential to establish that such an effect is not mediated at the level of the hypothalamus, pituitary or testis. Furthermore, epididymal histopathology and sperm function tests have not been standard in drug development and the assessment of toxicants; hence, the action of xenobiotics on this tissue may often have been overlooked.

Chemicals for Which the Epididymis Is an Explicit Target

Selective modification of functions carried out either in or by the epididymis should be of major value not only in the development of male contraceptives, but also for the treatment of male fertility problems with an etiology that arises in the epididymis. Since spermatozoa reside a relatively short time in the epididymis and since no genetic transformation is known to occur as spermatozoa undergo epididymal maturation, the epididymis can be viewed as an ideal target for the development of male contraceptives or drugs that can block or enhance the maturation process. Although no therapeutic agent has yet been developed that meets these objectives, a large number of approaches have been pursued to attain these goals. Most of these agents can be grouped into drugs that act via modulating hormonal dependence, neuronal activity, or metabolism.

Hormonal Regulation

Although, as described above, many hormones and hormone receptors have been found in the epididymis in various species, we will focus on androgens and estrogens, hormones for which the consequences of manipulating the endocrine signal have been reported.

BLOCKING ANDROGEN ACTION

Several laboratories have determined the effects on the epididymis of agents that act as androgen receptor antagonists, such as cyproterone acetate or hydroxyflutamide.[1137,1138] These compounds successfully block epididymal functions and cause a reduction in tissue weight. Interestingly, unlike the case with other androgen-dependent tissues, such as the prostate or seminal vesicles, exposure to androgen receptor antagonists does not result in changes in intracellular androgen receptor localization in the epididymis.[1139] The advent of new antiandrogens, such as enzalutamide,[1140] is not associated with any tissue specificity as they still target the androgen receptor, as opposed to co-recptors that are more likely to be tissue specific. The therapeutic potential of these compounds as male contraceptives targeting epididymal functions is limited, however, because, as expected, the action of androgens in other target tissues was also blocked, producing side effects equivalent to a chemical orchidectomy.

BLOCKING THE FORMATION OF DIHYDROTESTOSTERONE

It has been established that DHT is essential for the maturation of spermatozoa and that the androgen found in the nuclei of epididymal cells is DHT.[637,1141] Thus, one approach to block androgen action in the epididymis is to inhibit DHT formation. Several compounds inhibit either one or both forms of SRD5A in many tissues, including the epididymis.[1142–1152] The first report was that of a family of 5,10-secosteroids that are suicide substrates (irreversible inhibitors) of the enzyme in vitro and have been shown to inhibit the epididymal enzyme.[1143] In a series of studies, Rasmusson's group[1144,1153] found that four aza steroids were effective inhibitors of steroid-5α-reductase in the prostate and a variety of other tissues. The lead compound, (diethyl-4-methyl-3-oxo-4-aza-5α-androstane-17 β-carboxamide, 4-MA), a competitive inhibitor of the epididymal enzyme,[1145,1152] ushered in a new era in potent inhibitors of this enzyme activity; this inhibitor of the epididymal enzyme was shown in one study to alter the fertility of male rats.[1153] The first commercially available inhibitor of 5α reductase, finasteride, also a member of the azasteroid family, has a predominant effect on the type two isozyme,[1154] while more recently developed agents, such as dutasteride or PNU157706, act as dual inhibitors.[1146,1155] Using PNU157706 as a model inhibitor, it was shown that treatment of adult rats with this agent results in pronounced effects on the expression of epididymal genes involved in signal transduction, fatty acid and lipid metabolism, regulation of ion and fluid transport, luminal acidification, oxidative defense, and protein processing and degradation, all processes essential to the formation of the optimal luminal microenvironment required for proper sperm maturation.[1148] Treatment of adult rats with this dual inhibitor had effects on both sperm quality and pregnancy outcome but did not result in an arrest of fertility.[1149] Interestingly, recent clinical observations[1156] associate the use of 5α-reductase inhibitors prescribed for benign prostatic hyperplasia or allopecia with a loss of fertility.

BLOCKING ESTROGEN ACTION

Although, as discussed above, the presence and selective localization of both ESR1 and ESR2 along the epididymis has now been established in several species, few studies have focused on elaborating the consequences of blocking estrogen action in the epididymis. It is clear that the removal of estrogen action (null mutations) in the efferent ducts resulted in a dramatic reduction in the fluid uptake capacity of that tissue and consequent infertility,[738] but less is know about the consequences of withdrawing estrogen from the epididymis. Some tantalizing lines of evidence are that selective blockade of estrogen action, whether by treating with an aromatase inhibitor or an estrogen receptor antagonist, resulted in blocking the oxytocin receptor in the rabbit epididymis,[278] and that by using an estrogen receptor α blocker, ICI 182,780, the apical cytoplasm of narrow and clear cells was affected.[1157]

Neuronal Regulation

An alternate means by which xenobiotics can affect epididymal functions is by either increasing or decreasing sperm transit time. Either administration of guanethidine, a drug that causes chemical sympathetectomy, or surgical sympathetectomy results in a marked increase in sperm transit time as well as in cauda epididymal weight without other apparent effects.[269,1158–1160] In contrast, several drugs accelerate transport of spermatozoa through the epididymis. In 1975, Meistrich et al.[245] demonstrated that treatment of mice with estradiol resulted in an increased rate of transport of sperm through the epididymis; similarly, diethylstilbestrol accelerates epididymal sperm transit in the rat.[1160] Administration of either chloroethylmethanesulphonate, a chemical that causes a reduction in serum testosterone, or hydroxyflutamide also led to accelerated sperm transit.[1159] Sulphapyridine, a metabolite of the antibiotic sulphasalazine, caused a marked reduction in fertility in both rats and man; although its mechanism of action has yet to be elucidated, it was also found to accelerate sperm transit through the epididymis.[1161]

Metabolism

Several compounds that act on enzymes in the cellular metabolic pathways have been tested as potential male contraceptives. The ones that have held the greatest potential will be reviewed below. However, this promising approach has yet to have a viable candidate.

α-CHLOROHYDRIN

In the late 1960s a series of studies showed that α-chlorohydrin, a monochloro derivative of glycerol, reversibly inhibits fertility in an array of species.[1162,1163] This drug is converted by glycerol dehydrogenase to 3-phosphoglyceraldehyde, an inhibitory analog of the substrate for glyceraldehyde 3-phosphate dehydrogenase (GADPH), and acts, therefore, at low doses, to inhibit this key metabolic enzyme in spermatozoa residing in the cauda epididymidis,[1164] and to reduce sperm motility.[1165] At higher doses, however, α-chlorohydrin caused the formation of spermatoceles in the caput epididymidis of rodents, resulting in the blockade of sperm transport through the tissue and the consequent atrophy of the seminiferous tubules due to increases in back pressure.[1166] Wong and colleagues,[1167] demonstrated that α-chlorohydrin blocked the resorption of sodium and water from the cauda epididymidis. Although

α-chlorohydrin inhibits a ubiquitous metabolic enzyme, its selectivity of action on spermatozoa is based on the fact that spermatozoa have a GADPH isoenzyme with a higher molecular weight that is not cytosolic.[1168] Nevertheless, severe toxicity (bone marrow depression, kidney, liver) was associated with this compound when it was tested in primates,[1163,1169] and, therefore, it will not be developed as a contraceptive for man.

6-CHLORO-6-DEOXY-GLUCOSE

In 1978, Ford and Waites,[1170] described another antifertility compound, 6-chloro-6-deoxy glucose, with the ability to inactivate spermatozoa from the cauda epididymides; it also acts by blocking glyceraldehyde-3-phosphate dehydrogenase.[1166] This compound was also found to affect different functions of the epididymis, but due to its neurotoxicity in primates (associated with its effects on glucose transport and inhibition of GADPH), it is unlikely to be accepted as a male contraceptive in humans.

GOSSYPOL

While gossypol, a chemical found in cotton seed oil, has been studied extensively as a potential male contraceptive agent,[1171,1172] its mechanism of action is still poorly understood. Although it has been shown to have a high contraceptive efficacy, its toxicity, probably mediated via a hypokalemic action, is likely to preclude the clinical use of gossypol as a "stand alone" contraceptive,[1173] it may have a role at low does in combination with steroidal contraception.[1174] Gossypol caused shedding of spermatozoa from the seminiferous tubules, separation of sperm heads from their tails, and a decrease in sperm number in the cauda epididymides.[1171] Studies by Romualdo et al.[1175] have shown that treatment of rats during the pubertal time window resulted in an increase in the appearance of round cells in the epididymal lumen; these cells were most likely of epididymal epithelial origin since they stained for cysteine-rich secretory protein CRISP-1, also known as protein E, a marker of epididymal principal cells. CRISP-1 staining was not found in testicular cells, providing further evidence that the epididymis is indeed a target organ for gossypol.[1175]

Chemicals Targeted Principally at Other Organs Which Also Act on the Epididymis

The epididymis has not usually been studied as one of the target tissues for the toxicological effects of drugs or toxicants, and consequently little is known about the importance of this tissue as a target for the toxic effects of xenobiotics. However, there are now a few instances where the epididymis has been demonstrated to be a target of drug action.

Cyclophosphamide

Cyclophosphamide, a widely used anticancer and immunosuppressive drug, has been shown to act as a male-mediated developmental toxicant.[1176] Administration of this drug resulted in an increase in the number of clear cells and in the number of spermatozoa with abnormal tails in the epididymis of rats.[134] By using several complementary approaches, Qiu et al.[233] demonstrated that the increase in post-implantation embryo loss observed among progeny sired by male rats subjected to short-term (4 or 7 days) treatment with cyclophosphamide was mediated by the action of this drug on spermatozoa while transiting through the epididymis. Whether the drug action was mediated via an effect on the epididymal epithelium or directly on spermatozoa is unresolved.

Fungicides

Several fungicides, including mancozeb, ornidazole, carbendazim, and benzimidazole, have effects on male fertility.[1177–1181] For some of these compounds, sufficiently detailed studies have been undertaken to indicate that there is a selective action at the level of the epididymis. For example, benzimidazole causes occlusion of the epididymis and the efferent ducts, and ornidazole causes a decrease in sperm motility. Whether the members of this family of drugs have a similar mechanism of action is not clear, but it is interesting to note that treatment with ornidazole caused an inhibition of glyceraldehyde 3-phosphate dehydrogenase, a similar action to that of 6-chloro,6-deoxy fructose and α-chlorohydrin.[929]

Methyl Chloride

Another mechanism by which a xenobiotic can affect the epididymis is by increasing the inflammatory response. Exposure of male rats to methyl chloride, an industrial gas, resulted in infertility (a high rate of dominant lethal mutations) that is associated with testicular degeneration, epididymal inflammation, and sperm granuloma formation. Chellman et al.[1182] demonstrated that the infertility was associated with epididymal inflammation and that treatment with an anti-inflammatory drug resulted in a reversal of these effects.

Sulfonates

Exposure to either ethyl dimethyl sulfonate or chloroethylmethanesulfonate results in what is commonly viewed as a selective destruction of Leydig cells and commensurate reduction in testosterone production.[1183] These chemicals also cause a reduction in fertility. Although, the effect on fertility may be ascribed to the reduction in testosterone, Klinefelter et al.[1184] clearly demonstrated that these chemicals have, at similar doses, a direct effect on the epididymis, independent of their action on Leydig cells. The epithelial height of cells

along the corpus and proximal cauda epididymidis was reduced, there was a reduction in the fertilizing ability of cauda epididymal spermatozoa and these spermatozoa had a reduction in protein content. Although the specific mechanism of action of this family of chemicals on the epididymis is still unresolved, a selective reduction in SP22, a protein that is specifically acquired by spermatozoa as they traverse the epididymis, has been reported.[1185]

In addition to the effects of xenobiotics seen after the exposure of adults, a number of studies have demonstrated that exposure during fetal, early postnatal or pubertal time windows can result in abnormalities in the epididymis (weight, histology) or in the spermatozoa (number, motility) present in this tissue. Some of these chemicals include dibutyl phthalate, a plasticizer,[91,1186] 2,3,7,8-tetrachlorodibenzo-rho-dioxin,[1187] and pesticides such as PCB 169 and methoxychlor.[1188]

CONCLUSION

In recent decades, we have witnessed an explosion of information on a wide range of facets of epididymal gene and protein expression and their regulation, effects of null mutation and targeted transgenic expression of specific molecules, secretion of proteins by epididymal epithelial cells and their interactions with spermatozoa, and mechanisms for creating an ever changing luminal microenvironment in the fluid surrounding spermatozoa in the duct lumen. Many of these advances have been attained thanks to the application of novel technologies that range from laser capture microscopy to gene expression profiling by microarrays, from in situ electroporation to tissue targeted gene deletions and the development of immortalized cell lines.

We are beginning to get a grasp of the remarkable complexity of the epithelium lining the epididymal duct and of the milieu it creates in the lumen to allow spermatozoa to become mature, be stored, and be protected. However, in spite of these great strides, some of the major questions relating to the epididymis remain unanswered. What mechanisms regulate the lobe/segment/region specific expression of genes and proteins along the epididymis? How can adjacent principal cells have such dramatically different levels of expression of various proteins? What are the actual functions of each of the highly differentiated cell types in the duct? Why have we not yet succeeded in isolating and immortalizing each of these cell types? Is there a specific protein secreted by the epididymis that allows spermatozoa to attain a mature state or does this critical event result from a series of multiple interrelated steps involving changes in proteins, sugars and lipids? What aspects of the cauda epididymal fluid allow sperm to remain dormant and functional for protracted time periods? What is the role of the assortment of antimicrobials being discovered in this tissue? Why is primary cancer of the epididymis so rare? These and other questions have been challenging reproductive biologists for many decades. With the plethora of new tools that have recently been developed and that will certainly continue to emerge, we are now poised to elucidate how this remarkable tissue works.

Acknowledgments

We should like to acknowledge the support of the Canadian Institutes for Health Research (BR) and the National Institutes of Health (Eunice Kennedy Shriver Institute) NIH-NICHD HD068365 and 069654 (BTH). We should also like to express our thanks to Marie-Claire Orgebin-Crist and Louis Hermo for their participation in preparing earlier editions of this chapter, to Sylvie Breton and Barbara Hales for helpful comments and suggestions, and to Elise Boivin-Ford for excellent assistance in preparation of the final manuscript.

CHAPTER

18

Accessory Sex Glands in the Male

Gail S. Prins, Mark Lindgren

Department of Urology, University of Illinois at Chicago, Chicago, IL, USA

INTRODUCTION

The accessory reproductive organs in the male consist of a continuous series of paired ducts that transport sperm from the testis to the urethra (epididymis and ductus deferens, also known as vas deferens) and various glands that produce components of the seminal plasma. The accessory sex glands in the human male include the paired seminal vesicles, the prostate gland, the paired bulbourethral glands, and the glands of Littre (Figures 18.1 and 18.2). The main function of the sex accessory tissues collectively is to create the seminal plasma, the medium in which sperm are delivered in the ejaculate. The sex accessory tissues produce high concentrations of prostaglandins, fructose, citric acid, polyamines, zinc, and enzymes such as proteases and acid phosphatases. However, we do not have a clear understanding of the physiologic function of many of these substances or their relative importance to fertility. It is possible to remove sperm from the epididymis or testis and fertilize an ovum directly, thereby bypassing any exposure to the seminal plasma. Interestingly, rats remain fertile after surgical removal of either the ventral prostate or the seminal vesicles, but not both.[1] Thus, while the seminal plasma may not contain an absolutely essential ingredient for successful fertilization, the fluid and its components likely optimize conditions for sperm transport as they transit the female reproductive tract and maximize their chance at fertilization when they reach the ovum.

The variability of the anatomy and function of sex accessory tissues among mammals is striking. The seminal vesicles are prominent in the human, bull, and rat, but do not exist in the dog or cat. The prostate gland is found in all mammals. In the human and dog, it is a solitary structure, whereas rat and mouse prostates have distinct dorsal, ventral, and lateral lobes. Similarly, the seminal plasma varies widely among mammalian species. The average volume of ejaculate is approximately 70 ml for the horse, 4 ml for the bull, 9 ml for the dog, 3 ml for the human, and 250 ml for the boar. The human ejaculate clots and subsequently lyses within a short period of time, whereas the rodent ejaculate forms a solid copulatory plug. The major anion found in human ejaculate is citrate, whereas in the dog it is the chloride ion.[1] This wide variability is most likely the result of evolutionary pressure, perhaps due to differences in reproductive habits or environmental influences, but we can only speculate without further research.

Performing a literature search of the sex accessory glands reveals a difference in citations by orders of magnitude, with the prostate being far and away the most studied of these tissues. This is not unexpected, given the impact that the prostate has on public health. Prostate cancer is the most common noncutaneous malignancy in the United States, representing one-fourth of all such cancers, and is the second leading cause of cancer deaths in American men.[2] Additionally, nonmalignant growth of the prostate with age, benign prostatic hyperplasia (BPH), is seen in 40–50% of men at the age of 50, and over 80% of men in their 80s.[3] This prostatic overgrowth can lead to urinary symptoms and even obstruction. Up to half of all men by the age of 70 have urinary symptoms that warrant daily medication or surgery, and the majority of these symptomatic patients have an enlarged prostate as a cause of their suffering. The prostate is also susceptible to yet a third condition, an inflammatory process called prostatitis, which causes pelvic pain. Up to 16% of all men have this condition diagnosed in either an acute or chronic form at some time in their lives. The etiology of prostatitis is tied to a known bacterial cause in less than 10% of instances with the majority of cases being idiopathic. Studies have shown that between 2% and 12% of men older than 20 are currently experiencing prostatitis-like symptoms.[4,5]

Because of the enormous impact that the prostate has on men's health, it is rightfully the focus of much

more research than the other sex accessory tissues, and the prostate is the focus of this chapter as well. Nonetheless, there remains a need to conduct further research on the other sex accessory tissues, because they have a clear physiologic role and are less well understood. It is particularly notable that although the prostate has extremely high rates of disease, aberrant growth and cancers of the other male accessory sex glands are exceedingly rare. It has been suggested that the basis for differential disease predilection between the prostate and its immediate neighbor, the seminal vesicles, is their unique embryologic origin, with the prostate deriving from the endodermal layer and the seminal vesicles originating from the mesoderm.[6]

This review of the accessory sex glands will encompass their function, anatomy, hormonal regulation, and development including emerging evidence for perturbations by endocrine disrupting chemicals, all with an emphasis on the prostate gland where most information is available. We will also summarize diseases of the prostate and provide an overview of future directions and research needs.

History

The word prostate comes from the Greek word *προστάτης*, which means "one who stands before", "protector", or "guardian". The prostate was named for its anatomic position immediately preceding the bladder as a guardian or protector to the outside world. Herophilus provided the first known anatomic description of the prostate in the third century BC. He was a physician in Alexandria and performed dissections of the human body. Unfortunately, his writings were lost centuries later in the fire that destroyed the library in Alexandria in AD 391. Galen (AD 131 to 200), a physician in Rome, described urinary obstruction caused by a compressive mass within the prostatic urethra. Galen also noted that urinary obstruction could be due to inflammation or an abscess in the region of the bladder neck and prostatic urethra. Nicolo Massa, a Venetian physician, in 1536 provided the first accurate anatomic description of the prostate and its anatomic relationships to the bladder neck, seminal vesicles, and ampulla of the vas deferens.[7]

The first description of the pathophysiology of prostatic enlargement is attributed to Jean Riolan of France. In 1649, he observed that the urinary obstruction due to the enlarged prostate caused thickening of the bladder wall.[8] In 1769, Morgagni, the chair of anatomy at the University of Padua in Italy, added to the description a more detailed account of the changes that occurred from prostatic obstruction in both the bladder and the upper urinary tracts.[9] In 1786, John Hunter from Scotland observed that castration of prepubertal rats prevented prostate development, and that castration of adult rats caused atrophy of the gland.[10] This deeper insight into prostate developmental physiology was surprisingly ahead of its time.

Unfortunately, during the late 1800s and early 1900s, many less scientific theories arose in the medical literature regarding the etiology of prostate disease. The proposed causes of prostate disease included lascivious thoughts, horseback riding, high living, perverted indulgences, cold weather, alcohol, excessive intercourse, and masturbation. It might have been difficult for men in these times to discuss prostate-related symptoms, given the possible social implications of their disease.[11]

Over 100 years after Hunter's rat studies, the modern era of prostate research began with the pioneering work of Charles Huggins.[12] In 1941, Huggins discovered that prostate cancer regresses following androgen withdrawal, and established the role of sex hormones in prostate cancer growth. This was the first report of a regression of a cancer or tumor by chemical manipulation. It is for this work that he was awarded the 1966 Nobel Prize for Physiology or Medicine. He additionally studied the atrophic effects of androgen withdrawal on BPH. In 1944, Moore observed that patients who were either eunuchs or had pituitary infantilism had no evidence of BPH. Further observations in the 1940s led to the theory that BPH was a disease of hormonal imbalance, caused by decreased ratio of androgen to estrogen in the aging male. In 1969, Shutsung Liao discovered the androgen receptor (AR)[13]; he subsequently sequenced and cloned the AR in 1988.[14] In 1972, Cunha made the landmark discovery that embryonic urogenital mesenchyme induces adjacent epithelial cells to differentiate into the prostate epithelial phenotype.[15] To this day, the communication between stroma and epithelium and vice versa continues to be an important area of research.

From the early description of the prostate by Herophilus, to the modern discoveries linking prostate physiology and pathophysiology to hormones and stromal–epithelial cross-talk, these historical studies have become the foundation upon which prostate research is conducted today.

ANATOMY AND HISTOLOGY

Prostate Anatomy

The human prostate is a small walnut-sized gland situated at the base of the bladder between the symphysis pubis and the rectum (Figures 18.1 and 18.2). It is conically shaped, with the superior aspect abutting the bladder and the apex tapering inferiorly at the level of the internal urethral sphincter. The prostate completely

surrounds the pelvic urethra from the base of the bladder to the prostatic apex. The prostatic urethra is anatomically and functionally divided into two segments (proximal and distal) denoted by a sharp anterior angulation of the proximal segment at the verumontanum, a midline projection from the posterior wall of the urethra, also referred to as the seminal colliculus. The proximal urethra, which courses from the bladder to midway through the prostate along its 3 cm length, is surrounded by a smooth muscle sphincter, the preprostatic sphincter, which contracts during ejaculation preventing retrograde flow of semen into the bladder. The distal prostatic urethra begins at the verumontanum with a 35-degree anterior angle and is surrounded by the external urethral sphincter. Approximately 95% of the glandular prostatic ducts empty into the distal urethra at or below the verumontanum. The seminal fluid contributions from the seminal vesicles and vas deferens empty into the left and right prostatic sinuses via paired ejaculatory ducts. The ejaculatory ducts enter the prostate at its base, posterolateral to the urethra on the left and right, course approximately 2 cm inward, and empty into the prostatic urethra on either side of the verumontanum.

Although the human prostate is a single structure without the distinct lobes observed in rodents, McNeal has described a zonal anatomy of the adult human prostate (Figure 18.3) based on histologically distinct zones, and this anatomic description is the one most widely accepted today.[16] The prostatic urethra represents the primary anatomic reference point, and it divides the prostate into an anterior fibromuscular zone (30% volume) and a posterior glandular portion (70% volume) which contains the peripheral, central, and transition zones. The tubuloaveolar glands in the posterior prostate empty into the prostate sinuses via 20–30 ductules. The two principal regions of the glandular or posterior prostate are the peripheral zone (approximately 70% of the glandular volume) and the central zone (approximately 20% of the glandular volume). Anatomically, the central zone is a wedge-shaped area at the base of the prostate that narrows centrally and surrounds the ejaculatory ducts. The central zone comprises approximately 15–25% of the glandular volume in the prostate. The peripheral zone, comprising 70% of glandular prostate volume, surrounds the central zone at the base of the prostate and is in close association with the distal urethra in the prostatic apex. The glandular structure of these two zones is distinctive. The functional unit of a gland is a small, sac-like structure known as an acinus. The central zone contains irregularly contoured acini in close association with long, compact stromal elements, whereas the peripheral zone contains small, round, regular acini with loosely associated stromal connections. The transition zone, which accounts for less than 10% of glandular volume, lies adjacent to the lower portion of the proximal urethra and contacts the central and transition zone in this region. This zone, which consists of two separate lobules, is in intimate contact with the preprostatic sphincter. Histologically, the acini resemble those in the peripheral zone, surrounded by stroma that is dense and compact. A final region, the periurethral region, is comprised of tiny ductal branches scattered throughout the proximal urethral wall entirely confined within the preprostatic sphincter.

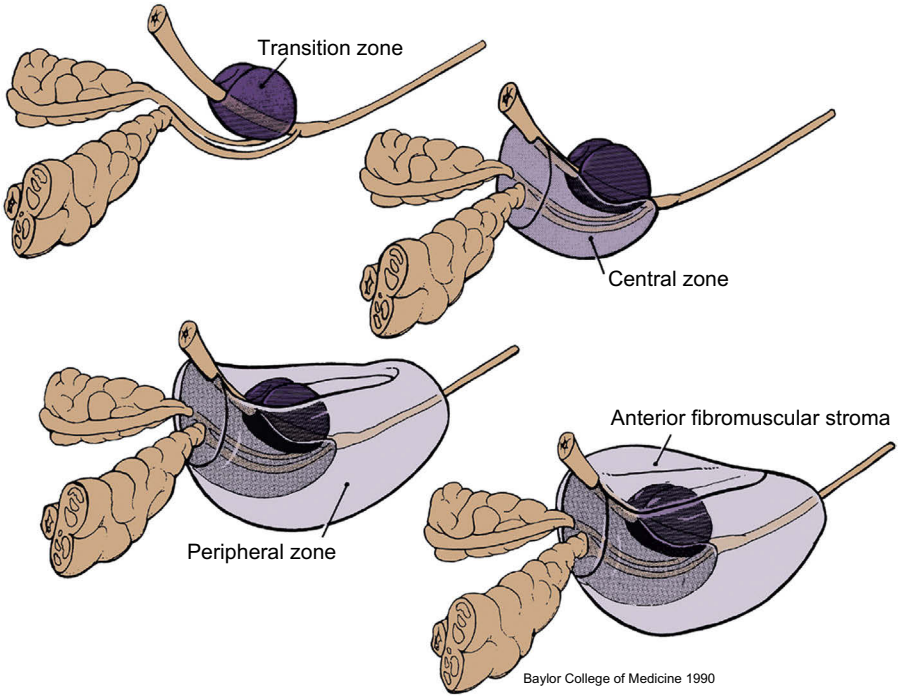

FIGURE 18.3 Zonal anatomy of the human prostate. The transition zone surrounds the urethra just proximal to the ejaculatory ducts. The central zone surrounds the ejaculatory ducts. The peripheral zone comprises the bulk of the posterior, lateral, and apical aspects of the prostate. The anterior fibromuscular stroma extends from the bladder neck to the external urethral sphincter. *Source: From Ref. 17.*

The inferior vesicle artery supplies the prostate, which is drained by three venous plexuses—one anterior and two lateral. The anterior plexus receives drainage from the deep dorsal vein of the penis and can be a source of significant bleeding during surgical removal of the prostate. Lymphatic drainage from the prostate travels primarily to the obturator and internal iliac nodes.[17] The prostate is innervated by both sympathetic and parasympathetic fibers via the cavernous nerves. Parasympathetic stimulation promotes prostatic secretion, whereas sympathetic stimulation causes contraction of smooth muscle within the stroma.

Prostate anatomy varies widely among the species, and comparative analysis has been thoroughly described by Dorothy Price.[18,19] The rodent is the most common research model to study prostate physiology and disease, and it has distinct anatomic and morphologic features from the human gland. The rodent prostate has three distinct paired lobes termed the ventral, lateral, and dorsal lobes, based upon their relative position in reference to the urethra (Figure 18.4). The rat lobes have increased complexity as compared to the mouse prostate, particularly in the lateral lobe, where two ductal types are observed in the rat, designated LP1 and LP2.[20] In addition, both species contain a coagulating gland, also referred to as the anterior prostate, which resides in the curvature of the paired seminal vesicles, and produces the seminal plug or coagulum that is not found in humans.

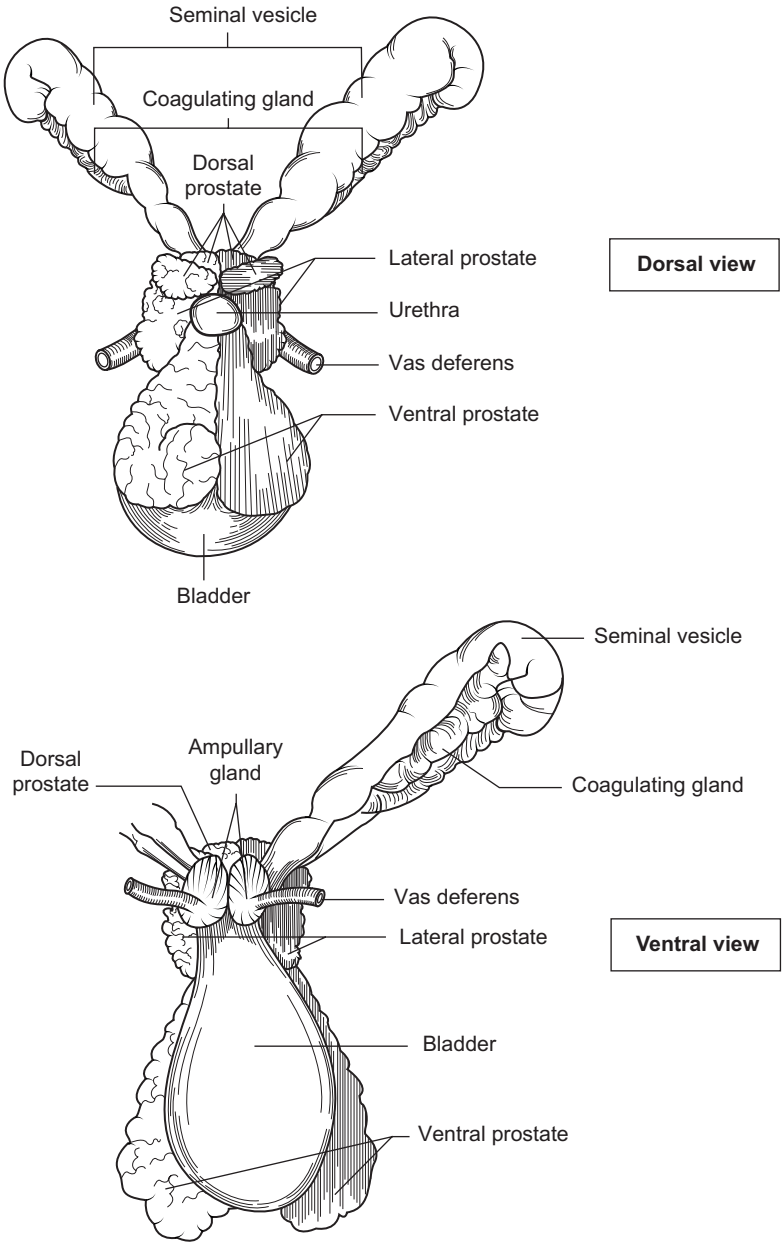

FIGURE 18.4 **Dorsal and ventral views of the rat prostate lobes and seminal vesicles.**

The ventral, lateral, and dorsal lobes of the rat prostate are each composed of a complex system of branched ducts that have a characteristic pattern unique to each lobe.[20] Together they contain 30–35 main ducts that drain the acini and empty secretions directly into the urethra along the anterior (dorsal lobe) to posterior (ventral lobe) axis.[21] The separate lobes have unique histology as well as lobe-specific secretions, which have been capitalized on to understand and model human prostate heterogeneity. The dorsal and lateral lobes resemble each other more than the ventral lobe, and the lateral prostate has been described as having the most histologic similarity to the human peripheral zone.[19] Although the rodent ventral lobes do not have a counterpart in the human (because the ventral buds regress during development) and have been suggested as a poorer model than the lateral and dorsal lobes, this distinction is somewhat artificial, because the lobular nature of the rodent prostate does not have a direct human counterpart. For example, recent studies have revealed that the rat ventral prostate has the highest expression of *Hox*b13, a homeobox gene essential for prostate identity,[22] which is significant since *HOX*B13 was recently identified as a key susceptibility gene for human prostate cancer.[23]

Prostate Histology

The mature prostate ducts contain three phenotypically and functionally distinct epithelial cell types—basal, luminal, and neuroendocrine cells—embedded in a fibromuscular stroma.[24] The exocrine product of prostate glands is produced by secretory luminal cells, which line the lumen of the glandular acini. Secretory cells are columnar and rest on a layer of basal cells over the basement membrane. They secrete a variety of proteins and products, which will be discussed later, into the lumen of the glands at the apex of the cell.[25] Basal cells are flat to cuboidal, nonsecretory epithelial cells. Human prostates have a continuous layer of basal cells with an approximate 1:1 ratio to secretory cells, while multiple other species have a discontinuous layer of basal cells with an average ratio of 1:7 basal to secretory.[26] Within the basal cell layer reside the prostate epithelial cell stem cells. An additional type of cell is seen in the epithelium, the neuroendocrine cell, which secretes hormones and cell-signaling factors in response to neural stimulation. These neuroendocrine cells are much less numerous and scattered sparsely throughout the acini and ducts.[27] Secretory epithelial cells in the human prostate are commonly identified by their expression of prostate-specific antigen (PSA); prostatic acid phosphatase (PAP); AR; homeobox gene *Nkx*3.1; and cytokeratins CK8 and CK18 but not CK5. Basal epithelial cells express CK5, CK14, and p63, and do not express PSA and PAP.[28–32] Neuroendocrine cells do not express PSA or AR, and can be identified by their expression of calcitonin and the neuropeptide chromogranin A.[33,34] The rodent prostate expresses similar cytokeratin and prostate-specific transcription factors with certain rodent-specific differences including variable expression among the distinct prostatic lobes.[35] In the rat, the ventral prostate expresses prostate-binding protein (PBP); the lateral lobe contains high levels of probasin and prostate-specific protein 94 (PSP94), also known as β-microseminoprotein and found in the human prostate; and the dorsal lobes contain low probasin levels and high levels of seminal vesicle secretory protein or SVS-II and DP-1.[36]

Secretory cells depend on androgen signaling for their survival and secretory activity and express high levels of AR.[37] Basal cells are largely AR negative,[38] although they may be androgen responsive through luminal cell and stromal cell paracrine signaling. Gap junction proteins exist between basal and luminal cells in the human prostate, which suggests an intimate level of communication. Additionally, the basal cells have junction-like structures between each other, which is reminiscent of the barrier in the testis and has led some to propose a similar blood–prostate barrier exists.[26,39] Little is known about the function of neuroendocrine cells; however, they express a wide variety of peptide hormones, biogenic amines, and carrier proteins. Interestingly, neuroendocrine cells are seen throughout the prostate glands at birth, and subsequently rapidly decline in numbers, only to reappear at puberty.[40]

The prostatic stroma is predominantly composed of smooth muscle and fibroblast cells, which contribute to both the structure and function of the prostate.[41] The smooth muscle cells provide the mechanical means by which prostatic secretions are expelled during emission.[42] Interestingly, the distribution of smooth muscle cells varies between species, with rodent smooth muscle being found strictly in a periacinar distribution and human smooth muscle found in the interductal stroma as well as periacinar. In addition to the mechanical roles of support and contractile elements, the stroma plays a critical role in epithelial homeostasis and development through the secretion of essential paracrine acting factors that drive epithelial proliferation and differentiation, as discussed in subsequent sections.[43] It is believed that aberrant growth with BPH and cancer is driven in part through reawakening of the embryonic growth potential of prostatic stroma, and evidence clearly shows a critical role for cancer-associated fibroblasts in driving prostate cancer progression.[16] The regional variations in epithelial proliferation and apoptosis along the prostatic ducts are associated with differing stromal organization. In the rodent prostate, the distribution of fibroblasts and smooth muscle cells varies along the length of a duct. In the distal regions, there is a discontinuous layer of fibroblasts between the smooth muscle cells, which surround the gland, whereas the stroma surrounding the proximal

duct has multiple continuous layers of smooth muscle with only a few rare fibroblasts interspersed.[41]

Prostatic smooth muscle cells consistently express AR, whereas fibroblasts do not. In the mature prostate, smooth muscle AR is believed to cause paracrine signaling, which helps maintain fully differentiated growth-quiescent epithelium.[38,44,45] Stromal growth factor expression has regional variation along prostatic ducts and is associated with differential epithelial responses.[41] It appears that, in general, fibroblastic signaling promotes epithelial proliferation, whereas smooth muscle signaling promotes cell death.

Seminal Vesicle Anatomy and Histology

In the adult human, seminal vesicles are paired structures posterior to the bladder and adjacent to the rectum (Figures 18.1 and 18.2). Positioned lateral to the posterior aspect of the prostate, the seminal vesicle lumens join with the ampullary region of the vas deferens, forming the ejaculatory ducts that transverse the central zone of the prostate and empty into the posterior urethra at either side of the verumontanum. The seminal vesicles are each 5–7 cm long with a volume of approximately 13 ml.[46] Unlike the prostate, the seminal vesicles are not branched structures and contain a singular common lumen; however, the glandular tissue is highly convoluted and infolded, thereby enabling its large secretory capacity. Similar to the prostate, the seminal vesicle epithelium consists of columnar secretory cells atop a discontinuous layer of basal cells; however, no neuroendocrine cells are found.[47] The epithelium is surrounded by a thick layer of smooth muscle cells innervated by sacral nerves S2–S4, and contracts during emission to expel the luminal contents into the ejaculatory ducts.

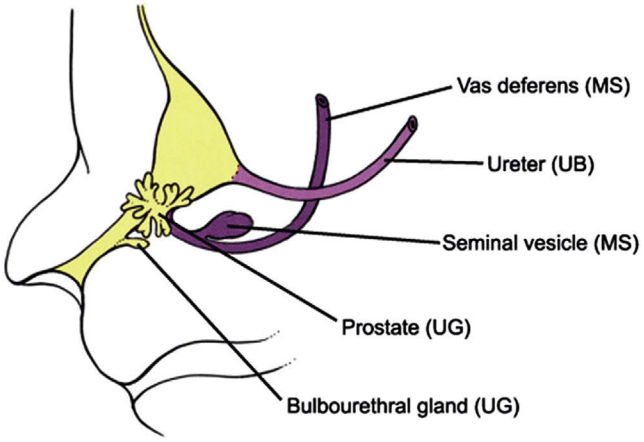

FIGURE 18.5 Development of human male accessory sex glands. The prostate and bulbourethral glands originate from endodermal urogenital sinus (UG) tissue, whereas the seminal vesicle and vas deferens derive from mesodermal mesonephric ducts (MS). The ureter develops from the ureteric bud (UB). *Source: From Park JM. Normal development of the genitourinary tract. In:* Campbell-Walsh Urology. *10th ed. Philadelphia: Elsevier Saunders; 2011. p. 58.*

Bulbourethral Glands and Glands of Littre

The paired bulbourethral glands, also known as Cowper's glands, are approximately the size and shape of peas and are located within the urogenital diaphragm immediately posterior and lateral to the membranous urethra (Figures 18.1 and 18.2).[48] They each contain tubuloalveolar glands, which empty into 2-cm ducts that drain into the bulbar urethra. They have a common developmental history to the prostate—both originating as epithelial buds from the urogenital sinus (UGS)—and are under similar androgenic regulation. The clear secretions of the bulbourethral gland perform primarily a lubrication function prior to and during the initial phase of ejaculation. An additional physiologic role is believed to involve immunoprotection to the reproductive tract, based on the high content of IgA and secretory component that is produced and secreted by these glands (see Chapter 19).[49] The glands of Littre are very small urethral glands that line the penile urethra. They are tubuloacinar mucinous glands that serve to lubricate the penile urethra prior to ejaculation.

EMBRYOLOGY AND DEVELOPMENT

Prostate Gland Development

In contrast to the seminal vesicles and vas deferens, which develop embryologically from the Wolffian ducts and are mesodermal in origin, the prostate gland originates from the UGS and is entirely an endodermal structure (Figure 18.5). It has been suggested that this endodermal embryologic origin may account in part for the high rates of aberrant growth and cancer in the prostate gland, whereas the other accessory glands have low rates of disease. A significant amount of information about prostate gland development at the morphologic, cellular, and molecular levels has been derived from studies using rodent models, while similar details for the human prostate are limited. This section will first discuss the embryologic and developmental details known for the human prostate and then proceed to the specifics of rodent prostate development including hormonal and molecular signaling that cooperate to regulate the process.

Human

Although the prostate developmental process is continuous, it can be categorized in distinct stages involving determination, initiation or budding, branching morphogenesis, differentiation, and pubertal maturation.[50]

Determination of the prostate occurs prior to clear morphological evidence of a developing structure and involves expression of molecular signals that commit a specific field of UGS cells to a prostatic cell fate. Phenotypic human prostate development commences as UGS epithelial cells form outgrowths or buds, which penetrate into the surrounding UGS mesenchyme in the anterior, posterior, and lateral directions caudal to the bladder. Prostate development occurs during the second and third trimester and is complete at the time of birth.[51–53] Primordia of the prostate gland appear during gestational weeks 10–12 in humans as solid outgrowths from the UGS immediately below the developing bladder. These epithelial buds penetrate the surrounding mesenchyme that accompanies the UGS. Stromal differentiation occurs as mesenchymal cells form lamina propria around the epithelial outgrowths.[54] The ducts grow rapidly in length, and arborize and lumenize, so that by weeks 14–18 there are approximately 70 tubuloacinar ducts that exhibit signs of secretory cytodifferentiation. In 1912, Lowsley classified anatomic lobes of the adult prostate based on his observation that prostatic epithelial buds originated in five different regions of the UGS that embryonically formed different regions within the gland: anterior, posterior, middle, and two lateral lobes.[51] Later studies have revealed that the distinctions that Lowsley observed in the fetal prostate do not appear to exist in the adult prostate, perhaps due in part to the regression of the anterior buds, and that embryonic extrapolations do not explain adult morphology. However, it is noteworthy that at the earliest embryonic stage, regional differences are found in the prostate. There is some evidence to indicate that the prostate also contains a small mesodermal contribution arising from mesonephric and paramesonephric tissues when buds penetrate dorsoposteriorly into the vicinity of the developing ejaculatory ducts.[55] This region would be contained within the central zone of the adult prostate.

The fetal prostate exhibits extensive squamous metaplasia in the acini of the developing central zone, which is evident at 22 weeks and gestational age and increases as the fetus matures.[56] This metaplastic activity peaks in the 36th week and declines thereafter, and the metaplastic cells are sloughed within the first weeks following birth. The significance of metaplasia is unclear, although it appears to be driven by maternal estrogenic actions. Trace amounts of prostatic secretions are observed as early as the 14th gestational week in the peripheral zone and increase in incidence and degree so that in the later weeks of gestation, several lumina are filled with mucopolysaccharides. Metaplasia and secretory activity appear to be mutually exclusive in the embryonic human prostate.

In humans, prostate development is largely complete at the time of birth, and the gland remains relatively dormant until puberty. At puberty, the prostate undergoes a rapid growth spurt (1–2 g before puberty to 12–20 g in a young adult), largely as a result of the pubertal surge in testosterone production (see Chapter 32). Quantitation of this growth spurt in baboons indicated that the increase in stromal mass preceded growth of the epithelial fraction, which concurs with the concept that mesenchyme and stroma are growth inductive for the prostate epithelium.[57] Prior to puberty, the prostate epithelium appears homogenous throughout the gland, whereas at puberty the epithelium in the central zone and peripheral zone undergoes final maturation and differentiation, becoming histologically distinct and heterogeneous. Prepubertally, only the proximal portion of the preprostatic sphincter is developed, and final maturation with distal extension to the verumontanum takes place during the pubertal growth spurt.

Rodent

In contrast to the human, the rodent prostate gland is rudimentary at birth and undergoes the majority of its development during the first 15 days of life. Immediately prior to birth, buds from the UGS epithelium penetrate into the surrounding UGS mesenchyme in the ventral, lateral, and dorsal directions to give rise to the distinct prostate lobes. Of interest, the coagulating gland (the anterior prostate) is a hybrid structure that originates embryologically from UGS epithelial cells that penetrate anteriorly into mesenchyme associated with the mesodermal seminal vesicles, to which they fuse. In the mouse, the initial outgrowth of epithelial buds occurs between fetal day 16.5–17.5 (f16.5–17.5) in a 19-day gestation strain,[58] while in the rat it occurs at f18.5 in a 21-day gestation strain.[20] At birth, the ventral, dorsal, and lateral rodent prostate lobes primarily consist of unbranched, solid elongating buds or ducts, and subsequent outgrowth and patterning occur postnatally. During this time, proliferation of epithelial cells occurs primarily at the leading edge of the ducts (i.e., distal tips).[44] Branching morphogenesis begins when the elongating UGS epithelial buds contact the prostate mesenchymal pads that are peripheral to the periurethral smooth muscle. At that point, secondary, tertiary, and further branch points are established with continued proximal-to-distal outgrowth and complexity.[59] Branching patterns are lobe-specific with ventral branching preceding that in the dorsolateral lobes by 3–4 days.[20] Morphogenesis of the entire complex is completed between postnatal days 15 and 30. Final growth and maturation occur at puberty (days 25–40), when circulating androgen levels rise sharply (see Chapter 30).

Epithelial and mesenchymal cell differentiation is coordinated with branching morphogenesis and occurs in the proximal-to-distal direction.[42,60,61] Epithelial differentiation from stem/progenitor cells into differentiated

basal and luminal cells has been documented in the rat prostate with changing patterns of cytokeratins as well as alterations in AR expression, an early marker of epithelial cell differentiation.[60] The process initiates between days 3–5 in the rat ventral prostate and about 2 days later in the dorsal and lateral lobes. Lumenization of the solid epithelial cords is concomitant with differentiation into basal and luminal cell layers and initiates in the proximal ducts around postnatal day 5, extending to the distal tips by about day 12. Between days 10 and 15 in the rat, functional differentiation commences, as defined by the synthesis of secretory products by differentiated luminal epithelial cells. Concomitant with epithelial differentiation, the prostatic mesenchyme undergoes differentiation postnatally. As UGS epithelial ducts penetrate into the prostate mesenchymal pads, mesenchymal cells condensate around the tip and form a distinctive pattern along the length of the basement membrane. Between postnatal days 3 and 5, cells adjacent to the ducts form a periductal layer of smooth muscle cells while interductal cells differentiate into mature fibroblasts.[60] Lying between the basement membrane and the periductal smooth muscle is an extremely thin single-cell layer of differentiated fibroblasts that thins in the distal direction.[62] As the prostate undergoes branching morphogenesis, a branched vascular bed forms in parallel with neovascularization forming within the prostatic stromal elements and capillary beds extending to the ductal basement membrane.[21,63]

Prostate Stem Cells

Adult prostate stem and progenitor cells have had a more thorough analysis than those found in the developing prostate. Consequently, our knowledge of hierarchical relationships and regulatory pathways is largely based on adult stem cells. Adult prostate epithelial stem cells have been identified in human and rodent prostate glands, where they play an essential role in tissue replenishment throughout life.[64–67] This rare cell type self-renews and has the potential to differentiate into the three distinct epithelial cell types, which are essential characteristics of bona fide stem cells. Adult prostate stem cells are relatively growth quiescent, occasionally dividing to self-renew and generate daughter progenitor cells. Studies across multiple systems as well as the prostate epithelium have characterized two types of stem cell divisions: (1) symmetric division, also known as symmetric self-renewal, which generates two identical stem cells; and (2) asymmetric division, which generates a single self-renewing stem cell and a daughter cell that has entered the earliest stage of differentiation (progenitor cell).[68–71] Unlike the stem cell, the daughter progenitor cell has transit-amplifying capacity through rapid cell divisions. As the progenitor cell proliferative potential is exhausted, it undergoes terminal differentiation.

Although prostate stem cells are present in several regions of rodent prostatic ducts, accumulated prostate stem cells with considerable growth potential have been found in the proximal region of ducts close to the UGS, and the survival of these cells does not require the presence of androgens.[72,73] Primitive proximal prostate stem cells that are able to regenerate functional prostatic tissue in vivo are also programmed to reestablish a proximal–distal ductal axis. In contrast, prostate stem cells in the distal region of the prostate duct have more limited growth potential and require androgens for survival.

Although the lineage hierarchy for the prostate epithelium has not been settled, epithelial differentiation of stem cells into differentiated basal, luminal, and neuroendocrine cells has been documented in the rodent prostate and in isolated human prostate cancer stem cells.[74–78] These studies on stem cell differentiation have been observed with changing patterns of cytokeratins, cell-specific markers, and alterations in AR expression, an early marker of luminal epithelial cell differentiation. Two models have been proposed for the prostate epithelial stem cell lineage into differentiated basal, luminal, and neuroendocrine cell types. In the traditional linear hierarchy model (Figure 18.6), self-renewing prostate stem cells residing

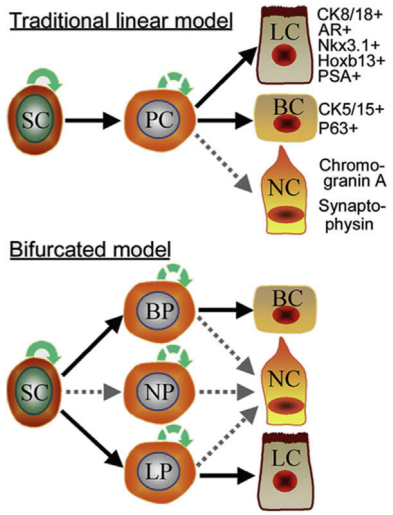

FIGURE 18.6 Prostate stem cell hierarchical models. In the traditional linear hierarchy model (top), self-renewing prostate stem cells (SC) give rise to intermediate, transit-amplifying progenitor cells (PC). These cells have high proliferative capacity and enter differentiation pathways to give rise to terminally differentiated luminal epithelial cells (LC), basal cells (BC), and neuroendocrine cells (NC). In the bifurcated model (bottom), a common SC with self-renewal capacity undergoes asynchronous cell division to give rise to lineage-restricted basal progenitor cells (BP) and luminal progenitor cells (LP). These PCs possess transient self-renewal capacity and terminally differentiate into BC and LC. The lineage of NC is unclear, and may arise from the hierarchical intermediate BP and LP that produce BC and LC, or it may have a separate neuroendocrine progenitor (NP) origin.

in the basal cell layer undergo asymmetric cell division, giving rise to daughter progenitor cells with high proliferative potential, referred to as transit-amplifying cells. In response to signals from the stem cell niche, these cells enter early differentiation pathways to eventually form separate basal, luminal, and neuroendocrine cells.[74,79,80] Phenotypic intermediate-type cells that co-express basal and luminal markers have been observed both in vitro and in vivo.[60,81] This suggests that basal and luminal cells are hierarchically related through common progenitor cells that give rise to differentiated basal cells and luminal cells. In the bifurcated model, basal cells and luminal cells represent separate epithelial cell lineages that originate from a common stem cell that undergoes asymmetric cell division to yield lineage-specific progenitor cells. These lineages may be sustained by intermediate transit-amplifying cells prior to final stages of terminal differentiation.

The lineage of neuroendocrine cells is unclear. Neuroendocrine cells may arise from the hierarchical prostate epithelial stem and progenitor cells that produce basal and luminal cells, or they may have a separate progenitor cell origin suggested for the bifurcated model. Critical to stem cell self-renewal, lineage commitment, and differentiation is the stem cell niche, or microenvironment, that is believed to provide signals that regulate these events.[82] This niche in both the developing and adult glands would include the mesenchyme/stromal and resident immune cells that communicate with stem cells through paracrine factors as well as neighboring epithelial cells that can communicate through gap junctions, cell adhesion molecules, and paracrine signaling.

Prostate epithelial stem and early progenitor cells are AR negative[83,84] and are thus not directly regulated by androgen action. As a result, any effects of androgens on prostate epithelial stem cell homeostasis and differentiation are most likely mediated through indirect actions via the stem cell niche that includes AR^+ stromal cells and in the mature prostate, AR^+ luminal epithelial cells.[85] Interestingly, recent data show that human prostate stem/progenitor cells express estrogen receptors ERα, ERβ, and GPR30 and show proliferative responses to estrogens, implicating their involvement in maintenance of the stem/progenitor pool.[86] Similar to stem cells in other systems, prostate stem cells also express several retinoic acid receptors (RARs and RXRs) through which retinoids promote differentiation.[84] This suggests that together, multiple signaling molecules may directly and indirectly contribute to the controlled equilibrium between self-renewal and differentiation in prostate epithelial stem cell populations.

Seminal Vesicle Development

The bilateral mesonephric or Wolffian ducts develop into the epididymis proximally (in relation to the testis); and the vas deferens, seminal vesicles, and ejaculatory ducts distally (Figure 18.5). Thus unlike the endodermal prostate, the seminal vesicles are of mesodermal origin. In the human, seminal vesicle development begins at 12 weeks gestation as a localized dilatation of the distal Wolffian duct. This dilatation expands into the saccular convoluted structure of the mature seminal vesicle. The entire Wolffian duct then achieves its characteristic thick investment of smooth muscle and relatively narrow lumen along its length. These confluent structures establish a channel that will carry fluid and sperm from the epididymis and vas deferens to the ejaculatory duct and urethra. The seminal vesicle joins the shared lumen of this channel at the level of the ejaculatory duct, which traverses the prostate posterolaterally and empties into the posterior urethra. The ejaculatory duct carries the combined contributions from the vas deferens and epididymis as well as the seminal vesicle.[87]

Morphogenesis of the rat seminal vesicle initiates in utero at f17 with two outgrowths budding anterior to the UGS. At birth, the rodent seminal vesicle is rudimentary consisting of a hollow tube surrounded by mesenchyme.[88] Unlike the prostate, the seminal vesicle contains a singular main duct that undergoes elongation and lateral branching during the postnatal period. *Fgf*10 signaling is essential for lateral branching. This was demonstrated in a mouse model with a spontaneous recessive mutation (*svs*) and subsequent *Fgf*R2iiib splice variant isoform that resulted in decreased lateral branching without a decrease in overall growth. The seminal vesicle structure primarily increases in complexity through extensive epithelial infolding into the glandular lumen that provides significant secretory capacity to the epithelium. The seminal vesicle mesenchyme differentiates into a thick layer of smooth muscle cells, which surrounds the ductal structure. A thin layer of fibroblasts differentiates between the smooth muscle cells and the basement membrane epithelium.[42]

Regulation of Accessory Gland Development

Androgens

The determination and initiation of prostatic and seminal vesicle development in the human and rodent fetus is entirely dependent upon androgens produced by the fetal testes. Surgical or chemical castration (i.e., antiandrogen administration) during critical periods of fetal life results in inhibition of prostate development.[18,88–91] However, the extent of inhibition depends on the timing of androgen ablation with removal prior to the time of budding in the murine or rat embryo blocking prostatic outgrowths altogether and removal after bud outgrowth reducing bud numbers in a temporal-dependent manner.[90,91] These findings indicate that although androgens are essential for prostate

determination, bud initiation, and maximal bud number and length, budding can continue to a large degree in the absence of testosterone due to irreversible commitment of the tissue. Rodent neonatal prostate explant cultures have further shown that although branching morphogenesis can occur in the absence of exogenous androgens, maximal organ growth with full branching as well as complete cellular cytodifferentiation are only realized with the addition of exogenous testosterone.[92,93]

In the 1970s, it was determined that the primary androgen responsible for prostatic development is dihydrotestosterone (DHT), the reduced metabolite of testosterone.[94] DHT is formed intracellularly in the prostate epithelium by 5α-reductase (SRD5A1 and SRD5A2) and has a higher affinity for AR as compared to the parent compound, testosterone.[13] Human males with 5α-reductase deficiency syndrome have complete absence of prostate morphogenesis, with normal development of the seminal vesicles and vas deferens, which empty into a blind vagina.[95] Similarly, treatment of pregnant female rats with a 5α-reductase inhibitor from f14-22 obliterated the formation of prostatic buds, an effect that could be reversed with concomitant administration of DHT.[96]

Androgen action is mediated through interaction with nuclear AR, which is a member of a nuclear receptor superfamily of transcription factors.[97,98] Evidence for the essential requirement of AR for prostate development comes from the observation of prostatic absence in mice or humans with complete dysfunctional AR.[99] AR is highly expressed in the UGS mesenchyme prior to and during prostate morphogenesis, whereas epithelial AR expression is induced after budding and branching morphogenesis has begun.[60,100] Classical tissue recombinant studies by Cunha demonstrated that AR in the mesenchyme, and not epithelial AR, are responsible for prostatic morphogenesis.[43,101] Although further analysis revealed that epithelial AR are required for expression of secretory proteins,[60,102] epithelial proliferation and cytodifferentiation appear to be largely driven by paracrine factors under mesenchymal AR control.[103] Nonetheless, mesenchymal differentiation into smooth muscle requires reciprocal signals from the epithelium, and because AR induction in prostate epithelium begins as early as postnatal day 1 or 2 (prior to cytodifferentiation of the epithelium and mesenchyme), it is possible that androgen-mediated actions in the epithelium are also involved in normal prostate morphogenesis.[60,104] AR inactivation restricted to murine prostate epithelial cells confirms the above model and also provides evidence that epithelial AR restricts epithelial cell proliferation and serves to maintain homeostasis of epithelial cell numbers.[70,105]

Estrogens

There is also clear evidence for a role of estrogens during prostate and seminal vesicle development. Although low levels of circulating estrogens are present throughout life in males, there are two time periods, during in utero development and upon aging, when males are exposed to relatively higher levels of circulating estradiol, which have been shown to impact the prostate gland. Estrogen receptors are expressed during early prostate and seminal vesicle development, with ERα expressed in developing prostate stromal cells[35,106] and ERβ localized primarily to luminal epithelial cells during early differentiation.[107] Extensive studies on the process of developmental estrogenization (referred to as estrogen imprinting or estrogen reprogramming) have shown that exposure to high-dose estrogens during the critical window of development inhibits prostate growth, leads to differentiation defects of epithelial and mesenchymal cells, and effects marked structural reorganization of the developing prostate.[108] Conversely, low-dose estrogen exposures during prostate development can produce opposite effects and increase prostate gland bud numbers and adult prostate size, indicating nonmonotonic dose responses.[109] The seminal vesicles are also influenced by early-life estrogens, which can program the structure in a manner similar to that in the prostate. The prostatic reprogramming events are mediated through stromal ERα, which in turn alters expression of multiple steroid receptors.[23,110] Downstream mediators of altered prostatic steroid signaling involve perturbed expression of several key transcription factors and secreted morphogens, including *Nkx*3.1, *Hoxb*13, *Bmp*4, *Fgf*10, and *Shh*, which are essential for normal prostate gland development.[111–113] Importantly, exposure to natural, synthetic, and environmental estrogenic compounds during fetal or neonatal development can lead directly to prostate neoplasia, dysplasia, and chronic inflammation with aging, if doses are high, and increase susceptibility to hormone-driven carcinogenesis with aging if doses are low.[112,114] It is thought that these lifelong changes as a function of brief, early-life exposure to estrogens are a result of epigenetic reprogramming of the prostate cells early in development that leads to altered epigenetic memory at the level of DNA methylation, histone modifications, and noncoding RNAs.[115] Whether estrogen reprogramming occurs in humans is unclear. However, squamous metaplasia in fetal human prostate epithelium is driven by maternal estradiol.[56] Furthermore, indicators of high estrogen levels during pregnancy, such as high birthweight and jaundice in the newborn, are associated with increased risk of prostate cancer, whereas indicators of low estrogen levels, such as preeclampsia, are related to decreased risk.[116] Together, this supports a growing body of evidence for a developmental origin for adult disease and extends this emerging paradigm to include prostate disease and cancer.

Retinoids

Retinoic acid and retinoids are derivatives of vitamin A and play an important role in organ development and tissue homeostasis. Their actions are mediated through retinoid receptors RARα, β, and γ and RXRα, β, and γ, which form RAR/RXR dimers that directly regulate target gene expression.[117] Retinoic acid receptors are expressed in a cell-specific manner in the developing rat prostate gland,[118] and retinoids play an important role in prostate bud initiation.[119]

Neural Regulation

It has been suggested that the developing prostate may have a neural regulatory component as well. Alpha-1 and beta-2 adrenergic receptors as well as M(1) cholinergic receptors are found at high densities in the prostate. Studies involving surgical denervation as well as botulinum toxin have given evidence that neural stimulation may be involved in prostate growth.[120,121] Additional study is needed in this aspect of development.

Developmental Genes

The branching morphogenesis that occurs in the developing prostate and to a lesser degree in the seminal vesicles is driven by time-specific and region-specific expression of key regulatory genes that are evolutionarily conserved throughout the animal kingdom. These conserved signaling pathways are seen repeatedly across species, suggesting that a common "morphogenetic code" or common set of rules exists that is used repeatedly in different combinations to result in formation of unique organs.[122] Similar pathways are seen among the different branched glandular structures within the same species; however, spatial and temporal differences, unique combinations of gene expression, and organ-specific genes result in unique structures. There are two major categories of developmental genes: those that encode for nuclear transcription factors and for secreted morphogens that effect responses through cell-specific expression of membrane receptors. Most of the available information derives from studies in the rodent prostate with limited evaluation undertaken in the seminal vesicles. This section will review nuclear transcription factors including common and organ-specific homeobox genes, as well as secreted signaling ligands, which provide the well-coordinated paracrine and autocrine communication between epithelial and stromal mesenchymal cells in the developing glands (Figure 18.7). It is important to note that several of these genes are direct downstream targets of steroid action, while expression of others is indirectly influenced by androgens, estrogens, and retinoids, which explains in part how these factors influence the divergent developmental processes.

Homeobox Genes and Transcription Factors

The homeobox superfamily of genes are involved in axis positioning and tissue determination, and several members of this group of genes have been identified as active within the developing prostate and seminal vesicles.[123] The common feature defining these genes is the homeobox, a highly conserved 180 base pair segment that encodes a 60 amino acid peptide segment that binds to specific regulatory regions of target genes.

Hox Genes

Hox genes are the largest and most extensively studied members of the homeobox superfamily and determine patterning in body regions from *Drosophilia* to humans. Mammals have 39 Hox genes, which are grouped into four clusters (A, B, C, and D) found on four separate chromosomes.[124] Similar genes in the separate clusters are considered paralogs and largely, although not always, have redundant functions. Expression of these genes, from the 3′ to 5′ end of each cluster, follows a strict pattern of spatial and temporal colinearity during embryogenesis. The 3′ genes (*Hox*1, 2, 3, …) designate anterior regions while the 5′ genes (*Hox*13, 12, 11, …) encode posterior or caudal regions. A generalized model

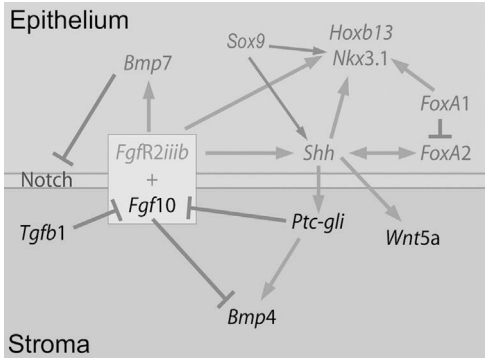

FIGURE 18.7 A schematic representation of regulatory networks between secreted morphogens and transcription factors in the epithelial and stromal cells at the distal signaling center of the developing rat prostate gland. *Fgf*10 (stromal) and *Fgf*R2iiib (epithelial) upregulate epithelial expression of *Shh* and *Bmp*7, which are involved in branching morphogenesis, as well as *Hox*b13 and *Nkx*3.1, which drive epithelial differentiation. Furthermore, epithelial *Sox*9 upregulates *Shh* and *Nkx*3.1 expression while *Fox*A1 stimulates *Nkx*3.1 and inhibits *Fox*A2 expression, which has reciprocal upregulation with *Shh*. In turn, secreted *Shh* upregulates *Ptc-gli* expression in adjacent mesenchymal cells, which downregulates *Fgf*10 expression, thus establishing a negative feedback loop for controlled growth. *Shh* and *Ptc-gli* also upregulate the growth-inhibitory *Wnt*5a and *Bmp*4 molecules in the mesenchyme, while *Fgf*10 downregulates their expression, which further serves to tightly control localized tissue growth. Stromal *Tgf*β1 suppresses *Fgf*10 expression, which may serve as a brake for growth as development nears completion. *Source: Adapted from Ref. 50.*

for regional tissue specification is that nested, partially overlapping expression domains of several genes in a Hox cluster determine segment identity.

As the accessory sex glands are the most posterior organs in the male, the posterior *Hox* genes, *Hox*9–13, are involved in their development and identity. The male accessory reproductive organs in the anterior-to-posterior order are the epididymis, vas deferens, seminal vesicles, coagulating gland, dorsal prostate, lateral prostate, ventral prostate gland, and bulbourethral glands, and a unique Hox code for each of these structures contributes to the organ-specific and prostate lobe-specific identities.[22] Studies in null mutant mice have demonstrated the functionally redundant *Hox*a13 and *Hox*d13 are necessary for prostate growth and branching, with compound mutants exhibiting normal testes and severely hypoplastic prostate tissue. Interestingly, in the mouse prostate, expression of *Hox*a13 and *Hox*d13 is highest during fetal life with a decline postnatally, whereas the rat prostate has the opposite pattern, with higher expression levels in the adult.[22,125–128] This implies that these highly conserved genes and morphogens actually function in different ways among species.

Although the A and D *Hox*13 paralogs are more strongly expressed in the mesenchyme with lesser expression in the epithelium, *Hox*b13 is only seen within the epithelial cells of mouse and rat prostates with expression rising in the postnatal period to peak levels in adult prostate epithelium.[22,129,130] Furthermore, while the A and D *Hox*13 paralogs are also expressed within the seminal vesicles, *Hox*b13 is only expressed in UGS-derived accessory sex glands, indicating relative specificity of this paralog within the male reproductive tract.[22] Importantly, *Hox*b13 has been shown to be essential for normal prostate epithelial cell differentiation, and its targeted expression is capable of driving undifferentiated prostate epithelial cells into an early differentiation pathway.[22,130] This is particularly notable in light of the recent discovery that *HOX*B13 in the human prostate gland is a susceptibility gene for prostate cancer,[131] with a germ-line mutation identified in 5% of patients with early-onset familial prostate cancer.[131,132]

In addition to Hox genes, several Hox protein cofactors are expressed in tissues that modify Hox gene specificity.[133] Of high relevance, Hox cofactors *Meis*1, *Meis*2, and *Pbx*1 were recently identified through a genomic screen as differentially expressed between matched patient specimens of seminal vesicles and prostate and that may explain, in part, the vastly different rates of cancer in these two structures.[134] Downregulation of *Meis*1, *Meis*2, and *Pbx*1 in prostate cancer tissue identified their critical roles as tumor suppressor genes. This contributes to the growing body of evidence that dysregulation of key developmental genes plays a key role in prostate cancer initiation and progression.

Nkx*3.1*

*Nkx*3.1 is a homeobox gene with expression limited to the UGS-derived prostate and bulbourethral gland epithelium.[135,136] In the fetal mouse UGS, *Nkx*3.1 is expressed at bud sites prior to bud formation, which suggests it has a role in prostate determination.[30,135] Null mutant mice exhibit defective branching patterns and perturbed epithelial differentiation,[30] and a sharp but transient peak of expression in the rat prostate epithelium during the second week of life concomitant with cytodifferentiation suggests involvement in that process.[112] Its continued expression in the adult prostate indicates its essential role in homeostasis.[137] Furthermore, multiple studies have shown *Nkx*3.1 to be a tumor suppressor gene, with loss of expression leading to prostate carcinogenesis and progression.[138]

*Nkx*3.1 expression is under direct androgen regulation and is upregulated by androgens in the adult mouse prostate, developing rat prostate, and a human prostate LNCaP cell line.[135,139,140] However, in the developing prostate, initial *Nkx*3.1 expression in the UGS epithelial cells is not likely a result of direct androgen action, because these cells are AR negative at that time. It has been shown that *Nkx*3.1 expression during prostate formation is dependent on epithelial sonic hedgehog (Shh) expression; thus its developmental expression is likely a function of gene regulatory networks operative at that time.[141]

Fox*A1 and A2*

Forkhead box genes (*Fox*) encode a superfamily of winged-helix transcription factors.[142] Multiple Fox genes are specific to endodermal-derived structures and are involved in their organ development.[143] *Fox*A1 (formerly *Hnf*3) is found in the developing prostate epithelium in the early stages of prostate formation and is involved in ductal morphogenesis and epithelial polarity and differentiation.[144,145] Although *Fox*A2 is only expressed at the mesenchymal interface of prostate epithelial cells during early budding and then subsides, *Fox*A1 expression in the rat and mouse increases with prostate development and is maintained throughout life.[144–146] In humans, continued *FOX*A1 expression is required for PSA expression, through interactions between *Fox*A *cis*-regulatory elements and AR on gene promoters.[146] In this regard, *Fox*A1 is now recognized as an essential pioneer factor for steroid receptors, where it guides AR binding to androgen response elements (AREs) throughout the genome.[147] Importantly, *Fox*A1 has been found to play a role in advanced prostate cancer.

Sox*9*

A member of the Sry box family, *Sox*9 has been found to be essential for normal prostate budding and branching morphogenesis.[148,149] *Sox*9 is expressed early in the fetal prostate epithelial cells, and *Sox*9$^{-/-}$ null

mutant mice fail to develop a ventral prostate and show deficient branching in the dorsolateral and anterior prostate lobes. Importantly, it was shown to be upstream of other critical genes in the developing prostate including *Nkx*3.1, *Shh*, and *Fgf*10.[148] SOX9 is expressed in human fetal prostate epithelium and localizes to basal epithelial cells in the adult human prostate.[150,151] As with several other developmental genes, aberrant SOX9 signaling has been found in prostate cancer cells, where it is frequently overexpressed and upregulates AR.[150]

Juxtacrine Signaling

NOTCH1/DELTA/JAGGED

The notch signaling pathway is highly conserved and involved in cell fate specification and patterning in developing tissues.[152] The notch receptor is a single-pass transmembrane glycoprotein that interacts with jagged/delta membrane proteins on adjacent cells. The pathway is activated by proteolytic cleavage of notch, which results in the intracellular domain translocating to the nucleus and interacting with transcription factors with subsequent changes in gene expression including *Hes*1, a known downstream target. Both *Hes*1 expression as well as nuclear localization of the intracellular domain of *Notch*1 have been demonstrated in mouse UGS epithelium and early prostate buds. Additionally, delta-like ligand1 (Dll1) localizes to epithelial cells where buds emerge, and *Jagged*1 expression localizes to both epithelial cells and mesenchyme at the time of budding.[153] These patterns demonstrate active *Notch*1 signaling at the time and place where bud initiation occurs, which suggests a potential role in prostate specification.

The newborn mouse prostate has high expression of *Notch*1 throughout morphogenesis and subsequently declines to low expression in adults.[154] *Notch*1 is initially expressed in all progenitor cells, but localizes to basal epithelial cells upon cytodifferentiation. Using secretase inhibitors to prevent *Notch* cleavage in neonatal rat ventral prostate organ culture results in markedly reduced branching morphogenesis and epithelial differentiation.[155,156] Recently, studies revealed a positive reciprocal regulatory loop between *Tgf*β and *Notch* in maintaining prostate basal stem cell dormancy,[157] and targeting the Notch pathway is a vibrant area of research for controlling prostate cancer growth and progression.

Secreted Signaling Molecules

In addition to the above transcription factors, multiple secreted signaling molecules play essential roles in bud initiation, branching morphogenesis and cell differentiation in the developing prostate. Specifically, combinations of Hedgehogs, Wnts, fibroblast growth factors (Fgf), and members of the transforming growth factor β family (Tgfβ), including bone morphogenic proteins (Bmp), and activins, are involved as secreted paracrine and autocrine signals in the complex interplay between mesenchymal and epithelial cells to drive and control prostate development. These positive and negative regulatory molecules are spatially and temporally regulated and communicate signals between cells via their cognate receptors. Here we highlight the key families known to be involved in this process.

Sonic Hedgehog

Sonic hedgehog (Shh) is a glycoprotein secreted by epithelial cells at the mesenchymal interface and is involved in proliferation, embryonic patterning, and cell fate determination in developing tissues.[158] *Shh* binds to membrane-bound patched (*Ptc*) receptors on adjacent mesenchymal cells, establishing epithelial-mesenchymal cross-talk. Binding of *Shh* to *Ptc* leads to activation of smoothened (Smo) and downstream activation of the Gli transcription factors. There are three known Gli transcripts in vertebrates: *Gli*1, *Gli*2, and *Gli*3. *Shh* has been shown to have both short-range and long-range actions dependent upon concentration gradients and regulates the expression of other morphogens in multiple structures including the prostate.[159] *Shh* plays several critical roles during prostate gland development, including an essential role for bud initiation, ductal elongation, maintenance of stem and progenitor cell populations, and normal epithelial differentiation. These findings have been reached through studies by multiple laboratories using $Shh^{-/-}$ null mutant mice, organ culture of murine and rat prostate lobes, tissue recombinants, and cell culture work, and the readers are referred to a review for further details.[50]

Shh is expressed in rodent prostate epithelial cells during prostate bud induction and rapidly declines over several days as morphogenesis is completed.[160–163] Its expression follows a spatial pattern, with initial broad expression throughout the bud epithelium transitioning to localized expression at the distal tips of elongating ducts.[163] The *Ptc* receptor is localized to mesenchymal cells adjacent to the distal tips of elongating ducts, with weaker *Ptc* expression seen within the epithelial cells, which is suggestive of an Shh autocrine action in the distal epithelium. *Gli*1, *gli*2, and *gli*3 exhibit a spatial pattern of expression as well, with *gli*1 and *gli*2 expressed in periductal mesenchyme along the length of the duct, while *gli*3 is only found in the mesenchyme adjacent to the tips.[161,163] The human fetal prostate expresses *SHH* with two strong peaks occurring at 10–13 weeks during active morphogenesis as well as at week 28 with corresponding elevated proliferation at that time. Additionally, the SHH signaling pathway genes including *PTC*1 and *GLI*1 have been shown to be active in the human fetal prostate, supporting its role in human prostate development.[164,165]

Androgens have been shown to upregulate prostatic *Shh* expression, but similar *Shh* levels in both male and female f17 UGS tissues and continued *Shh* expression in the male UGS despite AR blockade have cast doubt on the absolute necessity of androgens for developmental expression of *Shh*.[160,163,166] Additionally, *Shh* is expressed in fetal UGS epithelial cells and early prostate buds despite their AR^- status at that time. *Fgf*10 and *Sox*9 have been shown to be upstream of *Shh* in developing prostates, which supports the model of a complex regulatory network between secreted morphogens and transcription factors that ultimately regulates prostate development.[50] As with many developmental genes, strong evidence implicates dysregulation of *Shh* signaling during the process of prostate carcinogenesis and progression, and readers are referred to reviews and recent manuscripts on this topic.[167–169]

Fibroblast Growth Factor-10

Fgfs are a large family of secreted morphogens (23 known members) with a high affinity for heparin and glycosaminoglycans, which position them with interaction with Fgf receptors (FgfR) on target cells.[170–172] *Fgf*10 has been shown to play a critical role in initiation and directional outgrowth and branching of multiple branched structures including the prostate gland.[173,174] In the prostate, *Fgf*10 expression is spatially restricted to the distal aspects of the glands, where it is believed to function as a chemoattractant for elongating ducts and an inducer of ductal branching through stimulation of epithelial cell proliferation.[174] The expression pattern of *Fgf*10 in the prostate mesenchymal pad is broad during early budding stages and subsequently condenses around the elongating ducts with strongest expression at the distal tips during branching.[175] *Fgf*10 binds to the Fgf receptor splice variant *Fgf*R2iiib, a specific receptor for *Fgf*10, which is localized to epithelial cells in the distal tips of elongating rat prostate ducts.[175] This activates downstream intracellular signals in the *ras-raf-Mek-Erk*1/2 pathway to mediate its effects.[175] *Fgf*10 plays an essential role in prostate bud initiation, ductal elongation, and branching morphogenesis.[174–177] It accomplishes this through direct stimulation of epithelial cell proliferation as well as regulation of multiple growth stimulatory and inhibitor factors, which together permit localized domains of active cell division, leading to focal outgrowths and branchpoint formation.[175] *Fgf*10 expression declines to nadir levels as branching morphogenesis is complete, thus limiting continued growth of the tissue.

*Fgf*10 was initially described as prostatic andromedin, defined as a paracrine-acting, androgen-regulated, secreted mesenchymal factor that drives proliferation or differentiation of the epithelium.[178] Although subsequent studies have identified other secreted factors that are downstream of androgen action in the prostate, short-term organ-culture experiments have shown that *Fgf*10 as well as *Fgf*R2iiib are directly regulated by androgens during early morphogenesis, and as such, *Fgf*10 qualifies as a secreted androgen mediator.[140,175] Furthermore, *Fgf*10 signaling was shown to be essential in testosterone-mediated upregulation of *Shh*, *Bmp*7, and *Hox*b13, and downregulation of *Bmp*4 expression in the ventral rat prostate. Together, this provides compelling evidence that *Fgf*10 is an androgen-regulated paracrine factor that influences the expression of additional morphogenic genes. In turn, *Fgf*10 is upregulated by *Sox*9 and downregulated by *Shh-ptc-gli* and *Tgf*β1, contributing to a tight regulatory network of genes for controlled bud outgrowth and branching at specific sites.

Bmps/Tgfβ/Activins

Bone morphogenetic proteins (Bmp) are members of the Tgfβ superfamily, and act as inhibitors of proliferation during development.[179] *Bmp*4 is expressed broadly in the mouse and rat urogenital mesenchyme (UGM) before and during bud initiation, subsequently localizes to the periductal mesenchyme of elongating ducts, and declines to nadir levels shortly after birth.[112,180] $Bmp4^{-/-}$ is embryonic lethal; however, heterozygotic $Bmp4^{+/-}$ mouse ventral prostates exhibited increased branching tips consistent with *Bmp*4 acting as a growth inhibitor. Furthermore, organ culture studies with exogenous *Bmp*4 prevented ductal budding and outgrowth.[112,180] Androgens decrease *Bmp*4 expression, in part through *Fgf*10 signaling, indicating that androgens stimulate prostate growth not only through production of growth stimulatory factors but also by downregulation of growth repressors.[140] A second member of the bone morphogenetic protein family, *Bmp*7, has also been shown to play an inhibitory role in prostate development; however, due to expression in distinctly different cell compartments, the mechanisms of growth inhibition are likely different.[153] *Bmp*7 is expressed in mouse UGM prior to bud initiation and prostate epithelial cells postnatally. Null mutant $Bmp7^{-/-}$ mice exhibit a twofold increase in prostate gland branching, and organ cultures studies showed that exogenous *Bmp*7 restricts prostate growth and branching. *Bmp*7 represses *Notch*1 expression, and it is proposed that *Bmp*7 may restrict branching by limiting epithelial domains with *Notch*1 activity.

Bmp actions are locally regulated through *noggin*, a secreted inhibitor of *Bmp*4 and, to a lesser degree, *Bmp*7. *Noggin* binds Bmp ligands in the extracellular space, thereby blocking their ability to activate membrane receptors. Null mutant $noggin^{-/-}$ mice have complete absence of ventral prostate budding and much-reduced budding in the dorsolateral regions, which is likely due to the unopposed action of Bmps.[181]

*Tgf*β1 has also demonstrated a role in growth inhibition in the developing prostate. *Tgf*β1 expression is localized to the rodent periductal mesenchymal cells and the secreted latent protein, once activated extracellularly, drives their differentiation into smooth muscle cells.[182] Furthermore, paracrine actions on developing prostate epithelium play a role in initiating a differentiation program. *Tgf*β receptors *Tgf*βR1 and *Tgf*βR2 are found in both developing prostate stroma and epithelial cells. Organ culture studies with newborn mouse and rat prostates exposed to exogenous *Tgf*β1 exhibited an inhibition of testosterone-induced growth and branching.[183,184] Interestingly, the action of *Tgf*β1 varies along the proximal–distal axis, with inhibition of proliferation in the proximal ducts and stimulation at the distal tips.[185] *Tgf*β1 has been shown to both decrease *Fgf*10 expression as well as redistribute nuclear AR to the cytoplasm, which may contribute to the growth-inhibitory actions of *Tgf*β1.[185,186]

Activins, another member of the *Tgf*β superfamily, are also involved in prostate development. Activins are comprised of homodimers and heterodimers of βA and βB subunits that form activins A, AB, and B. Activin βA is expressed in mesenchymal cells adjacent to the distal tips of prostate ducts, and activin βB is expressed in mesenchymal and fibroblastic stromal cells. Upon differentiation of the epithelium into luminal cells, activin βB is strongly expressed. Exogenous activin A inhibits ductal branching and elongation in newborn rat ventral prostate lobes. Follistatin binds activins and counteracts their actions. Follistatin is expressed in the epithelium of both developing and mature prostates. Newborn prostate culture subjected to follistatin exhibited increased growth and branching, which supports the role of activins as an inhibitor of prostate development.[187] Together these findings support a balanced interaction between activins and follistatins in regulating ductal outgrowth and branching.

Wnt Genes and Secreted Signaling Regulators

Wnt gene products are a family of secreted glycoproteins involved in tissue patterning, cell fate, and proliferation throughout many different tissues.[188–190] The 19 known mammalian Wnt proteins are divided into two categories based on their downstream signaling pathway. Canonical Wnts signal via nuclear β-catenin/TCF-LEF and noncanonical Wnts function via Ca^{+}/PKC or RhoA/JNK. Both pathways involve initial binding to membrane frizzled (Fzd) receptors on target cells; however, the canonical pathway has a cell membrane coreceptor *LRP*5/6 not seen in the noncanonical pathway.[191] Wnt signaling is tightly controlled by multiple secreted negative regulators including Wnt inhibitor factors (WIF), secreted frizzled related proteins (sFRPs), and dickkopf (Dkk) proteins that locally antagonize Wnt actions. This complexity stresses the importance for tight control of Wnt signaling to effect normal development and maintain tissue homeostasis.[192,193]

The numerous functions of Wnt signaling in animal development include crucial morphogenic roles of many, if not most, organs; thus it is expected that this includes the prostate gland. The rodent developing prostate glands express all components of the Wnt signaling system with cell-specific expression of particular Wnt ligands as well as secreted regulators in a spatially restricted and temporal manner. Wnt ligands with high developmental expression, and thus an assumed specific role, include *Wnt*2, *Wnt*2b, *Wnt*4, *Wnt*5a, *Wnt*7a, *Wnt*7b, *Wnt*10b, *Wnt*11, and *Wnt*16.[50,93,194,195] Although the individual roles for each ligand have not been delineated, studies have shown a role for *Wnt*5a in positional identity of buds and an inhibitory role in duct elongation and branching.[113] Constitutive expression of stable β-catenin in prostate epithelium of transgenic mice resulted in epithelial hyperplasia and squamous metaplasia by 8 weeks of age with transdifferentiation to epidermal-like cell lineages suggesting that canonical Wnt signaling plays a key role in prostate cell determination, differentiation, and proliferation.[196] Canonical signaling through *Lef*-1 plays an important androgen-independent role in progenitor cell proliferation at distal tips of elongating buds.[197] Further, recent studies with conditional deletion of β-catenin in transgenic mice revealed an essential role for canonical Wnt signaling in early prostate lineage specification of UGS epithelial cells as well as initial bud outgrowth.[198] A role for β-catenin is also suggested for adult prostate epithelial proliferation, because nuclear β-catenin levels increase in proliferating prostate epithelium of castrated rat prostates following androgen replacement.[199] However, conditional deletion of β-catenin in the adult prostate did not markedly alter homeostasis, suggesting that sustained expression and β-catenin action is not essential in adult prostate epithelium.[198]

Equally important in mediating proper Wnt signaling and directing prostate morphogenesis are the specific secreted Wnt regulators. *SFrp*1 and *sFrp*2 were found to be highly expressed in the early UGM and prostate mesenchyme and somewhat later in ductal epithelium during bud initiation and elongation.[194,200] Using *sFrp*1$^{-/-}$ null mutant mice, this Wnt inhibitor was shown to be a key paracrine modulator of branching morphogenesis, epithelial proliferation, and differentiation through interference in noncanonical Wnt signaling.[201] *Wif*1, which localizes to developing prostate mesenchyme and elongating ducts, is an androgen regulated factor that increases ductal branching through basal cell proliferation.[202] The addition of Dkk1 protein, which specifically interferes with *Lrp*5/6, to prostate explant cultures increased branching, suggesting that canonical

Wnt signaling also plays an inhibitory role with regards to epithelial cell proliferation during development.[50,200]

FUNCTION OF SEX ACCESSORY TISSUES

The main function of the sex accessory tissues is the production of seminal plasma, the nongamete portion of the semen that serves as a buffered, nutrient transport medium for sperm as they are transported to the female genital tract. Although individual components influence the fertilizing capacity of sperm, it is recognized that seminal plasma substances are not required for fertilization of the egg by mature spermatozoa. Normal rates of fertilization are achieved in vitro using epididymal sperm from animals as well as from humans, obtained by testicular sperm extraction or TESE, a now routine procedure in assisted reproductive laboratories. However, it is accepted that the various components of seminal plasma greatly enhance spermatozoa's in vivo capacity for fertilization. Seminal plasma is slightly alkaline (pH 7.2–7.8), which helps to neutralize the acidic environment of the vagina. Seminal plasma is high in fructose, which serves as an immediate energy substrate for sperm at the time of ejaculation. Prostaglandins in seminal plasma increase female genital tract smooth muscle contractions, which aid in sperm transport, while additional factors are believed to prevent premature capacitation and activate enzymes necessary for oocyte penetration. Zinc and IgA serve as bacteriostatic factors while prostatic proteins prevent sperm from autoagglutination (Table 18.1).

TABLE 18.1 Human Seminal Plasma Components

Component	Concentration (mg/dl)
Phosphorylcholine	1000
Prostate-specific antigen (PSA)	50–500
Citric acid	376
Fructose	200
Spermine	50–350
Cholesterol	103
Prostatic acid phosphatase (PAP)	30–100
Phospholipids	83
Prostaglandins	10–30
Zinc	14
Immunoglobulins	
IgG	7–22
IgA	0–6
IgM	Detected

The normal human ejaculate volume is 1–6 ml and is comprised of mature sperm and seminal plasma. Although the average human ejaculate contains 100 million sperm per milliliter, spermatozoa represent less than 1% of the ejaculate volume, the rest being derived from the accessory sex ducts and glands. At the time of emission/ejaculation, the accessory sex glands do not contract simultaneously but rather in an organ-specific sequence. In man, a small initial fraction from the glands of Littre and bulbourethral gland is released prior to ejaculation and lubricates the urethra. Next, a sperm-rich fraction is expelled due to rapid peristaltic contractions from the distal epididymis and vas deferens, comprising about 5% of the volume. This occurs simultaneously with prostatic contractions and secretions, which contribute approximately 25% of the ejaculate volume. Together in humans, this first fraction is 0.3–0.5 ml and contains the greatest concentration of sperm. The last and largest fraction of the ejaculate originates in the seminal vesicles and varies from 1.0–2.5 ml or 75% of the ejaculate volume in man. Exceptions to this sequence include the bull, where accessory sex glands contract simultaneously, and the dog, which has no seminal vesicles.

The production of seminal plasma is under hormonal control and driven by the presence of androgens, which are always present in normal males. Seminal secretions that do not become the part of an ejaculate are thought to either be passively resorbed by surrounding tissues or expelled via the urethra during urination. During sexual activity, emission is the process by which spermatozoa and seminal plasma are expelled from the accessory sex structures into the urethra. Emission occurs due to contractile tissues in the vas deferens, seminal vesicles, and prostate, which are believed to be largely under alpha adrenergic control. Ejaculation is a separate process, also under sympathetic control, by which the contents of the urethra are expelled from the penis via the urethral meatus. Ejaculation is a penile event beyond the scope of this chapter and covered elsewhere in this textbook.

Coagulation/Liquefaction

Semen coagulates soon after ejaculation due to clotting factors produced by the seminal vesicles and forms a gelatinous mass. This coagulation process, while similar to blood coagulation, is unique to semen and is not inhibited by sodium citrate or heparin and does not involve prothrombin, fibrinogen, or the hematologic clotting factors. Under electron microscopy, coagulated semen contains a dense network of fibers, which trap and restrict the movement of spermatozoa.[203] The main protein products forming the fibrous coagulum are semenogelin I and II, which are produced in the seminal vesicles. The coagulated semen liquefies after 15–60 min

due to proteolytic enzymes produced in the prostatic secretions, including seminin, plasminogen activators, and PSA. This subsequent liquefaction frees the sperm, which can continue their journey to the uterus and beyond. This coagulation permits coating of the sperm with nutrients and factors that contribute to fertilization (e.g., capacitation factor) and also permits deposition of the sperm near the vaginal os. The subsequent liquefaction allows sperm to swim out of the coagulum and into the cervix and uterus. Absent or incomplete liquefaction process can lead to reduced fertility potential, and addition of α-amylase to the semen in the laboratory can rectify this problem. Some rodents produce additional coagulating products produced by a separate coagulating gland, leading to a hardened copulatory plug within the vagina, which prevents backflow of semen from the female reproductive tract.

Components of Seminal Plasma

Mammalian seminal plasma contains a large number of components and considerable variation exists between species. Some are present in the serum and are likely exudates from the circulation, whereas others are produced solely by the accessory sex glands, ducts, and testes, and are unique to seminal plasma. Due to the wide interspecies variability in sex accessory tissues and semen composition, this section will focus on human seminal plasma except where otherwise noted.

Zinc

Normal human seminal plasma contains over 100 times the concentration of zinc compared to serum with a mean value of 140 μg/ml.[204] This high level of zinc comes from the prostate, which has the highest concentration of zinc of any organ in the body.[205] There have been many theories regarding the physiologic role of zinc in the prostate and seminal plasma. There are many known zinc-containing metalloenzymes; however, the levels seen within the prostate would exceed that needed for such enzymes. Zinc is also known to bind multiple proteins,[206,207] and zinc in the seminal plasma may be involved in regulation of liquefaction by binding to semenogelin I and II.[208] Zinc may also serve as an antibacterial factor in both seminal plasma and non-ejaculatory prostatic secretions. In concentrations normally found in prostatic secretions, in vitro studies have shown zinc to be bactericidal against a variety of gram-positive and gram-negative bacteria. Additionally, expressed prostatic secretions from 36 normal men without bacterial infection had a mean value zinc concentration of 350 μg/ml compared to secretions in 15 patients with a documented history of chronic bacterial prostatitis with mean zinc levels of only 50 μg/ml.[207] Further study is needed to determine the precise cause and effect relationship between chronic bacterial prostatitis and zinc levels.

Citric Acid

The concentration of citrate in the ejaculate (mean, 376 mg/dl) is 500–1000 times higher than that in blood plasma. It is one of the major anions of human seminal plasma and is a potent binder of metal ions. Its concentration (20 mM) is similar to that of the divalent metals together, 13.6 mM (calcium 7 mM; magnesium 4.5 mM; zinc 2.1 mM). Seminal plasma citrate predominantly originates in the prostate, with a 100-fold less concentration found in seminal vesicle secretions.[209] The high levels of citrate have been linked to the decreased ability of prostatic mitochondria to oxidize citrate, which results in an imbalance between citrate production and oxidation.[210,211] Kavanagh[212] measured citrate and isocitrate levels and found the prostate to have a 33:1 ratio, whereas other tissues demonstrated 10:1 ratios. This finding suggests decreased aconitase activity as the reason behind such high citrate levels in prostatic secretions.

Fructose

Seminal plasma has a high concentration of fructose (mean, 200 mg/dl), which originates in the seminal vesicles.[203] Based on this, a fructose test on semen is used clinically to evaluate the seminal vesicle contribution to the ejaculate and evaluate potential ejaculatory duct obstruction. Additionally, this can aid in determining the etiology of azoospermia, because congenital absence of the seminal vesicles always occurs with absence of the vas deferens leading to ejaculatory azoospermia despite the potential presence of testicular spermatogenesis.[213] The seminal vesicles also secrete smaller amounts of other free sugars including glucose, sorbitol, ribose, and fructose, but the sum total of these is less than 1/20th the concentration of fructose. This high level of fructose is under androgenic regulation, but other factors such as blood glucose level, frequency of ejaculation, and nutritional status affect the seminal vesicle concentration. Because of the many factors involved, a wide variation in seminal plasma fructose levels can be seen in different semen samples from a single patient.[203]

Fructose in the seminal vesicles is produced from glucose, which undergoes aldose reduction to sorbitol, then ketone reduction to fructose. Fructose in the seminal plasma provides both an aerobic and anaerobic source of energy for spermatozoa. Additionally, cervical mucus has high concentrations of glucose with very little fructose, but sperm are capable of utilizing either sugar for energy.[203]

Phosphorylcholine

Mammalian semen is rich in choline produced mainly in the epididymis, and in the human, phosphorylcholine

predominates. Phosphorylcholine is a specific substrate for PAP, an enzyme that is active in the seminal plasma. This enzymatic reaction results in the rapid formation of choline in the ejaculate. These choline compounds are not metabolized by, nor do they affect the respiration of sperm, and their physiologic role is unclear.[214]

Spermine

Polyamines are basic, positively charged, small organic molecules. They are found in all eukaryotic cells and are believed to be involved in a variety of physiologic processes including cell proliferation. Spermine, a polyamine first discovered in semen, is found in seminal plasma at concentrations of 50–350 mg/dl and gives semen its unique odor. The prostate is the source of spermine and has the highest levels found in the body. The rate-limiting step in the synthesis of polyamines and spermine is mediated by the enzyme ornithine decarboxylase (ODC). ODC expression has been studied in BPH tissue and found to be increased suggesting a possible role for polyamines in that disease process.

Spermine has four positive charges, which bind strongly to acidic or negatively charged molecules such as phosphate ions, nucleic acids, or phospholipids. Spermine is created via a series of enzymatic reactions on other polyamines that proceed from ornithine to putrescine to spermidine to spermine. Spermine is oxidized enzymatically by diamine oxidase, which is found in the seminal plasma. The aldehyde products from this reaction are very reactive and toxic to both sperm and bacteria.[215,216] This is one reason why prolonged exposure of sperm to seminal plasma will reduce its fertilizing capacity.

Prostaglandins

In 1934, von Euler coined the term "prostaglandins" to describe the active components in seminal plasma in the assumption that they were produced by the prostate. Over 20 years later, Eliasson determined that the seminal vesicles were the primary producer of prostaglandins; however, the name stands to this day.[217] Prostaglandins are found in a wide variety of tissues, but the seminal vesicles have the highest levels by far in humans. The seminal plasma contains 15 different prostaglandins at a concentration of 100–300 μg/ml. Prostaglandins are 20-carbon hydroxyl fatty acids containing a cyclopentane ring and two side chains. They are classified into four major groups (A, B, E, and F) based on the structure of the cyclopentane ring and given a number based on the structure of the side chain (e.g., PGE3).

The E group of prostaglandins predominates in the male reproductive tract, while the F group predominates in the female. Prostaglandins have a variety of potent proposed physiologic effects in the male and are involved in erection, ejaculation, sperm motility, and testicular and penile contractions. Additionally, seminal fluid prostaglandins deposited in the vagina affect cervical mucus, vaginal secretions, uterine contractions, and thus rapid transport of sperm in the female genital tract independent of their motility.

Cholesterol and Lipids

Human seminal plasma contains 185 mg/dl of total lipids, 103 mg/dl of cholesterol, and 83 mg/dl of phospholipids. The phospholipids have been further characterized as 44% sphingomyelin, 12.3% ethanolamine plasmalogen, and 11.2% phosphatidylserine. It has been proposed that the ratio of cholesterol to phospholipid helps stabilize the sperm against temperature and environmental shock.[218,219]

Immunoglobulins

Immunoglobulins are found in the seminal plasma at levels lower than in blood. Specifically, IgG is measured from 7 to 22 mg/dl and IgA from 0 to 6 mg/dl. IgM has also been detected in the seminal plasma at very low levels.[220] Given the lower levels of immunoglobulins, it is theorized that these may simply be exudates; however, IgA has been localized more to the bulbourethral glands and suggests an immunologic component to the bulbourethral gland function.

Acid Phosphatase

Acid phosphatase activity is more than 200 times more abundant in the prostate than any other tissue. PAP is a 102-kd glycoprotein dimer with seminal plasma levels of 0.3–1 g/l. Interestingly, the level of PAP in the human prostate is 1000 times higher per gram of tissue than in the rat prostate. The substrate for PAP in the seminal plasma may be phosphorylcholine phosphate, which is rapidly hydrolyzed by the enzyme. However, the physiologic significance of the high levels of PAP and their function are not well understood.[221,222] There was previously greater interest in acid phosphatase assays in serum as a potential marker of metastatic prostate cancer; however, this interest has waned with the more sensitive and specific assay for PSA.

Prostate-Specific Antigen

PSA is a 33-kd glycoprotein that acts as a serine protease and is produced almost exclusively in prostate epithelial cells.[223] PSA is involved in lysing the ejaculatory clot with semenogelin as its substrate. The PSA gene (*hKLK3*) is a member of the kallikrein family of genes, which are all located on chromosome 19.[224] Clinically, PSA is used as an important serum marker for prostate cancer and prostate disease, because its presence in the circulation indicates a breakdown in the epithelial/basement membrane barrier. Unfortunately, while PSA is organ-specific, it is not cancer-specific and is found

in the serum of patients with BPH as well as prostatitis. PSA is found in seminal plasma in concentrations from 0.5 to 5 mg/ml, whereas PSA in serum of men 50–80 years of age without prostate disease is 1000-fold less, at 1.0–4.0 ng/ml.[225] The serum level of PSA in men with prostate cancer is generally elevated (>4.0 ng/ml), but not until its level is >10 ng/ml does this measurement suggest specificity for prostate cancer. As prostate cancer cells remain AR-dependent, even in the absence of androgens, circulating levels of PSA in patients with metastatic disease can reach into the hundreds and monitoring levels over time can be a useful indicator of progression and relapse after treatment failure.[226,227]

REGULATION OF THE ADULT PROSTATE

As with the developing accessory sex glands, the normal adult prostate, seminal vesicles, and bulbourethral glands are hormone-regulated and hormone-dependent tissues, requiring continued support for their homeostasis and functional activity. Although this is primarily mediated through androgens, other hormones influence these glands as well. Again, the majority of research on this topic has focused on the prostate, which will be highlighted here. In essence, the hormones that maintain the adult prostate can be divided into two categories, the steroidal and protein hormones. These hormones and their molecular mechanisms of action are described in greater detail in Chapters 9, 16 and 20.

Steroid Hormones

Androgens

The adult male accessory glands are entirely dependent on androgen action, mediated through AR, for homeostasis and functional activity. Removal of androgens results in rapid involution of the prostate epithelium, and to a lesser degree, stromal cells (within days) through programmed cell death or apoptosis.[228] This action is the basis for androgen deprivation therapy for the treatment of prostate cancer for which Charles Huggins was awarded the Nobel Prize in 1966.[229] Androgen replacement restores prostate size through rapid proliferation of stromal and epithelial cells and restores secretory capacity in the epithelium. Importantly, once prostate cell numbers reach baseline adult levels, negative feedback mechanisms, involving stromal–epithelial cross-talk through secreted growth regulators, result in growth cessation and prevent overgrowth of the gland. For the most part, these factors include many of the same mediators (e.g., *Tgf*β_1, *Bmp*4, and activin A) that regulate normal development as discussed above.[230]

Most androgens used by prostate cells are synthesized in the testes, although adrenal androgens can contribute to prostate health and disease. Testosterone enters prostate cells through passive diffusion as well as sex hormone binding globulin (SHBG)-facilitated transport and is rapidly and irreversibly metabolized to DHT by 5α-reductase (SRD5A1, SRD5A2) expressed in prostate cells.[231] DHT formation is highest in stromal cells and it rapidly diffuses into the prostate epithelium, although the epithelial cells also express this enzyme. Due to its higher affinity for the AR relative to testosterone, DHT is considered the primary androgen for the prostate, although testosterone can mediate similar effects.[232] The differential potency of AR for the separate androgens permits higher androgenic actions in the androgen-dependent prostate, seminal vesicles, and bulbourethral glands under physiologic circulating levels of testosterone.[233]

AR is expressed at high levels in all adult prostate luminal epithelial cells, while the basal and neuroendocrine cells are largely AR$^-$.[38,234] AR expression in adult prostate stroma is highest in smooth muscle cells with variable expression in fibroblasts.[38,234] Although prostatic endothelial cells are AR$^-$, vascular smooth muscle cells express AR and rapidly respond to androgen actions.[235] In the adult prostate, androgens primarily function to regulate the secretory activity of luminal prostate epithelial cells in addition to maintenance of homeostatic growth and survival. Thus the production of PSA, PAP, and multiple other secreted proteins in the human prostate (discussed later) and PBP and probasin in the rat prostate are under the direct regulation of DHT-AR at the promoter level of regulated genes. In contrast, androgen-mediated growth homeostasis of the adult prostate gland is primarily mediated through AR in stromal cells that regulate paracrine signaling between stromal and epithelial cells to control limited cell renewal and apoptosis. Of note, recent research has also determined that epithelial cell AR serves as a negative regulator of epithelial cell proliferation in the adult prostate, thus maintaining tight control over tissue size.[70]

Estrogens

Aging males are exposed to relatively higher levels of circulating estradiol, which have been shown to impact the prostate gland. In addition, estrogens are produced locally within the prostate via conversion of testosterone to 17β-estradiol by aromatase expressed within the prostate stroma[236,237]; thus estrogen action in the prostate can occur independent of serum levels of this steroid. The relative levels of free circulating estrogens increase as men age, which can increase estrogenic action in the prostate gland. Bioavailable testosterone levels decline in the aging male due to decreased production by the testis and increased SHGB levels combine to lower

free circulating testosterone.[238] However, circulating levels of free estradiol remain constant in the aging male due to an age-related increase in body weight and adipose cells, which express high levels of aromatase and peripherally convert androgens to estrogens.[239] The net result is a significant increase in the estrogen to testosterone ratio, allowing the balance between androgen and estrogen regulation of prostate growth to shift towards estrogen dominance. It has been proposed that increased estrogenic stimulation of the prostate in the aging male may lead to reactivation of growth and subsequent neoplastic transformation.[240,241]

Estrogen action in the adult prostate is mediated through ERα and ERβ, which are expressed in different cellular compartments of the prostate gland; ERα localizes to scattered prostatic stromal cells and ERβ is primarily expressed in prostate epithelium. This differential location as well as differential affinity of the two ERs for ligands, enhancers and co-activators may explain the diverse biological functions of estrogens within the prostate gland and may also be exploited for regulation of prostate disease. Recent reviews on ERs and their actions in the prostate gland provide extensive details of their expression, mechanisms of action, and functional roles.[242–244] In brief, ERβ is the predominant estrogen receptor expressed in both basal and luminal cells of the adult prostate gland, where it plays a role in maintaining the differentiated state of the epithelium. A study using βERKO mice ($ER\beta^{-/-}$) showed a shift in basal, intermediate, and luminal epithelial cell markers in the prostate towards a less differentiated gland that supports this function.[245] ERβ also has an important antiproliferative role in the prostate and participates as a brake for androgenic stimulation of prostate growth.[244,246] Further, it maintains prostate epithelial numbers in the adult prostate through targeted apoptosis of the basal and progenitor cell population, thus contributing to growth regulation of the adult gland.[247]

Retinoids and Vitamin D

Retinoic acid and retinoids are derivatives of vitamin A and play a major role in organ development and tissue homeostasis. Their actions are mediated through retinoid receptors RARα, β, γ, and RXRα, β, γ, which form RAR/RXR dimers that directly regulate target gene expression.[117] Adult human prostate stem and progenitor cells from disease-free donors express RARs and RXRs, and treatment with retinoic acid drives their differentiation into a luminal cell fate, indicating that retinoids maintain epithelial homeostatis in the adult gland.[84] Retinoic acid and its synthetic analogs trigger antiproliferative effects and differentiation in a variety of tumor cells, which has led to much research as potential anticarcinogenic agents. Many studies have explored the usefulness of retinoids in chemoprevention and treatment of prostate cancer, although mixed results have limited their widespread use in this regard.[248–250]

Vitamin D_3 is synthesized in the skin via ultraviolet light exposure and is also acquired in the diet. Following metabolism to the bioactive 1,25 hydroxyvitamin D_3 (1,25OH-D_3), this hormone binds to the vitamin D receptor (VDR), which forms an obligate heterodimer with RXRα to regulate gene transcription in target cells. Conversion of 25OH-D_3 to the active 1,25OH-D_3 by CYP27B1 occurs within the normal prostate and indicates that local production of this hormone may play a critical role in normal growth and differentiation.[251] VDR/RXRα are highly expressed in normal prostate epithelium where vitamin D_3 regulates hundreds of genes and possesses chemopreventive activities against prostate carcinogenesis.[252] Vitamin D_3 has antiproliferative and prodifferentiation effects on prostate epithelium, which is the basis for its chemopreventive actions. VDR null mutant mice produce more aggressive tumors when crossed with transgenic mice targeted for prostate cancer, further supporting the anticancer properties of vitamin D_3.[253] Recently, 1,25OH-D_3 was shown to induce cell cycle arrest in adult mouse prostate epithelial stem/progenitor populations and drive them towards luminal epithelial cell differentiation.[254] These findings for vitamin D_3, similar to the retinoid findings, are suggestive of a possible chemopreventive or therapeutic role by targeting adult prostate stem/progenitor cells, limiting their proliferation, and driving them into differentiated phenotypes. Whether this would be applicable to prostate cancer stem cells remains to be determined.

Protein Hormones

Prolactin

Prolactin (PRL) has direct effects on the prostate gland through PRL receptors (PRLR) expressed by prostate epithelial cells. Seminal work by Grayhack and others established that PRL drives prostate growth and enhances its secretory capacity.[255,256] Later studies revealed that PRL mediates these actions in part through upregulation of AR[257] as well as through direct and androgen-independent pathways.[258,259] Equally important, the rodent and human prostates produce their own PRL.[260,261] Extensive studies by Nevalainen have established that downstream actions of PRL in prostate cells are mediated through the *PRL-Jak*2-*Stat*5a/b signaling.[262]

Growth Hormone and Insulin-Like Growth Factor

Growth hormone (GH) has both direct and indirect actions on the prostate gland through GH receptors (GHR) expressed on epithelial cells as well through induction of hepatic synthesis of *Igf*-1. Clinical and epidemiological studies suggest that the GH/IGF axis is

important for normal human prostate growth. Chronic GH deficiency in adulthood is associated with reduced prostate volume,[263] whereas the prevalence of prostate hyperplasia was lower in GH-deficient patients as compared to controls.[264] Further, acromegalics have enlarged prostates that decrease significantly in size in response to somatostatin analogs or after surgical removal of a pituitary tumor to lower GH levels.[265]

Insulin-like growth factor-1 (Igf-1) is an important mediator of many of the biological activities of GH through *Igf*R expressed on target cells[266] and this is an important pathway for prostate development and homeostasis as well. *Igf*-1/*Igf*R signaling activates multiple downstream pathways, most notable p-*Akt* activation, leading to proliferation, differentiation, and proapoptotic actions. Conditional deletion of *Igf*1R in adult transgenic mice led to a hyperproliferative prostate epithelium indicating that the *Igf*-1/*Igf*R axis plays a key role in limiting cell proliferation.[267] Similarly, in normal adult human prostate epithelial cells, IGF promoted differentiation to luminal cells and not proliferation.[268]

Although there is ample evidence in human and animal studies that the *Igf*-1/*Igf*R axis plays an important role in prostate growth and homeostasis, it is important to note that not all of GH actions on the prostate are mediated through this downstream effector. Rodent models with deletion of the GH or GHR axis through spontaneous or targeted deletion have suggested a direct role of GH signaling independent of *Igf*-1 in maintaining normal prostate size and facilitating carcinogenesis and progression with aging.[269] This is supported by further studies that show that targeted deletion of hepatic *Igf*-1 is not sufficient to inhibit prostate cancer progression.[270] Taken together, these findings suggest that concomitant regulation of *Igf*-1 signaling and reduction in GH levels may be more effective in managing prostate disease.

Endocrine Disrupting Chemicals

Increasing evidence from both epidemiologic studies and animal models has implicated certain environmental chemicals as possibly influencing the development or progression of prostate diseases.[271–273] In most instances, these compounds are known endocrine disrupting chemicals (EDCs) and effects appear to be primarily, although not exclusively, linked to estrogen and androgen signaling, either by interacting directly with receptors or by influencing steroid metabolism and altering endogenous hormone levels.[271] The chemicals showing associations with aberrant growth and prostate cancer include certain pesticides (atrazine, chlorpyrifos, fonofos, phorate), arsenic, polychlorinated biphenols (PCBs), and bisphenol A (BPA). Unfortunately, these EDCs perturb homeostasis at low, environmentally relevant levels. because they hijack the endocrine system, which itself is geared to rapidly respond to low circulating levels of hormones in the picomolar and nanomolar range. This necessitates the widespread screening of manmade chemicals for hormone activity, a focused goal by the Environmental Protection Agency (EPA) and other regulatory agencies worldwide. Further, it demands that policymakers mandate effective screening strategies and regulations going forward (e.g., Toxic Chemicals Safety Act, or TSCA) to limit EDC exposures that may harm wildlife and human health.

DISEASES OF THE PROSTATE GLAND

Prostate Cancer

Prostate cancer is the most common noncutaneous malignancy in men in the United States. One in six American men will be diagnosed with prostate cancer and one in 36 will die of this disease, making prostate cancer a leading cause of cancer deaths (Figure 18.8), second only to lung cancer.[2] Prostate cancer poses a particular challenge to clinicians in that it has a high prevalence but is often an indolent disease. Autopsy studies have found prostate cancer in approximately 42% of American men 50 years or older who died of causes other than prostate cancer.[274,275] Prostate cancer is rarely diagnosed in men younger than 50, representing only 2% of cases, and has a median age of diagnosis of 68 years.[276,277] African American men have the highest incidence of prostate cancer worldwide, with a relative incidence of 1.6 as compared to Caucasian-American men. Furthermore, African-Americans with prostate cancer are more than twice as likely to die of the disease as Caucasian men.[2]

Prostate cancer is most likely to arise in the peripheral zone, which accounts for 70% or more of cases. The transition zone accounts for 10–20% of cases; and although the central zone comprises approximately 15–25% of the glandular volume in the prostate, only 1–5% of prostate cancers arise in this region.

Prostate cancer that has not metastasized is a curable disease, with most patients choosing either surgical removal through radical prostatectomy or radiation therapy. Unfortunately, both of these therapies have significant long-term risks associated with them, including impotence and incontinence, making it of critical importance to identify patients with indolent versus aggressive prostate cancer to best determine who would benefit from treatment versus surveillance. These indicators are not presently available, and continued research for blood and urinary markers as well as molecular markers in biopsy specimens is urgently needed. Aggressive prostate cancer that has progressed and metastasized is initially responsive to androgen

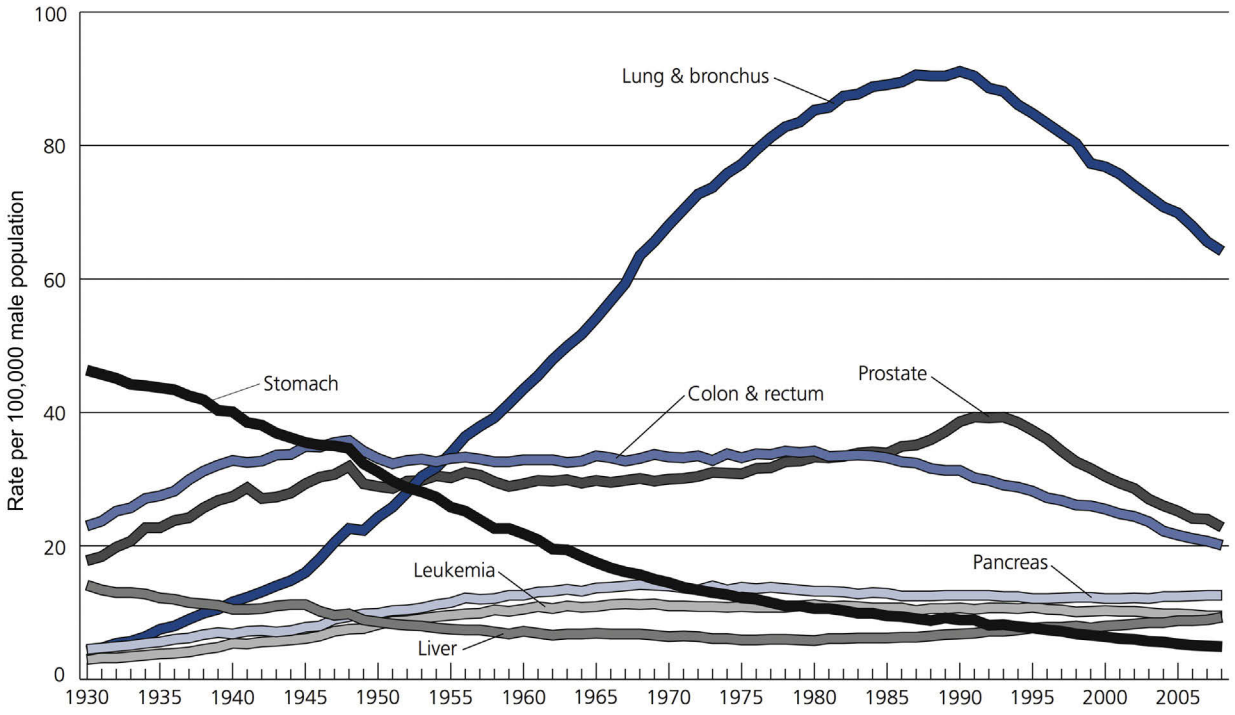

FIGURE 18.8 Age-adjusted American male cancer death rates (per 100,000, age adjusted to the 2000 US standard population) by site, US 1930–2008. Note: Due to changes in ICD coding, numerator information has changed over time. Rates for cancer of the liver, lung and bronchus, and colon and rectum are affected by these coding changes. *Source: From American Cancer Society; US Mortality Volumes 1930 to 1959, US Mortality Data 1960 to 2008, National Center for Health Statistics, Centers for Disease Control and Prevention.*

deprivation therapy, with patients going into remission for variable periods of time. However, prostate cancer almost universally becomes an androgen-independent disease and progresses despite androgen ablation after 12–36 months.[278–280] Although this castration-resistant prostate cancer (CRPC) is androgen-independent, it is important to stress that it remains AR-dependent in the vast majority of cases due to AR mutations, overexpression, ligand-independent activation, and autocrine production of local androgens by the cancer cells themselves. Thus new generation treatment modalities include, among other approaches, compounds that inhibit AR action and nuclear AR localization to prevent downstream signaling as well as novel steroid synthesis inhibitors.[281] The number of drugs available for CRPC has grown considerably in the past few years, with even more agents currently in trials, which will hopefully expand the arsenal of therapeutics against this challenging and deadly disease.

Prostate Cancer Stem Cells

A great amount of research effort over the past decade has gone into understanding the rare stem cell in the prostate gland and how its regulation and physiology may provide insight into the origin and treatment of prostate cancer. The cell of origin of prostate cancer, known as the tumor-initiating cell, appears to be heterogeneous and can include the differentiated basal, luminal, and perhaps neuroendocrine cells or involve transformation of the stem or early progenitor cells themselves, as has been shown in the hematopoietic system.[282–284] Regardless of origin, it is becoming clear that prostate cancers have stem cells of their own, which seed and maintain tumor growth. Evidence has shown that prostate cancer stem cells are highly resistant to hormonal and chemotherapy and are responsible for continuously seeding and maintaining growth, which may be the root cause of relapse after androgen ablative therapy ceases to work.[285] Learning more about normal prostate stem cells and prostate cancer stem cells in the future may lead to novel strategies for effectively treating prostate cancer.

Hormonal Influence

Aberrant AR signaling plays an essential role in both androgen-dependent and androgen-independent prostate carcinogenesis and progression. There are multiple factors that account for this, including AR polymorphisms, AR gain-of-function mutations, AR gene amplification, expression of AR variants lacking a ligand-binding domain, post-translational

modifications, alterations in AR co-regulators, and activation of AR through kinase cascades.[286–288] Androgens are also involved in mediating epithelial-mesenchymal transition of transformed epithelial cells, an initial step for metastatic spread.[289] Further, there is strong evidence for aberrant metabolism of androgens in prostate carcinogenesis and progression.[290] Readers are referred to these pertinent reviews for greater detail.

Estrogens play a significant role in the etiology and progression of prostate diseases in the aging male. There is a clear role for estrogens in mediating prostate carcinogenesis and prostate cancer progression, driving BPH, and as an underlying cause of some forms of prostatitis. These effects are mediated through ERα, ERβ, and the more recently characterized G-protein coupled receptor, GPR30, which facilitates estrogen actions at the cell membrane.[86,291–293] The readers are referred to recent comprehensive reviews on estrogen's action in abnormal growth and disease of the prostate.[242–244,294]

Elevated circulating levels of PRL that occur in some aging men have been shown to promote BPH and stimulate prostatitis in animal models.[295–297] Equally important, the rodent and human prostates produce their own PRL, and dysregulation of this signaling pathway can drive prostate carcinogenesis and progression.[260,261] Extensive studies by Nevalainen have established that downstream actions of PRL in prostate cells are mediated through the *PRL-Jak*2-*Stat*5a/b signaling.[262] Current work by this group is focused on utilizing this axis as an effective chemopreventive and therapeutic target for prostate cancer treatment.[262,298] Importantly, this approach shows potential for treating prostate diseases through a nonsteroidal axis, which universally fails due to the emergence of androgen-independent disease.

GH signaling has been shown to regulate proliferation of human prostate cancer cell lines, and their growth is slowed when transplanted in GH-deficient Little mice (*Ghrhr*$^{lit/lit}$) relative to controls.[299,300] These studies support the notion that GH signaling is important for the growth of advanced human prostate cancers.

In contrast, IGF treatment to prostate cancer cells stimulates cell proliferation, suggesting a differential response to this signaling axis in the transformed state.[268] Prospective epidemiology studies identified a positive association between serum IGF-I and prostate cancer risk,[301–303] and current clinical trials targeting this axis with specific antibodies and small molecules show therapeutic potential.

Benign Prostatic Hyperplasia

Nonmalignant growth of the prostate with age, BPH, occurs in 40–50% of men by age 50, and over 80% of men in their 80s.[3] This prostatic overgrowth can lead to urinary symptoms and, in severe cases, obstruction. Up to half of all men by the age of 70 have urinary symptoms that warrant daily medication or surgery, and the majority of these symptomatic patients have an enlarged prostate as a cause of their suffering.[304,305] BPH predominantly occurs in the periurethral transition zone, which can subsequently impinge on the urine flow through the prostatic urethra and become an obstructive process. BPH is a hyperplastic not a hypertrophic process, in which there is a net increase in the number of cells and not the size of cells.[306] This includes increased epithelial cell proliferation as well as stromal cell hyperplasia, which may underlie the disease through stromal–epithelial growth induction. Medical treatments for BPH and lower urinary tract symptoms include 5α-reductase inhibitors, which block the conversion of testosterone to DHT, resulting in a significant reduction in the volume of the prostate as well as symptoms in men with enlarged prostates.[307] The alpha-adrenergic blockers are another treatment option for BPH, which address the active component of obstruction by inhibiting α1 receptors on smooth muscle cells in the prostate and bladder neck, causing relaxation and improvement in symptoms in many patients.[308] Patients with symptoms refractory to medical treatment can benefit from a variety of procedures that all have the common goal of removing the offending enlarged portion of the prostate. These procedures include open surgical removal of the prostate adenoma and a variety of transurethral endoscopic procedures including transurethral resection of the prostate (TURP), laser ablation, microwave ablation, radiofrequency needle ablation, and electrical vaporization of the prostate.

Prostatitis

The prostate is also susceptible to an inflammatory process called prostatitis, which causes pelvic pain. Up to 16% of all men have this condition diagnosed in either an acute or chronic form at some time in their lives. The etiology of their prostatitis is tied to a known bacterial cause in less than 10% of cases, with the majority being idiopathic.[309] Prostatitis is classified into four categories: category I acute bacterial prostatitis, category II chronic bacterial prostatitis, category III chronic (nonbacterial) pelvic pain syndrome, and category IV asymptomatic inflammatory prostatitis, which is incidentally found as inflammation in a pathology specimen. Treatment depends on the category of prostatitis and includes culture-directed antibiotics, empiric antibiotics, nonsteroidal anti-inflammatory drugs, and alpha-adrenergic blockers particularly in patients with concomitant lower urinary tract symptoms. The etiology of nonbacterial prostatitis is unclear, with various proposed mechanisms including an autoimmune response, dysregulated cytokine production, a neurogenic cause, and a hormonal

basis involving elevated estrogens and prolactin with aging.[310] Further research is needed to better understand and treat this widespread disease.

CONCLUSION

The prostate continues to have an enormous impact on men's health due to its highly prevalent diseases: prostate cancer, BPH, and prostatitis. Multiple key areas of research have been identified to better understand the pathophysiology of prostate disease. Androgen signaling plays a crucial role in prostate development, growth, and homeostasis throughout life, and similarly, androgens and the AR are an integral part of prostate cancer growth and BPH. Other hormones such as estrogen, PRL, and GH, which have been less studied in relation to the prostate, contribute to physiologic and pathophysiologic processes. Disruption of endocrine signaling from environmental substances has also been implicated as a contributing factor in prostate disease. Future research is required to identify the molecular intricacies of this hormonal interplay that is intimately involved in dysregulated growth of this organ with aging. In addition to hormonal signaling, much more work is needed to better understand the exceedingly complex interactions between the stroma and epithelia of the prostate in development and normal maintenance as well as the communication breakdown that occurs in prostate disease. Another critical research concern is the prostate stem cell and prostate cancer stem cell, which may hold the key to future prostate cancer therapies. Our knowledge of prostate physiology and disease has grown by leaps and bounds since the first edition of this text in 1988, but many questions remain and the prostate continues to impact men's health greatly. It is hoped that continued research in this field may lead to future treatments and cures for these aging-associated diseases. In contrast to the prostate, relatively little work has been performed on the more enigmatic bulbourethral gland and seminal vesicle, largely due to their lack of disease. Nonetheless, a clearer understanding of all of the sex accessory glands' physiology and the interaction between sperm, seminal plasma, and the female reproductive tract may lead to better understanding of and treatment for male infertility.

The Immunophysiology of Male Reproduction

Mark P. Hedger

Monash Institute of Medical Research, Monash University, Melbourne, VIC, Australia

INTRODUCTION

The Male Reproductive Tract as a Unique Immunological Environment

The male reproductive tract, and the male gamete especially, present a unique challenge to the immune system. The human testis continuously produces highly differentiated sperm derived from a pool of spermatogonial stem cells at a level of productivity and complexity matched only by the hematopoietic system. In contrast to the hematopoietic tissues, however, differentiated sperm first appear at the time of sexual maturation, long after the maturation of the immune system and the establishment of systemic immune tolerance (Figure 19.1).[1] In humans, the period between the editing of the lymphocyte repertoire and the first appearance of significant numbers of the earliest premeiotic germ cell (the spermatocytes) is generally more than 10 years. As a consequence, spermatogenic cells express many cell-specific proteins and other molecules that have the potential to be seen as "foreign" or "nonself" by the immune system.

We know that the immune system tends to view spermatogenic cells as foreign because of the relatively high incidence of autoimmune infertility among human populations. Even in developed countries with modern health care, sperm autoantibodies represent 5–10% of all male infertility,[2,3] while testicular biopsies from infertile men frequently display evidence of asymptomatic inflammatory reactions.[4,5] In other forms of autoimmune disease, such as type 1 diabetes or gastritis, the development of autoimmunity is due to disruption of the normal regulatory controls of the immune system, leading to reactions against antigens that normally are ignored. Only a limited number of antigens are involved and a specific dominant autoantigen usually has been identified.[6] In the case of the male reproductive tract, by contrast, autoimmunity generally involves antigens that would not be edited out of the self-reactive repertoire in the first place. Hence, autoimmune infertility generally involves multiple antigens as well as different antigens from one individual to another.[7–9] Moreover, infertility is not the only urological problem with an immunological basis. Chronic pelvic inflammatory disease in men, which may be accompanied by recurrent and even debilitating perineal or scrotal pain, is a serious and frequently intractable condition.[10–12] Infections may represent the initial cause of the majority of such cases, but the underlying mechanisms almost certainly involve an autoimmune component.[10]

Unraveling the origin of these immunologically-based disturbances of reproductive function is an important clinical goal, but the converse, and equally important, scientific question is: *What is it about the male reproductive tract that permits the continuous production of huge numbers of immunogenic cells expressing multiple autoantigens without apparent problems in the majority of individuals?* In most respects, the immune system within the male reproductive tract appears relatively normal, with effective lymphatic drainage and relatively free access of immune cells.[13,14] Certainly, there are some unique structural characteristics of the male reproductive tract that may contribute. For example, the male gametes are held at a substantially lower temperature than the rest of the body in species with scrotal testes and epididymides. There also exists a very effective blood–testis barrier that sequesters most of the spermatogenic cells in the testis.[15–18] Nonetheless, these physical elements cannot account for all the manifestations of immunological protection in the male reproductive tract.

Instead, studies over many years have confirmed that the male reproductive tract, and the testis in particular, constitutes a unique immunoregulatory environment. There are communication and regulatory networks that are common to both male reproduction and the immune system, providing many striking overlaps between the

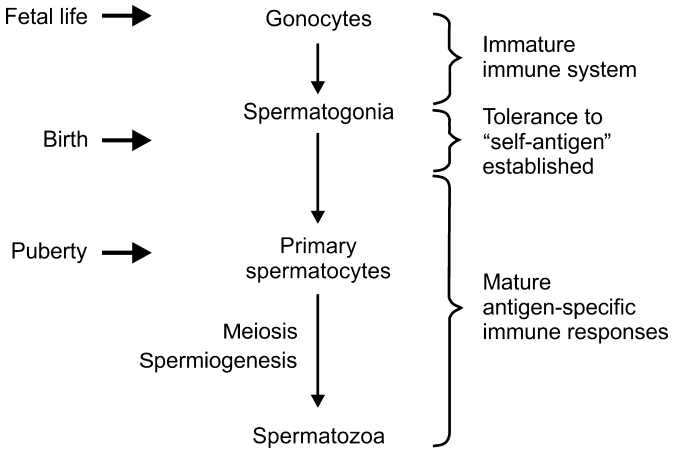

FIGURE 19.1 Developmental timeline of spermatogenesis and the maturation of the immune system. The majority of spermatogenic cells do not appear in the testis until the initiation of meiosis at puberty, whereas tolerance to self-antigen is largely established by the time of birth. As the development of spermatozoa from the spermatogonial stem cell population involves complex processes of nuclear reorganization (meiosis) and cellular differentiation (spermiogenesis) that are unique to the testis, there exists enormous potential for antigens of spermatogenesis to evade conventional tolerance mechanisms.

control of spermatogenesis and the processes of inflammation and immune activation. Part of this network includes local immunoregulatory and immunosuppressive mechanisms, which exist to provide protection for the endogenous antigens of spermatogenesis, protection that also extends to antigens expressed by foreign grafts inserted into the testis environment.[19] Immune cells that enter the environment of the male reproductive tract become functionally modified to restrict their proinflammatory activity and provide an immunologically constrained environment where antigen-specific immune responses are closely controlled. Balanced against this, of course, is the question of how the male reproductive tract is able to protect itself from recurrent infections and tumor development under these circumstances.

The observation that reproductive dysfunction is not only associated with local infection and its accompanying inflammation, but also with systemic disease, provides further evidence of an intimate relationship between the male reproductive tract and the immune system.[20,21] Many systemic illnesses are accompanied by a reduction in both serum androgen levels and sperm output, indicating that male sexual function and general well-being maintain a reciprocal relationship. It has been suggested that this represents a physiologically important mechanism, having evolved to limit reproductive activity during periods of illness. The possibility that acute inflammatory dysregulation of male reproductive function can lead to more permanent problems, such as autoimmune infertility or chronic inflammatory disease, also must be considered. It may even be the case that pre-existing hypogonadism predisposes men to inflammatory disease. At a fundamental level, the ability of the immune system and the male reproductive system to co-exist is no less essential to male reproductive success than the normal operation of the hypothalamic-pituitary unit or the critical interactions between somatic cells and spermatogenic cells. The use of the term *immunophysiology* in this context highlights the fact that the immunology and basic physiology of male reproduction cannot actually be separated.

Since the original publication of this chapter, nearly a decade ago, there have been considerable advances in our understanding of male reproductive immunophysiology. Most significantly, inflammation has moved to center stage in male infertility, with more testicular pathologies now being recognized as possessing inflammatory features,[22,23] and there is growing awareness that basic immunological mechanisms underlie normal reproductive tract function.[24] There has been a considerable increase in knowledge of the mechanisms responsible for controlling testicular immune responses, as well as advances in understanding of the unique immunology of the epididymis and excurrent ducts. The principal aim of this chapter is to provide a comprehensive overview of the field, including how it has developed, its basic tenets and mechanisms, and a broad outline of the current state of knowledge. The overview is confined to consideration of mammalian species, as particularly relevant to the human.

Historical Aspects

The study of male reproductive tract immunophysiology extends back to the very beginnings of endocrinology and immunology. Inflammation of the testis and its association with mumps parotitis was known in ancient times, having been described in the writings of Hippocrates (c. 460–377 BC). Studies on the transplantation of testes in domestic chickens, generally considered to be the earliest studies in the field of endocrinology, were undertaken in the eighteenth century by Hunter and by Michaelis (cited by Setchell, 1990),[25] although the first systematic experiments actually were reported by Berthold in 1849.[26] "Successful" transplants of mammalian testes had to wait until some time later.[27–29] In the early part of the last century prior to the discovery of the male sex hormone, testosterone, transplantation of male gonads, including transplants of animal gonads into humans, was undertaken by charlatans and serious researchers alike in the search for treatments to increase male health and virility.[30,31] It was quickly noted that, although the function of the interstitial tissue appeared to continue in these transplant experiments, tubule function was not preserved.[32] While there is no doubt that temperature and revascularization issues were

important limitations, it is now obvious that many of these experiments faced a crucial immunological impediment. Even today, grafts of testicular tissue generally are more successful in an immunologically compatible or immunocompromised host.[33] The concept of immunoregulation entered the story with the discovery that allogeneic testicular grafts could be made to survive much more successfully if tolerance had been induced by injection of the donor allogeneic cells at the time of birth in the donor,[34] or when transferred into the anterior chamber of the eye.[35,36] Sometime later, Billingham and others conducted a series of investigations into so-called immunologically privileged sites that led to recognition of the testis as a tissue that was particularly favorable for graft survival.[37]

Evidence that the spermatozoon itself is immunogenic to its autologous host dates back to the discovery of antibodies against sperm by Lansteiner[38] and Metchnikoff.[39] In the 1920s,[40] Guyer was able to produce infertility in rabbits and guinea pigs by passive immunization with sperm specific antisera, while Kennedy reported degenerative changes in the testis following active immunization with autologous sperm.[41] By the middle of the century, Voisin and colleagues were able to produce aspermatogenesis in guinea pigs by active immunization with testicular extracts.[42] Eventually, an association between sperm autoantibody formation and infertility in humans was noted.[43,44] Further experimental evidence confirming the possibility of autoimmune reactions against the sperm led to a general acceptance that these are an important cause of infertility in men.[2,45] In time, this led to the broader concept that the testis environment must provide protection for the spermatogenic cells through specific regulatory mechanisms.

Biological sex exerts a significant influence on the immune system. Gender differences in health and the greater prevalence, earlier onset, and severity of autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, among women had been recognized long before a real understanding of autoimmunity existed.[46,47] A specific effect of the testes on the immune system was reported as early as 1898 by Calzolari,[48] when he found that castration of rabbits prior to puberty led to an increase or maintenance of the size of the thymus. This effect has been repeatedly confirmed and extended to include cell-mediated immunity and graft survival.[49,50] Many studies have shown that various immunological processes have gender-specific differences or can be affected by castration and/or sex steroid replacement. These data clearly established that products of the testis, and sex steroids in particular, regulate the immune system either directly or indirectly, setting the stage for the modern era of male reproductive immunophysiology.

STRUCTURE AND FUNCTION OF THE MALE REPRODUCTIVE TRACT RELEVANT TO IMMUNOPHYSIOLOGY

The anatomy and physiology of the testis and other components of the male reproductive tract are covered in detail elsewhere in this volume (see Chapters 3, 14, 16, 17, and 18). A brief outline highlighting the issues relevant to understanding the interface between the immune system and male reproductive tract is provided here.

The Testis

Structural Organization

Functionally and anatomically, the testis is separated into an avascular spermatogenic compartment, the seminiferous tubules, and a highly vascularized endocrine compartment, the interstitial tissue. The testis is enclosed by a fibrous capsule, but there is considerable species variation in the connective tissue of the testicular parenchyma. In the human, the testis is physically partitioned by connective tissue septa into discrete lobules containing the loops of the seminiferous tubules, which connect at both ends to the rete testis located along one pole of the testis.[51] The products of the seminiferous tubules are collected by the rete testis and transferred to the adjacent epididymis, which is connected to the rete testis via a series of efferent ducts. The testes of rodent species, such as rat and mouse, comprise only very loose connective tissue with no distinct septa separating the seminiferous tubules.[52] The interstitial tissue completely surrounds the seminiferous tubules (Figure 19.2), and contains the vasculature, lymphatic vessels, and nerves of the testis. The testicular blood supply arises from the abdominal aorta, and this produces a comparatively long and highly coiled spermatic artery that is particularly susceptible to physical insult and torsion in species with scrotal testes. The arterioles, capillaries, and venules of the testis thoroughly permeate the interstitial tissue surrounding the seminiferous tubules and rete testis. Consequently, these structures are close to an effective blood supply at all times in spite of the completely avascular nature of the spermatogenic compartment.

Unlike the capillaries of other endocrine glands, the majority of testicular capillaries are not fenestrated,[53] and the mechanisms whereby molecules enter and exit the testis via this route still await resolution.[54] There appears to be very little functional restriction on the exchange of even large molecules across this barrier and the interstitial fluid is very similar in its overall composition to that of the circulating blood.[55] The venous drainage of the testis via the spermatic veins is closely associated with the arterial supply, which together form a very effective countercurrent heat and solute exchange structure, called the pampiniform plexus.[56]

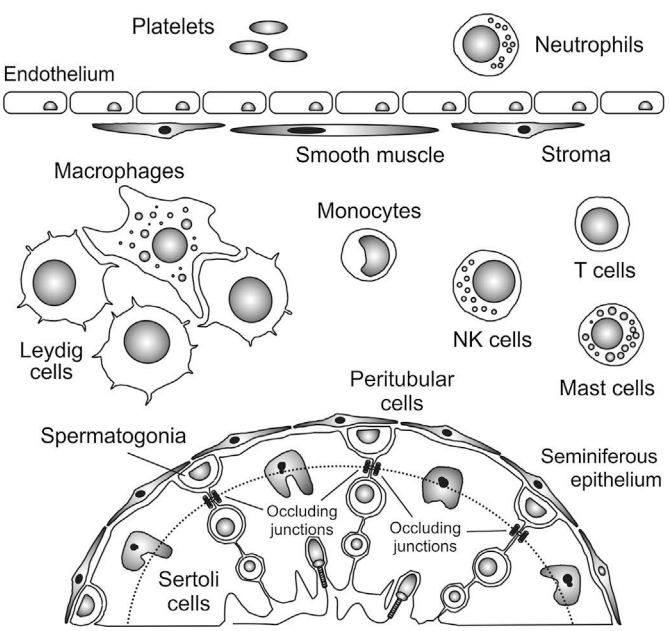

FIGURE 19.2 Immunological compartmentalization of the testis. The mammalian testis comprises three immunologically distinct compartments: the vascular compartment and intertubular (or interstitial) compartment are separated by a layer of nonfenestrated endothelium, while the intertubular and spermatogenic compartments are separated by a layer of peritubular myoid cells and by occluding junctions between adjacent Sertoli cells. These junctions constitute the blood–testis barrier, which further divides the seminiferous epithelium into a basal and an adluminal region (dotted line). The adluminal region contains the meiotic germ cells within a highly specialized microenvironment. Under normal conditions, monocytes, macrophages, T cells, NK cells and, in some species, mast cells and/or eosinophils have relatively free access to the intertubular compartment, but are entirely excluded from the adluminal region of the seminiferous epithelium. Neutrophils are confined to the vascular compartment except during specific immunological events.

The organization of the testicular lymphatics varies between species, ranging from irregular channels or sinusoids that are incompletely bounded by endothelial cells in rodents, to large discrete lymphatic vessels in humans, to very small, rapid flow lymphatics in porcine species.[52,57] These lymphatics completely invest the entire interstitial tissue and pass without restriction to local draining lymph nodes, principally the lumbar or para-aortic lymph nodes.[58,59] In the laboratory rat, drainage to the iliac and renal nodes predominates, but there may be some lymphatic drainage directly to the thoracic ducts without passing through regional lymph nodes.[13]

The most prominent cell type present in the interstitium is the Leydig cell,[60] which produces androgens.[61] Macrophages are commonly observed in the interstitium of most, if not all, species and many testes also contain variable numbers of mast cells and/or eosinophils.[62,63] Less numerous, but ubiquitous nonetheless, are the intratesticular lymphocytes: T cells and natural killer (NK) cells.[64–70]

The seminiferous tubules are bounded by a circumferential layer of peritubular cells and the basal lamina, which together form the limiting structure on which rests the Sertoli cells and the spermatogonia (Figure 19.2). Immune cells are occasionally seen within this boundary layer.[71] The Sertoli cell provides the structural framework for the organization of the seminiferous epithelium, but also plays a crucial role in supporting and directing the development of the spermatogenic cells. Adjacent Sertoli cells and spermatogenic cells maintain intimate contact at all times, with junctional and membrane specializations providing physical contact and communication.[72] At the time of puberty, cohorts of mitotically dividing spermatogonia begin to enter meiosis at regular intervals, moving away from the periphery of the tubule and becoming spermatocytes. Meiosis produces haploid round spermatids, which subsequently undergo considerable structural differentiation to become mature or elongated spermatids. Once these cells are released by the Sertoli cell into the tubule lumen they are called spermatozoa and fluid secreted by the Sertoli cells sweeps the released spermatozoa toward the rete testis.

The seminiferous epithelium is highly organized. As each cohort of spermatogonia becomes committed to the spermatogenic process, they displace earlier cohorts toward the lumen of the tubule, so that multiple generations of developing germ cells co-exist in each segment of the seminiferous epithelium. As a consequence of the regular intervals of spermatogonial commitment and the constant rate of the spermatogenic process itself, the generations form specific associations of germ cells at different levels of maturity within the epithelium. These associations constitute the stages of a recurring developmental sequence, called the "cycle of the seminiferous epithelium," which is also promulgated along the entire length of the tubule (see Chapters 16).[51] This organized complexity implies a high degree of communication and regulation across the generations as well as between spermatogenic cells and supporting Sertoli cells.

Elaborate occluding junctions between adjacent Sertoli cells form an intercellular barrier that is completely impermeable even to small molecules.[15,16] This constitutes the main component of the blood–testis barrier and separates the premeiotic and early meiotic cells in the basal region of the seminiferous epithelium from the adluminal spermatocytes and spermatids (Figure 19.2). In this way, a large majority of the developing germ cells

are sequestered within a highly specialized environment and effectively isolated from the vasculature and immune system. In contrast, the rete testis epithelium lacks both Sertoli cells and their highly specialized junctional specializations. The epithelial barrier restricting movement from the blood into the rete testis appears to be substantially less effective than that of the seminiferous epithelium, with the result that immunoglobulins and possibly even immune cells are able to cross the epithelium.[64,73]

Endocrine Regulation

Male reproduction is maintained by pulsatile secretion of gonadotropin releasing hormone (GnRH) by the hypothalamus, which stimulates concordant pulses of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary.[74] In the testis, LH binds to specific G-coupled receptors on the surface of the Leydig cells, thereby stimulating adenylate cyclase to produce the intracellular second messenger, cAMP, and activating the cAMP-dependent protein kinase A (Figure 19.3).[61] This activation mobilizes cholesterol from intracellular stores, extracellular lipoprotein sources, or de novo synthesis from acetate, and stimulates the transfer of the cholesterol to the inner-mitochondrial membrane through the action of the steroidogenic acute regulatory protein (STAR).[75] Ongoing maintenance of steroidogenic enzyme expression is also under LH/cAMP control.[76] Once cholesterol enters the mitochondrion, it is metabolized to pregnenolone via the action of the cytochrome P450 cholesterol side-chain cleavage enzyme (CYP11A) residing on the inside face of the inner matrix membrane. Pregnenolone diffuses out of the mitochondrion to the smooth endoplasmic reticulum, where it may be converted to progesterone by 3β-hydroxysteroid dehydrogenase/Δ4-Δ5 isomerase (HSD3β). Pregnenolone and progesterone are first metabolized to their 17α-hydroxy forms and then to the weak androgens, dehydroepiandrosterone and androstenedione, respectively, by the action of steroid 17α-hydroxylase/17,20 lyase (CYP17A). Finally, androstenedione is converted to testosterone by the action of hydroxysteroid (17β) dehydrogenase (HSD17β), and dehydroepiandrosterone is converted to androstenediol and then testosterone, by the sequential actions of HSD17β and HSD3β. Testosterone is secreted from the Leydig cell and serves as the principal androgen in both the testis and circulation.

Both testosterone and FSH bind to specific Sertoli cell receptors to regulate spermatogenesis and Sertoli cell functions, including secretion of the protein hormone, inhibin.[77] In turn, testosterone and inhibin operate via a negative feedback loop to regulate LH and FSH synthesis and secretion at the pituitary and hypothalamic levels.[78] Withdrawal of androgens leads to rapid cessation of spermatogenesis, although the levels of intratesticular testosterone required to maintain qualitatively normal spermatogenesis are considerably lower than the intratesticular concentrations that normally exist.[79,80] Consequently, spermatogenesis can tolerate even relatively large declines in testicular androgen production with relatively minor losses of efficiency. In contrast, peripheral levels of androgens are critical; even small reductions can have profound effects on many androgen-dependent functions, including accessory gland function, secondary sex characteristics, and libido.[81] Peripheral androgen levels are dependent upon both Leydig cell production and testicular vascular function, so that interference with the vasculature of the testis can alter circulating testosterone levels quite significantly.[82] Conversion of testosterone and androstenedione to estrogens by the cytochrome P450 enzyme aromatase (CYP19A) in the Leydig cell and Sertoli cell is also required for normal development and function of the efferent ducts and epididymis.[83]

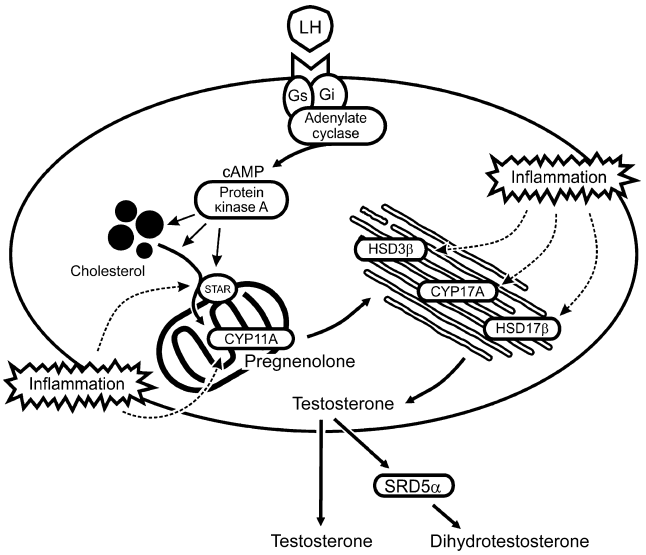

FIGURE 19.3 Regulation of testosterone biosynthesis in Leydig cells and sites of inhibition during inflammation. The gonadotropin, LH, binds to a G protein-coupled receptor on the cell surface, thereby activating adenylate cyclase, production of cAMP and protein kinase A activity. This stimulates the transfer of cholesterol from intracellular stores into the mitochondria through the action of the steroidogenic acute regulatory protein (STAR), where the cholesterol side-chain cleavage enzyme (CYP11A) converts the cholesterol to pregnenolone. Pregnenolone is converted to testosterone in the smooth endoplasmic reticulum by the enzymes, 3β-hydroxysteroid dehydrogenase/Δ4-Δ5 isomerase (HSD3β), steroid 17α-hydroxylase/17,20 lyase (CYP17A) and hydroxysteroid (17β) dehydrogenase (HSD17β). Testosterone is reduced by the action of the 5α-reductase enzyme (SRD5α) to the more potent androgen, dihydrotestosterone. Inflammation inhibits the activity of STAR and all the main enzymes of the steroidogenic pathway.

The Epididymis, Vas Deferens, and Accessory Glands

The epididymis comprises a long single, highly coiled epididymal duct lined primarily by columnar principal cells with extensive apical stereocilia. Testicular fluid

secreted by the Sertoli cells is largely reabsorbed by the epithelial cells of the efferent ducts and the proximal regions (caput) of the epididymis.[84] Sperm maturation occurs during transit through the epididymal duct and sperm are stored prior to ejaculation in the distal (cauda) region of the epididymis.[85,86] The cauda epididymis is connected to the vas deferens, a highly muscularized duct that drives the epididymal contents toward the urethra at the time of ejaculation. The testicular and epididymal secretions constitute only about 10% of the ejaculate, with the remaining 90% of the semen coming from the accessory glands: the seminal vesicles and prostate, in particular.[87] All the post-testicular ductal structures of the male tract and the accessory glands are dependent upon androgens for normal development and maintenance of function.[81] However, in contrast to the testis, conversion of testosterone to the more potent androgen, 5α-dihydrotestosterone (DHT), by the action of steroid 5α-reductase (SRD5α) is usually necessary in most other androgen-responsive tissues.[88]

It might be assumed that sperm spend the majority of their time in the testis and epididymis and appear only briefly within the vas deferens and urethra during ejaculation. Critically, however, some sperm may be retained within the tract for much longer periods, as spermatozoa continue to appear in the ejaculates of vasectomized men for several months even after a successful procedure.[89] In fact, the presence of intact sperm even has been noted in human prostate glands collected following prostatic surgery or postmortem, suggesting that such ectopic sperm may play a role in the etiology of prostatic inflammation and possibly even sperm autoimmunity.[90]

There is a blood–epididymis barrier restricting movement of molecules across the epididymal epithelium, although evidence suggests that this barrier is not as elaborate or effective as the blood–testis barrier.[72,86,91–93] In normal adults, circulating immunoglobulin appears to be restricted, although perhaps not entirely excluded, from passage into the epididymal fluid.[91] The most striking contrast with the seminiferous epithelium is the presence of macrophages and lymphocytes within the epididymal epithelium.[65,94–102] The presence of these cells suggests the existence of a very different immunological environment compared with that of the testis. Epithelial-type barriers, similar to that present in the epididymis, are found throughout the remainder of the reproductive tract.[72,93,103]

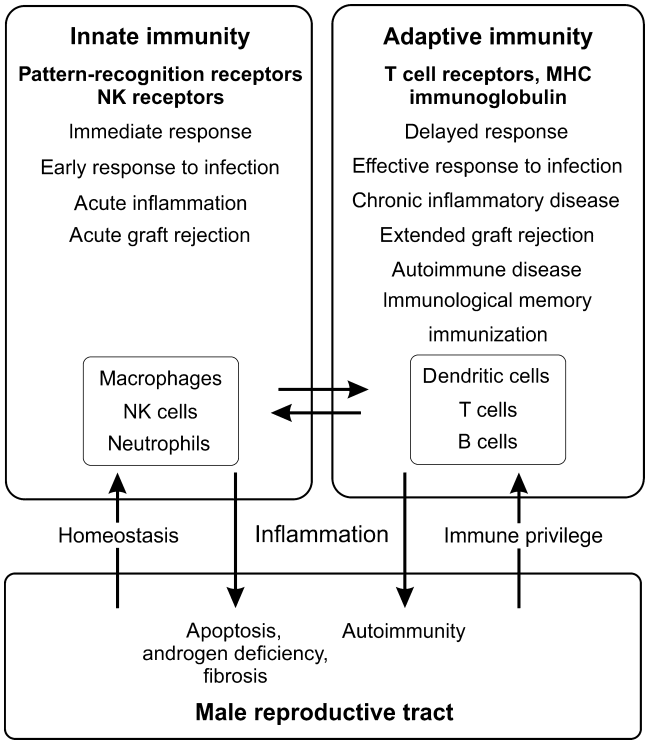

FIGURE 19.4 Components and properties of the innate and adaptive immune systems, and their interaction with the male reproductive tract. Innate immunity is the immediate response to infection and other external threats, subsequently activating the more delayed adaptive immune response. The male reproductive tract regulates innate and adaptive immunity in order to maintain protection against infections, while at the same time suppressing antigen-specific immunity to protect the spermatogenic cells (immune privilege). Activation of the innate and adaptive immune systems, due to infection or other inflammatory stimulus, has detrimental effects on male reproductive tract function, resulting in loss of androgens and spermatogenic disruption, and can lead to tissue damage, ongoing autoimmunity and infertility.

THE IMMUNE SYSTEM AND ITS ENDOCRINE CONTROL

General Principles

Fundamentally, the immune system provides protection for more complex animals from invading organisms that seek to exploit vulnerabilities or other opportunities to infect their host. This protection involves a complex suite of cells and molecules that allows the animal to identify and then eliminate the invading pathogen. In vertebrates, the immune system comprises an innate immune system, which generally recognizes uniquely conserved molecular patterns expressed by various pathogens, and the adaptive (or acquired) immune system, which specifically recognizes molecular patterns that are foreign to the host. Neither system operates in isolation and many of the cellular and molecular mechanisms overlap (Figure 19.4). The functions of both innate and adaptive immunity impact upon the male reproductive tract at multiple levels and have profound consequences for male reproduction.

The cellular components of the immune system are the leukocytes, or white blood cells. These cells and their products circulate continuously through the blood, lymph, and tissues in both surveillance and effector modes. The innate immune system is comprised principally of the mononuclear phagocytes (monocytes and

macrophages) and granulocytes or polymorphonuclear cells (neutrophils, eosinophils, basophils, and mast cells), but also involves cells more closely aligned with the adaptive responses (NK cells and dendritic cells). The cellular components of the adaptive immune system are the lymphocytes (T cells, B cells, and NK cells), and the "professional" antigen-presenting cells (dendritic cells and macrophages). In modern immunology, the cells of the immune system and their various functional subsets are primarily identified and even defined by expression of specific antigens, called cluster designation (CD) markers, recognized by well-characterized monoclonal antibodies (Table 19.1).[104]

The Innate Immune Response

The innate immune system provides the first line of defense against external threats through an inherent ability to recognize and rapidly respond to a broad range of pathogens and other immunogens, and by promoting the process of inflammation. Innate immunity plays a fundamental role in the response of the male reproductive tract to infections, but it also exhibits a much wider role in male reproduction because a number of regulatory mechanisms are shared by the innate immune and the reproductive systems.

Pattern Recognition Receptors and Activation of Innate Immunity

Activation of the innate immune response involves pattern-recognition receptors, which recognize specific motifs, or pathogen-associated molecular patterns (PAMPs), produced by bacterial, viral, fungal, and protozoan pathogens.[105] Unlike classical ligand receptors, these receptors are able to respond to multiple ligands that possess related, rather than identical, structures. The canonical pattern-recognition receptors are a family of transmembrane receptors called the Toll-like receptors (TLR), which are expressed on the cell surface and on intracellular endosomes.[106] There are several families of intracytoplasmic pattern-recognition receptors: the nucleotide binding and oligomerization domain (NOD)-like receptors (NLR), the retinoic acid-inducible gene (RIG)-like receptors (RLR), and the C-type lectin receptors (CLR).[107] Importantly, many of these receptors can also interact with endogenous molecules released by cell damage, called danger-associated molecular patterns (DAMPs), which include high-mobility group box 1 protein (HMGB1), heat shock proteins, extracellular matrix components, and nucleic acids.[108]

The TLRs are highly expressed by myeloid-lineage cells (monocytes, macrophages, and dendritic cells), but are also found on other leukocytes, epithelial cells, and stromal cells. There are 10 TLRs (numbered TLR1–10) in the human, but the laboratory rodents (rats and mice) possess an additional three TLRs (TLR11–13).[106,109] These receptors detect unique ligands of bacterial, viral, and fungal origin, such as bacterial and viral nucleic acids, bacterial lipopeptides, peptidoglycans, and lipopolysaccharides (LPS). LPS is a component of the cell wall of gram-negative bacteria, such as *Escherichia coli*, and the receptor for LPS is TLR4, which requires a co-receptor called MD2 (myeloid differentiation 2 protein), and the LPS-binding protein CD14 for full activation.[110,111]

The ligand-binding region of the TLRs is characterized by multiple N-terminal leucine-rich repeats, which facilitate detection of specific molecular patterns. These receptors are functionally related to the interleukin-1 (IL1) receptor (IL1R), with which they share a conserved cytoplasmic domain called the Toll/IL1R (TIR) domain.[106,112] Activation of the TLRs involves receptor dimerization and interaction of the TIR domain with an intracellular TIR domain-containing adaptor protein (Figure 19.5). In the case of all the TLRs, except TLR3, the adaptor protein is myeloid differentiation primary-response protein 88 (MYD88), which signals via IL1 receptor-associated kinase (IRAK) and tumor necrosis factor (TNF) receptor-associated factor 6 (TRAF6). This leads to activation of the p38 mitogen-activated protein kinase (MAPK14) and Jun N-terminal kinase (MAPK8), and nuclear translocation of the transcription factors, nuclear factor kappa B (NFκB), and activated protein-1 (AP-1).[113,114] This, in turn, induces expression of genes encoding the key pro-inflammatory cytokines and mediators, including both IL1α and β forms (IL1α and IL1β), TNF, IL6, IL8 (C-X-C motif ligand 8; CXCL8), IL12, inducible nitric oxide synthase (NOS2) and prostaglandin-endoperoxide synthase 2 (PTGS2; cyclooxygenase 2; Table 19.2).[115,116] In addition, TLR3 and TLR4 interact with the adaptor protein, TIR domain-containing adaptor molecule 1 (TICAM1), to activate TRAF3 and the transcription factor, interferon regulatory factor 3 (IRF3), resulting in production of the type 1 interferons (IFNα and IFNβ).[115] Some of the NLRs, which detect various bacterial PAMPs within the cytosol, likewise exert their actions via activation of NFκB and the MAP kinases, but a subset of the NLRs work by induction of the cysteine protease, caspase-1 (CASP1; interleukin-1β converting enzyme), through assembly of a large intracellular protein complex called the inflammasome.[117,118] Inflammasomes are generically composed of a pattern-recognition domain-containing protein, an adaptor molecule bearing a caspase activation and recruitment domain (CARD), and CASP1 itself, which activates the key pro-inflammatory cytokines, IL1β and IL18, by processing their inactive precursors (Figure 19.5).[118] These complexes are activated by various PAMPs and DAMPs, including bacterial toxins, viral RNA, and particulates, such as silica and uric acid crystals. Activation of the pattern-recognition receptors

TABLE 19.1 Cluster Designation (CD) Markers Relevant to the Male Reproductive Tract[a]

Marker	Gene Name, Common or Superseded Designation(s)	Function(s)
CD1	Ly-38, R3 (CD1D)	Nonclassical MHC; presentation of lipid and glycolipid antigens
CD3	T3, Leu 4	Signaling component of the TCR complex
CD4	T4, Leu 3	Co-receptor for recognition of MHC class II; component of the TCR complex
CD8	Ly-2, Ly-3, T8, Leu 2	Co-receptor for recognition of MHC class I; component of the TCR complex
CD11a CD11b CD11c	ITGAL, LFA-1, Ly-15, Ly-21 ITGAM, Mac-1, Ly-40 ITGAX, Leu M5	Integrin α chains; adhesion molecules, expressed on leukocytes
CD14	LPS-R	Lipopolysaccharide-binding protein complex co-receptor; TLR4 co-receptor
CD16	FCGR3, FcγRIII, Ly-17	Receptor for Fc fragment of immunoglobulin G; expressed on subset of NK cells
CD18	ITGB2, LCAMB	Integrin β2; adhesion molecule, pairs with CD11
CD25	IL2RA, Ly-43	IL2 receptor α chain; marker for activated and Treg cells
CD28	T44	Receptor for CD80 and CD86; expressed on activated T cells, NK cells
CD30	TNFRSF8	TNF receptor superfamily, member 8; expressed on activated T cells, B cells
CD40	TNFRSF5	TNF receptor superfamily, member 5; co-stimulatory receptor; expressed on antigen-presenting cells
CD45	PTPRC, LCA, Ly-5, T200	Protein tyrosine phosphatase, receptor type, C; leukocyte common antigen; expressed on all leukocytes
CD46	MCP	Membrane cofactor protein; complement regulatory protein
CD52	CAMPATH-1 antigen	Complement regulatory protein; Treg co-stimulatory co-receptor
CD54	ICAM1, Ly-47	Intercellular cell adhesion molecule-1; expressed on activated endothelial cells
CD55	DAF	Decay accelerating factor for complement; complement regulatory protein
CD56	NCAM1	Neural cell adhesion molecule-1; specific variant expressed on NK cells
CD59	MAC-IP	Membrane attack complex inhibition factor; complement regulatory protein
CD68	Macrosialin	Lysosomal membrane glycoprotein; expressed by dendritic cells, monocytes, some macrophages
CD80	B7-1, B7/BB1, Ly-53	Co-stimulatory co-receptor; ligand for CD28; expressed on antigen-presenting cells
CD86	B7-2, Ly-58	Co-stimulatory co-receptor; ligand for CD28; expressed on antigen-presenting cells
CD95	FAS, APO-1	Receptor for CD95 ligand; mediates apoptosis; expressed on activated lymphocytes
CD106	VCAM1	Vascular cell adhesion molecule-1; expressed on activated endothelial cells
CD126	IL6R	Interleukin-6 receptor subunit; pairs with interleukin-6 signal transducer
CD130	IL6ST, gp130	Interleukin-6 signal transducer
CD152	CTLA4	Cytotoxic T-lymphocyte-associated antigen 4; inhibitory receptor for CD80 and CD86; expressed on T cells
CD154	CD40LG	Ligand for CD40; co-stimulatory co-receptor; expressed on T cells
CD163	M130	Scavenger receptor for hemoglobin-haptoglobin complex; expressed on macrophage subset (M2)
CD206	MRC1	Macrophage mannose receptor 1; expressed on macrophage subset (M2)

[a]*Refer to text for full details. Note that some designations represent multiple protein members.*

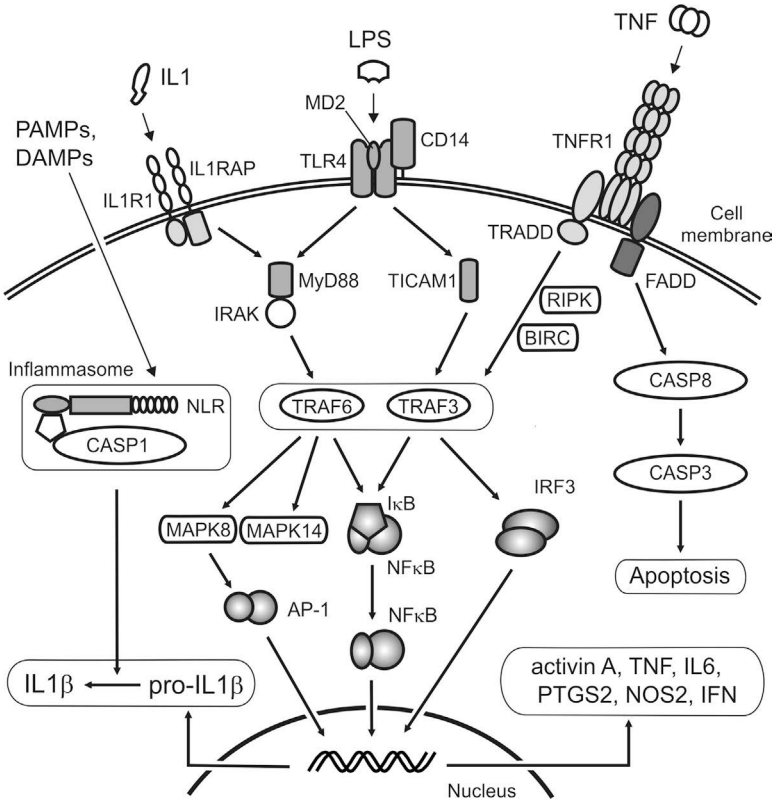

FIGURE 19.5 Schematic of inflammatory signaling pathways. Binding of bacterial LPS to Toll-like receptor 4 (TLR4), which also comprises co-receptor proteins MD2 and CD14, or binding of IL1 to the IL1 receptor (IL1R1) and engagement of the ILR acceptor protein (IL1RAP), leads to interaction with the adaptor molecules, MYD88 or TICAM1. Signaling via MYD88 occurs through the IL1 receptor-associated kinase (IRAK) and TNFR-associated factor 6 (TRAF6), leading to degradation of the NFκB repressor protein IκB, and activation of mitogen-activated protein kinases (MAPK8 and MAPK14). These kinases activate multiple downstream events, including production of the transcription factor AP-1. Signaling via TICAM1 occurs through TRAF3 and activates the interferon-induced transcription factor, IRF3. However, there is considerable potential for overlap between signaling pathways. Depending upon which adaptor molecule is engaged, binding of TNF to its receptor (TNFR1) can lead to activation of TRAFs via the TNFR-associated death domain protein (TRADD)-mediated pathway, via receptor interacting serine–threonine kinase (RIPK) or baculoviral IAP repeat containing protein (BIRC), or to the caspase activation cascade and apoptosis through the FAS-associated death domain protein (FADD). The transcription factors, NFκB, AP-1 and IRF3, translocate to the nucleus to induce transcription of inflammatory genes. Various pathogen-associated and endogenous molecules (PAMPs and DAMPs) bind to intracellular pattern-recognition receptors associated with the inflammasome, such as the NOD-like receptors (NLR), and activate caspase-1 (CASP1), which is required to process pro-IL1β into the active pro-inflammatory protein. Note that the pathways shown are highly simplified – not all intermediates or potential interactions are depicted.

TABLE 19.2 Key Enzymes Involved in Inflammation and Immunity in the Male Reproductive Tract

Enzyme Name	Gene Name	Common Names	Properties/Function
Nitric oxide synthase, type I	NOS1	Neuronal NOS (nNOS)	Ca/calmodulin regulated
Nitric oxide synthase, type II	NOS2	Inducible NOS (iNOS)	Transcriptionally and translationally regulated
Nitric oxide synthase, type III	NOS3	Endothelial NOS (eNOS)	Ca/calmodulin regulated
Phospholipase A2	Multiple genes		Hydrolysis of free fatty acid from membrane phospholipids
Prostaglandin-endoperoxide synthase 1	PTGS1	Cyclooxygenase 1 (COX1)	Constitutive, converts arachidonic acid to prostaglandin G/H
Prostaglandin-endoperoxide synthase 2	PTGS2	Cyclooxygenase 2 (COX2)	Inducible, converts arachidonic acid to prostaglandin G/H
Prostaglandin E synthase	PTGES		Converts prostaglandin H to prostaglandin E
Caspase 1	CASP1	Interleukin-1β converting enzyme (ICE)	Activation of IL1β and IL18
Caspase 3	CASP3		Mediates apoptotic pathway
Caspase 8	CASP8		Mediates apoptotic pathway
Indoleamine 2,3-dioxygenase	IDO		Metabolism of tryptophan, immunoregulation
Interleukin-1 receptor-associated kinase	IRAK		Activation of TRAF6, 3
IκB kinase	IKBK		Activation of NFκB
Mitogen-activated protein kinase 14	MAPK14	p38 MAP kinase	Stress/inflammatory signaling
Mitogen-activated protein kinase 8	MAPK8	JUN N-terminal kinase (JNK)	Stress/inflammatory signaling, activation of AP-1

(Continued)

TABLE 19.2 Key Enzymes Involved in Inflammation and Immunity in the Male Reproductive Tract—cont'd

Enzyme Name	Gene Name	Common Names	Properties/Function
Mitogen-activated protein kinase 3	MAPK3	Extracellular signal-regulated kinase 1 (ERK1)	Stress/inflammatory signaling
Mitogen-activated protein kinase 1	MAPK1	Extracellular signal-regulated kinase 1 (ERK2)	Stress/inflammatory signaling
Akt protein kinase	AKT	Protein kinase B	Cell survival, stress/inflammatory signaling
Tyrosine-protein kinase Src	SRC		Immunoregulation
Janus kinase	JAK		Activation of STAT
Phosphatidylinositol-4,5-biphosphate 3-kinase	PIK3	Phosphoinositide-3-kinase (PI3K)	Stress/inflammatory signaling
Protein kinase, cAMP-dependent	PRKA	Protein kinase A	Protein phosphorylation, signaling
Protein kinase C	PRKC		Protein phosphorylation, signaling

leads to functional activation of immune cells and sets the inflammatory response in train.

Inflammation

Inflammation is the immune system's initial response to a pathological challenge and involves major changes in homeostasis: fever, activation of immune cells, increased blood flow at the site of inflammation, and enhanced pain sensitivity.[119] Apart from specific pathogens, the inflammatory cascade can be triggered by tissue injury, insoluble particulates, activation of the plasma complement and clotting/fibrinolytic protease pathways, opsonized (antibody or complement-coated) particles or immune complexes, and intracellular components released by tissue damage. Monocytes and macrophages are by far the most effective promoters of the inflammatory response. Mast cells regulate vascular permeability, vasodilation, and leukocyte recruitment and play a critical role in allergic inflammation.[120] Neutrophils provide rapid and effective clearance of extracellular pathogens.[121] These immune cell types also exert a regulatory influence over the subsequent immune response.

In addition to the pro-inflammatory cytokines, the main mediators of the inflammatory process are pro-inflammatory prostaglandins and leukotrienes, neuropeptides such as substance P, vasoactive amines produced by basophils and mast cells (histamine and serotonin) and acute phase proteins from the liver, such as C-reactive protein and serum amyloid A. Local production of chemoattractive cytokines (chemokines), such as IL8 and chemokine (C–C motif) ligand 2 (CCL2; monocyte chemoattractant protein-1), together with upregulation of specific adhesion molecules on the endothelium (selectin E, selectin P, intercellular adhesion molecule-1 (ICAM1), vascular adhesion molecule-1 (VCAM1)) and on the leukocytes (selectin L, integrins), allow circulating neutrophils, monocytes and lymphocytes to specifically target and enter the affected tissues.[122] Resolution of the inflammatory response involves production of anti-inflammatory immunoregulatory cytokines, such as transforming growth factor-β (TGFβ) and IL10, some prostaglandins, late-acute-phase proteins, and activation of the hypothalamic-pituitary-adrenal axis to produce anti-inflammatory corticosteroids.[123–125] Long-term consequences of inflammation include increased tissue fibrosis and persistent alterations in the number, type, and activity of leukocytes within the affected tissue.[126]

The main effectors of the innate immune system are hydrolytic enzymes (e.g., lysozyme, serprocidins), antimicrobial proteins (e.g., complement, defensins), cytotoxic reactive oxygen species (ROS), NO, cytotoxic cytokines such as TNF, and the antiviral interferons.[119] Moreover, activation of the innate immune system leads to recruitment of the adaptive immune system.

The Adaptive Immune Response

The adaptive immune system involves complex cellular interactions that promote the functional maturation and expansion of regulatory and effector lymphocytes, thereby providing efficacy, specificity, and memory to the immune response, but requiring time to become effective. It operates through the ability to recognize and respond to molecular motifs (antigens), usually associated with proteins, that are not part of the normal host repertoire, and may indicate the presence of an external threat. Adaptive immunity is responsible for autoimmune reactions in the male reproductive tract that can lead to infertility and chronic inflammatory conditions. These reactions are mediated, but also regulated, by T cells, B cells, and NK cells, which have access to the male reproductive tract.

T-Cell and B-Cell Regulation and Functions

The adaptive immune system is dependent upon the unique ability of lymphocytes to generate a vast repertoire of cell surface receptors that can bind to almost any conceivable molecular surface, without ever having encountered the molecule before. On B cells, these receptors are surface-bound immunoglobulins, from which are derived the circulating antibodies. The core proteins of the T-cell receptor (TCR) are structurally related to the immunoglobulins, but the TCR itself is a complex of interacting surface proteins.[127] The diversity of these receptors involves extensive rearrangements of the basic immunoglobulin and TCR gene regions, which produce randomly reassembled genes encoding proteins, each with a very specific and unique topography.[128,129] Each precursor T cell and B cell expresses a surface receptor that is specific for a unique antigenic determinant and all their offspring (clones) will express the same receptor and specificity. B cells interact more or less directly with the antigenic molecule in situ. However, more precise regulation of the immune response involving T cells is determined by proteins of the highly polymorphic major histocompatibility complex (MHC), expressed on the surface of antigen-presenting cells.[130] Almost all cells in the body can act as antigen-presenting cells by proteolytically converting intracellular proteins, of either endogenous or infectious (e.g. viral) origin, into short antigenic peptides, which are then incorporated into a structural groove on the extracellular surface of the MHC protein complex during its assembly in the endoplasmic reticulum.[131] Some antigen-presenting cells (dendritic cells and macrophages) are able to phagocytose exogenous proteins, typically proteins of pathogenic origin, but also proteins derived from endogenous sources including the spermatogenic cells, and process these proteins for antigen-MHC complex formation. The TCR subsequently binds to the antigen-MHC complex on the surface of the antigen-presenting cell leading to the activation and proliferation of the T cell (Figure 19.6).

Typically, circulating T cells express one of the co-receptor proteins, CD4 and CD8, as part of their TCR, which permit them to recognize antigens associated with MHC class II or MHC class I molecules, respectively.[132] Antigens are presented to $CD4^+$ T cells by the professional antigen-presenting cells that express MHC class II antigens (dendritic cells, macrophages, and B cells).[133] On the other hand, $CD8^+$ T cells are recognized by MHC class I antigens, which are ubiquitously expressed. Activation of the T cell requires physical interaction between co-stimulatory ligand-receptor pairs, particularly CD28:B7 (CD80/CD86) and CD40:CD40 ligand (CD40LG), and production of either type 1 cytokines [IL2, IL12 and interferon-γ (IFNγ)] or type 2 cytokines (IL4, IL5, IL10 and IL13; Figure 19.6).[134,135] As a result of this complexity, T-cell

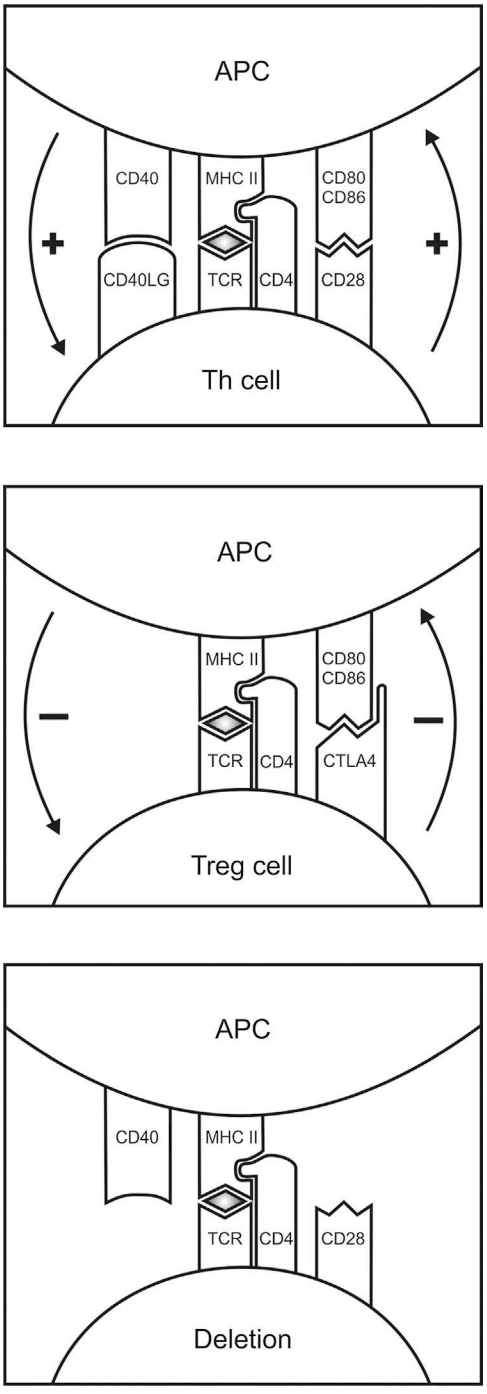

FIGURE 19.6 The antigen-presenting cell (APC)–T-cell synapse and the adaptive immune response. Recognition of the MHC class II-peptide antigen complex by the T-cell receptor (TCR) of a naïve Th cell together with engagement of the CD28:CD80/CD86 and CD40/CD40LG receptor/co-receptor pairs can lead to generation of Th1 cells, if type 1 cytokines (IL12 and IFNγ) are present. If interleukin-6 (IL6) and type 2 cytokines (IL4, IL5 and IL13) are present, Th2 cells are produced, and Th17 cells are produced when IL6 and transforming growth factor-β (TGFβ) are present. Engagement between the APC and T cell via the CTLA4 receptor produces an inhibitory response, as occurs in Treg cell interactions. Engagement of the APC and T cell in the absence of adequate co-stimulation or cytokine activity results in deletion or inactivation (anergy) of the Th cell.

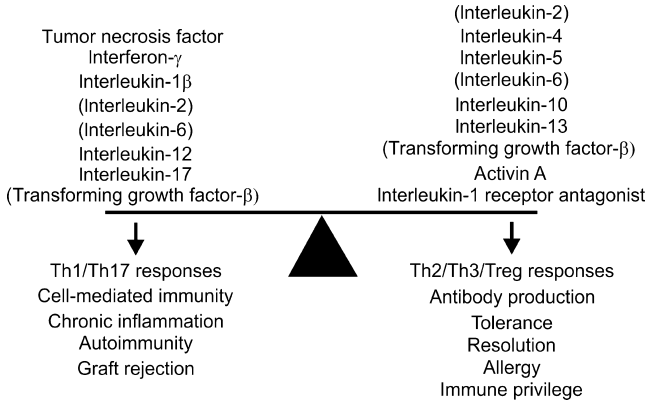

FIGURE 19.7 The cytokine balance and immune deviation. Cytokines can be designated either pro-inflammatory or anti-inflammatory/immunoregulatory, depending upon their predominant activities. The former group is associated with Th1 or Th17 type responses (cell-mediated immunity, autoimmunity) and the latter with Th2, Th3, or Treg type responses (antibody production, allergy, tolerance). It is important to note that several cytokines, such as IL6 and TGFβ, possess both pro- and anti-inflammatory properties, and fall within both groups. It is the combination of cytokines present that determines the T-cell response outcome.

activation can produce different outcomes depending upon the co-stimulatory molecules engaged and cytokines produced. Accordingly, naïve $CD4^+$ T cells may become type 1 helper (Th1) cells, which produce Th1 cytokines, direct the development of the cellular immune response involving cytotoxic $CD8^+$ T cells, and are associated with graft rejection, or they may become type 2 helper (Th2) cells, which produce Th2 cytokines, promote B cell development and antibody responses, and regulate allergic responses (Figure 19.7).[134,135]

In addition to the Th1 and Th2 cell subsets, which are primarily responsible for dictating the nature of the subsequent immune response to a particular antigen, there are a number of other T-cell subsets with specialized functions, which have been more recently described. The Th17 cell subset is functionally related to the Th1 subset but characteristically produces IL17, IL21, and IL22.[136] The Th17 cell is generated by exposure to IL6 and TGFβ and regulates protection against extracellular pathogens, including recruitment and activation of neutrophils, differentiation of B cells, and the inflammatory activity of epithelial cells.[137] However, these cells also have been implicated in the development of autoimmune disease and in allergy.[136,138] Absence of appropriate co-stimulatory molecule interactions and/or the presence of anti-inflammatory or immunosuppressive cytokines may lead to T-cell inactivation (anergy) and deletion or the generation of regulatory or suppressor T cells (Figure 19.6).[139,140] These T-cell subsets are responsible for regulating antigen-specific immunity and maintaining peripheral immune tolerance.

The development of B cells into antibody-secreting plasma cells following interaction with antigen requires specific Th2 cell help.[141] Once activated, these cells initially secrete multivalent IgM, but the cells gradually mature to produce high affinity IgG with the same antigenic specificity.[128] Finally, following the resolution of the immune response, at least some activated T and B cells clones persist as memory cells, with the result that lymphocyte responses to antigens generally develop much faster upon second exposure to the antigen.[142,143]

NK Cell and NK T-Cell Regulation and Functions

NK cells are lymphocytes that span the interface between the innate and adaptive immune systems.[144] These cells are developmentally related to cytotoxic $CD8^+$ T cells but are capable of recognizing and destroying transformed cells, such as virally-infected or tumor cells, without the need for prior sensitization by exposure to antigen. They can be activated by pro-inflammatory cytokines, notably IL12 and antiviral type 1 interferons.[145] They interact with their targets via a complex of stimulatory and inhibitory surface receptors, which allow them to recognize ligands uniquely expressed by transformed cells and to detect the lack of MHC class I expression, a characteristic of transformed cells.[144,146] Accordingly, NK cells are able to rapidly mobilize against pathogenic challenges long before T- and B-cell responses can develop. However, activated NK cells also participate in the adaptive immune response. They possess antigen-specific receptors, similar to cytotoxic $CD8^+$ T cells, and have been shown to regulate dendritic cell responses in a positive or negative manner, for example, by inducing dendritic cell death through contact-mediated lysis or by producing immunoregulatory cytokines, such as IFNγ, IL4, and TGFβ.[144,147]

NK T cells are a distinct cytotoxic lymphocyte subset that is defined by responsiveness to bacterial and mammalian glycolipid antigens presented by the nonclassical MHC class I molecule, designated CD1D.[148] These cells are considered to be T cells with NK activity, rather than NK cells per se, but they also appear to play an important role in immune regulation through production of either IFNγ or IL4/IL10.[149,150] Accordingly, both NK T cells and NK cells promote and mediate immunity to bacteria, viruses, and tumors, but are also capable of suppressing cell-mediated autoimmunity and graft rejection responses.

Immunological Tolerance and Regulatory Lymphocyte Subsets

The ability of randomly-generated, antigen-specific T and B cell clones to ignore antigens expressed by the host organism relies upon an effective cell-editing process, collectively referred to as tolerance. The tolerogenic process involves central and peripheral mechanisms, both

of which play a crucial role in protecting the spermatogenic cells and other antigenic components of the male reproductive tract from the immune system. Central tolerance occurs primarily in the thymus, during normal development, when expression of antigens by the thymic epithelium leads to functional deletion of self-reactive T cells by inactivation and apoptosis.[1] A similar mechanism mediates B-cell editing in the bone marrow.[151] It is now recognized that this process involves the promiscuous expression of many tissue-specific antigens in the thymic epithelium induced by the transcription factor, autoimmune regulator (AIRE).[152] Even sperm-specific antigens have been found to be expressed in the thymus under this mechanism.[153] However, this mechanism is not completely efficacious because autoreactive lymphocytes persist and may expand or become activated later in life, resulting in autoimmune disease.[154,155]

The mechanisms of peripheral tolerance, which need to operate effectively throughout life, are more complex. Peripheral tolerance involves functional deletion of autoreactive lymphocytes in the peripheral (secondary) lymphoid tissues due to weak antigen-stimulation in the absence of appropriate co-stimulation, production of blocking and anti-idiotypic antibodies, and development of antigen-specific regulatory and suppressor lymphocytes.[139,156] This involves an ongoing process of low-dose exposure of these cells to their antigen, accompanied by either modified co-stimulatory or specific immunoregulatory signals from antigen-presenting cells, regulatory lymphocytes, or other cell types in the vicinity.[157] This means, for example, that engagement of the peptide-MHC class II complex with the TCR in the absence of linkage of CD80/CD86 to CD28, in the presence of immunoregulatory cytokines, such as IL10 or TGFβ, or engagement by CD80/86 of the inhibitory T cell receptor, CTLA4, in place of CD28, leads to T-cell deletion by inactivation or apoptosis, and/or induction of regulatory/suppressor T-cell activity (Figure 19.6).[140,158] The best characterized, and arguably the most important, of these regulatory lymphocytes is the $CD4^+CD25^+$ regulatory T cell (Treg) subset, which expresses the transcription factor, FOXP3.[140] These cells can be induced by TGFβ and IL2, and selectively produce immunoregulatory TGFβ and IL10, but also appear to act via direct contact with antigen-presenting cells and other T cell subsets.[159,160] Both NK cells and NK T cells are also capable of antigen-recognition and immunosuppressive activity. Other T cell subsets implicated in immunosuppression through their ability to produce TGFβ and IL10 include Th3 cells, Tr1 (T regulatory 1) cells and γδ T cells.[161–163]

Autoimmunity and Rejection Responses in Immunity

Autoimmune disease generally represents the failure of tolerance. Somatic mutation of the antigen-receptor expressed by a T cell or B cell may result in the creation of new self-reactive clones, thereby subverting central tolerance.[164] Autoimmunity may result from an inflammatory response to an infection that damages or overwhelms normal mechanisms of self-tolerance, or where the infection involves organisms that express antigens that may cross-react with self-antigens (molecular mimicry).[165] Studies of disease models in humans and experimental rodents have also established that autoimmunity may have a genetic basis, as in the case of polyglandular autoimmune (PGA) syndromes. In humans, type 1 PGA is associated with a mutation in the AIRE transcription factor,[166] while type 2 PGA is related to a defect in regulatory T cell function.[167]

Failure of tolerance results in autoimmunity, but failure to induce tolerance in the first place lies behind transplantation rejection responses. The leukocytes of both the graft recipient and the donor tissue react toward their respective antigens, leading to the rejection of tissues that are not antigenically matched, in a process called graft-versus-host disease.[168] The response is said to be allogeneic if it occurs across genetic boundaries within the same species (allograft), while xenogeneic responses involve a graft and host belonging to different species (xenograft). The extensive polymorphism of the MHC, which is also called the human leukocyte antigen (HLA) complex in the human, is a major contributor to the allogeneic rejection response. Rejection responses typically involve the classical MHC class 1a (HLA-A, HLA-B and HLA-C) and MHC class II (HLA-D) antigens responsible for antigen presentation during T-cell activation.[131] On the other hand, nonclassical MHC antigens that are able to inhibit T cell and NK cell activity, such as HLA-G and HLA-E, are associated with suppression of the adaptive immune response and maintaining peripheral tolerance.[169] Consequently, both classical and nonclassical MHC are involved in regulating autoimmune responses, including autoimmunity in the male reproductive tract.

Initiation and Control of the Immune Response and Immunity

Antigen-specific immune responses are initiated in the secondary lymphoid tissues, particularly within the follicles and germinal centers of the draining lymph nodes and spleen or lymphoepithelial aggregates of mucosal tissues, where antigen-presenting cells come into contact with large numbers of T and B cells.[170] This implies that antigens normally must travel via the lymphatics to one of these organs, either by simple diffusion or carried by an antigen-presenting cell. Generally, immunologists do not consider that primary immune activation can occur within nonlymphoid tissues or assume that any response generated there is likely to be vigorous enough to lead to full participation by the immune system. However, there is some evidence that primary activation can

occur outside the lymphoid tissues, especially during graft rejection.[171,172]

Moreover, an alternative immune activation model has been proposed that combines elements of both the innate and adaptive immune system. This is called the danger hypothesis, which proposes that antigen-presenting cells responds to substances that cause or signal damage, rather than to those that are simply unrecognized.[173] These danger signals include CD40LG, the early pro-inflammatory cytokines IL1β and TNF, interferons, and heat-shock proteins, as well as substances that are normally only found inside cells (e.g. nucleotides, unmethylated CpG sequences in mammalian double-stranded DNA) and hyaluron breakdown products.[173] In this model, activation of the immune system occurs as a response to evidence of an extant threat rather than toward a specific feature of the threat itself. This mechanism may serve to explain the onset of certain autoimmune diseases.

Inflammation and immunity are damaging to the tissues in which they occur. Apart from the normal mechanisms of tolerance, the immune system needs to limit inflammation and immune responses to minimize such damage. Accordingly, inflammation triggers secretion from the adrenal gland of glucocorticosteroids, which repress expression of NFκB, inhibit the production of pro-inflammatory cytokines and mediators while stimulating the anti-inflammatory cytokines, IL4 and IL10, reduce expression of leukocyte adhesion molecules, and induce lymphocyte apoptosis.[124,174–177] The immune cells themselves produce other anti-inflammatory and immunosuppressive molecules, including prostaglandins D and J and lipoxins.[178,179] Moreover, activated lymphocytes have a limited lifespan, undergoing a process of activation-induced cell death following upregulation of the extrinsic apoptotic signal mediated by interaction of the FAS receptor with its ligand (FASL), eventually leaving behind a relatively small population of long-lived memory cells.[143,180] There are also specific mechanisms to inhibit antibody activity and promote antibody clearance, such as the induction of anti-idiotype (antitopographical) antibodies.[181]

Mucosal Immunity

Muscosal immunity concerns immunity at the interface between the external and internal environments. Mechanisms involved in mucosal immune responses are very similar to those of other tissues and lymphoid organs. Discrete lymphoepithelial aggregates (mucosa-associated lymphoepithelial tissue or MALT) within mucosal surface tissues allow interaction between antigen-presenting cells and lymphocytes to facilitate local immune responses.[182] Reactions to inhaled or digested antigens are controlled through a process called mucosal tolerance,[162,182] and failure of tolerance in the gastrointestinal and respiratory tracts may result in allergies. The mechanisms of mucosal tolerance involve clonal T-cell deletion or anergy and active suppression by regulatory/suppressor T cells.[183] Although $CD8^+$ T cells predominate in the mucosal epithelium, it is the $CD4^+$ T cells that are responsible for mucosal tolerance, producing IL4 and IL10 (Th2 cells), and TGFβ (Th3 cells).[162,183,184] Mucosal intraepithelial lymphocytes also express CD1D constitutively and can activate immunoregulatory NK T cells in the epithelium.[185]

A key feature of mucosal immunity is the isotype of the antibodies normally involved at mucosal surfaces. Tight junctions between the epithelial cells restrict passage of both antigen and antibody, so that antibody responses are dominated by secretory IgA, which lacks the ability to activate complement and possesses strong anti-inflammatory properties.[186] In order to cross epithelial barriers, a unique mechanism for transport of dimers of IgA through the epithelial cells involving a protein called secretory component is necessary.[187] Thus, IgA is generally the major immunoglobulin in secretions of mucosal surfaces. In mucosa, the epithelial cells also play an important role in host defense by producing many molecules associated with innate and adaptive immunity, including defensins, regulatory cytokines, TLRs, MHC antigens, leukocyte adhesion molecules, and co-stimulatory molecules.[188,189]

There is strong evidence that the male reproductive tract is a constituent of the mucosal immune system.[91,190] As far as the male reproductive tract is concerned, both IgA and serum-derived IgG appear in semen and bound to the sperm of men with autoimmune infertility.[3,45,191] It would be expected that the epithelial cells of the male urogenital tract might play a similar active role in regulating local immune responses. Although discrete MALTs have never been described within the male tract, the existence of similar or analogous structures cannot be entirely excluded.

Regulation of Immunity by Hormones and Gender

Corticosteroid Control of Inflammation and Immunity

Corticosteroids are essential physiological regulators of the immune response, acting through the ubiquitously expressed glucocorticoid receptor to exert negative feedback on the inflammatory response and control innate and acquired immunity at multiple levels.[124,174–177] Clinically, they are widely used in the treatment of autoimmune and inflammatory diseases. The particular relevance of corticosteroids for male reproductive function is the fact that they have inhibitory effects on testicular development

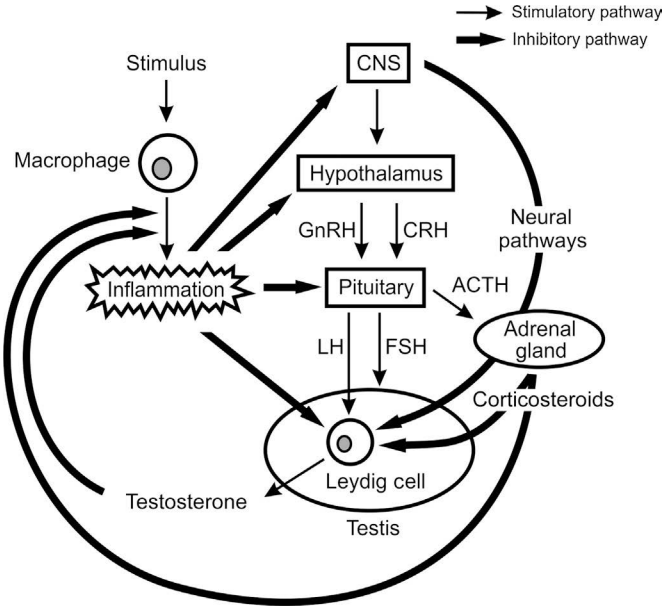

FIGURE 19.8 The interface between the hypothalamic-pituitary-gonadal-adrenal axis and inflammation. Regulation of the testes and adrenal glands is under the control of the central nervous system (CNS), which integrates information from the periphery and modulates secretion of the gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH) by the hypothalamus. These hypothalamic peptides stimulate secretion of the gonadotropins (LH and FSH) and adrenocorticotropic hormone (ACTH), respectively. LH acts directly on the Leydig cells to stimulate steroidogenesis, while FSH controls the development and activity of the Sertoli cells. ACTH stimulates secretion of corticosteroids by the adrenals, which generally exert direct inhibitory effects on Leydig cell steroidogenic activity. Activation of macrophage function by an inflammatory stimulus triggers a cascade of events and secretions, which interact with the hypothalamic-pituitary-gonadal axis at all levels, inhibiting gonadotropin secretion and steroidogenesis and stimulating the hypothalamic-pituitary-adrenal axis. There is evidence that inhibitory regulation of steroidogenesis in response to inflammation also involves direct neural pathways from the CNS. As a consequence, inflammation profoundly inhibits the ability of the Leydig cell to produce testosterone. Eventually, steroids produced by the adrenals and testis exert feedback inhibitory effects on the inflammatory process, bringing about the resolution of the inflammation and recovery of testicular testosterone production.

and suppress Leydig cell steroidogenesis at all levels of the hypothalamic-pituitary-testicular axis with the result that activation of the hypothalamic-pituitary-adrenal axis during inflammation negatively impacts upon male reproductive function (Figure 19.8).[192]

Sex-Specific Regulation of Immune Function

The male reproductive system exerts a profound inhibitory effect on the development and function of the immune system. Compared with females, males have lower serum immunoglobulin levels, reduced cellular immunity and less effective responses to antigenic challenge, while the incidence of autoimmune diseases are generally far less common and less severe in males than in females.[193] This can be attributed, in part, to genetic and epigenetic differences between the sexes, as indicated by studies in sex-reversed mice, which established that XX-bearing mice displayed greater susceptibility to autoimmune disease than XY-bearing mice, independent of gonad type or hormones.[194] However, testis ablation and male sex steroid replacement studies have also established a critical role for products secreted by the testis in this divergence. Such studies demonstrated that androgens inhibit many immune parameters, particularly the size of the thymus and other immune tissues, lymphocyte number and activity, and antibody production, but also graft rejection, autoimmune responses, and resistance to infection.[195–197] These findings have been supported in more recent years by studies in transgenic animals lacking the androgen receptor,[198,199] and by clinical data from hypogonadotropic men.[200,201] Studies on macrophages and other androgen-responsive cell types in vitro have indicated that androgens are able to inhibit NFκB and expression of inflammatory genes, such as TLR4, IL1, and TNF.[202–204] On the other hand, androgens appear to stimulate neutrophil proliferation growth and function through activation of the extracellular signal-regulated (ERK) kinases (mitogen-activated kinase 3/mitogen-activated protein kinase 1; MAPK3/MAPK1) and production of the neutrophil growth factor, granulocyte colony stimulating factor.[198,205]

The classical androgen receptor is a cytoplasmic protein that binds androgens with high affinity, and translocates to the nucleus, where it acts as a transcription factor by binding to androgen-response elements in the promoter of responsive genes.[206] Studies by early researchers established that functional androgen receptors were primarily expressed on the stromal and epithelial cells of the immune tissues,[207,208] suggesting that the effects of androgens on immunity were exerted indirectly at the tissue level, rather than by direct effects on the circulating lymphocytes. In fact, the expression and relative importance of the classical androgen receptor on lymphocytes remains somewhat equivocal.[209,210] However, it is now clear that steroids can also interact with membrane-bound G protein-coupled receptors to trigger nongenomic responses in target cells.[211,212] Studies have shown that androgens can alter [Ca] fluxes in lymphocytes and macrophages via such membrane-mediated interactions,[213,214] and that this signaling affects gene expression and function in the target cells.[215]

Obviously, many questions remain concerning the detailed cellular mechanisms that mediate the actions of androgens on immune cells, but it is clear that these steroids have profound effects on immune responses and are capable of directly modulating these functions within the male reproductive tract and adjacent draining lymph nodes. Furthermore, this regulation may also involve other steroids produced by the testis, such as progesterone and the estrogens, which also have direct effects on immune cell function.[196,216] Estrogens, in particular,

have been implicated in regulating the differentiation and maturation of dendritic cells, and inhibiting their co-stimulatory activity.[217,218] There is even evidence that LH and FSH themselves directly regulate macrophage and lymphocyte growth and cytokine production acting through specific receptors expressed by these cells.[219,220]

Protein hormones and neuropeptides produced by the testis have direct effects on immunity. These include the pro-opiomelanocortin gene-derived peptides β-endorphin and α-melanocyte-stimulating hormone (α-MSH), which are produced by the Leydig cells and macrophages of the testis, and testicular GnRH.[221–223] The testis is a significant source of cytokines with immunoregulatory activity, specifically, members of the highly immunosuppressive/anti-inflammatory TGFβ family.[224,225] There is no doubt that exposure of circulating immune cells to these molecules within the testis, and/or their secretion into the blood and lymph, plays a significant role in local immunoregulation and sexual dimorphism of immune function.

IMMUNE CELLS OF THE MALE REPRODUCTIVE TRACT

Far from being a site where the immune system is restricted entry, macrophages, lymphocytes and granulocytes are characteristic features of the male reproductive tract (Table 19.3). There are substantial differences in the number and type of these cells within the different tissues and from species to species, which have important implications for understanding the immunophysiology of the male tract.

TABLE 19.3 Quantification of Immune Cells in the Normal Testis of Adult Rats and Humans[a]

Cell Type	Rat Testis ($\times 10^6$/g tissue)	Human Testis ($\times 10^6$/g tissue)
Macrophages	5–10	10–25[b]
Dendritic cells	0.2–0.3	Present
T cells	1–2	1.4–2.4
$CD8^+$ T cells	0.6–1.8	Present
$CD4^+$ T cells	0.2–0.3	Present
NK cells	0.6–1.0	1.0–2.8
Mast cells	Capsule region only	Present

[a]*Estimates based on data from stereological analysis of testes from Sprague–Dawley rats and from adult human testes with normal spermatogenesis (Hedger MP and Hayes RD, unpublished data).[69,70,226,227] The study of Vergouwen and colleagues[228] indicates that CBA/P mouse testes contain approximately 2–4 × 10^6 macrophages/g tissue, but there are no definitive quantitative studies of other leukocyte subsets in the mouse testis.*
[b]*Upper limit calculated from data obtained by Frungieri and colleagues[229] using a well-characterized monoclonal antibody against CD68. The observation that macrophage numbers in the normal human testis are at least as large, if not larger, than those found in the either the rat or mouse testis is consistent with nonquantitative observations using several macrophage markers.[67,230–232]*

Macrophages and Dendritic Cells in the Testis

Macrophages and dendritic cells are found in every tissue of the body. Although some dendritic cells have a lymphoid origin,[233] these cell types are chiefly derived from the circulating monocyte pool and are directed along tissue-specific developmental pathways by the influence of the local immunological environment.[234] As a consequence, macrophages, in particular, are extremely heterogeneous in appearance and function.[235,236] Superficially, the microglial cells of the brain and the Kupffer cells of the liver have little in common, but both cell types are macrophages and share common features: they express markers of the mononuclear phagocyte lineage, are actively mobile, phagocytic, cytotoxic, and are involved in tissue restructuring and antigen-presentation to $CD4^+$ T cells.

Distribution and Properties of the Testicular Macrophage Population

Early interest in testicular macrophages arose from studies on the accumulation of nondigestible tracers and radionuclides in the testicular interstitial tissue.[237,238] In spite of some early speculation that these cells might have a nonhematopoietic origin, studies by Miller and colleagues,[237,239,240] and subsequently by Hutson and colleagues,[241–244] established that the testicular macrophages share the classical characteristics of resident macrophages or tissue-fixed macrophages. They display the characteristic nuclear and cytoplasmic morphology of the mononuclear phagocyte lineage, are actively phagocytic, bactericidal and adherent in culture, and they express macrophage-specific enzymes, cytokine receptors, and surface antigen markers.[69,239,240,243,245–247]

There are substantial populations of resident macrophages in both the rat and mouse testes.[69,228,248–250] Other species with large numbers of testicular macrophages include the guinea pig, hamster, horse, bull, and human.[229,251–253] These cells are almost entirely confined to the interstitial tissue under normal (noninflamed) conditions. In the boar, which has a relatively sparse testicular interstitial connective tissue and very large numbers of Leydig cells, macrophages appear to represent a smaller proportion of total interstitial cells.[254] Curiously, the ram testis appears to possess only small numbers of recognizable macrophages, in spite of the general similarity of the testicular interstitial tissue and lymphatic organization in this species with that of the bull or human.[52,68] Testicular macrophages have been most intensively studied in the rat, with less extensive investigation in the mouse, and relatively limited investigations in other species. It generally has been assumed that the rat testicular macrophages are representative, but data suggest that there are significant functional differences even between rat and mouse testis macrophages. Further study on the macrophages of other species, particularly

the human and primates, is clearly necessary, and discussion of this complex cell type in the testis necessarily reflects the rather narrow available knowledge base.

In the rat and mouse, the ratio of macrophages to Leydig cells appears to be relatively fixed at approximately one macrophage to every four or five Leydig cells,[245,248–250] and macrophages display a very close physical and functional relationship with the Leydig cells. Ultrastructural studies have established the existence of highly-specialized cytoplasmic interdigitations linking the two cell types, indicating the potential for direct exchange of information and material,[60,240,244,255] while macrophages and Leydig cells undergo parallel alterations in morphology and cytoplasmic volume in experimental models of cryptorchidism and vasectomy in the adult rat.[256,257] During aging, testicular macrophages retain their morphological association with Leydig cells, but the cytoplasmic interdigitations are lost.[258] Aging testicular macrophages also acquire lipofuscin granules similar to those observed in aged Leydig cells.[258] Most surprising, however, was the discovery that macrophages play an essential role in normal Leydig cell development and in maintaining Leydig cell steroidogenic function in the adult.[208,259–265] It appears that the testicular macrophages have an integral role in testicular biology that goes beyond the typical functions of tissue-fixed macrophages in phagocytosis of cellular debris, connective tissue remodeling, maintenance of innate immunity, and regulation of adaptive immunity.

The immunological functions of the testicular macrophage population have been investigated in a number of studies, but the data are by no means comprehensive and many questions still remain. Although several studies have shown that the majority of rat macrophages express MHC class II molecules under normal conditions, indicating a capacity for antigen-presentation to helper and regulatory T cell subsets,[68,246,266] Tung and colleagues reported that strong class II expression in the normal mouse testis was restricted to cells located around the rete testis and was only upregulated in the interstitial tissue following immunization with testicular antigens in the presence of adjuvant.[267,268] This seems to indicate a fundamental difference in baseline activation status and antigen-presenting activity between the testicular macrophages of the rat and mouse. Human testicular macrophages appear to be more like those of the rat, with significant MHC class II expression found throughout interstitial tissue samples from normal men.[67,230] Studies of the ability of rat testicular macrophages to provide help for T cell activation in vitro indicate that these cells are deficient in co-stimulatory activity.[269,270] In the mouse testis, a lack of expression of the essential co-stimulatory molecules for T cell activation, CD80 and CD86, has been reported,[271] but this does not appear to be true for the rat.[272] With respect to inflammation, selective depletion of testicular macrophages in the rat with a macrophage-specific toxin exacerbated the testicular inflammatory response induced by hyperstimulation of the Leydig cells with pathological doses of the LH agonist, human chorionic gonadotropin (hCG).[273] Significantly, rat testicular macrophages display relatively poor expression of critical proinflammatory genes and proteins, including IL1β, TNF, IL6, IL12, NOS2, and macrophage migration inhibitory factor (MIF), in response to activation by bacterial LPS or regulatory cytokines[269,274–278]; however, these cells express constitutively high levels of the anti-inflammatory/immunosuppressive cytokine, IL10.[270] Examination of murine testicular macrophages indicates a similarly reduced pro-inflammatory capacity (Hedger MP and Winnall WR, unpublished data).

The accumulated data confirm that macrophages from both rat and mouse testes, although different in some functional respects, have reduced inflammatory and co-stimulatory activities. Macrophages displaying such properties are called alternatively activated or M2 macrophages (analogous to Th2 cells); they are characteristic of tumors and late-stage inflammation.[236,279] During inflammatory and immune responses, M2 macrophages serve to regulate the activity of pro-inflammatory or classical M1 macrophages to moderate cell-mediated immunity, and thereby play important roles in reducing autoimmune and rejection responses.

Heterogeneity of the Testicular Macrophage Population

Although testicular macrophages collectively display an alternatively activated phenotype, quantitative studies of macrophage numbers using specific antigenic markers in the rat testis indicate that testicular macrophages do not represent a homogenous population.[69,226,276] The majority of testicular macrophages in the rat express a molecule that is specific to tissue-fixed macrophages in most non-lymphoid tissues, recognized by the monoclonal antibody, ED2.[280] This molecule has been identified as CD163, a member of the group B scavenger receptor cysteine-rich protein superfamily.[281] It has been implicated in the stimulation of IL10 production by monocytes and macrophages following the endocytosis of hemoglobin:haptoglobin complexes, and is highly expressed by M2 macrophages.[282,283] However, a significant subset of testicular macrophages in the rat (about 15–20% of the total) do not express this marker. These macrophages can be identified by expression of the lysosomal antigen, CD68, recognized by antibody ED1, which suggests they may be recently recruited or even transient macrophages.[69,268,276,284] Moreover, about half of the $CD163^+$ subset appears to have lost CD68 expression. These data indicate the existence of several populations of macrophages in the normal rat testis, putatively representing different stages of development and/or functional states (Figure 19.9).[284]

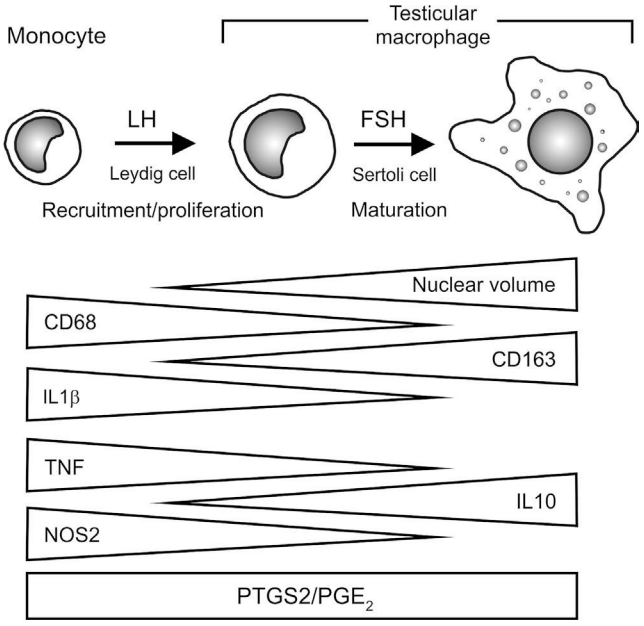

FIGURE 19.9 Maturation of the resident macrophage population of the rat testis. Macrophages in the rat testis are heterogeneous, corresponding to different stages of maturation from circulating monocytes through to a distinct testicular resident macrophage phenotype. This testicular phenotype is characterized by an increased nuclear and cytoplasmic volume, loss of the CD68 marker recognized by antibody ED1, upregulation of the resident macrophage surface marker ED2 (CD163), loss of ability to produce pro-inflammatory mediators and constitutive production of the immunoregulatory cytokine, interleukin-10 (IL10). Expression of the inducible form of prostaglandin-endoperoxide synthase (PTGS2) and the ability to produce prostaglandins, such as PGE_2, does not appear to change. Recruitment of macrophages to the testis and/or their proliferation is under the control of LH, acting via the Leydig cells, while maturation to the mature testicular phenotype appears to be FSH-dependent, indicating regulation by the Sertoli cells.

This heterogeneity may have functional correlates. Compared with $CD68^-$ macrophages, $CD68^+$ testicular macrophages possesses a distinctly smaller nuclear diameter and displayed overall higher levels of expression of NOS2 and CCL2 in normal and LPS-stimulated rats, based on immunohistochemical studies.[276,285] Expression of IL1β protein after LPS treatment appears to be confined to a relatively small subset of testicular macrophages.[274] Since the $CD68^+CD163^-$ macrophage subset increases in number in the testis after LPS treatment, it may be assumed that this subpopulation represents newly-arrived pro-inflammatory macrophages. However, when macrophages were isolated from non-inflamed rat testes on the basis of CD163 expression by flow cytometery, the $CD163^-$ subpopulation displayed very poor production of either proinflammatory cytokines or IL10 in response to LPS in vitro.[270] Altogether, these data suggest that the $CD68^+CD163^-$ subpopulation present in the normal testis comprises recently recruited or transient macrophages, and it is functionally distinct from the proinflammatory $CD68^+CD163^-$ macrophages that invade the rat testis following an LPS challenge in vivo.[276,286]

There is evidence for macrophage heterogeneity in mouse and human testes, as well. Studies have shown that macrophages isolated from the mouse testis are heterogeneous in their ability to produce TGFβ in vitro,[287] and approximately 20% express high levels of the alternative-activation marker, Ym1.[288] In the human testis, Frungieri and colleagues found that $CD68^+$ macrophages displayed substantial variation in expression of CD163.[229] All these observations are consistent with the hypothesis that the testis contains subsets of macrophages with varying pro-inflammatory capacities, although it appears that an alternatively activated, anti-inflammatory/immunosuppressive phenotype predominates under normal conditions.

Intratesticular Dendritic Cells

Dendritic cells, which are distinguishable from macrophages by their distinctive morphology and expression of specific functional markers, such as integrin αx (ITGAX; CD11c) and integrin αE2, have been observed in the rat, mouse, and human testis.[230,266,289–291] Dendritic cells are found throughout the interstitium, but they are much less prominent than the testicular macrophages. In spite of the common lineage, dendritic cells lack the efficient phagocytic and cell-killing capabilities of macrophages, although they are much more effective as antigen-presenting cells.[133] Crucially, dendritic cells are able to promote either cell-mediated immunity or tolerance to specific antigens, depending upon their maturity and activation status.[156] These cells are involved in directing immune responses within the testis and adjacent lymph nodes, and studies suggest that immature dendritic cells play a role in regulating tolerance in the normal testis.[271,272,292]

Recruitment and Regulation of Testicular Macrophages

At birth, there are relatively few macrophages in the testis, but macrophage numbers expand dramatically during testicular development, coinciding with proliferation of the adult Leydig cell population and the appearance of the meiotic spermatocytes.[228,248,249,293] Indeed, the development of both the testicular macrophage and the adult Leydig cell populations appears to be interdependent. There is considerable evidence that macrophages are required for adult Leydig cell development and function.[208,259,261,262,264] Conversely, studies from a number of groups have shown that the accumulation of macrophages during testicular development and maintenance of their numbers in the adult are dependent upon the action of pituitary LH and, more specifically, the Leydig cells themselves (Figure 19.9).[69,226,293–297] Depletion of the Leydig cells or suppression of their activity in the adult

testis by various means causes a progressive decline in the number of testicular macrophages.[69,226,294–298] Although there is evidence that macrophages in the testis possess LH receptors,[299,300] the balance of the data suggest that the Leydig cell is responsible, rather than a direct action of LH itself. Testicular macrophage depletion occurs in models in which serum LH is increased (e.g. following treatment with the Leydig cell toxin, ethane dimethane sulfonate (EDS))[69] or decreased (e.g. hypophysectomy, GnRH immunization, suppression of endogenous androgen with subcutaneous testosterone implants).[294–298]

The precise mechanisms involved in maintaining the testicular macrophage population are not known. Complete depletion of spermatogenic cells by cryptorchidism has absolutely no effect on testicular macrophage numbers in the rat,[226] suggesting that their regulation does not involve the seminiferous epithelium. Moreover, it does not appear that androgens are directly involved.[226,293,295] However, it is likely that direct contact with the Leydig cell membrane and/or nonandrogenic products of the Leydig cells may be responsible.[240,244] Studies have clearly indicated that normal development of the testicular macrophage population, as in other tissues, involves the macrophage growth factor, colony stimulating factor-1 (CSF1).[247,264,285,301] The chemoattractant cytokine, MIF, which is constitutively expressed by the Leydig cells, likewise may be involved.[226,278,302] Furthermore, intratesticular production of the chemokines, chemokine (C-X3-C motif) ligand 1 (CX_3CL1; fractalkine) and CCL2, is implicated in the recruitment of circulating monocytes under normal conditions and during inflammation, respectively.[285,286,303]

It remains an area of ongoing discussion whether resident macrophages found in most tissues under noninflammatory conditions are largely derived and sustained from the circulating monocytes or by proliferation within the tissue itself.[235,304] The significant population of macrophages expressing CD68, but not CD163, in the normal testis suggests that there may be constant recruitment of these cells from the monocyte pool.[284] On the other hand, there is evidence that testicular resident macrophages may undergo active proliferation by mitosis, at least under certain circumstances: during the early inflammatory phase following destruction of the Leydig cells by EDS[305] and during testis development in rats and mice.[293,306] Consequently, it is not absolutely clear whether the resident macrophage population of the testis, once established, is maintained by recruitment of new monocytes or by local proliferation. In fact, it is most likely that both processes are involved. Based on the extended persistence of radionuclides in rodent, canine, and human testicular macrophages, on the other hand, it would appear that most resident macrophages do not escape the testis alive.[237,238]

While initial evidence that testicular macrophages respond directly to FSH has been shown to be due to an experimental artifact,[307] a stereological examination of macrophage recruitment to the testis in GnRH-immunized rats given recombinant FSH replacement demonstrated that FSH stimulates an increase in macrophage nuclear volume.[294] This indicates an effect on macrophage activity in the testis, which is almost certainly mediated via the Sertoli cell, the only testicular cell type able to respond directly to FSH. It appears that, while Leydig cells are responsible for recruiting and maintaining the testicular macrophage population, the Sertoli cell may play a role in directing at least some of the testis-specific functions of these cells (Figure 19.9). These two somatic cells act together to recruit and modify the function of the testicular macrophages, thereby bringing about the unique resident macrophage phenotype found in this organ.

Lymphocytes in the Testis

It is a common misconception that lymphocytes are not found within the normal testis. In fact, lymphocytes are relatively prominent within and adjacent to the epithelium of the rete testis and are sparsely distributed throughout the testicular interstitial tissue in all species so far studied.[65–70,231] In the rat and human testes, lymphocytes actually represent about 10–20% of the total leukocyte population, although the proportion of these cells in the normal mouse testis appears to be somewhat lower (Table 19.3) (Hedger MP, unpublished data).[69,227] It is worth noting that considerable differences may exist among different strains of animals and between animals raised under different degrees of exposure to environmental pathogens, as lymphocyte populations are very sensitive to differences in genetic background and past immunological events. Functional characterization of these cells has received relatively little attention: T cells and NK cells, but not B cells, have been described in the normal rat, mouse and human testis.[65,67–70,227] Most evidence suggests that the intratesticular lymphocyte population is skewed toward major histocompatibility complex (MHC) class I restricted ($CD8^+$) cells and cells expressing NK cell markers (Hedger MP, unpublished data).[65,69,70,227]

Typically, T cells circulate through tissues as part of their surveillance function, and it is widely believed that activated T cells tend to recirculate in tissues where they initially encountered an antigen.[308,309] The phenotype of the majority of the T cells of the rat testis is certainly consistent with activated or memory T cells.[70] There is clear evidence that lymphocyte numbers increase in the testes of men with infertility and sperm autoimmunity,[66,232] and lymphocyte numbers in the rat testis appear to gradually increase with age while macrophage numbers remain relatively constant (Hedger MP, unpublished data). These data suggest that at least some of the T cells

in the testis are specific for testicular autoantigens. Alternatively, some of these cells may represent T cells that have been exposed to exogenous antigens within the testis environs during past infections.

The observation that there are substantial numbers of cells expressing NK markers in the testes of rats, mice, and humans is particularly significant (Hedger MP and Aridi DZ, unpublished data).[70] Following isolation from the normal rat and mouse testis, it was confirmed that these cells have specific NK activity against transformed cells in vitro, and that a significant proportion of these cells are actually NK T cells (Hedger MP and Aridi DZ, unpublished data). In addition, $CD4^+CD25^+FOXP3^+$ Treg cells are present in both rodent species, but are considerably more prominent in the mouse testis than in the rat. Immunohistochemistry has recently localized Treg cells to the human testis, as well.[310] The T cells and NK T cells from the rat testis were found to produce IL10 under both unstimulated and PMA/ionomycin-stimulated conditions, although the T cells displayed a very high proportion of anergic and apoptotic cells compared with T cells from other tissues (Hedger MP and Aridi DZ, unpublished data). These observations indicate that the lymphocytes found in the normal testis comprise cells involved in cell-killing and innate immunity, that immunoregulatory subsets (NK, NK T and Treg cells) are highly represented, and that intratesticular T-cell responses to activation are significantly abrogated.

In normal testes, lymphocytes are rarely, if ever, observed within the epithelium or lumen of the seminiferous tubules, although lymphocytes appear to be able to cross the epithelium of the rete testis.[64–66] Nonetheless, the number of lymphocytes and macrophages increases dramatically within the testicular interstitial tissue during testicular infection, experimental autoimmune orchitis, leukemic relapse, and testicular tumorigenesis.[311–316] This infiltration is generally associated with failure of spermatogenesis, and the immune cells may eventually breach the tight junctions of the blood–testis barrier and invade the seminiferous epithelium. Moreover, human infertility is often associated with increased numbers of intratesticular lymphocytes and macrophages, as evidence of ongoing inflammation even in the absence of an overt immune event.[4,5] It remains to be determined whether this is a cause or a response to testicular damage or failure, but there tends to be a relationship between the number of intratesticular lymphocytes and the extent of testicular disruption.

Mast Cells and Eosinophils in the Testis

Mast cells and eosinophils are specialized mediators and regulators of inflammation, particularly in the context of allergic responses.[120,121] Mast cells, in particular, are found in almost all tissues, including those of the male reproductive tract, but their distribution in the testis displays very distinctive, species-specific differences.[62] In the testes of the rat, mouse, dog, cat, bull, and deer, these cells are largely absent from the testicular parenchyma but are frequently associated with blood vessels in the testicular capsule. In contrast, mast cells are found throughout the interstitial tissue in equine and human testes,[62,71,317] while both mast cells and eosinophils are relatively abundant in porcine species.[62] The functional significance of these cells in the testis is not known, but it is reasonable to assume that they play a role in local innate immunity and possibly a role in the fine control of testicular blood flow. In humans, testicular mast cell numbers decline with advancing age.[317] However, increased numbers of intratesticular mast cells and increased mast cell expression of PTGS2 are associated with various forms of testicular failure, and they have been found to correlate with the severity of damage and increased NOS2 expression in the Leydig cells.[22,318–320] In contrast to mast cells and eosinophils, neutrophils are only found in the testis in conditions of testicular inflammation or damage.[276,314,321,322]

In the adult rat, mast cells are normally confined to the subcapsular region, but they proliferate dramatically throughout the testicular parenchyma following ablation of the Leydig cells by EDS.[69,323–325] The degree of proliferation appears to be under the control of the Leydig cells, suggesting that these cells produce an inhibitor of mast cell activity.[69,325] However, the increased mast cell numbers persist even after the Leydig cells recover and testis function returns to normal following EDS treatment. The species distribution of mast cells and eosinophils suggests some relationship with the level of aromatase activity of the Leydig cells,[326,327] and neonatal estrogen treatment increases mast cell numbers in the rat testis.[325,328] Stem cell factor (SCF), which is growth factor for both mast cells and Leydig cells that is produced by the Sertoli cell, also may be involved.[329,330] While eosinophils are not a feature of the normal rat or mouse testis, these cells were occasionally observed in the testes of GnRH-immunized rats.[294] It appears that the regulatory mechanisms for the two different granulocyte subsets in the testis may be quite separate and distinct.

Immune Cells in the Epididymis

In contrast to the testis, macrophages and lymphocytes in the epididymis are frequently observed within the epithelium, where they are commonly identified as halo cells, as well as the interstitial tissue.[64–66,94–100,331–334] Published immune cell subset data for the epididymis have been complicated by the fact that some studies have not clearly differentiated between lymphocytes and macrophages because the CD4 and CD8 antigens are also expressed by rat and human monocytes and

macrophages.[335,336] Studies in the mouse, where these antigens are more restricted to lymphocyte subsets, indicate that macrophages are the major epididymal leukocytes, located chiefly in the interstitial and peritubular regions, and that there appears to be a slight preponderance of MHC class II restricted $CD4^+$ T cells (helper and regulatory T cell subsets) over the $CD8^+$ T cell subset in the interstitial tissue, typical of blood and most other tissues.[95,96,99] Conversely, the intraepithelial lymphocytes are predominantly $CD8^+$ T cells, which is a common feature of mucosal epithelia.[65,96,98,334] This distribution of T cell subsets is consistent with the observation that the interstitial tissue macrophages express MHC class II antigens, whereas macrophages within the epididymal epithelium mostly do not.[96,99] As in the testis, development of the epididymal macrophages is dependent upon CSF1.[337] Studies have suggested that the basal cells, located adjacent to the basal lamina of the epididymis, exhibit structural and antigenic properties typical of macrophages.[94,338] The numbers of the basal cells expressing macrophage-specific markers in the mouse are increased by the presence of damaged sperm, and it has been speculated that these cells are actually a type of resident macrophages, which could play a role in regulating immunity in the epididymis.[338,339]

Recently, dendritic cells have been identified, using specific reporter-labeled fluorescence imaging, as a major component of the epididymal epithelium in the mouse.[102] These cells form a dense network in the basal region of the epithelium and extend their processes between the epithelial cells. They express characteristic dendritic cell and antigen-presenting surface markers, including ITGAX, CX_3CR1, MHC class II antigens and CD80/86, and possess effective antigen-presenting activity in vitro. These cells are completely distinct in morphology and functional properties from the conventional intraepithelial macrophages or the basal cells.

Immune cells are found in all regions of the epididymis, although there is a tendency toward larger numbers and activity of all leukocyte subsets within the peritubular zone and epithelium of the caput, compared with the cauda.[96–99,338] The number of intraepithelial macrophage and $CD8^+$ T cells increases preferentially in the more proximal regions of the epithelium during aging and increased spermatogenic disturbance in rats, as well.[100] Moreover, the intraepithelial dendritic cells appear to be particularly active within the proximal caput, such that their processes can extend all the way through the epithelium; they presumably can sample antigens within the epididymal lumen and present them to $CD4^+$ T cells in the epididymal stroma and local lymph nodes.[102] The lymphatics of the epididymis have been studied in detail in the rat and mouse; they show a distinct regional distribution favoring the cauda, but otherwise appear to be unremarkable.[340–342]

The very different distribution of leukocytes in the epididymis compared with the testis indicates the existence of a different immunological environment, where separation between the antigenic sperm and the local immune cells is less robust, and more dynamic interactions are possible. Obviously, separation of antigens and immune cells is not the principal mechanism protecting sperm from immunological attack in this organ. In fact, it has been speculated that the macrophages within the epididymal duct may even be responsible for phagocytosis of senescent and excess sperm, although the evidence for this is equivocal.[333,343–345] The immunophysiological functions of the macrophages and lymphocytes within the epididymis are only just being uncovered, and they represent a fertile area for future research.

Immune Cells in the Vas Deferens, Accessory Glands, and Urethra

The organization of the vas deferens is very different from that of the epididymis: it is not coiled but has an extensively convoluted epithelium and multiple layers of smooth muscle. Sperm are not stored in the vas, and the majority of sperm pass through the duct only transiently at the time of ejaculation, but this structure plays a special role in our understanding of autoimmunity in the male tract because of the widespread use of vasectomy as a contraceptive method. Approximately 70% of all vasectomized men develop sperm antibodies; in many of these men, the antibodies are persistent, thereby frustrating later attempts to restore fertility.[346,347] Sperm antibodies are likewise associated with obstructive azoospermia and congenital absence of the vas (CAV) in men,[348] and similar antibody responses occur in experimental animal models.[332,349–352] These observations clearly indicate that obstruction or damage to the vas deferens is a potent inducer of sperm autoimmunity.

Although less prominent than in the epididymis, intraepithelial lymphocytes, principally $CD8^+$ T cells, are found throughout the vas deferens, seminal vesicles, prostate, and urethra.[64,66,353–357] Macrophages appear to be relatively rare in the epithelia, but they are found in the stroma of these tissues even under noninflammatory conditions, where they are dependent upon CSF1 for their development.[337,353] Relatively little is known about the immunological properties of these cells, but a predominance of cytotoxic $CD8^+$ T cells is a common characteristic of all mucosal epithelia. While an immunoregulatory role of these lymphocytes in the reproductive epithelium remains to be determined, these cells are almost certainly involved in mediating cellular immunity at these sites.

It is self-evident that the leukocytes found in semen, even in men with no obvious infection or other inflammatory condition, must originate from the epithelium of the ducts and organs of the male reproductive tract.[358]

Logically, immune cells pass with relative ease across the epithelium in certain areas, thereby coming into physical contact with the sperm at the time of ejaculation. It is nonetheless curious that, while macrophages and lymphocytes are typically present, the leukocytes most commonly found in the semen are neutrophils, which are not a major leukocyte subset within either the stroma or epithelia of the male reproductive tract.[358–364] Because vasectomy dramatically reduces leukocyte numbers in the ejaculate, the epididymis and proximal vas deferens appear to be a major source of these cells, at least under normal conditions, but the accessory glands (seminal vesicles and prostate) are also implicated as a source of the seminal neutrophils.[364–366]

IMMUNOLOGICAL AND INFLAMMATORY MEDIATORS IN THE TESTIS

Inflammation and activation of the immune response has immediate and mostly negative effects on male reproduction and fertility.[20,21,367] It is widely assumed that this reproductive disruption is related to fever and the effects of raised body temperature on spermatogenesis in febrile patients, but there is actually very little experimental evidence to support this assumption. In fact, there is an enormous body of research to indicate that other inflammatory mechanisms can affect male reproductive function and are much more likely to disrupt reproduction.

More than 25 years ago, it was reported that rat testicular extracts contained a protein with properties similar to IL1, which eventually turned out to be IL1, produced by Sertoli cells rather than by intratesticular leukocytes.[368,369] Although generic molecules with inflammation-regulating activity, such as the prostaglandins, were already known to be produced by the reproductive tract, this discovery provided the first indication that an inflammatory molecule belonging to the immune system could be produced by a somatic cell of the male reproductive system. In subsequent years, it became increasingly obvious that many inflammatory and immunoregulatory cytokines could be produced by somatic and spermatogenic cells of the testis in response to an inflammatory stimulus, including IL1, IL6, TNF, and TGFβ family members and interferons. Moreover, once it became apparent that their production was constitutive, in the absence of any evidence of cryptic inflammation, or could be stimulated by physiological stimuli, such as hormones or cell–cell interactions, a role in normal reproductive physiology was anticipated. It is now very evident that inflammatory and immunoregulatory molecules produced by the testis are involved in regulating both immunological processes within the testis and many aspects of normal testicular function associated with fertility. The production and actions of the most prominent of these molecules are briefly outlined in this section of the review. Integration of their actions and the consequences for testicular immune responses and fertility are covered in later sections.

The Interleukin-1 Family and the TLRs

These molecules are related by the fact that the IL1 receptor and the TLRs belong to a family of dimerizing receptors that contain the conserved cytoplasmic TIR domain.[106,112] Both IL1 and TLR ligands act through similar signaling pathways to activate intracellular MAP kinases and the pro-inflammatory transcription factor, NFκB, and induce the expression of early pro-inflammatory genes, including IL1 (Figure 19.5).

Interleukin-1

The archetypical pro-inflammatory cytokine, IL1 is represented by two related proteins (IL1α and IL1β) capable of binding to the same receptor to exert an almost identical range of effects.[370] These proteins are produced by many cells types, but activated monocytes and macrophage are the major source of secreted IL1.[370] Both IL1α and IL1β are single chain proteins, with only about 25% homology at the mature protein level. They are synthesized as 31–33 kDa precursor proteins that are cleaved enzymatically to active 17-kDa forms (Figure 19.10). Both the precursor and mature forms of IL1α are biologically active, but the IL1β precursor is inactive. Consequently, production of active IL1β is a two-step process involving NFκB-induced transcription and translation of the IL1β precursor gene, followed by cleavage of the precursor to the mature cytokine by CASP1.[117,118] This processing of IL1β is linked to its secretion into the extracellular space. Conversion of IL1α does not involve CASP1, but the precursor can be cleaved by calcium-dependent membrane-associated cysteine proteases, or calpains, and extracellular proteases.[371] In contrast to IL1β, the majority of IL1α tends to remain within the cell or associated with the cell membrane, although it may be found in secretions as well.[370] It is generally believed to act as an autocrine growth factor or as a mediator of direct cell-to-cell communication, but the mechanisms involved are poorly defined. Both IL1α and IL1β differ from most cytokines in that they lack a signal sequence and their mechanisms of secretion remains to be elucidated.

Intratesticular Production of Interleukin-1

Intratesticular IL1α and IL1β have been observed in many species, including the human,[372] but have been most extensively studied in the rat. Endogenous production of IL1α appears in the rat testis at around 20 days of age, more or less coinciding with progression of the first wave of spermatogenesis.[369,373–376]

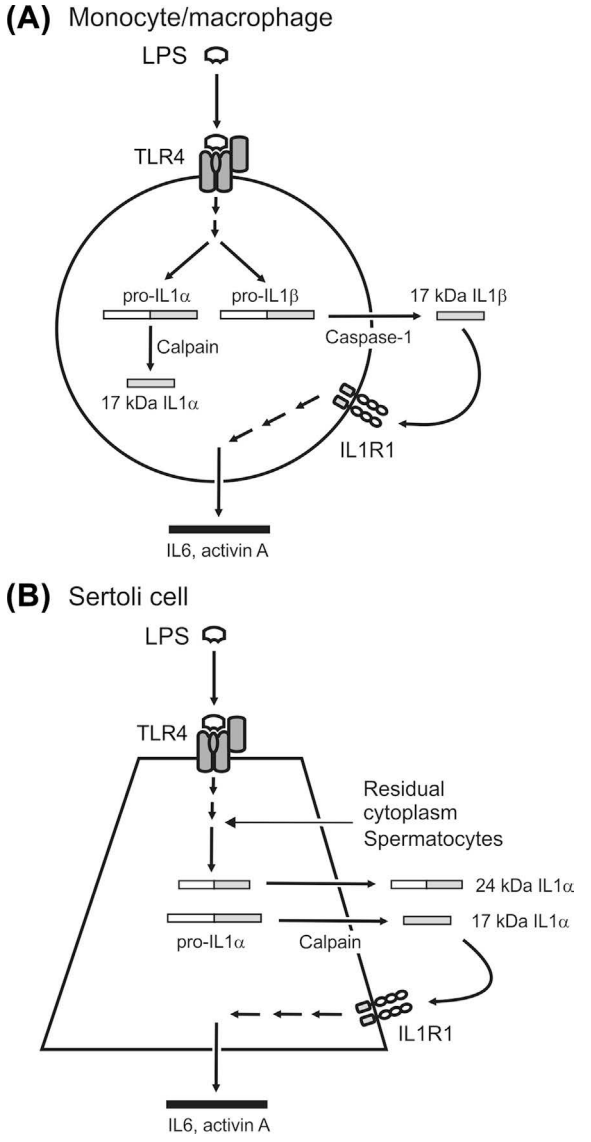

FIGURE 19.10 Comparison of the regulation and production of interleukin-1 (IL1), IL6 and activin A in the monocyte/macrophage and Sertoli cell. (A) Activation of the TLR4 complex on the surface of the macrophage by bacterial lipopolysaccharide (LPS) upregulates expression of both IL1α and IL1β, which subsequently are processed to their mature bioactive 17-kDa forms by the action of calpain and caspase-1, respectively. IL1α tends to remain associated with the cell, but IL1β is secreted upon cleavage and binds to the IL1 receptor (IL1R1) on the cell surface to stimulate production of other inflammatory cytokines, such as IL6 and activin A. (B) The Sertoli responds to stimulation by LPS, spermatocytes and the residual cytoplasm of released spermatozoa by producing IL1α, preferentially. Two alternate transcripts of IL1α are produced by the Sertoli cell, including a transcript lacking the calpain cleavage site domain, which encodes a 24-kDa form of IL1α with reduced bioactivity. Both forms appear to be secreted by the adult Sertoli cell and both are able to signal via the IL1 receptor to stimulate the production of IL6 and activin A.

This appears to be almost entirely due to the Sertoli cells, which synthesize and secrete both the mature 17-kDa IL1α molecule and a slightly larger 24-kDa testis-specific form of IL1α—the latter being the product of an altered mRNA transcript lacking the calpain cleavage site necessary for processing of the precursor (Figure 19.10).[377–379] Adult rat seminiferous tubule extracts also contain an immunoreactive 45-kDa IL1α protein that has yet to be fully characterized, but may be another variant of the precursor mRNA with one or more introns retained. These testis-specific transcripts are biologically active, although less potent than mature 17-kDa IL1α.[377,380] There is some evidence that rat spermatocytes and spermatids also express IL1α constitutively.[381]

Production of IL1α by the Sertoli is under control of the spermatogenic cells and shows a distinct cyclical variation that is related to the changes in spermatogenic cell associations as determined by the cycle of the seminiferous epithelium.[373,382–384] It is strongly stimulated by phagocytosis of the residual cytoplasm cast off by the spermatids when they are released into the tubule lumen.[375,376,385] Sertoli cell production and secretion of IL1α in vitro is induced by various inflammatory stimuli, including LPS and IL1 itself, but not by FSH.[376,385–388] Studies indicate that Sertoli cells from prepubertal rats produce, but do not secrete, IL1α, whereas Sertoli cells from adult rats are able to secrete biologically active IL1α.[369,379,389] The mechanism underlying this maturational change in ability of the Sertoli cell to secrete IL1α is unknown.

In contrast to IL1α, IL1β appears not to be produced in significant amounts in the rat testis under normal conditions, but is upregulated in a subset of testicular macrophages and the Leydig cells during inflammation.[274,369,373] Curiously, the majority of this secreted testicular IL1β is present as the precursor protein.[274] Studies have shown that Leydig cells express the mRNA for both IL1α and IL1β in vitro in response to stimulation by LPS or exogenous IL1,[390–392] and whole testes and isolated macrophages collected from LPS-treated rats or mice express IL1β mRNA,[393–395] and the immunoreactive protein.[396] Thus, while IL1β expression in the normal testis is relatively low, it increases during inflammation, possibly due to production by interstitial cells rather than by the Sertoli cells. The response of testicular IL1α to inflammation in vivo is less clear: although production by the Sertoli cell is upregulated by inflammatory stimuli in vitro, recent in vivo studies report either no response or reduction during systemic inflammation.[396,397]

Intratesticular Actions of Interleukin-1

Numerous studies have established that IL1, whether produced intratesticularly or external to the testis, is an effective regulator of Leydig cell steroidogenesis, spermatogonial and spermatocyte development, and various Sertoli cell functions associated with supporting spermatogenesis.

The actions of IL1 are mediated by the IL1 type I receptor (IL1R1), which belongs to the immunoglobulin superfamily of receptors, but also bears an intracellular TIR domain (Figure 19.5).[106,112] Following ligand binding, a second TIR domain-containing subunit, called the IL1R acceptor protein (IL1RAP), is recruited to form a complex that binds the MYD88 adaptor protein and activates IRAK, leading to NFκB nuclear translocation and MAP kinase activation. Moreover, IL1 is able to activate other signaling pathways through induction of phosphatidylinositol-4,5-bisphosphate 3-kinase (PIK3)/Akt protein kinase (AKT) and tyrosine-protein kinase Src (SRC), hydrolysis of GTP, phosphatidylcholine, phosphatidylserine or phosphatidylethanolamine, release of ceramide by neutral sphingomyelinase, and release of arachidonic acid by phospholipase A_2 (PLA_2).[370,398] There is an IL1 type II receptor (IL1R2), which lacks a TIR domain and can act as a decoy or inhibitory receptor.[399]

In cultures of Leydig cells from immature rats (10–20 days of age), IL1β caused a dose-dependent increase in DNA synthesis, and IL1α was much less potent than IL1β.[400] The effect of IL1β was not observed in Leydig cells isolated from older animals, suggesting that macrophage-derived IL1β could play a role in Leydig cell proliferation during prepubertal development.[400] The possible involvement of prostaglandins in this developmental regulation is indicated by the observations that IL1β stimulates the expression of PTGS2, both IL1 isoforms and IL6 in rat progenitor Leydig cells, and that prostaglandins act as intermediates in this stimulatory pathway.[401]

A review of the literature dealing with the direct effects of IL1 on testosterone production by mature Leydig cells in vitro reveals reports of stimulation, inhibition or even of no effect.[395,402–406] Presumably, these apparent discrepancies arise from differences in the experimental conditions or methodologies employed. On balance, studies suggest that IL1 is either stimulatory or has no effect on basal testosterone production by adult Leydig cells,[406–408] and there is general agreement that IL1 inhibits LH/hCG and/or cAMP stimulated testosterone production.[395,402,403,406,407,409] In the mouse, the major site of inhibition is at the level of CYP17A expression (Figure 19.3).[403,410] In the rat, IL1 appears to regulate Leydig cell steroidogenesis at the level of CYP11A, while STAR gene expression and protein synthesis are unaffected.[404,411] The effects of testicular IL1α on Leydig cell steroidogenesis may be dependent on both the variant of IL1α involved and on the stage of development of the Leydig cell. The 32-kDa IL1α precursor and the 17-kDa mature IL1α are both inhibitory to gonadotropin-stimulated or cAMP-stimulated steroidogenesis in mature Leydig cells, whereas the testis-specific 24-kDa IL1α splice variant has no effect.[380] In contrast, all three forms of IL1α stimulated testosterone production by immature rat Leydig cells. When IL1β was injected into the immature rat testis, Leydig cell steroidogenesis and serum testosterone levels were stimulated within 24 h, although Leydig cell activity had declined several days later.[412] No similar effect was observed in the adult testis. The signaling mechanisms mediating IL1 effects on the Leydig cells involve PTGS2 enzyme expression and PGE_2 acting as an intermediate.[402,413] Studies using Leydig cells from immature rats have also implicated the MAP kinases, MAPK14 and MAPK3/MAPK1, in the regulation of STAR and cholesterol mobilization.[380,414]

The IL1 receptor (IL1R1), along with the decoy receptor (IL1R2), has been localized to most testicular cell types in rat, mouse and/or human testis, including the spermatogenic cells and Sertoli cells.[415] It has been shown that IL1α is able to stimulate mitotic DNA synthesis in intermediate and B type spermatogonia and meiotic DNA synthesis in preleptotene spermatocytes.[382–384,416] In vitro, IL1 stimulates proliferation of prepubertal Sertoli cells[417] and regulates a number of activities of more mature Sertoli cell that support or control spermatogenesis, including aromatase activity,[418] production of glucose transporters, lactate and transferrin,[419–421] and production of IL1α, IL6 and the IL1 receptor.[375,385] IL1 also regulates production by the Sertoli cell of the inhibin B heterodimer and the homologous β-subunit homodimer, activin A, in an inverse relationship with FSH.[389,422] Considered more broadly, IL1 opposes the mostly stimulatory effects of FSH on Sertoli cell activity. Moreover, IL1 regulates the ability of the Sertoli cell to maintain contact with other Sertoli cells and developing spermatogenic cells, by altering the Sertoli cell cytoskeleton, and stimulates opening of the occluding junctions that make up the blood–testis barrier.[423] Regulation of Sertoli cell function by exogenous IL1 has been found to involve multiple pathway intermediates, including MAPK14, MAPK8 and MAPK3/MAPK1, PIK3/AKT, PTGS2/PGE_2 and NOS2/NO, although the more predictable participation of MYD88 and NFκB still awaits investigation.[417,424–427]

Interleukin-18 and Other Interleukin-1 Family Cytokines

The IL1 family comprises several structurally related proteins, which appear to have arisen by gene duplication.[428] The most closely-related to IL1α and IL1β is IL18, which is normally processed to its mature form by the inflammasome and the action of CASP1, like IL1β, but acts via a distinct IL18 receptor.[429] Both IL18 and its receptor have been found in the seminiferous epithelium of the rat, with IL18 mRNA and protein localized to spermatocytes and round spermatids.[430] Murine Leydig cells produce IL18, CASP1, and the IL18

receptor in response to stimulation by LPS,[431] and IL18 has been detected by immunohistochemistry in human testis, where its expression is reduced in impaired spermatogenesis.[432] Recombinant IL18 stimulates spermatogonial DNA synthesis in cultures of rat seminiferous tubules, without influencing germ cell apoptosis.[430] As is the case for IL1β, the majority of IL18 produced within the rat testis is in the precursor form,[430] indicating that the processing of these cytokines by the inflammasome/CASP1 in the testis is an area that merits more investigation.

The IL1 receptor antagonist (IL1RN) binds to the IL1 receptors but lacks the ability to transduce a signal, and so acts as a competitive antagonist of IL1 action.[433] It has been shown to be produced by mouse Sertoli cells, and its production is stimulated by FSH, LPS and IL1.[434] Male mice lacking IL1RN have higher intratesticular levels of IL1α and IL1β, along with reduced fertility and litter sizes and increased morphological abnormalities and premature activation of their sperm, although sperm number and motility is not affected.[435]

The TLRs

Studies have revealed that TLRs are widely expressed in the male reproductive tract (Table 19.4).[24,101] The other pattern-recognition receptor families have yet to receive much attention in this context, but several NLR and RLR family members have already been identified in the testis.[436,445,446]

Studies in the rat and mouse have established that Sertoli cells express TLR1-6 at significant levels, with relatively low expression of TLR7 and 13 in the mouse and of TLR 10 and 11 in the rat.[388,436–440] Quantitative examination of the TLR4 complex in rat Sertoli cells confirmed that the level of expression of TLR4 and its co-receptor, MD2, was similar in the Sertoli cell and testicular macrophage, but that Sertoli cells displayed low basal or LPS-induced expression of the TLR4 accessory protein, CD14.[388] Cytokine production responses to TLR1-6 ligands have been confirmed in both rat and mouse cells. The Sertoli cells produce appropriate cytokines, such as IL1α, IL6, and CCL2, in response to TLR4 activation by LPS,[379,388,436,437] and type 1 interferons in response to TLR3 or TLR4 activation[438–440]; however, the precise roles of specific signaling pathways in these responses requires further clarification, particularly with respect to the importance of the adaptor protein MYD88 and the transcription factor NFκB.[436–440]

The majority of studies on the effects of TLR ligands on Sertoli cells have employed LPS, which induces inflammatory gene responses in the Sertoli cells that are similar to those observed in macrophages.[24] However, LPS obtained from different bacterial strains can have quite different chemical composition and is frequently contaminated by other TLR ligands (e.g. bacterial lipoproteins

TABLE 19.4 Toll-like Receptor Expression in the Epithelium of the Male Reproductive Tract[a]

Receptor	Principal Ligands	Principal Pathogens	Cellular Location	Sertoli Cells	Epididymis	Vas Deferens
TLR1	Triacyl lipopeptides	Bacteria, mycobacteria	Cell surface	+++	++	+++

and peptidoglycans).[447] This means that many studies in the literature using LPS actually describe responses involving multiple TLRs (usually TLR2 and TLR4). When highly purified LPS was used, rat Sertoli cells were more than 10-fold less sensitive to LPS than testicular macrophages, but they expressed similar levels of IL1α and IL6 and much greater levels of activin A when maximally stimulated.[388] These Sertoli cells also responded to the synthetic lipopeptide Pam3Cys (a specific TLR2 ligand) with a more prolonged pattern of gene expression. The need for relatively high doses of LPS to stimulate the Sertoli cell is probably related to the relatively low level of expression of the accessory protein, CD14, which serves to amplify the response to LPS in macrophages.[110] These data indicate that Sertoli cells respond to bacterial ligands acting through both TLR2 and TLR4, although they are less sensitive to these ligands in comparison with local macrophages and display a Sertoli cell-specific pattern of gene expression in response.

There have been few studies on the effects of TLR ligands on noninflammatory responses in the Sertoli cell: exposure of Sertoli cells to LPS in vitro directly inhibited lactate production and plasminogen activator activity, which are important functions for supporting spermatogenic cell development.[448] In other studies, LPS induced oxidative stress in Sertoli cells by increasing ROS production and reducing antioxidant activity,[449] while activation of TLR3, a receptor for viral double-stranded RNA, stimulated scavenger receptor expression and phagocytosis of apoptotic spermatogenic cells by Sertoli cells in culture.[439]

In rat and/or mouse studies, mRNA for TLR2, 3, 4, 7, 9, 10, and 12, along with low levels of MD2 and CD14, have been observed in Leydig cells; TLR2, 3, 4, 6, and 11 have been observed in peritubular cells; and TLR2, 3, and 4 have been observed in spermatogenic cells (Hedger MP and Winnall WR, unpublished data).[388,436,450,451] These cells also respond to TLR ligands in vitro. Leydig cells produce pro-inflammatory cytokines and type 1 interferons, but they reduce their sterodogenic activity when stimulated with LPS or a TLR3 agonist.[390,392,450] Peritubular cells respond to LPS by producing the macrophage chemoattractant, CCL2.[303] Most remarkably, activation of TLR3 has been reported to induce the inflammatory transcription factors, NFκB and IRF3, and a range of genes involved in inflammation and antiviral responses in mouse spermatogonia and spermatocytes.[451]

In the immune system, the TLRs and IL1 are fundamental regulators of NFκB activity. The regulation and functional role of this pro-inflammatory transcription factor in normal spermatogenesis is not fully understood at this time, but existing data suggest that there is an interaction between endogenously-expressed inflammatory molecules and NFκB in controlling seminiferous epithelial function. NFκB is constitutively present and active in the nucleus of cultured rat Sertoli cells and displays a cyclical localization within the nuclei of the Sertoli cells and spermatogenic cells throughout the cycle of the seminiferous epithelium.[452] Induced expression of NFκB stimulates androgen receptor expression, and therefore androgen responsiveness, in rat Sertoli cells,[453] but activation of NFκB in Sertoli and/or spermatogenic cells has also been implicated as an apoptosis-inducing signal in damage models, involving exposure to toxins, ischemia-reperfusion injury, and cryptorchidism.[454–457]

The TNF Family

Tumor Necrosis Factor

Members of the TNF family of cytokines are commonly membrane-bound homotrimers that can be released as soluble ligands by proteolytic cleavage. The canonical member of this family, TNF is a 17-kDa glycosylated polypeptide that is secreted principally by activated monocytes and macrophages, and binds to receptors that are present on most cells in the body.[458] This cytokine plays a central role in the initiation of the inflammatory response, and can exert pro-inflammatory or cytotoxic effects depending upon the receptor subtype engaged and the expression of specific adaptor proteins within the target cells (Figure 19.5). There are two families of TNF receptors (TNFR).[459,460] The TNFR type 1 family of receptors induce cell death through a motif in their cytoplasmic regions called the death domain (DD), and includes TNFR1, FAS and the death receptors (DR)3-6. When TNF binds to TNFR1, there is recruitment to the DD of the intracellular adaptor proteins TRADD (TNFR-associated death domain) and FADD (Fas-associated death domain), leading to activation of the cell death caspase pathway. However, the binding of TRADD can also lead to recruitment of the cellular inhibitor of apoptosis (baculoviral IAP repeat containing; BIRC) protein or receptor interacting serine–threonine kinase (RIPK), enabling the binding of TRAF2. This complex mediates activation of the NFκB pathway and the MAP kinases, MAPK14 and MAPK8. The TNFR type 2 receptors, which include TNFR2, TNFR superfamily member 8 (TNFRSF8, CD30) and 5 (TNFRSF5, CD40), and the lymphotoxin receptor, do not contain a DD in their intracellular domains, and instead associate with TRAFs leading to the activation of cell signaling events.

Intratesticular Production and Actions of TNF

In common with IL1, TNF regulates Leydig cell steroidogenesis and the spermatogenesis-supporting functions of the Sertoli cell, but TNF appears to act as a regulator of spermatogenic cell survival, rather than of proliferation or development. In situ hybridization studies in mice first identified the presence of TNF mRNA

in round spermatids, pachytene spermatocytes, and testicular interstitial macrophages.[461] Bioactive TNF was produced by the round spermatids in vitro and mRNA for the corresponding receptor was located on Sertoli and Leydig cells. Similarly, in the seminiferous epithelium of the rat, TNF has been localized to the spermatogenic cell compartment, and TNF receptors primarily localized to the Sertoli cells.[462] Treatment of isolated rat or mouse testicular macrophages with LPS also induces TNF secretion.[463,464]

The majority of studies performed using a variety of systems, including intact animal studies,[465,466] isolated primary cultures of Leydig cells,[410,467–469] and MA-10 tumor Leydig cells transfected with CYP17A-reporter constructs,[470] report inhibitory effects of TNF on Leydig cell steroidogenesis. Inhibition of LH/hCG binding, STAR expression, and cholesterol mobilization has been observed,[466,471] but these studies also indicate that inhibition by TNF occurs downstream of cAMP production at the level of steroidogenic gene expression (Figure 19.3). In cultured mouse Leydig cells, TNF had no effect on basal expression of CYP11A, but it suppressed basal expression of HSD3β and the expression of CYP11A, CYP17A, and HSD3β induced by analogs of cAMP.[410,468] The inhibitory effect of TNF on CYP17A gene expression was found to be mediated through protein kinase C, possibly by activation of MAPK8, MAPK3/MAPK1, and the transcription factors, NFκB and AP-1.[467,470,472] Several other studies have implicated the sphingomyelin/ceramide-dependent pathway in TNF-mediated inhibition of Leydig cell testosterone secretion.[466,469] Although the levels of testosterone and the mRNA levels of steroidogenesis-related genes were significantly lower after puberty in TNF knockout mouse testes than in wild-type testes, this may be attributed to increased levels of anti-Müllerian hormone in these animals.[473]

Within the seminiferous epithelium, TNF appears to play a complex role in the regulation of Sertoli cell and peritubular cell function, which is probably attributable to the ability of TNF to stimulate both cell-killing and cell signaling pathways. Many of the effects of TNF have been shown to involve the activation of NFκB and MAP kinases in the Sertoli cell.[453,474–478] Similar to IL1, TNF stimulates basal lactate production by cultured Sertoli cells, but generally antagonizes the actions of FSH on Sertoli cell function, including the stimulation of lactate production, aromatase activity and inhibin.[479–481] Nevertheless, TNF receptor subunit protein expression has been shown to be stimulated by FSH in porcine Sertoli cells.[482] TNF stimulates the expression of inflammatory cytokines, chemokines, and leukocyte adhesion molecules expression in both Sertoli cells and peritubular cells.[303,387,477,478] Furthermore, TNF stimulates plasminogen activator inhibitor expression in rat testicular peritubular cells, indicating that it plays a key role in controlling testicular protease activity.[483] In Sertoli cell monolayer cultures, TNF disrupts inter-Sertoli cell tight-junction assembly by inhibiting production of the junction protein, occludin, and by regulating matrix metalloprotease and protease inhibitor activity.[484] Delfino and colleagues have shown that TNF stimulates androgen receptor expression in Sertoli cells via upregulation of NFκB, which binds to several enhancer motifs in the androgen receptor promoter.[453]

Single nucleotide polymorphisms in the TNF gene cluster producing elevated TNF levels have been shown to be associated with reduced sperm count and sperm motility in infertile men,[485] but the outcomes for spermatogenesis of TNF action are not always so clear-cut. Paradoxically, TNF reduces spontaneous spermatogenic cell degeneration in cultured human and rat seminiferous tubules, apparently by regulating FASL and/or NFκB levels in the Sertoli cell, indicative of a germ cell survival role for TNF mediated through the Sertoli cell.[475,476] At first glance, this would appear to run counter to the observation that activation of NFκB in the Sertoli cell or germ cells induces spermatogenic cell apoptosis in various damage models,[454–457] and the studies that have identified a role for germ cell-secreted TNF in the disruption of spermatogenesis in response to cytotoxic injury of the Sertoli cell.[486] However, NFκB is also able to regulate and interact with pro-survival genes, such as the inhibitor of apoptosis (IAP) and BCL2 families.[459,487] The interactions between TNF, NFκB and different apoptotic regulators produces complicated outcomes for spermatogenic cell survival in different situations, and the responsible mechanisms invite further investigation.

FAS and FAS Ligand

The death receptor FAS and its ligand (FASL) most commonly act as membrane-bound trimeric ligand–receptor pairs mediating cell–cell interactions, and FAS–FASL binding on activated T cells is essential for moderating the immune response.[180] Typically, the DD in the cytoplasmic region of FAS recruits the FADD adaptor protein and induces T cell death via caspase-dependent apoptosis.[488] In the testis, FAS and FASL have been implicated in regulating spermatogenic cell apoptosis during testicular damage and, more controversially, in maintaining immune privilege.[489,490] Studies intended to localize FASL in the testis under normal conditions have produced conflicting results, which may be attributed to differences in detection methods, limitations of the reagents employed, and the fact that these molecules are readily inducible.[491,492] Thus, FASL has been described as being present in rat, mouse, porcine, and human Sertoli cells, and absent in most germ cells,[489,490,493,494] but others have reported that FASL expression in the rat seminiferous epithelium is confined to the germ

cells.[492,495] FAS has been identified on isolated mouse Sertoli cells,[496] but in intact testes it has been localized to spermatogonia and spermatocytes from the pubertal period onwards.[490,495,497]

Nonetheless, FAS expression is clearly associated with spermatogenic cells that are undergoing apoptosis.[475,486,490,497] Furthermore, FAS can be induced in the Sertoli cell by the action of TNF and IFNγ.[474,496] Expression of both FAS and FASL is upregulated in various models of seminiferous epithelium damage, indicating that this mechanism is important in regulating germ cell apoptosis in cases of physical and toxicological insult.[490,498] Induction of FAS and FASL is also implicated in the testicular response to inflammation.[499]

Interleukin-6

In contrast to either IL1 or TNF, IL6 is a cytokine with both pro-inflammatory and anti-inflammatory actions (Figure 19.7); for example, IL6 stimulates B cell growth and differentiation and promotes neutrophil activity and survival, but inhibits the effects of IL1 and TNF, and induces IL1RN and IL10 expression.[125,500] In the late inflammatory phase, it stimulates the acute-phase response and promotes fibrosis. Outside the immune system, IL6 plays crucial roles in hematopoiesis, liver and neuronal function, energy metabolism, and cancer. Cytokines of the IL6 type, which include leukemia inhibitory factor (LIF) and IL11, exert their action via binding to specific receptors that can form complexes with a common, ubiquitously-expressed membrane signal transducer, glycoprotein 130 (interleukin-6 signal transducer; IL6ST).[501] In lymphocytes and hepatocytes, IL6 binds to its specific membrane-bound receptor (IL6R; CD126), which has no intrinsic kinase activity and dimerization with IL6ST leads to activation of the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) and MAP kinase signaling pathways (classic IL6 signaling). However, all cells that express IL6ST are able to respond to IL6 bound to soluble IL6R, which may be produced from an alternatively-spliced mRNA transcript or released by proteolytic cleavage of membrane-bound IL6R, a process called trans-signaling.

In vitro, IL6 is constitutively produced by Sertoli cells and Leydig cells.[375,386,390,502–504] Production of IL6 in rat or mouse Sertoli cells is stimulated by a range of agents, including FSH, testosterone, IL1, TNF, and LPS, and is inhibited by INFG.[387,496] Phagocytosis of residual cytoplasm shed by late spermatids at the time of spermiation triggers Sertoli cell IL1α production, which stimulates IL6 secretion in an autocrine manner, by activating leukotriene production via the lipoxygenase pathway (Figure 19.10).[375,387] Leydig cells are strong producers of IL6 after stimulation by LH, LPS, or IL1 in vitro, and may be the major source of this cytokine in the testis.[390,503,504] Human peritubular cells express IL6 mRNA, but possibly not the protein, when stimulated by TNF,[478] and isolated spermatogenic cells from adult mice express IL6 mRNA and protein when stimulated with a TLR3 ligand, poly(I:C).[451]

Although not as intensively studied in the testis as either IL1 or TNF, it appears that IL6 regulates the function of somatic, spermatogenic, and immune cells. Both IL6R and IL6ST mRNA are expressed in rat Sertoli cells and are stimulated by IL1 and by IL6, but only the IL6R subunit is stimulated by FSH.[505] In the Sertoli cell, IL6 increases basal and FSH-induced transferrin and cyclic GMP secretion,[506,507] but reduces κ opioid receptor mRNA levels.[508] IL6 has been shown to act as an inhibitor of meiotic DNA synthesis in preleptotene spermatocytes.[509] An effect of IL6 on testicular steroidogenesis at the level of both the Leydig cell and the hypothalamic-pituitary levels is indicated by the observation that subcutaneous IL6 administration in men produced prolonged suppression of serum testosterone levels, without apparent changes in gonadotropins.[510]

The Transforming Growth Factor-β Family

Cytokines of the TGFβ family, similar to IL6, possess both pro-inflammatory/pro-fibrotic and anti-inflammatory/immunosuppressive properties (Figure 19.7), but also regulate growth and differentiation at a fundamental level throughout the entire body. They are mostly homo- or heterodimers that act by binding two transmembrane receptor kinases, denoted as type I and type II, and assembling them into an active heterotetramer.[511,512] This triggers a transphosphorylation cascade that begins with the activation of the type I subunit kinase by the type II subunit kinase, and is propagated by the canonical SMAD (small for body size/mothers against decapentaplegic homolog) protein signaling pathway, which in the case of TGFβ and activin involves SMADs 2, 3 and 4, and to non-SMAD-mediated signaling pathways.[511,513] These receptors are expressed in most cells and tissues.

Transforming Growth Factor-β

The three forms of TGFβ (TGFβ1, TGFβ2, and TGFβ3) found in mammals are disulfide-linked dimers of approximately 25 kDa in mass, derived from three structurally-similar subunits possessing intrastrand disulfide bonds that form a cysteine knot folding motif (Figure 19.11).[514] Heterodimers of the subunits can also occur but are less abundant. All three forms are differentially expressed by Sertoli cells, peritubular cells, and Leydig cells, particularly in the fetal and immature testis, although production appears to decline considerably during the establishment of complete spermatogenesis.[515,516] In the postpubertal testis, they also have been localized to the spermatogenic cells in a development-specific pattern of expression.[225,517,518]

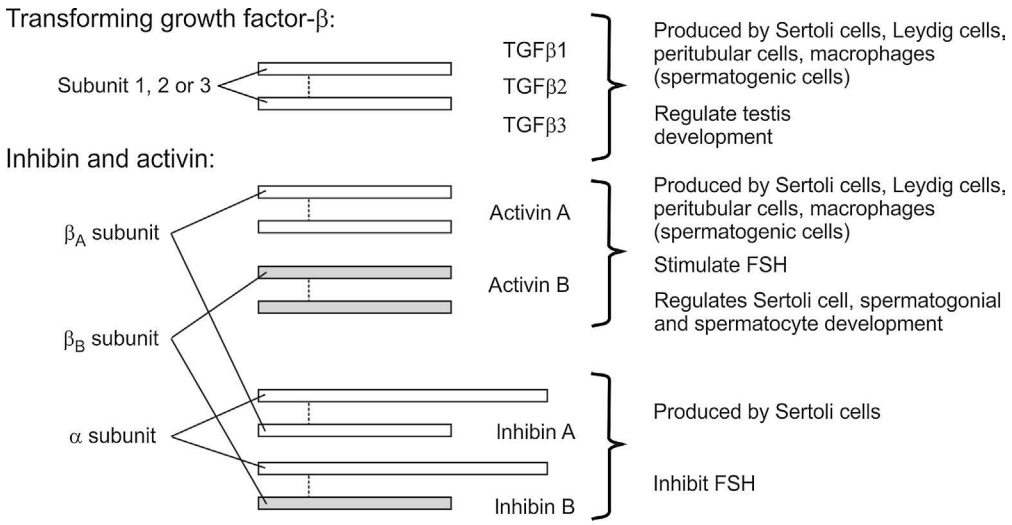

FIGURE 19.11 The transforming growth factor-β (TGFβ) and activin/inhibin family of cytokines. These cytokines are dimers of disulfide-linked subunits with considerable sequence and structural homology, and have diverse actions within the reproductive and immune systems. Three distinct subunits lead to production of homodimers (or less frequently heterodimers) of TGFβ1, 2, or 3. Dimerization of two homologous β-subunits lead to either activin A, activin B, or less commonly activin AB (not shown). Dimerization of the activin subunits with the closely related α-subunit produces the inhibins, which are produced almost exclusively by the Sertoli cells. Activins derived from the β_C-subunit (not shown), appear to play regulatory roles through formation of nonactivating homodimers and heterodimers.

The receptors for TGFβ are found in both somatic and spermatogenic cells.[225,517,519] In the fetal and immature testis, TGFβ has been implicated in controlling the development and apoptosis of gonocytes and spermatogonia, seminiferous tubule formation and Leydig cell differentiation, and Sertoli cell-peritubular cell interactions.[516,520–522] In the adult testis, TGFβ stimulates apoptosis and inhibits meiosis during spermatogenesis,[523–525] and inhibits Leydig cell steroidogenesis at the level of LH receptor number and signaling, as well as distal to cAMP production at the level of CYP17A expression.[526,527] Crucially, TGFβ2 and TGFβ3 regulate Sertoli cell tight junction dynamics, via the MAPK14 pathway, indicating a role for TGFβ-mediated signaling pathways in regulating the permeability of the blood–testis barrier.[528] Finally, TGFβ is a potent regulator of inflammation and the activity of immune cells, particularly of Th17 and Treg cells,[529,530] suggesting a role in controlling intratesticular immune responses.

Activin

The activins display a high degree of sequence and structural homology with TGFβ, operate through a similar receptor system, and signal via common pathways; nonetheless, they have their own characteristic range of biological actions.[531] There are four forms of activin subunits in mammals (β_A, β_B, β_C and β_E), but only the first three appear to be particularly relevant to the male reproductive tract.[224] Activins A and B are dimers of the β-subunits of inhibin A and B, which are themselves heterodimers of one of two β-subunits (β_A and β_B) with a common α-subunit (Figure 19.11).[532] Consequently, activin A ($\beta_A\beta_A$), activin B ($\beta_B\beta_B$), or activin AB ($\beta_A\beta_B$) forms exist, although most studies to date have concentrated on the activin A homodimer. Activin A is commonly believed to be the most biologically active form.[533] Whereas the chief physiological role of inhibin is to inhibit FSH at the anterior pituitary level, activin A and B stimulate FSH production.[534] Although both inhibin and the activins circulate in the blood, production of inhibin is almost exclusively confined to the Sertoli cell,[535,536] while the activins are produced in many different cell types and tissues, including the anterior pituitary, where they act as local regulators of FSH .[535,537–539]

Activins bind to one of two specific type II activin receptors (ACVR2A or ACVR2B), which are able to dimerize with a type I activin receptor serine/threonine kinase (activin receptor-like kinase, ALK).[512,540] As is the case for TGFβ, postreceptor signaling occurs via SMAD2/3/4, and several alternative signaling pathways, including inflammatory pathways involving MAPK14, MAPK8, and MAPK3/MAPK1.[512,513,541] Inhibin acts as a competitive inhibitor of activin because it can bind to the type II activin receptors but cannot bring about receptor subunit multimerization: this interaction of inhibin with the activin receptor is facilitated by a specific co-receptor protein called TGFβ receptor type III (TGFBR3), or betaglycan.[542] Activin C is a dimer of the structurally-related β_C-subunit, which does not appear to dimerize with the inhibin α-subunit and is unable to facilitate activin receptor signaling.[543,544] It is most highly expressed in the liver but is present in the testis.[545] Homodimers and heterodimers comprising the β_B- and β_C-subunits appear to act as weak competitive

agonists or antagonists of activin A.[533,544,546,547] Moreover, activin bioactivity can be effectively neutralized in the circulation and in tissues by an endogenous, high-affinity activin binding protein, follistatin.[548]

In the hematopoietic and immune systems, activin A is produced by activated monocytes, macrophages and dendritic cells, Th2 cells, bone marrow stromal cells, mast cells and neutrophils, and is stimulated by IL1, TLR ligands, and TNF, acting through MYD88/TRAF signaling, MAPK14 and MAPK8.[531] The β_A-subunit gene promoter comprises one or more AP-1 binding sites, but there do not appear to be any typical consensus NFκB sites within the proximal promoter.[549,550] Expression is stimulated in a synergistic manner by the Th2 cell transcription factor c-MAF and NFAT, a transcription factor that is expressed in immune cells.[551] Transcription of the β_A-subunit in response to cAMP probably involves the cAMP-responsive transcription factor, AP-2.[552] The presence of multiple phorbol ester-responsive elements (AP-1 and AP-2) in the promoter, and the stimulation of activin A production by phorbol esters in several cell types, also implicate protein kinase C in its regulation.[550,552] Multiple AP-1 and AP-2 sites have been identified in the promoter of the β_B-subunit, suggesting that activin B may be, at least in part, regulated in a similar manner to that of activin A.[552,553] In the murine liver, expression of the β_B-subunit is stimulated by systemic administration of LPS, implicating TLR signaling in its regulation.[554]

A large body of evidence suggests that activin A acts to promote inflammation and activation of macrophages and dendritic cells during the initial phase of the immune response, but suppresses immune responses once inflammation is established and activin A concentrations increase.[531] In cells of the monocyte/macrophage lineage that had not been activated, activin A induced nuclear translocation of NFκB, and production of pro-inflammatory mediators, such as IL1β, TNF, IL6, NO, and prostanoids.[555,556] However, in activated monocyte/macrophages, activin A inhibited processing of the IL1β precursor and production of TLR4, CD14, and pro-inflammatory mediators and increased production of IL1RN.[557,558] Similarly, activin A stimulated the recruitment and development of monocyte-derived dendritic cells,[559,560] but inhibited the ability of dendritic cells to mature and stimulate T cell activation.[561,562] Inhibitory effects of activin A on the antigen-presenting activity of macrophages have been observed as well,[563] and activin A stimulates the development of antigen-specific Treg cells.[564] Furthermore, activin A inhibits many of the actions regulated by IL1, IL6, and IFNγ, including T-cell and B-cell proliferation, monocyte phagocytosis, and production of acute-phase proteins.[557,565–567] Together with the fact that activin A is produced by Th2 cells and has been implicated in promoting various Th2-regulated immune responses, such as asthma and atopy,[568] mast cell recruitment, maturation, and activity,[569] and B cell immunoglobulin production,[555,570] these observations suggest that activin A may be a crucial Th2 cytokine. Likewise, the effects of activin A on macrophage inflammatory responses indicate an ability to switch pro-inflammatory M1 macrophages to an alternatively-activated, anti-inflammatory M2 phenotype. Finally, activin A has been shown to be both a fundamental regulator and an important intermediary in the process leading from inflammation to fibrosis, which is also associated with the M2 macrophage phenotype.[279,571]

In the adult testis, β_A-subunit mRNA or activin A protein is found in the Sertoli cells, Leydig cells, peritubular cells, resident macrophages, mast cells, and most spermatogenic cells, except spermatogonia.[224,572,573] In the adult rat, intratesticular fluid levels of activin A are 5–10 times higher than normal circulating concentrations.[274] In cultured Sertoli cells, activin A is stimulated by IL1 and TLR ligands (Figure 19.10), and inhibited by FSH and the cAMP/protein kinase A signaling pathway.[379,388,389,422,481,573] Immediately following spermiation, there is a spike in activin A production by the Sertoli cells, possibly driven by the surge of ILα produced by the Sertoli cell at this time.[572,573] Testicular macrophages, Leydig cells, and Sertoli cells respond to LPS by increasing β_A-subunit expression in vitro, although the Sertoli cells display a much more robust response and higher basal levels of production.[224,388] However, the actual role of activin A in testicular inflammation remains to be determined because the high intratesticular levels of activin A in the adult rat were not acutely affected by LPS treatment in vivo.[274] Significant production of activin B in the testis has yet to be confirmed: the β_B-subunit is produced by the Sertoli cell, but it is not clear whether any of this goes to form activin B homodimers, as inhibin B heterodimers are by far the major form of inhibin in the testes of most species, including the human.[422,574] The activin β_C-subunit has been immunolocalized to Sertoli cells, peritubular cells and Leydig cells, as well as spermatogonia, primary spermatocytes, and elongating spermatids.[545,575]

Activin receptors are expressed by most, if not all, of the somatic and spermatogenic cells of the testis.[572,576,577] Activin, together with TGFβ, exerts complex regulation of spermatogenic cell, Sertoli cell and Leydig cell development and function, and disorders of activin/TGFβ signaling are implicated in the onset of testicular cancer.[578] Depending upon the culture system employed, activin A exerts both stimulatory and inhibitory effects on spermatogonial cell proliferation,[579–581] and is able to maintain the condensed mitochondrial morphology found in spermatogenic cells beyond the leptotene stage of the first meiotic prophase.[582] Activin A regulates mature Sertoli cell function by disrupting tight junction formation and blood–testis-barrier function, and stimulating their

proliferative activity.[583] Activin A has been shown to regulate steroidogenesis by immature and adult Leydig cells in culture and by the MA-10 Leydig cell line,[584–586] although these effects were only evident after extended culture under non-physiological conditions. In mice, deletion of the β_C-subunit had no overt effect on testis function,[587] but overexpression of the β_C-subunit resulted in progressive hypospermatogenesis, which was proposed to be due to antagonism of activin A (and possibly activin B) in the testis.[547] Like TGFβ, activin is expected to be involved in controlling inflammation and immunity in the testis, by regulation of the maturation and activity of the intratesticular macrophages and lymphocytes.

The Interferons

The interferons are functionally-related cytokines with antiviral, antiproliferative, and immunomodulatory actions, comprising three main groups (α, β, and γ), based on their structural relationships and major cellular sources.[115,588] The type I interferons (IFNα and β) are produced by a broad range of cell types: typically, multiple forms of IFNα are produced by monocytes and macrophages, while two forms of IFNβ are produced by fibroblasts and epithelial cells, but they all exert their antiviral and antiproliferative effects via the IFNα receptor (IFNAR). The single type II interferon, IFNγ, is produced by NK and NK T cells, activated T cells and, under certain conditions, by macrophages and dendritic cells.[589,590] It acts through the IFNγ receptor (IFNGR), and regulates the activity of antigen-presenting cells as part of the adaptive immune response, in addition to its antiviral functions. In other words, IFNγ is a type II interferon, but a type 1 (Th1) cytokine. Production of type I interferons is normally stimulated through TLR3, which detects double-stranded viral RNA, and through TLR4, the receptor for bacterial LPS.[115] These TLRs upregulate the interferon-inducing transcription factor, IRF3, by engagement of the TICAM1 adaptor protein and interaction with TRAF3 (Figure 19.5).[106,115] Induction of IFNγ involves IL12 and IL18, type 1 interferons, JAK/STAT signaling, and the transcription factors, NFκB and AP-1, in a cell-specific manner.[589,590]

Viral infections stimulate type 1 interferon and IFNγ production by Sertoli cells, peritubular cells, Leydig cells, and testicular macrophages, leading to production of canonical antiviral proteins in the testis.[438,591–593] In vitro, type 1 interferon expression was induced by activation of TLR3 or TLR4 in murine Sertoli cells,[438,439] and by activation of TLR3 in murine spermatogenic cells.[451] Production of IFNγ in the testis has been implicated in both the regulation of immune privilege and onset of autoimmune orchitis.[594,595] Moreover, IFNγ stimulates Sertoli cell production of FAS and CASP1, and is implicated as the mediator of Sertoli cell and germ cell apoptosis under various conditions.[496,596] In a transgenic mouse model, overexpression of IFNβ in the seminiferous tubules caused spermatogenic cell loss and sterility.[597] These disparate observations are indicative of a complex relationship between the interferons, the local immune system, and spermatogenesis.

In a study on normal, healthy men, treatment with human IFNα significantly decreased serum testosterone levels.[598] This was most likely due to inhibition of steroidogenesis at the Leydig cell and hypothalamic-pituitary levels, because serum gonadotropin levels were unaffected. Both IFNα and IFNγ can inhibit testosterone production in primary cultures of porcine Leydig cells, and studies indicated that IFNγ inhibits cholesterol transport into the mitochondria, and inhibits expression of the STAR protein, CYP11A, and CYP17A (Figure 19.3).[599,600] In other experimental studies, human and murine IFNα inhibited steroidogenesis in rat Leydig cells.[601] These data indicate that interferons may contribute to the overall decline in steroidogenic function that is commonly observed in viral infections.[21,602,603] However, Dejucq and colleagues[592] have shown that Sertoli and Leydig cells in the rat testis strongly expressed IFNα and IFNγ during infection with Sendai virus, and that elevation in expression was associated with an increase in testosterone production by Leydig cells infected with Sendai virus in vitro. This result highlights the fact that responses to some infections may exert a stimulatory effect on steroidogenesis within the testis, even though factors that are inhibitory to steroidogenesis are induced.[604]

The Eicosanoids

The eicosanoids are formed by oxidation of the 20-carbon fatty acid, arachidonic acid, and encompass the prostaglandins (PGD, PGE, and PGF), prostacyclins (PGI), thromboxanes (Tx), lipoxins, and leukotrienes (LT) (Figure 19.12). These lipids are signaling molecules, fundamentally involved in physiological processes, including inflammation and immunity. They arise from hydrolysis of arachidonic acid from membrane glycerophospholipids, through the action of phospholipase A_2 (PLA2).[605] The rate-limiting step in the conversion of arachidonic acid to the prostanoids is cyclooxygenation, catalyzed by one of two closely related enzymes, PTGS1 and PTGS2 (Table 19.2). While PTGS1 is constitutively expressed, PTGS2 expression is inducible during inflammation, through the IL1/TLR and TNF signaling pathways.[606] Production of the specific prostanoid classes, however, requires the subsequent actions of specific prostaglandin synthases and thromboxane synthase.[607] In turn, the prostaglandins and thromboxanes interact with their respective membrane-bound G protein-coupled receptors to regulate cell growth, vascular smooth muscle tone, vascular permeability, and immune cell activity.[608] Prostanoids exert both pro-inflammatory and immunosuppressive actions through these receptor

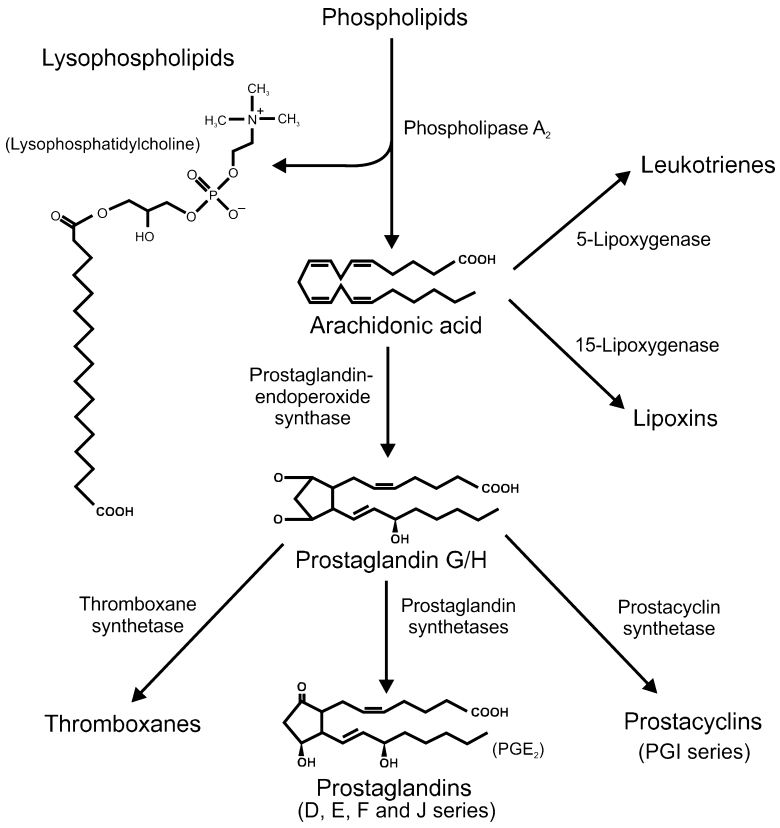

FIGURE 19.12 Synthesis of bioactive lipids. Cleavage of membrane-bound phospholipids by the action of phospholipase A_2 leads to production of arachidonic acid and lysophospholipids, such as the lysophosphatidylcholines. Arachidonic acid may be converted to prostaglandins, prostacyclins or thromboxanes via the intermediates prostaglandin G and H by the action of the rate-limiting prostaglandin-endoperoxide synthase (PTGS) enzymes. Alternatively, lipoxygenases may catalyze the conversion of arachidonic acid to leukotrienes or lipoxins. Most of the products in these complex pathways have specific regulatory activities, including profound effects on immune responses and the vasculature.

interactions, or through metabolism to other active immunoregulatory metabolites, such as the immunosuppressive ligand for peroxisome proliferator-activated receptor-γ (PPARγ), 15deoxy-PGJ_2.[609,610] An alternative synthetic pathway, catalyzed by the lipoxygenases, converts arachidonic acid to the closely-related leukotrienes and lipoxins, which likewise possess diverse metabolic, vascular, and inflammation-regulating activities.[178,611]

The enzymes responsible for prostanoid biosynthesis are expressed throughout the male reproductive tract.[612–615] Most testicular cells express both forms of PTGS and possess the capacity to produce prostaglandins in vitro,[615] although there are significant cell type-specific and species-specific differences in the relative levels of expression.[616–618] In the normal rat testis, PTGS2 is responsible for the majority of prostaglandin production, and chronic treatment with a specific PTGS2 inhibitor, celecoxib, considerably reduces intratesticular PGE_2 levels.[615,619] On the other hand, intratesticular PGE_2 levels are barely affected by acute LPS treatment.[615] This may be due to the fact that macrophages in the rat testis express PTGS2 at very low levels, relative to other testicular cells, but they are the only testis cell type to respond to an inflammatory stimulus with a significant increase in PTGS2 activity.[615] These data indicate a maintenance role for the so-called inducible PTGS2 enzyme in testicular function.

Prostaglandins, particularly PGE_2 and $PGF_{2\alpha}$, are clearly implicated in the control of Leydig cell development in the immature testis, production of pro-inflammatory cytokines by the Leydig cell, autoregulation of steroidogenesis in the adult, and the decline in Leydig cell function that occurs during aging.[401,620,621] However, the actual importance of prostanoids in regulating testicular function remains uncertain: male mice lacking either PTGS2 or PTGS1 are considered to be fertile,[622] and studies on the effects of prostaglandins or various PTGS inhibitors on spermatogenesis and fertility have produced conflicting outcomes.[618,619,623,624] Products of the lipoxygenase pathway, most notably LTB_4, have been implicated in the regulation of Leydig cell steroidogenesis by LH.[625,626] Furthermore, production of PGE_2 and $PGF_{2\alpha}$ induced by PTGS2 mediates the effects of IL1 on protein and lipid regulation by the Sertoli cell involved in supporting spermatogenesis and inflammation in the testis.[424,425] A relationship between expression levels of IL1β and PTGS2 in the testes of infertile men also has been reported.[627] These observations suggest that PTGS2 and prostanoid production mediate at least some of the effects of inflammation on testicular function.

Oxidative Enzymes, Nitric Oxide Synthases, and Reactive Oxygen Species

Reactive oxygen species are normal products of metabolism. They are produced continuously as byproducts of mitochondrial and microsomal electron transport

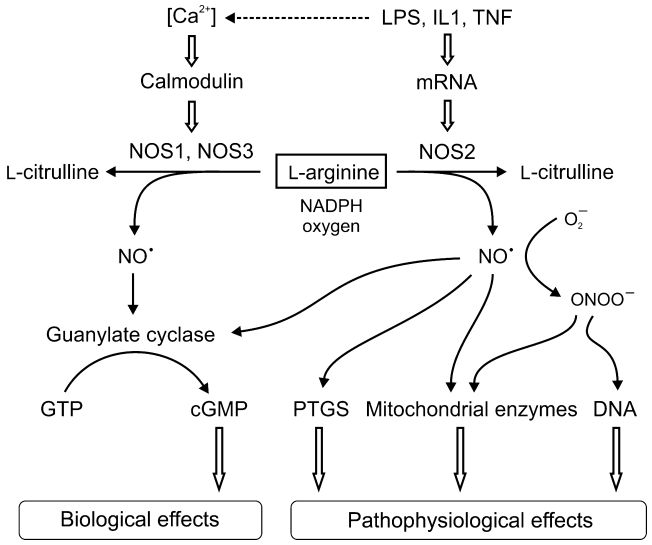

FIGURE 19.13 Regulation and actions of nitric oxide synthase (NOS) and NO production in normal physiology and pathophysiology. NO is produced by conversion of L-arginine to L-citrulline by NOS, and the freely diffusible NO radical (NO·) exerts a variety of physiological functions through regulation of cGMP-dependent protein kinases. The activity of the constitutively expressed isoforms, endothelial NOS (NOS3), and neuronal NOS (NOS1) are regulated through calcium-calmodulin. Synthesis of a constitutively active form of NOS (NOS2) is induced by inflammatory mediators and is responsible for the large upregulation of NO production during inflammation. High levels of NO· can be detrimental due to direct reaction with the heme group of prostaglandin-endoperoxide synthase (PTGS), mitochondrial enzymes and DNA, effects which can be potentiated by interaction with superoxide to produce the extremely reactive peroxynitrite anion. Peroxynitrite is the reaction product of NO and superoxide, and is one of the major cytotoxic agents produced during sepsis, inflammation and ischemia/reperfusion. Peroxynitrite decomposes to produce the hydroxyl radicals, which are potent oxidants.

reactions and other metabolic processes.[628] Cytochrome P450 enzymes, such as those that constitute the steroid synthetic pathways, produce ROS as a by-product of their catalytic mechanism.[629,630] However, rapid production of ROS as part of a respiratory burst by macrophages and neutrophils is also an important component of the early response to infection.[121,631]

The most important ROS are the superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl radical (HO·), nitric oxide (NO·), and peroxynitrite anion ($ONOO^-$)(Figure 19.13). During inflammation, their rapid production is stimulated by the activity of the enzymes NADPH oxidase and NOS2.[631,632] These small molecules are cytotoxic to microorganisms, although some play a more complex role in cell signaling processes, as well.[633] They also interact with vital intracellular macromolecules, such as proteins, lipids and DNA, to cause oxidative damage.[633,634] Cellular antioxidant systems that normally protect cells from oxidative damage include mitochondrial superoxide dismutase, catalase and glutathione peroxidases.[635] Excess production of ROS during oxidative stress, such as occurs during ischemia-reperfusion injury or excessive inflammation, can overwhelm these protective mechanisms, resulting in cell damage, and apoptosis or necrosis of affected cells, thereby contributing to the pathology of many diseases.[636]

At high levels, NO is extremely cytotoxic, especially as a precursor of the peroxynitrite anion, but at low levels NO acts as an intracellular and extracellular signaling molecule and has potent vasodilatory effects.[637] It can be produced by one of three related enzymes, neuronal NOS (NOS1), NOS2, and endothelial NOS (NOS3), which catalyze the conversion of L-arginine to L-citrulline and NO.[638] These enzymes are homodimeric proteins encoded by three separate genes. Both NOS1 and NOS3 are constitutively expressed enzymes whose activity is regulated through a calcium-calmodulin mediated mechanism, whereas NOS2 is a constitutively activated enzyme that is regulated at the transcriptional and translational levels by inflammatory mediators, including LPS, IL1, and TNF.[637]

Studies have reported the presence of NOS in Sertoli, Leydig, and peritubular cells, spermatogenic cells, testicular macrophages, and vascular endothelial cells of various species.[639–642] The NOS3 gene also produces a testis-specific isoform, TnNOS, which has been localized to Leydig cells.[643] In the normal rat seminiferous epithelium, NOS2 is expressed by elongating spermatids and pachytene spermatocytes, particularly during the stages immediately following sperm release, with relatively lower levels of expression in Sertoli cells and peritubular cells throughout the entire cycle.[641] Moreover, NOS2 is upregulated by LPS treatment in Leydig, Sertoli, peritubular, and spermatogenic cells, as well as a subset of the testicular macrophages.[276,641,644,645] This macrophage expression of NOS2 appears to be preferentially expressed by the infiltrating $CD163^-$ macrophages of the testis and is not detectable in the majority of resident macrophages.[276,641] Testicular cell NOS2 expression and NO production are also increased by inflammatory events induced by testicular ischemia-reperfusion injury or heat.[646–649]

Nitric oxide is an important regulator of spermatogenesis. Localized production of NO, by spermatogenic cells in particular, is implicated in control of the formation and disassembly of the Sertoli cell junctions that constitute the blood–testis barrier, as well as the junctional complexes involved in Sertoli-germ cell adhesion.[640] In transgenic mice lacking NOS2, pachytene and round spermatid apoptosis is significantly reduced, leading to an increase in daily sperm output and indicating a key role for NOS2 in limiting germ cell survival and/or the carrying capacity of the Sertoli cells.[647] Sertoli cell and Leydig cell numbers are also increased in these mice, indicating that developmental effects of NOS2 and NO are involved.[650] On the other hand, spermatogenic

damage caused by testicular torsion or cryptorchidism can be ameliorated by reducing NOS or NO levels.[649,651] Increased NOS2 is related to severity of testicular failure and mast cell numbers in infertile men.[320]

Treatment of murine Leydig cell primary cultures or MA-10 Leydig tumor cells with hydrogen peroxide causes oxidative damage, resulting in a marked reduction of the mitochondrial electrochemical gradient ($\Delta\Psi m$) and decreased STAR and HSD3β protein levels.[652–654] Elevation of endogenous ROS, particularly the superoxide anion and hydrogen peroxide, inhibits the activity of cytochrome P450 enzymes in the steroidogenic pathway, and plays a critical role in Leydig cell desensitization to hyperstimulation by LH or exogenous hCG,[629,630] which is used to treat delayed testicular descent in young boys.[655] In a similar manner, NO inhibits Leydig cell steroidogenesis directly, and treatment with NOS inhibitors counteracts the decrease in testosterone associated with inflammation or stress.[656–659] While this may involve oxidative damage via generation of reactive nitrogen species such as the peroxynitrite anion, it has been shown that NO inhibits steroid biosynthesis by binding reversibly to the heme group of cytochrome P450 enzymes.[656,660] Increased testosterone in NOS2-deficient mice may account for the developmental effects observed in these mice.[650] Moreover, NO is a potent vasodilator, and plays a role in the endogenous control of testicular blood flow and formation of the interstitial fluid, which also can impact upon Leydig cell function and spermatogenesis.[641,658]

Inflammatory Signaling Pathways and Testicular Function

It is now clear that inflammatory and immunoregulatory factors and pathways are constitutively active in the normal (noninflamed) testis, and that these factors and pathways have consequences for spermatogenesis and steroidogenesis. Clinically, there is a growing recognition that testicular failure, irrespective of etiology, correlates with increased inflammatory gene expression and immune cell infiltrates in infertile men.[4,5,22,23,229,318,320,372,432,627] *What is the actual physiological relevance of these experimental and clinical observations, and what might this mean for understanding the effects of infection, inflammation and immune responses on male fertility?* The physiological implications may be broadly separated into outcomes for effects on testicular steroidogenesis, which could lead to androgen deficiency problems, and more direct effects on spermatogenesis and sperm output.

Steroidogenesis

In terms of normal Leydig cell steroidogenesis, it may be anticipated that local production of cytokines, and small molecule inflammatory mediators, such as NO and prostanoids, will influence intratesticular androgen levels. These molecules may play a role in facilitating communication between cells of the seminiferous epithelium—the Sertoli cells, peritubular cells and spermatogenic cells—and the Leydig cell. Such paracrine actions have long been associated with local control of steroidogenesis, as a mechanism for modulating the response of the Leydig cell to stimulation by LH, in response to changing requirements of the seminiferous epithelium.[61,661] Moreover, since Leydig cells themselves produce these inflammatory regulators, they could be involved in autocrine regulation of steroidogenesis as well. Certainly, production of NO and other ROS, either by the Leydig cell itself or through its close physical relationship with the resident macrophages, is implicated in Leydig cell desensitization to stimulation by LH.[394,409,629,630] In terms of pathology, increased levels of inflammatory regulators, arising from either the circulation or the testis, during infection and inflammation, should similarly impact upon steroidogenesis.

Spermatogenesis and the Cycle of the Seminiferous Epithelium

Studies in the rat and mouse indicate that certain cytokines and inflammatory mediators are expressed in a dynamic manner throughout the spermatogenic process, in the complete absence of external drivers of inflammation. Specifically, there is a surge of production of ILα, IL6 and activin A by the Sertoli cell at the time of the release of mature spermatids from the seminiferous epithelium (spermiation), which is reflected in a concomitant increase in nuclear translocation of NFκB and production of TNF and NOS2 in the meiotic and postmeiotic spermatogenic cells.[373,375,384,452,461,509,572,573,641] This is a time when a number of critical physiological events occur within the seminiferous epithelium, including the phagocytosis of spermatid residual cytoplasm by the Sertoli cells, an increase in DNA synthesis associated with spermatogonial mitosis and the entry of preleptotene spermatocytes into meiosis, and the transition of these early spermatocytes through the tight junctions that normally constitute the blood–testis barrier.[18] The coincidence of these events is particularly significant because it has been established that ILα, IL6, and activin A are regulators of spermatogonial proliferation and differentiation,[382–384,416,509,579–581] while IL1α, activin A, TNF, and NO have all been shown to stimulate the opening of the blood–testis barrier by modifying the Sertoli cell cytoskeleton, inhibiting production of proteins involved in Sertoli–Sertoli and Sertoli-spermatogenic cell junctions and/or regulating protease and protease inhibitor activity.[423,484,583,640]

These observations suggest the existence of a fundamental mechanism, whereby the spermatogenic cells themselves drive inflammatory pathways within the seminiferous epithelium (Figure 19.14).[24,224] In this

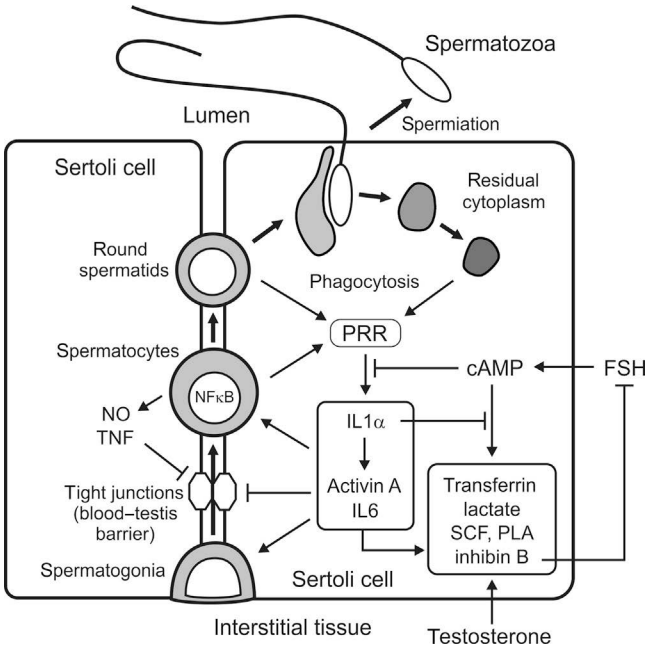

FIGURE 19.14 Hypothetical roles of inflammatory signaling pathways in control of spermatogenesis. Spermatogonia enter meiosis to become spermatocytes and pass through the tight junctions between adjacent Sertoli cells. At the end of meiosis, the resulting haploid spermatids undergo major structural differentiation and are released from the seminiferous epithelium as spermatozoa (spermiation), leaving behind most their (residual) cytoplasm, which is phagocytosed by the Sertoli cells. Spermiation coincides with a surge of production of inflammatory mediators, such as interleukin-1α (IL1α), IL6, and activin A by the Sertoli cells, and tumor necrosis factor (TNF) and NO by the spermatogenic cells, which regulate the proliferation and maturation of the nearby spermatogonia and spermatocytes, and reorganization of the tight junctions to allow spermatocytes to pass into the luminal compartment. This localized inflammatory response may be mediated through activation of pattern-recognition receptors (PRR) in the Sertoli cell by endogenous spermatogenic molecules. Degenerating spermatogenic cells may also drive these pathways at other stages of the spermatogenic cycle, and inflammation caused by infection will disrupt these processes. Inflammatory mediators also regulate the supportive functions of the Sertoli cells, such as the production of transferrin, lactate, stem cell factor (SCF), plasminogen activator (PLA), and inhibin B, which are stimulated by androgens and by FSH acting via cAMP. Although these separate signaling pathways control some functional outcomes in common, there is clear evidence for reciprocal inhibitory regulation between the signaling pathways as well.

model, phagocytosis of the residual cytoplasm at the time of spermiation stimulates inflammatory signaling and cytokine production in the Sertoli cells,[375,376,385,387,573] which subsequently induce NFκB nuclear translocation and inflammatory gene expression in the spermatogenic cells.[451,452,641] These induced inflammatory mediators, in turn, regulate the proliferation and differentiation of the spermatogonia and spermatocytes, and regulate the integrity of the tight junctions to allow the germ cells to pass through the blood–testis barrier. At the same time, these cytokines regulate the activity of the Sertoli cell and modulate the response of the cell to hormonal stimulation. This represents a feasible mechanism whereby the most recent generation of mature spermatozoa is able to communicate with and coordinate the activity of subsequent generations of spermatogenic cells.

In immunology, this type of inflammatory pathway activation is called sterile or non-pathogen-mediated inflammation, and similar mechanisms have been proposed for controlling activities in the epithelia of the intestine and lung, and in the vascular endothelium.[662–664] The actual trigger for this response in the Sertoli cell may involve the physical process of phagocytosis of the residual cytoplasm and activation of pattern-recognition receptors (PRR in Figure 19.14), such as the TLRs and the inflammasome.[108,117] These receptors are capable of detecting and responding to various endogenous intracellular ligands, including the nuclear protein, HMGB1, heat shock proteins, CpG-rich DNA and RNA, all of which are found in spermatogenic cells.[7,108,291,665]

Furthermore, some endogenously-produced inflammatory mediators, most notably IL1α, remain elevated within the Sertoli cell long after the spermiation event, which comprises only a brief period within the process of spermatogenesis.[373,375,384,452,461,502,509,641] This may be attributable to ongoing contact between the spermatogenic cells and Sertoli cell, mediated by pattern-recognition receptors on the cell surface, and/or by phagocytosis of degenerating cells, since many spermatogenic cells do not survive to complete spermatogenesis and are lost through apoptosis.[490,666] In support of this possibility, Zhang and colleagues have recently reported that damaged spermatogenic cells induce inflammatory gene expression, including IL1β, TNF, and IL6, in mouse Sertoli cells through activation of TLR2 and 4.[667] Such interactions may be driving other cyclical functions of the Sertoli cell, including the responsiveness of the Sertoli cell to FSH and androgen,[668,669] and the expression of regulators of cytokine activity, such as follistatin.[572,670]

The Significance of Inflammatory Signaling Pathways for Male Fertility

Studies on inflammatory processes in normal testicular function, or male reproductive function in general, should be tempered by two considerations. Firstly, because the mediators of inflammation and their signaling pathways are exquisitely sensitive to stimulation by microbial contamination, stress, or even the very act of cell isolation, it should not be assumed that expression levels are always indicative of a role in normal physiology. Many early studies of these processes may have been compromised by failure to eliminate endotoxin (endogenous LPS) contamination from the experiments, or the extreme sensitivity and nonquantitative nature of the detection methods used, such as RT-PCR. It is only when molecules have been repeatedly shown to be constitutively and substantially expressed in the absence of

exogenous inflammatory stimuli, and to have consistent and coherent effects on reproductive function in diverse studies, that we may assume that these molecules play a role over and above the usual response to infection or other immune activation events.

The second consideration lies in the fact that mice with transgenic deletions of many of these inflammatory and immunoregulatory factors, their synthetic enzymes or receptors, appear to be fertile.[671–674] However, this assessment may fail to take into account the fact that the reproductive phenotype is subtle, or even enhances fertility, as occurs in the NOS2-deficient mouse.[647,650] Sometimes, more careful examination of the reproductive tract and fertility reveals reproductive defects in male mice that are, nonetheless, capable of producing offspring.[264,435] Moreover, given the extraordinary complexity, diversity and redundancy of the immune system, effects may only manifest after compound deletions of multiple functions, or on certain genetic backgrounds. Some effects may not be evident under normal animal husbandry conditions, and may only become evident in older animals or in animals living in the wild exposed to environmental stresses, dietary deficiency or specific pathogens. Some effects may only become evident when other physiological processes are also compromised, such as occurs in male mice infected with *Taenia crassiceps*.[672] Wild-type mice with this infection display increased IL6 expression and become feminized due to excessive aromatase activity. This steroidogenic deviation is completely prevented in IL6 deficient mice, which otherwise have similar reproductive functions to those of wild-type mice. This observation is consistent with studies implicating IL6 as a regulator of aromatase activity,[675] but also provides an example of a reproductive knockout phenotype that only manifests itself following specific immunological events.

EFFECTS OF IMMUNE CELLS AND INFLAMMATION ON MALE REPRODUCTION

The Role of Macrophages in Leydig Cell Development and Steroidogenesis

Macrophages play an important role in Leydig cell development. During puberty, there is a close temporal link between the maturation of the adult Leydig cell population and the increasing number of testicular resident macrophages.[228,249,293] Moreover, specific depletion of the intratesticular macrophages inhibits the development of Leydig cells in immature rats, as well as the recovery of Leydig cells after EDS-treatment in adult rats.[259,261,262] The *op/op* mouse, which has an inactivating mutation in the CSF1 gene and consequently has reduced numbers of macrophages, also displays very poor fertility and reduced testosterone production due to developmental and steroidogenic abnormalities of the Leydig cells.[264,301] The influence of the testicular macrophages on Leydig cell growth and differentiation may involve specific macrophage-derived cytokines, such as IL1,[400] or the intercytoplasmic specializations between the two cell types, which appear very early in adult testicular development in the rat.[244]

Studies on the effects of resident macrophages on Leydig cell steroidogenesis under non-inflammatory conditions have produced inconsistent results. Stimulation of macrophage phagocytosis with an intratesticular injection of latex beads increased the steroidogenic capacity of Leydig cells in adult rats.[676] However, in macrophage-depleted adult rat testes, both a decline[263,273] and an increase[260,265] in testosterone production have been reported by different groups using essentially the same model. Moreover, medium collected from supposedly unstimulated testicular macrophages in culture have been shown to both stimulate[677,678] and inhibit[405,408,678] Leydig cell steroidogenesis in vitro. Similar discrepancies were observed in Leydig-macrophage co-cultures. The most likely explanation for these differences is that partial activation of the macrophages during isolation, or possibly endotoxin contamination, may have affected the results. Neuroendocrine influences also may be important; for example, studies of the bank vole revealed that testosterone production by Leydig cells from long photoperiod animals was more sensitive to stimulation by testicular macrophage conditioned medium and more sensitive to IL1α-mediated inhibition in comparison with short photoperiod animals.[679] On balance, however, the published data seem to indicate that resting testicular macrophages have a positive or trophic effect on Leydig cell steroidogenesis.

Testicular macrophages have been shown to express the cholesterol 25-hydroxylase enzyme and produce 25-hydroxycholesterol.[677] It has been proposed that testicular macrophages, due to their close association with the Leydig cells, provide 25-hydroxycholesterol as a substrate for testosterone biosynthesis, by-passing the need for STAR and supporting basal steroidogenesis. Interestingly, the 25-hydroxylase enzyme is negatively regulated by testosterone suggesting that there may be a feedback loop between the macrophages and Leydig cells.[680,681] Furthermore, 25-hydroxycholesterol has been suggested to be one of the factors which macrophages secrete in support of Leydig cell proliferation and development.[682]

Effects of Inflammation on the Leydig Cell and Steroidogenesis

Reduced testosterone production is an important mechanism underlying the inhibition of male fertility associated with inflammatory disease, regardless of whether or not infection is involved. This can involve inhibitory

effects at multiple levels of the hypothalamic-pituitary-testicular axis. Men with critical illness, burn trauma, sepsis, and rheumatoid arthritis have elevated serum TNF and IL1 levels and reduced testosterone.[367,683–685] Similar decreases in gonadal function have been reproduced in experimental animal models of chronic inflammation and systemic immune activation. For example, experimental adjuvant-induced arthritis causes a dramatic reduction in serum testosterone levels in rats,[686,687] and conditioned medium from testicular macrophages isolated from adjuvant-induced arthritic rats is inhibitory to Leydig cell testosterone production in vitro.[687]

The literature contains numerous experimental models that have been used to study the effects of inflammation on testicular function, although interpretation of the results can often be problematic. In general, studies employing bacterial or viral infections are complicated by the difficulties in distinguishing the effects of inflammation from the actions of the pathogen itself, or the subsequent immune response to the pathogen. Furthermore, although inflammation is characteristically inhibitory to Leydig cells steroidogenesis, increases in androgen production may be observed in some models of infection.[592,604] Likewise, experimental models involving active immunization, spontaneous autoimmunity, vasectomy, or tumors suffer from similar complications, where it is difficult to separate the inflammatory response from the immune response. More precise information can be obtained from studies using LPS, other TLR ligands, or inflammatory cytokines, to induce inflammation in the absence of a specific pathogen or antigen.

Lipopolysaccharide-Induced and Cytokine-Induced Inflammation Models

Intraperitoneal or intravenous injection of LPS in rats, mice, and rams or induction of sepsis with cecal matter in rats is followed by a significant decrease in intratesticular and serum testosterone levels.[322,658,688–691] There have been distinct differences reported in the dynamics and severity of this inhibition, from study to study and between different species. Responses in mice generally appear to be more rapid, larger, and more prolonged than those of rats, which showed a biphasic response at approximately 6 and 24 h after treatment with a brief recovery period in between.[322,393,689,690,692] Serum testosterone levels actually appear to rise in the boar following endotoxin treatment, as a result of increases in pulsatile LH secretion.[693–695] However, one should not conclude that all differences in experimental results obtained using LPS are simply due to differences between animal models. The LPS obtained from different bacterial strains, and even from different batches of the same strain, can have quite different chemical composition and potency, and is usually contaminated to varying degrees by other TLR ligands.[447]

What is evident is that systemic administration of LPS exerts predominantly inhibitory effects on Leydig cell steroidogenesis at the testicular level and at the hypothalamic-pituitary level, and inhibition may also involve peripheral responses to inflammation, such as corticosteroid production (Figure 19.8). In the rat model, suppression of steroidogenesis by LPS across a very broad range of doses was found to be due to inhibition of both LH secretion and a reduced capacity of the Leydig cells to produce testosterone in response to LH-stimulation.[322,393,696] Furthermore, the data indicated that the early phase of suppression of testosterone was due primarily to direct inhibition of Leydig cell steroidogenesis, whereas the later phase involved extratesticular mechanisms, including glucocorticoid-induced inhibition.[322,393]

Similar inhibitory effects to those caused by LPS on testicular steroidogenesis and serum testosterone levels can be induced in male rats by infusion of TNF alone.[465,466] In the human, Van der Poll and colleagues injected six healthy men with recombinant TNF and measured serum concentrations of gonadotropins, testosterone, and sex hormone-binding globulin (SHBG).[697] The TNF induced an early and transient increase in serum LH, whereas the concentrations of FSH remained unchanged. The increase in LH concentrations was followed by a transient decrease in serum testosterone levels after 4 h. LH had returned to control values when the testosterone levels reached a nadir, and SHBG was not affected. The results indicate that TNF affects the hypothalamic-pituitary-testicular axis at multiple levels in normal men.[697] In a similar study, serum testosterone was decreased without significant effects on LH levels in men treated with high doses of IL6.[698] In yet another study, male patients treated with high doses of IL2 as therapy for metastatic cancer were found to have significantly reduced serum testosterone levels.[699] Finally, multiple inflammatory markers, including IL1β, TNF, and IL6, are elevated in obese men and men with type 2 diabetes,[700,701] conditions known to be associated with hypogonadism and decreased circulating testosterone levels. Collectively, these experimental and clinical observations predict that in conditions characterized by elevated inflammatory mediators, in the absence of infection, there is a concomitant decrease in serum testosterone levels.

Effects of Inflammation on Leydig Cell Steroidogenesis at the Testicular Level

Most evidence suggests that the effects of LPS-induced inflammation on the Leydig cell itself are mediated through exposure to increased levels of pro-inflammatory molecules that inhibit steroidogenesis, most notably IL1, TNF, NO, and other ROS, and PGE_2, as outlined earlier (Figure 19.3). Although isolated Leydig cells express the LPS receptor subunits at relatively low levels,[388] and

there is evidence that they respond to LPS by increased expression of inflammatory cytokines, including IL1β and TNF,[431,450] it is extremely difficult to completely eliminate macrophages from Leydig cell preparations. Consequently, it remains unclear whether LPS can regulate Leydig cell steroidogenesis by direct action. Regardless of this uncertainty, there are several significant sources of pro-inflammatory molecules within the testis. The testicular macrophages produce IL1, TNF, NO, and other ROS, and PGE_2 when stimulated by LPS, although their production capacity is reduced compared with macrophages from other sites.[243,269,270,274,276,277,394,395,464,615,645,702] Sertoli cells, peritubular cells, and spermatogenic cells are also potential sources of these pro-inflammatory molecules.[369,381,461,615,641] The role of NO and other ROS may be particularly important: treatment of adult mice with LPS causes oxidative damage to Leydig cells, which manifests as a marked reduction of the mitochondrial electrochemical gradient, decreased STAR and HSD3β protein levels, and a fall in serum testosterone, similar to the effects of oxidation by hydrogen peroxide in cultured Leydig cells.[652–654] Moreover, treatment of rodents with NOS inhibitors counteracts the decrease in serum testosterone levels caused by stress and sepsis.[657,658] Curiously, pretreatment of adult rats with the PTGS2 inhibitor, celecoxib, reduced endogenous intratesticular PGE_2 levels, and partially reversed the inhibition of testosterone in response to LPS, without blocking the increased expression of IL1β, TNF, or NOS2 in the testis.[619]

An increase in peripheral levels of cytokines from the circulation due to activation of macrophages and other immune cells in the blood and tissues may also be involved in inhibiting Leydig cell steroidogenesis during LPS-induced inflammation. This may involve the same pro-inflammatory molecules that are produced in the testis following LPS treatment, but potentially other cytokines as well. For example, IL2, which is an autocrine T cell growth factor, inhibits gonadotropin-stimulated testosterone production by rat Leydig cells at the level of CYP17A,[703] but IL2 also stimulates IL1, TNF, and IFNγ.[704,705]

The Neural-Immuno-Endocrine Axis in Control of Testicular Steroidogenesis

In addition to direct effects of inflammatory mediators on the Leydig cells, testicular steroidogenesis is modulated during inflammation by neuroendocrine and neuroimmunological regulatory networks (Figure 19.8). These include the hypothalamic-pituitary-adrenal axis, central control of gonadotropin secretion from the anterior pituitary and neural inputs into the testis that regulate Leydig cell function by direct action or through changes in the testicular vasculature.

Activation of the hypothalamic-pituitary-adrenal axis and resulting production of corticosteroids are the key elements of the normal stress response that, among other things, modulates and limits the severity of the inflammatory response.[124,174–177] Moreover, corticosteroids inhibit LH and FSH secretion from the pituitary,[706] but also regulate steroidogenesis directly via specific receptors expressed on the Leydig cell surface,[255,707] acting principally through suppression of the critical steroidogenic enzymes, CYP11A, HSD3β and CYP17A, and induction of Leydig cell apoptosis.[192,708,709] The response of the Leydig cells to corticosteroids is modulated by the actions of corticosteroid 11β-dehydrogenase (HSD11β), and inhibition of Leydig cell function occurs when glucocorticoid levels exceed the capacity of this enzyme to metabolize them.[192] These mechanisms are activated, and impact upon testicular steroidogenesis, in LPS-induced inflammation.[393] Hypothalamic corticotropin-releasing hormone (CRH) also inhibits gonadotropin secretion during stress and inflammatory responses.[710]

Inflammatory mediators themselves can directly act upon the hypothalamic-pituitary unit to inhibit reproduction. Several studies have shown that LPS, IL1, IL6, and TNF can inhibit GnRH release and/or LH secretion at the level of the hypothalamus and pituitary,[711–714] although NO appears to have the opposite effect.[715,716] Furthermore, the observation that IL1 administered intracerebrally can reduce Leydig cell testosterone responses in the absence of decreased LH secretion, for example, in rats pretreated with a GnRH antagonist and therefore lacking LH secretion, led Rivier and colleagues to postulate that there is a direct neuronal connection between the brain and the testis that is activated by cytokines and other stressors within the central nervous system.[717,718] Injection of pseudorabies virus, a transganglionic retrograde tracer, into the testes labeled the spinal cord, the brain stem, and the hypothalamus, while spinal cord injury significantly reduced this staining, and abolished the ability of either IL1β or CRH administered centrally to inhibit testosterone responses to hCG.[719,720] Studies indicate that these agents stimulate a neural pathway within the brain, possibly involving central catecholamine pathways and NO, which suppresses Leydig cell function by inhibiting cholesterol transport protein levels, independent of effects on the pituitary.[720,721]

Furthermore, there is considerable evidence for the control of steroidogenesis by conventional neural pathways acting either directly on the Leydig cells or on the testicular vasculature. Leydig cell steroidogenesis and circulating androgen levels are extremely sensitive to reductions in testicular blood flow, as may occur during inflammation.[658,722] Moreover, Leydig cells can be directly inhibited by a number of neurotransmitters, including serotonin and the catecholamines and the testis is well-supplied by both catecholinergic and serotonergic innervation.[723–726] Activation of these neural pathways during inflammation, or alterations in other

neural pathways supplying the testis, may contribute to the overall suppression of Leydig cell steroidogenesis.

Vascular Inflammation and Leydig Cell Function

While changes in testicular blood flow affect Leydig cell function and steroidogenic output, disruption of blood flow can be a source of inflammation as well. Torsion of the spermatic cord, or experimental clamping of the testicular artery in laboratory rodents, renders the testis ischemic, and subsequent reperfusion causes an increase in oxidative stress and intratesticular inflammation, as indicated by increased intratesticular IL1β and TNF expression, activation of NFκB and stress-related kinase signaling pathways in the Sertoli cells, and neutrophil recruitment, resulting in decreased testosterone production and spermatogenesis.[82,457,727,728] Local increases in reactive oxygen and nitrogen species are also implicated in the suppression of Leydig cell steroidogenesis in this model.[648,729,730] The degree of damage (ischemia-reperfusion injury) is related to the duration of the torsion and resulting stress, and Leydig cell function is compromised in the long term.[82] Similar effects on Leydig cell steroidogenesis can be observed after treatment of rats with other vasoactive inflammatory mediators, such as serotonin and histamine.[731,732]

Effects of Inflammation on Spermatogenesis

Spermatogenesis is affected by inflammation through direct interactions with the inflammatory process and indirectly through alterations in hormone levels and the testicular vasculature. Specifically, this section is concerned with the effects of innate immune responses on Sertoli cell function and spermatogenesis, as distinct from antigen-specific reactions to the cells of the seminiferous epithelium.

Lipopolysaccharide-Induced Inflammation and Spermatogenesis

Acute systemic administration of LPS has been found to affect spermatogenesis in a number of species, resulting in apoptosis and progressive loss of spermatogenesis in the testis within days of administration, and reduced sperm concentration, motility, and viability for extended periods afterward.[322,499,688,693,694,696,733] In the adult rat, administration of a single dose of LPS across a very broad range of sublethal concentrations inhibited the formation of testicular interstitial fluid and suppressed intratesticular and circulating levels of testosterone, by inhibiting LH secretion from the anterior pituitary and reducing the capacity of the Leydig cells to produce testosterone in response to stimulation.[24,322,393,696] At the highest doses of LPS, this was followed by apoptosis of spermatogonia and spermatocytes, and premature release of spermatocytes and early round spermatids from the epithelium several days later.[322] Detailed stereological analysis established that the effects on spermatogenesis were quite specific.[696] At 24 h after treatment, there was a significant delay of spermatocyte development at the leptotene/zygotene phase of meiosis, followed within 6 days by premature release of these cells and the adjacent, but more luminally located, generation of round spermatids. There was also an increase in apoptosis of nearby spermatocytes and spermatids within the same timeframe.[696] These effects occurred more rapidly and were quite different from the effects of androgen withdrawal, which inhibits the release of mature spermatids into the tubule lumen and the integrity of the junctions between the Sertoli cells and midphase round spermatids.[734,735] In fact, lower doses of LPS caused a similar degree of inhibition of intratesticular testosterone levels to that caused by high dose LPS, without causing significant spermatogenic damage.[24,322] Moreover, even very high doses of LPS did not reduce intratesticular levels of testosterone in the rat much below 30% of control, well above the threshold necessary to sustain spermatogenesis in this species.[79,80,734]

Although there are elements of the LPS-mediated response that resemble damage caused by testicular heating, in fact, rodents have a very poor fever response to LPS and the doses of LPS that affect spermatogenesis in rats actually caused a fall in body temperature.[24,322,736] Nor was the pattern of spermatogenic degeneration consistent with vascular disruption. Administration of LPS did appear to alter blood flow through the rat testis, possibly as a result of vasodilation of the testicular arteries due to increased testicular NOS2 expression,[322,641] but there was no evidence of ischemia or ischemic damage.[276,322] Paradoxically, while LPS treatment caused an increase in vascular endothelial cell leakage in the testis, the inflammation was not accompanied by edema; in fact, interstitial fluid volume in the testis fell quite dramatically in this model.[322]

A primary cause of damage to spermatogenesis in LPS-induced inflammation could be the action of pro-inflammatory regulators on the seminiferous epithelium itself. This might be the result of increased levels of circulating molecules as well as their local production by intratesticular immune cells and somatic cells. In addition to the resident macrophage population, LPS stimulates an increase in intratesticular monocytes in the rat,[276,285] and neutrophils in the boar testis interstitium.[694,695] In vivo, LPS treatment upregulates testicular expression of pro-inflammatory genes, including CCL2, IL1β, TNF, IL6, and NOS2.[274,276,285,322,393,396,619,641,691,737–739] These molecules are constitutively produced by testicular macrophages, Sertoli cells, peritubular cells, Leydig cells, and/or spermatogenic cells, and their production can be stimulated by LPS in most, if not all, of these cells in vitro. Most importantly, these molecules are involved

in normal spermatogenic function, with direct and complex effects on spermatogonial and spermatocyte development, the tight junctions of the blood–testis barrier, and local immune cell activity, mediated via inflammatory signaling pathways within the seminiferous epithelium (Figure 19.14). Moreover, FAS and FASL, which have been implicated in regulating spermatogenic cell apoptosis under normal and pathological conditions, are also increased in the seminiferous epithelium of the LPS-treated mouse.[499] Overexpression of these regulators and universal activation of inflammatory signaling pathways in the testis, induced by LPS, would disrupt the normal regulatory processes underlying spermatogenesis. Critically, as most of the normal functions of the seminiferous epithelium are dependent upon androgen support, these effects of inflammatory disturbances could be exacerbated by the concomitant reduction in testosterone levels within the testis.

The severity of the LPS-induced inflammation appears to influence the resulting pattern of spermatogenic damage. In some studies in rats, high doses of LPS are associated with rapid and pronounced epithelial damage, and focal spermatogonial/spermatocyte apoptosis, within 3 days after LPS administration.[24,322] Studies have demonstrated an association between these earlier, more severe, damage events and testicular oxidative stress responses,[691,740] and anti-oxidants can have a protective effect on testicular damage responses to LPS in vitro and in vivo.[738,741,742] Responses include the induction of the stress proteins, heat shock protein 60 (HSP-60), HMGB1 and HMGB2, as well as increased lipid peroxidation, reduced antioxidant activities, mitochondrial dysfunction and spermatogenic cell apoptosis. Several of these induced molecules can activate TLR signaling as well,[24,108] potentially mediating additional damage.

In summary, the damaging effects of LPS-induced inflammation on spermatogenesis involve multiple mechanisms related to the severity of the stimulus and inflammatory response. These can include direct or indirect inhibition of Leydig cell function, vascular disruption and oxidative stress, as well as interference with the endogenous inflammatory pathways involved in normal regulation of the seminiferous epithelium (Figure 19.14). Differences in damage susceptibility may be attributable to actual differences in sensitivity to LPS at the cellular level, or the probability that circulating LPS may have variable access to the various compartments of the testis. For example, Sertoli cells are much less sensitive to stimulation by LPS than are testicular macrophages, possibly due to differences in expression of the TLR4 accessory protein, CD14.[388] Moreover, higher concentrations may be required to permit sufficient LPS to traverse the vascular and lymphatic endothelium of the interstitial tissue as well as the peritubular basement membrane and cell layers to directly affect seminiferous epithelial function. As would be expected, direct injection of LPS into the mouse seminiferous tubules, via the efferent ducts, caused extensive spermatogenic disruption,[743] but there have been no quantitative, comparative studies of the effects of systemic and intratesticular routes of administration to date.

Vascular Inflammation Models

Whereas LPS causes inflammation by direct activation, there are a number of clinical and experimental models of testicular inflammation that are secondary to vascular disruption; these include ischemia-reperfusion injury, vascular malformations (e.g. varicocele), heat or cryptorchidism, and hyperstimulation of the Leydig cells with LH/hCG. These models display similarities, but also some significant differences, to LPS-induced inflammation.

Experimental ischemia-reperfusion injury causes rapid apoptosis of the spermatogenic cells entering mitosis—spermatogonia and the very early spermatocytes—followed by progressive depopulation of the seminiferous epithelium.[744,745] Damage is proportional to the duration of ischemia and, when the procedure is performed unilaterally, the contralateral testis is also affected, which has been attributed to an autoimmune response or to reflex vasoconstriction via neural pathways.[746–750] Although Leydig cell function is compromised, this is not the primary cause of damage in this model.[82] Intratesticular inflammation and oxidative stress are implicated, however, because there is activation of NFκB, increased MAP kinase activity and production of IL1β and TNF in the affected testis, together with increased local ROS production and an increase in intratesticular immune cells.[457,727,729,751,752] Accordingly, treatment with antioxidants and anti-inflammatories can reduce the resulting spermatogenic damage.[753,754] The role of NO is less clear, because this molecule has both protective and damaging effects in ischemia-reperfusion injury models, and its impact on the testis may depend on the severity of the ischemic insult.[648,649,755] The most characteristic feature of experimental ischemia-reperfusion injury is a large increase in neutrophils in the testicular subcapsular venules of both the treated and untreated testis, and testicular damage can be reduced or prevented by blocking neutrophil recruitment or activity.[727,729,756–758] Thus, ischemia-reperfusion injury to spermatogenesis is an inflammatory event mediated primarily by infiltrating neutrophils, with altered blood flow and oxidative stress leading to apoptosis of early spermatogenic cells, in particular.

A varicocele is a dilation of the testicular veins and swelling of the pampiniform venous plexus, and is a cause of altered testicular blood flow, frequently observed in male infertility patients.[759] In both humans

and experimental animals, varicocele is associated with increased intratesticular NO levels and oxidative stress, an increase in intratesticular inflammatory markers, including IL1, and reduced spermatogenesis.[760–764] These observations clearly indicate that this apparently minor vascular anomaly can be a cause of inflammation and damage in the testis, although its clinical significance and the benefits of treatment are a source of ongoing discussion.

Administration of high doses of hCG is used in the treatment of delayed testicular descent in young boys and its impact on testicular function has been extensively studied in adult rats.[655] This treatment causes a hyperstimulation syndrome comprising a transient decrease in testicular blood flow, immediately followed by increased testicular blood flow and pressure, opening of the vascular endothelial cell junctions, and an increase in testicular interstitial fluid volume some 16–24 h later.[765] The syndrome is accompanied by accumulation of intravascular and interstitial neutrophils in the testis,[766,767] an increase in intratesticular expression of IL1β and other pro-inflammatory cytokines,[768] failure of mature sperm release, vacuolation of the seminiferous epithelium and apoptosis, and loss of spermatogonia and primary spermatocytes.[676,769] In rats, the response to hCG can be eliminated by depletion of the Leydig cells with EDS,[770] or depletion of neutrophils with a specific antiserum,[766] and exogenous IL1β is able to replicate most of the effects of hCG.[391,771] These observations suggest that this is an inflammatory response, possibly mediated via IL1β secreted by the Leydig cells. Interestingly, the vascular response is quite different to that of LPS-induced inflammation, which causes a massive reduction in interstitial fluid volume in the testis,[322] although some of the germ cell damage seen is similar in both models. It is significant that disruption of the seminiferous epithelium in both the hCG-hyperstimulation rat model and the ischemia-reperfusion model appear to be dependent upon recruitment of neutrophils to the testicular vasculature or interstitial tissue. Equally significant is the observation that both depletion of the testicular macrophages using liposome-encapsulated dichloromethylene diphosphonate[273] or stimulation of the macrophages with latex beads[676] exacerbate the effects of hCG on the testis, suggesting that the resident macrophages normally play a role in limiting the inflammatory response.

In general, there is a close relationship between vascular disturbance in the testis and inflammation, production of NO, and oxidative stress, leading to spermatogenic damage. These same processes are also implicated in other models of testicular damage, such as the response to heat or cryptorchidism, irradiation, and posttesticular obstruction events.[646,651,772,773] While Leydig cell function is frequently compromised in models of testicular inflammation, reduction of androgens is not the primary cause of spermatogenic failure. It is clear that inflammation has direct inhibitory effects on one or more stages of spermatogenic cell development. It also should be pointed out that, as in most other tissues, inflammatory responses in the testis do not appear to automatically produce autoimmune complications. However, inflammation can lead to increased fibrosis in the testis, presumably through increased production of pro-fibrotic cytokines, such as TNF, TGFβ and activin A, and increased testicular fibrosis is associated with spermatogenic failure and infertility.[318,774,775]

Inflammation in the Epididymis, Vas Deferens, and Accessory Glands

In comparison with the testis, there have been relatively few studies on inflammatory pathways or the effects of inflammation within the remainder of the male reproductive tract. These tissues display a high degree of regional, or segmental, specialization, corresponding to differential gene expression, leukocyte populations, and physiological functions.

Production and Actions of Inflammatory Mediators

The TLRs are found throughout the epithelium, and in immune cells, of the posttesticular reproductive tract.[109,441–444,776] Studies in the rat and mouse have produced some conflicting data, but overall indicate that expression levels of TLR1-6 in the epididymis are similar to those found in the testis, with expression progressively declining toward the vas deferens. On the other hand, expression of TLRs 7, 9, and 11 tends to be higher in the epididymis and vas deferens than in the testis (Table 19.4). This may have an influence on bacterial and viral pathogenicity in the different regions of the tract. The crucial TLR adaptor proteins, MYD88 and TICAM1, have been detected in all segments of the rat epididymis and vas deferens,[441] and the TLR4 co-receptor CD14 has been localized to the epididymis in the rat and human, where it appears to be more highly expressed than in the testis.[443,777]

All 10 human TLRs, as well as MYD88, TICAM1, and CD14, have been detected in human prostate samples.[778] The TLR2 and 4 proteins were localized to epithelial cells in the rat prostate,[779–781] and TLR2 and 9 have been shown to be expressed by human prostate cancer cell lines.[782,783] In the human prostate, TLR3 and 8 immunoreactivity was observed on the apical surface of luminal epithelial cells, and epithelial cells exhibited TLR9 in the penile urethra.[784] In rat seminal vesicles, mRNA for TLR2, 5, 6, 7, 8, 9, 10, and 11 were highly expressed, with low levels of the remaining TLRs.[776] Notably, expression of CD14 was higher in the prostate and seminal vesicles of the rat than in any other tissue of the male reproductive tract.[443] Studies have shown that sequence variants

in TLR4 and the TLR1-TLR6-TLR10 gene cluster in the human are associated with an increased risk of prostate cancer, suggesting a link between susceptibility to inflammation and tumorigenesis in this organ.[785,786]

Roles for TLR signaling in controlling functions of the epididymis and vas deferens, similar to those proposed for the testis, can be anticipated. The epithelium of the caput epididymis comprises numerous functionally active immune cells, particularly dendritic cells and macrophages, but also $CD8^+$ T cells.[96–98,102] This is consistent with the relatively high expression of TLRs in this region of the epididymis. In the regions of the epididymis closest to the testis, moreover, epithelial cell apoptosis is inhibited by repression of NFκB and STAT signaling and activation of the MAPK3/MAPK1 pathway, under the control of androgens, cytokines, or other secretions from the testis.[787,788] These pathways are normally regulated by pathways involved in TLR signaling, and the relationship between the TLRs and testicular factors in their control requires elucidation. Recently, it was discovered that activin A is highly expressed in the epithelium of the caput epididymis.[789–791] This expression is likely to be driven by TLR signaling, and because activin A is a critical regulator of macrophage, dendritic cell and T cell functions, one can assume that this cytokine influences immune cell activity and inflammation in the proximal epididymis. However, other functions of activin A also may be anticipated. In transgenic mice that overexpress the activin-binding protein, follistatin, fluid resorption and sperm transport in the efferent ducts and proximal epididymis is impaired, suggesting a role for endogenous activin in the control of fluid dynamics.[792] Furthermore, activin A has been shown to induce SRD5α in genital fibroblasts,[793] and the caput epididymis is the site of highest expression of this enzyme, indicating that activin A may regulate androgen activity in the epididymis.

In the more distal epididymis (corpus and cauda) and passing into the vas deferens, the pattern of cytokine and inflammatory regulator activity is different to that found in the caput epididymis (Figure 19.15). Activin A production progressively declines, while local production of follistatin increases to the point where follistatin expression levels are higher in the murine vas deferens than in any other tissue examined.[537,789,791,794] These observations suggest that controlling activin activity in the distal epididymis and vas deferens is functionally important. Significantly, the progressive reduction in activin bioactivity parallels the reduction in immune cell number and activity in the epithelium. Expression of TGFβ1 also appears to be greatest in the caput of the marmoset and mouse,[794,795] but displays a more distal distribution in the rat.[794,796,797] Furthermore, TGFβ3 was most highly expressed in the corpus of the rat epididymis, but TGFβ2 was not detected.[797] Removal of the testis or inhibition

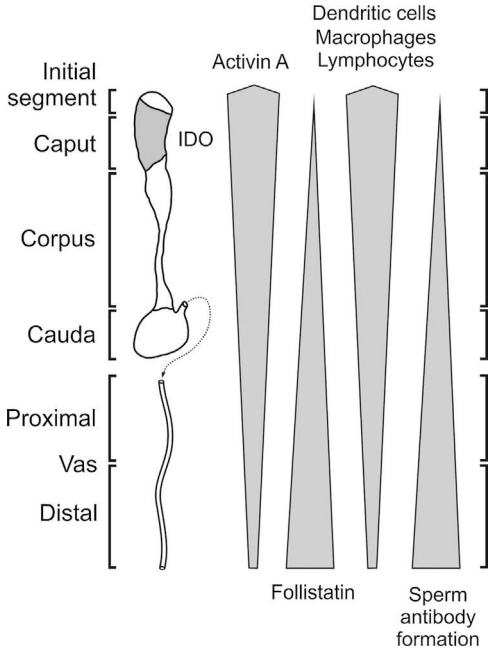

FIGURE 19.15 Region-specific immunity in the epididymis and vas deferens. Activin A and its binding protein, follistatin, are inversely distributed in a distinctive proximal-to-distal pattern, with highest levels of activin A expression in the caput, and highest follistatin expression in the distal vas. Elevated production of activin A coincides with increased numbers and apparent activity of intra-epithelial immune cells, most notably dendritic cells, but also macrophages and $CD8^+$ T cells. The immunoregulatory enzyme, indoleamine 2,3-dioxygenase (IDO), is highly expressed in the caput, with the exception of the region directly adjacent to the testis (initial segment). Susceptibility to sperm antibody formation following damage to the reproductive tract increases in a proximal-to-distal pattern, indicating a progressive decline in local immunoregulatory mechanisms.

of SRD5α activity increased expression of both TGFβ1 and TGFβ3, particularly in the caput.[796,798] These studies indicate species-specific differences in TGFβ expression that are, most likely, androgen-regulated. Functional roles for TGFβ in the epididymis or vas deferens have yet to be established, but a potential role for TGFβ1 in regulating tight junction formation between epithelial cells from the vas deferens has been demonstrated.[799] In direct contrast with activin A and TGFβ, NOS enzyme activity and PTGS2 expression are much greater in the cauda epididymis and vas deferens than in the more proximal regions of the epididymis.[614,616,800,801]

The data indicate that sperm are exposed to a dynamically changing immunoregulatory environment regulated by local inflammatory signaling pathways in the epithelial cells of the male reproductive tract. Moreover, there is evidence that the sperm themselves respond directly to inflammatory stimuli. Human sperm express TLR receptor proteins and respond to bacterial TLR2 and 4 ligands with reduced motility and increased apoptosis.[442,802,803] TNF has been shown to regulate sperm membrane lipid peroxidation and NO production, and

inhibit sperm viability and/or motility,[804–806] and MAP kinase signaling pathways in sperm are implicated in controlling motility, capacitation, and the acrosome reaction.[807]

Effects of Inflammation

There have been limited studies on the effects of inflammation, as distinct from infection, on cellular and molecular responses of the epididymis, vas deferens, or accessory glands. In rats, systemic administration of LPS induced activation of NFκB in the epididymis and increased several inflammation-responsive genes, including IL1β, although it was not clear that this was a response of the epididymal epithelium, since TLR4 expression was also localized to macrophages in the stroma.[443] In a similar study, no immediate morphological changes to the epididymis, at least at the light microscope level, were observed.[322] Injection of LPS directly into the caput epididymis of the rat, however, caused an increase in IL1β expression, as well as hyperemia, edema, and accumulation of immune cells in the interstitium, along with inflammatory damage to the epididymal epithelium, reduced sperm motility and decreased expression of several β-defensins.[808] Similarly, retrograde inoculation via the vas deferens using *E. coli* as a source of LPS caused a neutrophilic infiltration and edema in the cauda epididymis and proximal vas deferens, and elevated expression of IL1α, IL1β and IL4, although several other cytokines, including IL6 and TNF, were not significantly altered three days later.[809] The IL1 receptor has been detected in the murine epididymal epithelium, indicating the ability to respond directly to this fundamental pro-inflammatory cytokine.[415] An experimental left varicocele in the rat significantly reduced epididymal weight and diameter of the duct, together with increased apoptosis of principal cells, proportional to the duration of the varicocele.[810] Chronic treatment of mice with the anti-inflammatory PTGS2 inhibitor, nimesulide, caused epithelial cell damage and apoptosis in the vas deferens, and a large reduction in sperm motility, but not sperm count or viability.[811]

Treatment with LPS of the murine caput epididymal epithelial cell line PC1, which expresses TLR4, induced NFκB activation and expression of the pattern-recognition receptor for bacterial peptidoglycan, nucleotide-binding oligomerization domain 2 (NOD2).[812] Sequential stimulation with LPS and the peptidoglycan muramyl dipeptide enhanced TNF mRNA expression in these cells. Infection of rat cauda epididymal epithelial cells in culture with *Staphylococcus aureus* activated NFκB and MAPK14, production of IL1β, TNF and NO, and expression of mRNA for TLR2 and NOS2.[444] Similarly, treatment with LPS and IFNγ together stimulated NOS2 expression and NO production by cultured rat epididymal epithelial cells.[813] The epithelial cells of the prostate and seminal vesicles also respond to inflammation induced by LPS or bacteria, with activation of NFκB, increased TLR receptor expression, production of inflammatory mediators, such as NO, and various chemokines, resulting in immune cell infiltration in vivo.[103,779,781,814,815]

Overall, these studies provide clear evidence that inflammation both regulates and disrupts cellular responses throughout the male reproductive tract, with direct consequences for function and fertility. There are obvious parallels with the testis, but the underlying mechanisms in these tissues remain to be fully elucidated, and more investigation is warranted. This is particularly important when considering syndromes of chronic, antibiotic-resistant pelvic or perineal pain, such as chronic prostatitis, which are suspected to have an inflammatory basis, but lack a coherent etiology or pathology.[10–12]

Inflammation, Semen, and Seminal Leukocytes

In humans, seminal plasma is generally the only window available for investigating the immunology of the male reproductive tract. More invasive procedures such as biopsies are rarely performed, produce limited and selective samples, and have the potential to cause inflammatory reactions themselves. Much is made, therefore, of the relationship between measurements of leukocytes, antibodies and cytokines in seminal plasma, and fertility. However, while there is little doubt that sperm antibodies contribute to infertility, and that elevated cytokines are an indicator of ongoing infection, inflammation or other immune events, the diagnostic significance of cytokines and, especially, leukocytes in the semen is a subject of ongoing debate.

Many pro-inflammatory and immunoregulatory cytokines are found in samples of seminal plasma, even those from men with apparently normal fertility.[816] The list also includes molecules that modulate the activity of specific cytokines, such as the soluble IL2 and IL6 receptors, and follistatin.[817,818] This is not particularly surprising because these cytokines are present in most biological fluids and are modulated by the general health status of the individual. Elevated cytokine concentrations, both pro- and anti-inflammatory, in seminal plasma are commonly associated with inflammation, infection and increased leukocyte numbers in the male tract, but specific positive and negative associations with infertility of a noninflammatory nature have proven less consistent.[819–821] In a recent evaluation of the extensive literature on this topic, Pilatz and colleagues concluded that, while seminal cytokine profiles might be useful for diagnosis and monitoring of urogenital infections and inflammation, there was no obvious evidence for any associations with poor semen quality or infertility.[822] However, a relationship has been reported between NO

levels and oxidative stress in seminal plasma and infertility due to varicocele and other vascular anomalies, or prostatic inflammation/autoimmunity.[823,824]

An elevated number of leukocytes in the semen is usually considered to be an indication of infection, and the World Health Organization (WHO) has set an arbitrary level of 1×10^6/ml as the threshold of normality. In fact, leukocytes are present even in semen of fully fertile men, with many studies agreeing that 10^4–10^5/ml is a relatively normal value, and even in men with urogenital infections leukocyte numbers do not always reach the WHO level.[358,825] Indeed, leukocyte numbers alone may be a very unreliable indicator of the presence or absence of infection. The origin of these cells is also somewhat obscure. Evidence suggest that the epididymis or vas may be a major source,[364–366] but the primary leukocyte subset present in most semen samples are neutrophils.[358–364] Neutrophils are not a normal feature of the tissues of the tract, but may enter the semen via the accessory glands. This may involve the production of neutrophil-attracting chemokines, such as CXCL6 and CXCL9, by epithelial cells in the epididymis and prostate.[826,827]

Finally, the impact of these cells on fertility is poorly understood. Some studies have shown a relationship between leukocytospermia and impaired sperm function,[828–830] and data suggest that these cells might be a major source of ROS or other molecules causing sperm damage.[358,831,832] Other studies have failed to confirm a clear link between seminal leukocytes and infertility or sperm antibody formation.[358,362,833] It even has been suggested that they might play a beneficial role by the removal by phagocytosis of abnormal sperm or assisting in sperm capacitation.[343,362] It is fair to say that the role of leukocytes in semen is more complicated than might be expected, and many questions still remain.[358,364,833]

AUTOIMMUNITY IN THE MALE REPRODUCTIVE TRACT

Sperm Antibodies

Clinically, the most common immunological dysfunction of the male reproductive tract is the formation of sperm antibodies, which may inhibit sperm motility through agglutination reactions, target the sperm for immunological destruction in the male or female tract, or block essential surface receptors and molecules required for fertilization (Figure 19.16).[834,835] There is no single dominant antigen associated with sperm autoimmunity, and multiple antigens are usually involved.[7–9,291] These antigens have been extensively studied in experimental animals and in infertile patients, and include numerous sperm surface, as well as intracellular proteins, glycoproteins, and glycolipids.

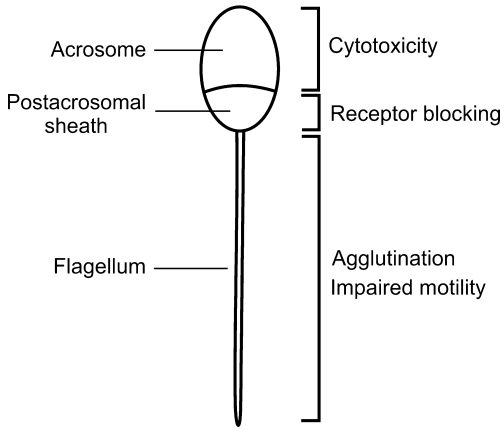

FIGURE 19.16 Sperm antibody binding sites and effects. The principal sequelae of antibody binding to spermatozoa are: (1) activation of immune cells against the sperm via complement or through interaction with immunoglobulin Fc receptors on phagocytes leading to cytotoxicity; (2) blocking or interfering with surface recognition molecules, in particular the egg binding receptors in the postacrosomal region; and (3) agglutination caused by cross-linking of sperm by multivalent antibody which may impede the ability of sperm to swim freely in the female tract.

The Origins of Sperm Antibody Formation

Physical damage to the male reproductive tract can lead to sperm antibody formation. This is best exemplified by the high incidence of sperm antibodies associated with vasectomy, where up to 70% of patients develop antibodies after the procedure.[346–348] Blunt trauma and testicular biopsy may cause sperm antibodies to form as well.[836,837] Sperm antibodies are associated with obstructive azoospermia and congenital absence of the vas deferens,[348,838] and with reproductive tract infection involving orchitis and/or epididymitis, although there is evidence that inflammation alone may not be sufficient to cause antibody formation.[839,840] There is a definite relationship between sperm antibodies and the existence of other autoantibodies, suggesting an important role for genetic factors in predisposition to sperm antibody formation.[841,842] A separate subset of antibodies directed against steroidogenesis-specific antigens expressed by the Leydig cells is associated with polyglandular autoimmunity, although sperm antibodies also may be found in patients with these conditions.[843,844]

In animal models, sperm antibodies can be induced by active immunization with spermatogenic cells or whole sperm, or with testicular or epididymal extracts. This procedure usually involves the use of adjuvants to boost the immune response, but protocols leading to antibody formation without adjuvants also have been reported.[845] As in humans, antibodies may develop following experimental vasectomy or vasal obstruction in rats, guinea pigs, mice, rabbits, and monkeys.[97,332,349,351,352,846,847] The strength of the response and its outcomes are very much strain-dependent. In some of these experimental models,

the formation of antibodies is associated with the development of orchitis and variable degrees of damage to the seminiferous epithelium, an outcome that is rarely, if ever, observed in humans under the same conditions.

Measurement and Clinical Significance of Sperm Antibodies

There has been considerable debate regarding the clinical significance of sperm antibodies or, perhaps more precisely, the tests used to measure them. Although antibody levels in seminal plasma or even blood are frequently quantified, it has been suggested that only antibodies that are actually bound to the sperm, and more specifically the anterior portion of the sperm, should be considered to be of real significance, and then only when a majority of the sperm are affected.[2,835,848,849] Hence, studies that use tests that detect sperm bound antibodies (e.g. agglutination and immunobead binding tests) are most likely to provide reliable results.[834,850,851] Although IgG can cross the reproductive tract epithelium at sites such as the rete testis to bind to sperm,[852] it also has been argued that only IgA antibodies are evidence of a specific mucosal immune response and should be considered of greater prognostic value in semen samples. The most rigorous approach to this issue involves confirmation that the antibody binding has functional consequences using a sperm function test, such as the mucus penetration assay, before accepting the pathological significance of the antibodies.[2,835,849]

Even allowing for the variation in methods employed, it appears that populations vary widely in the incidence of sperm antibodies. This may be due in part to genetic differences in susceptibility to antibody formation, although the prevalence of reproductive tract infections in the population and a lack of suitable treatment options are probably a stronger determinant. In developed nations, the incidence of sperm antibodies is around 5–10% of all infertility cases.[2,3] On the other hand, in parts of central Africa where treatment for reproductive tract infection is limited, or there is a reliance on self-medication and alternative therapies, the incidence of sperm antibodies among infertile populations is much higher.[853] In considering these figures, it also should be borne in mind that sperm antibodies may be present in the semen or blood of men of proven normal fertility.[854] Moreover, in the absence of any other underlying cause being evident, the presence of sperm antibodies tends to be assumed to be the cause of the infertility. It is quite possible that the incidence of infertility due primarily to sperm antibody reactions is lower than these values might suggest. While treatment with high dose corticosteroids has been used with limited success in the past to treat sperm antibodies, sperm washing coupled with intrauterine insemination, in vitro fertilization or intracytoplasmic sperm injection are the current methods of choice.[834,837]

Equally serious for the infertile couple is the development of sperm antibodies in the female tract. While largely outside the scope of this review, it is important to recognize that histocompatibility differences between partners may create potential problems for sperm survival and successful fertilization.[855–857]

Autoimmune Orchitis

The Etiology of Orchitis

In humans, isolated orchitis is usually associated with viral infections, most commonly postpubertal mumps.[858–863] Nonviral causes include mycobacteria (e.g. *Mycobacterium leprae* and *M. tuberculosis*) and parasites, such as Filariasis and Malaria. Bacterial orchitis is usually caused by retrograde ascent of urethral pathogens, such as *E. coli, Chlamydia trachomatis,* and *Neisseria gonorrhoeae*, and is almost invariably associated with inflammation of the epididymis (epididymo-orchitis). In both clinical and experimental models of infectious orchitis,[313,603,864] the immunological response to the infection may cause collateral damage to testicular cells, causing obstruction, fibrosis, and displacement or ischemia, and increases the risk of subsequent autoimmune reactions against testicular antigens. Autoimmune orchitis may also develop as a consequence of neoplasia, in response to an external antigenic challenge (e.g. vasectomy or active immunization), or may arise spontaneously, in the sense that no obvious cause can be discerned.[859,860,865] Whereas infectious orchitis resolves once the infection has been cleared, autoimmunity may lead to chronic inflammatory disease. In contrast with the incidence of sperm autoantibodies, however, autoimmune reactions against spermatogenic cells within the testis appear to be comparatively rare among most human populations.

While there are several animal models of spontaneous autoimmune orchitis, generally attributable to genetic or epigenetic causes, in the mink,[866] rats,[867] and dogs,[868] the incidence of such events have been difficult to establish in humans, given that the autoimmune event and its diagnosis might be separated by many years. There is evidence for immune complex formation in the basement membrane of the seminiferous epithelium,[869–871] and a high prevalence of asymptomatic testicular inflammatory lesions,[4,5] among infertile men. The problem lies in establishing whether these lesions are evidence of a past autoimmune reaction or secondary to inflammation from other causes. The testis is one of the organs that is affected in PGA syndromes, which are caused by failure of normal mechanisms of tolerance,[166,167,872] suggesting that other genetic causes for autoimmune orchitis may exist. There is some evidence of an association of orchitis with other autoimmune inflammatory diseases, particularly vasculitis (inflammation of the blood vessels) in men.[873] A genetic predisposition for development of

autoimmunity may require a secondary trigger, in the form of a precipitating infection, physical trauma to the reproductive tract or other inflammatory event, in order to proceed to actual autoimmune orchitis.

Experimental Autoimmune Orchitis

Several experimental animal models of autoimmune orchitis have been extensively studied by a number of groups, seeking to understand testicular immunophysiology and the causes of autoimmune infertility.[155,311,313–315,331,845,874,875] Most of these models involve immunization with testicular antigens, including spermatogenic cell, somatic cell, and extracellular matrix antigens, using complete adjuvants (containing active or inactivated microbial agents), or adoptive transfer of lymphocytes from animals with on-going autoimmune orchitis. However, at least one model of induced orchitis involving subcutaneous injection of syngeneic (genetically identical) spermatogenic cells into a susceptible strain of mice has been described.[876,877] A particularly interesting model of orchitis development occurs subsequent to vasectomy in some animals. Whereas vasectomy leads to sperm antibody formation alone in most strains of rats and mice, vasectomy results in a rapid progression to full-blown orchitis in the Lewis rat,[349–351] and SWR/J mouse.[878] Similar responses to vasectomy or epididymal obstruction have been observed in the rabbit,[879] guinea pig,[880] and rhesus monkey.[881] Finally, removal of the thymus gland around postnatal day three in mice causes polyglandular autoimmunity, which can include autoimmune orchitis similar to that found in humans,[155,874,875] indicating that immunoregulation by T cells is involved in the normal protection of at least some testis-specific antigens. These models have been crucial to the development of our concepts of the control of immune responses in the testis.

The majority of research has been focused upon autoimmune reactions to the germ cells, but testicular autoimmune disease also may involve the somatic cells. Autoimmune polyglandular diseases, most notably Addison's disease, are associated with specific immune reactions to steroidogenic cells throughout the body, including Leydig cells, thereby leading to hypogonadism.[843,882] This autoimmunity primarily involves reactions against the steroidogenic enzymes and hormone receptors,[883,884] although spermatogenic cell autoantibodies are commonly observed, as well.[844]

Although the models of experimental autoimmune orchitis differ in respect of the method of induction, there are common features in the progression of disease, which are summarized here. The onset of autoimmune orchitis in animals generally involves the appearance of testicular antibodies and immune complexes, followed by infiltration and activation of macrophages, dendritic cells and effector lymphocytes, invasion of the seminiferous tubules, sloughing of germ cells and focal necrosis, accumulation of neutrophils and/or eosinophils, and finally aspermatogenesis.[311,314,331,885–887] The epididymis and vas deferens are frequently involved. In adoptive transfer studies in mice, it was shown that $CD4^+$ T cells, but not antibody, can transfer orchitis from one animal to another, clearly implicating a cellular rather than humorally-mediated mechanism of disease development.[267,268,864] In adoptive transfer, moreover, the early disease almost invariably occurs in the region where the seminiferous tubules connect to the rete testis,[267,268] consistent with the fact that this is where access to the antigens of spermatogenesis is likely to be greatest,[64,73,267] and there is a greater concentration of MHC class II positive macrophages.[267,268,314,331,888] In the adjuvant-free model of induced orchitis, a similar pattern of disease initiation has been observed in this region.[889] Active immunization protocols using adjuvant, on the other hand, cause a more widespread induction of disease throughout the testis.[267,311]

Progression of autoimmune orchitis is marked by expansion and activation of the testicular dendritic cell and macrophage populations, which remain elevated throughout the course of the disease.[292,887] Increases in IL17-producing $CD4^+$ Th17 cells and $CD8^+$ T cells, and even Treg cells have been observed during the onset of autoimmune orchitis in the rat, and persist through the chronic phase, indicating that interaction between these cell subsets may determine the course of the disease.[885,886] Several immunodominant antigens have been identified in the rat, and include antigens that are not specific to the testis.[291] The pro-inflammatory cytokines, TNF and IFNγ, FAS and FASL, and NOS2 have been identified as potential causative factors in the development of orchitis, principally by stimulating antigen-presentation activity and spermatogenic cell apoptosis.[595,890–894] Although IL6 production by testicular macrophages increased during experimental autoimmune orchitis in rats,[895] and was implicated in the disruption of the inter-Sertoli cell tight junctions,[896] administration of IL6 has been shown to inhibit the progression of orchitis in LPS-resistant mice.[897] The progression of orchitis may also be inhibited by IL10 and by androgens.[898,899] The crucial requirement in the development of orchitis is to overcome the normal mechanism of systemic tolerance to testicular antigens, as well as the local immunoregulatory mechanisms.

Typically, immunological events induced in one testis can lead to damage in the contralateral testis, a condition sometimes called sympathetic orchiopathia. Such responses have been observed following a unilateral physical or toxic insult,[900,901] infection with *E. coli* or other pathogens,[902,903] and ischemia or ischemia-reperfusion injury.[746–748,904] This is usually attributable to generation of autoreactive lymphocytes and antibodies caused by events in one testis traveling to the other testis to initiate

disease, in a manner comparable to adoptive transfer of autoimmunity from one animal to another.

The precise reasons why some animal strains are more susceptible to the development of autoimmune orchitis remain to be fully explained, but it is obvious that susceptibility to autoimmune reactions to sperm and testis antigens is genetically determined.[905,906] Clinically, there is an association between sperm antibodies and other autoimmune antibodies,[841,842] and the development of sperm antibodies following vasectomy is strongly associated with the MHC.[907] In mice, specific orchitis susceptibility genes have been mapped to both MHC and non-MHC regions, and the loci linked to development of orchitis also have been shown to govern susceptibility to other autoimmune diseases, such as encephalomyelitis and diabetes.[908,909]

Autoimmunity in the Epididymis, Vas Deferens, and Prostate

Clinically, epididymitis is the most common intrascrotal inflammation, manifesting as pain, nodules, edema, urinary difficulties, fever, urethral discharge, and/or infertility, although it also can be asymptomatic. Acute epididymitis is most commonly due to retrograde ascent of urethral pathogens and sexually-transmitted bacterial infections—most notably *C. trachomatis* and *N. gonorrhoeae*, but also *Ureaplasma urealyticum*, *E. coli*, *Enterococcus faecalis,* and *Pseudomonas aeruginosa*.[860] Less frequently, systemic bacterial infections, such as *M. tuberculosis*, *Haemophilus influenzae type B*, and *Salmonella*, or nonbacterial infections, such as cytomegalovirus and filariasis, may be responsible, especially in children or immunocompromised individuals. Epididymitis also may have noninfectious origins in various medical procedures, the arrhythmia drug amiodarone, trauma, physical stress, vasectomy, urinary reflux, neoplasia, postinfectious and systemic inflammation, vasculitis, and systemic autoimmunity.[11,12,860,910,911] Vasitis is relatively rare and is usually caused by injury, bacterial infection, and following surgical manipulation, postvasectomy or following prostatectomy.[912] It may present as pain or be asymptomatic. If the inflammatory response in the epididymis or vas deferens is severe enough, this can lead to damage to the mucosal epithelium and/or obstructive lesions that may inhibit fertility. Prostatitis and vesiculitis are most commonly caused by bacterial infections, although antibiotic-resistant chronic prostatitis/chronic pelvic pain has suspected inflammatory, probably autoimmune, origins.[10,860,910,911]

Epididymitis is much more frequent than isolated orchitis, which may be a reflection of closer proximity to the external environment. However, different immunoregulatory mechanisms in the two organs may also be a contributing factor. Experimental evidence suggests that the epididymis may be more susceptible to inflammation and subsequent leukocytic infiltration than is the testis. For example, infiltration of lymphocytes and neutrophils into the interstitial tissue are frequently observed in the epididymis and vas deferens, but rarely in the testis, of aging mice.[913] In mice injected intravenously with *Bordetella pertussis* and adjuvant, neutrophils invade the stroma of the epididymis, vas deferens and accessory glands, but the testis is not affected.[914] In the alymphoplastic (aly) mouse, eosinophils and macrophages spontaneously accumulate in the stroma of the epididymis and vas deferens, but not the testis.[915]

Experimentally, epididymitis can be induced by retrograde inoculation with bacteria, such as *E. coli*, via the vas deferens, which leads to epididymitis, vasitis and orchitis, but is complicated by the presence of the bacteria itself.[95,809,916–918] Noninfectious models of epididymitis involve active immunization, neonatal thymectomy, and vasectomy. Epididymitis (actually epididymo-orchitis) and vasitis can occur following active immunization with testicular extracts in the presence of suitable adjuvants in rats, mice and guinea-pigs.[267,314,331] Passive transfer of T cells from mice immunized in this manner also leads to epididymitis, with testicular involvement initially confined to the region around the rete testis and the efferent ducts.[267,268,890] Subcutaneous injection of syngeneic testicular spermatogenic cells into mice in the absence of adjuvant causes orchitis without epididymitis,[876] but passive transfer of the lymphocytes from these mice after stimulation in vitro, favors the induction of epididymitis.[919,920] In other words, the transfer of T cells activated specifically against spermatogenic antigens selectively induces epididymitis in nonimmunized mice.[889] Removal of the thymus at 3 days of age in mice, which abrogates peripheral tolerance mediated by regulatory T cells,[921] initially causes epididymovasitis in the postpubertal period, followed by an increasing, but always smaller, incidence of orchitis many weeks later.[874,922] Likewise, mice with a targeted deletion of the immunoregulatory AIRE transcription factor developed sperm antibodies and leukocytic infiltrates in the epididymis, without orchitis.[923] Vasectomized A/J mice that have been immunized with syngeneic testicular spermatogenic cells develop epididymitis independent of orchitis,[924,925] suggesting that the epididymis can be the primary site of immune reactions following vasectomy, as well. The epididymis is also more susceptible than the testis to spermatic granuloma formation in humans and in experimental mice.[926,927] Taken altogether, these observations highlight a greater susceptibility of the epididymis to inflammation, relative to the testis, when responses to spermatogenic antigens occur. Accordingly, detailed studies in mice have established that the immunogenetics underlying susceptibility to autoimmune orchitis and epididymitis are quite distinct.[906]

Infection and inflammation in the epididymis is characterized by infiltration of macrophages, lymphocytes and neutrophils into the interstitial and peritubular zones, as well as the epididymal epithelium.[95,99,331,332,845,874,922,925,928] The consequences include reduced sperm productivity and function, increased sperm antibody formation, as well as damage to the epithelium and potential obstruction of the epididymal duct. Similar responses in the vas deferens and accessory glands may interfere with seminal fluid production and sperm transport. As in the testis, these disruptions of function may be due to the actions of the activated immune cells, but may also be due to altered epithelial cell or stromal cell function, through the activation of TLR signaling pathways, pro-inflammatory cytokines and other inflammatory mediators. Importantly, ongoing inflammation in these tissues, regardless of the cause, may be a source of chronic pelvic or perineal discomfort or pain.

IMMUNE PRIVILEGE IN THE MALE REPRODUCTIVE TRACT

Based on the data as outlined in previous sections, it is evident that the testis is an immunological target, and that autoimmune responses to spermatogenic antigens will occur given the right conditions, prompting the question: *What are the normal systems that exist within the testis to prevent or regulate development of autoimmunity there? In other words, what is the functional and physiological basis of "immune privilege" in the testis?* The concept of immunological privilege has generally been used by immunologists to describe tissues that are not readily accessible to antigen-presenting cells and circulating lymphocytes or that have deficient lymphatic drainage to local lymph nodes, such as the brain, the anterior chamber of the eye and the placenta.[37,873,929] Neither of these properties applies to the testis, and the most common misconception centers on the role of the blood–testis barrier.

The Immunological Role of the Blood–Testis Barrier

The actual location of the blood–testis barrier lies in tight occluding junctional specializations (zonulae occludens) between adjacent Sertoli cells in the seminiferous epithelium (Figure 19.2).[16,17] These elaborate junctions are quite distinct in organization from the normal adhering junctions and gap junctions found in most epithelia and are assembled at the time of puberty to form a complete seal separating the basal and adluminal compartments of the epithelium.[15,866] Their primary role is to create a unique physiological environment for the meiotic and postmeiotic germ cells, and all spermatogenic cells beyond the leptotene or zygotene spermatocyte stage are completely surrounded by the cytoplasm of adjacent Sertoli cells and are entirely dependent upon these cells for their support and regulation.[72,77,930,931] The process of movement of the spermatogenic cells themselves through the junctions during spermatogenesis does not involve a breach of junctional integrity.[72,931] Indeed, loss of barrier function is a precipitating factor in many forms of testicular failure, including spermatogenic damage during inflammation and infection.

A broader definition of the blood–testis barrier beyond the concept of a physiological barrier incorporates protection of the spermatogenic cells from harmful influences. Some definitions of the blood–testis barrier, therefore, also include the efflux-pump barrier system involving drug-transport proteins, such as p-glycoprotein and the multidrug resistance associated protein-1, on the capillary endothelium, peritubular myoid cells, and the basal aspect of the Sertoli cells.[932,933] While these elements may certainly be important for protection of the testis against toxic agents, their contribution to immunoregulation is likely to be marginal.

There are several lines of evidence that the blood–testis barrier does not account for all the manifestations of immune privilege in the testis. Studies have shown that spermatogenic cell autoantigens are not confined behind the Sertoli cell tight junctions, and are expressed by spermatogonia and the early spermatocytes.[934] Moreover, there is clear evidence that the barrier is incomplete in the epithelium of the rete testis. Significantly, orchitis can be passively transferred to naïve mice by lymphocytes from mice with active autoimmune orchitis.[267,268,919] In many seasonally breeding species, annual regression of both the later spermatogenic cells and blood–testis barrier occurs without inducing overt inflammation or autoimmunity.[72,866] Finally, the blood–testis barrier cannot explain the enhanced survival of grafts within the interstitial tissue.[14,266] On balance, the data lead to the conclusion that the blood–testis barrier does not prevent exposure of germ cell antigens to the immune system, indeed antibodies and lymphocytes specific for spermatogenic antigens may be a normal feature of the circulating immune repertoire.[854] Although the sequestration of a large proportion of the antigenic burden behind the blood–testis barrier no doubt plays a role in this process, it cannot be the primary explanation for functional immune privilege in the testis.

Evidence from Transplantation Studies

Perhaps the most intriguing aspect of immune responses in the male tract is the observation that allografts and even xenografts into the testicular interstitial tissue outside the blood–testis barrier are preserved for extended periods of time, possibly even

indefinitely.[14,266,935–937] This enhanced survival is not simply due to the reduced ambient temperature of the testis, as grafts to the equally hypothermic skin of the ear are not preserved,[266] while grafts continue to survive in testes that have been translocated to the abdominal cavity.[266,936,937] Moreover, the efferent lymphatics of the testis do not show any evidence of functional deficiency.[13] However, intratesticular parathyroid allografts fail to survive in rats sensitized against the donor antigens, while long-established intratesticular allografts are rapidly rejected following active immunization of the recipient with donor tissue.[14] These observations led to the hypothesis that local immunoregulation mechanisms are responsible for graft survival, and, more specifically, that the inductive phase of the immune response is suppressed within the testis and/or its draining lymph nodes. In other words, the immune system may be unable to recognize and/or respond to foreign antigens within the testicular environment.

It should be noted that studies on graft survival in the testes of laboratory rodents have been very successful, but the data in other species are less consistent. Similar transplant studies in the ram and cynomolgus monkey have proven unsuccessful.[938,939] Moreover, the type of graft also may be a factor. Selawry and colleagues were able to demonstrate survival of pancreatic islet allografts or xenografts in abdominally-located testes, but not in scrotal testes, of the rat.[937] Whether these differences in outcome are due to differences in testicular architecture, differences in lymphatic organization or vascularization, the size, health, and type of graft, the underlying immunogenetics of the donor and host, effectiveness of local immunoregulatory mechanisms, species differences in systemic immunity, or even the surgical procedures employed, remains to be answered.

Evidence suggests that testicular tissue and some testicular cells, in particular, have inherent characteristics that may make them more amenable to transplantation.[30,940,941] However, just as intratesticular grafts produce different outcomes in different studies, studies on transplantation of testicular tissue have met with variable degrees of success. Early observations were that fetal and postnatal testis tissues are viable as grafts under the kidney capsule of outbred rats, but that adult testis tissue is quickly rejected.[941,942] Perhaps surprisingly, transplantation of fragments of intact testicular tissue from numerous species under the skin of immunodeficient mice tends to be extremely successful, with vascularization, normal steroidogenesis and even complete spermatogenesis becoming established, although there is no exit for the spermatozoa that are produced.[943] The ability of spermatogenesis to occur in such grafts is probably related to the reduced temperature of the skin, but immunocompromised recipient animals are generally required to avoid rejection responses. On the other hand, adult testis allografts have been observed to survive under the kidney capsule in immunocompetent mice,[489] and allogeneic transplantation of spermatogenic cells, which were subsequently able to undergo normal spermatogenic development, have been successfully performed in several domestic species with intact immune systems.[944–946] Kimmel and colleagues observed that human testis xenografts to the murine kidney failed to survive in intact mice, but survival was possible in recipient mice with an inactivating deletion of MHC class II expression, thereby implicating a $CD4^+$ T cell-mediated rejection process.[947] Discovering the reasons why different models produce such widely different outcomes may provide a better understanding of the fundamental requirements for immunological privilege in the testis.

Immune Tolerance and Immunoregulation

It has become increasingly apparent that central and peripheral immune tolerance contributes to testicular immune privilege. This was first indicated by the fact that hypogonadism and sperm autoimmunity are frequently associated with the PGA syndromes, type 1 and 2, which are due to a mutation in the AIRE transcription factor that controls thymic antigen expression during immune development,[166] and a defect in regulatory T cell function,[167] respectively. Mice with a deletion of AIRE develop sperm antibodies and inflammatory lesions in the epididymis (O'Bryan MK, personal communication).[923] Exposure to testicular antigens during maturation of the immune system has been shown to reduce the severity of induced autoimmune orchitis in adult genetically-immunodeficient mice that have had their immune system re-constituted.[948] Moreover, the cluster of autoimmune endocrinopathies induced by thymectomy at 3 days of age in mice and rats frequently includes orchitis.[155,872,874,875,922] These disease models in humans and rodents establish a link between testicular autoimmunity and failure of tolerance, more precisely, a shift in the balance between autoreactive T cells and specific regulatory T cells.

Suppressor or regulatory T cells have experienced a major revival in interest in recent times, with most attention directed toward the $CD4^+CD25^+FOXP3^+$ Treg cell subset, but there is also evidence for $CD8^+$ regulatory T cell populations.[949,950] As would be expected, Treg cells can be found in both the normal and inflamed testis,[310,885] even if their actual role in the testis has yet to be firmly established. Nonetheless, several studies indicate that exposure of T cells to the testis environment induces an immune deviation response, that is, a switch from cell-mediated (Th1) type immunity to a Th2/Treg response that is predominantly immunoregulatory and tolerogenic (Figure 19.7). Injection of soluble antigen into the testis produces specific suppression of T cell-mediated

responses against the injected antigens.[951–953] Studies on pancreatic islet cell allografts in the mouse testis indicate that activated or memory T cells directed against graft antigens are destroyed when they enter the testis environment and that graft antigen-specific Treg cells are preferentially produced.[954,955] Isolation of a $CD4^+$ T cell line that was able to downregulate the development of adoptive transfer of autoimmune orchitis in mice has been reported,[956] and a crucial role for Treg cells in controlling the development of orchitis in response to vasectomy also has been demonstrated in mice.[957] A substantial increase in evidence linking Treg cells and other regulatory T cell subsets to the control of testicular immune responses can be anticipated in the near future.

FAS Ligand

In 1995, Bellgrau and colleagues[489] reported that expression of FASL was expressed by mouse Sertoli cells, and that mice deficient in either FASL or its receptor, FAS, did not show evidence of testicular immune privilege. In this study, FAS-FASL interaction was implicated in the prevention of antigen-specific responses within the testis, and subsequently, in other immune-privileged or immune-deficient sites.[958] It was proposed that T cells entering the testis and becoming activated by exposure to their respective antigen are immediately killed by interaction between FAS on their surface and FASL, either expressed on, or secreted by, the Sertoli cells. While this was an attractive hypothesis, a number of concerns regarding the FASL expression hypothesis as an overarching explanation for immune privilege arose. Several groups found that expression of FASL did not confer immunoprotection in their own studies in the testis or in other tissues, and in fact caused quite virulent inflammatory reactions in some cases.[959,960] FASL also appeared to be expressed at relatively high levels in epithelia of human tissues not generally thought of as immunologically privileged, such as the esophagus and lung.[961] Finally, Kimmel and colleagues reported being unable to detect FASL expression at all in normal human testes which had been flushed of all peripheral blood cell contamination prior to collection of RNA.[947]

The role of FASL in normal testis function or immunophysiology still remains unresolved. Several studies have suggested that, although FASL mRNA can be detected in Sertoli cells using very sensitive methods such as RT-PCR, the protein is not significantly expressed by the Sertoli cells in the normal adult testis, and in fact it may only be the spermatogenic cells that express the ligand constitutively.[492,959,962] In the immature rat and porcine testis FASL protein has been detected in Sertoli cells by immunohistochemistry,[490,963] but the specificity of FASL antisera used for this purpose has been challenged in at least one major review of the issue.[491] While it appears certain that modulation of FAS and FASL in the seminiferous epithelium plays an important role in regulating spermatogenic cell apoptosis, particularly in various testicular damage models,[490,772,964] a crucial role in maintaining immune privilege in the testis remains doubtful on the weight of evidence.

Major Histocompatibility Complex Expression in the Testis

Most studies have reported a characteristic absence of expression of both MHC class I and class II proteins on the cells of the seminiferous epithelium under normal conditions.[67,68,230,232,266,267,315,965–967] This suggests that spermatogenic cells may be able to avoid direct recognition by $CD4^+$ and $CD8^+$ T cells, which might be important for reducing the potential for antigen-specific immune responses in the seminiferous epithelium. On the other hand, there are some data to indicate that mRNA and protein for both MHC class I and class II molecules are expressed in human spermatozoa,[968–970] suggesting that mRNA present in the spermatogenic cells may be translated into protein at some time after they are released from the testis. This delayed expression of MHC molecules may play a role in protection of the sperm against infection or immune cells in the reproductive tract.

In contrast to the seminiferous epithelium, both MHC class I and II proteins are expressed in the testicular interstitial tissue. As would be expected, MHC class I expression is found on most interstitial cells, including the Leydig cells.[230,965] In the rat and human, testicular macrophages and dendritic cells express MHC class II throughout the interstitium,[239,246,266,965] but studies on the mouse testis indicate that expression of MHC class II is concentrated on cells in regions adjacent to the rete testis.[267,268] A greatly reduced number of MHC class II positive cells in the ram testis is consistent with the relatively low number of resident macrophages in this species.[68] In light of all the observations, however, it appears unlikely that a lack of MHC class II-positive antigen-presenting cells is a contributing factor in testicular immune privilege. Differences in the distribution of such cells, however, may be reflected in differences in susceptibility and development of autoimmune reactions between species, or possibly even between different strains. During the development of experimental autoimmune orchitis, which requires overcoming peripheral tolerance to intratesticular antigens, MHC class II expression and the cells bearing these molecules—dendritic cells and macrophages—are increased within the testis and in the draining lymph nodes.[292,887]

The nonclassical MHC class I genes, HLA-G and HLA-E, are associated with suppression of the adaptive immune response.[169,971] The soluble form of the HLA-G molecule has been localized by immunohistochemistry to Sertoli cells, spermatocytes, spermatids and some interstitial cells in the rhesus monkey testis,[972,973] and

expression of HLA-G and HLA-E has been detected in isolated human spermatogenic cells.[970] More recently, HLA-G has been detected in the seminiferous tubules and efferent duct epithelium of the human testis.[974] This molecule is associated with the placenta in protecting fetal alloantigens from the maternal immune system,[169,972] and its soluble form has been implicated in apoptosis of alloreactive $CD8^+$ T cells.[971] Its significance to the testis is entirely unknown at this time.

Immunological Responses in the Testis

It is evident that maintenance of peripheral tolerance is important for testicular immune privilege, and that loss of tolerance to testicular antigens leads to autoimmunity and testicular damage. Obviously, the MHC class II-expressing antigen-presenting cells of the testis must play a crucial role in this process, by creating a tolerogenic environment. The balance of data suggest that the majority of dendritic cells and macrophages in the mouse display reduced expression of MHC class II molecule and the regulatory CD80/CD86 co-receptors,[267,271] suggesting that they may be more likely to promote tolerance, but this does not appear to be true for the rat.[266,272] However, expression of other co-regulatory ligands and receptors, for example CD40LG or inhibitory variants of CD80/CD86,[975] have yet to be investigated in these cells. On the other hand, it is well-established that the macrophages of the rat and mouse display the anti-inflammatory/immunosuppressive M2 phenotype, manifesting as preferential production of immunosuppressive cytokines, such as IL10, and a reduced capacity for T cell activation.[269,270,275,287,288] This suggests that the predominantly immunosuppressive phenotype of the testicular macrophages is a critical element in maintaining testicular immune privilege, and that deviation of the macrophage and dendritic cell phenotype toward support of cell-mediated immunity is an essential event leading to autoimmune orchitis.[272,292,887,893]

Based on the existing evidence, it can be proposed that circulating $CD4^+$ effector T cells entering the testis are inactivated, deleted, or made tolerogenic by the resident antigen-presenting cell population. This model of tolerance in the testis is consistent with the presence in the testicular interstitial tissue of Treg cells,[310,885] but also of NK and NK T cells (Hedger MP and Aridi DZ, unpublished data).[70] Cells of the NK lineage are able to modulate dendritic cell activity to control adaptive immune responses.[976–978] These cells play a key role in promoting graft survival,[149,168] and have been implicated in the generation of $CD8^+$ regulatory/suppressor T cells in another immune privileged site, the anterior chamber of the eye.[150,979,980] Consequently, it is anticipated that intratesticular NK and NK T cells are involved in production of regulatory/suppressor T cells specific to the testis. Finally, a role for γδ T cells, a minor subset of T cells that possess an alternate TCR structure, has been invoked in suppressing autoimmune reactions in bacterial-induced autoimmune orchitis in the mouse, in part through production of IL10 and TGFβ.[313,903] This lymphocyte subset also appears to be involved in maintaining immune privilege in the eye.[981]

Testicular Immunoregulatory Mechanisms

Immune privilege, in the classical sense of providing extended graft protection, is restricted to a small number of tissues, so there must be some specific properties of the testis that create an environment where adaptive immunity is so closely regulated. Historically, the spermatogenic cells and Leydig cells have been implicated,[982,983] as they are cell types with functions that are unique to the testis. Early studies showed that spermatogenic cells can inhibit lymphocyte activity in vitro and in vivo.[983,984] More recently, Cheng and colleagues reported that the CD80/CD86 variant T cell regulator, programmed death-1 ligand-1 (PD-L1 or B7-H1), is expressed on murine spermatocytes and spermatids, and supports the survival of intratesticular pancreatic islet allografts.[985] However, contact between T cells and these cells behind the blood–testis barrier is unlikely, and complete disruption of spermatogenesis by translocation of the testis to the abdominal cavity does not appear to abrogate survival of intratesticular allografts or xenografts.[266,937,986] Nonetheless, even if the spermatogenic cells do not play a direct role in immunoregulation, it remains possible that these cells play a role by stimulation of immunoregulatory functions of the Leydig cells, and more importantly, the Sertoli cells.

The Role of the Sertoli Cell

There is little doubt that the Sertoli cell possesses unique immunoregulatory properties. Sertoli cells from immature rat, murine or porcine testes display extended survival as allografts or xenografts, and co-transplantation of Sertoli cells or testis cell mixtures containing these cells confers increased survival on a number of cell and tissue allografts and xenografts, including neural cells, pancreatic islets and skin.[987–990] Such procedures have even been used for protection of islet transplants in humans, with some success and controversy.[991] Although the immunoprotective properties of the Sertoli cells appear to be dependent upon their number and ability to form intercellular tight junctions and tubule-like structures, survival of co-transplanted cells adjacent to, but outside, these structures indicates that the protective mechanism does not require the creation of a physical barrier.[992] Protection appears to be an inherent property of the Sertoli cell, involving factors expressed on the surface or secreted from the cell (Figure 19.17).

Sertoli cells express comparatively low levels of classical MHC antigens, and produce the nonclassical MHC class I antigen, HLA-G, which would enhance

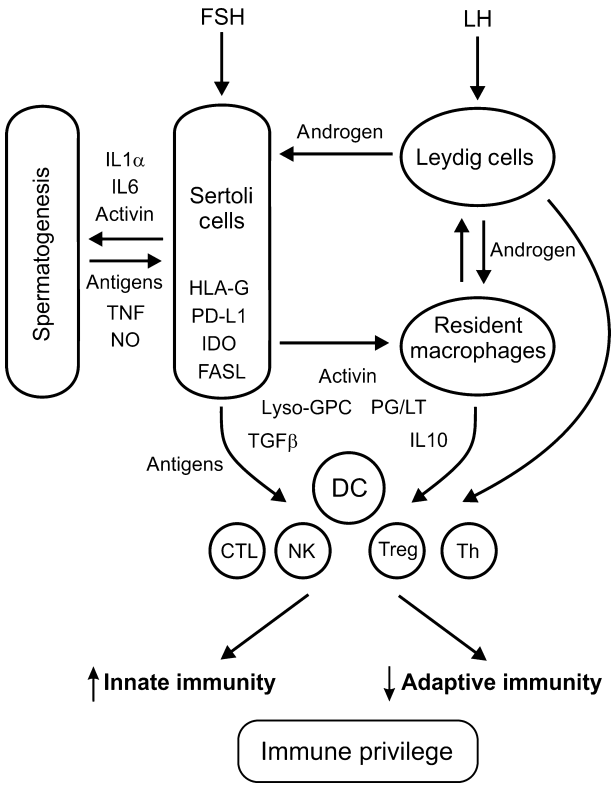

FIGURE 19.17 Intercompartmental interactions regulating steroidogenesis, spermatogenesis and immune responses in the adult testis. Within the seminiferous epithelium, the Sertoli cell supports and regulates spermatogenesis, through production of cytokines, including interleukin-1α (IL1α), IL6, and activin. Production of these cytokines is stimulated by the presence of the spermatogenic cells. Spermatogenic cells also produce tumor necrosis factor (TNF) and NO, which regulate Sertoli cell functions, such as the maintenance of the blood–testis barrier. Sertoli cells possess a number of immunosuppressive activities, which include expression of indoleamine 2,3-dioxygenase (IDO), HLA-G, programmed death-1 ligand-1 (PD-L1), and FAS ligand (FASL). Spermatogenic antigens released from the seminiferous epithelium, together with local production of immunoregulatory molecules, including IL10, transforming growth factor-β (TGFβ), activin, prostaglandins/leukotrienes (PG/LT), and lyso-glycerophosphatidylcholines (lyso-GPCs), create an environment that promotes tolerogenic responses (alternatively activated resident macrophages, Treg cells) and innate immunity (NK cells, cytotoxic T cell), while inhibiting cell-mediated immunity (helper T cells). Leydig cells are responsible for recruiting macrophages into the testis and may have further immunomodulatory actions through production of androgens, and other molecules with immunoregulatory actions, such as prostaglandins (PGs). DC, dendritic cells; NK, NK cells: CTL, cytotoxic lymphocytes; Th, helper T cells; Treg, regulatory T cells.

their potential to avoid detection by T cells and subsequent immune activation.[230,967,972,993] On the other hand, expression of ICAM1 and VCAM1 by the Sertoli cells suggests that these cells can selectively bind and interact directly with circulating lymphocytes.[477,994] Mouse Sertoli cells increase expression of PD-L1, but not positive co-stimulatory molecules, in response to IFNγ in vitro.[594] Human Sertoli cells were found to suppress MHC class II and inflammatory gene expression in human endothelial cell cultures stimulated with INFγ or TNF, and to inhibit the ability of these cells to stimulate spleen lymphocyte proliferation.[995] Finally, Sertoli cells are similar to macrophages in that they possess an enormous capacity for phagocytosis of senescent cells, cell debris, and other potentially antigenic complexes. Together with the inherent ability of the Sertoli cell to provide a highly supportive environment for cell growth and differentiation,[996] these characteristics no doubt all contribute to the unique graft-protecting abilities of the Sertoli cell.

Sertoli cells express and secrete a wide range of immunoregulatory molecules, several of which have been implicated in graft protection or immune privilege.[997] Studies have shown that Sertoli cells secrete lymphocyte-inhibiting activity in culture,[998,999] and are major sites of production of both TGFβ and activin A.[224,225] Production of TGFβ1 by co-transplanted Sertoli cells has been implicated in protection of syngeneic transplants of pancreatic islets in streptozotocin-induced diabetic rats and nonobese diabetic mice.[990,1000] There is evidence that FASL expression on the Sertoli cell may enhance graft survival, as well.[988,1000,1001] Sertoli cells produce several complement inhibitors, as well as inhibitors of granzyme B, which is a lytic molecule produced by cytotoxic lymphocytes.[1002–1004] Furthermore, IL6, which is secreted by the Sertoli cell under hormonal control, has a number of immunoregulatory properties, stimulating the production of anti-inflammatory cytokines by T cells,[125] and inhibiting the maturation of dendritic cells from circulating monocytes.[234] Cultured murine Sertoli cells progressively produce indoleamine 2,3-dioxygenase (IDO), an enzyme which catalyzes the metabolism of tryptophan, and which has been shown to stimulate dendritic cell-initiated tolerance,[1005] and to stimulate the development of Treg cells in tumors and in pregnancy.[1006,1007] Silencing of IDO with si-mRNA inhibited the ability of these cells to reduce diabetes in non-obese diabetic mice.[1006] Finally, mice with a Sertoli cell-specific deletion of the androgen receptor have a defective blood–testis barrier, the testis becomes infiltrated by macrophages, neutrophils, plasma cells, and eosinophils, and they develop antibodies against spermatogenic cells.[1008] This suggests that loss of androgen regulation in the Sertoli cell leads to a loss of testicular immune privilege.

The Role of the Leydig Cell and Androgens

It seems likely that Leydig cells actually promote inflammation-related responses of the testis, as these cells produce several inflammatory mediators constitutively (MIF, NOS2) or in response to inflammatory stimuli (IL1, IL6, and CCL2).[226,276,278,285,390–392,503,504,641,1009] These cells also play a central role in the regulation of interstitial fluid formation in both hCG-hyperstimulation and LPS-induced inflammation through control of endothelial cell permeability.[397,1010,1011] Conversely, early

studies established that mouse Leydig cells, but not other testicular cells, bound to lymphocytes, macrophages and eosinophils specifically in vitro,[1012,1013] and that the presence of rat or mouse Leydig cells could inhibit lymphocyte proliferation responses in vitro.[982] This binding may have been due, at least in part, to a variant of VCAM1 expressed on the Leydig cell surface,[1014] while inhibition of lymphocytes by Leydig cells in vitro appears to involve both direct contact and secretion of soluble inhibitory factors.[1015] The Leydig cell-secreted cytokine, MIF, is a potent inhibitor of cytotoxic T cell and NK cell activity,[1016–1018] and it may be that a function of this cytokine in the testis is to restrain cell killing in the absence of an overt immunological challenge. However, the most significant role of the Leydig cells in mediating immune control of the testis may lie in their ability to facilitate recruitment of resident macrophages in the testis (Figure 19.17).[69,226,293,296] Junctional specializations between Leydig cells and resident macrophages mediate close physical attachment of these cells in the normal testis,[240,244] and the immunoregulatory significance of these interactions has yet to be explored in any detail.

The principal endocrine function of the Leydig cell is the production of testosterone, and concentrations of this androgen are extremely high within the testicular interstitial tissue.[79,80] There is some evidence in vitro that androgens are able to regulate lymphocyte-mediated immunity by stimulating the production of IL10 by $CD4^+$ T cells, and stimulating the induction or proliferation of Treg cells.[197,210,213,214,899] A more general effect of androgens on the Th1/Th2 cytokine balance was demonstrated by the fact that administration of testosterone to hypogonadal men stimulated baseline IL10 levels and inhibited IL1β and TNF levels in serum.[1019] However, in vivo evidence for local immunoregulation by androgens in the testis is conflicting. Androgens do not appear to directly regulate macrophage or lymphocyte numbers,[226,227,295] and manipulation of Leydig cell function and androgen production by a number of methods had no effect on survival of parathyroid or pancreatic cell allografts in the rat testis.[935,936,986,1020] On the other hand, treatment with exogenous testosterone suppressed the progression of autoimmune orchitis in rats, by reducing the intratesticular accumulation of macrophages and $CD4^+$ T cells, and pro-inflammatory/Th1 cytokine expression, while increasing the number of Treg cells.[899]

Treatment with estrogen of the recipient rats prior to placement of parathyroid allografts was found to abrogate graft survival in the normal scrotal testis.[266] The problem with interpreting this finding is that estrogen inhibits androgen production by the Leydig cell, but probably has direct effects on immune responses and graft rejection in the testis as well. Estrogens regulate dendritic cell differentiation and activity,[217,218] and overexpression of CYP19A, leading to an elevated estrogen-to-androgen ratio causes progressively severe inflammation in the mouse testis, with massive proliferation and activation of intratesticular macrophages and testicular damage.[1021] Overall, it remains difficult to say what important role androgens and estrogens may play in regulating immune responses in the testis. Moreover, it should be noted that in addition to steroids, Leydig cells produce several other factors with lymphocyte regulating activity. These include the antiproliferative pro-opiomelanocortin peptides,[223,1022] and MIF, which notwithstanding its pro-inflammatory functions, inhibits the cell killing activity of cytotoxic T cells and NK cells.[1016–1018]

Soluble Immunosuppressive Activities and Bioactive Lipids

Rat testicular interstitial fluid is a potent inhibitor of T cell activation responses in vitro, in spite of the presence of substantial levels of locally-produced IL1, clearly indicating that soluble immunosuppressive factors are a principal influence on lymphocytes circulating through the interstitial tissue.[965,1023] Similar inhibitory effects on lymphocytes in vitro have been observed using whole testis extracts from mice.[1024] Early investigations established that this inhibition could not be attributed to androgens,[1023,1025] or to other candidate molecules known to be present in testicular interstitial fluid, such as PGE_2,[1026] TGFβ family members,[274,1027] or IL10.[1028]

Purification of this activity established that the lymphocyte inhibition was due to the presence of several lyso-glycerophosphatidylcholines (lyso-GPCs) in the interstitial fluid.[1029] These molecules are produced by the cleavage of a single fatty acid chain from plasma membrane phosphocholine-containing phospholipids via the action of PLA_2, and are known to possess potent anti-inflammatory and immunoregulatory functions (Figure 19.12).[1030] The actual mechanisms have proven difficult to study because lysophospholipids are cytotoxic at high concentrations.[1031] It still remains to be established whether the effects of lyso-GPCs on T-cell activity at physiological concentrations are mediated by a specific receptor, a direct physical interaction with the cell membrane, or both. However, it has been demonstrated that these lyso-GPCs are specific ligands for CD1D-restricted T cells, suggesting a role for these molecules in controlling NK T-cell responses and activity in the testis.[1032] Other lysophospholipds, such as lysophosphatidic acid and sphingosine-1-phosphate, for which G protein-coupled receptors are already known, have been implicated in regulating spermatogenesis and spermatogenic cell survival.[1033] The production, regulation, and activity of these molecules within the testis certainly deserve further study.

Prostanoids, which are derived from arachidonic acid cleaved from plasma membrane phospholipids by

the action of PLA_2, are widely produced throughout the testis due to the promiscuous expression of PTGS2 and PTGS1.[615] In culture, Sertoli and/or Leydig cells can produce all the classes of prostanoids: PGE_2, $PGF_{2\alpha}$, PGD_2, PGI_2 and TxA.[425,617,1034,1035] In the adult rat testis, PGE_2 and $PGF_{2\alpha}$ predominate, with PGD_2 detected at much lower levels; there is no comparable data for TxA or PGI_2.[1036] Direct evidence for the role of prostanoids in regulating testicular inflammation and immunity, however, is slight.

In macrophages from other tissues, PGE_2 has been shown to reduce pro-inflammatory activity and promote an alternatively activated (M2) macrophage functional phenotype.[1037–1039] Studies by Kern and colleagues confirmed that the addition of the broad PTGS inhibitor, indomethacin, to cultures of rat testicular macrophages stimulated their production of IL1β, IL6 and TNF in response to LPS-stimulation and blocked their inhibitory effect on peripheral blood lymphocyte proliferation in vitro.[269,277] It was suggested that PGE_2 might be responsible for the testicular macrophage phenotype that favors immune privilege. Working against this hypothesis, testicular macrophages produce little PGE_2 under normal conditions, and blocking PTGS2 activity in vivo or in vitro did not affect the production of pro-inflammatory cytokines in the testis in response to LPS.[276,615,619] However, chronic inhibition of PTGS2 did inhibit interstitial fluid formation in rat normal testes, even though this treatment ameliorated the loss of fluid that usually occurs during LPS-induced inflammation.[619] These data indicate that prostanoids are involved in control of vascular tone in the normal and inflamed testis. This suggests that the use of anti-inflammatories by men with marginal fertility might need to be considered as a factor when undertaking assisted reproductive therapies.

Spermatogenic Cell and Testis Transplantation

Since the pioneering work of Brinster and colleagues,[1040] the restoration of fertility in mice with congenital or chemically-induced absence of spermatogenesis, through transfer of isolated spermatogonial stem cells from fertile donors is now routine. This procedure usually involves injection of spermatogonia directly into the rete testis or efferent ducts of the recipient. Cross-species transplantation has only been fully successful in the case of rat spermatogonia to the mouse testis,[1041] although spermatogonial proliferation and even partial spermatogenesis in the murine testis has been observed for a range of species, including the human.[1042,1043] Spermatogenic development of transplanted stem cells in the testis of species other than the mouse also has been achieved, including rat into rat,[1044] and mouse into rat, bovine or monkey testes.[1045,1046] Successful transplantation of Sertoli cells[1047,1048] and Leydig cell stem cells[1049] have been reported in mice, using similar protocols.

Studies on spermatogenic stem cell transplantation generally employ a histocompatible or immunodeficient recipient. Allogeneic transplantation has been performed in a number of domestic animals and in monkeys with intact immune systems, causing minor inflammatory complications, but with some degree of success.[1050–1052] Transplantation of rat spermatogenic stem cells into immunocompetent mice, producing epididymal spermatozoa in a small number of animals, has also been reported.[1053] A characteristic feature of transplantation in immunologically intact animals appears to be an increase in peritubular macrophages and macrophage invasion into the seminiferous epithelium and tubule lumen.[1054,1055] Whether these cells may be serving an immunoprotective function, or are simply responding to an inflammatory stimulus from degenerating spermatogenic cells, is unclear. In a limited study of the immunological parameters affecting spermatogonial transplantation,[33] Kanatsu-Shinohara and colleagues found that allogeneic transplantation of mouse spermatogonia was only partially successful, with arrest at the round spermatid stage in highly disorganized tubules, mononuclear cell infiltration in the interstitial tissue and eventual rejection after several months. Mature spermatozoa and successful natural mating was able to be achieved by the use of donor stem cells from immature testes and treatment of the recipient animal with anti-CD4 and anti-CD8 antibodies or the immunosuppressive agent, rapamycin, to inhibit T cell activity.

The available data suggest that spermatogonial stem cell transplantation can be performed across allogeneic and xenogeneic barriers without rejection, but that the preparation of the donor cells and recipient and the transfer procedure itself may affect the outcome. This appears comparable to the variable success experienced in studies on engraftment into the interstitial tissue. It is not yet clear what the critical factors may be, but it should be noted that the spermatogonial cells normally are injected via the rete testis or efferent ducts, and into testes that lack mature germ cells. The rete testis is the most susceptible region of the testis for initiation of autoimmune reactions.[267,268,888] It is possible that the cytotoxic treatments used to deplete the endogenous spermatogenic cells may increase the risk of graft failure and rejection, or that the lack of endogenous spermatogenic cells may contribute to an absence or failure of tolerance to these cells, or alterations in the local immunoprotective environment. Possibly the most important factor that requires investigation is the composition of the spermatogonial cell preparation itself, and the degree to which it might be "contaminated" with resident testicular macrophages or Sertoli cells, as these have potent immunoregulatory properties.

The Definition and Significance of Testicular Immune Privilege

The original definition of immune privilege specifically applied to tissues where normal rejection responses against foreign tissue grafts, specifically allografts or xenografts, are reduced or prevented,[37,929] but the term is most commonly used to refer to a site where lymphatic drainage is deficient or access by immune cell is restricted. Sequestration of antigens of the central nervous system behind the blood–brain barrier is usually considered to be the best example of this.[1056] However, these are principally functional definitions, which emerged prior to discovery of the cellular and molecular mechanisms underlying immunological tolerance and the regulation of immunity. A more contemporary definition of immune privilege, which encompasses both of these traditional concepts as well as more recent immunophysiological principles, can be stated as "the extended survival of cells expressing antigens that under normal circumstances should provoke an immune response, as well as the mechanisms that contribute to this survival".[1057]

It appears that testicular immune privilege is dependent upon a number of overlapping mechanisms: (1) maintenance of central and peripheral tolerance, (2) the blood–testis barrier, (3) reduced immunogenicity of the testicular cells, (4) the anti-inflammatory phenotype of the resident macrophages, (5) immunosuppressive properties of the Sertoli cells and Leydig cells, and (6) local production of immunoregulatory/immunosuppressive cytokines, steroids and other bioactive lipids. The existence of multiple mechanisms may help to explain why orchitis and testicular autoimmunity affects only a minor subset of patients with PGA syndromes, and are not universally induced by day 3 postthymectomy in rats and mice. Moreover, based on the evidence from transplantation studies, it would appear that the ability of antigens within the testis to evade the immune system is not an absolute property of the testis or its draining lymph nodes, but is provisional upon certain criteria being met, such as the absence of testicular damage or other precipitating events. Tissues traditionally identified as being immunologically privileged, such as the testis and anterior chamber of the eye, may simply lie at one extreme of a range, as many of the mechanisms implicated in testicular immune privilege also exist to a more or lesser extent in most tissues. It might be most appropriate to think of immune privilege as simply a manifestation of a particularly effective immunoregulatory environment. The need for enhanced immunoregulation in tissues such as the testis or the eye may be related to the burden of the autoantigens present, and/or the need to prevent active inflammation causing damage to particularly susceptible tissues. While it is debatable whether autoimmunity to spermatogenic cells is more catastrophic to the organism than autoimmune gastritis, diabetes or thyroiditis, there must have been considerable evolutionary selection pressure applied to ensure that the immune system was restrained from attacking the post-meiotic germ cells the moment that they appeared during sexual maturation.

Immunology of the Epididymis and Vas Deferens

In contrast to the testis, the remainder of the male reproductive tract does not appear to be immunologically privileged, at least not in terms of extended graft survival.[1058,1059] This raises the question as to how sperm are able to continue to evade the immune system once they leave the testis environment. It is evident that the epithelial tight junctions of the epididymis and vas deferens are not as elaborate or effective as those of the blood–testis barrier.[72,86,91–93] Moreover, leukocytes—dendritic cells, macrophages and $CD8^+$ T cells, in particular—are commonly found within the epithelium of these tissues and appear to be able to have contact with the luminal contents.[65,96,98,102,334] Nonetheless, the fact that autoantigenic sperm can survive within the epididymis for considerable periods of time without eliciting an autoimmune response indicates that effective immunoregulatory mechanisms must be in operation.[101]

In general, the epididymis and vas deferens appear to be significantly more susceptible to inflammation and autoimmunity than the testis. Immune cell infiltrates are much more likely to appear in the epididymis than the testis in aging mice, in mice injected with *B. pertussis* and adjuvant, in mice with the alymphoplasia mutation, and in mice with a deletion of the AIRE transcription factor.[913–915,923] In addition, epididymitis or epididymovasitis precedes orchitis in the day 3 thymectomized mouse model, and following transfer of lymphocytes from mice immunized against spermatogenic cell antigens.[267,874,876] These observations suggest that the epididymis and vas deferens may be much more reliant on maintenance of tolerance to protect the sperm from immunological damage, compared with the testis.

Investigation of the incidence of sperm antibodies in men with obstructive azoospermia, congenital absence of the vas or following vasectomy indicated that lesions in the caput epididymis are associated with negligible antibody formation, whereas 66–100% of patients with obstructions in the cauda epididymis or postvasectomy had sperm antibodies (Figure 19.15).[348] This clearly indicates that obstruction or damage to the epididymis and vas deferens is a potent inducer of sperm autoimmunity, but that proximity to the testis reduces the severity of the response. Expression of inflammatory and immunoregulatory molecules and the distribution of immune cells in the epididymis and vas deferens is highly regionalized.

Specifically, there is a much greater number of dendritic cells, macrophages and T cells in the proximal epididymis, than in the more distal epididymis and vas deferens, and the dendritic cells appear to be more active.[96,98,102] Recently, it has been discovered that the immunoregulatory enzyme, IDO, is highly expressed in this region of the epididymis, and pro-inflammatory cytokine expression is higher than normal in the caput epididymis of IDO-deficient mice.[1060,1061] Moreover, IDO is regulated through the SMAD2/3/4 signaling pathway that is activated by activin A,[1005] and activin A levels are also highest in this region of the epididymis.[789] It can be proposed that activin A may drive IDO expression in the proximal epididymis, and together these immunoregulatory proteins induce a tolerogenic program in the intraepithelial dendritic cell and T cell populations. Although this hypothesis still remains to be confirmed, this would provide an effective mechanism for promoting tolerance to sperm antigens as they emerge from the immune privileged environment of the testis. The activity of Treg cells has been shown to control the pattern and severity of autoimmune responses to vasectomy in mice.[957]

Within the wider mucosal immune system, there is evidence that epithelial cells themselves can present antigen to activate immunosuppressive/regulatory T cell function,[188,1062,1063] and in this regard it is relevant that the principal cells of the epididymis are constantly absorbing large quantities of luminal fluid and its contents, including spermatozoa.[1064,1065] There is evidence that these cells also produce IL10.[809,1066] Moreover, epithelial cells of the epididymis and vas deferens express the glycosylphosphatidylinositol–anchored protein, CD52,[1067] which is a co-stimulatory molecule for Treg cell development,[1068] but may also play a role in protecting sperm against complement-mediated damage.[1069,1070] Consequently, removal of defective sperm from the epididymal lumen by the principal cells and presentation of their antigens to the intraepithelial lymphocytes might present an additional mechanism for controlling sperm autoimmunity in the epididymis, and possibly the vas deferens as well.

In addition to the tolerogenic mechanisms shared with the common mucosal system, there is evidence of other immunoregulatory mechanisms that may be more specific to the male reproductive tract. For example, immunosuppressive factors produced by the testis may diffuse into the epididymal fluid, and contribute to the unique immunoregulatory environment of the caput epididymis.[348] Modifications of the sperm surface membrane by epididymal secretions may act to obscure sperm antigens,[85] and expression of immunoregulatory molecules on the surface of the sperm itself, which include classical and nonclassical MHC antigens,[968,970] a CD4-like MHC ligand,[1071,1072] bacterial and viral TLRs,[451,802] and FASL,[492] also may play a role in evading immune responses in the epididymis and vas deferens.

Immunoregulation by Seminal Plasma

Seminal plasma is profoundly immunosuppressive, as defined by the ability to inhibit various T cell and NK cell activities in vitro.[1073,1074] This immunosuppressive activity has been proposed to play a role in preventing lymphocyte responses against sperm autoantigens in the male and female reproductive tracts,[856,1075] and, more recently, to prime the female immune system to tolerate paternal antigens on the developing fetus.[1076] The activity can been attributed to a number of specific and nonspecific factors, including prostasomes,[1077,1078] oxidized polyamines,[1079] prostaglandins of the E series,[1074,1080] nonspecific lymphocyte-suppressing proteins,[1081,1082] and immunoregulatory cytokines.[817,818,1083–1085]

Prostasomes are multilaminar vesicles secreted by the normal prostate, and are a major component of human semen.[1078] Pure preparations of prostasomes inhibit mitogen-induced T cell proliferation and inhibit macrophage phagocytic activity in vitro.[1077] The complement inhibitors, CD46, CD55 and CD59, have been found on the surface of prostasomes.[1086,1087] Seminal plasma also contains very high concentrations of the polyamines, spermine and spermidine.[1079] These polyamines are not immunosuppressive themselves, but are converted to their oxidized forms that are inhibitory of cell growth by the action of polyamine oxidase, an enzyme found in serum used in culture media.[1088] Oxidized polyamines are unstable and rapidly metabolized to the cytotoxic molecules, acrolein and putrescine.[1089] Prostasomes and polyamines are responsible for much of the apparent immunosuppressive activity of the ejaculate measured using lymphocyte cultures, but whether these factors have any physiological significance in terms of controlling immune responses in vivo remains speculative.[1090] On the other hand, following removal of the prostasomes and inactivation of polyamine activity in human seminal plasma samples from infertility clinic patients an inverse relationship between T cell inhibitory activity and the incidence autoimmune infertility associated with sperm antibodies has been observed.[1091]

Human seminal plasma contains extraordinarily high concentrations of PGE_2, PGE_1 and their 19-hydroxylated forms.[1092,1093] Aside from their well-characterized effects on vascular permeability and smooth muscle contractility, these hormones inhibit T cell proliferation, NK cell cytotoxicity and the pro-inflammatory activities of macrophages and T cells.[609,1094] They are produced throughout the male reproductive tract: the prostaglandins in seminal plasma largely come from the seminal vesicles, although the vas deferens also may be a major source because this tissue expresses extremely high levels of COX2 under normal conditions.[614,801] Following removal of the prostasomes and inhibition of polyamine oxidation, prostaglandins appear to be

responsible for most of the immunosuppressive activity of human seminal plasma.[284,818] Seminal plasma PGE_2 has been implicated in the promotion of tolerogenic responses in dendritic cells and the production of Treg cells.[1076,1095]

The cytokines with immunosuppressive/immunoregulatory activity that have been positively identified in human seminal plasma are TGFβ1 and TGFβ2,[1083,1085,1096] IL10,[817,1084,1097] and the activins, A and B.[1098,1099] The TGFβ in seminal plasma is derived from the distal tract, comprising the seminal vesicles and/or the prostate gland.[1096] IL10 is a product of monocyte/macrophages and T cells, but epithelial cells of the male tract are also a potential source of this cytokine.[809,1066] Although activin A subunit mRNA and protein is expressed in the human and mouse prostate,[537,1100] activin A levels in human seminal plasma are effectively eliminated by vasectomy, indicating a principally testicular or, more likely, epididymal origin.[789,1098] The most abundant and effective of the immunosuppressive cytokines in seminal plasma is TGFβ1, by a considerable margin.[818,1091,1101]

A positive relationship between the level of immunosuppressive activity in human seminal plasma and the presence of sperm antibodies has been observed,[818] but the actual relationship between immunosuppressive molecules in seminal plasma and immunological infertility in men remains to be established. It also should be borne in mind that these molecules have direct effects on the epithelia, stroma and leukocytes of the female genital tract.[1101,1102] Animal studies show an intense but transient inflammatory response in the endometrium at mating stimulated by seminal plasma and one consequence of this inflammatory response is the induction of a state of hyporesponsiveness to paternal MHC class I antigens.[1103] Insemination is causally linked to the activation and expansion of populations of lymphocytes mediating active immune tolerance at the embryo implantation site, specifically Treg cells, a process in which seminal plasma TGFβ1 and PGE_2 have been particularly implicated.[857,1101,1103] Semen may therefore play a critical role in providing the antigenic and environmental signals necessary to initiate an appropriate maternal immune response to the conceptus during pregnancy.

Other immunosuppressive/immunoregulatory molecules that are neither prostaglandins nor cytokines, have been detected in seminal plasma or accessory gland secretions from various species.[1081,1082] Some of these molecules have been identified, including the protein clusterin and a prostatic steroid binding protein in rats,[1104,1105] IgA,[816] and soluble HLA-G.[974] The actual significance of these molecules in immune regulation and autoimmune fertility requires further functional characterization.

INNATE IMMUNITY IN THE MALE REPRODUCTIVE TRACT: THE RESPONSE TO INFECTIONS AND TUMORS

If the male reproductive tract, and the testis in particular, is a site of reduced antigen-specific immune responses, then the question must be asked: *How does the genital tract avoid recurrent infections or the development of tumors?* Interest in the question has been stimulated by the fact that the male reproductive tract is a major site of transmission of human immunodeficiency virus (HIV),[1106] and by the observation that relapsing lymphoblastic leukemia in the testis following treatment is a frequent problem in male patients.[1107] While the progression of HIV in the male reproductive tract is very poorly defined, destruction of the spermatogenic cells is a characteristic feature of HIV infection in men.[1108] The testis is also suspected to be a sanctuary where HIV may be able to take refuge during therapy, possibly behind the blood–testis barrier, thereby subverting therapeutic effectiveness.[1109,1110] Studies by Jahnukainen and colleagues in rats have suggested that testicular relapse of leukemia may be due to the unique immunoregulatory environment of the testis and, specifically, the ability of Leydig cells to bind lymphocytes.[1111] Moreover, it appears that the immunological protection in the testis is extended not just to spermatogenic cell antigens and graft antigens, but also to tumor-specific antigens that would induce immune reactions elsewhere in the body.[1112]

As a result of these and other observations, it has been suggested that virally or tumorigenically transformed cells might be able to evade both the immune system and cytotoxic drugs by 'hiding-out' in the testis. The reality is, however, that infection of the testis is relatively rare compared with the remainder of the genital tract,[860] and testicular tumors are no more frequent than tumors in other parts of the body.[1113] Moreover, when they do occur, testicular tumors are accompanied by the expected mononuclear cell infiltrates, which are related to the size, progression and type of the tumor.[312,316] The effective deficiency in adaptive immune responses within the testis, therefore, implies that innate (pathogen-specific) immunity might have increased importance for dealing with tumors and infected cells at this site. Hypothetically, relying principally on mechanisms of innate immunity to provide protection against infections and tumors reduces the risk that inflammation will lead to antigen-specific immune responses and subsequent autoimmune damage to fertility. There is some justification for this assumption, based on studies of the male reproductive tract and from analogy with the rest of the common mucosal system. The mechanisms responsible broadly fall into cell-mediated responses and secreted molecules.

Cellular Responses

Although the environment of the male reproductive tract tends toward suppression of antigen-specific immunity and maintaining tolerance, these tissues are densely populated by effector cells involved in innate immunity, specifically macrophages and lymphocytes expressing CD8, which is expressed by both cytotoxic T cells and NK cells.[65,66,70,96,98,227,334,354,357] Significantly, NK cells are able to recognize and destroy infected or transformed cells without prior immunization, and so can act independently of the adaptive immune response. In addition to the testicular macrophages, both the Sertoli cell and Leydig cell are able to recognize and respond to bacterial pathogens directly,[376,386,387,390,392,994] through expression of specific TLRs on their surface. The importance of the TLRs in protecting against infection in the male reproductive tract is indicated by the fact that pathogens can increase their virulence by subverting the function of these molecules, for example, in the case of uropathogenic strains of *E. coli*.[275,436] Suppression of TLR expression throughout the male reproductive tract also appears to be a strategy utilized by HIV to evade immunity.[784]

All mucosa protect themselves through a number of nonimmunological mechanisms that support the integrity of the epithelial barrier. These include: tight junctions that restrict passage between cells, secretion of mucins and other antigenically inert molecules, control of local pH, recruitment of phagocytes (macrophages and neutrophils) to the epithelium, and production of lysozyme, ROS, proteases, complement components and antimicrobial cytokines, and peptides.[162,182,190,1063] It could be productive to investigate the role of these processes in resisting infection in the male reproductive tract.

Secreted Factors

Immunoglobulins

Immunoglobulin A is found in the fluid of all tissues of the male reproductive tract, but as vasectomy does not substantially alter IgA levels in semen, it appears that most comes from the urethra and accessory glands; more specifically, from the prostate gland.[1114–1116] Plasma cells secreting IgA have been found in the urethral gland,[354,1117] but most IgA in the reproductive tract is believed to be derived initially from the circulation.[190,355] Production of secretory component by the prostatic epithelium, which is required for transport of IgA across the mucosa, is androgen regulated.[1116] In men, bacterial infection of the reproductive tract is associated with a large increase in secretion of IgA in prostatic fluid.[1114] This anti-inflammatory immunoglobulin presumably plays an important first line of defense against infection in the male reproductive tract.

Interferons

These molecules possess a range of immunoregulatory and antiviral actions, including suppression of viral proliferation, cytotoxicity and, in the case of the type 2 interferon, IFNγ, stimulation of MHC class I and class II expression.[115,1118] The viral pathogen receptor, TLR3, which acts via the TICAM1 adaptor protein to induce production of type 1 interferons, is expressed by testicular macrophages, Sertoli cells, Leydig cells, peritubular cells and spermatogenic cells, and by epithelial cells of the epididymis and vas deferens.[438,441,442,450,451] In the testis, activation of TLR3 increases interferon production and interferon-inducible genes involved in viral protection in Sertoli cells, Leydig cells, and even spermatogenic cells.[438–440,450,451,597] Interferon production may also be induced through activation of TLR4. Testicular macrophages produce type 1 interferons constitutively, but viral infections upregulate their expression in both macrophages and somatic cells of the testis.[591,592] The strongest interferon response to infection occurs in the Leydig and Sertoli cells, but only the Leydig cells appear to express IFNγ under such conditions.

Defensins

Defensins are small (3–4 kDa) positively-charged antimicrobial peptides, which are able to disrupt bacteria, fungi, parasites, and some enveloped viruses by forming multimeric pores in the cell membranes of these pathogens.[1119] The defensins belong to one of two families, the α- and β-defensins (DEFA and DEFB).[1120] The β-defensins are produced by most mucosal epithelial tissues, but appear to be preferentially expressed in the urogenital tract, particularly in the testis and epididymis in the male, and their production is stimulated by TLR ligands and cytokines.[1121,1122] Genes encoding these peptides are expressed in discrete clusters along the length of the male reproductive tract,[794,1123] and a number of epididymal-specific β-defensins have been identified in the mouse and the rat.[1124–1126] Several of the β-defensins appear to be required for normal sperm maturation or for maintaining sperm motility in the epididymis, so that changes in their expression during infection also may contribute to sperm dysfunction.[808,1124,1127]

IMPLICATIONS, APPLICATIONS, AND THE NEXT 10 YEARS

This review has concentrated almost exclusively upon inflammation and immunity in the male reproductive tract as a means to understanding immune-based infertility and the impact of infection and inflammation on male reproduction. However, these processes have broader implications relevant to other areas of research and, in this last section, applications to clinical issues of

contraceptive development, transplantation medicine and chronic pain are briefly highlighted.

Immunocontraception

Conceptually, immunocontraception involving a vaccine that targets sperm antigens or reproductive hormones has the advantages of a potentially high degree of specificity and convincing proof-of-principle from the many patients with pre-existing autoimmune infertility. Although vaccines against gonadotropins actually have been trialed,[1128] it is unlikely that such an approach would be readily applicable to contraception in men. Other contraceptive vaccine studies have concentrated on antigens involved in critical sperm functions.[1129,1130] Such approaches raise concerns related to safety, efficacy and reversibility, but progress has been impeded largely by the issue of variability of immune responses after vaccination.[1131] Genetic differences in immune response genes in the human population and the complexity of the immune system itself might make it difficult to develop a single vaccine that works effectively enough in all men to compete with currently available hormone-based approaches to contraception. Another concern would be the risk of inducing more widespread autoimmune disease, since there is an established relationship between sperm autoimmunity and autoimmunity in general.[841,842] Furthermore, it may be difficult to develop a contraceptive vaccine that is entirely reversible. Nonetheless, the targeting of critical reproductive antigens to control fertility is a very attractive idea, which will most likely continue to engage reproductive immunologists. Most benefit from such studies may come from the identification and characterization of molecules with crucial functions in fertility which might be used as molecular targets for other drug agents that are not nonimmunologically-based.

Transplantation Medicine and Immunotherapy

One of the most obvious potential benefits from understanding the principles of immunoregulation as they pertain to the male reproductive tract is the possibility that these mechanisms might be applicable to controlling immunity at other sites. If there are immunoregulatory mechanisms that are more or less unique to the testis, for example, where extended graft survival has already been shown to be feasible, then elucidation of these mechanisms has the potential to lead to entirely novel methods of reducing graft rejection in general. The current methods used in transplantation medicine involve broad spectrum immunosuppressives, principally cyclic peptides of fungal origin that interfere with T cell signaling and prevent proliferation of these immune cells in a nonselective manner.[1132,1133] These drugs have considerable harmful side-effects, such as generalized immune suppression, nephrotoxicity and inherent tumorigenicity,[1134,1135] and require close monitoring and adjustment for the remainder of life. They also have damaging effects on testicular steroidogenesis and spermatogenesis.[1136,1137] Real alternatives or adjuncts to these agents, based on more physiological regulatory principles, would definitely be desirable. In particular, the unique immunological properties of the Sertoli cell raise hopes of an exciting new therapeutic opportunity in cell-based gene therapy.[989,1138] Such applications could include, not only the use of ectopic Sertoli cells to support pancreatic islet engraftment, for example, but also the employment of genetically-engineered Sertoli cell lines for delivery of therapeutic proteins. Time will tell if such a cell-based gene therapy approach is clinically viable.

Sterile Inflammation and Chronic Pain

An important concept that has arisen from studies on inflammatory pathways and immunity in normal male reproduction is the realization that dysregulation of these processes may be a cause of sterile, antibiotic-resistant inflammation and chronic pain. Chronic pelvic and perineal pain is normally associated with epididymo-orchitis, vasitis and/or prostatitis.[10–12,860,910,912] These conditions are usually due to infection or physical damage, but the ongoing production of endogenous ligands and danger signals, autoimmunity or alterations in regulatory signaling may cause inflammation to persist long after the infection has cleared or the trauma has been repaired.[10,12,1139] Prostatic hyperplasia and tumors also may be a cause, and inflammation may arise spontaneously in a susceptible subpopulation of patients. These chronic inflammatory pain conditions are poorly understood, and frequently difficult to treat.[12] Treatment alternatives are limited to standard anti-inflammatory and pain-alleviating measures, and the actual mechanisms involved are not well-characterized. Several prostanoids, including PGE_2 and PGI_2, have pain-inducing properties,[1140] and there is an association between chronic pelvic pain and production of the pro-inflammatory cytokines, IL1β, TNF, IL8 and IFNγ, in particular,[1139,1141] but research in this area is still in need of a rational hypothetical background. Given that these conditions are so poorly understood, extremely debilitating and frequently untreatable, they provide a real opportunity for effective future investigations.

CONCLUSION

In summary, the need for a close functional relationship between the male reproductive and immune systems is self-evident. Spermatogenic cells are susceptible to immunological responses and activation of immunity

against sperm or other elements of the reproductive tract can lead to androgen insufficiency, infertility or chronic inflammation. Inflammation and immune activation directly inhibit the hypothalamic-pituitary-Leydig cell axis at several levels, interfere with essential interactions between the Sertoli cells and spermatogenic cells and increase the potential for sperm antibody formation, a major cause of infertility in men. Nonetheless, spermatogenic cells normally are ignored by the immune system, as are grafts of foreign tissue placed within the testicular capsule. Traditional explanations for the protection of these cells, based on 'immune privilege' of the testis maintained by the blood–testis barrier or by exclusion of immune cells, are not consistent with either the histological organization of the reproductive tract or modern concepts of immunoregulation. A more realistic understanding of the control of immune responses in the male reproductive tract encompasses the activity of immunoregulatory macrophages and lymphocytes and peripheral tolerance, as well as active suppression of antigen-specific immunity by somatic cells involving regulatory cytokines, androgenic steroids and other anti-inflammatory and immunosuppressive factors. Dysregulation of this normal environment caused by infection, local or systemic inflammation, toxic insult, active immunization or deletion of regulatory T cells may activate the circulating immune cells, leading to a range of effects from temporary disturbance of spermatogenesis and steroidogenesis, all the way through to the creation of testis-reactive T cells and autoimmunity. Equally important for maintaining fertility, it appears that the restraints on antigen-specific immunity in the male reproductive tract are counterbalanced by enhanced local innate immune mechanisms and conventional mucosal immunity. In fact, it is increasingly evident that inflammatory signaling pathways are fundamental to the control of normal functions of the seminiferous epithelium, and possibly other functions throughout the male reproductive tract. Studies also suggest that establishment of male reproductive function is linked to the normal development of the local immune environment.

This review is intended to establish the concept that normal male reproductive function and the response to disease represent different facets of the same regulatory environment, involving complex interactions between somatic cells, resident immune cells and the circulating cellular elements of the immune system. The use of the term *immunophysiology* is intended to reflect this conflation of immunology and organ function. Unraveling these processes has obvious importance for issues related to male reproduction, such as autoimmune infertility, germ cell and testis transplantation, reproductive tract infection and chronic inflammatory pain. There is still a long way to go in order to understand these interactions completely, and how they impact upon health and physiology. Many unanswered questions remain, including:

- What are the local factors that regulate recruitment and functional modulation of macrophages and dendritic cells in the testis and downstream reproductive tract?
- What are the specific roles of T cell subsets in protecting intratesticular and sperm antigens?
- What is the relative contribution of local immunosuppressive mechanisms, such as the lyso-GPCs, toward this protection?
- What are the molecular details of inflammatory signaling in the seminiferous epithelium, and how do these impact upon reproductive health?
- What is the real clinical significance of leukocytes, cytokines and antibodies in semen?
- What are the mechanisms that regulate passage through the various testicular compartments, including the testicular capillaries and blood–testis barrier?

It is certain that the dramatic increase in interest, awareness and research activity in this area of male reproductive biology clearly means that there will be considerable new discoveries in the near future, with exciting and perhaps even totally unexpected implications and benefits. Indeed, such studies are crucial, in light of the increasing incidence of idiopathic male reproductive disorders,[1142] established and emerging infections with reproductive tract involvement (severe acute respiratory syndrome, resistant strains of tuberculosis),[863] and the resurgence of preventable diseases, such as mumps orchitis,[858] that threaten male fertility and reproductive health.

CHAPTER

20

Gonadotropin Signaling in the Ovary

Mary Hunzicker-Dunn

School of Molecular Biosciences, Washington State University, Pullman, WA, USA

Kelly Mayo

Department of Molecular Biosciences, Center for Reproductive Science, Northwestern University, Evanston, IL, USA

INTRODUCTION

The gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) initiate signaling events in ovarian target cells that govern the reproductive cycle and thus the continuation of a species. The ovarian follicle is the key structure that houses the oocyte. Upon appropriate stimulation by FSH and LH, follicles produce hormones that promote the development of secondary sex characteristics and that regulate the hypothalamic–pituitary axis as well as uterine receptivity. Somatic cells of the follicle contribute to hormone production and provide an environment supportive of growth and maturation of the oocyte. Additionally, the follicle must extrude the oocyte at ovulation to allow for fertilization, and remaining cells within the follicle must differentiate into cells of the corpus luteum that produce hormones necessary to sustain pregnancy. In the absence of FSH, follicles do not develop beyond the preantral stage, and animals are infertile. Similarly, in the absence of LH, ovulation does not ensue, corpora lutea do not form, and animals are infertile. Although there is a great deal of species variability, LH is also uniformly required to initiate progesterone production by the corpus luteum, which is necessary for implantation and the maintenance of pregnancy. Both gonadotropic hormones initiate their activities by binding to cell surface protein receptors. Through complex signaling pathways, FSH and LH initiate distinct, highly coordinated programs of gene expression that are only now beginning to be unraveled.

The existence of the gonadotropins was postulated based on the pioneering physiological studies of Long and Evans in 1922, and this work was quickly followed by the separation of pituitary extracts into the distinct fractions that would become known as FSH and LH by Fevold, Hisaw, and Leonard in 1931.[1] As approaches for the purification of the gonadotropins from various species were perfected in the 1970s, it became possible to begin detailed studies of their actions, leading to our fundamental understanding of the critical roles that they play in both male and female reproduction. A classic study by Greep et al. in 1942 showed that while purified FSH was sufficient to stimulate maturation of ovarian follicles to a preovulatory stage in hypophysectomized rats, LH was required to promote follicle ovulation.[2] These results form the basis for all of the subsequent studies reviewed in this chapter that now define the mechanisms by which FSH promotes follicular maturation and LH stimulates ovulation and oocyte maturation.

Early advances in our understanding of gonadotropin receptor localization and actions were made possible by the development in the 1960s by Hunter and Greenwood of a technique to iodinate hormones.[3] The development of conditional gene knockout technology in mice using Cre-Lox-mediated recombination in the late 1980s allowed investigators to establish the requirement for, and in some cases the function of, hormones, growth factors, receptors, and signaling molecules.[4] Mapping of intracellular signaling pathways regulated by the gonadotropic hormones and growth factors occurred with the development of commercially available antibodies specific to phosphorylated proteins in the 1990s.

In this chapter we review current knowledge about the signaling pathways by which FSH promotes follicle maturation and LH promotes ovulation and corpus luteum formation. We refer the reader to excellent reviews of the FSH[5–7] and LH receptors.[8–10] We focus on FSH and LH

signaling in granulosa cells of immature preantral follicles and mature preovulatory follicles and in theca cells primarily of the rodent, although examples from other species are also discussed. We do not consider LH signaling pathways and the regulation of LH target gene expression in the corpus luteum; readers are referred to Chapter 23.

FSH SIGNALS PROMOTE FOLLICULAR MATURATION

Follicle Maturation

Initial formation and early growth of ovarian follicles occur in a gonadotropin-independent fashion and rely on a number of characterized locally acting regulatory proteins that signal between the oocyte and the somatic cells of the follicle.[11–14] Once the follicle acquires functional FSH receptors, it can respond to this pituitary gonadotropin to undergo further maturation in preparation for ovulation. Only a small subset of ovarian follicles survives to full maturity, with most being lost along the way to a programmed cell death process termed atresia.[15,16] FSH-stimulated maturation of ovarian follicles to a preovulatory phenotype encompasses not only an explosive increase in the proliferation of granulosa cells contained within the follicle, resulting in rapid follicle growth, but also granulosa cell differentiation. As a consequence, the follicle develops a fluid-filled antrum, although markers for antrum formation are not well established.

Recent microarray results and the Ovarian Kaleidoscope Database reveal that FSH regulates the expression of ~500 target genes[17,18] in granulosa cells that support follicle maturation. Well-known responses that are often used as markers for FSH-dependent granulosa cell differentiation include increased estrogen production resulting largely from expression of the rate-limiting enzyme in estrogen biosynthesis that converts testosterone to estrogen, P-450 aromatase (aromatase); increased progesterone production as a result of increased expression of the rate-limiting enzyme in progesterone production that converts cholesterol to pregnenolone, P-450 cholesterol side chain cleavage (SCC); increased expression of 3β-hydroxysteroid dehydrogenase (3β-HSD), which converts pregnenolone to progesterone; increased expression of membrane receptors for LH and epidermal growth factor (EGF), both of which are required for the ovulatory response; and expression of the α subunit of the hormone inhibin, which feeds back to the anterior pituitary to repress production of FSH.[19–23]

FSH also stimulates the transcription of genes that encode for intracellular signaling molecules, such as the regulatory (R) IIβ subunit of protein kinase A (PKA),[24] the A-kinase anchoring protein (AKAP) microtubule-associated protein 2D (MAP2D),[25] and serum glucocorticoid kinase (SGK).[26] FSH has also been shown to induce expression of the EGF receptor agonist epiregulin[27,28]; the transcription factors early growth response factor-1 (EGR-1),[29] gonadotropin inducible ovarian transcription factor-1 (GIOT-1),[30] and liver receptor homolog (LRH)-1[31]; the follicular-fluid associated protein pregnancy-associated plasma protein-A,[32] which is recognized to be the insulin-like growth factor (IGF) binding protein-4 protease[33]; phosphodiesterases (PDE) 4D1 and 4D2[34] to degrade cAMP; and vascular endothelial growth factor (VEGF), which is reported to be critical for antrum formation, granulosa cell proliferation, and estrogen production, and for increasing the vascularity of the theca cell layer.[35,36] FSH also inhibits the expression of calmodulin kinase IV (CaM kinase IV)[37] and 3,5,3′-triiodothyronine binding protein mRNA.[38]

FSH enhances expression at the protein level of immediate early genes such as JUNB, c-JUN, c-FOS, FRA,[39] and c-MYC,[40,41] although these increases could result in part from posttranslational modifications to enhance protein stability[42] rather than strictly transcriptional regulation. FSH also promotes increased expression of a number of genes involved in reorganization of the microtubule and actin cytoskeleton, such as β-tubulin, the heavy chain of kinesin, and tropomyosin-4.[36,43]

The predominant marker for granulosa cell proliferation is increased expression of cyclin D2.[44,45] Cyclin D2-deficient mice are infertile as a result of the inability of granulosa cells to proliferate in response to FSH.[44] It is interesting, however, that granulosa cells of cyclin D2–null mice differentiate to a preovulatory phenotype, and upon stimulation with an ovulatory concentration of LH, follicles do not ovulate but granulosa cells luteinize in follicles with entrapped ova.[44] While FSH is sufficient to induce certainly the majority of granulosa cell differentiation markers in serum-free primary granulosa cell cultures, expression of cyclin D2 requires not only FSH but also activin.[46–49] These results suggest that in the intact animal, granulosa cell proliferation requires both FSH and paracrine actions of activin.

Taken together these results indicate that the response of granulosa cells to FSH involves a complex and coordinated program of gene expression that comprises the regulation of hundreds of genes.[17,18] The stimulus to promote granulosa cell differentiation requires relatively low but constant levels of FSH; withdrawal of FSH or its mediator cAMP during the 48-h time course of granulosa cell differentiation (of the 4-day rodent estrous cycle) results in incomplete induction of differentiation markers.[50,51]

FSH and the FSH Receptor

FSH is a glycoprotein hormone consisting of two distinct subunits, an α subunit shared with the related

glycoprotein hormones LH, human chorionic gonadotropin (hCG), and thyroid-stimulating hormone, and a unique β subunit (Figure 20.1). FSH is produced in gonadotrope cells of the anterior pituitary, and its synthesis and secretion are highly regulated by neural, pituitary, and gonadal factors.[53,54] The FSH receptor is a seven membrane-spanning G protein-coupled receptor (GPCR) that belongs to the rhodopsin/β-adrenergic family of GPCRs.[55] GPCRs are characterized by the presence of intracellular and extracellular loops linked by transmembrane (TM) α-helices and by their ability to couple to one or more guanine (G) nucleotide binding proteins. The FSH receptor belongs to the subgroup of class A GPCRs that contains Leu-rich-repeat motifs in their extracellular domain as well as the AsnSerxxAsnProxx-Tyr motif in TM 7 and the DRY motif at the border of TM 3 and inner loop 2.[56] The extracellular domain contains at least eight Leu-rich-repeat motifs of approximately 24 residues[6] that are believed to provide structural integrity to the receptor.[5] FSH binds to the large extracellular N-terminal domain of the receptor,[57] although one report stated that the interior of the receptor is also important for both hormone binding and signal generation.[58] Upon binding of FSH to this receptor, the receptor becomes activated. Activation of GPCRs is believed to represent a conformational change that alters the orientation of the TM domains.[59] Circular dichroism studies detected a difference in the secondary structure of the receptor when FSH was bound compared with the unbound state, consistent with the generation of an altered conformation upon hormone binding.[60] Binding of a partially deglycosylated human FSH to the extracellular domain of the FSH receptor showed that specificity is mediated by both the FSH α and β subunits and that upon hormone binding, FSH undergoes a conformational change to a more rigid structure.[61] While these investigators provided structural evidence for the existence of FSH receptor dimerization,[61] a recent report observed a trimeric association between FSH and the extracellular domain of the receptor.[62] These investigators additionally suggest that FSH first binds to a high-affinity subdomain on the receptor, which results in the formation of a sulfotyrosine binding pocket on FSH, with sulfated Tyr335 of the receptor then being inserted into the FSH pocket, leading to receptor activation.[62]

The predominant intracellular signal generated upon FSH receptor activation is cAMP, consistent with receptor coupling primarily to the stimulatory G protein (Gs).[6] Although there are reports that the FSH receptor can also couple to a pertussis toxin-sensitive Gi protein to modulate cAMP production in a Chinese hamster ovarian cell line,[63] and to activate phospholipase C (PLC) upon receptor overexpression in human embryonic kidney (HEK) cells,[64,65] the physiological relevance of these results has not been established.

The FSH GPCR is encoded by a single, rather large gene that consists of 10 exons and 9 introns.[5,6,66] The extracellular domain is encoded by the first 9 exons; the C-terminal part of the extracellular domain, the transmembrane domains, and the intracellular C-terminal domains are encoded by exon 10.[66] This receptor is expressed in females only on follicular granulosa cells[6]; expression is absent from ovaries of postmenopausal women.[6] FSH receptor-null mice are infertile, and follicles do not develop beyond the preantral stage,[67,68] consistent with the view that this receptor is necessary

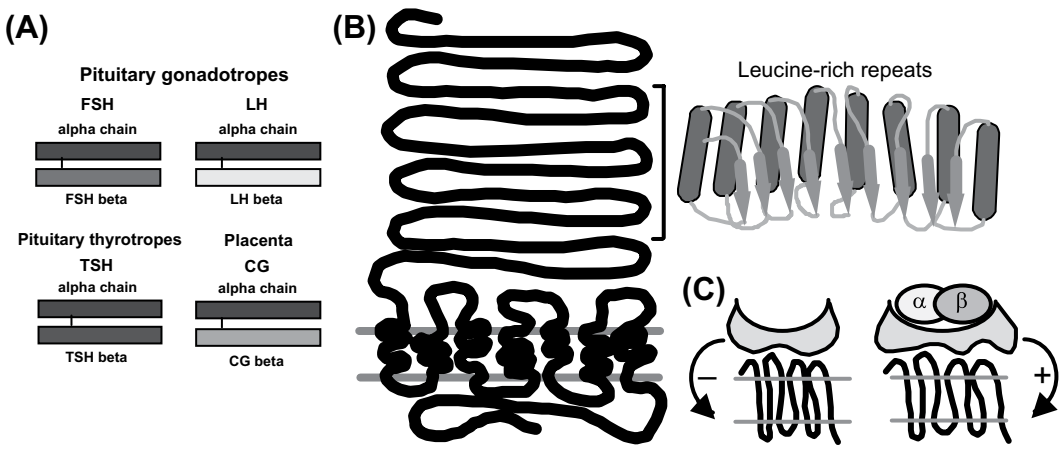

FIGURE 20.1 The gonadotropins and gonadotropin receptors. (A) A schematic of the family of dimeric glycoproteins hormones, which includes the pituitary gonadotropins FSH and LH, pituitary thyroid-stimulating hormone, and, in some species, placental chorionic gonadotropin. The α subunit is shared by all four hormones. (B) Generic schematic of the glycoprotein hormone receptors, indicating the large extracellular domain and the seven membrane-spanning domains characteristic of GPCRs. A significant portion of the extracellular domain is composed of leucine-rich repeats, each composed of a β-strand followed by an α-helix, and these are proposed to form a horseshoe-shaped domain as shown that likely plays an important role in ligand binding. (C) A model showing the view that the extracellular domain of the receptor plays a repressive role in the absence of ligand binding and that ligand interaction and ensuing conformational changes relieve this repression, allowing G protein activation. *Source: Modeled after Ref. 52.*

and sufficient to mediate the effects of FSH. FSH receptor expression is not detected in primordial follicles but has been detected on granulosa cells of preantral follicles from postnatal day 3 in rats; therefore, it is expressed at the very early stages of follicular development.[69–71] FSH receptor expression is increased by FSH or cAMP,[72,73] activin,[72–74] transforming-growth factorβ (TGFβ),[70] nerve growth factor,[75] and IGF-1,[72,76] and is abolished by the preovulatory LH surge that promotes ovulation.[69] Freshly harvested granulosa cells from preantral follicles of rats contain approximately 4500 receptors per cell.[77] Although the promoter of the FSH receptor gene contains an E-box, which is conserved among species and binds basic helix-loop-helix transcription factors such as upstream stimulatory factors 1 and 2, c-Myc and its dimerization partners Max or Mad, and hypoxia-inducible factor 1 (HIF-1),[78,79] and activation of the FSH receptor promoter requires steroidogenic factor (SF)-1[78,80] as well as binding of upstream stimulatory factors to the E-box, the mechanism for selective expression of the FSH receptor only in granulosa cells of female mammals has eluded identification. Exhaustive studies by Heckert and colleagues[7,79] revealed that elements required for cell-selective expression of the receptor are not present within the −5000 to +123 gene region surrounding the transcription start site.

Several naturally occurring inactivating mutations of the FSH receptor gene in humans have been described that result in arrested follicular development and hypergonadotropism. These include the following amino acid changes: Ile143Thr, Ala172Val, and Asp207Val in the extracellular domain, Lys584Val in the extracellular loop 3, and Arg556Cys in cytoplasmic loop 35. These mutations reduce or block FSH-stimulated cAMP generation, either as a result of poor hormone binding to the receptor and/or poor coupling to Gs. Directed point mutations in cytoplasmic loop 2 (Arg450His, Thr453Ala) either block or enhance receptor activation (Lys260Asp), consistent with the notion that this loop acts as a conformational switch.[81] A potential binding motif in cytoplasmic loop 3 for coupling to Gs (BXXBB, where B and X represent basic and nonbasic amino acids, respectively) has been identified.[81] A small molecule "negative allosteric modulator" that binds to the FSH-bound receptor in HEK cells overexpressing the FSH receptor and inhibits cAMP formation ($IC_{50} = 0.7 \pm 0.2\,\mu M$) by apparently stabilizing an inactive conformation of the receptor was recently reported, although the binding site for this compound was not identified.[82]

The only naturally occurring activating mutation identified for the human FSH receptor is Asp550Gly, located in cytoplasmic loop 3.[83] The FSH receptor with this mutation exhibits a modest increase in basal cAMP levels upon transfection into heterologous cells.[83] While the patient with this mutation exhibited normal testis function despite being hypophysectomized (because of a pituitary tumor), he received testosterone replacement therapy that might have contributed to the maintenance of spermatogenesis.[6,83] Directed mutation of Asp580His, a hot spot for activating mutations in other glycoprotein hormone receptors, results in enhanced granulosa cell proliferation, estrogen production, loss of small follicles, and development of hemorrhagic cysts in a mouse model.[84] It is surprising that more activating mutations of this receptor have not been identified.

Like most other GPCRs, the FSH receptor appears to exhibit desensitization or reduced FSH-stimulated cAMP production[65,85] upon exposure to saturating agonist, although granulosa cells likely never see saturating concentrations of FSH under physiological conditions. The mechanism of GPCR desensitization has been particularly well studied for the β-adrenergic receptor. Desensitization of the β-adrenergic receptor occurs rapidly after receptor activation and is characterized by both a rightward shift in the agonist dose–response curve and a decrease in maximal stimulation of adenylyl cyclase.[86] β-adrenergic receptor desensitization requires the phosphorylation of the activated receptor by a G protein-regulated kinase[87] and the consequent high affinity binding of arrestin2 (β-arrestin1) or arrestin3 (β-arrestin2) to the phosphorylated receptor.[88,89] Receptor phosphorylation functions to increase the affinity of the receptor for the arrestin.[88,90,91] Arrestins also play an integral role in receptor internalization based on their ability to bind both clathrin and β_2-adaptin of the AP-2 protein complex.[92–94] Thus, GPCR internalization often is linked to and follows receptor desensitization. Arrestins have also been shown in some cellular contexts to function as adaptors to bind signaling intermediates, such as upstream components in the mitogen-activated protein kinase (MAPK)/extracellular regulated protein kinase (ERK) and c-Jun NH2-terminal kinase (JNK) pathways, to redirect receptor signals to other pathways.[95]

The FSH receptor, upon overexpression (by approximately 10-fold) in a heterologous cell model, becomes phosphorylated in response to FSH on Ser/Thr residues in intracellular loops 1 and 3[96] in a G-protein-regulated kinase 2-dependent manner.[97,98] Mutation of the phosphorylatable residues in intracellular loop 1 leads to reduced receptor internalization.[96] Most of the internalized ligand-bound receptor recycles back to the cell surface, and intact hormone dissociates.[99] FSH also promotes the phosphorylation of a cluster of five Ser/Thr residues in the C-terminal tail of the receptor expressed in heterologous cells that stabilizes the binding of β-arrestin and is required for receptor desensitization but not for receptor internalization.[80] However, neither the rate nor the extent of FSH receptor internalization or FSH receptor desensitization has been studied under physiological conditions in granulosa cells.

There is also evidence that upon overexpression in a heterologous cell model, the FSH receptor not only binds β-arrestin[80] but also binds APPL1 (adaptor protein containing PH domain, PTB domain, and leucine zipper motif).[100] While these authors identified the binding site of APPL1 within intracellular loop 1 of the receptor (Lys376),[64] the physiological significance of this interaction is difficult to establish since the APPL1-null mouse is fertile.[101]

There is a report of an alternatively spliced FSH receptor that contains the first eight exons of the classic FSH GPCR plus a unique C-terminal extension that is hypothesized to traverse the plasma membrane a single time.[102] This receptor, upon expression in HEK cells, localizes to the plasma membrane and binds FSH in a specific and high-affinity manner but does not appear to couple to Gs to activate adenylyl cyclse.[102,103] This alternative FSH receptor is reported to be expressed in mouse ovaries[104] and to activate the ERK pathway in immortalized granulosa cells.[105] The physiological significance of this alternative FSH receptor to granulosa cell function remains to be elucidated.

FSH SIGNALING PATHWAYS THAT STIMULATE GRANULOSA CELL DIFFERENTIATION AND PROLIFERATION: cAMP AND PKA-DEPENDENT SIGNALING

The predominant intracellular signal generated by FSH-dependent signaling through its GPCR is cAMP (Figure 20.2), based on the ability of forskolin to mimic FSH's ability to induce such differentiation markers as progesterone synthesis and LH receptors[50,51,106,107] (reviewed in Ref. 19). cAMP signals predominately by activating the cAMP-dependent protein kinase (PKA).[108] PKA is a tetrameric holoenzyme that consists of two regulatory (R) subunits and two catalytic (C) subunits.

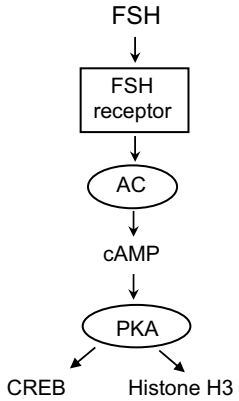

FIGURE 20.2 FSH signals via cAMP to activate PKA. Two PKA substrates in immature granulosa cells are CREB and histone H3.

PKA is activated upon binding of cAMP to the R subunits, resulting in the dissociation of the C subunits that function as active kinases to phosphorylate substrates.[109] Although representatives of an alternative family of cAMP effectors, consisting of cAMP-activated guanine nucleotide exchange factors also known as exchange proteins activated by cAMP (EPACs),[110,111] have been identified in rodent and human granulosa cells,[112] FSH either does not[113] activate or marginally (40%)[114] activates the EPAC target RAP1 in granulosa cells. Moreover, an EPAC-selective cAMP analog does not promote induction of aromatase,[115] a well-known marker of granulosa cell differentiation, or activation of the phosphatidylinositol-3 kinase (PI-3K) pathway.[116] Rather, in granulosa cells FSH activates PKA downstream of cAMP.[117] The cell-permeable selective PKA C subunit inhibitor peptide myristoylated-(Myr-) PKI, the active portion of the ubiquitous PKA inhibitor protein, inhibits the induction of a number of proteins induced by FSH, including MAP2D, inhibin-α, and progesterone producing enzymes.[113,118] PKI functions by binding to the substrate binding site of the C subunits of PKA, thus preventing other PKA substrates from binding, and preventing PKA from phosphorylating substrates.[119] While competitive ATP antagonists that are established inhibitors of PKA, such as H89 and KT5720,[120,121] also inhibit many of these responses initiated by FSH, including the induction of progesterone synthesis, aromatase, LH receptor, RIIβ, EGR-1, SGK, and MAP2D,[29,113,122] these inhibitors also inhibit other kinases, including p70 ribosomal S6 kinase (p70 S6 kinase) and RHO kinase (H89)[123] and phosphoinositide-dependent kinase 1 (PDK-1; KT5720).[124] Taken together, however, these results suggest that PKA is necessary for FSH-stimulated granulosa cell differentiation.

Two classes of PKA holoenzymes, PKA I and PKA II, exist based on the association of two possible RI subunits (RIα and RIβ) or two possible RII subunits (RIIα and RIIβ) with four possible C subunits (α, β1, β2, and γ).[109] PKA phosphorylates a large number of substrates in various cells.[125] Well-documented PKA substrates include CREB (cAMP response element binding protein),[126] PDE4D3,[127] SRC tyrosine kinase,[128] histone H3,[129] glycogen synthase kinase (GSK) α and β,[130,131] and L-type Ca^{2+} channels.[132]

But is PKA sufficient to promote granulosa cell differentiation? This remains a controversial topic that will be addressed throughout this review. The question of whether PKA is sufficient to drive granulosa cell proliferation has been addressed directly over the past 10 years by the Zeleznik group. Increasing intracellular levels of cAMP in preantral granulosa cells to levels equal to those stimulated by FSH either by transducing cells with adenovirally expressed constitutively active Gs[115] or constitutively active LH receptor[133] mimicked the ability of FSH to activate some (*Hsd3b2*, *Inha*) but not other

(*Lhcgr*, *Cyp19a1*) target genes to levels achieved by FSH 48 h posttreatment. However, cotransduction with constitutively active Gs and AKT (protein kinase B) rescued gene expression to levels equal to or greater than FSH,[115] suggesting that signaling via cAMP and AKT pathways is sufficient to activate FSH target genes. Correspondingly, while reducing FSH-stimulated cAMP levels ~ three-fold by transducing granulosa cells with adenovirally expressed constitutively active Gq greatly reduced the ability of FSH to activate key FSH target genes (*Lhcgr*, *Cyp19a1*, *Hsd3b2*, *Cyp11a1*), responses were rescued by the cell permeable cAMP analogue 8-bromo-cAMP.[134] Most compelling are results from a study in which granulosa cells were transduced with lentivirally expressed constitutively active PKA C subunit and compared to cells stimulated with FSH.[17] Microarray analysis of genes regulated 48 h posttreatment showed that the majority of genes were activated to the same extent by FSH and constitutively active PKA, although there were subsets that differed. The two caveats of this approach, as pointed out by the author, are: (1) constitutively active PKA cannot bind to AKAPs, thereby obscuring intracellular compartmentation, and (2) by 48 h, some FSH targets (*Lhcgr*, *Cyp19a1*) may begin to undergo downregulation in response to the potential of the constitutively active PKA C subunit to mimic the surge of LH. We conclude with our present state of knowledge that PKA appears to be sufficient to mediate granulosa cell differentiation, at least qualitatively. However, we expect that additional pathways activated by FSH contribute to optimal target gene regulation to yield a preovulatory follicle.

While most PKA in ovaries with preantral follicles consists of a PKA IIβ holoenzyme,[135] based on DEAE-cellulose chromatography, RIIβ knockout mice are fertile.[136] PKA Iα holoenzyme comprises less than 5% of the PKA activity detected in preantral follicle-dominated ovaries, although there is a large amount of C subunit–free RI.[135] The presence of substantial C subunit–free RI is surprising because RIα not bound to C is reported to be rapidly degraded[137] and may suggest the presence of activated PKA Iα, since free C subunit does not bind to DEAE-cellulose. Rodent ovaries do not express RIβ.[138] Taken together, these results suggest that the actions of FSH could be mediated by PKA Iα rather than by the seemingly more abundant PKA IIβ holoenzyme. Because RIα-null mice died at embryonic day 10.5,[139] proof that RIα is crucial to granulosa cell differentiation requires the generation of mice with an RIα deletion targeted to granulosa cells.

AKAPs Target PKA to Specific Subcellular Locations

The specificity of PKA action is accomplished by the targeting of PKA as well as its substrates to specific cellular locales by virtue of the binding of PKA regulatory subunits to a large family of AKAPs. It has been estimated that more that 75% of PKA holoenzymes are targeted to specific intracellular sites via association of PKA regulatory subunits with AKAPs.[109] RII subunits bind with nM affinity to AKAPs.[109,140] The domain on the AKAP responsible for RII binding comprises an amphipathic helix that binds the N-termini of the PKA-RII dimer.[141] AKAPs direct PKA to such locations as the mitochondria, Golgi apparatus, centrosome, nuclear envelope, and actin and microtubule cytoskeletons by the presence of specific subcellular targeting domains on each AKAP,[142–144] as depicted in Figure 20.3. Localization of PKA and one or more substrates to distinct regions within the cell is thought to promote both specific and efficient substrate phosphorylation in response to a stimulus.[144] AKAPs not only bind PKA but also function as platforms to coordinate signaling cascades by binding additional signaling proteins such as CaM, PDEs, protein phosphatases such as PP1 and PP2A, and protein kinases such as the tyrosine kinase ABL and the Ser/Thr protein kinase C (PKC) enzymes.[143,144] By confining PKA and specific substrates to isolated cAMP gradients at discrete cellular locations, not only are signaling cascades optimized but also their fidelity is maintained, thereby preventing inappropriate cross talk among pathways.[143]

Most known AKAPs anchor PKA II holoenzymes and exhibit at least a 100-fold lower affinity for PKA I holoenzymes.[143] Although there are a growing number of "dual specificity" AKAPs that readily bind PKA I holoenzymes, these AKAPs still exhibit a 10- to 25-fold preference for RII.[145] However, fibrous sheath protein 1,[146] the *Caenorhabditis elegans* $AKAP_{CE}$,[147] the peripheral benzodiazepine receptor-associated protein PAP7,[148] the neurofibromatosis 2 tumor-suppresser protein merlin,[149] sphingosine kinase interacting protein,[150] and GRB2

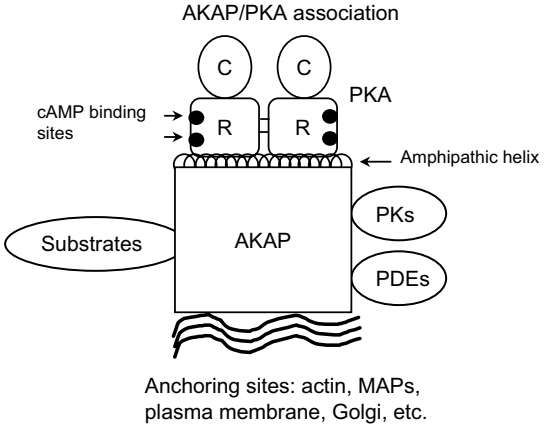

FIGURE 20.3 Schematic model of the association of AKAPs with PKA, other protein kinases (PKs), PDEs, substrates, and anchoring sites in cells.

(growth factor receptor binding protein 2) associated binding protein 2 (GAB2)[116] appear to preferentially bind RI and thus are PKA I AKAPs.

Preantral follicle-dominated ovaries express a large number of AKAPs, including AKAP-KL, AKAP79, Ezrin, AKAP-149, AKAP95, AKAP220, and AKAP100, based on RII overlay and western blotting results.[135] However, neither the selective link of each AKAP to individual PKA substrates and signaling pathways nor the cellular location of these AKAPs has been investigated. Thus, the cellular mechanism(s) by which each of the AKAPs present in granulosa cells modulates cellular functions is not known. We recently identified GAB2 as an RI AKAP and a direct PKA substrate in preantral granulosa cells that appears to orchestrate signaling of PKA into the PI-3K pathway, as discussed below, although formal proof of this link is lacking.[116]

PKA Targets in Undifferentiated Granulosa Cells: CREB and Histones H3 and H1

Defining the signaling pathways that are activated by FSH in granulosa cells and determining how PKA coordinates signaling into these pathways remains a central challenge in ovarian biology. Although details of the signaling pathways activated by FSH are just beginning to be elucidated, it is clear that FSH stimulates the PKA-dependent phosphorylation of the established PKA substrates CREB on Ser133[151,152] and histone H3 on Ser10.[117,118] Both FSH-stimulated CREB and histone H3 phosphorylations in granulosa cells are abrogated by the PKA inhibitor Myr-PKI, suggesting that PKA is the predominant kinase that phosphorylates these proteins (Figure 20.2). CREB and histone H3 are direct PKA substrates.[118,153]

It is interesting that in other cellular models, both CREB and histone H3 are phosphorylated on the same sites by protein kinases other than PKA. For example, CREB kinases in other cells include the PI-3K substrate AKT,[154] CaM kinases, the ERK substrates p90 ribosomal S6 protein kinases (RSK) and the mitogen- and stress-activated protein kinases 1 and 2 (MSK1 and -2), and the p38 MAPK substrates MAPK-activated protein kinases 2 and 3 (MK-2 and -3)[155,156]; however, inhibitors of these kinases do not reduce FSH-stimulated CREB phosphorylation in granulosa cells.[113,118] Similarly, in other cells histone H3 is commonly phosphorylated by the ERK substrate RSK2 and by the ERK and p38 MAPK substrate MSK-1.[157–159] However, inhibitors of ERK activation and of activated p38 MAPK do not reduce histone H3 phosphorylation in granulosa cells.[118] These data support the notion that PKA plays a unique role in granulosa cells to regulate signaling pathways.

FSH enhances the phosphorylation of histone H3 on Ser10 as well as the acetylation of Lys14, although it is not clear whether these modifications occur simultaneously or in a sequential manner.[118] The histone code hypothesis put forth by Strahl and Allis[160] stated that covalent modifications of core histone tails result in the remodeling of chromatin to affect downstream events. The best-known core histone modifications consist of the covalent addition of an acetyl group to Lys, the addition of one or more methyl groups to Lys or Arg, and addition of a phospho group to Ser or Thr. These additions occur primarily on the N-terminal tails of histones H3 and H4. Acetylation neutralizes the positive charge of the histone and phosphorylation adds a negative charge, thereby decreasing the affinity of histone for DNA.[161] The predicted result of histone acetylation and/or phosphorylation is the loosening of chromatin structure, resulting in increased access of select promoter regions to transcription factors and co-activators.[160,162] Methylation can correlate either with gene activation or gene inhibition and can occur on the same Lys residues that are acetylated, and Lys residues can be mono-, di-, or trimethylated, whereas Arg residues can be mono- or dimethylated. Arg methylation of histone H3 generally correlates with gene activation.[163] For histone H3, methylation of Lys4 correlates with gene activation, whereas methylation of Lys9 and Lys27 correlates with gene repression.[164,165] Histone acetylation is catalyzed by histone acetyltransferases, such as CREB binding protein (CBP), histone deacetylation is catalyzed by histone deacetylases, and histone methylation is catalyzed by methyltransferases.

Consistent with the histone code hypothesis, increased *c-Fos*, *Sgk*, and *Inha* promoter DNA is detected in the dual-phosphorylated and -acetylated histone H3-chromatin pools in response to FSH treatment of granulosa cells in chromatin immunoprecipitation (CHIP) assays.[118] Because the *c-Fos* promoter contains a functional cAMP response element,[166] signaling to activate *c-Fos* in granulosa cells probably reflects contributions from CREB. In this instance, the C subunit of PKA would function not only to phosphorylate CREB to promote binding of CBP[167,168] but also to phosphorylate histone H3, whereas CBP perhaps promotes the acetylation of histone H3 as well as recruitment of other co-activators and the basal transcription machinery.

Activation of the *Sgk* gene in response to FSH/PKA requires an Sp1 (specificity protein 1) binding site.[26] Because the phosphorylation and acetylation of histone H3 are linked to the rapid activation of the *Sgk* gene, perhaps co-activators with histone acetyltransferases activity as well as the C subunit of PKA complex with Sp1 at the *Sgk* promoter. It is possible that the stimulatory effect of PKA on *Sgk* transcription reflects H3 phosphorylation and chromatin reorganization in addition to direct phosphorylation of transcription factors. The mechanism by which PKA enhances the transcriptional activity of Sp1 is not clear, but as discussed later in "Cross Talk among FSH-Regulated Signaling Pathways and Transcriptional

Activators to Regulate Gene Expression," both ERK and the AKT target PKCζ are candidate kinases.[169] Histone H3 phosphorylation and acetylation is also linked to activation of *Inha* subunit gene expression. Activation of the *Inha* promoter requires synergism among PKA-phosphorylated CREB, SF-1, or LRH-1, and the co-activators CBP and the *Ncoa1* product steroid receptor co-activator-1 (SRC-1).[170] SF-1 and CREB constitutively bind to and interact (directly or indirectly) on the *Inha* promoter,[170] and CBP is recruited by and binds to phosphorylated CREB[167,168] and to SF-1.[171] The dependence on PKA for activation of the *Inha* gene has historically been assumed to be a consequence of the phosphorylation of CREB,[153] leading to CBP recruitment.[168,170] However, it is likely that a member of the cAMP-regulated transcriptional co-activator (CRTC) family also contributes to the ability of CREB to activate the *Inha* gene.[172] In response to elevated intracellular levels of cAMP, CRTC becomes dephosphorylated and translocates from the cytoplasm to the nucleus, where it binds to phosphorylated CREB and enhances its association with DNA.[172,173] It is also well established that PKA potentiates SF-1 transactivation activity. Although SF-1 can be phosphorylated by PKA in vitro, mutation of its consensus PKA phosphorylation site (Ser430Ala) does not affect the stimulatory effects of PKA on SF-1 transactivational activity.[174] It is now recognized that the transcriptional activity of SF-1 requires the co-activator β-catenin.[175,176] We have recently shown that FSH promotes the PKA-dependent phosphorylation of β-catenin on Ser552 and Ser675,[177] consistent with reports in other tissues,[178,179] and consequent activation of the β-catenin/T cell factor (TCF) artificial promoter-luciferase construct, TOPFlash,[177] as discussed below.

It is likely that the rapid phosphorylation of histone H3 on Ser10 by PKA and acetylation on Lys14 by CBP or other histone acetyltransferases constitute a necessary step in the transcriptional activation of many FSH responsive genes, leading to granulosa cell differentiation. FSH is also predicted to promote alterations in the methylation patterns of histone H3, although this H3 modification in granulosa cells preantral granulosa cells has not yet been reported. It is possible that histone H3, in its phosphorylated, acetylated, and possibly methylated conformation, functions as a scaffold to mediate the assembly of the multiprotein complex of transcription factors, co-activators, and basal transcription factors, which leads to transcription.[160] Based on results in a HEK cell line,[170] it is also expected that histone H4 is covalently modified in granulosa cells in response to FSH. Using the CHIP assay with an antibody to acetylated histone H4, it was shown that PKA increased histone H4 acetylation associated with the *Inha* promoter.[170] The increased histone acetyltransferase activity could result either from the recruitment of CBP[180,181] or the recruitment by CBP of a p300/CBP-associated factor PCAF.[182,183]

Histone H1 is also phosphorylated in granulosa cells in response to FSH, although with a slower time course than that of histone H3.[117] Histone H1 binds to the outer surface of the DNA that surrounds the core histones and to the stretches of linker DNA that connect nucleosomes.[184] Histone H1 is known to be an in vitro PKA substrate, with phosphorylation on Ser37,[129,185] and is phosphorylated on Ser37 in vivo in liver in response to glucagon treatment[129] and in response to forskolin addition to N18 neuroblastoma cells.[185] It is predicted that histone H1 phosphorylation contributes to chromatin remodeling, although less is known about the role of this histone in regulating transcriptional activation.

Because most of the known differentiation responses to FSH are mediated by PKA, it was initially assumed that the genes activated by FSH would all contain CREB-binding sites. However, cAMP response elements have been identified only in the promoters of a subset of FSH-regulated genes, including *Inha*,[186] *Cyp19a1*,[152] *Giot-1*,[30] *EGR-1*,[29] and *c-Fos*.[166] Therefore, FSH via PKA must phosphorylate additional targets to activate signaling pathways. Indeed, as discussed later, FSH also stimulates activation of the ERKs and PI-3K pathways in a PKA-dependent manner.

PKA Signals to Activate the ERKs in Undifferentiated Granulosa Cells

The ubiquitous ERKs, which belong to the MAPK family, are activated by a variety of receptor agonists. These kinases are classically activated by receptor tyrosine kinases such as the insulin, EGF, or IGF-1 receptors. Upon activation of these receptors, their consequent autophosphorylation creates specific binding sites for Src homology 2 (SH2) containing proteins such as GRB2.[187] GRB2, complexed with SOS, binds to the receptor tyrosine kinase, and the guanine nucleotide exchange factor SOS promotes activation of RAS by stimulating its GDP release. Active RAS then promotes activation of the Ser/Thr kinase RAF-1, which, in turn, phosphorylates/activates the ERK kinase MEK. MEK then phosphorylates ERK on Thr and Tyr residues, resulting in ERK activation. GPCRs activate ERKs generally by promoting the transactivation of a receptor tyrosine kinase,[188] resulting in its phosphorylation and consequent stimulation of the pathway leading to ERK activation, although the mechanisms of receptor tyrosine kinase transactivation vary among GPCRs and are incompletely understood.[189–191] While GPCR-generated cAMP is most commonly reported to inhibit ERK activation, especially in nonendocrine cells,[192] cAMP has been reported to activate ERK either via PKA by stimulating the phosphorylation of the small G protein RAP1, leading to the activation of B-RAF, MEK, and ERK,[193,194] or by directly binding to and activating the RAP1 guanine nucleotide exchange factor EPAC, leading to activation of B-RAF, MEK, and ERK.[110,111]

While FSH promotes the rapid albeit transient activation of ERK via a PKA-dependent pathway,[85,113,195] the mechanism by which PKA regulates ERK activity in preantral granulosa cells appears to depend in part on the extracellular matrix to which cells attach in vitro. When cells are attached to fibronectin, FSH does not promote the phosphorylation/activation of MEK; rather FSH regulates the association of a 100-kDa protein tyrosine phosphatase (PTP) with ERK in a PKA-dependent manner.[113] In the absence of FSH, a tonic stimulatory pathway promotes activation of the components of the ERK pathway upstream of ERK, including MEK; however, ERK activity is blunted by its association with a PTP that inactivates ERK (Figure 20.4). Consistent with this scheme, the MEK inhibitor PD98059 blocks FSH-stimulated ERK phosphorylation.[113] In the presence of FSH, PKA catalyzes the phosphorylation of the 100-kDa PTP that is complexed with ERK, resulting in dissociation of the phosphatase from ERK.[113] In the absence of the associated PTP, ERK is relieved from inhibition and is activated by the tonic stimulatory pathway.[113] This granulosa cell PTP is recognized by an antibody that recognizes PTP-SL, but based on its larger size and lack of recognition by other PTP-SL antibodies, the ERK-associated PTP in granulosa cells appears to be distinct from PTP-SL and has not been identified.[113]

Regulation of the tonic pathway that promotes activation of MEK in granulosa cells is poorly understood. Both extracellular Ca^{2+}, the EGF receptor, and the tyrosine kinase SRC (Rous sarcoma oncogene) appear to be necessary for FSH-stimulated ERK activation, based on the abilities of Ca^{2+} chelation with ethyleneglycotetraacetic acid, the EGF receptor inhibitor AG1478,[196] and the SRC inhibitor PP1 to abrogate this response.[113] Moreover, Ca^{2+} entry appears to be mediated by L-type Ca^{2+} channels, based on the ability of the L-type Ca^{2+} channel inhibitor nifedipine[113] to block FSH-stimulated ERK activation. Ca^{2+} entry also appears to be upstream of the EGF receptor and Src, because the EGF receptor inhibitor AG1478 and the SRC inhibitor PP1 block the ability of the Ca^{2+} ionophore A23187 to stimulate ERK phosphorylation[113] (Figure 20.4).

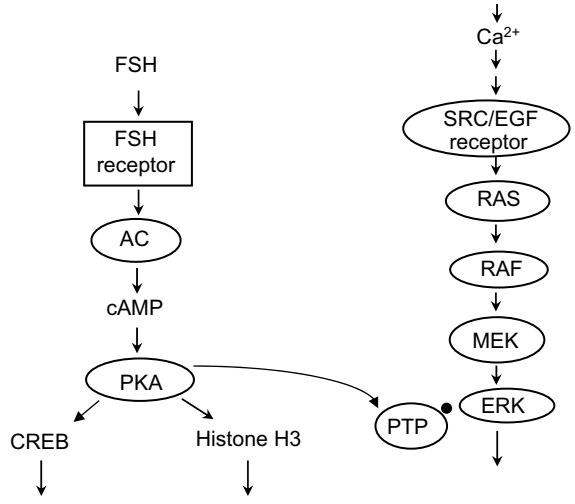

FIGURE 20.4 FSH via cAMP/PKA activates ERK by stimulating the phosphorylation and consequent dissociation of an inhibitory protein tyrosine phosphatase (PTP). A tonic pathway that includes Ca^{2+}, SRC, EGF receptor, RAS, and RAF promotes MEK phosphorylation.

Under similar experimental conditions, FSH-stimulated ERK activation requires PKA, SRC kinase activity, and the EGF receptor, although MEK phosphorylation in the absence of FSH (i.e., the tonic pathway) was not investigated.[185] In contrast, when cells are attached to serum-coated plates, FSH appears to signal via an EGF receptor and SRC-dependent route to activate RAS, leading to ERK activation.[107] There is also evidence that AMP-kinase (AMPK), which is active (phosphorylated on Thr172[197]) in the absence of FSH,[198] complexes with and inhibits ERK activity.[199] While FSH promotes the inactivation of AMPK,[199] the mechanism by which AMPK regulates ERK activity is not known.

Despite an incomplete understanding of the ERK activation pathway in granulosa cells, FSH-stimulated ERK appears to be necessary, but not sufficient, for induction of the MAP2D[113] and cyclin D2, based on protein/mRNA expression in the absence and presence of the MEK inhibitor, PD98059.[198,200] Similarly, this MEK inhibitor attenuates the FSH-dependent induction of the immediate early gene EGR-1 in granulosa cells,[29] suggesting that induction of EGR-1 by FSH requires MEK-dependent ERK activation.

FSH has also been shown to increase protein expression for a number of immediate early genes that comprise the AP-1 family, including JUNB, c-JUN, c-FOS, and FRA2,[39] as well as c-MYC.[40,201] JUNB has been shown in granulosa cells to regulate the expression of the *Inhb* promoter.[202] A recent report suggested ERK-dependent phosphorylation of these proteins stabilizes them by inhibiting their degradation; however, this response requires persistent ERK activation over a time course inconsistent with the expression of these immediate early genes.[42] Based on the transient activation of ERK in granulosa cells (which is generally undetectable by 1–2 h post FSH[113,195]), it is unlikely that the mechanism by which FSH increases the expression of these proteins rests with their ERK-dependent phosphorylation.

ERK can also phosphorylate or direct the phosphorylation of a number of transcription factors and co-activators that have been identified as participants in the induction of FSH target genes. Figure 20.5 reviews ERK targets that have been established in various cellular models.[156] For example, ERK is established to phosphorylate SF-1 on Ser203, resulting in recruitment of co-activators as well as driving the formation of a compact

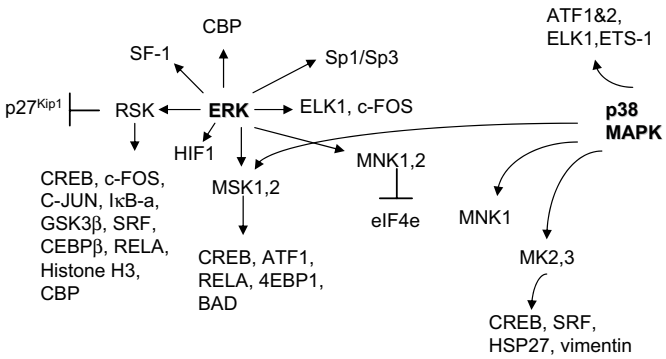

FIGURE 20.5 Summary of identified ERK and p38 MAPK substrates. Arrows indicate stimulation; perpendicular lines indicate inhibition of activity.

structure that results in formation of an active conformation.[203,204] ERK also phosphorylates Sp1/Sp3 on Thr266, thereby enhancing its DNA binding activity.[205] ERK is believed to phosphorylate CBP on Ser436,[206] and this phosphorylation has been suggested to be necessary for its recruitment of the AP-1 complex.[207] It is interesting that p300 lacks this phosphorylation site.[207] However, phosphorylation of CBP by ERK in vivo has not yet been reported, to our knowledge. ERK also phosphorylates a number of kinases, including RSKs 1–4, MSK1 and -2, and MAPK-interacting kinases (MNK1 and -2).[156] These kinases, in turn, phosphorylate a number of transcription factors, in a cell-specific manner, as reviewed in Figure 20.5. Only ERK-catalyzed RSK phosphorylation has been positively identified in granulosa cells treated with FSH,[118] although a number of additional ERK substrates are expected to be phosphorylated in granulosa cells in response to FSH. Although RSK can phosphorylate CREB and histone H3 in some cells, FSH-stimulated phosphorylation of these proteins is not inhibited by the MEK inhibitor PD98059,[118] indicating that neither CREB nor histone H3 is a RSK substrate in granulosa cells. Unphosphorylated RSK has been reported to sequester CBP and inhibit its histone acetyltransferase activity,[208,209] although this might be cell specific because RSK has also been reported to enhance co-activator activity of CBP.[210] An association between RSK and CBP has not been investigated in granulosa cells, but based on the number of transcription factors that require CBP in FSH-regulated signaling pathways in granulosa cells, including CREB,[167,211] HIF-1,[212] and FOXO1,[213] as described later, or that bind CBP, including SF-1[171] and SMAD,[214,215] regulation of the availability of CBP could be an important regulatory mechanism by which FSH enhances target gene expression. Thus, ERK signaling likely participates at least indirectly in the regulation of the expression of a number of FSH target genes by regulating the phosphorylation of a number of transcription factors and/or co-activators. The importance of the ERK pathway to follicle development is also evidenced by the expression of a constitutively active RAS (KRAS-Gly12Asp) in preantral granulosa cells that resulted in subfertile mice, reduced induction of *Lhcgr*, and development of abnormal follicles devoid of mitotic and apoptotic cells.[216]

Mammalian cells contain two additional MAPKs, the p38 MAPKs and the JNKs. Although activation of the JNKs by FSH to our knowledge has not been reported, the p38 MAPKs are activated by FSH in rat granulosa cells.[217–219] The effect of FSH is mimicked by forskolin[219] and appears to be PKA dependent, based on the ability of H89 to inhibit p38 MAPK phosphorylation,[219] although this result is controversial.[114,218] A downstream p38 MAPK target whose phosphorylation is increased by FSH is the small heat shock protein HSP27[219] (Figure 20.5). Although the significance of HSP27 phosphorylation in granulosa cells has not been delineated, upon phosphorylation HSP27 loses its ability to form oligomers and to block actin polymerization.[220] HSP27 is also recognized to inhibit apoptosis in various cellular models.[220] Rounding of granulosa cells, a characteristic response to FSH stimulation,[221] is inhibited by the p38 MAPK inhibitor SB203580, suggesting that the p38 MAPK pathway contributes to granulosa cell cytoskeletal changes.[222] Although FSH activates the upstream p38 MAPK kinases MKK3 and MKK6,[217] the cellular mechanism by which FSH, presumably via PKA, signals into this pathway is not known. Often, this pathway is activated by the small GTPases of the RHO family, leading to the activation of a number of possible kinases that direct activation of MKK3/6.[156] The potential ability of FSH to signal to a RHO family member has not been investigated to our knowledge.

The phosphorylation of a number of transcription factors in various cells is also regulated by p38 MAPK, as reviewed in Figure 20.5, and it promotes the phosphorylation of MNK1 (but not MNK2) and MK2 and -3.[156] HSP27 is actually phosphorylated by MK2 and -3 and not directly by p38 MAPK. CREB can also be a target of MK2 and -3 but is not likely to be phosphorylated by these kinases in granulosa cells in response to FSH, based on the inability of the p38 MAPK inhibitor SB203580 to affect FSH-stimulated CREB phosphorylation.[118] Other than HSP27, p38 MAPK targets in immature granulosa cells have not been identified.

FSH Increases Intracellular Ca^{2+} in Undifferentiated Granulosa Cells

FSH is reported to increase intracellular Ca^{2+} in a cAMP-dependent manner in porcine granulosa cells, and the Ca^{2+} appears to be derived largely from extracellular sources.[223–225] Ca^{2+} entry is inhibited with verapamil, an L-type Ca^{2+} channel blocker, suggesting that plasma membrane Ca^{2+} channels are opened by cAMP

or PKA.[225] Moreover, Ca^{2+} is required for FSH to activate the *Cyp11a1* promoter-reporter in porcine granulosa cells.[223] Although cAMP analogs that selectively activate PKA mimic the actions of FSH to raise intracellular Ca^{2+} levels in Sertoli cells,[226] equivalent studies have not been performed in granulosa cells. In contrast to reports on porcine granulosa cells, there are two reports that FSH does not mobilize intracellular Ca^{2+}, one in HEK cells heterologously expressing the human FSH receptor[227] and another in a rat ovarian granulosa cell line.[228] There is also a report that FSH increases intracellular Ca^{2+} in the human KGN cell line overexpressing FSH receptors.[64] In rat granulosa cells in culture, a Ca^{2+} signal is required for FSH-stimulated ERK activation, as discussed earlier.[113] Consistent with these data, Carnegie and Tsang[229] reported that ethyleneglycotetraacetic acid and the Ca^{2+} channel blocker verapamil inhibit FSH-stimulated progesterone production and the Ca^{2+} ionophore A23187 stimulates progesterone production in rat granulosa cells. Taken together, these results suggest that Ca^{2+}contributes to the actions of FSH. Whereas FSH appears to promote the entry of Ca^{2+} into porcine granulosa cells in a cAMP-dependent manner, the regulation of intracellular Ca^{2+} in rat granulosa cells is less clear.

Ca^{2+}-dependent downstream signaling pathways have also been studied in granulosa cells. CaM kinases II and IV are present in immature rat and porcine granulosa cells,[37,230] and FSH promotes a decline in CaM kinase IV expression to undetectable levels by 24 h in rat granulosa cells.[37] Mice deficient in CaM kinase IV exhibit impaired follicular development and ovulation.[37] Cotransfection of active CaM kinase IV with a *Cyp11a1* promoter-luciferase construct into porcine granulosa/luteal cells resulted in a significant increase in basal transcription of this gene that was blocked by a dominant negative CREB mutant.[230] Cotransfection with CaM kinase II was ineffective.[230] This result suggests that CREB is a possible CaM kinase IV target in porcine granulosa/luteal cells. Ser133 on CREB is a recognized CaM kinase IV target in neuronal cells.[231] Although these results suggest that CaM kinase IV plays a role in the basal transcription of *Cyp11a1* in mature granulosa cells, the role of CaM kinases in immature cells is less clear. An early report by Conti and collaborators[232] showed that FSH treatment of rat granulosa cells activated a cAMP-PDE that required Ca^{2+}/CaM. Additionally, FSH-stimulated progesterone production in rat granulosa cells is reported to be inhibited by the CaM inhibitor R24571,[229] although FSH-stimulated ERK activation (Hunzicker-Dunn, unpublished data) is not inhibited by the CaM kinase II inhibitor Kn62.[233] Thus, additional studies are required to clarify the role of Ca^{2+} and its regulated kinases in FSH actions.

PKA Signals to Activate the PI-3K Pathway in Immature Granulosa Cells

There is abundant evidence that FSH promotes the activation of PI-3K, leading to activation of AKT and downstream targets in granulosa cells that promote cell survival, translation, proliferation, and differentiation[113,115,218,234–236] (Figure 20.6). The PI-3K inhibitors wortmannin and/or LY294002 block FSH-stimulated induction of target gene products that characterize differentiated granulosa cells, including the LH receptor, MAP2D, VEGF, inhibin-α, and RIIβ.[235] In addition, constitutively active AKT enhances and dominant negative AKT blocks FSH-stimulated induction of the LH receptor, aromatase, inhibin-α, and/or 3β-HSD.[115,237] These data suggest that FSH-dependent activation of the PI-3K pathway is obligatory for the induction of critical genes that characterize the differentiated granulosa cell phenotype.

PI-3K. PI-3K consists of a 110-kDa catalytic subunit and an inhibitory 85-kDa regulatory subunit.[238] PI-3K is most commonly activated downstream of receptor tyrosine kinases such as the insulin receptor, IGF-1 receptor, and EGF receptor, which, upon ligand binding and

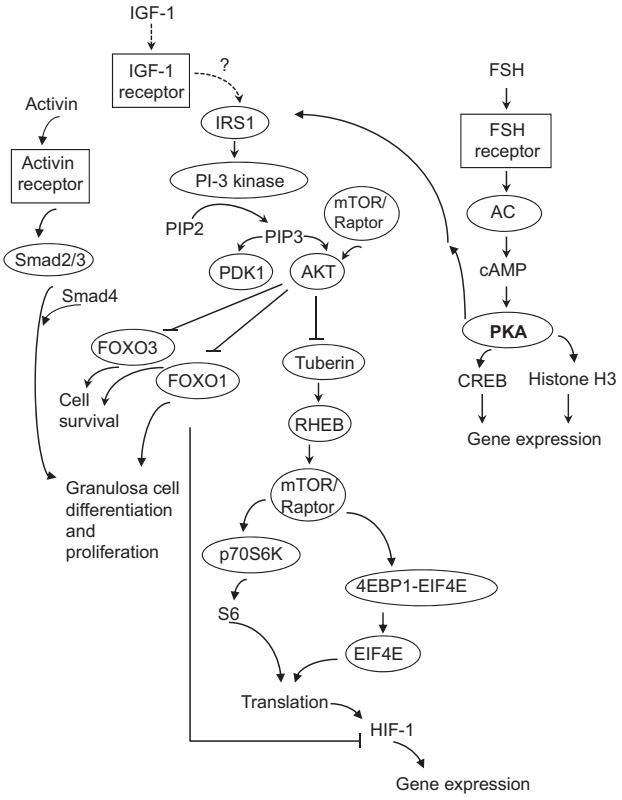

FIGURE 20.6 FSH via cAMP/PKA signals to activate PI-3K, leading to mTOR1-stimulated translation and inhibition of FOXO1 and FOXO3 targets. FSH and activin synergize to promote gene expression. Multiple arrows indicate more than one step in pathway. Potential contribution of IGF-1 and IGF-1 receptor is indicated by dashed lines.

dimerization, phosphorylate adaptor proteins (insulin receptor substrates 1/2 [IRS 1/2] or GAB 1/2) on specific Tyr residues. Activation of PI-3K catalytic subunit occurs on binding of both SH2 domains of the regulatory subunit to dual phosphorylated TyrXXMet (where X represents any amino acid, p-YXXM) motifs either on the adaptor protein IRS 1/2 or GAB 1/2.[238] While the catalytic subunit of PI-3K also contains a RAS binding domain, the contribution of active RAS to PI-3K activation under physiological conditions is not clear.[238] Activated PI-3K phosphorylates the 3′-OH position of the inositol ring of phosphatidylinositol 4,5-bis phosphate (PIP2), generating phosphatidylinositol 3,4,5-trisphosphate (PIP3). Increased concentrations of PIP3 at the plasma membrane create high affinity binding sites for PDK-1 and AKT through their pleckstrin homology domains, localizing both kinases in juxtaposition. PDK-1 then phosphorylates AKT on Thr308; AKT is subsequently phosphorylated on Ser473 by mTORC2 that consists of the mammalian target of rapamycin (mTOR)/Rictor complex, resulting in the full activation of AKT and its translocation to the nucleus and other cellular locations.[239] The mechanism by which GPCRs activate PI-3K is less-well understood and often involves direct activation of the 110-kDa catalytic subunit by Gβγ subunits.[238]

Consistent with the classic manner in which the PI-3K pathway is activated, in granulosa cells exogenous IGF-1 activates the PI-3K pathway via the IGF-1 receptor tyrosine kinase.[218,235,237,240] That IGF-1 is important for follicular function is evidenced by the fact that IGF-1-null mice are infertile; follicles of IGF-1-null mice do not progress beyond the preantral stage of development.[241] Although granulosa cells of preantral and antral follicles are the primary site of IGF-1 synthesis,[242] FSH does not promote IGF-1 expression by rat granulosa cells.[76,243] A recent report showed that granulosa cells express a basal level of IGF-1.[237] It is well established that FSH and IGF-1 strongly synergize to activate a number of FSH target genes, including those for *Cyp11a1*, *Cyp19a1*, and *Lhcgr*.[47,243–246] However, IGF-1 alone promotes only a minimal activation of these target genes,[47,243,247] indicating that additional FSH targets/responses are required to induce the full differentiation response.

The cellular mechanism by which FSH activates the PI-3K pathway in granulosa cells is beginning to be unraveled (Figure 20.6). FSH-stimulated AKT phosphorylation is detected within 5–10 min of FSH addition to rat granulosa cells.[116,235] Signaling by FSH to activate the PI-3K leading to the phosphorylation of AKT in granulosa cells is mimicked by cell-permeable cAMP analogs or the adenylyl cyclase activator forskolin[115,218,235] and is mediated by PKA.[116] PKA promotes the phosphorylation of IRS-1 on Tyr989, a canonical YXXM binding site for the regulatory subunit of PI-3K, resulting in phosphorylation of AKT on both Thr308 and Ser473.[116] These phosphorylations of IRS-1 and AKT are all abrogated by the specific PKA inhibitor PKI. The adaptor GAB2 appears to coordinate signaling of PKA to PI-3K, as depicted in Figure 20.7. GAB2 is present in granulosa cells in a preformed complex with IRS-1 and the PI-3K heterodimer. GAB2 is an RI-AKAP and a direct PKA target, and is rapidly phosphorylated on Ser159 in response to FSH. Overexpression of GAB2 enhances FSH-stimulated AKT phosphorylation.[116] However, there remain many unanswered questions, including the identity of the tyrosine kinase that phosphorylates IRS-1 on Tyr989, the mechanism by which PKA apparently activates this tyrosine kinase and/or inhibits a tyrosine phosphatase, and the mechanism by which GAB2 appears to coordinate this signaling cascade.

A recent report has shed new light on the contribution of IGF-1 to the FSH signaling pathway that leads to AKT phosphorylation. Granulosa cells, cultured in the presence of transferrin, selenium, insulin, amino acids, and a cholesterol source, express ~1 ng/ml IGF-1 under basal conditions.[237] FSH or dibutryl cAMP coupled with autocrine-generated IGF-1 signal via the IGF-1 receptor tyrosine kinase to activate AKT to induce *Cyp19a1*.[237] Addition of selective IGF-1 receptor antagonists or transduction of cells with lentivirus expressing short hairpin RNAs for IGF-1 or the IGF-1 receptor markedly reduced the ability of FSH to induce *Cyp19a1*. Also, AKT phosphorylation (Ser473) detected 1 h post FSH was abrogated by a selective IGF-1 receptor antagonist (NVP-AEW541[248]).[237] Together, these results suggest that in some manner FSH in combination with IGF-1

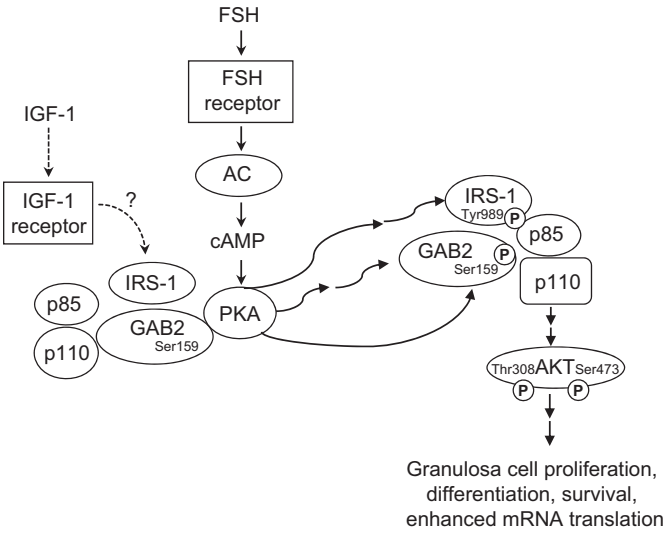

FIGURE 20.7 Mechanism by which FSH via PKA activates PI-3K leading to AKT activation. Multiple arrows indicate more than one step in the pathway. Potential contribution of IGF-1 and IGF-1 receptor is indicated by dashed lines.

activates the IGF-1 receptor to signal to AKT.[237] Additional studies are necessary to clarify the contributions of IGF-1 and the IGF-1 receptor to FSH signaling into the PI-3K pathway.

While the overexpression of constitutively active RAS (Gly12Asp) in immature granulosa cells elevates basal AKT phosphorylation,[216] transduction of granulosa cells with an adenovirus expressing a dominant negative RAS (Ser17Asn) does not prevent AKT phosphorylation on Ser473 or Thr308.[116] Taken together these results support the current view that RAS is not a major regulator of PI-3K activity under physiological conditions.[238]

AKT Substrates. General downstream targets of AKT in a variety of tissues can include the transcription factor CREB, the proapoptotic protein BAD, the phosphodiesterase PDE3β, nitric oxide synthase (NOS), the translation antagonist tuberin, GSK3β, the p53 E3 ubituitin ligase MDM2, the RAB-GTPase activating protein AS160 that regulates the cellular location of glucose transporter 4, select members of the FOXO transcription factor family, D-type cyclins, the cell cycle inhibitor $p27^{Kip1}$, the translation elongation factor E2F, and others[154,239] (Figure 20.8). Thus, AKT can signal to regulate transcription, translation, metabolism, cell survival, and differentiation, in a cell-specific and agonist-dependent manner.

CREB. In rat granulosa cells, FSH-stimulates CREB phosphorylation on Ser133. However, CREB phosphorylation is mediated by PKA in granulosa cells, as reviewed earlier, and not by AKT. This conclusion is based on the inability of the PI-3K inhibitor wortmannin[249] to reduce CREB phosphorylation[113] and the inability of CREB to be further phosphorylated in granulosa cells transduced with constitutively active AKT.[115]

Tuberin and Translational Regulation. FSH also stimulates the phosphorylation of tuberin, a product of the tuberous sclerosis (TSC) tumor suppressor gene[235] (Figure 20.6). In its unphosphorylated state, tuberin (TSC2) in a complex with TSC1 (Hamartin) is active and inhibits translation.[250] The tuberin–TSC1 complex functions as a GTPase-activating protein for the protein RAS homolog enriched in brain (RHEB).[251] This TSC complex stimulates the hydrolysis of the GTP bound to RHEB, converting RHEBGTP to RHEBGDP, resulting in the inactivation of RHEB. Phosphorylation of tuberin on Thr1462 by AKT results in an inhibition of the GTPase-activating protein activity of the TSC1–TSC2 complex.[251] As a result, RHEB is maintained in its active conformation. By a poorly understood mechanism, RHEBGTP promotes activation of mTORC1 (mTOR/Raptor complex). mTORC1 signals to at least two substrate proteins to stimulate translation, p70 S6 kinase, and a binding protein that sequesters the eukaryotic translation initiation factor eIF4E (eIF4E-BP1).[252–254] Phosphorylation of p70 S6 kinase on Thr389 leads to the phosphorylation of the ribosomal protein S6. Phosphorylation of S6, one of 30 ribosomal proteins that along with the 18S rRNA comprises the 40S ribosomal subunit complex, stimulates the translation of mRNAs containing a 5′-oligopyrimidine tract.[255] Phosphorylation of eIF4E-BP1 on Ser65 and other sites frees eIF4E[256,257] to bind to the 5′-methyl cap of mRNAs.[255,258] This stimulates cap-dependent translation and is the rate-limiting step in translation initiation.[258]

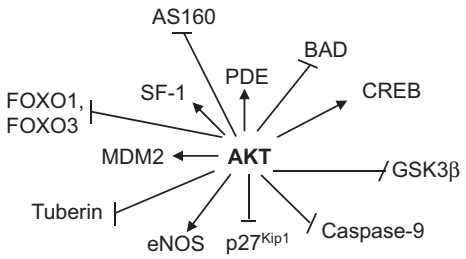

FIGURE 20.8 Summary of identified AKT substrates. Arrows indicate stimulation; perpendicular lines indicate inhibition.

FSH, via PI-3K/AKT, stimulates the phosphorylation of tuberin on Thr1462 within 10 min, leading to the activation of mTORC1 and phosphorylation of its substrates p70 S6 kinase and downstream S6 protein as well as 4E-BP1 in rat granulosa cells.[235] That mTORC1 activation is crucial for activation of a subset of FSH target genes is evidenced by the ability of the mTORC1 inhibitor rapamycin[252] to inhibit the induction of MAP2D and RIIβ protein expression as well as promoter-reporter activities for *Lhcgr*, *Vegf*, and *Inha*.[235] These results suggest that a very rapid effect of FSH in granulosa cells is to stimulate translation. Indeed, it has been suggested that activation of the PI-3K and ERK pathways in general preferentially promotes translation rather than transcription.[259] mTORC1-dependent targets of translation whose expression is increased in various cellular models include the cyclins, resulting in increased cell proliferation.[260,261] Certainly a future area of research should be the identification of FSH-targeted translation products via some of the newer proteomics approaches or via ribosome profiling.

There is also a report that FSH promotes the phosphorylation of tuberin via an ERK-dependent, AKT-independent pathway that leads to phosphorylation of p70 S6 kinase and increased cyclin D2 mRNA that is partially reduced by the mTORC1 inhibitor rapamycin, using granulosa cells seeded on serum-coated plates.[262] While the ERK target RSK has been reported to phosphorylate tuberin,[251] it is not clear how the mTORC1 pathway leads to enhanced cyclin D2 transcription.

It is quite interesting that IGF-1 also stimulates the phosphorylation of AKT, tuberin, p70 S6 kinase, and S6 protein in rat granulosa cells,[235] but as already indicated, IGF-1 does not stimulate expression of FSH target genes,[47,243] at least to levels observed with FSH. This

result suggests that additional pathways activated by FSH but not by IGF-1 are required for FSH target gene expression.

HIF-1α. One of the mRNAs whose translation is increased by FSH downstream of AKT and tuberin in granulosa cells is the transcription factor HIF-1α.[235] HIF-1 is a heterodimer, consisting of HIF-1α and HIF-1β, the latter also known as the aryl hydrocarbon receptor nuclear transporter. HIF-1 is a member of the basic helix-loop-helix/Per/aryl hydrocarbon receptor nuclear transporter/Sim family of transcription factors that bind to a modified E-box on DNA promoters.[263] HIF-1β is constitutively expressed; HIF-1α protein levels are regulated. HIF-1 is best known for its regulation of cellular responses to hypoxia.

Under normoxic conditions, HIF-1α is hydroxylated on two critical proline residues by oxygen-dependent prolyl hydroxylases, triggering HIF-1α degradation.[263,264] Hydroxylation of the Pro residues creates a binding site for the protein product of the von Hippel–Lindau tumor suppressor gene, VHL. VHL is an E3-ubiquitin ligase and promotes the polyubiquitination of proline hydroxylated forms of HIF-1α, leading to their degradation by the proteosomal system. Cobalt has been shown to inhibit the interaction of HIF-1α and VHL[265] and is often used experimentally to stabilize HIF-1α protein levels. HIF-1 activity is also regulated by a second oxygen-dependent mechanism. Under normoxic conditions, a protein called "factor inhibiting HIF-1" catalyzes the hydroxylation of an Asn residue in the C-terminal transactivation domain of HIF-1α, preventing the binding of its co-activator p300/CBP. Under hypoxic conditions, the activity of the oxygen-dependent prolyl hydroxylases is reduced, and HIF-1α protein is stabilized. The activity of the asparaginyl hydroxylase is also reduced under hypoxic conditions, thereby allowing the binding of p300/CBP to stimulate HIF-1 activity. The prolyl hydroxylases require iron as a cofactor, so agents that chelate iron such as desferrioxamine inhibit the propyl hydroxylases, thereby stabilizing HIF-1α protein levels.

HIF-1α protein can also be regulated at the level of translation upon activation of the PI-3K pathway by insulin or IGF-1.[266,267] In these studies, expression of HIF-1α protein correlated with activation of HIF-1 DNA binding activity and/or HIF-1-dependent reporter gene activities. Inhibitors that abrogate the ability of these growth factors to stimulate the phosphorylation of p70 S6 kinase and 4E-BP1 block the increase in HIF-1α protein.[266,267]

In rat granulosa cells, FSH promotes an increase in HIF-1α protein accumulation under normoxic conditions (Figure 20.6), which is detected in the presence either of a proteosomal inhibitor or $CoCl_2$.[235] FSH also promotes an increase in HIF-1 activity, detected using a minimal hypoxia response element linked to the luciferase reporter in rat granulosa cells. Moreover, co-expression of a HIF-1 dominant negative construct, lacking its DNA binding and transactivation domains,[268] reduces the ability of FSH to activate promoters for *Lhcgr*, *Vegf*, and *Inha*, as detected using promoter-reporter assays.[235] These results suggest that HIF-1 activity is required for FSH to activate *Lhcgr*, *Vegf*, and *Inha* genes. However, although each of these genes contains apparent HIF response elements and VEGF is an established HIF-1 target, only *Vegf* in granulosa cells has been shown to be a direct HIF-1 target.[247]

While there is some evidence that the granulosa cell environment may become increasingly hypoxic as the follicle grows,[269] hypoxia does not appear to be a prominent contributor to the ability of FSH to induce target genes such as *Lhcgr* (E. Donaubauer and M. Hunzicker-Dunn, unpublished).

IGF-1 also promotes an increase in the accumulation of HIF-1α protein in rat granulosa cells to levels equivalent to those achieved with FSH; however, interestingly IGF-1 does not enhance HIF-1 activity, based on a promoter-reporter assays.[247] This result shows that the mere presence of HIF-1α protein is not sufficient to generate an active HIF-1 transcriptional factor. Thus, additional unidentified signaling events independent of the PI-3K pathway that are activated by FSH are required to "activate" HIF-1.

Transcriptional activity of HIF-1α requires binding of CBP/p300 to the C-terminal transactivation domain.[264] The binding of CBP/p300 is negatively regulated in an oxygen-dependent manner by the hydroxylation of Asn803 by "factor inhibiting HIF-1".[264] HIF-1 transcriptional activity in a number of cellular models is also positively regulated by ERK, although whether ERK directly phosphorylates HIF-1α is controversial.[247] Moreover, activation of VEGF transcription in various cell models requires cooperation between HIF-1 and an AP-1 complex.[212] Thus, ERK could contribute to HIF-1 activity by phosphorylating HIF-1α protein, by phosphorylating CBP, or by phosphorylating members of the AP-1 family, as summed in Figure 20.5. In rat granulosa cells, *HIF-1* promoter-reporter activities and the interaction of HIF-1α with the *Vegf* promoter in a CHIP assay are inhibited by the MEK inhibitor PD98058, consistent with the potential contribution of ERK phosphorylation to HIF-1 transcriptional activity.[247] Moreover, IGF-1 in rat granulosa cells does not activate ERK phosphorylation, suggesting that the inability of IGF-1 to promote HIF-1 transcriptional activity is the result of the lack of ERK activation by IGF-1.[247] However, transient expression of a constitutively active MEK was not sufficient to rescue IGF-1-stimulated HIF-1 activity.[247] Based on our evidence that ERK activity in immature granulosa cells is restrained by a PTP whose activity is inhibited by FSH,[113] the potential contribution of ERK needs to be reevaluated in cells transduced with adenovirally expressed constitutively active ERK.

FOXO1 and FOXO3. A second AKT target in rat and porcine granulosa cells is FOXO1.[48,112,234,270,271] FOXO1 is a member of the forkhead O class of transcription factors that was originally identified by its disruption in the pediatric tumor rhabdomyosarcoma.[272] Three of the members of this family are AKT targets: FOXO1, FOXO3, and FOXO4.[273] FOXO-regulated genes control the cell cycle, cellular metabolism, and cell death. These transcription factors bind to DNA as monomers at the insulin response element consensus sequence TT(A/G)TT(T/G)(A/G)(T/C) on target genes. In the absence of signaling through the PI-3K pathway, these FOXO transcription factors are bound to DNA and are active. They can function as transcriptional activators to stimulate such target genes as the cell cycle inhibitor $p27^{Kip1}$, glucose-6-phosphatase activity,[274] and IGF binding protein-1, as well as transcriptional repressors to suppress such target genes as cyclin D1 and D2.[273] Upon phosphorylation by AKT, FOXO1, -04, and -03 exit the nucleus and are targeted for degradation. Three Ser/Thr residues on FOXO proteins are phosphorylated by AKT. For FOXO1, phosphorylation of Ser256 diminishes DNA binding and is necessary for the phosphorylation of Thr24 and Ser319.[275] Phosphorylation of Thr24 disrupts association of FOXO1 with CBP and stimulates binding to 14-3-3 proteins, and phosphorylation of Ser319 stimulates nuclear export.[273]

FOXO factors also bind nuclear receptors, including those for estrogen (preferentially ER-α over ER-β), progesterone, androgen, thyroid hormone, glucocorticoid, and retinoid acid, presumably via the conserved LeuXXLeuLeu domain located in the C-terminal region of the FOXO protein.[273] Although the actions of the FOXO factors can require binding to DNA, there is also evidence that they can affect transcription of target genes independent of their DNA binding activity, possibly via their association with co-activators such as CBP or with steroid receptors.[276] FOXO factors can also be acetylated, possibly by CBP, a modification that is thought to activate FOXO transcriptional activity, although the effect of acetylation is controversial (reviewed in Ref. 273).

There is accumulating evidence from a number of cellular models that FOXO factors promote cell cycle arrest.[273,277] Cell cycle arrest can occur as a result of increased expression of the cyclin-dependent kinase (CDK) inhibitors $p27^{Kip1}$, $p21^{Cip1}$, and p130, and/or by decreased expression of the CDK or their binding partners cyclin D or cyclin E. In general, progression from G_1 to the S phase of the cell cycle is mediated by increased expression of cyclin D, which partners with CDK 4/6, followed by increased expression of the CDK 2 partner cyclin E. Hyperphosphorylation of the retinoblastoma protein catalyzed by CDK 4/6 and CDK 2 relieves inhibition of the transcription factor E2F by retinoblastoma, allowing for the expression of genes necessary for DNA replication and S phase entry.

FOXO transcription factors have been reported to inhibit cell cycle progression by enhancing transcription of $p27^{Kip1}$ and other CDK inhibitors, by repressing cyclin D transcription, and/or by increasing transcription of the unconventional cyclin G2, which inhibits the cell cycle.[278] Porcine granulosa cells undergo proliferation upon stimulation with FSH and insulin.[270] Transduction of porcine granulosa cells with a dominant negative FOXO1 truncation mutant, which lacks its transactivation domain, increases entry of these cells into the S phase of the cell cycle by redirecting the compartmentalization of $p27^{Kip1}$ from the nucleus to the cytosol and decreasing $p27^{Kip1}$ content.[270] Although $p27^{Kip1}$ is known to be phosphorylated on Thr157 by AKT, resulting in its redistribution from the nucleus to the cytosol,[279–283] the mechanism by which FOXO1 directs relocation of $p27^{Kip1}$ to the cytosol followed by its apparent degradation is not known.

It is not known if FSH promotes a redistribution of $p27^{Kip1}$ to the cytosolic fraction in rat granulosa cells upon FOXO1 phosphorylation as occurs in porcine granulosa cells.[270] However, $p27^{Kip1}$ does not show any evidence of downregulation, and interestingly, the phosphorylatable Thr157 residue believed to be responsible for exit of $p27^{Kip1}$ from the nucleus is not conserved in rodents.[279,280]

In contrast to porcine granulosa cells, proliferation of rat granulosa cells and the obligatory induction of cyclin D2[45] and the S-phase marker proliferating cell nuclear antigen, under primary serum-free culture conditions, does not occur in the presence of FSH alone or FSH plus IGF-1.[44,47,49] However, as shown in Figure 20.6, in the presence of activin, cyclin D2 mRNA expression is strongly enhanced by FSH under serum-free culture conditions.[46,227,276] These results suggest that FSH, directly or indirectly, stimulates the expression of activin or a similar TGFβ-family ligand and that both of these ligands converge to stimulate cyclin D2 expression and consequent granulosa cell proliferation. Rat granulosa cells are reported to produce activin subunits throughout early follicular development.[284] However, activin levels produced under culture conditions are apparently too low to synergize with FSH, possibly due to contributions from the activin inhibitor follistatin and/or to utilization of activin subunits by inhibin-α, as these cells also produce follistatin and inhibin.[285]

FOXO1 functions to repress activation not only of the *Ccnd2* (cyclin D2) gene but also to repress activation of a subset of FSH targets that characterize the preovulatory phenotype, including *Nr5A1* (SF-1), *Nr5A2* (LRH-1), *Cyp19a1* and *Cyp11a1*, *Inha,* and *Ereg* (epiregulin).[48] The list of genes repressed by FOXO1 in immature granulosa cells has been expanded to include genes required for cholesterol biosynthesis and steroidogenesis as well as *Lhcgr*.[271] Phosphorylation of FOXO1 by AKT is necessary but likely not sufficient to achieve the induction of

these FSH target genes, as evidenced by the established regulation of *Inha*[170,186] and *Cyp19a1*[152,286] promoters, for example, by a number of transcriptional activators. The ability of FOXO1 to repress activation of these FSH target genes is based on studies in which granulosa cells were transduced with an adenoviral vector encoding a constitutively active FOXO1 mutant in which the three AKT phosphorylation sites were mutated to Ala (A3-FOXO1). Direct binding of FOXO1 to the cyclin D2 promoter was evidenced by CHIP assays, this association was abrogated upon stimulation of cells with FSH, and the association was enhanced and not regulated in cells transduced with the constitutively active A3-FOXO1 mutant.[48] However, it is not known if other FSH target genes regulated by inactivation of FOXO1 are repressed directly or indirectly by FOXO1.

FOXO1 also represses the ability of FSH to promote the accumulation of HIF-1α, as evidenced in cells transduced with A3-FOXO1 compared to empty adenovirus, and thus activation of HIF-1 transcriptional activity[247] (Figure 20.6). While the FOXO1 target is likely a ubiquitin ligase, this ligase has not been identified. The ability of FOXO1 to repress the accumulation of HIF-1α in the absence of FSH may be a mechanism to prevent inappropriate actions of HIF-1 in granulosa cells.

The induction of *Ccnd2*, *Nr5a1*, *Inha*, *Cyp11a1*, *Cyp19a1*, and *Ereg* was also abrogated in granulosa cells transduced with a dominant negative Smad2/3 mutant.[48] These results suggest that induction of these proliferation and differentiation responses requires not only relief from repression by FOXO1 but also the contribution of the Smad2/3 transcription factors (Figure 20.6). However, the mechanism by which Smad2/3 cooperates with the AKT pathway leading to FOXO1 phosphorylation to promote expression of at least a subset of FSH target genes has not been elucidated. It is interesting that active (unphosphorylated) FOXO1 can complex with phospho-Smad to promote expression of the cell cycle inhibitor $p21^{Cip1}$ in neuroepithelial and glioblastoma cell lines.[287] In granulosa cells, however, phospho-Smad2/3 functions upon inactivation of FOXO1 to drive proliferation. Thus, the cross talk between these two pathways is cell specific.

A similar repressive function in follicular maturation has been attributed to FOXO3, but at a much earlier stage of follicular development. Unlike FOXO1-null mice, which die at embryonic day 10.5,[288] FOXO3-null mice show global activation of primordial follicles, resulting in oocyte death and depletion of follicles as a result of increased granulosa cell mitotic activity.[289] These results suggest that FOXO3, most likely in oocytes, functions to suppress maturation of primordial follicles.

FOXO3 has also recently been shown to promote expression of the pro-apoptotic protein Bcl-2-interacting mediator of cell death/Bcl-2-related ovarian death agonist (BIM/BOD) in porcine granulosa cells.[290] CHIP assays place FOXO3 on the *Bim(Bcl2l11)* promoter in the absence of FSH.[290] FSH via the PI-3K/AKT pathway stimulated the phosphorylation of FOXO3 on Ser253, resulting in its inactivation and exit from the nucleus. Consistent with the positive effect of FOXO3 on BIM/BOD expression in the absence of FSH, FSH reduced expression of BIM/BOD.[290] These results suggest that FOXO3 is a transcriptional activator of *Bim*, and that FSH reduces the expression of the pro-apoptotic protein product to promote granulosa cell survival.

Owing to the embryonic lethality and premature ovarian failure of global FOXO1[288] and FOXO3[289] knockouts, respectively, FOXO1 and FOXO3 were recently selectively deleted from granulosa cells.[291] While targeted deletion of FOXO1 resulted in a subfertile mouse (some mural granulosa cells retained FOXO1 expression), targeted deletion of FOXO3 did not reduce fertility. However, dual targeted deletion of FOXO1 and FOXO3 generated an infertile mouse in which follicle growth was arrested at the preantral/early antral stage of follicle development.[291] Deletion of FOXO1/FOXO3 would be expected to reduce expression of those genes that are positively regulated by FOXO1/FOXO3. However, enhanced expression of genes that are repressed by FOXO1/FOXO3 might not occur due to the absence of positive transcriptional regulators. These double mutant mice exhibit severely reduced serum FSH levels[291] and thus would not be expected to express genes repressed by FOXO1/FOXO3. Granulosa cells of the double mutant mouse exhibited reduced apoptosis, associated with reduced expression of the FOXO3 target[290] *Bcl2l11* (that encodes for BIM/BOD) and *Bmp2* that encodes bone morphogenic protein 2 (BMP2), a protein selectively expressed in follicles undergoing apoptosis.[291] Granulosa cells of these double mutant mice also exhibited reduced expression of a number of apparent FOXO1/FOXO3 targets, including *Igf1* (insulin-like growth factor 1), *Ctgf* (conective tissue growth factor), *Amh* (anti-Mullerian hormone), and *Nr0b1* (nuclear receptor subfamily 0, group B, member 1; Dax1),[291] the expression of which likely contributes to the immature granulosa cell phenotype (in the absence of FSH). Studies with isolated granulosa cells showed that the positive effects of (active) FOXO1/FOXO3 on the expression of these genes was enhanced by activin, consistent with the interaction of FOXO1/FOXO3 with pathways downstream of activin.[291] It is interesting that activin signaling pathways appear to converge both with the positive effects of FOXO1/FOXO3 on target genes that maintain granulosa cells in an immature state (in the absence of FSH)[291] and with FSH signaling pathways that promote inactivation of FOXO1/FOXO3 to drive granulosa cell maturation.[48]

GSK3β and the WNT signaling pathway. An additional AKT target in many cells is the Ser/Thr protein kinase GSK3β (Figure 20.8). GSK3β is active when the PI-3K pathway is silent. Active AKT phosphorylates GSK3β on Ser9, resulting in the inactivation of GSK3β.[292] One of the GSK3β targets in a number of cellular models is the D-type cyclins. In the absence of signaling through the PI-3 kinase pathway, GSK3β phosphorylates the D-type cyclins, leading to their ubiquitination and degradation.[293] Activation of the PI-3K pathway promotes AKT-catalyzed phosphorylation of GSK3β, thereby rescuing D-type cyclins from degradation. Although there is evidence that FSH promotes the phosphorylation of GSK3β in rat granulosa cells,[218] it is not known if the stability of cyclin D2 in granulosa cells is also regulated by GSK3β. However, based on evidence that FSH stimulates only a modest two- to three-fold increase in cyclin D2 promoter-reporter activity in transiently transfected granulosa cells compared with the robust increase in cyclin D2 protein expression,[48] it is likely that FSH also stabilizes cyclin D2, possibly via inactivation of GSK3β.

GSK3β can also be phosphorylated on Ser9 by a number of other Ser/Thr kinases, including PKA, PKC, and the ERK substrate RSK, to reduce its activity.[294,295] Although FSH activates PKA, AKT, and RSK in granulosa cells,[113,115,117,118,218,234,235] FSH-stimulated GSK3β phosphorylation is strongly inhibited by PI-3 kinase inhibitors,[218] suggesting that GSK3β is predominately an AKT substrate in granulosa cells.

In addition to regulating the stability of the D-type cyclins, GSK3β is recognized to phosphorylate a number of transcriptional activators, including β-catenin, CREB, HIF-1, NF-κB, and AP-1, as well as structural proteins and metabolic and signaling proteins such as MAP2, kinesin light chains, glycogen synthase, eIF2B, PKA RIIβ subunit, and protein phosphatase 1.[294,295] Thus, GSK3β potentially regulates glucose production, translation, transcription, cell survival, and cell motility. Generally, GSK3β substrates are initially phosphorylated by another protein kinase, priming the substrate for phosphorylation by GSK3β.

The phosphorylation activity of GSK3β is also regulated by its association with a specific protein complex that includes its substrate, β-catenin, the obligatory priming kinase, and other proteins. This pathway is regulated by the paracrine/autocrine factor WNT.[296] In the absence of the WNT ligand, GSK3β is complexed with a scaffold protein (AXIN), casein kinase 1α, adenomatous polyposis coli (APC), and β-catenin, as depicted in Figure 20.9. In this complex, β-catenin is targeted for ubiquitination and proteosomal degradation as a result of a priming phosphorylation by casein kinase 1α on Ser45 followed by phosphorylation by GSK3β on Thr41, Ser37, and Ser33.[296] WNT signaling through the plasma membrane Frizzled receptor/lipoprotein receptor-related proteins 5 and 6

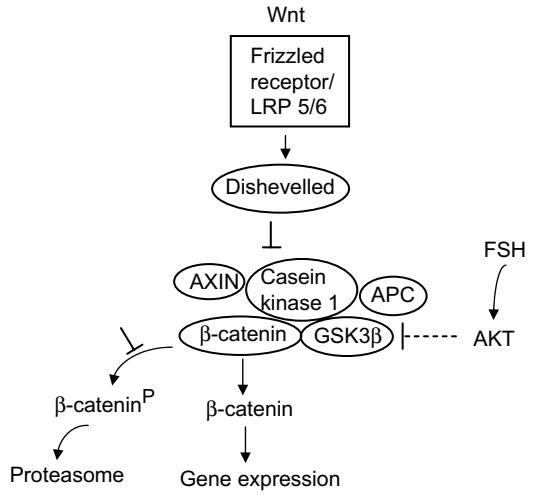

FIGURE 20.9 Schematic diagram of the rescue of hypophosphorylated β-catenin from proteosomal degradation by WNT signaling. A potential route for FSH to inhibit phosphorylation of β-catenin via AKT is depicted.

together with the scaffolding protein Dishevelled inhibits GSK3β activity by a poorly understood mechanism. As a result, β-catenin is not phosphorylated and escapes from degradation. Nonphosphorylated β-catenin translocates to the nucleus where it functions as a transcriptional co-activator. While β-catenin is best known for its ability to bind TCF/lymphoid enhancer factor (LEF) and to activate TCF/LEF–regulated genes,[297] β-catenin is also required for the transcriptional activation of SF-1.[175,176]

Immature granulosa cells express Wnt2, Wnt4, Frizzled1, Frizzled4, and Dishevelled2 mRNAs.[298,299] Conditional deletion of Wnt4 from granulosa cells using *Amhr2-Cre* reduced the number of antral follicles ~ 50%,[300] suggesting that Wnt4 contributes to follicular maturation. However, to our knowledge, there is no evidence that FSH enhances expression of Wnt4 to activate the canonical β-catenin pathway in granulosa cells. The Richards' laboratory used an alternative approach to evaluate the contribution of β-catenin to FSH-signaling pathways. Conditional expression of a dominant stable β-catenin in granulosa cells of small antral follicles (driven by *Amhr2-Cre*), in which exon 3 that contains the N-terminal phosphorylation sites required for degradation was excised, generated the formation of either abnormal follicles that lacked oocytes and were highly vascularized or cystic structures as well as some normal follicles, resulting in subfertile mice.[301] A microarray analysis of ovaries expressing this dominant stable β-catenin compared to control ovaries revealed abnormal overexpression of Wnt/β-catenin signaling antagonists such as AXIN as well as bone and neuronal cell markers.[302] Conditional expression of the dominant stable β-catenin in granulosa cells of follicles at a slightly later stage of maturation, driven by the *Cyp19-Cre*,

showed that β-catenin inhibits apoptosis and facilitates FSH-stimulated follicular growth by enhancing expression of *Fshr*, *Cyp19a1*, *Ccnd2*, and *Nr5a1* without affecting *Lhcgr* expression.[303] The ability of β-catenin to regulate expression of *Cyp19a1* agrees with previous reports in granulosa cells that β-catenin is required for transcriptional activation of SF-1 on the *Cyp19a1* promoter.[286,304] Fan et al.[303] showed that FSH activated the artificial TCF/β-catenin promoter-reporter TOPFlash, and that FSH enhanced the nuclear accumulation of nonphosphorylated β-catenin. The authors postulate that the mechanism by which FSH enhances nuclear accumulation of nonphosphorylated β-catenin may be via AKT-dependent phosphorylation/inactivation of GSK3β,[303] as shown in Figure 20.9. An alternate pathway by which FSH regulates β-catenin activity is discussed later in "Cross Talk among FSH-Regulated Signaling Pathways and Transcriptional Activators to Regulate Gene Expression." In contrast to enhancing FSH responses, persistent expression of the dominant stable β-catenin repressed LH-induced oocyte maturation, ovulation, and luteinization by inhibiting expression of LH target genes and thus compromised fertility.[303] The negative effect of the dominant stable β-catenin was at least in part due to reduced phosphorylation of CREB, MEK, and ERK in response to hCG, although it is not clear how dominant stable β-catenin interferes with CREB and MEK/ERK phosphorylations.

SGK. FSH and forskolin also induce the immediate early gene SGK[118,122,218] and stimulate its apparent phosphorylation, based on an upward shift in mobility on sodium dodecyl phosphate polyacrylamide gel electrophoresis.[199] SGK bears similarities to AKT, as it is activated in a PI-3K-dependent manner by PDK-1[305] and phosphorylates many of the same substrates phosphorylated by AKT, including members of the FOXO family.[306] However, recent evidence suggests that the primary function of this kinase is to regulate the abundance of Na^+, K^+, and Cl^- ion channels by preventing their proteosomal degradation[307,308] by phosphorylating and inactivating a ubiquitin ligase.[309] SGK is induced in granulosa cells in a PKA-dependent manner, and its induction is prevented by the PKA inhibitor H89.[106] SGK is not induced in granulosa cells by IGF-1.[199] In contrast to the signaling pathway that regulates the FSH-stimulated induction of SGK in granulosa cells, FSH-stimulated phosphorylation of SGK in granulosa cells is abolished by PI-3K inhibitors wortmannin and LY294002, consistent with FSH signaling to stimulate phosphorylation/activation of SGK via the PI-3K pathway.[199] However, neither the substrates nor the function of SGK in granulosa cells is known.

Apoptosis-related PI-3K Substrates. The PI-3K pathway is also known to regulate cell survival. Indeed, addition of the PI-3K inhibitor LY294002 to rat granulosa cells induces apoptosis.[310] Up to 99% of the ovarian follicles undergo apoptosis primarily at the early antral stage of development (in rats).[311] Follicles survive and proceed to final stages of maturation only if they are rescued from apoptosis, predominately by FSH. It is not surprising that apoptosis is a highly regulated event in the ovary and that a number of proteins in the apoptotic pathway have been identified as being highly expressed in ovarian cells.[290,311]

There are two major pathways that lead to apoptosis: one directed by the death receptors of the tumor necrosis family (TNF) and one directed by the release of cytochrome c (and other proteins) from mitochondria as a result of various cellular stresses such as heat shock, oxidative stress, and DNA damage.[312] In both of these pathways, cysteine aspartic acid-specific proteases (caspases) become activated and cleave proteins that are crucial to cellular function, resulting in programmed cell death. Initiator caspases are activated in response to a proapoptotic signal, and they in turn activate effector caspases that catalyze substrate proteolysis, leading to cell death.

FSH appears to inhibit apoptosis primarily by controlling the release of cytochrome c from mitochondria, as depicted in Figure 20.10. The proteins that regulate this pathway are members of the BCL-2 (B-cell leukemia/lymphoma 2) family and share one or more BCL-2 homology (BH) domains.[313,314] Group I, the anti-apoptotic proteins that contain four BH (BH 1–4) domains, includes BCL-2, BCL-XL (extra large), MCL-1(myeloid cell lymphoma-1), and DIVA. They prevent apoptosis by binding to and blocking the activity of the Group II pro-apoptotic BH123 domain proteins BAX, BAK318 and possibly BOX (BCL-2–related ovarian killer).[315] BAX and BAK, upon activation, oligomerize at the outer mitochondrial membrane and create pores for the exit of cytochrome c. Group III BH3 domain-only proteins stimulate apoptosis upon receipt of an apoptotic stimulus most likely by inhibiting the interaction of Group I anti-apoptotic proteins with Group II pro-apoptotic proteins[314] and include BAD (BCL-XL/BCL-2–associated death promoter), BID, PUMA, BIM (aka BOD, BCL-2-related ovarian death agonist), and NOXA. These proteins are restrained in the absence of an apoptotic signal at the transcriptional (BIM, PUMA, NOXA), posttranslational (BAD), or precursor (BID) levels.[313] They bind with selectivity and high affinity to Group I anti-apoptotic proteins, effectively freeing Group II pro-apoptotic (BH123) proteins to oligomerize and stimulate cytochrome c release.[314]

Upon release of cytochrome c from the mitochondria, cytochrome c complexes with APAF-1 (apoptotic protease activating factor-1), resulting in the oligomerization of APAF-1 and recruitment of procaspase-9.[312] Caspase-9 becomes activated as a result of an autocatalytic event, forming the active apoptosome, leading to the activation of effector caspases-3 and -7, which promote the

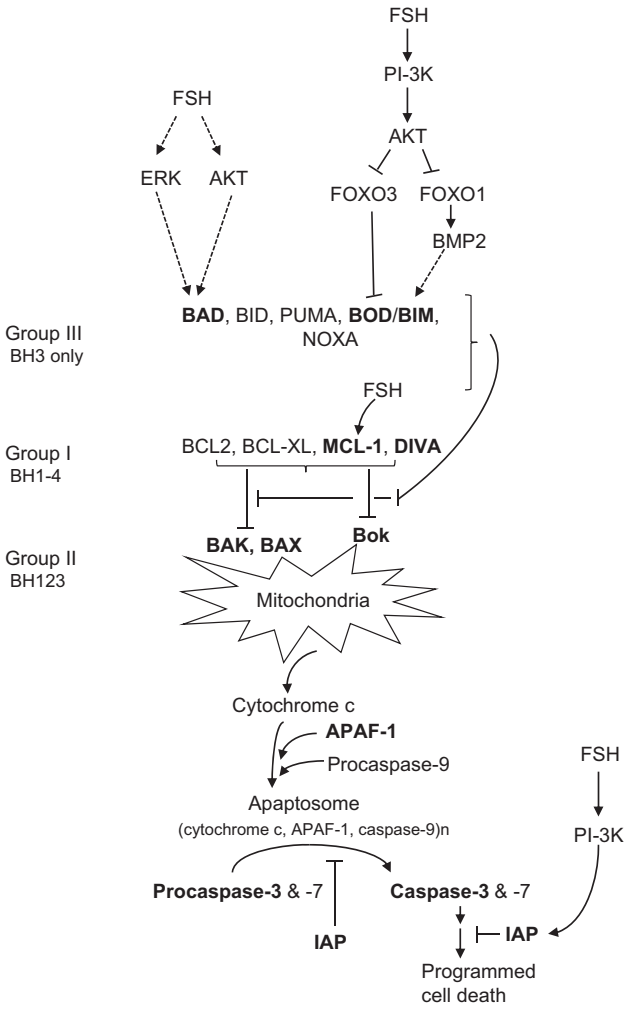

FIGURE 20.10 Schematic diagram of the mitochondrial-dependent apoptotic pathway in ovarian cells and sites at which FSH has been reported to inhibit (perpendicular lines) or stimulate (arrows). Bold names represent proteins identified in granulosa cells. Dashed lines represent expected but not demonstrated regulation.

proteolysis of a large number of proteins crucial to cell survival and consequent cell death.[312] PI-3K–stimulated AKT has been reported to phosphorylate and inactivate caspase-9[316]; however, the AKT phosphorylation site found in human caspase-9 is not conserved in rat, mouse, or monkey caspase-9.[317] Thus, regulation of caspase-9 phosphorylation/activity at least by AKT does not appear to be a widespread mechanism by which PI-3K signaling promotes cell survival. Although IGF-1 has been shown in porcine granulosa cells to inhibit apoptosis,[240] a definitive role for IGF-1 in rat granulosa cell apoptosis, to our knowledge, has not been reported.

The fate of a cell is determined by the balance between survival and apoptotic signals. Transgenic mice overexpressing the Group I anti-apoptotic protein BCL-2 in the ovary show decreased follicular apoptosis and increased folliculogenesis; however, BCL-2 does not appear to be expressed in the ovary.[318] Rather, ovaries appear to express predominately MCL-1, and expression of MCL-1 is increased by treatment of rats with the FSH receptor agonist pregnant mare's serum gonadotropin (PMSG).[319] While increased expression of MCL-1 likely contributes to the ability of FSH to promote cell survival, the mechanism by which FSH increases MCL-1 expression was not explored. Yeast two-hybrid analysis showed that MCL-1 interacted with BAK, BAX, and BOK (Group II BH123 pro-apoptotic proteins) to inhibit apoptosis, and with BAD and BIM (Group III BH3-only pro-apoptotic proteins) to promote apoptosis, consistent with the current view of the mechanism by which Group III proteins promote apoptosis. Ovaries also express high levels of the Group I anti-apoptotic protein DIVA.[298]

Yeast two-hybrid studies with an ovarian cDNA library showed that a mutant, nonphosphorylated BAD (Group III BH3-only protein) interacts with MCL-1, thereby diminishing the anti-apoptotic effect of MCL-1.[319] The phosphorylation of BAD prevents its interaction with MCL-1, thereby allowing MCL-1 to inhibit apoptosis, and promotes its binding to 14-3-3 proteins. BAD is phosphorylated on Ser136 by AKT, and on Ser112 and Ser155 by PKA or RSK in a cell-specific manner.[320] Phosphorylation of Ser155 is thought to be rate limiting and to require priming phosphorylations at Ser112 and Ser136.[320] Based on the ability of FSH to activate PKA, AKT, and RSK, it is likely that BAD phosphorylation contributes to the ability of FSH to promote granulosa cell survival. However, FSH-stimulated BAD phosphorylation has not been formally demonstrated in granulosa cells.

FSH has recently been shown to promote granulosa cell survival by inhibiting the transcription of *Bcl2l11* that encodes BIM/BOD, a BH3-only Group III pro-apoptotic protein.[290] In the absence of FSH, FOXO3 is a transcriptional activator *Bcl2l11*.[290] The effect of FOXO3 appears to be facilitated by FOXO1 activation of *Bmp2* expression; BMP2 also enhances expression of *Bcl2l11* to promote apoptosis.[291] FSH via the PI-3K/AKT pathway stimulates the phosphorylation of FOXO3 on Ser253, resulting in its inactivation and exit from the nucleus.[290] AKT-stimulated FOXO1 phosphorylation in response to FSH is also expected to reduce expression of BMP2 and consequently of *Bcl2l11*, although this has not been demonstrated. Together, these results show that in the absence of FSH, FOXO3 and FOXO1 via BMP2 are activators of *Bcl2l11* expression. FSH reduces the expression of BIM/BOD in a PI-3K/AKT–dependent manner by regulating the activity of FOXO3 and likely of FOXO1 (Figure 20.10). Thus, in the absence of FSH, FOXO1 and FOXO3 contribute to granulosa cell apoptosis.

Granulosa cells express APAF-1 and, in the absence of gonadotropin support, exhibit increased activation of caspase-3.[321] There is also evidence that gonadotropins decrease APAF-1 expression[294] (Figure 20.10), a response expected to be anti-apoptotic. Although granulosa cells

of caspase-3-null mice show attenuated apoptosis, these cells do undergo apoptosis, suggesting that other effector caspases can compensate for caspase-3.[322]

Additional regulation of the apoptotic pathway occurs via a family of inhibitors of apoptosis (IAPs) that act as substrate inhibitors of caspases and block the activation of both effector caspases and, at higher concentrations, initiator caspases.[297] Of these IAPs, the X-linked IAP (XIAP) is reported to be the most potent.[297] FSH has been shown to increase expression of XIAP in rat granulosa cells[236,310] (Figure 20.10). Based on evidence that the addition of XIAP antisense oligonucleotides to granulosa cells enhances apoptosis,[310] it is likely that the FSH-dependent regulation of XIAP expression contributes to the anti-apoptotic effect of FSH.[323] There is also a report that AKT interacts with and phosphorylates XIAP, protecting it from ubiquitin-directed degradation.[324] These results suggest that the regulation of XIAP is crucial to the ability of FSH to rescue granulosa cells from programmed cell death and that FSH potentially regulates XIAP at multiple levels. However, FSH-stimulated XIAP phosphorylation via AKT has not been demonstrated in granulosa cells. A second group of regulators of the apoptotic pathway function as inhibitors primarily of the initiator caspases. One of the members of this group of proteins is FLICE inhibitory protein, or FLIP.[297] Although FSH has not been shown to regulate the expression of FLIP in granulosa cells, the prosurvival effects of TNF-α in rat granulosa cells are accompanied by increased expression of both XIAP and FLIP.[325,326]

NF-κB. The PI-3K pathway can also signal to regulate cell survival by promoting the nuclear translocation of the ubiquitous transcription factor NF-κB. Seven proteins comprise the NF-κB family: p105 and its proteolytic product p50, p100 and its proteolytic product p52, RELA (p65), RELB, and c-REL.[327] These transcription factors function as heterodimers and bind to κB response elements on target genes. More than 200 genes have been reported to be regulated by NF-κB.[328] The prototypical NF-κB transcription factor complex consists of p50 and RELA.[327] p50/RELA exists in the cytosol as a latent transcription factor complexed to an IκB inhibitor, as shown schematically in Figure 20.11. The family of IκB inhibitors include IκB-α, the prototypical IκB inhibitor, as well as IκB-β, γ, and ε.[327] In response to growth factor or cytokine stimulation, the IκB kinase (IKK2; which exists in the cytosol in a complex with IKK1 and the scaffold protein NEMO) is activated and phosphorylates the IκB inhibitor, targeting IκB for ubiquinitation and proteosome-mediated degradation.[327] With the dissociation of IκB, the nuclear localization signal of RELA becomes exposed and p50/RELA translocates into the nucleus. Transcriptional activation of this complex, however, additionally requires the phosphorylation of RELA in a cell-specific manner.[327] RelA kinases include

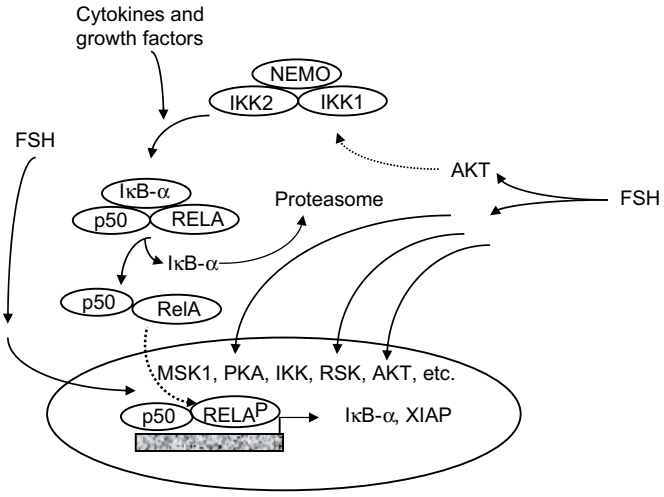

FIGURE 20.11 Schematic diagram of the pathway leading to NF-κB-dependent activation of target genes. Potential sites of FSH stimulation of this pathway are indicated. Dashed lines represent expected but not demonstrated regulation.

PKA, MSK1, RSK, AKT, PKCζ, casein kinase 2, IKK, and NF-κB-activating kinase.[327,329] Phosphorylation of RELA generally increases the binding of co-activators, like CBP, and/or DNA binding activity.[313]

FSH has been shown to promote the translocation of RELA from the cytoplasm to the nucleus of rat granulosa cells (as shown in Figure 20.11) and to increase NF-κB–DNA binding activity, detected by formation of a protein–DNA complex using the consensus κB binding site and granulosa cell nuclear extracts in mobility shift assays.[236] Additionally, the DNA–protein complex could be supershifted by antibodies to p50 and RELA, consistent with the presence of these proteins in the protein–DNA complex.[236] Inhibition of the nuclear translocation of p50/RELA with SN50, a drug that binds to and blocks the nuclear localization signal of NF-κB, inhibited the ability of FSH to induce the anti-apoptotic protein XIAP and suppressed NF-κB–DNA binding activity.[236] These results suggest that the caspase inhibitor XIAP may be an NF-κB target in granulosa cells (Figure 20.11). Pretreatment of granulosa cells with the PI-3K inhibitors LY292004 or wortmannin inhibited FSH-stimulated activation of p50/RELA DNA-binding activity as well as XIAP expression, suggesting a role for PI-3K in this pathway.[236] However, these authors did not determine whether the PI-3K inhibitors blocked translocation of NF-κB or affected its transactivation activity. Because AKT has been reported to enhance IKK activity[292] to phosphorylate IκB and to promote transactivation of RELA,[315] either/or both sites of action of PI-3K is possible. However, these authors did not detect the phosphorylation of IκB-α or its degradation during the first 30 min after treatment with FSH, in contrast to results with TNF-α-treated granulosa cells.[236] Moreover, modest (2.5-fold) overexpression of a dominant

negative IκB-α (which had its IKK phosphorylation sites mutated from Ser to Ala) did not inhibit the ability of FSH to increase p50/RELA DNA-binding activity or XIAP expression but did inhibit the ability of TNF-α to increase p50/RELA DNA-binding activity.[236] One interpretation of these results is that FSH regulates the nuclear translocation of p50/RELA by an alternative pathway independent of IκB phosphorylation. Because the transactivation of RELA can also be enhanced by PKA,[313] it is tempting to speculate that FSH-stimulated PKA also participates in RELA transcriptional activation (see Figure 20.11). Additional studies are thus required to clarify the mechanism by which FSH enhances NF-κB activity and to identify additional NF-κB target genes in granulosa cells.

NOS. An additional AKT substrate is endothelial nitric oxide synthase (eNOS; *Nos3*). NOS catalyzes the oxidation of L-arginine to nitric oxide (NO) and L-citrulline. NO regulates a number of biological functions including apoptosis, cell migration, and angiogenesis.[330] Phosphorylation of eNOS on Ser1177 by AKT results in its activation.[331] A major target of NO is the soluble guanylyl cyclase, the activation of which results in the production of cGMP.

Ovarian cells have been shown to express both eNOS (*Nos3*) and inducible NOS (iNOS; *Nos2*) in both a gonadotropin-dependent and -independent manner. Both eNOS and iNOS appear to be expressed in theca and stroma of immature rat follicles in the absence of gonadotropin stimulation[332]; eNOS, but not iNOS, is also expressed on the surface of oocytes.[332] The injection of PMSG to immature rats or addition of FSH to porcine granulosa cells induces the expression of eNOS, but not iNOS, in mural granulosa cells (~2.5-fold).[332] hCG injection to immature rats further increases eNOS expression 5–7 fold.[332] While iNOS-null mice do not exhibit a striking reproductive phenotype,[333] eNOS-null mice exhibit reduced rates of ovulation and oocyte maturation (>50%), and a five-fold increase in estrogen at a time when estrogen is 50% lower than proestrus peak levels in wild-type mice.[333,334] eNOS expression in response to both PMSG and hCG is regulated, in part, by nuclear orphan receptor LRH-1 (*Nr5a2*).[335] Conditional deletion of *Nr5a2* from granulosa cells, driven by *Amhr2-Cre*, results in reduced *Nos3* expression at 40 h post PMSG and 4 h post hCG, and CHIP assays place *Nr5a2* on the *Nos3* promoter 40 h post PMSG.[335] Conditional deletion of *Nr5a2* from granulosa cells also prevents the fall in estrogen that normally precedes ovulation, as discussed below in "Luteinization," consistent with the notion that LHR-1–regulated *Nos3* expression contributes to the LH/hCG-induced down-regulation of *Cyp19a1*. These results suggest that eNOS is most likely activated in response to the preovulatory surge of LH.

The signaling pathways that regulate eNOS activation to generate NO have not been studied in granulosa cells, although regulation by the PI-3K pathway downstream, at least of LH/hCG, is likely, based on evidence that the phosphorylation of eNOS on Ser1177 by AKT is activating.[331] FSH has been shown to produce only a minimal increase in cGMP levels,[336] and direct activation of soluble guanylyl cyclase in rat granulosa cells results in reduced FSH-stimulated cAMP production, estrogen, and inhibin-α synthesis.[336,337] These latter results suggest that it is unlikely that FSH signals to activate guanylyl cyclase activity in mural granulosa cells. However, FSH-dependent NO signaling to regulate pathways other than guanylyl cyclase cannot be excluded.

Testosterone Synergizes with FSH

It is common for investigators to include either testosterone or estrogen in primary granulosa cell cultures, based on evidence that they enhance FSH actions.[19] However, the mechanisms by which either estrogen or testosterone contributes to FSH-stimulated responses are undefined. A recent study showed that conditional deletion of the androgen receptor from preantral follicles, using *Amhr2-Cre*, resulted in subfertile mice that ovulated ~75% fewer oocytes, with ovaries that contained fewer preovulatory follicles and corpora lutea, and increased preantral and atretic follicles.[338] Follicles grew more slowly and appeared to be halted at the preantral stage of follicle development, consistent with the notion that the androgen receptor in conjunction with FSH is required for follicular maturation to the preovulatory state. In agreement with these results, addition of 1 μM testosterone to primary granulosa cells for 96 h promotes a striking (>15-fold) increase in *Cyp19a1* mRNA expression that is mediated, in part, by increased expression of *Nr5a2* (LRH-1), and increased association of *Nr5a2*, and not *Nr5a1*, with the *Cyp19a1* promoter, as evidenced by CHIP assay.[339] Testosterone plus FSH yields a synergistic increase in *Cyp19a1* mRNA expression.[339] Estrogen elicits a more modest ~two-fold induction of *Cyp19a1* mRNA while the testosterone metabolite 5α-dihydrotesterone (DHT) is ~50% as effective as testosterone.[339] In contrast to these studies, there are reports that DHT inhibits follicular maturation.[19] Indeed, Menon's group showed that DHT (~ 25 nM, 24 h) inhibits FSH-stimulated ERK, Tuberin, and p70 S6 kinase phosphorylations resulting in reduced induction of cyclin D2 expression in granulosa cells.[262] The actions of DHT were mediated, in part, by promoting the phosphorylation of AMPK on Thr172, thereby activating this kinase.[199] While AMPK co-immunoprecipitates with ERK, the mechanism by which active AMPK inhibits FSH-stimulated ERK activation was not investigated.[199]

CROSS TALK AMONG FSH-REGULATED SIGNALING PATHWAYS AND TRANSCRIPTIONAL ACTIVATORS TO REGULATE GENE EXPRESSION DURING GRANULOSA CELL DIFFERENTIATION

As reviewed in the preceding sections, FSH regulates gene expression to inhibit apoptosis, drive proliferation, stimulate steroidogenesis, and promote a complex differentiation response that enables granulosa cells to respond appropriately to the LH surge. FSH accomplishes this array of functions by regulating posttranslational modifications of proteins that function as transcriptional activators, co-activators, repressors, or co-repressors, and of proteins that remodel chromatin to modulate gene activation. The majority of the responses to FSH appear to be mediated by PKA, as reviewed earlier. PKA can directly phosphorylate transcriptional activators, like CREB, and co-activators, like β-catenin, as discussed below, or can initiate signaling cascades that promote posttranslational modifications of transcriptional activators, such as GATA-4/6, co-activators, repressors, and co-repressors. PKA also enhances the translation of preexisting mRNA, such as that for HIF-1α, and newly transcribed mRNA. Figure 20.12 reviews some of the FSH target genes that are regulated directly or indirectly downstream of PKA-regulated transcriptional activators, co-activators, and repressors, as described in preceding and subsequent sections. As we will review below, it is apparent that no single transcriptional activator is sufficient to activate a target gene, and that a number of pathways converge on the promoters of these genes to activate multiple transcriptional activators and co-activators, to remodel chromatin, and to remove repressors and co-repressors. FSH also represses expression of target genes, such as those that stimulate apoptosis (*BIM*),[290] as previously discussed; however, this topic is less well defined. FSH also stabilizes mRNA, at least for the *Lhcgr*; this FSH response is also poorly understood.[340] In this section, we will summarize our current understanding of the convergence of signaling pathways on various transcriptional regulators to stimulate or inhibit expression of select FSH target genes.

LH Receptor

The rate of *Lhcgr* transcription and *Lhcgr* mRNA stability are increased by FSH.[340] While cAMP is required to stabilize *Lhcgr* mRNA in granulosa cells, the mechanisms of its actions are complex and poorly understood.[340] Transcriptional regulation of *Lhcgr* has been more extensively investigated. cAMP responsiveness of the 5′-*Lhcgr* promoter was attributed, in part, to three Sp1 binding sites.[341] Sp1 is a common PKA-dependent transcriptional activator for a number of FSH target genes, including *Sgk*,[26] *Egr-1*,[29] and *Ereg*.[27] Sp1 binds to "GC"-rich motifs, and its transcriptional activity is enhanced upon phosphorylation at a number of Ser/Thr residues by various kinases including ERK or PKCζ downstream of PI-3K.[169] As both the ERK and PI-3K pathways are activated in a PKA-dependent manner in granulosa cells, as previously reviewed, Sp1 could be regulated by either or both kinases. Consistent with a role for ERK in FSH-stimulated expression of EGR-1, FSH-stimulated Sp1 binding to the *Egr-1* promoter is reduced by pretreatment of granulosa cells with the MEK inhibitor PD98059.[29] However, the ability of either ERK or PKCζ to phosphorylate Sp1 and regulate its binding to FSH target genes has not been demonstrated in granulosa cells.

We recently showed that the co-activator β-catenin contributes to the ability of PKA to activate *Lhcgr*

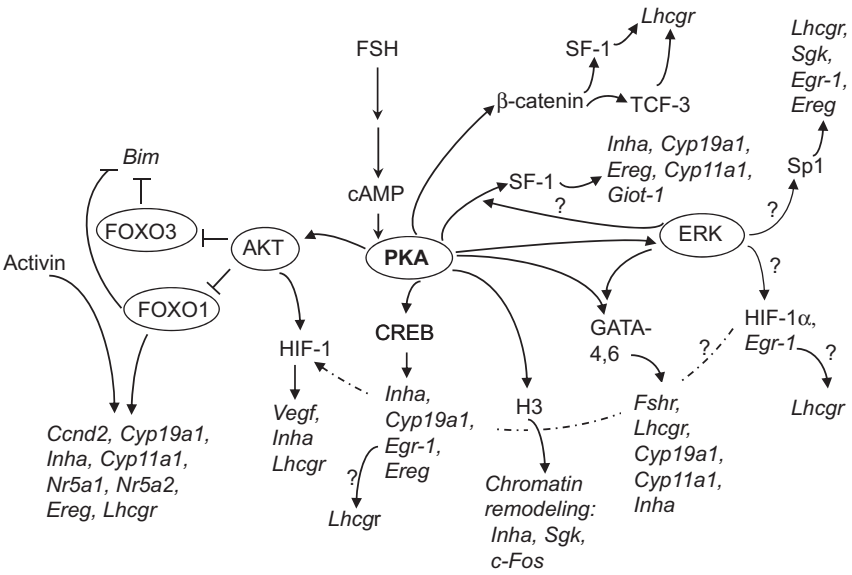

FIGURE 20.12 Composite regulation of FSH-responsive gene targets. Question marks (?) for ERK signaling reflect inhibition by a MEK inhibitor but not proof of target phosphorylation. Regulation of Lhcgr by Egr-1 is suggested by literature.

transcription[177]. Transduction of granulosa cells with an adenovirus that expresses a mutant SF-1 that cannot bind β-catenin[342] blocks the ability of FSH to promote *Lhcgr* mRNA expression. This result suggests that SF-1 is necessary for *Lhcgr* mRNA expression and that FSH activates β-catenin. FSH stimulates the PKA-dependent phosphorylation of β-catenin on Ser552 and Ser665, sites that have been linked with the ability of β-catenin to act as a co-activator for transcriptional factors,[178,179] and activation of the TCF artificial promoter-reporter TOPFlash, consistent with a previous report.[303] In support of these results, transduction of granulosa cells with an adenoviral β-catenin mutant that mimics phosphorylation of these sites (Ser552Asp, Ser665Asp) enhanced *Lhcgr* mRNA expression in FSH-treated cells.[177] The ability of β-catenin to function as a co-activator for SF-1 is now recognized in a number of cell models.[175,176,286] SF-1 is also necessary for expression of other FSH target genes, such as *Cyp19a1*, *Ereg*, *Cyp11a1*, *Inha*, and *Giot-1*. We hypothesize that the PKA-dependent phosphorylation of β-catenin contributes to the PKA-dependent regulation of these genes and is the predominant mechanism by which β-catenin activity is regulated in granulosa cells. However, this hypothesis has not been formally tested for genes other than the *Lhcgr*.

Results also suggest that β-catenin functions in granulosa cells to promote expression of *Lhcgr* mRNA by displacing co-repressors from TCF3 bound to the *Lhcgr* promoter.[177] This conclusion is based on data showing that an adenoviral dominant negative TCF,[343] in which the β-catenin binding site was deleted, abrogated the ability of FSH to induce *Lhcgr* mRNA. This suggests that β-catenin functions not only as a co-activator for SF-1 but also competitively displaces a member of the co-repressor Groucho-related genes family to activate TCF3.[344] Consistent with these findings, CHIP results showed that TCF3 is constitutively associated with *Lhcgr* promoter, and that FSH stimulates association of β-catenin phosphorylated on Ser552 and Ser675 as well as SF-1 with *Lhcgr* promoter.[177] Microarray results suggest that TCF3 is a common activator of a number of FSH target genes, such as *Inha*, *Cyp19a1*, and others, but additional experiments are required to confirm this hypothesis.

Lhcgr mRNA expression also appears to require expression of the immediate early gene EGR-1, based on evidence that follicles of EGR-1-null mice do not acquire LH receptors and thus cannot ovulate.[345,346] EGR-1 is a zinc-finger transcription factor that binds GC-rich enhancer elements.[347] FSH transiently increases EGR-1 expression in granulosa cells.[29] Activation of the *Egr-1* promoter is PKA dependent and involves ERK-dependent binding of Sp1 and Sp3 and phosphorylated CREB, as evidenced by electromobility shift assays and promoter mutational analyses.[29] Evidence that EGR-1 regulates *Lhcgr* expression has only been provided indirectly by electrophoretic mobility shift assays and by the ability of overexpressed EGR-1 to modestly enhance *Lhcgr*-promoter luciferase activity in a Leydig cell line.[346] Additional studies are required to define more completely the regulation of *Lhcgr* by EGR-1.

Lhcgr mRNA expression also appears to require HIF-1 and relief from repression by FOXO1, both of which are regulated downstream of PKA and PI-3K signaling. Although formal evidence for the regulation of *Lhcgr* mRNA expression by HIF-1 is not available, indirect data showed that dominant-negative HIF-1α missing its DNA binding and transactivation domains abolished FSH-stimulated *Lhcgr* promoter-luciferase reporter activity.[235] *Lhcgr* has also been identified as a FOXO1 target whose FSH-stimulated mRNA expression is reduced in cells transduced with adenoviral A3-FOXO1.[177,271]

In summary, pathways that contribute to the transcriptional activation of this gene include: PKA via either ERK or PKCζ to phosphorylate/activate Sp1; PKA to phosphorylate/activate β-catenin to activate both SF-1 and TCF3; PKA via PI-3K to phosphorylate/inactivate FOXO1; PKA via PI-3K and another pathway, possibly ERK, to promote accumulation of HIF-1α and activate HIF-1; and PKA to phosphorylate/activate CREB plus ERK or PKCζ to phosphorylate/activate Sp1 to promote expression of the immediate early gene EGR-1. Finally, we hypothesize that PKA also promotes remodeling of chromatin associated with *Lhcgr* gene by stimulating the phosphorylation of Ser10 and acetylation on Lys14 of histone H3, as previously discussed for the *Inha* promoter.[118] However, there is no direct evidence that either of these histone H3 modifications is linked to the *Lhcgr* promoter.

Inhibin-α and Aromatase

The expression of both inhibin-α and aromatase have been extensively studied regarding the combinations of factors required to promote their transcription. Unlike the *Lhcgr* promoter, the *Inha* promoter contains a functional nonconcensus CREB binding site as well as an SF-1 binding site. SF-1/LRH-1, both of which bind to the same DNA element,[348] and cAMP/PKA synergize to activate the *Inha* promoter.[170,349] The SF-1 and CREB sites are adjacent to each other on the promoter, and although SF-1 and CREB can interact in extracts, it is not known if this interaction is direct.[170] The co-activators CBP and SRC-1 further increase *Inha* transcriptional activity in a mouse granulosa cell line, and the association of both with the *Inha* promoter is enhanced by forskolin, as evidenced by CHIP assays.[349] Recent studies suggest that the LIM domain protein four and a half LIM domain 2 (FHL2) also functions as a co-activator of SF-1/LRH-1 and CREB in granulosa cells.[350] FHL2 is recruited to the *Inha* promoter in a granulosa cell line in response to

elevated cAMP levels, although the mechanism of this recruitment was not investigated.[350] Unlike CBP and the co-activator SRC-1, FHL2 lacks enzymatic activity and may function as a scaffold to integrate the association of other co-activators.

CHIP assays also revealed that while SF-1 is associated with the *Inha* promoter in the basal state, forskolin stimulates the release of SF-1 and binding of LRH-1 (which is induced by forskolin) in a granulosa cell line.[349] These cAMP-dependent associations of SF-1/LRH-1 with the *Inha* promoter, as well as cAMP-stimulated *Inha* promoter-luciferase activity, were inhibited by the MEK inhibitor PD98059,[349] possibly reflecting ERK phosphorylation of SF-1[203] and LRH-1.[351] The mechanistic basis for the dynamic associations of SF-1 and LRH-1 with the *Inha* promoter is not known, but might reflect distinct posttranslational modifications or distinct associations of the co-activator β-catenin[175,176] with SF-1 versus LRH-1. While SF-1 and LRH-1 tend to have overlapping actions,[352] selective regulation of the *Cyp19a1* expression by LRH-1 in testosterone-treated granulosa cells has been reported and seems to be due to preferential expression of LRH-1 by testosterone.[339]

The ability of cAMP to activate the *Inha* promoter thus likely reflects actions at a number of sites. cAMP-activated PKA phosphorylates CREB on Ser133, promoting recruitment of CBP.[167,211] PKA also promotes the phosphorylation on Ser10 and acetylation on Lys14 of histone H3, as previously discussed, thus remodeling chromatin in the region of the *Inha* promoter.[118] PKA is also recognized to potentiate SF-1 transcriptional activity both via the phosphorylation/activation of β-catenin and via ERK-mediated phosphorylation of SF-1, as previously described. *Inha* expression is also regulated by HIF-1, based on the ability of a dominant-negative HIF-1α to reduce significantly the ability of FSH to activate *Inha* promoter-reporter activity.[235] Additionally, expression of constitutively active FOXO1 in granulosa cells reduces the ability of FSH plus activin to activate *Inha* expression,[48] although there is no formal evidence that FOXO1 represses *Inha* expression.

There is also accumulating evidence that GATA transcription factors regulate a number of FSH targets, including *Inha* in granulosa cells. GATA factors are zinc-finger DNA binding proteins. GATA-4 and -6 are highly expressed in granulosa cells,[353] and promoters of several FSH target genes contain functional (*Inha*, *Nr5a1*, *Hsd17b*, *Cyp11a1*, *Cyp19a1*, *Star*) or putative (*Lhcgr*, *Hsd3b1*) GATA regulatory elements.[354,355] GATA-4 is phosphorylated on Ser261 directly by PKA[356] and on Ser105 by ERK.[357] *Inha* gene expression is activated by GATA-1 in testicular cell lines,[358,359] and PKA-phosphorylated GATA-4 enhances an *Inha* promoter-reporter construct in CV-1 cells.[356] GATA-4 also regulates expression of *Cyp19a1* in granulosa cells.[360] FSH stimulates the association of GATA-4 with the *Cyp19a1* promoter, as shown by CHIP assays, and GATA-4 siRNA reduces the ability of FSH to promote *Cyp19a1* mRNA expression. A nonphosphorylatable Ser105 GATA-4 mutant prevents the induction of *Cyp19a1* mRNA by FSH, and the MEK inhibitor U0126 abolishes FSH-stimulated phosphorylation of GATA-4 that was transfected into granulosa cells.[360] That GATA-4 is required for follicular maturation was recently demonstrated with conditional deletion of both GATA-4 and GATA-6 in granulosa cells with the *Cyp19-Cre*.[353] Mice are infertile, follicular maturation is arrested prior to antrum formation, and granulosa cells exhibit reduced *Fshr*, *Lhcgr*, *Cyp19a1*, and *Cyp11a1* mRNA. Together these results show that GATA-4 is necessary for follicular maturation and that its transcriptional activity is regulated by PKA.

FSH also regulates the expression of a protein, DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia critical region, on the X-chromosome, gene 1, *Nrob1*), that functions as a transcriptional repressor of Nr5a1 (SF-1) and Nr5a2 (LRH-1).[342] FSH reduces DAX-1 mRNA and protein levels, and overexpression of DAX-1 has been shown to prevent activation of *Giot-1* promoter activity by SF-1 in granulosa cells.[30] Expression of the *Cyp19a1* gene is also inhibited by DAX-1,[361] suggesting that for those genes that require binding of SF-1 or LRH-1, decreased expression of DAX-1 may be a conserved response to FSH. However, the mechanism by which FSH downregulates *Dax-1* mRNA has not, to our knowledge, been investigated.

Taken together, FSH-stimulated target gene activation requires input from a number of pathways, as summarized in Figure 20.12. Inhibitors of PKA, PI-3K, and MEK abrogate the ability of FSH to activate select target genes. The requirements for both PKA-phosphorylated CREB as well as for SF-1 and/or Sp1 and/or GATA-4/6 to promote transcriptional activation of a number of FSH target genes coupled with their dependence on the PI-3K pathway explains, in part, why activation of the PI-3K pathway by IGF-1 is not sufficient to induce FSH target genes. Although some of the transcription factors and co-activators required to activate a small subset of FSH target genes have been identified, much needs to be learned regarding the combinatorial requirements for transcription factors and co-activators and how the activity of these factors is regulated. Moreover, it is likely that additional signaling pathways are regulated by FSH. Finally, we know very little about how FSH-dependent pathways converge with the many signaling systems involved in initial formation and early growth of the follicle, as discussed in Chapter 21. Thus, there is a great deal remaining to be elucidated regarding how FSH signals to promote follicular maturation.

LH SIGNALS THAT REGULATE THECA CELL FUNCTIONS

Follicles are exposed to relatively low levels of LH as follicle maturation proceeds. The resulting increased production of androgens provides the substrate for aromatase in granulosa cells to synthesize estrogen. In addition to facilitating the actions of FSH, these increasing levels of estrogen act in a positive feedback fashion on the brain to induce the preovulatory LH surge. In pathological conditions such as polycystic ovarian syndrome, theca cells produce elevated levels of androgens. Thus, an understanding of how LH regulates androgen production is important.

LH has been shown to enhance mRNA expression of the transcription factor required for cholesterol biosynthesis, sterol regulatory element binding transcription factor 1a (*Srebf1a*), and HMG-CoA reductase(*Hmgcr*), the rate-limiting enzyme in cholesterol biosynthesis.[362] LH also induces 17α-hydroxylase/C17-20-lyase (CYP17; *Cyp17a1*), the rate-limiting enzyme in androgen biosynthesis in theca cells,[363] and the low-[364] or high-[365] density lipoprotein receptor, depending on the species, to provide cholesterol for steroid biosynthesis. While the signaling pathways and transcriptional regulation of LH-regulated genes in theca cells have not been intensely investigated, recent studies have placed SF-1 on both the *Cyp17a1* and *Star* promoters, and GATA-6 on the *Cyp17a1* promoter, as shown by CHIP studies.[366] There is also evidence that the nuclear orphan receptor NR4A1/NUR77 contributes to the ability of LH to induce genes required for androgen biosynthesis including *Star*, *Cyp11a1*, *Cyp17a1*, and *Hsd3b2*.[367] Overexpression by adenoviral transduction of *Nr4a1* increases and knockdown of *Nr4a1* reduces the expression of all of these genes in response to LH. The induction of these mRNAs as well as that of *Nr4a1* is mimicked by forskolin, consistent with a cAMP-regulated pathway.[367] LH via a PKA-dependent step has been shown to signal into the AKT, Tuberin, mTORC/Raptor pathway to stimulate the phosphorylation of p70 S6 kinase, leading to the upregulation of cyclin D3, *Hsd3b1*, *Cyp11a1*, and *Cyp17a1*.[368] Although this pathway is generally reserved for regulating translation,[250] in theca cells p70 S6 kinase phosphorylates CREB on Ser133. CHIP assays place CREB on the *Cyp17a1* promoter.[368] The requirement for the mTORC/Raptor pathway to regulate expression of *Hsd3b1*, *Cyp11a1*, *Cyp17a1*, and *Ccnd3* is based on inhibition by the mTORC/raptor inhibitor rapamycin and by mTORC siRNA studies.[368]

Thus, while some of the signals leading to enhanced transcription of genes that promote androgen production have been identified, the persistent regulation of these pathways during the life of the follicle until the surge of LH remains incompletely understood. It is quite interesting, as discussed below, that the signaling pathways initiated by LH to regulate gene expression in theca cells are quite distinct from the pathways used by LH to regulate ovulation and corpus luteum formation.

THE LH SURGE PROMOTES OOCYTE MATURATION, OVULATION, AND CORPUS LUTEUM FORMATION

A Brief Overview of the Physiology of Oocyte Maturation, Ovulation, and Luteinization

Follicles are exposed to a single high level surge of LH, driven by the hypothalamic release of gonadotropin-releasing hormone that promotes ovulation and differentiation of mural granulosa and theca cells (but not cumulus granulosa cells) into luteal cells (luteinization) and triggers final maturation of the oocyte. These responses to LH require the induction of more than 500 genes.[369]

Cumulus Expansion. Preceding ovulation, the cumulus granulosa cells and oocyte become surrounded by a hyaluronan-rich extracellular matrix that facilitates the expansion/movement of cumulus granulosa cells within this matrix. Cumulus expansion and oocyte maturation require, for example, the induction of hyaluronic acid synthase-1 *Has-2*, pentraxin-related protein 3 *Ptx3*, and TNF-α-stimulated gene-6 *Tnfaip-6*.[370] Mice that are deficient in *Ptx3* and *Tnfaip-6* exhibit ovulation defects,[371,372] consistent with a link between cumulus expansion and ovulation.

Ovulation. Ovulation is a complex, incompletely understood process that results in the breakdown of the follicular wall and release of the oocyte and surrounding cumulus granulosa cells. The oocyte and surrounding cells escape through the mural granulosa cell layer, the basement membrane, the theca cell layer, and ovarian surface epithelium. LH induced genes that are required for ovulation include the cyclic nucleotide degrading phosphodiesterase *Pde4d*[34], *Ptgs2* that encodes the rate-limiting enzyme (prostaglandin-endoperoxide synthase) in prostaglandin synthesis,[373] and *Pgr* that encodes the progesterone receptor[374] and its downstream targets pituitary adenylate cyclase activating polypeptide (*Pacap*),[375,376] lysosomal protease cathepsin L (*Ctsl*),[377] and the matrix metalloproteinase *Adamts-1* (a disintegrin and metalloproteinase with thrombospondin-like repeats).[378]

Oocyte maturation. Oocytes are restrained in prophase I of meiosis until just before ovulation. Breakdown of the nuclear membrane, also known as germinal vesicle breakdown, marks an oocyte that has reinitiated meiosis. Completion of the second meiotic division after fertilization results in the production of two polar bodies and a single haploid oocyte.

Luteinization. Luteinization is associated with a cessation of granulosa and theca cell proliferation and is characterized by hypertrophy of both granulosa and theca cells[379] as well as by increased steroid hormone synthesis and secretion. Luteinization requires the downregulation of cyclin D2 (*Ccnd2*),[45] and expression of the rate-limiting enzyme in progesterone synthesis encoded by *Cyp11a1*,[380] the cholesterol-mobilizing protein *Star*,[376] and cell cycle inhibitors $p21^{Cip1}$ and $p27^{Kip1}$[45,381] encoded by *Cdkn1a* and *Cdkn1b*, respectively. The surge of LH also terminates the expression of select FSH target genes that were required for follicular maturation but are not required for luteal function. For example, the following genes are transcriptionally silenced, as discussed below, in response to LH: the FSH receptor (*Fshr*),[69] estrogen receptor β (*Esr2*),[382] *Cyp19a1* (aromatase),[383] *Inha* (inhibin-α),[384] and *Foxo1*.[112] The LH receptor[385] (*Lhcgr*) is transiently downregulated by the LH surge; however, the mechanism is not via reduced transcription, as discussed below. The expression of other FSH targets whose functions are required either during luteinization or for luteal function are not affected by the surge of LH include, for example, *Map2d*,[25] *Cyp11a1*,[380] and *Sgk*.[112] Some of these responses are also variable among species; for example, inhibin-α is repressed by the LH surge in the rodent,[384] but inhibin A is actively secreted during the luteal phase in the primate reproductive cycle.[386]

LH and the LH Receptor

The pituitary gonadotropin LH shares a common alpha subunit with FSH, but its synthesis and secretion from pituitary gonadotropes is under distinct regulation. For many of the studies discussed in this chapter, the related placental gonadotropin hCG (Figure 20.1) is used as an agonist of the LH receptor. The LH receptor, like the FSH GPCR, contains nine Leu-rich-repeat motifs in its extracellular domain and is classified in subgroup A of the rhodopsin/β-adrenergic family of GPCRs[9,387] (Figure 20.1). These Leu-rich-repeats contribute to hormone binding and structural integrity of this receptor.[388] The LH receptor is encoded by a gene with 11 exons and 10 introns.[6] Exons 1–7 encode the regions of the large extracellular domain that are essential for high affinity binding of LH receptor agonists and the placental-derived hCG.[389,390] Exons 9 and 10 also encode the extracellular domain, but this region appears to be less important for agonist binding.[386] Exon 11 encodes the seven TM domains and the C-terminal tail. The LH receptor in female mammals is expressed in the ovary in theca cells of ovarian follicles, in mural granulosa cells of mature preovulatory follicles, and in corpora lutea. LH receptor-null mice are infertile; their ovaries contain only early antral follicles and lack preovulatory follicles or corpora lutea.[391]

The absence of follicular development to a preovulatory stage in LH receptor-null mice likely reflects, at least in part, the reduced levels of theca-derived androgens and thus granulosa-derived estrogens,[391] and the apparent requirement of these steroid hormones for final follicular maturation. Granulosa cells also express androgen receptors.[392] Androgen receptor-null mice exhibit increased granulosa cell apoptosis and defective cumulus cell expansion in response to the LH surge,[393] and conditional deletion of the androgen receptor from granulosa cells results in subfertile mice that ovulate ~75% fewer oocytes.[338] Together these results suggest a role for androgens in granulosa cells distinct from their function as an aromatase substrate. Although granulosa cells express primarily ER-β and theca cells express ER-α, mice null for ER-α or ER-β ovulate in response to exogenous gonadotropins, although ovulation efficiency is reduced, suggesting that estrogen facilitates ovulation.[394] Incomplete follicular maturation in the LH receptor-null mice could also result from effects of basal LH on granulosa cells distinct from those described for the surge of LH.

In the absence of agonist, GPCRs are believed to exist in the membrane primarily in an inactive conformation that is in equilibrium with an active conformation.[59] Agonist binding is thought to stabilize the receptor in the active conformation. Consistent with this notion, and unlike the FSH receptor, a number of mutations in the LH receptor have been identified that stabilize the receptor in an active conformation in the absence of agonist.[395] The first human mutation of the LH receptor identified was Asp578 in TM 6 in patients with familial male-linked precocious puberty.[396] This mutation results in a constitutively active LH receptor, which in males leads to precocious puberty. For reasons that are not clear, females with this LH receptor mutation do not exhibit abnormal fertility.[395] This may reflect a stringent requirement for postpubertal levels of FSH to induce LH receptor expression in the female ovary. The absence of a phenotype in women with constitutively active LH receptors is especially unexpected in light of the clear phenotype in mice overexpressing a longer-lived LH mutant protein, which is characterized by precocious puberty, anovulation, and resulting infertility.[397] TM 6 and its extension into the cytoplasm as the third intracellular loop have been defined as hot spots for LH receptor mutations that promote a constitutively active receptor, and more than 16 mutations have been identified in this region.[395] Additionally, Ser431 in TM 3,[398] Arg442 in the second intracellular loop,[399] Asp397 in exoloop 1,[400] and Lys583 in exoloop 3[401] of the rat LH receptor appear to contribute to the stabilized agonist-dependent active conformation of the LH receptor to generate cAMP (without affecting agonist binding), whereas Lys583 in exoloop 3 also appears to stabilize the agonist-stimulated active state

of the receptor to generate inositol trisphosphate (IP_3).[402] A large number of inactivating mutations of the LH receptor in women have been reported.[395] These women exhibit amenorrhea and no preovulatory follicles or corpora lutea, consistent with the established functions for LH, and do not respond to exogenous hCG.

The LH receptor in granulosa cells is induced by FSH[403]; LH receptor synthesis then ceases in response to the surge of LH, as discussed below, and is reinitiated with the formation of the corpus luteum. Hormonal regulation of the induction of LH receptors in corpora lutea is species dependent,[404,405] consistent with the high degree of species specificity in the factors that regulate formation, maintenance, and regression of the corpus luteum. Theca cells appear to express LH receptors coincident with the morphological formation of this cell layer at very early stages of follicular development[69]; however, it is not known if LH receptor expression is constitutive in these cells or is regulated by a paracrine factor produced either by the oocyte or by adjacent granulosa cells.

The LH receptor couples to activate Gs,[406,407] uniformly resulting in activation of adenylyl cyclase to increase synthesis of cAMP.[408] The LH receptor has also been shown to activate Gi,[409–411] Gq/11, and G13, based on the ability of LH to stimulate binding of a GTP photoaffinity analog to these Gα proteins.[411] Although LH receptor activation can stimulate Gi to inhibit adenylyl cyclase activity upon expression in a heterologous cell model,[412] LH-stimulated adenylyl cyclase activity in porcine follicular membranes is not increased by pretreatment of membranes with pertussis toxin, which uncouples GPCRs from Gi.[409] Thus, the physiological significance of LH receptor coupling to Gi is not known. Constitutively active LH receptors expressed in heterologous cells also activate PLC, resulting in elevated levels of IP_3 and Ca^{2+}.[408,413,414] Similarly, when LH receptors are expressed at sufficiently high concentrations, receptor activation raises intracellular Ca^{2+} and activates PLC.[415–417] This response is pertussis toxin insensitive[410] and thus most likely mediated via activation of Gq/11. In rat granulosa cells, which express approximately 10,000 receptors per cell,[411] LH raises intracellular levels of IP_3 presumably via activation of PLC.[418] Thus, signaling through cAMP appears to be the predominant but not the only second messenger through which the LH receptor can modulate responses.

Although the exact residues that bind Gs on the LH receptor have not been identified, the C-terminal portion of the third intracellular loop extending into TM 6 domain is important, based on the ability of a synthetic peptide corresponding to this region to activate adenylyl cyclase in the absence of LH receptor expression.[419] Truncation of the C-terminal region of the rat LH receptor at residue 653 does not affect agonist-stimulated adenylyl cyclase activation but hampers receptor-stimulated PLC activation, suggesting that the G protein that activates PLC couples to a distinct region of the receptor from that which signals to Gs.[420]

The LH receptor also exhibits desensitization and, in heterologous cell models, relatively rapid internalization in response to saturating levels of agonist. However, the preovulatory LH surge does not promote rapid internalization of the LH receptor in granulosa cells. Rather, cell surface receptor numbers around the time of ovulation decrease with a T1/2 of approximately 8.5 h.[421–423] Although this receptor can be phosphorylated on up to five serine residues located in the C-terminal tail[424,425] in a G protein-regulated kinase-dependent manner,[426,427] phosphorylation of the human and porcine receptors does not contribute to either uncoupling from Gs/adenylyl cyclase[424,428–430] or receptor internalization.[431] Similarly, for the rat LH receptor, mutation of the serine residues in the C-terminal tail retards the rate of desensitization but does not affect the extent of LH receptor desensitization.[420,424,426] These results are consistent with evidence that truncation of the C-terminal tail of the LH receptor does not prevent LH receptor desensitization.[432] A protein that interacts with the C-terminus of the human LH receptor, the type I PDZ domain protein GIPC,[433] appears to regulate levels of cell surface LH receptor during hormone internalization and to play a role in ligand recycling.

Thus, unlike the β-adrenergic and rhodopsin GPCRs, in which high affinity binding of arrestin to the receptor is facilitated by receptor phosphorylation,[89,434] binding of arrestin to the LH receptor and consequent uncoupling from Gs appears to depend on receptor activation rather than phosphorylation.[431,435–437] Indeed, arrestin2 binds with pM affinity to a synthetic peptide corresponding to the third intracellular loop of the porcine LH receptor to promote desensitization.[438,439] The accessibility of arrestin2 to the LH receptor in porcine membranes and in HEK kidney cells stably transfected with the murine LH receptor is regulated by the association of arrestin2 with the small G protein ADP-ribosylation factor (ARF)6.[439,440] LH receptor activation promotes activation of membrane-delimited ARF6[441] by ARNO (ARF-nucleotide binding site opener) or a similar ARF6 activator,[442] releasing arrestin2 from its membrane docking site.[438] The binding of arrestin to GPCRs has been shown to sterically hinder the ability of the receptor to bind Gs.[439] Consistent with this model, both Gs binding and arrestin2 binding appear to require the C-terminal portion of the third intracellular loop of the LH receptor.[419,438] Although this pathway for ARF6-dependent desensitization has not been tested in other cellular models, overexpressed ARNO is reported to stimulate arrestin-dependent β-adrenergic receptor internalization, and an inactive ARF6 that cannot bind GTP inhibits β-adrenergic receptor internalization.[443] These results

suggest that ARF6 might play a more universal role in regulating arrestin availability to GPCRs.

Coupling of the LH receptor to Gs is also regulated in a poorly understood manner by PDE4D.[34] Unexpectedly, in granulosa cells of PDE4D null mice, the immediate (detected by 1 h) and the sustained (over 6 h) cAMP synthetic response to an ovulatory concentration of hCG (both in vivo and in vitro) is significantly blunted (and not increased), whereas the response to the adenylyl cyclase activator forskolin (in vitro) is equivalent compared with that of wild-type mice.[34] This result suggests that PDE4D in some manner facilitates coupling between the LH receptor and Gs to activate adenylyl cyclase and that in the absence of PDE4D, coupling between LH receptor and Gs is impaired. LH receptor-Gs coupling is likely regulated by the sustained levels of PDE4D induced in granulosa cells by FSH rather than that induced by LH.[34] How PDE4D enhances LH receptor-Gs coupling remains to be elucidated.

MECHANISMS BY WHICH LH STIMULATES OOCYTE MATURATION, OVULATION, AND LUTEINIZATION

LH-Regulated Signaling Pathways in Preovulatory Cells

The remainder of this chapter will focus on our current understanding of the cellular mechanisms by which LH stimulates oocyte maturation, ovulation, and luteinization. The reader is also referred to Chapter 22 on ovulation. We begin by summarizing LH-stimulated signaling pathways; however, additional information on specific pathways is provided in the context of the following sections.

cAMP- and PKA-Dependent Signaling to CREB and ERK. The LH receptor is believed to signal predominately via Gs to activate adenylyl cyclase and raise intracellular levels of cAMP. Consistent with this notion, the adenylyl cyclase activator forskolin mimics LH to stimulate expression of a number of LH target genes.[29,364,444–447] The primary cAMP target is PKA. Indeed, ovulatory concentrations of LH/hCG in preovulatory follicles lead to activation of PKA,[448] and the specific PKA inhibitor PKI[119] or the selective PKA inhibitor H89[123] inhibits the induction of a number of LH targets or responses.[29,364,448]

As in preantral granulosa cells, hCG or forskolin treatment of preovulatory granulosa cells stimulates the phosphorylation of the PKA target CREB on Ser133.[151,449] Although LH-stimulated CREB phosphorylation is undetectable when granulosa cells are pretreated with the selective PKA inhibitor H89,[424] it is possible that other pathways downstream of PKA also contribute to CREB phosphorylation. LH target genes that contain cAMP response elements and have been shown to bind CREB include EGR-1,[29] ICER,[450] and StAR.[451]

As will be highlighted in the following discussion, one of the most important signaling pathways by which LH regulates gene expression is via the ERK1/2 (MAPK3/1) pathway (Figure 20.13). The initial route to ERK is via PKA, based on the ability of H89 and Myr-PKI to strongly inhibit LH-stimulated ERK activity in mural granulosa cells.[452] However, in contrast to regulating the association of a PTP with ERK as is observed in preantral granulosa cells,[113] PKA signals to regulate ERK activity in preovulatory granulosa cells at a step upstream of MEK. While LH stimulates MEK phosphorylation,[452] the site of regulation by PKA has not been elucidated in preovulatory granulosa cells. In MA-10 and primary Leydig cells, LH signals via PKA into the ERK pathway to activate RAS.[452,453] However, the relevant direct PKA substrate in either of these cell types has yet to be identified.

Sustained ERK activation is required for LH responses that lead to oocyte maturation, ovulation, and luteinization. This is achieved by the ability of LH to promote activation of an EGF receptor located in both mural and cumulus granulosa cells in a PKA-dependent manner.[451,454] The EGF receptor family consists of the EGF receptor (ErbB1, HER), ErbB2 (Neu, HER2), ErbB3 (HER3), and ErbB4 (HER4); granulosa cells express ErbB1, ErbB2, and ErbB3.[455] ErbB1 binds EGF or EGF-like ligands to promote homo- or heterodimerization and activation of its tyrosine kinase activity.[456] An elegant series of studies have shown that LH generates a group of EGF-like ligands that include amphiregulin, epiregulin, and β-cellulin that are synthesized as transmembrane precursors and then shed as mature proteins by cleavage at the membrane surface by a metalloproteinase[454] (Figure 20.13). LH is believed to promote both the de novo synthesis of these ErbB ligands, based on inhibition by puromycin, and to activate a metalloproteinase, based on inhibition by pan-metalloproteinase inhibitors, to generate these EGF-like ligands in a PKA-dependent manner in mural granulosa cells.[451] The ErbB1 ligands promote activation of ErbB1 on both mural and cumulus granulosa cells to signal through the canonical EGF receptor pathway to activate ERK.[456] The functional significance of the ERK pathway to LH actions is discussed below. The ErbB1 ligands also signal via the EGF receptor to activate p38 MAPK (MAPK14), also discussed below.

LH also stimulates expression of the EGF-like factor neuroregulin-1, via an ERK-dependent pathway, and this ligand binds ErbB3.[455] The ErbB3 receptor appears to signal predominately to the PI-3K/AKT pathway in granulosa cells, based on the ability of neuroregulin-1 to enhance AKT but not ERK phosphorylation.[455] Both amphiregulin and neuroregulin-1 contribute to luteinization by enhancing expression of genes required for progesterone production and oocyte maturation.[455]

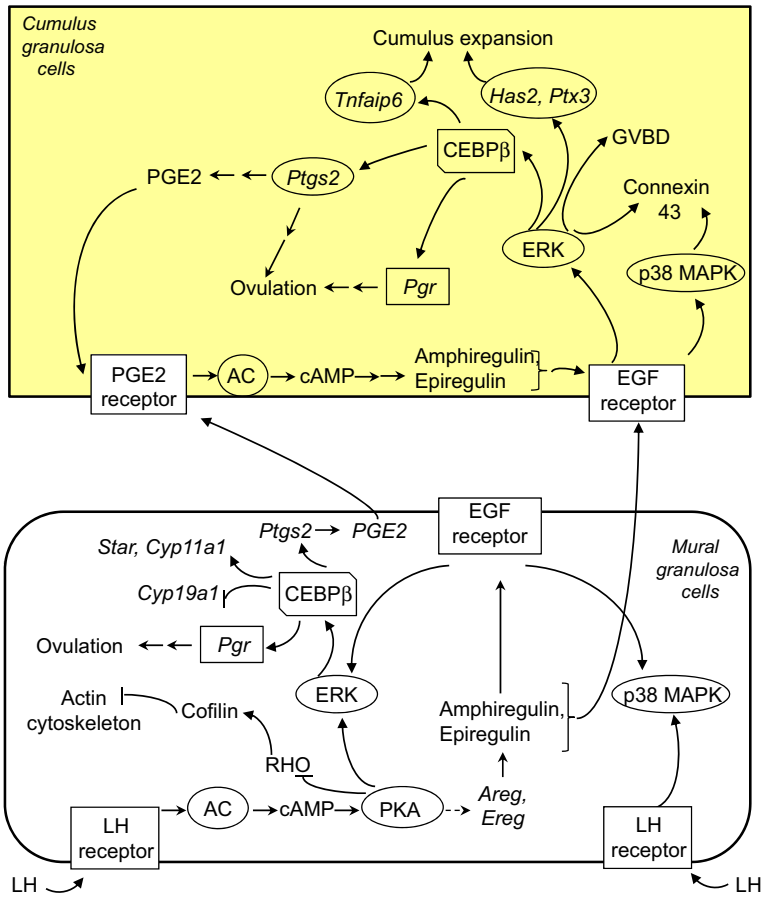

FIGURE 20.13 LH signals that regulate ovulation, cumulus granulosa cell expansion, and luteinization.

LH signaling to p38 MAPK. hCG signals to rapidly phosphorylate p38 MAPK(MAPK14) in preovulatory granulosa cells[452] as well as its upstream kinases MKK3 and MKK6.[217] However, at least the initial signaling into the p38 MAPK pathway appears to be independent of PKA, based on the inability of H89 to modulate hCG-stimulated p38 MAPK phosphorylation in cells in which hCG-stimulate CREB phosphorylation was blocked by H89.[452] The functional significance of the p38 MAPK pathway activated by hCG and ErbB1 ligands is discussed later.

LH Increases Intracellular Ca^{2+} but Does Not Appear to Activate PKC. It is well established that the LH receptor, upon expression in a heterologous cell, activates PLC to raise IP_3 levels and/or intracellular Ca^{2+}.[408,410,417,457] The rise in intracellular Ca^{2+} in one report was shown to be independent of the concomitant rise in cAMP and thus likely dependent on IP_3.[457] In rat granulosa cells, LH is reported to increase IP_3.[458] In porcine theca cells, LH has been shown to generate an oscillatory Ca^{2+} signal that is not inhibited by pertussis toxin (thus independent of Gi) but is inhibited by the Ca^{2+} chelator ethyleneglycotetraacetic acid and by the PLC inhibitor U73211.[459] The rise in intracellular Ca^{2+} likely activates a CaM kinase, and LH-stimulated progesterone production is reduced by 50% by the CaM kinase inhibitor Kn93.[444] Ca^{2+} has recently shown to be required for hCG/amphiregulin-stimulated increases in the activity of the protease calpain-2 in cumulus granulosa cell–oocyte complexes.[460] Active calpain-2 promotes degradation of proteins within the focal adhesion complex of cumulus cells, leading to cell detachment, and is believed to contribute to cell movement within the cumulus cell–oocyte complex.[460] It is also possible that LH activates one or more PKC isoforms.

PKC consists of a number of isoforms[461]: the conventional PKCs (α, β, and γ) require Ca^{2+}, diacylglycerol, and phosphatidylserine for activation; the novel PKCs (δ, ε, η, θ) do not require Ca^{2+}; and the atypical PKCs (ζ, ι/λ) require only phosphatidylserine for activation. Subovulatory concentrations of LH plus 200 nM PMA (phorbol myristate acetate), which binds the diacylglycerol binding site on conventional and novel forms of PKC, mimic the effect of an ovulatory concentration of LH to promote progesterone production, *Ptgs2* induction, and luteinization of granulosa cells[462]; 200 nM PMA mimics the surge of LH to stimulate expression of LH targets such as the *Pgr*[463] and *Egr-1*.[29] However, in contrast to these results, hCG treatment of granulosa cells does not appear to promote activation of the

conventional or novel isoforms of PKC.[449] The ability of LH to activate the atypical forms of PKC has not been thoroughly investigated, but LH is reported to stimulate the membrane translocation of the atypical PKC isoform PKCζ, and this pathway is proposed to mediate the induction of the immediate early transcription factor *NGF1B/EGR-2* in these cells[464] that is implicated in *Cyp19a1* gene repression,[465] as discussed later.

LH and Insulin/IGF-1 Synergize to Activate AKT and LH Target Genes. There is abundant evidence in preovulatory granulosa and theca cells that LH/hCG synergizes with insulin/IGF-1 to promote target gene expression. This synergism is observed in granulosa cells with respect to stimulation of progesterone production,[466,467] *Star* expression,[468,469] *Ldlr* (low-density lipoprotein receptor) promoter-reporter activity,[364] and, surprisingly, cAMP production.[468,469] Synergism is also evident in vivo with conditional deletion of the lipid phosphatase PTEN (phosphatase and tensin homolog) that degrades PIP3, as shown by increased numbers of ovulated oocytes and increased litter size.[470] Synergism is reported in theca cells for the *Cyp17a1* promoter-reporter.[363,468] Co-transfection with the PKA inhibitor PKI inhibited both LH stimulation and the LH/hCG synergism with insulin/IGF-1 in regulation of *Star*[364] and *Ldlr*[364] promoter-reporter activities, consistent with LH signaling to these targets via PKA. Synergism between these pathways to stimulate *Ldlr* promoter-reporter activity was also inhibited with the PI-3K inhibitors wortmannin and LY24002.[364]

Insulin/IGF-1 are expected to signal through their canonical receptor tyrosine kinase pathways to activate IRS-1/2, PI-3K, and AKT.[238] However, the cellular mechanism by which LH regulates the PI-3K/AKT pathway is poorly understood. There is one report, using an in vivo model in which LH was infused into the vena cava of diestrus rats, that investigated signaling to AKT.[469] These authors showed, through immunoprecipitation of indicated targets from ovarian extracts, that LH stimulates the tyrosine phosphorylation of the cytokine receptor-associated tyrosine kinase Janus kinase 2 (JAK2), the phosphorylation of JAK2 targets signal transducer and activator of transcription (STAT)-1 and -5b, the tyrosine phosphorylation of IRS-1 and its association with PI-3K, and AKT phosphorylation. They also demonstrated that LH stimulates the tyrosine phosphorylation of SHC,[469] an adaptor protein that binds to phosphorylated tyrosine residues and associates with GRB2/SOS to activate RAS[471] and leads to an activation of ERK.[469] Moreover, these authors reported that LH and insulin synergized to increase all these responses except for ERK activation and tyrosine phosphorylation of STAT-1.[469] Additional studies are required to confirm these observations and to determine the mechanism by which LH signals to regulate these phosphorylation events.

Cumulus Granulosa Cell Expansion and Oocyte Maturation

Oocyte Arrest. Oocytes are arrested in prophase I of meiosis prior to the surge of LH, as shown in Figure 20.14. Arrest is initially maintained by the absence of at least the maturation promoting factor (MPF) kinase CDK1,[472] and possibly other proteins in oocytes. Oocytes acquire competence to resume meiosis sometime between preantral and antral stages.[473] Arrest is then maintained by elevated levels of cAMP and cGMP within the oocyte.[474] cAMP levels sufficient to maintain meiotic arrest appear to be the product of signaling by the orphan GPCRs GPR3[475] and GPR12[476] to Gs and adenylyl cyclase. Downregulation of GPR3 and GPR12 promotes meiotic resumption.[476] The ligands that activate these receptors remain unidentified. A second key player is the oocyte-specific cAMP hydrolyzing phosphodiesterase PDE3A, whose activity is inhibited prior to the LH surge primarily by cGMP,[477] thereby maintaining elevated intra-oocyte levels of cAMP. PDE3A-null mice ovulate but are infertile because oocytes do not undergo germinal vesicle breakdown and thus remain arrested.[478]

cAMP via PKA maintains oocyte arrest by inhibiting the activation of maturation promoting factor MPF, which consists of the cyclin-dependent kinase CDK1(CDC2) and Cyclin B. PKA maintains CDK1 in

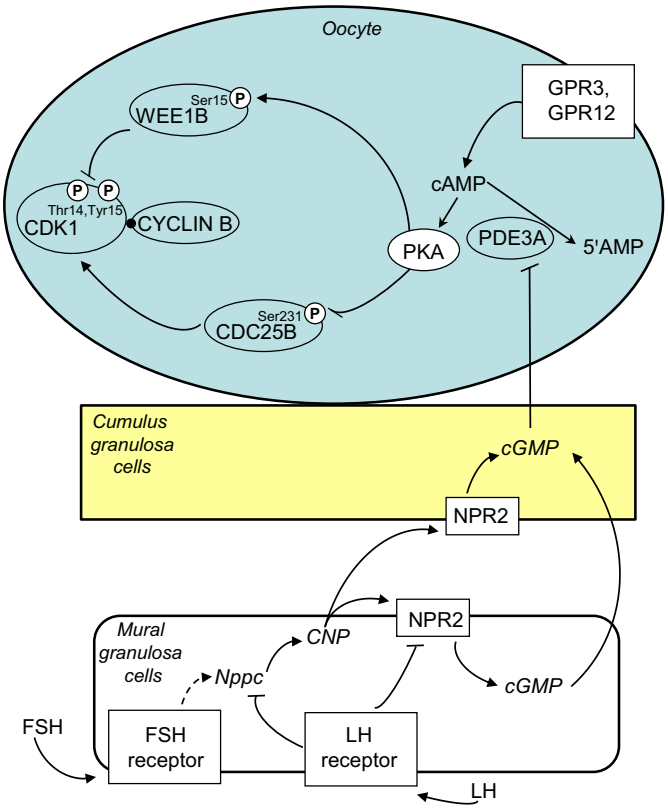

FIGURE 20.14 Mechanism by which LH promotes oocyte maturation.

an inactive conformation that resides in the nucleus by phosphorylating/activating the oocyte-specific dual-specificity kinase WEE1B on Ser15.[479] WEE1B phosphorylates CDK1 on Thr14 and Tyr15, inhibiting its activity.[480] PKA also maintains CDK1 in an inactive conformation by inhibiting the dual-specificity phosphatase CDC25B that can dephosphorylate Thr14 and Tyr15 on WEE1B. Phosphorylation of CDC25B on Ser321 promotes the association of CDC25B with 14-4-3 proteins in the cytosol, thus restricting accessibility to the substrate CDK1.[481]

Recent studies have elucidated key pathways that elevate levels of cGMP within cumulus granulosa cells to inhibit oocyte PDE3A. FSH enhances the expression of natriuretic peptide precursor C (*Nppc*) mRNA in mural granulosa cells.[482–485] The active peptide, C-type natriuretic peptide (CNP), is the ligand for the membrane guanylyl cyclase receptor NPR2 (natriuretic receptor B). NPR2 is expressed predominately in cumulus granulosa cells, to a lesser extent in mural cells, and not in oocytes.[482] The addition of CNP to cumulus–oocyte complexes elicits a rise in cGMP levels in both cumulus granulosa cells and oocytes; meiotic arrest is not maintained in oocytes from mice that are null for either *Nppc* or *Npr2*.[482] cGMP is believed to diffuse from the granulosa cell continuum into oocytes via gap junctions. Mice deficient in the major gap junction protein that connects cumulus cells and oocytes, Gja4 (Connexin 37), are infertile.[486] Expression of NPR2 in cumulus cells and the inner layer of mural granulosa cells is stimulated by oocyte-derived bone morphogenic protein 15 (BMP15), growth differentiation factor 9 (GDF9), and fibroblast growth factor 8B (FGF8B).[482]

Response to LH. The surge of LH rapidly reduces mural granulosa cell NPR2 activity[484] and more slowly reduces the expression of NPPC,[483] resulting in reduced levels of CNP in cumulus cells[484] (Figure 20.14). Additional pathways, described below, contribute to a rapid decrease in levels of cGMP in the oocyte.[477,487] The cGMP-dependent inhibition of the cAMP-hydrolyzing PDE3A is relieved, cAMP is hydrolyzed to 5′AMP, and PKA activation ceases.[474] As a result, CDC25B relocates to the nucleus[488] to dephosphorylate/activate CDK1, and meiosis resumes.

LH promotes rapid activation of ERK in mural granulosa cells via a PKA-dependent pathway[449] (Figure 20.13). LH also promotes the PKA-dependent[451] transactivation of the EGF receptor (ErbB1) in mural granulosa cells, leading to the sustained activation of ERK in mural and especially cumulus granulosa cells.[23,451,489] As described earlier, LH enhances expression of EGF-like ligands, especially epiregulin and amphiregulin, by mural granulosa cells. These EGF-like ligands act in an autocrine manner on mural granulosa cell EGF receptors and in a paracrine manner by diffusing through follicular fluid/extracellular spaces to activate EGF receptors in cumulus granulosa cells.[23] As a result, EGF receptor activation in cumulus cells is somewhat delayed compared to that in mural cells.[23,487] Expression of the EGF receptor on cumulus granulosa cells is regulated by oocyte-derived GDF9 and BMP15 via SMAD2/3 dependent pathways[490]; expression of EGF receptors in mural granulosa cells is regulated by FSH.[19]

Consistent with a major role for amphiregulin and epiregulin as mediators of LH actions, recombinant amphiregulin or epiregulin has been shown to mimic many of the responses elicited by LH, including cumulus expansion,[369,491] oocyte maturation,[487] and induction of genes required for ovulation, such as *Pgr* and *Ptgs2*.[369] Moreover, these responses are consistently inhibited by the EGF receptor antagonist AG1478 and are blunted with reduced expression paradigms for the EGF receptor.[369,487,489,492]

Amphiregulin has also been shown to promote a rapid decline in cGMP levels via mechanisms that are poorly understood but do not appear to be via activation of cGMP phosphodiesterases.[477,487] The pathway is inhibited by the EGF receptor antagonist AG1478, but cGMP levels are still greatly reduced in granulosa cells of mice with a conditional deletion of the EGF receptor, suggesting the presence of an alternative secondary pathway by which LH rapidly reduces cGMP levels.[487]

One of the major targets activated downstream of amphiregulin/EGF receptor in cumulus granulosa cells is ERK (Figure 20.13). Activated ERK closes the gap junctions that connect adjacent cumulus granulosa cells by directly phosphorylating connexin 43 on Ser255 and Ser262,[487] an event that contributes to, but apparently is not required for, oocyte maturation.[493] Activated ERK is necessary[369] but not sufficient for oocyte maturation and does not appear to contribute to the rapid fall in follicle cGMP induced by amphiregulin.[487] Activated ERK is required for expression of key cumulus expansion genes, such as *Has2* (hyaluronan synthase) and *Ptx3* (pentraxin-related protein), that generate the mucified, hyaluronan-rich matrix that contributes to the expansion of the cumulus cells surrounding the oocyte.[23,369] Activated ERK contributes to the expression of C/EBPβ (CCAAT-enhancer binding proteinα/β), and directly phosphorylates C/EBPβ.[369] ERK-induced C/EBPβ is necessary for amphiregulin to induce expression of genes required for ovulation, including *Pgr* that encodes for the progesterone receptor[369]; *Pgr* null mice do not ovulate.[374] C/EBPβ is also required for amphiregulin to promote expression of *Ptgs2* that encodes the rate-limiting enzyme for PGE2 synthesis.[23] PGE2 appears to function in a critical autocrine regulatory loop that increases the expression of amphiregulin and epiregulin by cumulus granulosa cells that in turn functions to sustain the actions of these EGF-like ligands[491] (Figure 20.13). Cumulus granulosa cells of *Ptgs2*-null mice express greatly reduced levels

of epiregulin and amphiregulin in response to an ovulatory concentration of hCG[491] and *Ptgs2*-null mice do not ovulate.[373] PGE2 via its receptor (EP2 subtype, *Ptger2*) and a cAMP/PKA pathway also promotes expression of *Tnfaip6* that contributes to cumulus expansion.[370,494] C/EBPβ is also required for expression of the EGF-like ligand type III neuroregulin I that, together with amphiregulin, apparently contributes to the fidelity of the expression of cumulus expansion genes.[455] C/EBPα/β-null mice exhibit normal cumulus expansion but fail to ovulate.[495] These results suggest that C/EBPβ targets are not required for cumulus expansion.

A potential mechanism to downregulate or modulate expression of C/EBPβ targets following ovulation was provided by evidence that theca and subsequently granulosa cells express a basic leucine zipper transcription factor, NFIL3 (nuclear factor interleukin-3), that can bind to the same response elements as C/EBPβ and CREB.[496] These proteins are expressed 8–24 h post hCG, and appear to act as repressors by competing with C/EBPβ and CREB for binding sites on both *Ptgs2* and *Areg* promoters. Overexpression of NFIL3 by adenoviral transduction of granulosa cells greatly reduces expression of *Areg*, *Ereg*, *Pgr*, and *Ptgs2* mRNA.[496]

The importance of ERK activation to oocyte maturation and ovulation was elegantly demonstrated with the conditional knockout of *Mapk1/3* (ERK 2/1) from granulosa cells using the *Cyp19a1-Cre*.[369] Mice did not exhibit cumulus expansion in response to hCG, due to a lack of expression of cumulus-expansion genes, and did not ovulate due, in part, to the absence of *Pgr* and *Ptgs2* expression (Figure 20.13). The absence of ERKs in cumulus granulosa cells prevents exogenous amphiregulin from stimulating cumulus expansion genes and genes required for ovulation. Oocyte maturation is also prevented, although how ERK contributes to this process is not clear. Follicles exhibit the normal initial increases in amphiregulin and epiregulin in response to hCG, but the induction is not sustained, likely as a result of the absence of PGE2 resulting from the absence of *Ptgs2* gene expression.

The conditional knock-in of a constitutively K-RAS, driven by *Cyp19a1-Cre*, that leads to activation of the ERK signaling pathway results in defects in cumulus expansion, oocyte maturation, and ovulation.[216] The majority of luteinized follicles exhibited entrapped oocytes. These results support a critical role for the appropriate regulation of ERK activation in response to the LH surge.

EGF receptor activation also appears to signal to activate p38 MAPK (MAPK14), based on reduced p38 MAPK phosphorylation (~50%) with conditional deletion of EGF receptor from granulosa cells.[487] p38 MAPK also appears to contribute to the phosphorylation of connexin 43, based on reduced phosphorylation of both Ser262 and Ser255 (50–60%) in follicles pretreated with the p38 inhibitor SB202190. The conditional deletion of p38 MAPK from granulosa cells had no effect on fertility.[497] However, while cumulus oocyte complexes respond normally to amphiregulin with the induction of cumulus expansion genes, *Areg* and *Ptgs2*, they fail to respond to PGE2, suggesting that the PGE2 regulatory loop in cumulus cells is mediated by p38 MAPK. Mural granulosa cells appear to compensate for the reduced expression of amphiregulin on cumulus cells by expressing elevated levels of amphiregulin and epiregulin.[497] One interpretation of these data is that while p38 MAPK contributes to EGF receptor-regulated pathways in cumulus cells, it is not essential.[474]

Ovulation

Ovulation requires both *Pgr* and *Ptgs2* induction by the LH signals that transactivate the EGF receptor leading to ERK activation and expression of C/EBPβ, as discussed earlier. PDE4D-null mice do not ovulate as a consequence of severely reduced expression of both *Pgr* and *Ptgs2*.[34] Reduced expression of these genes likely reflects the altered cAMP production that is two- to three-fold reduced and no longer transient. However, oocyte maturation and luteinization appear to be normal. Similarly, in anovulatory PGR-null mice, *Ptgs2* is induced, *Cyp19a1* is downregulated, luteal cells express *Cyp11a1*, and entrapped oocytes are functional.[377] Remodeling of the follicle wall is also believed to require one or more metalloproteinases, based on the ability of pharmacological inhibitors of this family of enzymes to block follicle rupture.[498] ADAMTS-1, a PGR target,[378] has recently been identified as a metalloproteinase that is required for follicle rupture; ADAMTS-1-null mice exhibit a 75% reduction in the rate of ovulation.[499] The proteoglycan versican is a major target of ADAMTS-1. Versican is induced by the LH surge in mural granulosa cells by a pathway that is independent of *Pgr* and *Ptgs2*, it binds hyaluronan, and relocalizes to the granulosa/theca cell boundary and to the cumulus oocyte complex.[500] ADAMTS-1-null mice exhibit a 75% reduction in versican cleavage at the granulosa/theca cell interface and within expanding cumulus cells.[500] ADAMTS-1-null mice also fail to exhibit the characteristic invagination at the theca cell border that is involved in vascularization of the follicular structure required for corpus luteum formation.[500] The remaining 25% of versican cleavage is presumably mediated by additional unidentified proteases.

The absolute requirement of *Pgr* expression for ovulation suggests that its ligand, progesterone, is required to activate PGR-regulated genes.[501] Progesterone production by mural granulosa cells requires induction of *Cyp11a1* and *Star*.[380,502] Reduced progesterone biosynthesis decreases ovulation rates.[503] Progesterone accumulation in granulosa cell medium also requires

dynamic reorganization of the actin cytoskeleton.[504] The key downstream target whose phosphorylation is regulated by hCG is the actin depolymerizing factor cofilin. Cofilin phosphorylated on Ser3 does not bind actin filaments, while dephosphorylated cofilin binds actin and enhances actin dynamics. hCG in a PKA-dependent manner, independent of ERK, inhibits the pathway from RHOGTP via RHO kinase and Lim kinase that stimulates the phosphorylation of cofilin on Ser3. hCG promotes inactivation of RHO (converting RHOGTP to RHOGDP), leading to the dephosphorylation/activation of cofilin. Transduction of granulosa cells with an adenoviral cofilin phospho-mimic, cofilin Ser3Glu, reduces hCG-stimulated progesterone production by 70%.[504] These results show that the surge of LH also regulates intracellular signaling pathways distinct from those leading to transcriptional regulation (see Figure 20.13).

Ovulation and cumulus expansion also require the orphan nuclear receptor LRH-1 (*Nr5a2*).[335] Conditional deletion of *Nr5a2* from granulosa cells, driven by *Amhr2-Cre*, abrogates LH-induced expression of *Ptgs2* and its target *Tnfaip6*, thus blocking cumulus expansion, as well as expression of *Star* and *Cyplla1*, thus preventing progesterone production and ovulation.[335] *Nr5a2*-null mice also fail to downregulate *Cyp19a1*, resulting in elevated estrogen production. The LH-induced downregulation of estrogen expression appears to be required for *Ptgs2* expression, based on evidence that *Sult1e1*-null mice, that fail to express the enzyme estrogen sulfotransferase that inactivates estrogen, exhibit elevated estrogen and reduced expression of both *Ptgs2* and *Tnfaip6*.[505] One relevant LRH-1 target in granulosa cells that appears to be required for downregulation of *Cyp19a1* is *Nos3*.[335] *Nr5a2*-null mice expressed reduced levels of *Nos3* mRNA, and CHIP assays show direct binding of LRH-1 to the *Nos3* promoter.[335] As discussed under the AKT target eNOS, *Nos3*-null mice exhibit reduced ovulation rates and oocyte maturation, and a marked increase in estrogen levels following the LH surge (rather than a decrease).[333,334] Together these results suggest that LH signals via the nuclear receptor LRH-1 not only to enhance expression of *Star* and *Cyplla1* but also to promote expression of *Nos3*. LH also potentially promotes activation of the *Nos3* product eNOS that is some manner is required for the downregulation of *Cyp19a1* and consequent upregulation of *Ptgs2*. However, the mechanism by which LH regulates LRH-1, how eNOS contributes to *Cyp19a1* downregulation, and how elevated estrogen inhibits expression of Ptgs2 are not known.

Luteinization

Luteinization defines a program of terminal differentiation that converts mural granulosa cells and theca cells to luteal cells. Proliferation ceases, the structure formed following ovulation becomes highly vascularized, and luteal cells produce high levels of progesterone. Genes specific to granulosa cells are downregulated, and genes required for luteal function are upregulated.

The LH surge suppresses granulosa cell proliferation by promoting downregulation of cyclin D2, encoded by *Ccnd2*,[45] and upregulation of cell cycle inhibitors $p21^{Cip1}$ and $p27^{Kip1}$,[45,381] encoded by *Cdkn1a* and *Cdkn1b*. Conditional deletion of ERK1/2 from granulosa cells prevents cell cycle arrest and luteinization.[369] Although luteinization is associated with cell cycle arrest, luteinization and exit from the cell cycle are independent responses to the surge of LH. Thus, in both $p27^{Kip1}$-null[381,506] and $p27^{Kip1}/p21^{Cip1}$ double-null mice,[381] preovulatory follicles undergo ovulation and luteinization to form a corpus luteum in response to the LH surge even when granulosa cells continue to proliferate, as evidenced by retention of cyclin D2 expression and high bromodeoxyuridine incorporation in cells expressing *Cyp11a1*. In cyclin D2–null mice, follicles do not ovulate, potentially due to reduced cumulus cell numbers,[507] but granulosa and theca cells still luteinize in follicles with entrapped ova.[44] Similarly, in PDE4D and C/EBPα/β-null mice, granulosa and theca cells luteinize without release of oocytes.[34,369]

Progesterone production is the hallmark of a functional corpus luteum. The preovulatory surge of LH accordingly induces the persistent and elevated expression of the rate-limiting enzyme in progesterone synthesis *Cyp11a1*[380] and the cholesterol-mobilizing protein *Star*.[376] Expression of both genes is blocked by conditional deletion of *Mapk1/3*[369] and *Cebpa/Cebpb*[495] from granulosa cells and reduced in mice conditionally expressing partially inactive EGF receptors.[492] These results show that ERK activation downstream of LH-stimulated EGF receptor transactivation is necessary to promote expression of both *Star* and *Cyp11a1*. Expression of both genes, however, requires input from additional signaling pathways.[48,353,355,367,369,495]

Luteinization involves the silencing of a number of genes induced by FSH that define the preovulatory phenotype, such as *Inha* and *Cyp19a1*. The surge of LH induces permanent silencing of the *Inha* gene in the rodent. Repression of inhibin expression during the periovulatory time window permits the secondary surge of FSH on the morning of estrous that contributes to follicle recruitment.[508] Reduced *Inha* transcriptional activity is initially accomplished by the rapid, albeit transient, induction in mural granulosa cells of the immediate early gene *Crem* (cAMP response element modulator) that encodes the inducible cAMP early repressor ICER.[346] ICER, along with CREB, C/EBPβ, and NFIL3 are basic leucine zipper transcription factors that bind DNA and homo- or heterodimerize to activate or repress transcription. As shown by CHIP assays, ICER competes with

phospho-CREB-Ser133 homodimers for occupancy of the cAMP response element on the *Inha* promoter.[509] As a result, the multiprotein complex that promotes transcription assembled on the CREB-occupied *Inha* promoter is disassembled, and *Inha* transcription ceases. Consistent with the transient induction of ICER, a second immediate early gene C/EBPβ is induced by 1 h and persists for 24 h that continues to repress transcription from the *Inha* promoter.[510] C/EBPβ-null mice do not form corpora lutea[511] and do not exhibit *Inha* downregulation following injection of hCG to PMSG-primed mice.[510] Although C/EBPβ can form inactive heterodimers with CREB, the predominant repressive mechanism appears to be via the binding of C/EBPβ homodimers to a nonconcensus binding site.[510]

Recent results show that histone modifications, which alter the accessibility of DNA to transcriptional activators, temporally followed by DNA methylation that further reduces binding of transcriptional activators, additionally contribute to LH-induced *Inha* silencing.[512] CHIP assays showed that histone H3 trimethylated on Lys4 (H3K4me3), a modification linked to active genes, was enriched on the *Inha* promoter in preovulatory cells, obtained 48 h post PMSG, and then declines 18–20 h post hCG. Conversely, histone modifications linked to repressed genes, H3K27me3 and H3K9me3, are low in preovulatory cells and substantially increase in ovulatory cells and further increase in luteal cells obtained 6 days post hCG.[512] DNA methylation within the cAMP response element, as determined by bisulfite sequencing, is low in preovulatory and ovulatory cells and markedly enhanced in corpora lutea. It is hypothesized that the repressors like ICER and C/EBPβ recruit histone-modifying enzymes that promote methylation of Lys27 and Lys9, and that these histone modifications contribute to recruitment of DNA methylation enzymes. Together these modifications prevent the binding of CREB and other transcriptional activators to *Inha*, resulting in its silencing.

Cyp19a1 is also downregulated as a result of the LH surge, at least in part as a negative-feedback pathway to release the hypothalamic–pituitary axis from stimulatory effects of estrogen that initiated and sustained the surge of LH. Mechanisms of repression at the promoter are less well defined for *Cyp19a1* compared to that for *Inha*. The immediate-early orphan nuclear receptors NR4A2 (nuclear receptor subfamily 4 group A member2)/NURR1 and NGF1B (nerve growth factor 1B)/EGR-2 have been implicated in the negative regulation of the *Cyp19a1* gene after the LH surge, using human granulosa-like tumor cell line, KGN, based on promoter-luciferase results and siRNA(silencing RNA)-mediated downregulation of *Nurr1*.[465] *Nurr1* and *Egr-2* mRNAs are rapidly and transiently upregulated in gonadotropin-primed rat ovaries in response to hCG, the former via a PKCζ pathway.[438] A member of the *Jun* family of immediate early genes may also contribute to the downregulation of *Cyp19a1* by binding to the cAMP response element usually occupied by phospho-CREB(Ser133).[513] The redistribution of CREB from the nucleus to the cytoplasm during luteinization may also contribute to the downregulation of targets such as *Cyp19a1*.[122]

ERK is required for *Cyp19a1* downregulation. ERK1/2-null mice do not exhibit *Cyp19a1* downregulation in response to an ovulatory concentration of hCG[369] (Figure 20.13). C/EBPα/β-null mice exhibit the same phenotype,[495] consistent with evidence that expression and activation of C/EBPβ is dependent on ERK1/2 activation[369] and with evidence of the repressive actions of C/EBPβ.[510] Likewise, granulosa cells expressing EGF receptors with compromised receptor tyrosine kinase activity exhibit decreased C/EBPβ and fail to downregulate *Cyp19a1*[492] (see Figure 20.13). Activation of the EGF-receptor/ERK1/2/C/EBPβ pathway is also required for the downregulation of *Fshr*[369,492] and *Lhcgr*,[369] and for the upregulation of *Cyp11a1*,[369,492,495] *Star*,[369,495] the estrogen-inactivating enzyme *Sult1e1*,[369] and runt-related transcription factor *Runx2*.[495,514] *Cyp19a1* downregulation also appears to be a consequence of LRH-1-induced *Nos3* expression,[335] as discussed earlier in "Ovulation," although the mechanism by which eNOS contributes to *Cyp19a1* expression is not known. As with *Inha*, the downregulation of *Cyp19a1* is linked with inactivating histone modifications, while the upregulation of *Star* is linked with activating histone modifications.[515] Similarly, DNase1 protection assays suggest that hCG enhances chromatin condensation for *Cyp19a1* and reduced chromatin condensation for *Star*.[515]

The ovulatory surge of LH promotes a transient downregulation of LH receptors that recover some 48–72 h later, in a species-specific manner, with the formation of the corpus luteum. LH receptor downregulation in granulosa cells is relatively slow, with a T1/2 of at least 8.5 h,[421–423] compared to that of most other GPCRs.[86,516] LH receptor downregulation in response to an hCG bolus has been extensively studied, as described below, using day-5 corpora lutea from superovulated pseudopregnant rats as a model. Recent studies have used primary cultures of human granulosa cells with equivalent results. A decline in *Lhcgr* mRNA is first detected ~ 6 h post hCG; *Lhcgr* mRNA is undetectable by 12 h post hCG, by northern analysis.[517] However, unlike the downregulation of *Inha* and *Cyp19a1*, there is no change in the rate of *Lhcgr* transcription. Rather, hCG promotes increased *Lhcgr* mRNA degradation.[518] Enhanced *Lhcgr* mRNA degradation is mediated by a 50 kDa LH receptor mRNA-binding protein (LRBP)[519] identified as mevolanate kinase.[520,521] Suppression of LRBP expression abrogated the ability of hCG to downregulate *Lhcgr* mRNA, suggesting that LRBP is not only

necessary but sufficient for this regulation.[522] LRBP binds an 18-base pair sequence within the coding region of *Lhcgr* mRNA.[519] LRBP binds *Lhcgr* mRNA at the ribosome, yielding an untranslatable complex that is targeted for degradation.[523] *Lhcgr* mRNA downregulation and the two-fold upregulation of LRBP protein detected 12 h post hCG is prevented by H89, consistent with a PKA-dependent response.[524] *Lhcgr* mRNA downregulation is also reversed by the ERK1/2 inhibitor U0126. The requirement of ERK1/2 activation for *Lhcgr* mRNA downregulation is supported by results with ERK1/2-null mice that fail to show a decline in *Lhcgr* mRNA post hCG.[369] The relevant ERK1/2 target has not been identified, but might be LRBP itself, especially since LRBP is readily detectable in granulosa cell extracts in the absence of hCG, consistent with regulation by a posttranslational mechanism.[524] While the mechanism by which surface LH receptors are downregulated in granulosa cells and corpora lutea following a bolus of LH or hCG has been clearly defined, the physiological consequence of blocking this response, especially in granulosa cells, has not to our knowledge been investigated.

MOLECULAR BASIS FOR THE DIFFERENTIAL REGULATION OF TARGET GENE EXPRESSION BY FSH IN PREANTRAL AND LH IN PREOVULATORY GRANULOSA CELLS

There have been many advances in the seven years since we last reviewed the cellular signaling pathways by which FSH and LH regulate target gene expression. Cyclic AMP/PKA play a major role in the actions of FSH and LH in granulosa cells. Despite the fact that these two gonadotropins are structurally related, act on similar receptors, and signal predominantly through cAMP-dependent mechanisms, FSH and LH elicit very different responses in preantral versus preovulatory granulosa cells. For example, FSH acts via cAMP/PKA to activate transcription of target genes such as *Cyp19a1*, *Inha*, and *Lhcgr* in preantral granulosa cells but does not stimulate expression of the *Ptgs2* or *Pgr*, whereas LH has the opposite effects in preovulatory granulosa cells and stimulates the downregulation of *Cyp19a1*, *Inha*, and *Lhcgr*, and activates transcription of the *Ptgs2* and *Pgr* genes. Thus, a central question in reproductive biology is how the same second messenger/effector exerts such different responses during the continuum of granulosa cell differentiation. Are the different responses attributable to the activation of distinct signaling pathways, such as only PKA for FSH and PKA plus PKC for LH, or to the duration of signaling? Or, do the different responses of the two cell types reflect the fact that preovulatory granulosa cells have differentiated and contain a different proteome, including distinct AKAPs, kinases, phosphatases, transcription factors, and other regulators important in generating their unique response?

To address the question of different signaling pathways for FSH versus LH, Zeleznik's group[115,133] cleverly investigated target gene expression after adenoviral transduction of preantral granulosa cells with constitutively active LH receptors (Asp578His). Results from these experiments showed that the LH receptor expressed in preantral cells partially mimics the responses of FSH and induces *Inha* and *Hsd3b2* but interestingly does not induce or minimally induces *Cyp19a1* or *Lhcgr*, even when cAMP levels are equivalent. These results suggest that these two GPCRs not only couple to overlapping signaling pathways but also appear to couple, perhaps more efficiently, to different signaling pathways to regulate distinct cellular events in preantral versus preovulatory granulosa cells.

Alternatively, rather than there being different second messengers generated by FSH versus LH receptor activation in preantral versus preovulatory granulosa cells, differences in the amount, duration, or cellular location of cAMP may distinguish FSH signaling from that of LH signaling. It is well known that sustained FSH at relatively low concentrations is necessary to stimulate granulosa cell differentiation,[106] whereas a bolus of LH is required to stimulate ovulation. Indeed, it has been proposed that the actions of LH and FSH are distinct in mature versus immature granulosa cells as a result of the ability of LH receptor activation in mature cells to generate greater levels of cAMP.[525] Although this view is supported in mature, preovulatory granulosa cells by the observation that high doses of recombinant FSH can substitute for LH/hCG in promoting ovulation and luteinization in the rat,[526] high levels of cAMP in immature cells do not seem to mimic actions of the LH surge in mature cells.[115,133] To our knowledge, it is not known if overexpression of the constitutively active LH receptor in immature cells promotes induction of genes characteristic of mature cells, such as *Pgr* and *Ptgs2*; however, the reduced expression of *Cyp19a1* and *Lhcgr* are reminiscent of downregulated genes in mature cells.

FSH and LH receptor activation also regulate the expression of the cAMP degrading PDEs.[527] PDEs certainly participate in LH receptor signaling because PDE4D-null mice exhibit an ovulation defect.[527] However, the contribution of the PDEs to the distinct signaling by FSH and LH receptors in immature and mature granulosa cells is not fully understood. There is also abundant evidence for the cellular compartmentalization of cAMP in various cellular models.[143,528] Consistent with the conceivably restricted production of cAMP in select cellular sites, PKA is recognized to be anchored to select cellular locations by the growing family of AKAPs.[142] Potentially, then, the distinct expression

of one or more AKAPs between immature and mature granulosa cells could also localize PKA and distinct PKA substrates to different cellular locals and account for distinct signaling in immature versus mature cells by FSH versus LH receptors. That PKA regulates ERK activity by distinct mechanisms in preantral versus preovulatory granulosa cells,[113,449,529] and the more prominent role of ERK signaling in preovulatory versus preantral cells[369] indicates that these two cell types are indeed quite distinct and that preovulatory cells are not simply preantral granulosa cells that express, for example, LH receptors.

CONCLUSION

As reviewed in this chapter, tremendous progress has been made in understanding mechanisms of gonadotropin action in regulating ovarian follicle maturation, oocyte maturation, and ovulation, and luteinization. The structures of FSH and hCG are now known to atomic level resolution; there is a fundamental understanding of the gonadotropin receptors and how they selectively bind FSH and LH; it is clear that cAMP serves as the key second messenger for nearly all gonadotropin actions in the ovary; substantial inroads have been made in defining the signaling pathways activated by gonadotropins; and many of the target genes activated by FSH or LH have been identified and their physiologic functions explored. In addition, genetic studies in mice and naturally occurring mutations in women have verified the fundamental importance of the gonadotropins and their receptors to ovarian function and allowed new insight into the precise stages and processes in which they act. Finally, some insight into what differentiates FSH and LH action in the ovary is now being obtained.

Despite this wealth of information, much remains to be learned about gonadotropin signaling pathways in the ovary. While the crystal structure of FSH in complex with the extracellular domain of the FSH receptor was recently reported,[62] the complete structures of the gonadotropin receptors, extending to the full-length proteins, are needed to gain further insight into hormone-binding selectivity and into the conformational changes that underlie receptor activation and G protein coupling. The recent ability to solve crystallographic structures of several model GPCRs sets the stage for these future challenges. Studies to more fully understand the tissue- and cell-specific expression and hormonal regulation of the gonadotropin receptors are also important. Although some of the major signaling pathways downstream of gonadotropin-regulated cAMP generation have been explored in depth, as discussed in this chapter, others are just beginning to be appreciated, and more detailed analyses are required. New advances in proteomics are likely to be important here, particularly methods to carefully examine the phosphorylation status of kinase target proteins in ovarian cells and to more fully characterize the kinases and phosphatases involved in particular regulatory events. As discussed, limited data also point to activation of additional signaling mechanisms via cAMP-independent pathways in ovarian cells, and this is an area worthy of further investigation. A wealth of new information is accumulating from gene expression profiling and other high throughput analyses with respect to potential target genes activated by gonadotropin signaling, and verifying these targets, establishing mechanisms of their regulation, and exploring their functions in the ovary promises to be a significant focus of future work.

Cross talk between signaling pathways is an often discussed but poorly understood aspect of signaling that is likely to be increasingly important as we begin to understand the molecular details of individual pathways. It will be particularly valuable to understand how gonadotropin signaling integrates with the many other signaling pathways important for follicle formation and maintenance. For example, TGFβ family proteins play numerous roles in cell communication in the follicle, but little is known regarding how these pathways impact gonadotropin signaling and vice versa. Similarly, understanding how other signaling pathways influence the fundamental processes of cell proliferation, cell differentiation, and cell death in the ovary, and how gonadotropin action might modify these events remains a key challenge.

We raised the issue of spatially regulated signaling as it relates to the AKAPs and their roles in determining cell-specific responses to cAMP, but the broader issue of spatially restricted signaling domains is likely to be an important one that applies to many pathways and contributes in a significant way to tissue- and cell-selective responses. Further characterization of such spatial domains in ovarian cells is warranted. This also reinforces the view that signaling principles learned in generic cell systems are not always applicable to granulosa or theca cells and must be tested in the ovary. The temporal aspects of regulation are likely to be just as important. We broadly define for the purposes of this discussion preantral and preovulatory granulosa cells as distinct stages of differentiation in the follicle that respond differentially to the gonadotropins, yet the reality is that there is a continuum of differentiation states that defines the precise nature of the response to gonadotropins or other stimuli.

Gene disruption technologies in mice have been an integral component of studies of gonadotropin signaling pathways. A significant number of gene knockouts yield reproductive phenotypes, and as discussed throughout the chapter, these mice have been invaluable in establishing roles for particular signaling proteins and pathways

in the ovary. However, many gene disruptions are not particularly informative with respect to reproduction because of early lethality or broad spectrum phenotypes that impact reproduction in an indirect fashion. Thus conditional disruption approaches, including both ovary-specific and temporally regulated knockouts, are likely to be very informative for deciphering details of gene and protein functions in gonadotropin-dependent signaling. In the same vein, recent advances in RNA interference technologies that include in vivo delivery hold much promise for downregulating selective gene products in targets like the ovary so as to establish their functional importance.

Finally, studies of gonadotropin action in the ovary continue to be informed by clinical investigation and genetic analysis of reproductive disorders, and this is an area that will surely receive much more attention in the future. Naturally occurring mutations in the gonadotropins and their receptors provide a rich context in which to learn about interaction with and activation of the gonadotropin receptors. An increasing number of mutations in signaling molecules and transcription factors exhibit some reproductive phenotype, and these are tremendously informative in inferring the functional importance of particular genes and pathways. Even complex diseases that impact the ovarian reserve, leading to premature ovarian failure, or that impact follicle maturation, leading to polycystic ovarian syndrome, are now being explored in genetic detail, and aspects of gonadotropin signaling will likely come into play in these as well. Thus, the future holds much promise for better understanding the molecular details of how FSH and LH function as master regulators in the maturation, ovulation, and luteinization of the ovarian follicle.

Acknowledgments

INTRODUCTION

The first scientists in gonadal biology were likely farmers in antiquity that spayed and neutered female and male animals in order to, respectively, control fertility and behavior. Aristotle (384–322 BC) believed that the male provided the "seed" that grew within the female "soil."[1] Galen (129–199 AD) and Soranus of Ephesus (c. 50 AD) described ovarian structures and possibly believed that a female seed existed.[2] After Galen, there was not much written about reproduction for over 1000 years. By the sixteenth century, ovaries had been described by Leonardo Da Vinci, Berengario da Carpi, Andreas Vesalius, Gabrielle Fallopio, and Hieronymus Fabricius. Andreas Vesalius also appreciated the existence of follicles within the ovary and described what was likely a corpus luteum. In the seventeenth century, William Harvey proclaimed "ex ovo omnia," or everything comes from the egg.[3] However, Harvey was most likely referring to the products of conception rather than the germ cell, as he did not believe that the ovary had much to do with conception. Niels Stensen and Regnier de Graaf believed that the whole follicle was the egg that became fertilized in the ovary and that only the fertilized egg escaped the ovary, while others at that time thought that follicular fluid was female semen.[4] It took another 150 years for von Baer in 1827 to discover that the egg within the follicle was the "female seed." The seventeenth century also saw the rise and fall of preformationists, who believed that we are derived from miniature versions of ourselves (i.e., we are all preformed).[5] Although preformationists are considered incorrect, we now know that oocytes store proteins and RNAs necessary for fertilization and early embryogenesis, and hence we are "preformed" to a certain degree at the molecular level. In this chapter, we will focus on the current understanding of ovarian folliculogenesis and, where appropriate, touch upon some of the controversies that exist in the field.

Folliculogenesis is the process by which the female germ cell develops within the somatic cells of the ovary and matures into a fertilizable egg.[6–8] Follicle development is complex and involves the integration of signals from multiple organ systems. While early folliculogenesis appears to be directed by signals within the ovary, endocrine hormones from the pituitary are necessary for folliculogenesis to proceed beyond these early stages. In turn, the ovary produces a number of feedback and feedforward hormones that regulate hypothalamic and pituitary function. Within the ovary, cross-talk between the oocyte and the somatic-derived granulosa and theca cells occurs at every stage for normal follicle development.[9] Advancing genetic and genomic technologies have accelerated our understanding of the genetics and physiology of reproduction. Complete genome sequences are available for many organisms, including the human, rat, mouse, chicken, cow, pig, dog, sheep, and cat, and, together with rapidly improving sequencing technologies, are allowing a much faster discovery of reproductively relevant

naturally occurring mutations in humans and other animals. In addition, large-scale sequencing of cDNA libraries generated from a variety of human and rodent tissues, including newborn and adult ovaries and isolated oocytes, is leading to the unprecedented discovery of many novel genes that are critical for reproductive processes.[10–13] Large-scale projects to determine the functional significance of the genome have shown that a substantial portion appears to either bind various regulatory proteins or transcribe small and long noncoding RNAs in addition to the protein-coding genes.[14] In addition, genome-wide association studies identified multiple loci that associate with menopause and highlight the importance of DNA repair and immune pathways in reproductive senescence.[15] Many of the loci contain genes not previously known to be involved in ovarian development or folliculogenesis, and they provide new targets for future studies that will have relevance to mechanisms that lead to ovarian senescence. These large-scale genomic projects provide a necessary infrastructure for basic investigators to overlay reproductive developmental pathways.

Genomic manipulation through engineered deletions, point mutations, duplications, and genomic rearrangements in the mouse have allowed investigators to generate new lines of mice lacking key reproductive genes that serve as in vivo models for human diseases, including infertility. The technology to delete mouse genes and generate nonfunctional loci (gene "knockouts") or novel expression patterns (gene "knockins" and transgenic overexpression lines) has resulted in more than 400 mouse models with reproductive phenotypes[16] (Table 21.1). These mice are invaluable for various reasons: they allow us to study physiology in order to infer the functional importance of a particular gene, they can give us insight into the compensatory mechanisms that occur when the particular gene is deleted, they can be used to model treatments of reproductive pathologies, and they can also be used to narrow the candidate genes for particular human disorders. One of the most instructive examples has been the mouse mutants for follicle-stimulating hormone (FSH) and its receptor, FSH receptor (FSHR), which closely mimic humans with mutations in these genes[21–24] (as discussed in this chapter).

A number of searchable internet-based databases are available for investigators interested in genes that have a reproductive function. Jackson Laboratories (http://www.jax.org) maintains an extensive website with complete mouse genome informatics where information can be queried under individual genes, and it includes detailed information about the expression and phenotypes of spontaneous and targeted mutations as well as relevant references. The Ovarian Kaleidoscope database (http://ovary.stanford.edu) keeps up-to-date information on the expression, function, and regulation of genes expressed in the ovary.[25] The National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov) has databases of genomes, sequences of many transcriptomes, and invaluable tools for analyzing and discovering genes important in ovarian development. Other online resources include the Mammalian Reproductive Genetics database (http://mrg.genetics.washington.edu), a database of the genes and literature relating to reproduction that is searchable by phenotype or expression pattern; and the GermOnline database (http://germonline.unibas.ch), a database of microarray expression data for genes relevant to mitosis, meiosis, and gametogenesis.

This chapter focuses on the development and analysis of mouse models for the study of follicle development. Although the emphasis is placed on mouse models, relevant studies in primates, including humans, and sheep are included where data are available. Understanding reproduction through the manipulation of the mouse genome has helped us delineate the function of genes important in mammalian ovarian, follicular, and oocyte development. These models are useful for some clinically relevant reproductive disorders and diseases in humans; however, it is also important to bear in mind that species-specific differences in mechanisms exist. Despite these concerns, studies among various species are helpful in delineating general themes that drive ovarian folliculogenesis.

MORPHOLOGY OF FOLLICULOGENESIS

Murine Folliculogenesis

Folliculogenesis is a highly regulated developmental sequence resulting in the growth and differentiation of the oocyte and associated somatic cells. A commonly used classification of oocytes and follicles for mice is that of Pedersen and Peters.[26,27] This classification is based on oocyte size, granulosa cell numbers, and follicular morphology (Figure 21.1). The classification is useful as a means of uniformly describing stages in follicular development. In addition, the commonly used names primordial, primary, secondary, preantral, and antral follicles often are vaguely defined but are useful for general purposes. Neither nomenclature is ideal, as not all follicles with the same oocyte size class share the same developmental fate.

In mice, oocytes enter meiosis during embryonic life, and at birth, some oocytes are in the transitory stages of prophase I (pachytene and early diplotene), while others have entered late diplotene and dictyate, where they will remain arrested until meiosis is again resumed shortly before ovulation. Centrally located within the newborn mouse ovary are oocytes that have been surrounded by a flat, squamous, epithelial-derived layer called the pregranulosa cells; these represent primordial follicles. Subsequently, primordial follicles populate the surface of the developing and adult ovaries. Once formed, primordial follicles are thought to represent the only available source of oocytes during the entire reproductive life span of

TABLE 21.1 Female Reproductive Phenotypes in Genetic Mouse Models

Gene	Name	Mouse Knockout Model: Female Reproductive Phenotype	References
SECRETED FACTORS AND RECEPTORS			
Acvr2	Activin receptor IIA	Infertility; follicles arrest at the early antral stage due to defects in pituitary function	257
Bmp15	Bone morphogenetic protein 15	Background-dependent subfertility; defects in ovulation and fertilization; enhanced defects when haploinsufficient for *Gdf9*$^{+/-}$	260
Bmpr1b	Bone morphogenetic protein receptor, type 1B	Infertility; defects in cumulus cell physiology and endometrium	261
Ccnd2	Cyclin D2	Infertility; granulosa cells do not proliferate in response to FSH	262
Cga	Glycoprotein hormones, alpha subunit	Infertility; FSH and LH deficiency	263
Fst	Follistatin	Complete loss of germ cells by birth; granulosa cell–specific knockout has early ovarian failure	264,265
Fshb	Follicle-stimulating hormone beta subunit	Infertility; preantral follicle block	22
Fshr	Follicle stimulating hormone receptor	Infertility; block prior to antral follicle formation	24
Gdf9	Growth differentiation factor 9	Infertility; arrest of follicle growth at the primary stage	266
Gnrh	Gonadotropin-releasing hormone	Infertility; hypogonadotropic hypogonadism	267
Ghr	Growth hormone receptor	Delayed puberty and prolonged pregnancy	268
Igf1	Insulin-like growth factor 1	Infertility; preantral follicle block	269
Inha	Inhibin alpha	Infertile; develop gonadal sex cord tumors with 100% penetrance	41
Inhba	Inhibin/activin beta A	Perinatal lethality	257
Inhbb	Inhibin/activin beta B	Extended gestation; unable to nurse offspring;	258
Lep	Leptin	Infertility in *ob/ob* mice; hypogonadotropic hypogonadism	270
Lhb	Luteinizing hormone beta	Infertility; hypogonadal; absence of large antral follicles and corpora lutea	271
Lhcgr	Luteinizing hormone/choriogonadotropin receptor	Infertility; folliculogenesis blocked at the antral stage	272,273
Ngfb	Nerve growth factor beta	Reduced primary and secondary follicles	189
Ntrk2	Neurotrophic tyrosine kinase receptor, type 2	Reduced number of secondary follicles and a decrease in granulosa cell proliferation	195
STEROIDS AND RECEPTORS			
Cyp19a1	Cytochrome P450, family 19, subfamily a, polypeptide 1 (aromatase)	Infertility; hypertrophied stromal cells; defects in ovulation; hemorrhagic cysts	274
Esr1	Estrogen receptor 1 (alpha)	Infertility; hemorrhagic ovarian cysts and uterine defects	275
Esr2	Estrogen receptor 2 (beta)	Subfertility; reduced litter sizes and granulosa cell defects	276
Ar	Androgen receptor	Subfertility, disrupted folliculogenesis, premature ovarian failure	277–280
STRUCTURAL PROTEINS/MISC.			
Gja4	Gap junction membrane channel protein alpha 4 (connexin 37)	Infertility; no large antral follicles; defects in ovulation; oocyte defects	281
Gja1	Gap junction membrane channel protein alpha 1 (connexin 43)	Neonatal lethality; neonatal ovaries have germ cell deficiency	282
Ptx3	Pentraxin related 3	Subfertility; defects in ovulation and fertilization	283
Tnfaip6	Tumor necrosis factor alpha–induced protein 6	Infertility; defects in cumulus cell physiology	284

TABLE 21.1 Female Reproductive Phenotypes in Genetic Mouse Models—cont'd

Gene	Name	Mouse Knockout Model: Female Reproductive Phenotype	References
TRANSCRIPTION FACTORS			
Figla	Factor in the germline alpha	Infertility; oocyte loss by postnatal day 2	90
Foxl2	Forkhead box L2	Infertility; absence of secondary follicles and oocyte atresia; follicular depletion	202,203
Foxo3	Forkhead box O3	Infertility by 15 weeks of age; widespread activation of follicle pool	135
Foxo1/3	Forkhead box O1 and forkhead box O3 (conditional)	Conditional *Foxo1/3* deletion in granulosa cells causes infertility and impaired folliculogenesis	285
Hesx1	Homeobox gene expressed in ES cells	Pituitary dysplasia	286
Lhx3	LIM homeobox protein 3	No development of anterior or intermediate lobes of pituitary gland	287
Nobox (Og2x)	Newborn ovary homeobox	Infertility; oocyte loss by postnatal day 14; disrupted primordial-to-primary transition	103
Lhx8	LIM homeobox protein 8	Infertility; oocyte loss by postnatal day 7; disrupted germ cell cyst breakdown, primordial follicle formation, and primordial-to-primary transition	96,100
Sohlh1, Sohlh2	Spermatogenesis and oogenesis specific basic helix–loop–helix 1 and 2	Infertility; oocyte loss by postnatal day 14; disrupted germ cell cyst breakdown, primordial follicle formation, and primordial-to-primary transition	96,98,99
Nr5a1	Nuclear receptor subfamily 5, group A, member 1 (SF1)	Gonadal agenesis; fail to produce FSH and LH	288,289
Prop1	Paired-like homeodomain factor 1	Infertility; multiple anterior pituitary defects and hypogonadism	290,291
Pit1	Pituitary specific transcription factor 1	Infertility; multiple anterior pituitary defects and hypogonadism	292
Otx1	Orthodenticle homolog 1 (Drosophila)	Hypogonadism; age-specific defects in folliculogenesis and fertility	293,294
Taf4b	$TAF_{II}105$ RNA polymerase II, TATA box binding protein (TBP)-associated factor	Infertility; arrest of follicles at preantral stage	295

The Phenotypes of representative female homozygous null mice are described above. There are over 300 genes with mouse mutations that affect ovarian function. Additional citations can be found in the text and in Refs 296–299.

the female. Controversy exists about whether postnatal oogenesis exists, with some investigators interpreting their studies to suggest that a population of oocyte-generating stem cells exists in adult ovaries,[28,29] while others deny such a possibility.[30,31] It remains to be determined whether the challengers of the current dogma (i.e., a fixed oocyte pool) can provide evidence to address criticisms and experimental findings that are difficult to explain if postnatal oogenesis occurs and contributes significantly to overall ovarian physiology. Primordial follicles are accepted by many in the field to represent the "ovarian reserve," or fixed number of germ cells formed following initial arrest in meiosis I that are available for the production of mature, fertilizable oocytes during the reproductive life of the female. Currently, primordial follicle physiology is under intense investigation as defects in the size or activation of the ovarian reserve are thought to limit reproductive life span in women.

Newborn mouse ovaries are densely packed with oocytes, most of which are present in clusters with no evidence of surrounding granulosa cells[27] (Figure 21.2(A),(D)). These oocytes have various terms, including "naked" oocytes, germ cell cysts, clusters, nests, or syncytia, and correspond to Type 1 follicles in the Peters and Pedersen classification.[27,32–34] Germ cell cysts disappear as primordial follicles appear, and the total number of oocytes declines as many oocytes undergo cell death. By postnatal day 3, a class of primary follicles is discernable by the presence of cuboidal granulosa cells and growth of the oocyte beyond 20 μm. These follicles correspond to Type 3a follicles in the Pedersen classification (Figures 21.1, 21.2(B),(E)). Numerous primordial follicles now replace the substantial number of germ cell cysts at the periphery of the ovary. At postnatal day 7, most of the germ cell cysts have disappeared and primordial follicles are the most abundant follicular type, but primary and secondary follicles are present in the medullary region (Figure 21.2). Secondary follicles (Type 4) (Figures 21.1 and 21.2(B),(E)) are distinguished from primary follicles as having more than one layer of granulosa cells as well as acquiring an additional somatic cell layer,

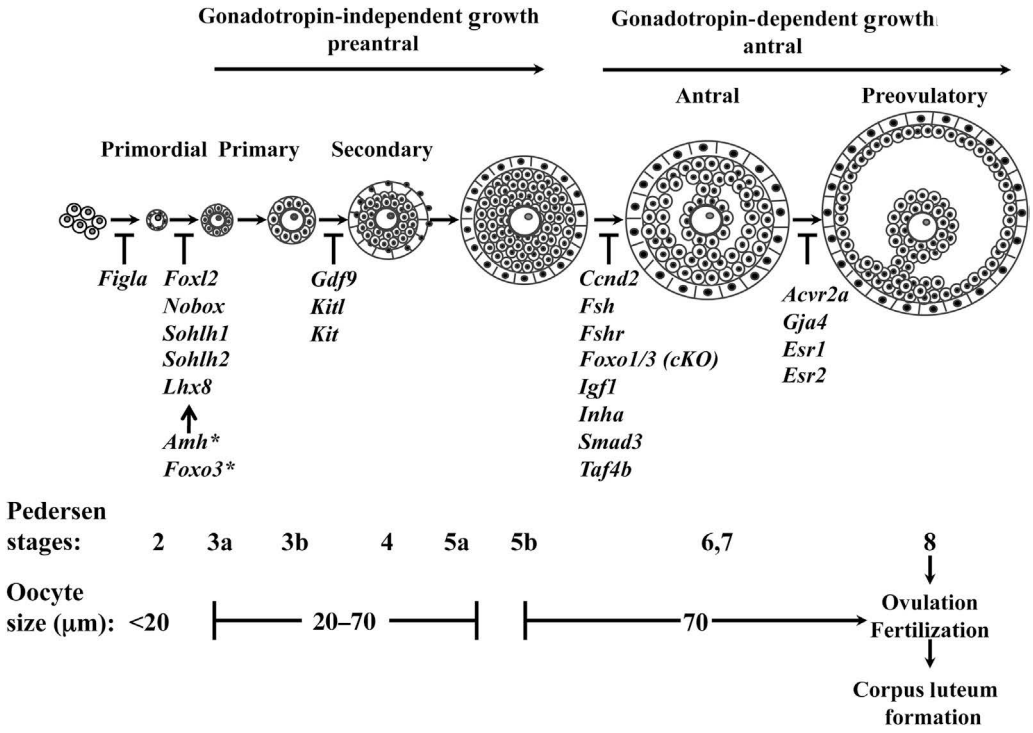

FIGURE 21.1 **Classification of mouse follicles.** From left to right, postnatal follicle development begins at the primordial stage to the antral stage. Prior to antrum formation, follicle growth is independent of pituitary gonadotropins. Following ovulation, granulosa cells undergo luteinization to become the corpus luteum. Pederson classification (Types 2–8) is shown for each stage. Corresponding oocyte diameters for each type are also indicated. A subset of genes implicated at various stages of follicular development is also listed when initial gross disruption is observed in respective mouse knockouts. **Amh* and *Foxo3* knockout mice show accelerated transition from primordial to primary follicles.

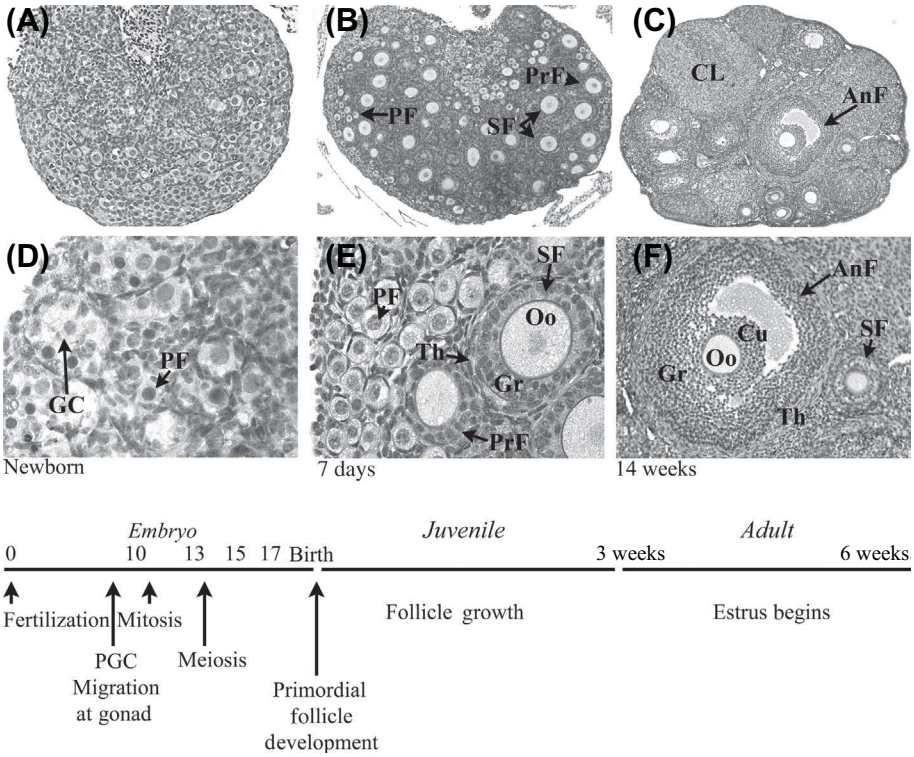

FIGURE 21.2 **Folliculogenesis in the mouse.** Light micrographs depicting follicle stages are shown in panels (A)–(F) above the timeline. Follicle development begins embryonically when primordial germ cells migrate to the developing gonad. By E11–13, the PGCs undergo mitotic division, and by E13.5 they begin meiosis. Oocytes will arrest in meiotic prophase I until ovulation. *Panels (A) and (D)*: Newborn ovaries contain oocytes in germ cell cysts (GCs) and are beginning to form primordial follicles (PFs). *Panels (B) and (E)*: By 7 days after birth, primary follicles (PrFs) and secondary follicles (SFs) have developed. Primary follicles contain a growing oocyte and are surrounded by cuboidal granulosa cells. These further develop into secondary follicles by proliferation of granulosa cells and the acquisition of a thecal cell layer (Th). A 4–5-day estrous cycle begins at 4 weeks of age, and pituitary gonadotropins are required to develop follicular stages beyond the secondary stage. *Panels (C) and (F)*: Adult ovaries contain multiple-stage follicles, including antral-stage follicles (AnF) and corpora lutea from previous ovulations (CL). Granulosa cells from antral follicles are divided into two types: mural granulosa cells (Gr) that line the follicle wall, and cumulus granulosa cells (Cu) that surround the oocyte (Oo). GC: germ cell cyst; PF: primordial follicle; PrF: primary follicle; SF: secondary follicle; AnF: antral follicle; CL: corpus luteum; Oo: oocyte; Gr: granulosa cell; Cu: cumulus granulosa cell; Th: thecal cell. Micrographs not shown to scale.

the theca. The thecal cell layer begins to form in growing follicles around the basement membrane and ultimately differentiates into the theca interna and theca externa. The theca interna layer differentiates into theca interstitial cells, whereas the theca externa layer differentiates into smooth muscle cells. Theca development also coincides with the development of numerous small blood vessels, presumably via angiogenesis.

A postnatal day 14 ovary looks similar to a day 7 ovary but is larger and contains multiple secondary follicles. Follicles are also degenerating at this stage, as lack of appropriate pituitary FSH levels does not support further follicular development. By postnatal day 21, Type 6 follicles are also discernable. In a Type 6 follicle, the oocyte reaches its final diameter of approximately 70 μm, and is surrounded by multiple layers of granulosa cells that contain scattered areas of interstitial fluid. Eventually, these scattered areas of fluid coalesce to form an antral cavity. This also divides the granulosa cells into two populations, mural and cumulus. Granulosa cells that surround the oocyte are called the cumulus granulosa cells, while granulosa cells that line the basement membrane are called mural granulosa cells. Cumulus and mural granulosa cells differ not only in their location but also in their expression of different molecular markers.

Antral follicles are highly differentiated endocrine structures, characterized by the formation of fluid-filled cavity (antrum) next to the oocyte, and they correspond to Type 6–8 follicles in the Pedersen classification (Figures 21.1 and 21.2(C),(F)). These follicles are responsive to gonadotropins and participate actively in the hypothalamic–pituitary–gonadal (HPG) axis. Unless rescued by FSH, the granulosa cells of most early antral follicles undergo widespread apoptosis and ultimately follicular death.[35,36] In dominant follicles, luteinizing hormone (LH) stimulates thecal cell androgen production, while FSH stimulates mural granulosa cell proliferation, aromatization of androgens to estrogens, and LH receptor expression.[37–40] Follicle-derived estrogens exert positive feedback on both the hypothalamus and pituitary to trigger the midcycle gonadotropin surge of LH that precedes ovulation. Inhibin, secreted by granulosa cells, also acts as an endocrine hormone and feeds back to the pituitary to inhibit FSH secretion.[41] The complicated web of interactions between the oocyte, granulosa cells, thecal cells, pituitary, and hypothalamus ultimately selects follicles that will ovulate.

The LH surge triggers release of the oocyte from meiotic arrest, breakdown of the follicle wall, and extrusion of the cumulus–oocyte complex. The cumulus cells surrounding the oocyte undergo a process of expansion and extracellular matrix production. The oocyte completes meiosis I, releases its first polar body, and progresses to the metaphase stage of meiosis II, where it arrests again until fertilization. Granulosa cells remaining in the postovulatory follicle undergo luteinization, a process that involves cell cycle exit, cellular hypertrophy, acquisition of steroidogenic morphology, and expression of cytochrome P450 cholesterol side chain cleavage. This results in formation of the corpus luteum (Figure 21.2(C)), which is a highly vascularized, transient endocrine organ that produces progesterone, which is essential for uterine preparation and maintenance of pregnancy (see Chapter 23). In mice, the entire process of the primordial follicle to maturity takes approximately 3 weeks—considerably shorter than the several months thought to be required in humans.

Human Folliculogenesis

Primordial follicle formation in humans occurs in utero.[42–44] Primordial follicles are observed in almost all ovaries after 20 weeks of gestation, whereas preantral and antral follicles are observed from 26 weeks onward. Three types of very small follicles can be defined in primates as well as other mammals: primordial follicles, follicles with mixed cuboidal and squamous granulosa cells (intermediate follicles), and primary follicles. It has been suggested that despite this histologic variation in granulosa cells of early follicles, human follicles with an oocyte nuclear diameter less than 19 μm can be considered resting.[45,46] Unfortunately, no molecular markers are known that differentiate resting from early-growing follicles, and "resting" may not be an accurate term, because transcription of many oocyte-specific genes still occurs.[47–49]

In newborn human females, approximately 400,000 follicles remain out of 6–7 million that were present midway (20 weeks) through gestation.[45,50,51] The newborn human ovary measures approximately 1.3 cm × 0.5 cm × 0.3 cm and weighs less than 0.3 g.[52,53] Follicular maturation and atresia occur prenatally and throughout childhood. Because ovulation does not occur, corpora lutea and corpora albicantia are absent in the prepubertal ovary, and all maturing follicles undergo atresia in a manner identical to that occurring in adults. By puberty, almost 90% of the initial pool is depleted, presumably by apoptosis, although other types of cell death have been detected in the rodent ovary.[54–56]

Beyond age 37, the number of follicles declines to approximately 25,000, and the rate of follicle loss increases so that by age 50, approximately 1000 follicles remain.[57,58] Thus, only approximately 400 follicles will ovulate during a woman's reproductive life, with the vast majority never reaching the mature stage.[59] Adult ovaries are ovoid, measure approximately 4 cm × 2 cm × 1 cm, and weigh approximately 7 g. In contrast, menopausal ovaries weigh half as much and contain few if any primordial follicles and a wide variety of stromal-like cells, including luteinized stromal cells.[60,61]

PRIMORDIAL FOLLICLE FORMATION

During fetal ovarian development, oocytes are contained within germ cell clusters or cysts (GCCs), which form by both clonal division and aggregation of oocytes.[62] Each GCC contains eight or more germ cells, with intercellular bridges connecting some of the oocytes. While loss of intercellular bridges through deletion of *Tex14* (testis-expressed gene 14), an inactive kinase required for intercellular bridge stability, reduces the number of germ cells at birth in females by approximately half, female fecundity is not affected.[63] During primordial follicle formation, projections from the somatic cells penetrate between the oocytes in GCCs, leading to constriction of the intracellular bridges and eventual enclosure of oocytes by the somatic cells.[32,64] GCC breakdown occurs during a relatively short time span in mice, initiating around embryonic day 17.5 (E17.5) and completed by postnatal day 4.[32] In sheep, primordial follicle formation occurs at days 75–100 of gestation,[65] between 70 and 90 days in pigs,[66] and after approximately 120 days of gestation in humans.[67]

The molecular events responsible for the breakdown of germ cell cysts and the concomitant formation of primordial follicles in the newborn ovary are still being defined. Breakdown of germ cells cysts is associated with germ cell death via apoptosis and autophagy, as well as progression through meiotic prophase I.[32,68] It is not clear how these processes are linked or regulated with respect to determining the size of the primordial follicle pool. Many studies have relied upon in vitro culturing of intact ovaries with recombinant ligands or small-molecule inhibitors to determine their effects on primordial follicle assembly. These studies have identified multiple signaling pathways that regulate this process, including steroid hormone signaling and signaling by members of the TGFβ family such as activin and anti-Müllerian hormone (AMH). Several comprehensive reviews covering this topic are available.[69–71] The remainder of this section highlights several pathways that regulate primordial follicle assembly.

Steroid Hormone Signaling

It has been suggested that high levels of maternal estradiol and progesterone inhibit primordial follicle assembly, and that in rodents the drop in steroid hormone levels after birth initiates follicular assembly.[72] Progesterone reduces the rate of primordial follicle assembly in mice and rats,[72,73] possibly through the reduction in germ cell apoptosis.[72] However, progesterone receptor (*Pgr*) knockout mice appear to have normal follicle development, but are infertile due to ovulation and uterine defects.[74] Thus, progesterone's effect on primordial follicle assembly may act through a nonclassical mechanism.[72] In other species, such as sheep, cattle, and human, primordial follicle assembly takes place during fetal development at times of high estradiol and progesterone levels. Therefore, if steroid signaling suppresses primordial follicle assembly in these species, additional mechanisms of regulation must occur, perhaps including the expression of hormone-binding proteins that may sequester steroid hormones and diminish their bioavailability.[75] In cattle, while maternal serum levels of steroids are high, progesterone and estradiol levels decline in fetal ovaries with increasing age.[76] In addition, estradiol and progesterone inhibit follicle formation in cultures of fetal bovine ovaries,[77,78] suggesting that steroid hormone regulation of primordial follicle assembly may be conserved to some extent in mammals. Therefore, a mechanism to limit steroid activity in fetal ovaries may have evolved to allow for prenatal primordial follicle formation.

Treatment of newborn mouse ovaries with estradiol, synthetic estrogens such as diethylstilbestrol (DES), or phytoestrogens such as genistein leads to the formation of follicles with multiple oocytes, termed polyovular follicles, or multiple oocyte follicles (MOFs).[73,79–81] The effects of genistein are likely mediated by the estrogen receptor beta isoform (ERβ) because polyovular follicle formation is prevented in estrogen receptor beta (*Esr2*) knockout mice but not estrogen receptor alpha (*Esr1*) knockouts.[82] DES and estradiol decrease expression of the protein subunits required to produce activin (*Inhba* and *Inhbb*), growth factors with important regulatory roles in follicle development (see the section Activins), and thus activin may mediate the effects of estrogen on primordial follicle assembly.[79] In line with this hypothesis, conditional deletion of the activin βA subunit in granulosa cells results in the formation of polyovular follicles.[83] In turn, it has been shown that activin induces expression of the estrogen receptors *Esr1* (*ERα*) and *Esr2* (*ERβ*), suggesting a feedback loop between estrogen and activin signaling.[84]

Notch Signaling

Notch signaling is a developmentally conserved metazoan-signaling pathway that mediates signaling between neighboring cells. *Notch* encodes a transmembrane receptor that binds to a membrane-bound ligand (Jagged (JAG1 and JAG2) or Delta-like 1 (DLL1), DLL2, and DLL4) on an adjacent cell. Binding of the ligand results in proteolysis of the Notch intracellular domain (NICD), which translocates to the nucleus and interacts with transcription factors of the C-promoter-binding factor 1/suppressor of hairless/Lag-1 (CSL) family. Of the four Notch paralogs (*Notch 1–4*), *Notch2* is most abundantly expressed in the ovary and is expressed in the pregranulosa cells of primordial follicles.[85] Oocytes express *Jag1*, the most highly expressed of the six ligands in the ovary.[85,86] Chemical inhibition of Notch signaling in cultures of newborn ovaries results in reduced germ cell cyst breakdown and a

lower percentage of primordial follicles.[85] Deletion of lunatic fringe (*Lfng*), an *N*-acetylglucosaminyltransferase that regulates Notch interactions with its ligands, causes infertility in mice and the presence of polyovular follicles in ovaries.[87] Perturbations of Notch–Jagged signaling have also been detected in mice null for neurotrophic tyrosine kinase receptor 2 (*Ntrk2* or *TrkB*) (see the section Nerve Growth Factor and Receptors).[88] *Ntrk2*$^{-/-}$ mice die within 2 weeks of birth, but when ovaries are transplanted to the kidney capsule and allowed to develop, the ovaries show reduced follicle assembly and massive oocyte loss.[89] *Ntrk2*$^{-/-}$ ovaries have reduced *Jag1* expression and Notch target gene expression, including *Hes1*, *Hey2*, and *Myc*.[88] Overexpression of *Jag1* in *Ntrk2*$^{-/-}$ oocytes in vitro increases *Myc* expression in granulosa cells, restores follicle growth, and causes granulosa cell proliferation.[88] These data support a model in which neurotrophin signaling acts via the Notch-signaling pathway to mediate oocyte–granulosa cell development, although how these interactions may lead to the formation of primordial follicles is still unresolved.

Factor in the Germline (*Figla*)

A mutation in the mouse helix–loop–helix transcription factor, factor in the germline alpha (*Figla*), causes a disruption of primordial follicle formation and the subsequent loss of most of the oocytes by postnatal day 2.[90] FIGLA is an oocyte-specific protein, which binds promoter elements (E-box) in the oocyte zona pellucida (ZP) genes to regulate their expression in vitro.[91] ZP proteins, encoded by *Zp1*, *Zp2*, and *Zp3*, are a major component of the glycoprotein-rich matrix that surrounds the developing oocyte and is required for fertilization. The ZP may also act as a barrier to the exchange of growth factors between the oocyte and the immediately adjacent granulosa cells.[92] Single *Zp1*, *Zp2*, or *Zp3* knockout mice are able to form primordial through antral follicles, and therefore, individual loss of the ZP genes cannot account for the observed phenotype of the *Figla* mutant mice.[93–96] It is likely that FIGLA regulates expression of other genes that are critical for follicle formation and oocyte survival. Indeed, microarray data analysis between wild-type and *Figla*$^{-/-}$ ovaries identified POU domain, class 5, transcription factor 1 (*Pou5f1/Oct4*); E2f transcription factor 5 (*E2f5*); signal transducer and activator of transcription 3 (*Stat3*); lymphocyte cytosolic protein 1 (*Lcp1*); cytoplasmic polyadenylation element–binding protein 3 (*Cpeb3*); ELAV (embryonic lethal, abnormal vision, *Drosophila*)-like 2 (*Elav2*); and cytoplasmic polyadenylation element–binding protein 1 (*Cpeb1*) as downregulated genes in the knockout.[97] Interestingly, depletion of oocytes in *Figla*$^{-/-}$ leads to overexpression of several testis-specific genes, a phenomenon also seen in the *Nobox*$^{-/-}$ ovaries[97,98] (see the section Newborn Ovary Homeobox Gene). These data suggest that *Figla* and other oocyte-expressed transcription factors such as *Nobox* may be important for ovarian determination by suppressing male-specific genes. This idea is further supported by data that ectopic expression of *Figla* in male germ cells suppresses expression of testis-associated genes, such as tudor domain containing 1, 6, and 7 (*Tdrd1*, *Tdrd6*, and *Tdrd7*).[99]

The human homolog of FIGLA also has restricted expression to germ cells, forms a heterodimer with the E12 protein, and binds to the E-box of the human Zp2 promoter.[47,100] *FIGLA* is expressed as early as 14 weeks of gestational age, with a dramatic increase in transcripts by midgestation (20 weeks gestational age, i.e., the time of primordial follicle formation in humans), suggesting a similarly conserved function of the human and mouse FIGLA proteins. Mutations in *Figla* can be detected in a subset of women with premature ovarian insufficiency,[101] a condition characterized by hypergonadotropic hypogonadism prior to age 40.

Newborn Ovary Homeobox Gene

Nobox is an oocyte-specific homeobox gene discovered in a screen to identify oocyte-specific genes using a computer database–based "in silico" subtraction of expressed sequence tag (EST) databases, and it was one of the first oocyte-specific homeobox genes to be discovered.[102] *Nobox* mRNA and protein are expressed in both germ cell cysts and primordial follicles and throughout folliculogenesis.[102,103] Female mice lacking NOBOX cannot form growing follicles, have an arrest in folliculogenesis at the transition from primordial to primary follicles, and are sterile.[103] Unlike *Gdf9* null ovaries, *Nobox*-deficient ovaries rapidly lose oocytes so that by 2 weeks after birth, very few follicles are found (Figure 21.3(C)). It is of interest to note that shortly after birth, *Nobox*$^{-/-}$ ovaries contain more oocytes in germ cell cysts and less in primordial follicles as compared to the wild-type ovaries. At day 7 after birth, *Nobox*$^{-/-}$ ovaries still have the majority of oocytes in the form of cysts, with only a few primordial follicles and no secondary follicles; by day 14, most oocytes are degenerating. Ultrastructural examination of *Nobox*$^{-/-}$ ovaries at E16.5 and shortly after birth revealed early postnatal defects in the breakdown of germ cell cysts.[64] In wild-type mice, the somatic cells surrounding the cysts produce long projections that penetrate between oocytes, leading to the breakage of the cytoplasmic bridges connecting oocytes and the separation and somatic envelopment of individual oocytes. Further invasion of somatic cells between the oocytes correlates with the formation of individual primordial follicles.[64] In *Nobox*-deficient mice, somatic cells have a limited number of very short projections as compared to the wild type, and do not show peri-oocyte invasion. This results in the formation of highly abnormal syncytial follicles

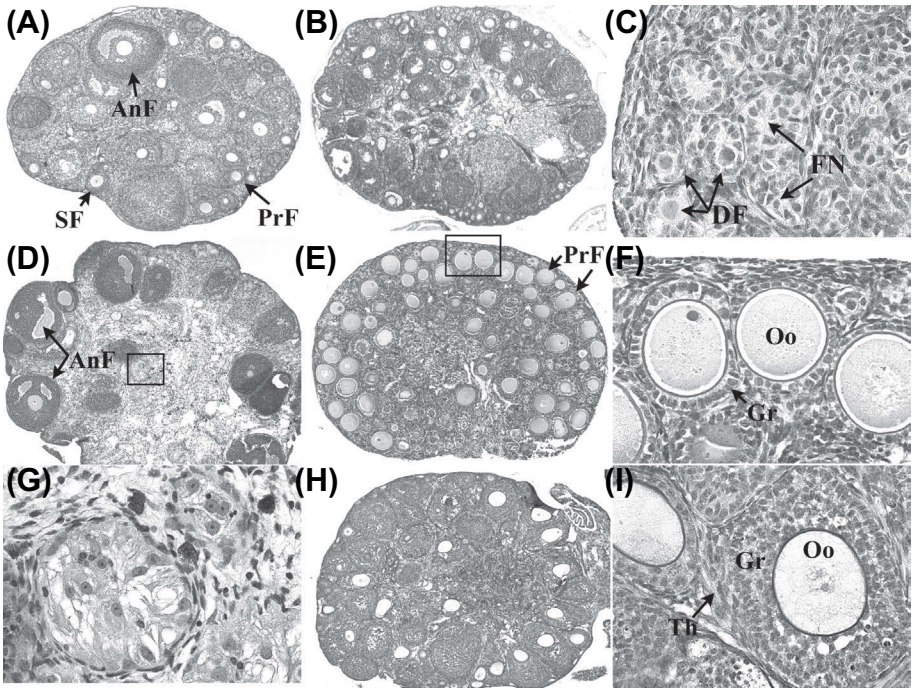

FIGURE 21.3 Ovarian histology for various mouse knockout models. Light micrographs of adult ovarian sections from knockout models. *Panel (A)*: Adult wild-type ovaries demonstrate follicles from many stages. *Panel (B)*: Adult *Fsh*$^{-/-}$ mutant ovaries lack antral follicles. *Panel (C)*: 14-day-old *Nobox*$^{-/-}$ ovaries contain only follicular nests and degenerating oocytes. *Panel (D)*: *Esr1*$^{-/-}$ *Esr2*$^{-/-}$ double-mutant ovaries containing many advanced follicle types as well as structures that resemble male seminiferous tubules (boxed and shown at higher magnification in *panel (G)*). *Panel (E)*: *Gdf9*$^{-/-}$ null ovaries arrest at the primary follicle stage. *Panel (F)*: Magnification of boxed *Gdf9*$^{-/-}$ follicles shown in *panel (E)*. *Panel (H)*: Double-mutant *Gdf9*$^{-/-}$ *Inha*$^{-/-}$ ovary demonstrates partial rescue of the *Gdf9*$^{-/-}$ phenotype. *Panel (I)*: Higher magnification of the *Gdf9*$^{-/-}$ *Inha*$^{-/-}$ showing multilaminar follicles and a thecal cell layer. PrF: primary follicle; SF: secondary follicle; AnF: antral follicle; Oo: oocyte; Gr: granulosa cell; Th: thecal cell; DF: degenerating follicle; FN: follicular nest. Micrographs not shown to scale.

composed of clusters of unseparated oocytes surrounded by 2–3 layers of somatic cells. These defects in germ cell cyst breakdown are in part responsible for abnormal formation of primordial follicles and associated oocyte loss. Persistent expression of *Stra8* (simulated by retinoic acid 8), a gene that controls meiotic initiation, in the *Nobox* knockout newborn ovary signifies that *Nobox*-deficient oocytes are immature at the molecular level, despite forming primordial-like follicles.[98] Moreover, *Nobox* deficiency likely affects the production of factors that oocytes use to communicate with surrounding somatic cells.

Nobox encodes a homeobox gene, and such genes encode transcription factors that play critical functions during organogenesis and can be either ubiquitous or cell type specific in their expression and function. Because *Nobox* expression is restricted to oocytes, it was hypothesized that NOBOX regulates expression of genes preferentially expressed in oocytes. Consistent with this hypothesis, it was demonstrated that the NOBOX deficiency preferentially disrupts expression of multiple oocyte-specific genes, including *Gdf9*, bone morphogenetic protein 15 (Bmp15), *Pou5f1* (*Oct4*), ret finger protein-like protein 4 (*Rfpl4*), and Maloney sarcoma oncogene (*Mos*). Overall, when comparing *Nobox* knockout and wild-type ovaries, 28 (74%) of 38 genes that downregulated more than fivefold in the absence of *Nobox* were preferentially expressed in the oocytes, whereas only five (15%) of 33 genes that upregulated more than fivefold in the absence of *Nobox* were preferentially expressed in oocytes.[98] NOBOX appears to directly regulate a subset of genes preferentially expressed in the oocytes, and seems to act as an activator of genes necessary for both folliculogenesis (*Gdf9* and *Bmp15*) and early postfertilization embryonic events (NLR family pyrin domain containing 5 (*Nlrp5/Mater*), DNA methyltransferase 1 (*Dnmt1*), zygotic arrest 1 (*Zar1*), and nucleoplasmin 2 (*Npm2*)).[98,104,105] In addition, pluripotency-associated genes, *Pou5f1* and sal-like 4 (*Sall4*), are drastically downregulated in *Nobox*-deficient ovaries, whereas testes-determining gene *Dmrt1* is overexpressed. These findings indicate that *Nobox* is likely an activator of oocyte-specific gene expression and suggest that the oocyte plays an important role in suppressing expression of male-determining genes, such as *Dmrt1*. The mechanism of follicle loss in *Nobox* null ovaries has yet to be determined, although it appears to be independent of known members of the apoptotic cascade (i.e., B-cell leukemia/lymphoma 2 (*Bcl2*), Caspase 2 (*Casp2*), BCL2-associated X protein (*Bax*), and Bcl2-like 2 (*Bcl2l2*)), which are normally expressed in *Nobox* null ovaries. It is possible that other oocyte-specific genes are essential for oocyte survival, and elucidation of their pathways in *Nobox*-deficient ovaries will be of great interest. The overall hierarchy of oocyte-specific transcriptional control in early folliculogenesis is still unknown; however, the list of important players keeps growing (Figure 21.4).

A human homolog of *Nobox* exists and mimics the expression observed in mice.[48] Human *NOBOX* expression within the ovary is oocyte specific, and observed from the primordial-stage ovarian follicle through to the metaphase II (MII) oocyte. *NOBOX* is a candidate gene for idiopathic (no known cause) and nonsyndromic (the

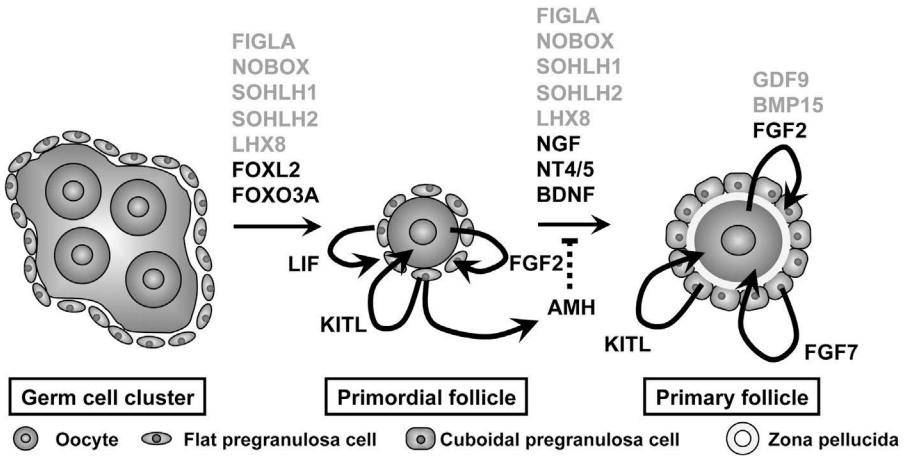

FIGURE 21.4 Early folliculogenesis. Germ cell cysts break down after birth, and primordial follicles form. Germ cell–specific factors considered part of the same pathway are shown in a lighter font. The factors are listed at the site of proximate action as derived from mouse transgenic and ovarian culture studies. LIF: leukemia inhibitory factor; KITL: kit ligand; FGF2: fibroblast growth factor; AMH: anti-Müllerian hormone; FGF7: fibroblast growth factor 7; NGF: nerve growth factor; NT4/5: nerve growth factor receptors; NOBOX: newborn ovary homeobox gene; FIGLA: factor in the germline alpha; FOXL2: forkhead box L2; GDF9: growth differentiation factor 9; BMP15: bone morphogenetic protein 15; BDNF: neurotrophic factor; NT4/5: neurotrophin 5; FOXO3A: forkhead transcription factor; LHX8: LIM homeodomain 8; SOHLH1: spermatogenesis and oogenesis helix loop helix 1; SOHLH2: spermatogenesis and oogenesis helix loop helix 1.

phenotype is confined to ovarian failure) human ovarian insufficiency. Indeed, several human studies have associated *NOBOX* mutations and deletions with premature ovarian insufficiency. Several groups have reported that mutations or deletions in the *Nobox* locus associate with primary ovarian insufficiency in humans.[106–109]

Spermatogenesis and Oogenesis Helix–Loop–Helix Transcriptional Regulators 1 and 2 (*Sohlh1* and *Sohlh2*)

In addition to *Figla*, two other basic helix–loop–helix (bHLH) transcriptional regulators have been implicated in early folliculogenesis. *Sohlh1* and *Sohlh2* are important bHLH germ cell specific transcription factors implicated in gonadal development. Both are strongly expressed in germ cell cysts and primordial follicles, moderately expressed in primary follicles, while not expressed in secondary follicles. The expression patterns of *Sohlh1* and *Sohlh2* are unique, as compared with *Figla*, *Nobox*, and *Lhx8*, which are expressed throughout folliculogenesis. This may indicate that *Sohlhs* play important and unique roles in primordial follicle formation, activation, and survival. Ovaries from *Sohlhs* mutant mice are completely devoid of follicles by 3 weeks postnatal age.[110–113] The defect lies in primordial follicle formation, and surrounding pregranulosa cells do not proliferate. *Sohlh1*$^{-/-}$ and *Sohlh2*$^{-/-}$ mutant mice have very similar ovarian phenotypes, with perturbed expression of nearly identical genes as assessed by RNA arrays, including several germ cell–specific genes such as *Gdf9*, *Bmp15*, *Zar1*, *Lhx8*, and *Nobox*.[110,111,113,114] The lack of granulosa cell proliferation in *Sohlh1* and *Sohlh2* knockouts can, in part, be explained by the downregulation of *Kit* and *Gdf9*, but unlike *Gdf9*$^{-/-}$ knockout ovaries, *Sohlh1*$^{-/-}$ and *Sohlh2*$^{-/-}$ oocytes grow to a size of greater than 30 μm in diameter without conversion of flat pregranulosa cells to the cuboidal cell type expected for oocytes of that size. These results are consistent with premature oocyte activation, which ultimately leads to the loss of follicles in mutant mice. SOHLH1 and SOHLH2 proteins can form homo- and heterodimers, and these dimers may play a role in the transcriptional control of early folliculogenesis. *Sohlh2* transcripts can be detected as early as E12 in mice, while *Sohlh1* transcripts are expressed later, at E16. Whether SOHLH2 and SOHLH1 regulate each other is unclear, and both SOHLH1 and SOHLH2 are downregulated in each other's deficiency. The nearly identical phenotypes in the two knockouts indicate that these two critical molecules act along similar, if not identical, pathways.

LIM Homeodomain Protein 8 (*Lhx8*)

Lhx8 is a homeobox gene that is preferentially expressed in oocytes and critical in folliculogenesis.[110,114] *Lhx8* encodes a LIM homeodomain protein that is expressed in the embryonic ovary from E18.5 throughout folliculogenesis. LIM proteins are found in invertebrate and vertebrate eukaryotes, and they have diverse biochemical functions. The LIM protein superfamily includes protein kinases and GTPase-activating factors, transcription factors, and transcriptional co-activators implicated in cellular architecture and intracellular signaling.[115,116] SOHLH1 transcriptional regulator binds the *Lhx8* promoter, as shown by chromatin immunoprecipitation

experiments,[110] and likely regulates *Lhx8* activity directly. *Lhx8* is therefore downstream of the SOHLH1–SOHLH2 pathway, and unlike *Sohlh1* and *Sohlh2* genes that also regulate spermatogonial differentiation in males,[117] *Lhx8* is only involved in the regulation of the female germline. Other regulators of *Lhx8* may include *Yin Yang1* (*Yy1*), a multifunctional transcription factor that can act as a transcriptional repressor and activator. *Lhx8* transcript expression is diminished in ovaries made conditionally deficient of *Yy1* by *Zp3*-driven *Cre* expression.[118] *Lhx8*-deficient mice are infertile due to lack of oocytes by postnatal day 7, with an early block in the formation of primordial and primary follicles. Several germ cell–specific genes known to be essential for oogenesis, such as *Gdf9*, *Bmp15*, *Nobox*, and *Figla*, are downregulated in *Lhx8*$^{-/-}$ovaries,[110,114] and many of the genes downregulated by *Lhx8* are also perturbed on *Sohlh1* and *Sohlh2* knockout RNA expression arrays. These results argue that *Lhx8* likely shares *Sohlh1* and *Sohlh2* pathways. The nature of signaling molecules and pathways that regulate expression of *Figla*, *Sohlh1*, *Sohlh2*, and *Lhx8* is unclear, and remains an important area of investigation.

Zinc Finger GATA-like Protein 1 (*Zglp1*)

Zinc finger GATA-like protein 1 (ZGLP1, also known as GLP1) is a nuclear protein containing two zinc fingers, one of which is highly homologous to the conserved GATA zinc finger DNA-binding motif. *Zglp1* is primarily expressed in the somatic cells of the developing gonads at E13.5 and granulosa cells of the adult ovaries.[119,120] Analysis of developing *Zglp1* null mouse ovaries shows that germ cells are appropriately specified and migrate normally to nascent gonads. Initial studies indicated that germ cell loss occurs as early as E17.5, at the time when oocyte meiosis is becoming arrested and prior to the formation of primordial follicles.[119] Subsequent studies suggest that the loss of germ cells begins at around E13.5 and is completed by birth.[120] Mutant mice have defects in the expression of genes associated with meiotic entry; however, it is unclear whether meiosis is perturbed and whether decreased gene expression is simply a reflection of fewer germ cells. Pregranulosa cell formation and function appear to be normal as *Foxl2* mRNA and protein expression, laminin deposition, and pregranulosa cell appearance are unaffected in *Zglp1* null embryonic ovaries as compared to wild-type ovaries. ZGLP1 can repress *Gata4* and *Gata6* expression; however, the role of GATA-regulated signaling in pregranulosa cells is unknown (see the section GATA Transcription Factors). *Zglp1* mutants exhibit one of the few known ovarian phenotypes where the major block occurs between the onset of meiosis and primordial follicle formation. Conditional inactivation would clarify the roles of *Zglp1* in later stages of folliculogenesis.

Prenatal Exposures to Toxins and Transgenerational Effects

The idea of fetal origins of disease stemmed from Barker's hypothesis that fetal growth restriction can lead to adult disorders,[121] and led to many subsequent studies that associated differential fetal exposures and chronic disease. The fetal gonad is a dynamic organ with many critical events, such as primordial germ cell proliferation, sex determination, meiosis, and epigenetic reprogramming, occurring during development. Fetal exposure to environmental toxins, mainly endocrine disruptors, may lead to impaired reproductive outcomes and ovarian pathology.[122–124] Interestingly, environmental toxins such as vinclozolin, an agricultural fungicide, and dioxin, a chemical contaminant generated from combustion and industrial processes, reduce the size of the primordial follicle pool in the offspring and subsequent generations, including the F3 generation, when administered to pregnant dams during gonadal sexual development.[125] These findings argue that transgenerational effects operate in the ovary. Mechanisms behind transgenerational inheritance are unclear, although epigenetics likely plays an important role.[122] It is also unclear whether transgenerational effects are physiologically significant or relevant to the human condition of premature ovarian insufficiency and polycystic ovarian syndrome (PCOS).

THE PRIMORDIAL TO PRIMARY FOLLICLE TRANSITION

The regulation of the nongrowing pool of primordial follicles is one of the most poorly understood processes in ovarian biology. The transition from primordial to growing follicle occurs spontaneously in newborn mouse ovaries cultured in medium in the presence of 10% fetal bovine serum.[126,127] After 8 days of culturing newborn ovaries, primary and secondary follicles form. Oocyte–granulosa cell complexes isolated from the 8-day organ cultures of newborn ovaries can be used to produce oocytes capable of fertilization, embryo formation, and live pups, albeit at a very low efficiency. Unlike mouse ovaries, follicular development in vitro occurs more rapidly in baboon ovaries, with many primary follicles observed by day 2 of culture and a much-diminished number of primordial follicles.[127,128] Removal of ovaries from their natural milieu may eliminate a potential inhibitor of follicular growth present in the surrounding tissue, peritoneum, or blood. On the other hand, it is possible that current culture media provide a much richer source of nutrients and oxygen, leading to premature activation of follicular growth.

Numerous factors accelerate the development of follicles in vitro. Primordial follicles from 4-day-old newborn

rat ovaries cultured in vitro develop faster when basic fibroblast growth factor (FGF), kit ligand (KITL), leukemia inhibitory factor (LIF), nerve growth factor (NGF), or bone morphogenetic protein 4 (BMP4) are introduced into the culture.[129–133] Typically, without treatment with growth factors, 50% of follicles grow in vitro; this rises to 60% upon treatment with particular growth factors. While small, the increase in growing follicles is statistically significant and indicates that numerous factors potentially enhance follicular growth.

PI3K–AKT and Tsc1–mTORC1 Signaling Pathways

The phosphatidylinositol 3-kinase–protein kinase B (PI3K–AKT) pathway is a conserved signaling pathway that regulates cell growth and survival in many different cell types. Regulation of primordial follicle activation by the PI3K pathway was first discovered when the transcription factor, forkhead box O3 (*Foxo3*), was deleted in mice. FOXO3 localizes to the oocyte nucleus during primordial follicle assembly, and is exported to the cytoplasm during oocyte activation.[134] In *Foxo3* null mice, primordial follicles form normally but do not undergo arrest. Thus, the entire pool undergoes global activation, resulting in premature follicle depletion and sterility by 15 weeks of age.[135] In addition, $Foxo3^{+/-}$ female mice have premature reproductive senescence due to an increased rate of primordial follicle activation.[136] Conditional deletion of *Foxo3* in oocytes of primordial follicles using the *Gdf9* promoter-driven *Cre* expression results in a similar phenotype, and confirms that the loss of FOXO3 in oocytes, as opposed to the somatic cells, is responsible for the activation of primordial follicles.[134]

AKT phosphorylates FOXO3 and causes FOXO3 cytoplasmic sequestration and degradation. Phosphatase and tensin homolog (PTEN) antagonizes PI3K, and removal of PTEN activates AKT, which in turn phosphorylates a wide range of intracellular targets, including FOXO3. It is therefore not surprising that oocyte-specific deletion of *Pten*, using *Gdf9* promoter-driven *Cre* expression, results in global activation of the primordial follicle pool.[137] Inducible conditional mutations in *Pten* have also been generated in primordial follicles of adult mice, and these mice also show enhanced primordial follicle activation, indicating that the PI3K pathway is important throughout the reproductive life span.[134] Oocyte loss in oocyte-specific *Pten* mutant ovaries may occur in part by the elevated levels of activity in the ribosomal protein kinase (S6K1)–ribosomal protein S6 signaling cascade, which regulates protein translation and ribosomal biogenesis.[137–139] Interestingly, conditional deletion of *Pten* in primary oocytes and beyond, using transgenic *Cre* expression driven by the *Zp3* promoter, had no effect on folliculogenesis or fertility.[140] These results argue that PTEN–PI3K–AKT signaling is stage dependent and confined to the primordial follicle pool. The nature of the external growth factors and stimuli within the ovary that activate the PTEN–PI3K–AKT signaling is currently unknown. A number of inhibitors and activators of this pathway are known and have been used to activate oocytes in human ovaries as a proof of principle that manipulation of the PTEN–PI3K–AKT pathway may facilitate generation of a large number of mature eggs for in vitro fertilization.[141,142] Despite promising results in rodents, little is known regarding whether the same pathways operate in humans or other mammals.

Premature loss of the ovarian reserve as well as elevated levels of serum FSH and LH in $Foxo3^{-/-}$ mice are reminiscent of premature ovarian failure (POF) in women.[135] Because the majority of POF cases are idiopathic, it is possible that in some instances, a similar mechanism may be operating through *Foxo3*. However, exon and flanking splice site sequencing of a large sample of POF or idiopathic primary amenorrhea failed to identify causal mutations,[136] arguing that *FOXO3* is not a major genetic determinant of human premature ovarian insufficiency.

Mammalian target of rapamycin complex 1 (mTORC1) is a key mediator of cell growth, and growth factor receptors activate mTORC1 by signaling through the PI3K–AKT and RAS–ERK mitogen-activated protein kinase (MAPK) pathways. mTORC1 promotes protein translation and cell growth largely through activation of S6K1 (by phosphorylation of threonine 389) and through phosphorylation and inactivation of eukaryotic translation initiation factor 4E (eIF4E)-binding proteins. S6K1 is responsible for phosphorylation and activation of ribosomal protein rpS6, which leads to enhanced protein translation and ribosome biogenesis. Tuberous sclerosis complex1 (TSC1) represses mTORC1 functions, and conditional inactivation of *Tsc1* in oocytes of primordial follicles causes massive PFA by enhancing mTORC1 activity.[143] These data also indicate the importance of the mTORC1 pathway in primordial follicle activation. The phenotype of the *Tsc1* conditional knockout ovaries is highly reminiscent of the *Pten* oocyte conditional knockout phenotype.

Kit Ligand (*Kitl*) and Kit Receptor (*Kit*)

Kit encodes a transmembrane receptor with tyrosine kinase activity and belongs to a family that includes colony-stimulating factor 1 (CSF1) and platelet-derived growth factors A and B (PDGFA and PDGFB). *White spotting* (*W*) and *Steel* (*Sl*) loci in the mouse encode KIT and its ligand, KITL, respectively.[144–147] KIT–KITL signaling plays important roles in hematopoiesis, gametogenesis, and melanogenesis.[148,149]

The first insight into the role of KITL and its receptor, KIT, came from the studies of mice spontaneously mutated at the *Kitl* and *Kit* loci.[150,151] There are more than 60 spontaneous mutations in the *Kitl* and *Kit* loci, and, depending on the severity of the loss of function, these mice show mild to severe defects in pigmentation, hematopoiesis, and reproduction. The mutant alleles are semidominant: some are lethal when homozygous, and others are viable. *Kit* expression can be detected as early as 7.5 days post conception and is high in proliferating germ cells.[144] *Kit* ceases to be expressed when oogonia enter meiosis, around E13.5, and is re-expressed in newborn ovaries. A similar pattern of expression is observed for *Kitl*.[145] *Kitl* is expressed in newborn ovaries in pregranulosa cells and continues to be expressed in granulosa cells throughout folliculogenesis.[152–154] *Kit* is expressed in primordial follicles and other oocytes throughout follicular growth.[152,155] KIT has also been detected in thecal cells, and KITL–KIT interactions can stimulate thecal cell growth and androstenedione production in the absence of gonadotropins.[156] Both in vivo and in vitro data provide evidence that KITL and KIT interactions play a significant role in the primordial to primary follicle transition.[157,158] The Sl^d allele causes infertility due to a complete absence of germ cells in the ovary.[159] The Sl^t allele, however, causes infertility due to the early growth arrest of ovarian follicles.[158] Folliculogenesis in mice that carry the Sl^t allele is arrested early, with many primordial follicles present and few growing follicles.[158]

Neutralizing antibodies against KIT have been used to study the functions of KIT in early folliculogenesis.[160] Mice injected with an anti-KIT neutralizing antibody at birth have blocked follicle development at the primordial follicle stage. Incorporation of BrdU into granulosa cells is diminished in these ovaries, indicating that DNA synthesis is compromised. If antibodies are injected starting at day 2, when primordial follicles are already apparent in mouse ovaries, primary follicular development is only slightly perturbed, and these mice have a diminished number of antral follicles with decreased proliferation and DNA synthesis in granulosa cells. Therefore, it appears that functional KIT is important at the very early stages of folliculogenesis as well as at the later antral stage. Because primordial follicle formation is not disturbed in any of these experiments, the conclusion can be made that KIT is not essential for the initial step of germ cell cyst breakdown into individual primordial follicles.

KIT is an attractive candidate for the transmembrane receptor tyrosine kinase that regulates PI3K activity. As discussed in this chapter, the PI3K–AKT-signaling pathway is an important regulator of primordial follicle activation; however, the nature of receptors and signals that converge upon it are unknown. KIT activates PI3K through a direct interaction with an SH2 domain on the p85 regulatory subunit of PI3K. This interaction is entirely dependent on the KIT tyrosine residue 719, which undergoes autophosphorylation following ligand binding. Mutation of this tyrosine residue prevents binding of KIT to p85 and thus completely abrogates KIT signaling via PI3K.[161] "Knockin" mice expressing KIT with a loss-of function mutation in tyrosine residue 719 (Kit^{Y719F}) are fertile and undergo primordial follicle activation. However, mice homozygous for the congenital Kit^{Y719F} mutation had accelerated primordial follicle depletion, and accumulated morphologically abnormal primary and secondary follicles.[162] Thus, KIT appears to be important in the maintenance of the primordial follicle reserve and in the primary to secondary follicle transition, but not in the primordial follicle activation.[162] These conclusions were based solely on analyzing the congenital Kit^{Y719F} mutation, and the phenotype of stage specific activation of the Kit^{Y719F} mutation is unknown.

Anti-Müllerian Hormone (*Amh*)

The dimeric glycoprotein anti-Müllerian hormone (AMH) is a member of the transforming growth factor beta (TGFβ) superfamily of growth and differentiation factors (see the section Regulation of Folliculogenesis by TGFβ Family Signaling in the Ovary). During embryogenesis, AMH induces degeneration of Müllerian (female) ducts during male fetal sex differentiation.[163] Postnatally in ovaries, AMH and its receptor AMHR2 are expressed in granulosa cells of primary and growing follicles in rodents and humans, but their expression is lost in FSH-responsive antral and preovulatory follicles.[164–167] AMH expression, however, is maintained in cumulus cells.[168] AMH appears to be the only natural ligand of the AMHR2 receptor, as *Amh* and *Amhr2* mutants phenocopy each other.[169] Although *Amh* null mouse females are fertile with normal litter sizes,[163] a careful histologic analysis of ovaries from 25-day-old, 4-month-old, and 13-month-old mice revealed significantly fewer primordial follicles in 4- and 13-month-old *Amh* null ovaries.[170] AMH therefore appears to inhibit the growth of primordial follicles, and absence of AMH leads to a faster depletion of primordial follicles. AMH also inhibits growth of primordial follicles in cultures of human ovarian cortical tissue biopsies.[171] In mice, experiments show that AMH attenuates the effects of FSH, and the absence of AMH potentiates the proliferative effects of FSH in the sexually mature ovary (4- and 13-month-old ovary), leading to greater recruitment of primordial follicles.[172] In vitro studies using 2-day postnatal mouse ovaries cultured in the presence and absence of AMH show that fewer growing follicles are found in ovaries treated with AMH.[173]

AMH is detectable in serum, and because of its expression pattern in growing preantral follicles, AMH

was proposed to be a measure of the ovarian reserve and ovarian function.[174,175] Serum AMH levels positively correlate with the size of the primordial follicle pool.[176] There is an interdependent relationship between the size of the resting and growing follicle pools,[177] and because AMH is expressed within growing follicles, AMH is still an indirect measure of ovarian reserves. AMH levels in women decline with age and ovarian dysfunction.[178–180] The proposed clinical uses of AMH include assessing the ovarian reserve prior to assisted reproduction, predicting gonadal function after cancer therapy or surgery, predicting the age at menopause, and diagnosing and measuring granulosa cell tumor recurrences.[181,182] AMH is a more sensitive marker of the ovarian reserve than the previously used marker, FSH, which has been a standard for clinical care.[183] However, the need remains for a better biomarker to directly measure the remaining oocyte pool and to reliably predict reproductive life span and ovarian failure. Such biomarkers are greatly needed to identify women at risk for ovarian failure, and to identify women who can benefit from advanced fertility preservation technologies prior to oocyte loss.[184]

Nerve Growth Factor and Receptors

Nerve growth factor (NGF) belongs to a family of proteins known as neurotrophins.[185] Neurotrophins are required for the survival and differentiation of neurons within both the central and peripheral nervous systems. In the rat ovary, *Ngf* and its two receptors, *Ngfr* and *Ntrk1* (also called *TrkA*), are expressed before primordial follicle formation, suggesting that NGF plays a role in early folliculogenesis.[186–188] Seven-day-old *Ngf* null mice have a drastic reduction in the number of primary and secondary follicles as compared to control mice.[189,190] Although the number of primordial follicles is equivalent, the number of oocytes within the germ cell cysts increases in the *Ngf* null ovaries. NGF may play a role in differentiation of flat pregranulosa cells into the cuboidal cells that characterize primary follicles. A reduction in the number of secondary follicles also could indicate that NGF functionally interacts with growth differentiation factor 9 (GDF9) and/or KITL to induce proliferation and differentiation of somatic cells surrounding the oocyte. The number of proliferating cell nuclear antigen (PCNA)-positive cells is distinctly lower in *Ngf* null ovaries, suggesting that somatic cells in *Ngf* null mice have reduced ovarian mitotic activity.

The lack of NGFR does not affect primordial, primary, or secondary follicle formation, as null mice are fertile.[191] Unfortunately, NTRK1 deficiency causes death at or shortly after birth.[192,193] The NTRK2 receptor (also called TrkB) is also expressed in primordial and growing oocytes, while ligands that bind NTRK2 (i.e., neurotrophin 4/5(NT5) and brain-derived neurotrophic factor (BDNF)) are expressed in rodent and human primordial oocytes and granulosa cells.[194,195] Both NTRK1 and NTRK2 receptors are necessary for the timely assembly of primordial follicles and for sustaining early follicular development.[89] *Ntrk2* deletion in mice does not affect the number of primordial follicles; however, the number of secondary follicles is significantly lower in 7-day ovaries.[195] Double mutants of *Nt5* and *Bdnf* also show significantly lower levels of secondary follicles.[195] As measured by PCNA, granulosa cell proliferation is diminished in NTRK2 null animals, while apoptosis is not increased. Quantitative real-time polymerase chain raction comparing *Ntrk2* null mice with wild-type mice did not identify mRNA differences between the growth factor genes *Gdf9* and *Kitl*, or their receptors *Bmpr2* (a receptor for BMPs and GDFs) and *Kit* (the receptor for KITL). On the other hand, the amount of FSH receptor mRNA was significantly reduced in *Ntrk2* null ovaries as compared to wild-type ovaries, and thus NTRK2 receptors appear to facilitate follicle development by inducing the formation of functional FSHR. FSH levels are somewhat diminished in NTRK2 null mice but not significantly different from those of heterozygous animals. NTRK2 deficiency is perinatal lethal, and NTRK2 null ovaries, when transplanted under the kidney capsule of adult female C57BL/6J mice, rapidly lose oocytes and arrest follicular development. Therefore, it appears that NTRK2, and its ligands NT5 and BDNF, act in similar fashion to KITL and KIT to regulate early survival of female germ cells. In vitro studies using a tyrosine kinase inhibitor, K252a, to block all NTRK receptors in the mouse newborn ovaries and human fetal ovaries show that NTRK receptors are important for germ cell survival.[196] In addition, studies using postnatal rat ovaries have shown that exogenous administration of neurotrophin NT3 to cultures promoted primordial to primary follicle transition, while BDNF only showed effects at high doses and nerve growth factor had no effect.[197] In total, these data indicate that neurotrophins provide support to nonneuronal targets and play an important role in intraovarian regulation of early folliculogenesis along with GDF9 and KITL.

Forkhead box L2 (*Foxl2*)

Blepharophimosis ptosis and epicanthus inversus syndrome can occur with (BPES I) or without ovarian failure (BPES II). Nonsense mutations and duplications in *FOXL2*, a member of the forkhead–hepatocyte nuclear factor 3 (FKH–HNF3) gene family of transcription factors, cause BPES.[198,199] The phenotype of BPES I women with ovarian failure ranges from ovaries that contain large numbers of primordial follicles to streak ovaries that have no germ cells as detected at the time of laparoscopy and during the examination of ovarian biopsies.[200,201] In humans, *FOXL2* is preferentially expressed in the ovary.

In situ hybridization of mouse ovaries indicates that *Foxl2* is expressed postnatally in the pregranulosa cells that surround primordial follicles.[198] Ovaries from *Foxl2*$^{-/-}$ mice contain oocytes surrounded by flat granulosa cells that grow slowly compared to wild-type ovaries.[202,203] Expression of the oocyte-specific genes *Figla*, *Gdf9*, and *Kit* is not affected by the lack of FOXL2, and ovarian morphology as well as oocyte count are also unaffected at birth. Granulosa cells in *Foxl2*$^{-/-}$ ovaries fail to complete the transition from squamous to cuboidal shape. In addition, *Foxl2*$^{-/-}$ follicles undergo massive activation followed by oocyte atresia and premature follicle loss.

A different phenotype develops when *Foxl2* is conditionally deleted from adult mouse ovaries. In this case, conditional deletion of *Foxl2* causes transdifferentiation of granulosa cells into Sertoli-like cells, and induces expression of male-specific genes, including SRY-box containing gene 9 (*Sox9*); nuclear receptor subfamily 0, group B, member 1(*Nr0b1/Dax1*); desert hedgehog (*Dhh*); doublesex and mab-3 related transcription factor 1 (*Dmrt1*); and GATA-binding protein 1 (*Gata1*).[204] Moreover, Sertoli-like cells within the mutant ovaries produce testosterone. FOXL2 and ESR1 cooperatively repress *Sox9* expression.[204] Thus, FOXL2 plays a critical role in actively maintaining the identity of granulosa cells and the ovary as a whole. FOXL2 appears to be a stage-specific regulator of sex determination, as the global gene knockout (i.e., as opposed to the conditional knockout) does not exhibit the same phenotype.

Several studies have identified additional downstream targets of FOXL2.[205] The steroidogenic acute regulatory (*Star*) gene contains multiple putative forkhead DNA consensus sites, and FOXL2 binds these sites directly.[206] FOXL2 acts as a repressor of *STAR*, and dominant negative mutations within FOXL2 most likely interfere with repressor activity of the wild-type protein and cause a de-repression of *STAR*.[206] Wild-type FOXL2 also represses cytochrome P450 cholesterol side chain cleavage enzyme (*CYP11A1*), aromatase (*CYP19a1*), and cyclin D2 (*CCND2*),[207] all known to be involved in granulosa cell growth and differentiation. However, de-repression of these genes in mice that lack *Foxl2* is probably not the cause of the early follicular block at the primordial or primary follicular stage, and those genes remain to be identified. Overexpression of *Foxl2* and subsequent microarray analysis showed 118 differentially expressed genes and five classes of potential transcriptional targets: chemokines, apoptosis-related genes, proteolysis, and various signal transduction components and transcription factors.[208] FOXL2 interacts with LATS1, a tumor suppressor gene in the Hippo-signaling pathway. LATS1 phosphorylates FOXL2, and this interaction enhances the ability of FOXL2 to repress *Star*.[209] Deletion of *Lats1* in mice causes soft tissue sarcomas and stromal tumors of the ovary by 3 months of age, as well as decreased female fertility.[210]

A mutation in *FOXL2* is pathognomonic for adult granulosa cell tumors (AGCTs); 97% of AGCTs harbor a somatic missense mutation in a highly conserved cysteine residue at amino acid position 134 (c.402C→G; p.C134W) in *FOXL2*.[211] The FOXL2 C134W mutation does not disrupt expression, localization, protein folding, or DNA binding,[211,212] so the role it plays in AGCT pathogenesis is currently unclear. Efforts have thus focused on finding DNA-interacting partners and identifying altered transcriptional targets. FOXL2 has known interactions with Dead (Asp–Glu–Ala–Asp) box 20 (DDX20), steroidogenic factor 1 (SF1, or NR5A1), ESR1, and Sma- and Mad-related proteins (SMAD) family member 3 (SMAD3), a TGFβ transcription factor.[204,213–218] The FOXL2 C134W mutation increases aromatase (*CYP19*) to a greater degree than the wild-type form.[205] In addition, the pathogenesis of FOXL2 in GCT may relate to its role in regulating apoptosis. Wild-type FOXL2 induces an apoptotic response in granulosa cells, but FOXL2 C134W cannot elicit the same response.[213,219] Ectopic expression of wild-type FOXL2 induces a mitochondria-mediated apoptotic cell death involving members of the BCL2 family, which is only weakly induced by FOXL2 C134W.[219] Moreover, cells that express the mutant FOXL2 are less susceptible to death receptor signaling (via tumor necrosis factor receptors 1 (TNFR1) and Fas) and serum deprivation than those expressing the wild-type form.[219] This may in part relate to disrupted protein–protein interactions of the mutant FOXL2, which does not induce apoptosis when co-expressed with CXXC finger 5 (CXXC5); glucocorticoid modulatory element–binding protein 1 (GMEB1); nuclear receptor subfamily 2, group C, member 1 (NR2C1); and nuclear antigen Sp100 (SP100), all of which have been shown to interact with wild-type FOXL2 to increase apoptosis.[220]

REGULATION OF FOLLICULOGENESIS BY TGFβ FAMILY SIGNALING IN THE OVARY

Proteins that comprise the TGFβ family form the largest structurally related group of growth factors. The 33 mammalian members include TGFβ, for which the family is named, as well as the bone morphogenetic proteins (BMPs), growth factors and GDFs, activins, inhibins, and AMH. These are multifunctional proteins that control cell proliferation and differentiation in many cell types. In the ovary, TGFβ family ligands are expressed from almost all cell types of the ovarian follicle, including two, *Gdf9* and *Bmp15*, which are exclusively expressed from oocytes. Members of the TGFβ family are secreted as dimeric proteins that are processed from larger pre-pro-precursor forms. The pro region is cleaved by a specific protease in the intracellular or extracellular

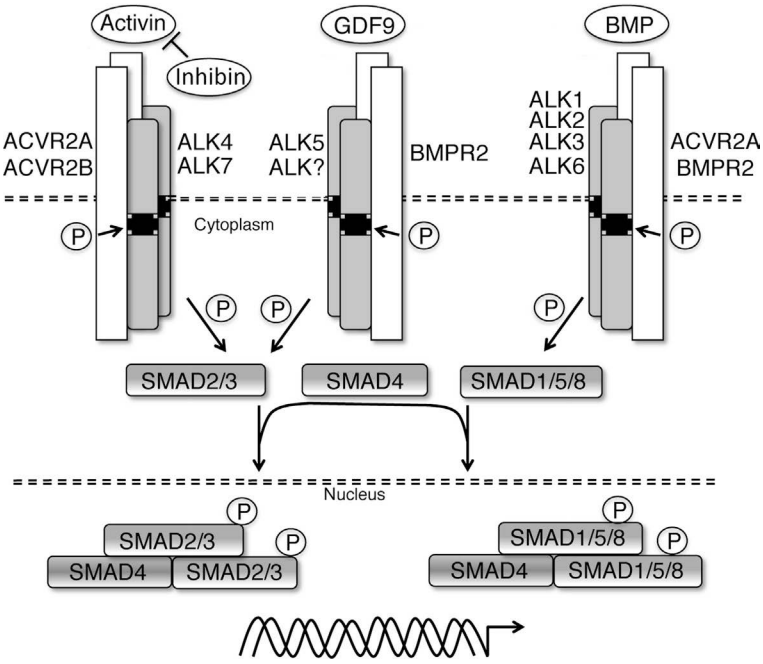

FIGURE 21.5 Summary of the core signaling pathway used by ligands of the TGFβ family. The TGFβ family signals through a membrane-bound receptor complex consisting of two type II and two type I receptors, which activate the intracellular SMAD transcription factors. Additional co-receptors and regulatory proteins are not shown. Activin signaling can be antagonized by inhibin (see the text for discussion). Activin signals through activin receptor type IIA (ACVR2A) or IIB (ACVR2B). BMPs may also signal through ACVR2A, but they also use the bone morphogenetic protein receptor type II (BMPR2). BMPR2 also binds GDF9. Once the ligand is bound, the type II receptor phosphorylates (P) and activates the type I receptor (ALK4 or ALK7 for activin, ALK5 for GDF9, and ALK1, ALK2, ALK3, or ALK6 for the BMPs). ALK5 has been shown to be a type I receptor for GDF9 in vitro but not in vivo; therefore, additional type I receptors (indicated by "ALK?") are likely also involved. Activated type I receptors then phosphorylate a restricted set of SMADs at a C-terminal motif. ALK4/5/7 phosphorylate SMAD2 and SMAD3, while ALK1/2/3/6 phosphorylate SMAD1/5/8. The receptor-restricted SMADs then form a trimeric complex with SMAD4, accumulate in the nucleus, and mediate gene transcription along with additional co-factors.

compartment to generate the bioactive mature domain. They bind to heteromeric cell surface receptor complexes that contain two types of receptors: type II and type I serine–threonine kinase receptors (Figure 21.5). In some instances, an additional, type III receptor facilitates ligand binding. Activation of the receptor complex results in phosphorylation of the intracellular SMAD transcription factors. Mouse models for the ligands, receptors, and signaling SMADs have elucidated the complex role of this protein family in follicle development, and often resulted in phenotypes that would not have been predicted from other types of analyses. This section is a summary of several of these models.

Inhibins

While the gonadotropins, FSH and LH, govern the final stages of follicular development and ovulation (see the section Key Roles of the Hypothalamus and Pituitary), the ovary participates in the endocrine control of gonadotrope function by the production of steroid and nonsteroid hormones in the hypothalamic–pituitary–gonadal axis. Some of the best-characterized nonsteroid hormones that regulate pituitary function are the activins and the inhibins (Figure 21.5).[221] Inhibin was first described as a proteinaceous substance from the testes that could inhibit FSH secretion.[222] Inhibin purification led to the discovery of activin, a protein that stimulates the release of pituitary FSH.[223,224] In addition, the ovary produces follistatin, a negative regulator of activin and BMP function.[225–227] Inhibin and activin share a common β subunit; activins are ββ dimers (primarily activin A (βA:βA), activin B (βB:βB), and activin AB (βA:βB)), while inhibins are αβ heterodimers (inhibin A (α:βA) or inhibin B (α:βB)). Genetic disruptions in inhibins, activins, and follistatin have demonstrated that these proteins have important autocrine, paracrine, as well as endocrine roles in the reproductive axis.

Inhibins are produced locally in many tissues, including the brain, pituitary, placenta, and adrenal gland,[228–233] but the major site of inhibin production is the gonads.[234–236] Castration of male or female rats results in the loss of circulating inhibin and the subsequent rise in pituitary FSH.[237,238] Serum inhibin is a major factor contributing to the rise in FSH, as demonstrated by the increase in FSH during passive immunization of rats with anti-inhibin antisera.[239–243] Inhibin was also hypothesized to have a paracrine role in the ovary since it was demonstrated that, in vitro, inhibins modulate thecal cell androgen production, follicular growth, and oocyte maturation.[244–248] In general, inhibin functions as an antagonist of activin, as no unique inhibin-binding receptor or signal transduction pathway has ever been conclusively demonstrated (Figure 21.5).[249,250] Experiments have shown that inhibin can block BMP signaling,[251] although inhibin suppression of BMP signaling in the ovary is less well defined than its action as an antagonist of activins.

In female rodents, inhibin A and inhibin B are produced from granulosa cells. In humans, inhibin α is also detected in thecal cells and corpora lutea.[252,253] While very little is understood about the biological differences between inhibin A and B isoforms, in the rat and mouse their production varies with follicle size and cycle stage.[237,254,255] Inhibin B is likely the product of small developing follicles,[256] and in rats, inhibin B is inversely correlated with FSH levels throughout the cycle and

TABLE 21.2 Phenotype Analysis of Female Double Mutants With *Inha*$^{-/-}$

Mouse Model	Female Phenotype	Survival Relative to *Inha*$^{-/-}$	References
Inha$^{-/-}$	Sex cord stromal tumors with cancer cachexia; death by 19 weeks of age		41
Activin signaling			
Inha$^{-/-}$ *Acvr2*$^{-/-}$	Tumors develop, elevated activin, but no evidence of cachexia	Increased	306
Inha$^{-/-}$ *MT-Fst*	Similar tumor development with less cachexia	Increased	492
Inha$^{-/-}$ *Smad3*$^{-/-}$	Delayed tumor development and delayed cachexia	Increased	310
Inha$^{-/-}$ *Smad2*^{cKO} *Amhr2cre*	Tumor development and cachexia similar to *Inha*$^{-/-}$	Unchanged	311
Cell cycle regulators			
Inha$^{-/-}$ *Ccnd2*$^{-/-}$	Slower tumor progression but elevated FSH	Increased	316
Inha$^{-/-}$ *Cdkn1b*$^{-/-}$	Early tumor development in females with increased serum activin and death by 8 weeks of age	Decreased	318
Inha$^{-/-}$ *Rb*^{cKO} *Amhr2cre*	Similar tumor histology, although increased mitosis; slightly increased death	Decreased	493
Estrogen signaling			
Inha$^{-/-}$ *Esr1*$^{-/-}$	Tumor development with a more pronounced cachexia	Decreased	494
Inha$^{-/-}$ *Esr2*$^{-/-}$	Similar to *Inha*$^{-/-}$	Similar	494
Inha$^{-/-}$ *Esr1*$^{-/-}$ *Esr2*$^{-/-}$	Aggressive tumor development and rapid death by 9 weeks	Decreased	494
Gonadotropin signaling			
Inha$^{-/-}$ *Fshb*$^{-/-}$	Slow-growing tumors with suppressed activin and estradiol and little cachexia	Increased	313
Inha$^{-/-}$ *Gnrh*$^{hpg/hpg}$	Pretumor foci without full tumor development	Increased	314
Inha$^{-/-}$ *Lhb*$^{-/-}$	Delayed tumor progression with lower FSH and estradiol	Increased	495
Other growth factors			
Inha$^{-/-}$ *Gdf9*$^{-/-}$	Adult tumor development similar	Unchanged	417

increases in response to FSH stimulation, remaining high through midcycle and declining following the primary gonadotropin surge.[237] In contrast, inhibin A levels are low following the primary gonadotropin surge, but expression is stimulated following the secondary FSH surge and slowly rises during early cycle stages.[237] Inhibin A, unlike inhibin B, correlates with estradiol production and the development of preovulatory follicles.[255] The highly regulated production of inhibin during the estrous cycle suggests that its regulation and function are critical to female fertility. It is not surprising, then, that genetic mutations in all three inhibin subunit genes (*Inha*, *Inhba*, and *Inhbb*)[41,257–259] show reproductive defects. In addition, the creation of an inhibin α (*Inha*) null mouse led to the unexpected discovery of inhibin α as a tumor suppressor gene.[41]

Mouse Models of Inhibin Action

Inha was the first of the three inhibin–activin genes to be knocked out in mice[41] (Table 21.2). Because the inhibin α subunit was targeted, activin (i.e., the βA and βB subunit) expression is left "intact." While mice null for inhibin α are viable during embryonic and prepubertal development, all homozygous mice develop tumors within the ovary and die from a cancerous, cachexia-like wasting syndrome by 12–17 weeks of age (Figure 21.6).[41,300] Tumors are mixed granulosa–Sertoli cell tumors. In adult mice, FSH levels are elevated two- to threefold, and activin expressed in the serum is 20-fold higher in the null mice when compared to wild-type mice. At 4 weeks of age, prior to gross tumor formation, granulosa cells appear abnormal but display hyperplasia. *Inha* null mice are infertile, and when immature mice are superovulated, they produce fewer eggs than wild-type mice.[301] Follicle development is abnormal in prepubertal *Inha* null mice. Ovaries from immature *Inha* null mice show precocious follicle development as seen by the appearance of large, multilayered follicles by 12 days of age.[302] Gonadectomy does not rescue the lethality of the *Inha* mutation because these mice also develop adrenal tumors.[300] Thus, the phenotype of *Inha* null mice is complex, and the contributions of elevated serum FSH and activins have been further analyzed.

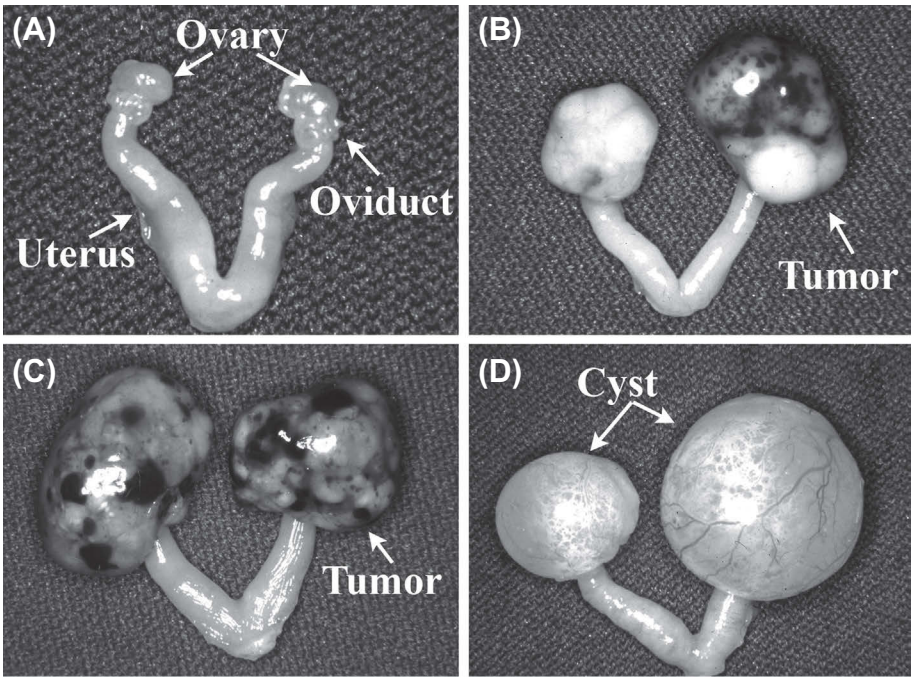

FIGURE 21.6 Gross anatomy of ovarian tumor and cyst formation in several mouse models. *Panel (A)*: Reproductive tract of an adult female mouse. *Panel (B)*: Female *Inha*$^{-/-}$ mice develop ovarian tumors with 100% penetrance. *Panel (C)*: Double-knockout *Inha*$^{-/-}$ *Acvr2*$^{-/-}$ mice develop tumors similar to those with *Inha*$^{-/-}$ despite the lack of activin signaling through ACVR2. *Panel (D)*: Bilateral fluid-filled cysts in a *Gdf9*$^{-/-}$*Bmp15*$^{-/-}$ double-knockout ovary.

Activin is a potent growth factor, and rodents treated in the short term with recombinant activin exhibit a wasting syndrome.[303,304] Thus, it was hypothesized that superphysiologic levels of activin cause cachexia.[300,305,306] Because activin partially signals through the activin type II receptor (ACVR2),[307] knockouts for the *Acvr2* gene (as discussed in this chapter)[257] were crossed to *Inha* mutant mice to generate double homozygotes (*Inha*$^{-/-}$ and *Acvr2*$^{-/-}$).[306] These mice are deficient in activin signaling through ACVR2 as well as FSH synthesis because mice null for *Acvr2* have reduced FSH levels due to the lack of activin signaling in the pituitary.[257] The double-homozygous mutant mice develop gonadal tumors similar to those in *Inha*$^{-/-}$ mice and reinforce the hypothesis that inhibin α is a tumor suppressor gene (Figure 21.6). However, despite elevated peripheral activin levels, double-homozygous mutant mice do not develop the wasting syndrome seen in the *Inha*$^{-/-}$ mice, demonstrating that early death, but not tumor formation, is due to activin signaling. However, another high-affinity receptor for activin, ACVR2B, is expressed in granulosa cells,[308] and it is unclear if additional activin signaling through this receptor also contributes to the tumor phenotype. Knockout mice for *Acvr2b* have been generated, but homozygous mice die shortly after birth due to cardiac defects,[309] leaving questions of additional activin signaling in the ovary currently unanswered. Activin signals through the SMAD transcription factors, SMAD2 and SMAD3, and female mice null for both *Inha* and *Smad3* have delayed tumor development and cancer cachexia.[310] In contrast, conditional loss of SMAD2 has very little effect on tumor development in *Inha*$^{-/-}$ females, indicating that SMAD2 is not required for gonadal tumor development in *Inha* null female mice.[311] The difference in these phenotypes may be due to the known functional redundancy between SMAD2 and SMAD3 in granulosa cells,[312] with SMAD3 transducing the essential signals leading to tumorigenesis.[311]

The contribution of elevated FSH to tumor formation in *Inha*$^{-/-}$ mice has also been examined. Elevated FSH by itself does not cause tumor development but results in the formation of hemorrhagic cysts in the ovaries, as demonstrated by overexpression of FSH in transgenic mice.[313] Eventually, these mice die due to enlarged cystic ovaries and urinary bladder obstructions.[313] Crosses of hypogonadal (*Gnrh*^{hpg}) mice, which lack hypothalamic gonadotropin-releasing hormone 1 (GnRH1), to *Inha* mice to generate *Gnrh1*$^{hpg/hpg}$ *Inha*$^{-/-}$ mice prevent the wasting syndrome, but in females this does not prevent premalignant ovarian tumor foci.[314] Granulosa cells from *Inha* null mice initiate an abnormal gene expression program in response to gonadotropin stimulation.[315] Instead of inducing antral follicle formation and cumulus expansion, exogenous gonadotropin treatment causes excessive proliferation of the granulosa cells, which results in loss of oocytes and the secretion of a large quantity of extracellular matrix.[315] The gene expression pattern in *Inha* null cells includes changes in extracellular matrix and cell adhesion genes, as well as genes encoding steroidogenic enzymes and regulators of the cell cycle.

A clear demonstration that FSH modulates granulosa cell tumor progression, but not tumor formation, was shown by generating *Inha*$^{-/-}$ *Fshb*$^{-/-}$ mice.[313] While these mice live longer than *Inha*$^{-/-}$ females,

double-homozygous female mice die by 39 weeks, in contrast to males, which survived to 1 year. Tumors from these mice grow slower and are less invasive. In addition, they do not display the high levels of activin and estradiol as do the *Inha*$^{-/-}$ single-mutant mice. Double mutants of *Inha* and both α and β forms of the estrogen receptor (or all three genes) in females do not affect tumor formation, indicating that estrogen signaling does not contribute to the tumor pathogenesis.[316] These data demonstrate that while FSH and activin signaling modulate the tumor phenotype, they do not directly contribute to the tumor formation. Additional and as-of-yet undescribed mechanisms for the tumor suppressor function of inhibin in sex cord–stromal tumors must be operating.

Because tumor suppressor genes function through an antiproliferative signal, the cell cycle regulatory genes, p27 and cyclin D2, were examined in the *Inha*$^{-/-}$ background. Cyclins, cyclin-dependent kinases (CDKs), and cyclin-dependent kinase inhibitors (CKIs) regulate cell cycle progression. Overexpression of cyclins and CDKs, or underexpression of CKIs, results in uncontrolled cell proliferation. Cyclin D and p27 are involved in the G1-S phase transition; cyclin D2–CDK promotes S phase commitment, while p27 inhibits it.[317] Cyclin D2 has been shown to be FSH responsive and cyclin D2 knockout mice are infertile due to a lack of granulosa cell proliferation,[262] and cyclin D2 is upregulated in *Inha*$^{-/-}$ mice.[318] Double-knockout mice of cyclin D2 and inhibin α have delayed ovarian tumorigenesis but eventually develop tumors and die by 29 weeks of age, very similar to *Inha*$^{-/-}$ *Fshb*$^{-/-}$ mice.[313,316] However, prior to advanced tumor stages, in the absence of inhibin, more advanced preantral follicles are seen than in the cyclin D2 knockout alone.[316] p27 is a CKI that, when mutated in mice, results in increased body size, hyperplasia of multiple organs, cancer, and infertility in female mice due to granulosa cell defects.[319–321] Double-homozygous mutants of p27 and inhibin α have an enhanced *Inha*$^{-/-}$ phenotype and die by 8 weeks of age.[318] It is clear from these studies that while modifiers of the *Inha*$^{-/-}$ phenotype have been discovered, the tumor-suppressing activity of inhibin is still largely a mystery.

Inhibin Mutations and Human Disease

Genetic mutations in the inhibin α gene associate with primary ovarian insufficiency (POI), also known as premature ovarian failure (POF). POI is usually without known cause (idiopathic) and is characterized by amenorrhea, hypoestrogenism, and elevated levels of gonadotropins in women under the age of 40. Because high levels of serum gonadotropins might indicate a disruption in the negative feedback from the gonads, inhibin represents a good candidate gene. Several studies of POI patients have identified mutations in the inhibin α gene. In one study of 43 POF patients from New Zealand and Slovenia, three women showed an G→A missense mutation at nucleotide 769, which would cause an alanine-to-threonine amino acid substitution in the coding region of inhibin α; only one out of 150 control subjects were found to carry this same mutation.[322] In a second study of a cohort of Italian women with ovarian failure, a significant increase was seen in the number of females with this same mutation in both POI (7/157) and primary-amenorrhea (3/12) but not in control (0/100) and early-menopause (0/36) patients.[323] This mutation has subsequently been verified in populations from India, Korea, and Argentina, but is not significantly different from the control frequency in a German cohort or a subsequent POI population from Italy.[324] Functional analysis showed that the mutation did not interfere with dimeric inhibin production, but instead expression of the mutant INHA subunit reduced the bioactivity of inhibin B compared to that of the wild type.[325] Additional studies have looked for links between inhibin and female reproductive disease, but currently no other mutations in inhibin α have been described. Upregulated inhibin A levels have been used as a marker for granulosa cell tumors and mucinous carcinomas,[326–330] but unlike the mouse model, loss of inhibin α has not been associated with granulosa cell tumors. This has led to the suggestion that granulosa cell tumors may acquire a resistance to the actions of inhibin.[301] In contrast, the absence of inhibin α expression and a loss of heterozygosity are associated with some forms of prostate cancer.[331,332]

PCOS is another ovarian pathology with many potential etiologies. PCOS patients show infertility, disrupted menstrual cycles, hyperandrogenism, hyperinsulinemia, and high levels of serum LH. Superficially, the phenotype of constitutive overexpression of inhibin α in mice resembles PCOS, but cyst morphology suggests that the mouse model and the human disease are different pathologies.[333] In addition, while some studies have shown higher levels of inhibin in cystic follicles of PCOS patients, other studies have not supported this.[334–338] Clearly, the etiology of PCOS is complex and multifactorial, and multiple perturbations in the reproductive axis are present. A genome-wide association study (GWAS) among Han Chinese women with PCOS identified eight highly significant loci.[339] Among these are three novel loci that contain LH–choriogonadotropin receptor (*LHCGR*), thyroid adenoma-associated gene (*THADA*), and differentially expressed in normal and neoplastic cells (DENN)–MAPK activating death domain (MADD) containing 1A (*DENND1A*). *THADA* and *DENND1A* loci associations have been replicated in some of the European cohorts.[340,341] Little is known about the roles of *THADA* and *DENND1A* in ovarian biology, and GWAS studies may have identified novel pathways relevant to

ovarian biology. Whether these particular loci or neighboring genes are the true causes of PCOS remains to be functionally proven.

Activins

Activins are dimers of the inhibin β subunit. There are four isoforms of the mammalian β subunit: β_A, β_B, β_C, and β_E. Biological activity of activin A (β_A:β_A) and activin B (β_B:β_B) homodimers has been well described,[342–344] but less is known about activin AB (β_A:β_B) heterodimers.[345] The β_C and β_D isoforms are liver specific, but knockout mice show no apparent defects, and therefore their biological significance is unclear.[346,347] Activins signal through a heteromeric assembly of membrane-bound serine–threonine kinase receptors that include a type II ligand-binding receptor and a type I signaling receptor.[307] Two type II receptors named ACVR2 and ACVR2B are the predominant activin-binding receptors.[41,348,349] The type II receptors complex with one of two type I receptors called activin receptor-like kinases (ALKs), primarily through ALK4 but also with ALK7,[350–352] which results in the phosphorylation and activation of the transcription factors SMAD2 and SMAD3.[353] SMAD2 and SMAD3 then mediate gene transcription with interactions with transcriptional co-activators and co-repressors.[354]

The roles of activin in the reproductive axis are diverse. A local feedback mechanism operates in the pituitary to activate synthesis and release of FSH.[355–359] Within the ovary, activin has been proposed to act on multiple cell compartments. Activin subunits are expressed in granulosa cells of rats, mice, and humans.[234,360–362] In vitro, activin induces granulosa cell proliferation and FSH receptor expression in immature follicles, and increases FSH-dependent aromatase activity.[166,363–366] In more mature follicles, activin can inhibit terminal differentiation by inhibiting premature luteinization through suppression of progesterone production.[366–368] In thecal cells, activin opposes inhibin and decreases androgen production.[244,369] Oocytes also respond to activin, and activin can promote oocyte maturation in primates and humans.[247,370] Thus, the potential paracrine effects of activin in the ovary are wide-ranging.

To understand activin's effects in vivo, knockout mice for activin β_A (*Inhba*) and β_B (*Inhbb*) were generated.[257,258] Mice homozygous for β_B are viable and give birth to live pups but are unable to nurse their offspring due to defects in milk production.[258] In contrast, *Inhba* null mice die shortly after birth with craniofacial defects, including cleft palate; loss of whiskers, upper and lower incisors, and lower molars; and defects in the retina.[257,371–373] The perinatal lethality is attributed to the inability of homozygous pups to suckle. The perinatal lethality and craniofacial defects can be rescued by "knocking in" the activin β_B subunit gene into the β_A locus, suggesting that activin A and activin B have redundant functions in craniofacial development.[259] Conditional deletion of the activin βA subunit in granulosa cells results in subfertility and the development of follicles containing multiple oocytes.[83] When the conditional deletion of activin βA is generated in mice that are homozygous null for the activin βB subunit, infertility results.[83] The most striking defect in activin-deficient ovaries is the progressive accumulation of corpora lutea, which causes a dramatic increase in overall size and a significant increase in serum progesterone levels. Corpora lutea in activin-deficient ovaries are unable to undergo structural regression, although the role of activins in luteolysis is not fully characterized. Connective tissue growth factor (*Ctgf*), a matricellular protein belonging to the CCN family with roles in cell adhesion, migration, proliferation, and angiogenesis,[374] is downregulated in activin-deficient ovaries,[83] and mice deficient in *Ctgf* show a similar, although milder, phenotype.[375,376] An accumulation of CLs is also seen in mice conditionally null in granulosa cells for *Tsc1*,[377] a negative regulator of mTORC1, and in granulosa cells deficient in *Pten*. How these pathways intersect to control corpus luteum regression is not known. However, unlike the activin-deficient mouse model, the *Tsc1* cKO and the *Pten* cKO are fertile, with enhanced ovulation and no changes in serum progesterone.[378] Because the activin-deficient ovary secretes high levels of progesterone but is also defective in structural regression of CLs, this indicates that the functional (endocrine) activity of CLs can be uncoupled from the structural luteolysis, and that activin signaling may lie upstream of the PI3K pathway during this process.

A null allele for one of the activin receptors, ACVR2, has also been generated.[257] Twenty percent of the homozygous null mice die perinatally with primary defects in the mandible and secondary defects in the palate. Surviving female homozygous *Acvr2* null mice display disrupted pituitary function related to the suppression of FSH. Ovaries from the surviving homozygous null females are small, with no corpora lutea and minimal antral follicle development. Transplants of $Acvr2^{-/-}$ ovaries to ovariectomized immunocompatible donor females showed normal follicular development and restored fertility to the host mice.[296] An additional activin receptor, ACVR2B, binds activin with a higher affinity than ACVR2,[349] and this receptor is expressed in mammalian ovaries.[308,361,379] The contribution of ACVR2B to activin signaling in the ovary remains to be explored since these null mice mostly die.

Activin signaling, like TGFβ signaling, results in the phosphorylation and activation of SMAD2 and SMAD3.[380,381] Null alleles for many of the Smad genes have been generated, but given the significance of TGFβ–activin- and BMP-signaling pathways in the formation of embryonic and extraembryonic tissues,

many of the knockouts are embryonic lethal. *Smad2* null embryos fail to gastrulate, are defective in mesoderm formation, display anteroposterior axis defects, and die at E6.5 through E8.5. Mice with congenital deficiency of *Smad3* are viable[382,383] and show reduced fertility.[384,385] Single conditional knockout of either *Smad2* or *Smad3* has no effect on female fertility,[312] but double conditional knockouts in granulosa cells of the ovary (*Smad2–Smad3* double knockout) are infertile by 5 months of age.[312] The phenotype of *Smad2–Smad3* double conditional knockout is very similar to that of the granulosa cell conditional knockout of *Smad4*, the common SMAD.[386] Both of these mouse models have ovaries with decreased numbers of antral follicles, oocytes trapped within luteinizing follicles, reduced ovulation, and impaired cumulus expansion. The cumulus expansion defects are likely attributable to loss of GDF9 signaling from the oocyte to the cumulus cells, as this is the pathway that GDF9 utilizes.[387,388] In addition, it has been shown that oocyte-secreted factors are required to specify the cumulus cell lineage and prevent premature luteinization of granulosa cells,[389] and these data support a role for GDF9 signaling through SMAD2/3 as a primary mediator of this activity. As TGFβ, activin, and GDF9 transmit signals through SMAD2 and SMAD3, the challenge will be to understand the molecular output of each of these ligands in normal ovarian physiology at the different stages of follicle development and how this is altered in the pathological state.

Follistatin

Follistatin was first identified from gonadal extracts as an FSH-modulatory factor.[226,390,391] Follistatin is a single polypeptide protein that is not structurally related to the TGFβ superfamily but acts as a binding protein and functional antagonist of activin.[379,392,393] In the ovary, granulosa cells and luteal cells are the main sites of production,[362,394,395] but this is stage dependent. Follistatin is not expressed in primordial and primary follicles, but is expressed from antral stages.[362,395]

Both loss-of-function and gain-of-function mutations have been generated for the follistatin gene.[396,397] Follistatin null mice die within hours after birth; however, these mice are a resource for understanding prenatal ovarian development since follistatin activity is required for embryonic ovarian development.[264] *Fst* null ovaries, similar to *Wnt4* null XX gonads, lose 90% of their germ cells at E16.5 and have almost none by birth. When both *Inhbb* and *Fst* are deleted together, normal ovary development is restored.[398] Follistatin is also known to block BMP signaling, and BMP2 is expressed in the developing ovary, although its role has not been fully established.[399] Conditional deletion of follistatin in the granulosa cells of postnatal mice results in fertility defects that include reduced litter size and number, ovulation and fertilization defects, and elevated levels of FSH and LH with reduced levels of testosterone.[265] In addition, the ovaries contain Sertoli-like structures also seen in inhibin α null mice, ERα and ERβ knockouts, and FSHβ, follistatin, and AMH transgenic mice.[41,397,400,401] Granulosa cell function appears generally disrupted, possibly because of unrestricted activity of activin. In humans, it is known that serum generally contains high levels of follistatin-bound, and therefore inactive, activin,[255] and follicular fluid shows high levels of unbound follistatin.[402] Disruptions in the balance of follistatin to activin would lead to more activin signaling, and potentially the disease state seen in follistatin-null ovaries. Transgenic mice that overexpress follistatin are viable but show reproductive defects.[397] In transgenic lines with the highest expression of follistatin, females were infertile. In the transgenic lines with less follistatin expression, females developed infertility within several months. Histologically, ovaries appeared similar to FSHβ and *Acvr2* null mice, with a follicle block prior to the antral stage and an increase in follicular atresia. The serum profiles confirmed that FSH was suppressed, and estradiol was undetectable. It is unclear whether all of the ovarian pathologies can be attributed to diminished pituitary function or whether there is a local abrogation of activin (and other TGFβ family) signaling in the ovary as well (Figure 21.5).

BMP Signaling SMADs

The BMPs signal through the BMP type I receptors, ACVRL1 (ALK1), ACVR1A (ALK2), BMPR1A (ALK3), and BMPR1B (ALK6), which phosphorylate SMAD1, SMAD5, and SMAD8. Mice conditionally null for these SMADs have been generated using *Amhr2cre* transgenic mice.[403] Similar to single deletions of *Smad2* or *Smad3*, single deletion of *Smad1* or *Smad5* has no effect on female fecundity. In addition, *Smad8* homozygous null mice are viable and fertile.[403,404] Generating a conditional *Smad1* or *Smad5* deletion in the *Smad8*$^{-/-}$ background does not affect the ability of female mice to reproduce. However, a combined deletion of *Smad1* and *Smad5* in granulosa cells initially results in a reduction in litter sizes and infertility at 4–6 months of age. The infertility at this age is likely caused by the development of granulosa cell tumors, which occurs in 100% of the *Smad1/Smad5* double-knockout mice. Conditional deletion of the BMP receptors, *Bmpr1a* and *Bmpr1b*, also causes granulosa cell tumor formation, although at later ages than with the *Smad1/Smad5* double knockout.[405] Granulosa cell tumors are identifiable histologically in ovaries in the *Smad1/Smad5* double conditional knockouts by 8 weeks of age, and by 8 months of age, peritoneal implants are found

in a majority of knockouts. The endocrine profile as well as tumor histology indicate that the *Smad1/Smad5* double-knockout tumors are similar to the juvenile form of granulosa cell tumors (JGCT).[406] The etiology of human JGCTs is unknown and, unlike the adult form (AGCT), does not contain a *FOXL2* C134W mutation. However, aggressive forms of JGCT are associated with decreased or absent levels of *FOXL2*.[407] *Smad1/Smad5* double-knockout tumors also show a significant reduction in levels of *Foxl2*, and genes differentially expressed in the *Smad1/Smad5* double-knockout tumors are enriched for FOXL2-binding sites within their promoters.[408] These data suggest that FOXL2 could play a key role in the pathogenesis of both forms of granulosa cell tumors.

Oocyte-specific TGFβ Members

Oocyte–granulosa cell interactions are paramount for the growth of oocytes and proliferation and differentiation of granulosa cells.[9] Currently, oocytes are ascribed a dominant role in directing folliculogenesis.[409,410] The hypothesis that oocytes control the rate of follicular development was tested by isolating oocytes from the secondary follicles of 12-day-old mice and combining these oocytes with the somatic cells isolated from newborn mouse ovaries. When these re-aggregates were implanted beneath the renal capsules of ovariectomized host females, antral follicles were visible in 9 days, indicating that the rate of follicular development was accelerated by almost twofold.[410] As a control, oocytes from primordial follicles of newborn mice were reaggregated with the same-age somatic cells from newborn mice, and after 9 days, only secondary follicles were observed with an absence of antral follicles. The granulosa cells from the reaggregated ovaries underwent cumulus expansion when exposed to FSH in vitro, and recovered oocytes were competent to undergo fertilization and embryonic development. These experiments indicate that a 12-day oocyte is able to accelerate somatic cell differentiation and proliferation with resulting accelerated production of antral follicles. Cumulus cells are directly coupled to the oocyte via gap junctions[411,412] and provide nutrient support for the oocytes, which are deficient in some cellular processes such as amino acids uptake, glycolysis, and cholesterol metabolism.[413] Oocyte–granulosa cell communication requires that oocytes secrete factors that have an autocrine or paracrine function, and/or express receptors on their cell surface for detecting granulosa cell–derived paracrine factors. GDF9 and BMP play dominant roles in mediating this interaction.

Growth Differentiation Factor 9

GDF9 is an oocyte-specific member of the TGFβ superfamily.[414] In mice, *Gdf9* is preferentially expressed in oocytes within the ovary as early Type 2 and Type 3a follicles, and its transcripts are found abundantly in unfertilized eggs.[414,415] *Gdf9* null mice form primary follicles with large oocytes that are greater than 70 μm in diameter and that are surrounded by a single layer of cuboidal granulosa cells (Figure 21.3).[254,266,416] Fully grown oocytes isolated from *Gdf9* null mice can progress to advanced stages of differentiation that are equivalent to sizes found in antral follicles of control mice.[416] In vitro maturation of oocytes from *Gdf9* null mice revealed that most of the oocytes are capable of resuming meiosis. Among the characteristic ultrastructural features of oocytes from *Gdf9* null mice are perinuclear organelle aggregation, unusual peripheral Golgi complexes, and a failure to form cortical granules.[416]

Gdf9 null mice showed convincingly for the first time that factors secreted by oocytes are critical for granulosa cell proliferation and follicular progression. The knockout model also demonstrated that GDF9 is not critical in the transition from primordial to primary follicles but plays a crucial role in the growth of follicles beyond the primary follicular stage. Molecular analysis of the *Gdf9* knockout revealed a lack of thecal cell markers (17α-hydroxylase, LH receptor, and KIT).[254] While thecal cell *Kit* expression is absent in these mice, *Kit* expression in the oocyte is unchanged. *Kitl* and inhibin α levels are upregulated in follicles that lack GDF9, indicating that GDF9 may negatively regulate these growth factors. In vitro studies corroborate the suppression of *Kitl* expression in granulosa cells of preantral and mural granulosa cells by recombinant GDF9.[154] The increase in oocyte size in the *Gdf9* null ovaries has been attributed to the upregulation of KITL leading to greater signaling through oocyte-expressed KIT.

A direct role for inhibin in the pathogenesis of the *Gdf9* knockout phenotype has also been described. Granulosa cells of arrested *Gdf9*$^{-/-}$ primary follicles expressed abnormally high levels of inhibin α.[254] *Inha* is also abnormally expressed in steroidogenic follicular nests and in follicles containing degenerating oocytes. To determine if the elevated inhibin levels were partly responsible for the nonproliferative state of granulosa cells in *Gdf9* null ovaries, crosses of *Inha* mutant mice to *Gdf9* mutant mice were generated. Unlike *Gdf9*$^{-/-}$ ovaries, double-mutant *Inha*$^{-/-}$ *Gdf9*$^{-/-}$ follicles become multilaminar and acquire a morphologically distinct thecal cell layer (Figure 21.3).[417] Thus, by decreasing inhibin α expression, granulosa cell proliferation and thecal cell recruitment were recovered. The increased proliferation of granulosa cells is not due to increases in FSH, because serum levels of FSH are lower in prepubertal *Inha*$^{-/-}$ *Gdf9*$^{-/-}$ mice compared to *Gdf9*$^{-/-}$ ovaries, and are similar to WT levels.[418] Serum levels of LH have not been measured in *Inha*$^{-/-}$ *Gdf9*$^{-/-}$ mice.[417]

Even though thecal cells develop in *Inha*$^{-/-}$ *Gdf9*$^{-/-}$ ovaries, they appear to be nonfunctional and do not

express markers associated with their differentiation, including LH receptor, *Kit*, and the steroidogenic enzyme 17alpha-hydroxylase (*Cyp17*). One possibility is that the elimination of inhibin α in double-null ovaries relieves the repression of granulosa cell growth and thecal cell recruitment by allowing the formation of activin dimers. Because activins are known regulators of preantral follicle growth and differentiation and have stage-specific effects on different classes of follicles, activins (or BMPs) may promote granulosa cell proliferation in the small preantral follicles.[363,364,419] However, follicles in *Inha*$^{-/-}$/*Gdf9*$^{-/-}$ double knockouts arrest again at the 5b stage, and thus additional proteins, including GDF9, may be necessary again at this stage for subsequent development. Because the inhibins and activins are secreted ligands and are functional antagonists, it is likely that their production as well as access to the cell signaling machinery are under strict molecular regulation.

Because *Gdf9* knockout ovaries arrest very early in postnatal folliculogenesis, studies looking for effects of GDF9 at later stages have had to rely on in vitro studies. These have shown that GDF9 signaling is critical in antral follicle growth and ovulation.[420–423] During ovulation, GDF9 induces cumulus cell expansion, an inflammation-like process that involves the mucification of the cells surrounding the oocyte. This process binds the cumulus cells to the oocyte, protects the oocyte during follicular extrusion, and assists in sperm binding and fertilization. Cumulus cell expansion partly involves the production of hyaluronic acid (HA), prostaglandin E2 (PGE2), pentraxin 3 (PTX3), and tumor necrosis factor alpha induced protein 6 (TNFαIP6),[283,284,424] all of which have been demonstrated to be regulated by GDF9 in vitro.[283,423,425] The role of GDF9 in preovulatory granulosa cells has been studied by isolating mural granulosa cells from large antral follicles, culturing them with and without recombinant GDF9, and comparing gene expression using oligonucleotide array hybridization with microarray chips. Genes noted to be highly induced in granulosa cells treated with recombinant GDF9 include *Ptx3*, *Tnfip6*, and gremlin.[283,426]

Ptx3 knockout female mice are subfertile and have defects in ovulation.[283,427] Superovulated *Ptx3* null mice release fewer oocytes than controls. Surprisingly, many oocytes isolated from *Ptx3* null mice were denuded of cumulus granulosa cells, whereas oocytes from control mice retained their cumulus cells. Ovulation induction followed by fertilization revealed that only 1.3% of oocytes fertilized in *Ptx3* knockout, while 55% fertilized in heterozygous controls. It is therefore likely that disruption in the cumulus mass surrounding the oocytes causes reduced fertilization and the subfertility in *Ptx3* knockout mice.

The importance of cumulus cell expansion in fertility has also been demonstrated by the knockout mouse model for tumor necrosis factor alpha induced protein 6 (*Tnfaip6*).[284] Female *Tnfaip6*$^{-/-}$ mice are infertile.[284] The cumulus cell complexes from these mice fail to expand due to the lack of hyaluronan and heavy-chain inter-α-trypsin inhibitor family complexes. Fertility can be restored by treating cumulus cell–oocyte complexes in vitro with recombinant TNFαIP6, which has been shown to catalyze the transfer of heavy chains to hyaluronan in cell-free systems.[284] Thus, knockout mice for two of the genes demonstrated to be downstream of GDF9 signaling, *Ptx3* and *Tnfaip6*, have severe defects in cumulus expansion that render the mice sterile.

The signaling receptor complex for GDF9 has not been fully elucidated. Blocking signaling from the TGFβ type I receptor (TGFBR1, also called ALK5) or the BMP type II receptor (BMPR2) inhibits GDF9 activity in mouse or rat granulosa cells.[428–430] However, mice with a conditional null mutation in *Tgfbr1* in the reproductive tract, while sterile, have minimal ovarian defects.[431] Cumulus cells from *Tgfbr1* conditional knockout mice undergo cumulus expansion in vitro and in vivo, and show normal regulation of GDF9 target genes. In addition, careful analysis shows that *Tgfbr1* expression in the mouse ovary is predominantly localized to thecal cells, corpora lutea, and oocytes, with minimal to background expression in granulosa cells.[431] These data suggest that GDF9 may signal via additional receptors. Small molecule inhibitors that block ALK4, ALK5, and ALK7 signaling also inhibit GDF9-induced phosphorylation of SMAD2/3 and gene expression.[428,429] Therefore, ALK4 and/or ALK7 may be the physiologic receptors for GDF9 in granulosa cells (Figure 21.5).

Mice lacking ALK4 die prior to gastrulation of embryos,[432] and the role of ALK4 in granulosa cells has not been determined. However, *Alk7* knockout mice are viable.[433] In the ovary, *Alk7* is expressed in steroidogenic factor1 (*SF1*, also called *Nr5a1*)–positive granulosa cells.[434] *Alk7* is also expressed in gonadotropes of the pituitary as well as some neurons of the neuroendocrine hypothalamus.[434] Female mice null for *Alk7* (*Alk7*$^{-/-}$) have a delayed reproductive cycle, although the phenotype is complicated due to the expression pattern in multiple reproductive tissues. However, there are more degenerating follicles in juvenile *Alk7*$^{-/-}$ ovaries, at a time when follicle growth is thought to be mainly independent of pituitary gonadotropins. In addition, superovulating juvenile mice with exogenous gonadotrophins produce fewer cumulus–oocyte complexes in *Alk7*$^{-/-}$ females than their wild-type controls, indicating an impaired ovulatory response. These data suggest that there may be defects in intraovarian signaling due to loss of ALK7. However, neither *Alk7*$^{-/-}$ nor *Alk5* cKO phenocopies *Gdf9* knockout ovaries, indicating either redundancy between receptors or that *Alk4* may be the predominant signaling receptor for GDF9 in mice.

TABLE 21.3 Sheep Mutations Causing Ovarian Defects

Mutation (Strain)	Gene	Type of Mutation	Region of Mutation	Possible Mechanism of Disruption
$FecX^{I}$ (Inverdale)	*BMP15*	Substitution D→V	Mature	Protein dimerization[17]
$FecX^{H}$ (Hanna)	*BMP15*	Substitution (premature stop)	Mature	Truncated protein product[17]
$FecX^{B}$	*BMP15*	Substitution S→I		Residue may be involved in type II receptor binding[18]
$FecX^{L}$	*BMP15*	Substitution C→Y		Prevents protein processing and disrupts secretion of precursor and mature[19]
$FecX^{G}$	*BMP15*	Substitution (premature stop)	Pre-pro	Premature termination in pre-pro region[18]
$FecG^{H}$	*GDF9*	Substitution S→F	Mature	Possibly interrupts type I receptor binding[18]
FecB (Booroola)	*BMPR1B*	Substitution Q→R	Kinase domain	Kinase activity[20]

There are species-specific differences in the signaling of recombinant GDF9. Mouse GDF9 is secreted in an active form, while human GDF9 is not.[387] Human GDF9 is secreted in the latent form in association with its pro-domain, and removal of the pro-domain will activate it.[435] Site-directed mutagenesis that introduces mouse residues into the pro-domains and mature domains of human GDF9 identified Gly^{391} as the residue that confers latency to human GDF9.[435] This residue lies in the mature domain of GDF9, which is 90% identical in mouse and human GDF9. Gly^{391} is found in all species except mouse, rat, hamster, galago, and possum, where it is found as an arginine.[435] This amino acid is located in the prehelix loop that forms the predicted type I receptor-binding pocket.[436,437] Arg at this residue increases affinity of GDF9 for its receptor.[435] Regulation of active and latent forms of GDF9 may contribute to the differences seen in follicle development and ovulation rates across species. Additionally, both mouse and human GDF9 form heterodimers with BMP15, and the mouse GDF9:BMP15 heterodimer has greater biopotency than homodimeric GDF9[438] (see the section Bone Morphogenetic Protein 15 (*Bmp15*)).

Bone Morphogenetic Protein 15 (Bmp15)

BMPs form the largest subgroup of the TGFβ superfamily of growth and differentiation factors,[297] and BMP15 was cloned using degenerative oligonucleotides to identify novel members of the BMP family.[439] BMP15 is expressed in the ovary, and by in situ hybridization, *Bmp15* appears to be exclusive to oocytes as early as Type 3a but also within oocytes of more advanced follicular stages.[415,439] Mouse and human BMP15 share 76% amino acid identity, and both map to the X chromosome.

Bmp15 null female mice are subfertile on certain genetic backgrounds and have few ovarian histopathologies.[260] Rather, these mice have defects in ovulation and fertilization rates. Because GDF9 and BMP15 expression patterns overlap, it was hypothesized that GDF9 and BMP15 have redundant functions or, alternatively, may function as heterodimers.[260] To address these questions, double-mutant mice were generated. $Bmp15^{-/-}$ $Gdf9^{+/-}$ ovaries have more defects than $Bmp15^{-/-}$ mutants alone, and double-homozygous $Bmp15^{-/-}$ $Gdf9^{-/-}$ resemble $Gdf9^{-/-}$ mutants and display oocyte loss and large fluid-filled cysts (Figure 21.6). Subsequently, it was shown that homodimeric mouse BMP15 is essentially inactive during in vitro assays that assess the process of cumulus expansion.[438] In contrast, heterodimers of mouse GDF9 with mouse BMP15 are 10- to 30-fold more potent than homodimeric mouse GDF9.[438] Thus, the phenotype of $Bmp15^{-/-}$ $Gdf9^{+/-}$ is likely due to loss of the GDF9:BMP15 heterodimer, as well as a decrease in homodimeric GDF9.[438]

In contrast to mouse, BMP15 is important for ovarian function in sheep. This was initially discovered in the study of Inverdale and Hanna sheep. Naturally occurring X-linked mutations cause increased ovulation in the heterozygote animals but primary ovarian failure in homozygote animals[440,441] (Table 21.3). Linkage mapping of the Inverdale mutation was used to identify *BMP15* as one of the candidate genes. *BMP15* gene sequence comparison between Inverdale and wild-type sheep identified a substitution of a highly conserved hydrophobic valine residue of the mature protein with aspartic acid.[17] Mutational analysis of the Hanna sheep identified a nonsense mutation in the *BMP15* coding region.[17,450] Ovarian follicles in sheep homozygous for the *BMP15* mutations do not normally grow beyond the primary follicle stage.[450–452] The ovarian pathology in the *BMP15* sheep mutants resembles the ovarian pathology observed in *Gdf9* null mice. Based on the data that in humans and mice the GDF9:BMP15 heterodimer is the most bioactive form and that only one homodimer is active (i.e., GDF9 in mice and BMP15 in humans),[438] the phenotypes of mutant sheep likely reflect loss of the GDF9:BMP15 heterodimer or the BMP15 homodimer. The differences in use of a GDF9 homodimer (in mice) versus a BMP15 homodimer (in sheep or human) may reflect a fundamental biological difference that remains to be characterized between polyovulatory (i.e., mice and rats) and monoovulatory animals (i.e., sheep, humans, and primates).

Mutations in human *BMP15* mutations have been discovered in a family that had ovarian dysgenesis (ovaries characterized by a lack of germ cells).[453] Two female siblings of an Italian family had primary amenorrhea, ovaries that lacked follicles, a normal 46 XX karyotype, and no evidence of autoimmune disease or consanguinity. A search for candidate genes revealed a mutation in the human *BMP15* gene that involved an A-to-G transition at nucleotide 704, changing a tyrosine at position 235 to a cysteine. The tyrosine residue is highly conserved in human, sheep, mouse, rat, and pig and is located in exon 2 in the propeptide region of the protein. The mutant Y235C protein is unable to stimulate incorporation of ^{3}H-thymidine into human granulosa cells, and it also inhibits wild-type BMP15's ability to stimulate ^{3}H-thymidine incorporation into granulosa cells. In addition, human granulosa cell proliferation is enhanced in the presence of wild-type BMP15, but is unaffected by mutant protein.[453] These data support a hypothesis that secretion of unprocessed monomer or dimeric mutant products causes dominant negative interactions with the wild-type protein, thereby resulting in an early block in folliculogenesis. In addition, it is unclear whether the Y235C mutation affects human BMP15 interactions with GDF9. Polymorphisms in human *BMP15* have also been associated with higher response to ovarian stimulation[454] as well as age at menopause.[455] Variants of BMP15 are also found in patients with premature ovarian failure.[456,457]

BMP Receptor Type IB Receptor (*Bmpr1b* and *Alk6*)

Receptor complexes for the TGFβ family members consist of two closely related transmembrane serine–threonine kinases, the type I and type II receptors. Seven type I and five type II receptors have been identified in mammals. Upon binding the dimeric ligands, the receptor complexes phosphorylate intracellular signaling molecules called SMADs, which subsequently accumulate to the nucleus and regulate transcription of target genes.[297,458,459] Studies on BMP15 signaling using rat primary granulosa cells from early antral follicles and a human granulosa cell line COV434 indicate that BMP15 binds with the highest affinity to ALK6 receptors on the surface of the granulosa cells.[460] Modeled after signaling by other BMP ligands, it has been proposed that the BMP15–ALK6 complex then recruits the type II receptor BMPR2, resulting in signal transduction (SMAD1/5/8 phosphorylation).[460] Human BMP15 also signals using the type I BMP receptor, *BMPR1B* (also called *ALK6*).[461] Consistent with these studies, purified recombinant BMP15 activates the SMAD1/5/8-signaling pathway and regulates cumulus expansion genes (*Ptx3*, *Has2*, *Tnfaip6*, and *Ptgs2*), inhibitor SMADs (*Smad6* and *Smad7*), and BMP antagonists (*Grem1* and *Fst*).[462] BMPR1B is also required for signaling by mouse and human GDF9:BMP15 heterodimers.[438]

The Q249R (glutamine→arginine) mutation in the regulatory serine–threonine kinase domain of the ALK6 (also called BMPR1B) receptor was identified in Booroola ewes and causes increased fertility[20,450,463] (Table 21.3). Females with one copy of this mutation have an ovulation rate of three or four, while those with two copies have an ovulation rate of between five and 14. Animals that carry both the Inverdale and Booroola mutation (i.e., the *BMP15* and *ALK6* mutation, respectively) have greater fertility, further corroborating an interaction between BMP15 and this receptor.[450] BMPR1B is expressed in primordial follicles, and careful examination of ovaries in BMPR1B mutant sheep suggests that BMPR1B affects follicle development from the onset of follicular formation.[464]

A mouse knockout of *Alk6* has been generated, and these mice show infertility, with effects both in the ovary and in the endometrium.[261] In mice, ALK6 is expressed in oocytes of maturing (Type 6) follicles and in oocytes and granulosa cells of antral follicles. No *Alk6* transcripts are detected in granulosa cells of resting, primordial, developing (Type 1–5b), or atretic follicles, corporal lutea, or theca, or in the uterine endometrium.[261] However, histological and transmission electron microscopy studies of *Alk6* null ovaries demonstrate no obvious differences between null and wild-type ovaries. Similar to *Bmp15* knockout mice, *Alk6* knockout mice show defects in cumulus expansion and fertilization in vivo. The mechanism for defective cumulus expansion is not clear, but neither FSH receptor mRNA levels nor prostaglandin E2 receptor mRNA levels are affected. Paradoxically, cyclooxygenase 2 (*Ptgs2*) mRNA levels are elevated in *Alk6* null mice, and this observation has not been explained. Just like the BMP15 ligand, the *Alk6* receptor knockout in mice has a phenotype quite different from that observed in sheep. However, it has not been fully demonstrated what type of mutation (inactivating or activating) the Booroola mutation represents and how changes in the receptor results in altered follicle development and ovulation.

TRANSCRIPTION FACTORS IN PREANTRAL-STAGE FOLLICULOGENESIS

TAF4B RNA Polymerase II and TATA Box Binding Protein (TBP)-Associated Factor (*Taf4b*)

A transcription factor that has been shown to have a critical role in later stages of folliculogenesis is TAF4B (also known as $TAF_{II}105$). TAF4B is a cell type–specific subunit of the core promoter transcription factor,

TFIID.[295] TFIID contains TBP (the TATA-binding protein) and several TAFs (TBP-associated factors).[465] TAF4B is preferentially and highly expressed in germ cells at E14.5 and postnatal day 2 (PD2).[466] After PD2, its expression in germ cells continues until PD25, when it starts to diminish. TAF4B is also expressed in granulosa cells of the adult ovary.[467] The *Taf4b*$^{-/-}$ ovaries are very small and lack functional follicles in the adult mice. *Taf4b*$^{-/-}$ ovaries have a reduced number of oocytes at PD3 and an increased proportion of atretic follicles. *Taf4b*$^{-/-}$ ovaries have fewer primordial follicles as compared with wild type by PD8.[466] In addition, *Taf4b*$^{-/-}$ mice show a premature reproductive senescence.[468] Induced ovulation in *Taf4b*$^{-/-}$ mice results in the release of abnormal oocytes surrounded by an abnormally low number of cumulus cells. Proliferation of granulosa cells is reduced, and the rates of germinal vesicle breakdown (GVBD) and polar body extrusion are reduced in mutant mice. Few oocytes are fertilized, and embryo development does not proceed beyond the two-cell stage.[466] Thus, TAF4B is essential for follicle formation, follicular development, and fertilization. Importantly, the AKT–FOXO3-signaling pathway is downregulated in *Taf4b*$^{-/-}$ adult ovaries.[468] Conditional deletion of *Taf4b* specifically in germ cells and granulosa cells will help to determine the separate contributions of *Taf4b*-deficient soma or germline to ovarian failure.

TATA-Binding Protein 2 (*Tbp2*)

TBP2 (also known as TBPL2 or TRF3) is a germ cell–specific transcription factor that binds to the TATA box of promoters, interacts with transcription factors IIA and IIB (TFIIA and TFIIB), and mediates RNA polymerase II transcription initiation in vitro. In the ovary, the expression of TBP2 has been detected exclusively in the oocytes throughout folliculogenesis.[469] *Tbp2*$^{-/-}$ mice are infertile due to a defect in folliculogenesis. Adult *Tbp2*$^{-/-}$ ovaries have an increased number of primordial and primary follicles, but a diminished number of secondary follicles, the majority of which are morphologically abnormal. In addition, a gene expression profiling study revealed downregulation of *Gdf9*, *Bmp15*, and *Zp3* and upregulation of *Oct4* and *Nobox* in *Tbp2*$^{-/-}$ ovaries.[470] The mechanisms that underlie TBP2 action remain to be elucidated.

Forkhead (*Foxo*) Transcription Factors

The forkhead transcription factors (FOXO) have roles in cell cycle arrest and apoptosis, and, as demonstrated by the embryonic lethality of a *Foxo1* knockout, these proteins are important in embryogenesis.[471] There are four FOXO family members—FOXO1, FOXO3, FOXO4, and FOXO6—although expression of the latter is predominantly restricted to the brain.[472] In contrast to *Foxo1*, the mouse knockout of *Foxo3* is viable but shows some hematologic defects in addition to an age-dependent infertility[135] (see the section PI3K–AKT and Tsc1–mTORC1 Signaling Pathways). *Foxo4* null mice are also viable and fertile, with no indication of reproductive dysfunction.[471] *Foxo1* is preferentially expressed in granulosa cells of growing follicles. Expression of a constitutively active FOXO1 in granulosa cells suppresses expression of key genes that control proliferation: cyclin D2 (*Ccnd2*), aromatase (*Cyp19a1*), FSH receptor (*Fshr*), and *Lhcgr*.[473] FOXO1 also negatively regulates genes involved in sterol and lipid biosynthesis,[474] and thus it is possible that defects in FSH, IGF1, or insulin signaling impact FOXO function, and thus underlie infertility in some human diseases such as diabetes.[475]

Conditional deletion of both *Foxo1* and *Foxo3* using either *Amhr2cre* or *Cyp19cre* results in female sterility.[285] Part of the phenotype arises because of undetectable levels of FSH; loss of FSH results from suppression of *Fshb* gene expression along with several of its transcriptional regulators in the pituitary. Gonadotropin stimulation can induce ovulation in younger mice (i.e., at 25 days of age), but ovulation is impaired by 2 months of age, indicating that gonadotropin loss cannot fully explain the phenotype. Ovariectomy in mutant mice results in an increase in *Fshb* expression and serum FSH levels, suggesting that the *Foxo1/Foxo3* double-knockout ovary produces an inhibitory substance that acts on the pituitary. Serum levels of estradiol and testosterone are similar to those of controls, and serum levels of inhibin A or inhibin B, or granulosa cell expression of *Inha*, *Inhba*, or *Inhbb*, are unchanged. This has led to the hypothesis that the ovary-derived FSH inhibitor substance is a potentially novel, nonclassical endocrine factor.[285] *Foxo1/Foxo3* null granulosa cells show a disrupted gene expression pattern characterized by a loss of growth-promoting and apoptosis-related genes.[320] Several growth-promoting genes are co-regulated by activin and FOXO1/3, while the apoptosis genes are co-regulated by BMP2 and FOXO1/3, suggesting that FOXO1 and FOXO3 interact with both SMAD pathways to exert control over granulosa cell growth and differentiation.[320]

GATA Transcription Factors

There are six members of the GATA family of transcription factors, GATA1–6, which regulate development and cell specification for variety of tissues. GATA factors bind to a consensus site, (A/T)GATA(A/G), from which their name is derived. *Gata4* and *Gata6* are highly expressed in granulosa cells and regulate the expression of genes involved in follicle development and steroid synthesis.[476–478] In the postnatal ovary, *Gata4* expression commences in granulosa cells during the transition from primordial to primary follicle,[477,479] while *Gata6* expression is delayed until adulthood.[477]

Deletion of *Gata6* in granulosa cells has no effect on female reproduction, although conditional deletion of *Gata4* causes subfertility.[480] Co-deletion of *Gata4* and *Gata6* causes irregular estrous cycles, a lack of follicular development, and an increase in atretic follicles.[480] This is due in part to loss of expression of *Fshr*, which is undetectable in ovaries of *Gata4* single conditional knockouts and *Gata4/Gata6* double conditional knockouts, as well as genes downstream of FSH signaling and markers of granulosa cell differentiation, such as *Lhcgr* and *Cyp19a1*.[480] Loss of *Fshr* can be attributed to loss of GATA4, as GATA4 directly binds and stimulates expression from the *Fshr* promoter.[480] Currently, there are no data supporting GATA4 regulation of *FSHR* in humans, although this may be a mechanism that could account for the low levels of FSHR in women with poor ovarian response to gonadotropin stimulation who are undergoing infertility treatments.[480]

ANTRAL FOLLICLE DEVELOPMENT

Key Roles of the Hypothalamus and Pituitary

Formation of the antrum heralds the final phases of folliculogenesis and the transition from intraovarian to extraovarian regulation. The hypothalamic–pituitary–gonadal (HPG) axis in females coordinates follicle maturation with sexual behavior and the physiologic preparation for pregnancy. Prior to a mature HPG axis, follicles are recruited to grow from primordial follicles, but cannot form antral follicles without sufficient gonadotropin stimulation. Spontaneous and targeted mutations in mice, as well as genetic disorders in humans, affecting pituitary production of various peptides and hormones have provided important insight into the hormonal regulation of folliculogenesis. This section will focus on the role of pituitary hormones in ovarian function.[481]

Follicle-Stimulating Hormone

The pituitary glycoprotein FSH plays an essential role in reproduction through interaction with gonadal FSH receptors. FSH is a dimeric glycoprotein composed of a unique β subunit complexed with a common α subunit that is shared with thyroid-stimulating hormone, LH, and chorionic gonadotropin. FSH binds to the FSH receptor and activates cell signals that lead to germ cell maturation and follicular growth.[482] Male mice deficient in FSH through deletion of the *Fshb* gene are fertile, but with decreased sperm concentration, sperm motility, and testes size. In contrast, females lacking FSH are infertile, with small uteri and ovaries, elevated LH, and lack of estrous cycles[22] (Figure 21.3(B)). Ovarian histology at 6 weeks revealed the presence of primordial, primary, and multilayered preantral follicles. However, no antral follicles are formed, and the knockout mice do not ovulate. Subsequently, it was shown that during the initial wave of postnatal follicle growth, there are fewer growing follicles in $Fshb^{-/-}$ mice, and FSH accelerates some functions necessary for oocyte development, such as the acquisition of developmental competence.[483]

Multiple genes are abnormally regulated in the FSHβ knockout mice.[484] *Fshr* is upregulated in FSHβ null mice almost twofold as compared to wild type. *Lhcgr* is expressed almost fivefold less in FSHβ null ovaries, consistent with the lack of corpora lutea and late-stage follicles. Serum- and glucocorticoid-inducible kinase (SGK), which is induced in preovulatory granulosa cells by FSH and is thought to play a role in the transition of the proliferative to terminal luteal stage,[485–487] is also downregulated in FSHβ knockout mice. As expected, *P450scc* mRNA levels are downregulated almost sixfold, also likely due to the lack of corpora lutea. Aromatase (CYP19), which converts androgens to estrogens,[488,489] is decreased sixfold in the FSHβ null mice.

FSH promotes granulosa cell proliferation, and FSHβ knockouts arrest at the preantral stages of follicular development. Cyclin D2 null[262] and *Igf1* null female mice[268,269] are also infertile and demonstrate an arrest at the same preantral follicle stages as FSHβ null ovaries. Interestingly, the lack of granulosa cell proliferation in FSHβ null mice is not due to lack of cyclin D2 since it continues to be expressed,[484] and the RNA levels of the cyclin-dependent kinases *Cdk2* and *Cdk4* are not affected in the FSHβ null ovaries. Although *Igf1* mRNA levels are not altered in FSHβ null ovaries, FSH receptor mRNA is depressed in *Igf1* null mice.[268] Thus, one of the major defects in the *Igf1* null ovaries is due to defective FSH signaling.

The phenotype of FSHβ null mice can be rescued by transgenes expressing a human FSHβ subunit gene under its own promoter, as well as constitutive and ectopic expression of human FSHβ under the control of the metallothionein-I promoter.[490] Complete restoration of fertility and folliculogenesis was accomplished when the human FSHβ gene was expressed, indicating that FSH function in mammals is evolutionarily conserved. In humans, inactivating mutations in the FSHβ gene exist, and several women with these mutations have been identified[443,444,491] (Table 21.4). A 27-year-old woman with primary amenorrhea, absent breast development, low FSH, and high LH was found to be homozygous for a two base pair (bp) deletion at codon 61 (Val61X). This frameshift mutation was predicted to change amino acids 61 to 86, followed by a stop codon resulting in truncated FSHβ protein lacking amino acids 86–111.[443] A second patient who was 15 years old had absent breast development, primary amenorrhea, low FSH, undetectable estradiol, and elevated LH. She was a compound heterozygote for two different FSHβ gene mutations, Val61X, and a Cys51Gly missense mutation. Both the Val61X and the Cys51Gly

TABLE 21.4 Human Mutations Causing Reproductive Axis Defects in Females

Gene	Mutation	Type of Mutation	Clinical Presentation	References
CYP19	$Arg^{435}Cys$ $Cys^{437}Tyr$	Loss-of-function (compound)	Primary amenorrhea and cystic ovaries	442
FSHB	Frameshift Val^{61} $Cys^{51}Gly$	Loss-of-function	Primary amenorrhea and infertility	443,444

LHR	$Cys^{554}X$ $Ala^{593}Pro$	Truncation Inactivating	Primary amenorrhea Secondary amenorrhea	447 448
LEPR	Mutation in splice donor site exon 16	Truncation	Primary amenorrhea	449

mutations resulted in unmeasurable immunoreactive and bioactive FSH levels.[444] The mouse FSHβ mutant mimics well the phenotype observed in women with the FSHβ mutations and shows the essential role that FSH plays in fertility of mice and humans. Women with FSH mutations gave further insight into the roles of FSH in androgen production. Although LH levels were high in one patient, she had normal levels of testosterone and no evidence of hirsutism. These findings argue that FSH is important in LH-induced androgen production in the theca, either by inducing inhibin and LH receptors, and or through other growth factors.[491] It is clear that studying animals and humans with induced and naturally occurring mutations in particular genes yields useful information with regard to hormonal function during folliculogenesis.

Follicle-Stimulating Hormone Receptor

FSHRs are transmembrane G (guanine nucleotide-binding) protein–coupled receptors. Members of this family have an extracellular hormone-binding domain, a seven transmembrane spanning region, and an intracellular region that couples to G proteins. Two different groups have generated FSHR-deficient mice by deleting the first exon and portions of the promoter and first intron.[23,24] Female mice lacking FSHRs are infertile. The ovaries and uteri of mutant mice are smaller and thinner in both studies, while in one study, vaginas were imperforate. A lack of biologically active estrogen is the probable cause for small uteri and imperforate vaginas. Primordial, primary, and secondary follicles are present, but large antral follicles and corpora lutea are absent, which accounts for the smaller size of the mutant ovaries. The lack of FSHR does not affect growth of early follicles, consistent with the FSHβ knockout[22] and the hypothesis that gonadotropins are not essential for the early stages of folliculogenesis. FSH and LH levels are higher in null mice as compared to control mice. Similar to FSHβ knockout mice,[22] continuous exposure of ovarian stroma to elevated LH levels most likely accounts for the observed hypertrophy of the interstitial tissue as well as numerous small lipid droplets.

Studies on female mice older than 8 weeks revealed formation of tumor-like structures and cysts by 12 months of age in FSHR null mice.[496] The histology of these tumors showed an equal admixture of tubular structures and vacuolated plump stromal cells reminiscent of Sertoli and Leydig cells, respectively. It is likely that elevated levels of gonadotropins are responsible for the tumor-like defects similar to those in mice that overexpress FSH, LH, or human choriogonadotropin (hCG).[313,497–499] However, there is no convincing evidence that inactivating mutations in FSHR cause tumors in primates and humans, and searches for such mutations in granulosa cell tumors have been unproductive.

The controversial role of FSHR in the primordial-to-primary follicle transition was also addressed using *Fshr* knockouts. *Fshr* mRNA is expressed in 1-day-old mice—a time when many germ cell cysts are present and primordial follicles form. Histomorphometric analysis, which measures follicle numbers by different types at 2, 10, and 24 days, showed the presence of primary and secondary follicles in 2-day-old knockout mice, while secondary follicles were not yet formed in the wild-type controls. There was a subsequent decrease in the total number of primordial, primary, and preantral follicles in the *Fshr* knockouts as compared to the wild type. The differences were modest but statistically significant. Based on these data, the lack of FSHR accelerates very early stages of follicular growth, which subsequently blocks at the preantral stage. Also, it is possible to conclude that FSHR plays a small but significant enough role in early follicular growth, and it is possible that the accelerated follicle recruitment in early ovaries leads to premature ovarian failure observed in 1-year-old female mice.

Only a few mutations in the *FSHR* gene in humans have been identified.[500] A Finish population-based study identified patients having XX gonadal dysgenesis (46,XX women with primary or secondary amenorrhea and

serum FSH > 40 MIU/ml).[21] These 75 cases comprised 57 sporadic cases and 18 cases having affected relatives (seven different families). Most cases were found in north-central Finland, a sparsely populated part of the country. The overall frequency of the disorder in Finland was one per 8300 live-born females, a relatively high incidence attributed to the founder effect. An alanine→valine mutation at position 189 of FSHR segregated with the phenotype. The effect of this mutation on FSHR expression and activity has been studied in vitro. The mutant receptor mutation is inactivating, with impaired trafficking and folding that ultimately result in the decreased ability of the receptor to bind FSH.[500,501] Compound heterozygous mutations in the FSHR gene were identified in a group of French women who had primary or secondary amenorrhea and follicle development up to the secondary stage.[502] These inactivating mutations are in the extracellular domain and affect ligand binding and receptor trafficking.[500]

Luteinizing Hormone

Similar to FSH, LH is a glycoprotein hormone with a common α subunit but a unique hormone-specific β subunit, and it is synthesized in the pituitary gonadotropes. Recently, a mouse model for the loss of LHβ has been generated.[271] *Lhβ* null mice are viable, but males and females are infertile. Female mice are hypogonadal with decreased serum levels of estradiol and progesterone. Histologic analysis of the ovaries demonstrates that large antral follicles and corpora lutea are absent. Primary and secondary follicles with intact thecal cell layers develop, and thecal cell markers *Lhcgr*, *Bmp4*, and *Cyp17a1* are expressed, indicating that LH is not necessary for initial differentiation of the thecal cell layer.[271] However, low serum steroid levels and the decreased expression of the steroidogenic enzymes *Cyp11a1*, *Cyp19a1*, and *Cyp17a1* demonstrate that LH is necessary for steroid production.[271] Similar to the FSHβ knockout mouse model, the phenotype of LHβ null mice can be rescued by treatment with exogenous gonadotropins, suggesting that the block in development is not irreversible.

Mutations in *LHB* in humans are rare, but the first was identified in a male with a family history of male infertility.[503] Female members of that family do not appear to be affected. Subsequently, two other mutations have been described.[504,505] In one of the families, a female with hypogonadism related to LH deficiency was the first woman shown to harbor an inactivating mutation in *LHB*.[504] She had normal pubertal development but secondary amenorrhea and infertility.[504]

LH Receptor (Lhcgr)

Like FSHRs, LH receptors are single-chain transmembrane glycoproteins that belong to the G protein–coupled receptor family. Although LH and FSH are not thought to play major roles in early folliculogenesis, truncated LH receptor mRNA is expressed in newborn ovaries[506] at the time when germ cell cysts are present and primordial follicles are formed. Full-length transcripts are not detectable until postnatal day 5, but based on all LHβ and LH receptor mutations, these transcripts are unlikely to play major roles in early follicular formation and function. To study the effects of LH receptor deletions on ovarian development and folliculogenesis, two knockouts have been generated. In the first knockout, exon 1 and the 5′ flanking region containing multiple transcription initiation sites and the promoter region were deleted.[272] Both male and female null mice were sterile. At 60 days, null females had markedly smaller ovaries (more than 50% less than the weight of wild-type ovaries) with pale and thin uteri and delayed vaginal opening. Preantral and antral follicles, but not preovulatory follicles or corpora lutea, were present in females lacking LH receptor. As compared to FSHR knockouts, LH receptor knockouts have more advanced follicular structures, but ovaries in both knockouts continue to be quite small. Like the LHβ knockout, this argues that LH receptor is not required for early gonadal and reproductive tract differentiation. Serum LH levels are high in LH receptor knockouts, which could be due to loss of estradiol negative feedback and/or loss of negative LH feedback on its own secretion through decreased hypothalamic GnRH levels in both sexes. Moderate elevation in serum FSH levels could be due to decreased gonadal inhibin secretion. FSHR and progesterone receptor mRNA levels were not significantly affected by the lack of LH receptor. Estrogen receptor α (*Esr1*) and *Star* mRNA levels are decreased in the LH receptor knockouts, and estrogen receptor β (*Esr2*) mRNA levels are increased in both ovaries and testes. Because LH maintains *Esr1* and *Star*, and inhibits *Esr2* mRNA levels, these results in the LH receptor knockout are consistent with those of previous studies. Hormone replacement therapy with estrogen and progesterone did not restore fertility or reverse ovarian morphology, which argues that other downstream targets of LHCGR are involved in stimulating follicular growth beyond the antral stage.

Another LH receptor knockout was generated by deleting exon 11 of the LH receptor, which encodes the transmembrane and cytoplasmic receptor domains and part of the 3′ extracellular domain, thus preventing the formation of full-length functional LH receptor capable of anchoring to the plasma membrane and of signal transduction.[273] These *Lhcgr* knockout mice did not synthesize any mRNA encoding the full-length functional LH receptor, and the phenotype was remarkably similar to the *Lhcgr* knockout (described here) in which the promoter and first exon were removed.

In humans, mutations in the LH receptor cause gonadal dysgenesis. Sultan et al.[507] tabulated the 46,XY cases, with nine having female phenotype and two having

micropenis. All 46,XX cases occurred in sibships in which an affected 46,XY male had Leydig cell hypoplasia. Latronico et al.[447] reported primary amenorrhea in a 22-year-old woman. In that family, three males and one female had a homozygous nonsense (stop) mutation at codon 554 (C554X). The newly produced stop codon resulted in a truncated protein having five rather than seven transmembrane domains. The affected female had breast development but only a single episode of menstrual bleeding at age 20 years. The mutation reduced signal transduction activity of the LH receptor gene. In a 46,XX case reported by Toledo et al.,[448] secondary amenorrhea occurred. The mutation was from alanine to proline at position 593.

LH signaling upregulates the expression of epidermal growth factor (EGF)-like family members during cumulus expansion at ovulation.[508,509] LH receptor, expressed on mural granulosa cells, responds to the peri-ovulatory LH surge by increasing epiregulin (*Ereg*), amphiregulin (*Areg*), and betacellulin (*Btc*) in a protein kinase A–dependent manner. Receptors for the EGF-like proteins are found in cumulus cells, and activated EGF receptor tyrosine kinase receptors, signaling through the MAPK pathway, induce expression of cumulus expansion genes *Has2*, *Ptgs2*, and *Tnfaip6*.[510] *Areg*$^{-/-}$ and *Ereg*$^{-/-}$ mice have cumulus expansion defects.[508] Furthermore, depletion of *Erk1/2* in granulosa cells causes infertility due to a failure of ovulation.[511] Cumulus oocyte complexes from mice with deletion of *Erk1/2* fail to expand, and oocytes do not resume meiosis. In addition, granulosa cells fail to terminally differentiate, and they continue to proliferate and generate estradiol.

Steroid-Signaling Pathways

Estrogen Signaling

Estrogen receptors α and β, encoded by *Esr1* and *Esr2*, respectively, are expressed in many organs, including the hypothalamus, anterior pituitary, mammary gland, uterus, and ovary.[400] Estradiol stimulates granulosa cell growth, increases synthesis of granulosa cell insulin-like growth factor 1 (IGF1), maintains FSH receptors, induces LH receptor, augments aromatase activity and subsequent estradiol production, and attenuates granulosa cell apoptosis. Estrogens bind specialized receptors that are nuclear transcription factors that bind DNA and activate transcription of other genes. Estrogen receptors are members of the steroid receptor superfamily of ligand-activated transcription factors. Estrogen receptors and their ligand, 17β-estradiol, play critical roles in the development of female secondary sexual characteristics as well as in the female reproductive tract, and they maintain pregnancy.

Esr2 is expressed at higher levels in granulosa cells of growing follicles as compared to *Esr1*, while *Esr1* is expressed in thecal cells and interstitial cells.[512] The mRNAs corresponding to *Esr1* and *Esr2* are first expressed around day 8 in the rat ovary, which at this age contains primordial, primary, and some secondary follicles. Although estrogen is thought to act mainly on antral follicles, earlier expression of mRNA of the receptors in growing follicles may indicate additional functions or possibly estrogen-independent activity of the receptors.

Initial observations in mice null for *Esr1* showed that ovaries from these mutant mice contained cystic and hemorrhagic follicles, and hypoplastic uteri.[275] The mouse model also indicated that another estrogen receptor existed, because estradiol binding in uterine preparation from mutant animals still occurred. This estrogen receptor turned out to be *Esr2*.[513–515] *Esr2* knockout mice are viable but subfertile.[276] Litter sizes in *Esr2* knockouts are 35% of wild type. Superovulation experiments showed a dramatic reduction in the number of oocytes ovulated per female, with only six oocytes per female in the knockouts as compared to 52 in the control mice. Other observed effects included decreases in the cellular mass of the cumulus cells, and an inadequate response to exogenous hormones. The endogenous gonadotropin levels were normal in these mice.

To study the effects of a complete lack of ERα and ERβ on reproduction, double knockouts have been generated.[400,516] The double-mutant ovaries have a more severe phenotype that is distinct from either single-receptor knockout. Unlike prepubertal wild-type ovaries that show mostly secondary follicles, prepubertal double-knockout mice possess adult-like follicles with defined antra and theca, characteristic of hypergonadotropic–precocious maturation of the ovary. Serum LH levels are higher in double knockouts as compared to *Esr1* knockout alone, which suggest that both estrogen receptors are required for estradiol-mediated regulation of LH secretion in the hypothalamic–hypophyseal axis. In 10-week- to 7-month-old ovaries, primordial and growing follicles are visible, but corpora lutea are lacking. Interestingly, follicles are replaced by structures that resemble seminiferous tubules of the testis in the double-knockout ovaries, some with degenerating oocytes, granulosa cells, and Sertoli-like cells (Figure 21.3(D),(G)). Sertoli cell differentiation markers, *Amh* and *Sox9*, are elevated in the *Esr1* and *Esr2* double knockouts. As discussed here, FOXL2 and ESR1 cooperatively repress *Sox9* expression, and conditional knockout of *Foxl2* also causes transdifferentiation in mice. Aromatase knockout ovaries (discussed further in this chapter) also develop Sertoli and Leydig-like cells at puberty, which argues that the lack of estrogens causes transdifferentiation of the granulosa cells.

The aromatase knockout (ArKO) gives additional insight into the effect of a complete lack of estrogen on follicular development.[274] Aromatase is a cytochrome P450 enzyme that catalyzes the formation of aromatic C18 estrogens from C19 androgens. Because aromatase

is required for the synthesis of estradiol, a knockout renders the mice fully estrogen deficient. Knockout mice are phenotypically normal but infertile. Testosterone levels are almost 10 times the wild-type levels. LH levels are elevated two- to 10-fold, and FSH levels are also elevated three- to fourfold, over the wild-type levels. These findings corroborate previous studies that showed the importance of estrogen in the negative-feedback regulation of gonadotropins, and the high testosterone levels presumably reflect LH-stimulated androgen production by the thecal cells. Ovaries from 12- to 14-week-old mice show the presence of many antral follicles, with hypertrophied stromal cells and atretic follicles. No corpora lutea are visible; therefore, no ovulation occurs. Another knockout was generated, and analysis of these mice showed that at 8 months of age, hemorrhagic cysts were observed, with mast cell infiltration and reduced number of follicles with widespread follicular atresia.[517] Although the aromatase knockout mice could not be superovulated, oocytes recovered from ArKO mice can be matured in vitro, with successful fertilization and early embryo development.[518] Estrogen appears to play an important role in feedback regulation of gonadotropin secretion and continued follicle growth but does not interfere with oocyte growth.

The role of estrogen metabolism is also important in humans. Ito et al.[442] reported a mutation in the *CYP19* (P450 aromatase) gene in an 18-year-old 46,XX woman with primary amenorrhea and cystic ovaries. The patient was a compound heterozygote for two different point mutations in exon 10. The mutant protein had no activity. Most of the mutations in humans involve amino acid substitutions as well as premature stop codons. It is a rare disorder, with only a few women reported.

Deficiency of the aromatase enzyme is more often associated with genital ambiguity. Shozu et al.[519] detected placental aromatase deficiency manifesting as maternal virilization during the third trimester. The 46,XX infant was born with genital ambiguity (female pseudohermaphroditism). Adrenal enzyme defects were not evident. The molecular basis of the mutation was an 87 bp insert in exon 6 of the aromatase gene, altering the splice junction site to produce a novel protein with 29 additional amino acids. Aromatase mutations in 46,XX female infants associate with genital ambiguity[442] or clitoromegaly.[520] In the later cases, clitoral enlargement occurred at puberty, but breast development did not. Multiple ovarian follicular cysts were evident. FSH was elevated, while estrone and estradiol were low. Estrogen and progesterone therapy resulted in a growth spurt, decreased FSH, decreased androstenedione, decreased testosterone, breast development, menarche, and fewer follicular cysts.

Androgen Signaling

Androgens play a central role in the development of male sex organs and secondary sexual characteristics, but less is known about androgen's role in the development and function of normal ovaries. Androgens are thought to mainly signal via the androgen receptors (ARs). ARs are highly expressed in the granulosa cells of rodent ovaries.[521] AR is encoded on the X chromosome and activates gene expression as a result of multiple events, including ligand binding, homodimerization, nuclear translocation, DNA binding, and complex formation with co-regulators and general transcription factors.[522] AR mouse knockouts are subfertile and have normal initial primordial follicle population, with disruption of later stages in folliculogenesis and eventual premature ovarian failure.[277,278] AR deficiency in the ovary reduces the number of corpora lutea, increases granulosa cell apoptosis, and decreases *Kitl* production. Selective ablation of ARs in the granulosa cells or oocytes suggests that the observed ovarian pathology is due to AR actions in the granulosa cells and not the oocytes.[279,280] Overall, these results suggest that AR has an important role in postnatal ovarian development and folliculogenesis, and future studies will be important to delineate the specific targets of AR action within the ovary.

Hyperandrogenism in women is associated with the relatively common PCOS, a syndrome where many arrested small antral follicles give rise to the cystic appearance of the ovary.[523] Androgens increase the growth of immature follicles in the primate ovary, and treatments with testosterone and its active form, dihydrotestosterone, caused significant, three- to fourfold increase in IGF-I mRNA concentration in granulosa, thecal, and interstitial ovarian compartments.[524] Both testosterone and dihydrotestosterone induced significant increases in the amount of IGF-I receptor mRNA, most notably in thecal cells and less markedly in granulosa and interstitium of the primate ovaries. These data suggest that IGF-I and its cognate receptor may mediate androgen-induced ovarian follicular and thecal–interstitial growth. Moreover, additional studies showed that androgen treatment significantly increased granulosa cell *FSHR* mRNA. These data suggest that androgens promote follicular growth and estrogen biosynthesis in part via enhancement of the FSH effect, which partially explains the enhanced responsiveness to gonadotropin stimulation noted in women with POCS.[525] Hyperandrogenism and its effects on ovarian development and PCOS are subjects of intense studies, with data suggesting that prenatal exposure to testosterone in humans, primates, and sheep can lead to multifollicular ovaries reminiscent of the PCOS-like phenotype.[526–529]

Gap Junction Membrane Channel Proteins and Connexins

Connexins are a family of at least 15 proteins that form intercellular membrane channels of gap junctions

and allow diffusional movement of ions, metabolites, and potential signaling molecules. These structural molecules play important roles in bidirectional communication between the oocyte and granulosa cells. Several connexins have been shown to be important during folliculogenesis. *Gja4* (connexin 37) is expressed in primary and growing follicles. Ovaries from *Gja4* knockouts at 2 weeks of age contain many developing preantral follicles, but not larger antral follicles.[281] Therefore, histologically, it appears that lack of *Gja4* blocks preantral-to-antral follicle development. Electron microscopy studies showed that while the *Gja4* knockouts contained adherens junctions, they lacked the gap junctions present on wild-type ovaries. In addition, despite the lack of Graafian follicles, the null ovaries displayed smaller structures resembling corpora lutea that were 5–10 times more abundant. Luteinization usually occurs following ovulation when oocyte–granulosa cell communication is lost. The premature luteinization observed in *Gja4* null animals suggests that junctional communication is a major mechanism regulating corpus luteum formation. It can be hypothesized that an inhibitory signal is transferred through gap junctions from the oocyte to the granulosa cells that result in the prevention of luteinization until after ovulation has occurred. An additional phenotype of the *Gja4* knockout was that the average oocyte size was smaller. While 52.8% of oocytes from $Gja4^{+/-}$ mice resumed meiosis, with 26.8% of these proceeding to metaphase of meiosis I and 26% to metaphase of meiosis II, only 2.2% of $Gja4^{-/-}$ mice resumed meiosis in culture, with the vast majority (86.3%) retaining germinal vesicles. All of these observations clearly indicate that *Gja4* is essential at the time of the preantral-to-antral follicle transition, and is most likely involved in the transport of metabolites necessary and critical for this transition.

GJA1 (connexin 43) protein is the most abundant connexin in the ovary, and is expressed as early as E14.5. GJA1 gap junctions interconnect granulosa cells that surround the oocyte as well as oocytes and granulosa cells. *Gja1* knockouts die at birth due to cardiovascular failure.[530] Ovaries in null mice, retrieved at the time of birth, are unusually small, apparently due to a deficiency of germ cells.[282] The germ cell deficiency was traced back as far as E11.5 of gestation, implying that it arises during early stages of germline development. To study postnatal folliculogenesis in $Gja1^{-/-}$ mice, fetal and neonatal ovaries have been grafted into the kidney capsule of an ovariectomized and immunocompromised $prkdc^{scid/scid}$ mouse.[531] The grafts were removed after 1–3 weeks, and ovarian histology was examined. After 3 weeks of development in kidney grafts, wild-type ovaries contain a range of follicles from primordial through primary, secondary, and tertiary stages. In contrast, *Gja1* null ovaries did not proceed beyond primary follicles. Mutant granulosa cells did not proliferate in grafts after 1, 2, and 3 weeks. Oocyte growth was also slower in mutants as compared to wild-type animals. Oocytes recovered from *Gja1* mutants could not be fertilized. Electron microscopy also showed that these oocytes are structurally abnormal as compared to the wild type.

Gja1 appears to be regulated by the gonadotropins, FSH and LH. Because *Gja1* is more abundant in large antral follicles as compared to small antral and preantral follicles, some have hypothesized that FSH induces GJA1 synthesis. Interestingly, *Gja1* mRNA levels drop after a preovulatory surge of LH.[532,533] Further corroboration came from experiments utilizing exogenous administration of gonadotropins. Injection of FSH into hypophysectomized rats promoted an increase in the ovarian gap junctional membrane, while hCG, which induces ovulation, led to a significant reduction in the quantity of gap junctions in granulosa cells.[534,535] In vitro administration of FSH and LH to granulosa cell lines corroborated in vivo observations.[536,537] It has been suggested that effects of the gonadotropins on *Gja1* are mediated through steroid hormones.[538] Other signaling pathways may also regulate *Gja1*, including the BMP–Smad and the MAPK–Ras pathways, which have been shown to regulate *Gja1* promoter in vitro.[539,540]

The gap–junctional coupling mediated by GJA1 channels plays indispensable roles in both germline development and postnatal folliculogenesis. The different ovarian phenotypes resulting from the *Gja4* and *Gja1* knockouts possibly indicate that gap-junctional coupling between the oocyte and its cumulus granulosa cells serves a distinct role from that between the granulosa cells themselves, possibly involving different molecules. However, ectopic expression of *Gja1* in *Gja4* null oocytes fully restores fertility to *Gja4* null mice, indicating that both connexins are equally able to couple oocytes to somatic cells.[541] GJB1is also expressed in the ovary, but knockout is not infertile,[542] meaning that redundant gap junction components exist.

Additional cellular connections may be important for antrum formation and granulosa cell–oocyte interactions. Intercellular communications between granulosa cells and oocytes are thought to be mediated by transzonal projections (TZPs) between the oocyte and granulosa cells.[92] Microtubule TZPs (MT-TZPs), in particular, appear to be involved in this communication.[92] The MT-TZP connections between the oocyte and granulosa cells have been hypothesized to be under the control of FSH.[543] FSH priming of wild-type and $Fsh^{-/-}$ mice results in alterations in the MT-TZP, such that the TZPs are retracted from the oocyte,[543] and enhances oocyte chromatin remodeling, apical centrosome positioning, and acquisition of meiotic competence.[543] From these experiments, it can be hypothesized that without FSH priming, granulosa cells have a stable interaction with the oocyte, allowing

for the paracrine exchange of factors. Once MT-TZPs are retracted, oocyte development is accelerated.

METABOLIC INFLUENCES ON FOLLICLE DEVELOPMENT

Globally, there are several peptide growth factors that may influence ovarian function due to their endocrine (metabolic) effects on the HPG axis.[298] In this section, we will briefly discuss intraovarian effects of leptin, growth hormone, and IGF1.

Leptin

The *Lep* gene (also known as the *ob* (obesity) gene) encodes leptin. Leptin is mainly secreted by adipose tissue, and much attention has been devoted to studying its effect on the central nervous system to diminish appetite and to increase energy consumption. In the murine ovary, leptin is expressed in oocytes, granulosa cells, and theca cells. Using immunohistochemistry, it appears that the highest expression of leptin is confined to the oocyte, while the leptin receptor has highest expression in theca cells.[544] Leptin administration does not affect spontaneous or induced maturation of either isolated denuded oocytes or cumulus–oocyte complexes, but it does significantly increase the rate of meiotic resumption in preovulatory follicle-enclosed oocytes.[544] This effect does not appear to be mediated by activation of phosphodiesterase 3B and subsequent cyclic adenosine monophosphate reduction.[544] It is possible that leptin induces secretion of a factor important in meiotic resumption.[544] In humans, leptin is immunolocalized to oocytes in primordial and primary follicles as well as granulosa cells surrounding the oocytes.[545] In preantral follicles, leptin is preferentially expressed in granulosa cells, and in antral follicles, leptin is preferentially expressed in the thecal layer. Rat studies also document expression of leptin and its receptor in granulosa, theca cells, and oocytes.[546] Interestingly, although leptin protein is detected in oocytes, the leptin mRNA is not detected in oocytes.

ob/ob mice, which are deficient in leptin, are morbidly obese and have a subnormal number of ovarian follicles.[270] Weight loss in *ob/ob* mice does not restore fertility, but *ob/ob* ovaries do produce viable eggs when transplanted into wild-type mice, indicating that nongonadal leptin can restore fertility.[547] Ovaries from *ob/ob* mice contain antral follicles with pronounced apoptosis of granulosa cells. The infertility in these mice is partially due to an altered pattern of GnRH secretion leading to decreased secretion of LH and FSH. Leptin replacement increases FSH and LH levels in *ob/ob* mice and restores fertility.[547] In addition, administration of gonadotropins also restores fertility, indicating that the absence of leptin influences the hypothalamus and pituitary. Because FSH and LH levels are only partially suppressed in *ob/ob* mice, and some direct effects of leptin on the gonads are likely also important, it is unclear whether the increased apoptosis of granulosa cells that is observed in the *ob/ob* preantral and antral follicles is due to low FSH and LH levels, a result of absent leptin signaling in the ovary, or a combination of both.

Leptin shows an important link between metabolism and reproduction. Leptin may serve as a metabolic signal informing the reproductive system that sufficient fat stores are available to meet the caloric demands of reproduction. Metabolic stresses such as food restriction and severe exercise will lead to low circulating levels of leptin and lower fertility. Ovarian transplantation experiments using leptin receptor–deficient mice (*db/db* animals) suggest that reproductive dysfunction is not due to impaired intraovarian signaling.[548] It appears that the majority of leptin actions on reproduction are mediated via the hypothalamus.

Leptin deficiency in humans is rare and causes morbid obesity. Follicular development and function as well as gonadotropin secretion in these children are unknown. Women with mutations in the leptin receptor are also obese and have primary amenorrhea.[449] FSH and LH levels are low to normal, and estradiol concentration is low. Consistent with the *db/db* mouse studies,[548] these findings reflect hypogonadism of central origin that is likely responsible for the observed infertility.

However, in vitro studies have supported that leptin has some local effects in the ovary. Leptin can suppress ovarian steroid synthesis in primary rat granulosa cells and in rat and human granulosa cell lines.[549] Other studies have shown that leptin inhibits IGF1 synergistic effects with FSH on estradiol production by rat granulosa cells as well as inhibiting aromatase activity.[550] In contrast, it has been reported that leptin increases aromatase mRNA and protein expression in human granulosa cells.[551] The use of supraphysiologic amounts of leptin may account for different results, and further studies may be helpful, such as conditional knockouts of leptin or its receptor in the ovary, to study the local effects of leptin in ovarian physiology and settle the hypothalamic versus intraovarian causes of reproductive dysfunction. In the rat, leptin mRNA increases threefold within 2 h of hCG administration, and leptin receptor mRNA levels also increase dramatically 9 h after hCG administration.[546] These results suggest that expression of leptin and its receptor peaks at the time of ovulation, but their specific functions are unknown. Lastly, leptin is also expressed in human vasculature as well as ovarian endothelial cells, and it promotes angiogenesis. Leptin-induced angiogenesis may be important in folliculogenesis.[552] The data discussed here suggest that leptin exerts its major effect via the hypothalamus, with intraovarian effects playing a minor role.

Growth Hormone

Growth hormone (GH) is secreted by the anterior pituitary and can act directly via binding to the growth hormone receptor (GHR) to effect growth and the onset of sexual maturity.[553] In addition, GH controls the synthesis of IGF1, which additionally affects ovarian function. GH receptor is expressed in multiple tissues, including the ovary. GHR RNA is located in the granulosa cells of antral follicles and the corpus luteum but is not detected in preantral follicles, theca, oocytes, or stroma.[554]

In horses and rodents, GHR RNA is detectable in oocytes, cumulus cells, and granulosa cells throughout folliculogenesis.[555,556] GH augments cumulus expansion and improves nuclear maturation in equine cumulus cell–oocyte complexes.[555] In the cow, GH receptor protein and RNA are detected as early as primordial oocytes and granulosa cells of primary follicles and more advanced follicles.[557] Mice that lack GHR are subfertile dwarfs[558–560] with delayed age of conception, low plasma IGF1, and elevated plasma GH levels.[561] A subset of GHR knockout females is infertile, although the reason for why some are subfertile while others are infertile is unknown, but it may have to do with epigenetic effects.[558] Treatment with recombinant human IGF1 normalizes the age of puberty.[561] However, IGF1 does not restore the ovulation rate in GHR knockout mice, and therefore growth hormone may affect follicular growth independent of IGF1.[562] More detailed analysis of ovaries from GHR knockouts revealed significantly smaller numbers of preovulatory follicles and corpora lutea, decreased plasma estradiol levels, and an increased number of apoptotic follicles.[558] It appears that *Ghr* deficiency in mice does not affect primordial follicle endowment but, rather, their recruitment into growing follicles.[563] Women with mutations in *GHR* (Laron syndrome) can become pregnant despite low levels of IGF1.[564–566] It is unclear whether these women are subfertile, as seen in *Ghr* knockout mice.

Female mice that overexpress bovine GH under the control of the strong phosphoenolpyruvate carboxykinase (PEPCK) promoter have a 60% rate of infertility, an increase in the numbers of preovulatory follicles and corpora lutea, and decreased granulosa cell apoptosis in developing follicles.[567,568] The mechanism of GH suppression of apoptosis may involve production of local as well as systemic IGF1[569,570] or poorly understood GH effects that are independent of the IGF1. Female mice that overexpress human GH using the metallothionein I (MT) promoter have a 20% rate of infertility. A similar rate of infertility is observed for bovine GH driven by the metallothionein I promoter.[570] Because PEPCK is a stronger promoter than MT, excess GH is disruptive to reproduction. Infertility in these transgenic mice may be due to inadequate luteal function since progesterone treatment led to pregnancy. In addition, GH-induced overstimulation of the tuberoinfundibular dopaminergic neurons and suppression of endogenous prolactin release could have adversely affected luteal function.[571] Acromegaly, a condition that causes excessive growth due to excess GH secretion, often leads to infertility. Because acromegaly is often caused by adenomas (benign tumors of the pituitary), infertility may be due to hyperprolactinemia as well as gonadotropin dysregulation; this is because the expanding tumor may affect other cell types in the pituitary. Analysis of 196 women with acromegaly revealed that 60% had amenorrhea, and of these 45% had elevated prolactin levels. FSH and LH levels in these women were not reported, but it is possible that GH hypersecretion alone can lead to infertility.[572] Other studies on women with acromegaly have suggested that all three mechanisms may operate: lactogenic effects of prolactin and GH on the gonadotropic axis, gonadotropin dysregulation due to tumor mass effects, and direct GH action on the ovary.[573]

IGF-signaling System

The IGF family has long been recognized as having an important role in female reproduction. The signaling components include two ligands (IGF1 and IGF2), two receptors (IGF1R and IGF2R), and a number of binding proteins (IGFBPs) that regulate IGF action.[574] Of these, IGF1 is known to be important and required for sexual development and reproduction.[575,576] *Igf1* is expressed in granulosa cells of growing follicles, and one receptor, *Igf1r*, is expressed in both growing and atretic follicles.[577,578] In mice, IGF1 levels are low at the primary follicle stage, but increase during preantral and antral follicle growth.[578] The expression of *Igf1* may be under local paracrine control, as microarray analysis has shown that recombinant mouse GDF9 can upregulate expression of the *Igf1* gene.[283,426] *Igf2* expression in the ovary is lower than *Igf1*,[578] and the *Igf1* knockout mouse has reproductive defects, while the *Igf2* null mouse has normal fertility.[269,579] Most *Igf1* null mice die perinatally, but those that survive to adulthood are infertile.[269] Ovaries from *Igf1* knockout mice do not contain antral follicles and cannot be ovulated. As mentioned in this chapter, this defect may be partially due to decreased FSH receptor expression and aromatase expression[268] because *Igf1* knockout mice phenocopy FSHβ and FSHR null mice.

CONCLUSION

Over the past decade, numerous mouse models have been generated that demonstrate the importance of multiple signaling systems in follicle development. These mice provide a basis for understanding mammalian infertility and disease as well as revealing new candidate genes for mutational analysis. Conditional knockouts

using the Cre–LoxP system allow specific cell-type deletions, thereby circumventing problems associated with global knockouts such as embryonic lethality and phenotypes associated with multiple tissue disruption. Combined, these models hold the promise of a comprehensive understanding of the physiology and pathology of human fertility.

Human GWASs on the aspects of reproductive biology, such as the age of menopause and menarche, have additionally opened new vistas into pathways that may play a role in ovarian biology and that should be functionally addressed by basic biologists.[15,580] For example, menopause GWASs discovered 17 loci, with an excess of them associating with DNA repair and immune pathways.[15,581] A number of these loci have not been previously linked to ovarian biology and may represent novel and fruitful pathways for further investigation. A nonsynonymous single nucleotide polymorphism in a minichromosome maintenance deficient 8 gene (*MCM8*) shows the strongest association with menopause, and its corresponding knockout mice have disrupted ovarian development and genome instability due to impaired homologous recombination.[582] Whether all of the associated loci have relevance to ovarian biology remains to be determined via functional studies in the future.

Acknowledgments

The authors wish to thank Dr Martin Matzuk (Baylor College of Medicine) for written contributions to this chapter in the prior edition of this book. A Burroughs Wellcome Career Award in the Biomedical Sciences, and the National Cancer Institute (grant no. R01CA138628), fund studies in the Pangas Laboratory. Studies in the Rajkovic Laboratory were funded by R01HD56351, R01HD070647, R01HD044858, and R21HD058125 grants.

INTRODUCTION

Ovulation of an oocyte capable of being fertilized is a primary function of the female gonad, the ovary (Figure 22.1). Ovulation *is a unique biological process* that is so precisely regulated in mammals that less than 1% of all oocytes present at birth are ever released from the surface of the ovary.[1,2] Most ovarian follicles succumb to atresia wherein granulosa cells undergo apoptosis (programmed cell death), oocytes die, and theca cells become part of the ovarian stroma. Thus, ovulation is the ultimate consequence of a follicle being in the right place at the right time. The ovulatory process is orchestrated, in part, by hormonal regulatory loops that control the ovarian–hypothalamic–pituitary axis and by intraovarian regulatory connections operating between theca–granulosa–cumulus cells and the oocyte.[3] Although ovulation is often referred to as "rupture" of the ovulatory follicle, the process is not explosive. Rather, motion pictures of the release of the oocyte surrounded by cumulus cells showed early on that ovulation is a slow extrusion process, a "rather gentle occurrence",[4] and likely occurs by degradation of the follicle wall.[5]

The dramatic events of ovulation are preceded by (1) the formation and development of ovarian follicles, (2) the hormonal-mediated differentiation of granulosa cells and theca cells to functional endocrine tissues, and (3) the acquisition of oocyte competence for meiotic progression and fertilization[6,7] (see Chapters 1, 2 and 21). Thus, at the ovarian level, successful ovulation depends upon specific cellular and molecular events that occur sequentially and precisely during follicular development.

Some of the hormonal, cellular, and molecular events controlling ovulation have been described in detail in previous reviews[1,7] and in earlier editions of the present book.[3,8] However, a brief overview will outline some of the highlights that preceded, paved the way, and provided the impetus for the studies reviewed in this chapter.

LH Receptors

Specifically, studies in the 1960s and 1970s elegantly used radio-immunoassays to quantify the levels of FSH and LH during reproductive cycles in many species and documented that elevated levels of LH are released during the preovulatory surge and initiate ovulation[9,10] (Chapters 26–29). At this time, radio-receptor assays were also developed and showed that not only do hormone levels in serum change dramatically during the cycle but the levels of receptors for these hormones in target tissues are highly regulated. Importantly, the acquisition of LH receptors in granulosa cells of preovulatory follicles is coordinated precisely with the LH surge, ensuring that only the preovulatory follicle can respond.[2,11] These studies of the LH receptor were subsequently integrated by those highlighting the roles of prostaglandins (PGs) and progesterone in ovulating follicles.

Prostaglandins

Studies in the 1980s and 1990s also began to document evidence that an ovulating follicle exhibited physical characteristics of inflammation such as hyperemia and edema.[12] In addition, the ovulating follicles exhibited biochemical features of inflammation including the production of prostaglandins (PGs) PGE1/2 and PGF2α.[13–17] Moreover, some studies indicated that ovulation could

Knobil and Neill's Physiology of Reproduction, Fourth Edition

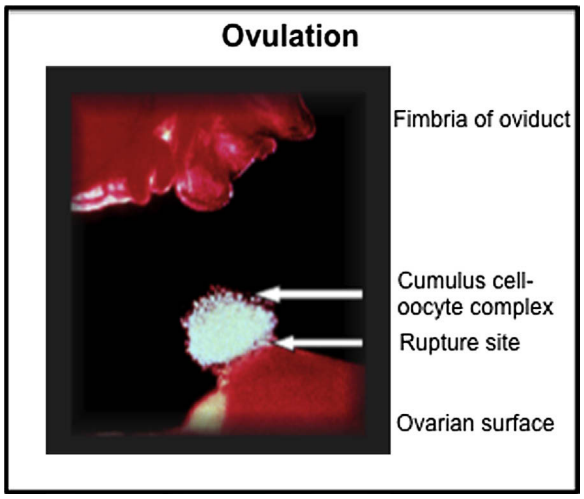

FIGURE 22.1 Moment of rupture of a rabbit follicle. This figure is reproduced in color in the color plate section. Ovulation of a fertilizable oocyte involves disintegration of the ovarian surface epithelium and extrusion of the expanded cumulus cell–oocyte complex (COC) through the ovulation pore. This is followed by retrieval of the COC by the ciliated cells of the oviduct and its subsequent transport down the oviduct where fertilization occurs. (See text.) *Source: Ref. 3.*

be blocked by the nonsteroidal inhibitor of PG biosynthesis, indomethacin.[18] Based on the accumulating evidence in his own laboratory and that of others, Dr Lawrence Espey was the first to describe ovulation as an inflammatory-like response in a key paper in 1980.[12] Since then many studies have supported and expanded this insightful hypothesis and will be highlighted briefly.

First, two immune-distinct forms and molecular weight variants (69 and 72 kDa) of the prostaglandin synthase (PGS), the rate-limiting step in PG biosynthesis, were identified in rat ovarian tissues.[19] These results indicated for the first time that there was not just one enzyme but two enzymes controlling PG biosynthesis. Furthermore, the 72-kDa form was induced specifically in granulosa cells of ovulating follicles by LH whereas the 69-kDa form was constitutively expressed in theca cells and other tissues.[20] Purification of the 72-kDa inducible form of PGS and amino-terminal sequence results documented that the inducible form was distinct from the constitutive form.[21] Ultimately, the genes encoding each distinct protein were cloned and are now known as prostaglandin synthase1, PTGS1 (also known as cyclooxygenase 1; COX-1) and PTGS2 (cyclooxygenase 2; COX-2).[22] Promoter analyses revealed that the *Ptgs2* gene was regulated by several factors including AP1 factors and C/EBPβ.[23] Lastly, targeted disruption of *Ptgs2*[24] or its receptor *Ptger2*[25,26] in mice led to anovulation and infertility, providing conclusive evidence that PGs play critical roles in the ovulation process. However, luteinization occurred in these mutant mice, as indicated by the presence of oocytes entrapped in corpora lutea. This result supported previous data that the role of PGs in ovulation was separable from that of factors controlling luteinization. Based on the knockout mice and in vitro studies we know that (1) PGs are essential for cumulus cell–oocyte complex (COC) expansion, the generation of a hyaluronan-rich matrix, and the stabilization of this matrix by a scaffolding of hyaluronan-binding proteins; and (2) proper COC expansion (also known as mucification) and the composition of the matrix is critical for release of COCs from the surface of the ovary.

Progesterone

Studies from the 1970s to the 1990s also began to document that the ovulation process was dependent on the increased production of the steroid hormone progesterone that occurs following LH stimulation of preovulatory follicles.[27,28] The progesterone synthesis inhibitor epostane blocked ovulation,[29] but this effect could be reversed by exogenous progesterone.[30] A functional role for progesterone in granulosa cells was first established when induction of the progesterone receptor (PGR) in these cells by LH was reported.[31] The essential roles of progesterone and its nuclear receptor were unequivocally documented by targeted disruption of the PGR in mice. The progesterone receptor knockout (PRKO) mice fail to ovulate, contain corpora lutea with entrapped oocytes, and are completely infertile.[32] Molecular analyses comparing control and mutant follicles have documented that progesterone regulates the expression of several genes that are critical for ovulation, including the EGF-like factor amphiregulin (*Areg*), the protease a disintegrin and metalloproteinase with thrombospondin-like motifs-1 (*Adamts1*),[33] and cGMP-dependent protein kinase 2 (*Prkg2*)[34] (discussed later). Overexpression of PGR-A and -B in granulosa cells in culture further documents that PGR-A is more critical than PGR-B and confirms the direct regulation of specific target genes in the absence of LH.[35] Additional studies show that PGR regulates the ADAMTS1 gene and other genes by acting as a co-regulatory factor that binds transcription factors such as SP1.[36] Thus, the role of PGRs in the ovulation process appears to be distinct from that of PGs.

EGF-Like Factors

More recently, the roles of the EGF-like factors, RAS and MAP kinases (ERK1/2), in ovulation have taken center stage.[7] As will be discussed in more detail in the review, LH induces the EGF-like factors that then activate the EGF receptor, RAS, and ERK1/2. Targeted disruption of the EGF receptors or ERK1/2 in granulosa cells completely blocks ovulation, oocyte maturation,

cumulus expansion, and luteinization. These results link the LH-induced cAMP signaling pathway to the EGF receptor tyrosine kinase pathway that has been implicated in inducing *Ptgs2* and other factors.[37]

The Oocyte

The critical role of the oocyte and oocyte-derived factors in controlling cumulus cell functions and ovulation will also be highlighted in the review.

The goal of this chapter is to highlight studies that have been published primarily since 2005 and that have made major impacts on our understanding of ovulation and the complexity of events that occur at the cellular and molecular levels during this process. In particular, this review will focus on new insights into how the LH surge regulates (1) granulosa cell functions, (2) the granulosa cell–cumulus cell–oocyte complex (COC) connection, and (3) ultimately, the cumulus cell–oocyte connections that are obligatory for ovulation. Of particular relevance, recent studies have unveiled how specific genes regulate the unique fates of granulosa cells and cumulus cells in response to the ovulatory LH signal. Granulosa cells eventually become endocrine, progesterone-producing luteal cells. Cumulus cells, on the other hand, provide a conveyance mechanism and protective system for oocytes during their release from the ovary and fertilization.[7]

The hormonal and molecular regulators of ovulation appear to be highly conserved in mammals, including the primates. Therefore our increased understanding of the underlying molecular mechanisms that control ovulation, using primarily knockout mouse models, has significant implications for understanding what controls ovulation in women, how in vitro fertilization (IVF) protocols might be improved, and how infertility-related diseases, such as polycystic ovarian syndrome (PCOS), obesity, and endometriosis, alter ovarian functions and ovulation.[38,39]

OVULATION: A PERFORMANCE PLAYED BY MANY ACTORS

Successful ovulation in response to the LH surge involves multiple cell types. These include the theca cells, granulosa cells, and cumulus cells within the preovulatory follicle itself, the surrounding stroma tissue, and the ovarian surface epithelium (OSE).[3] In essence, the follicle is a multilayered sphere, each layer being separated from the other by a specialized extracellular matrix (Figure 22.2). The theca cell layer is the outmost

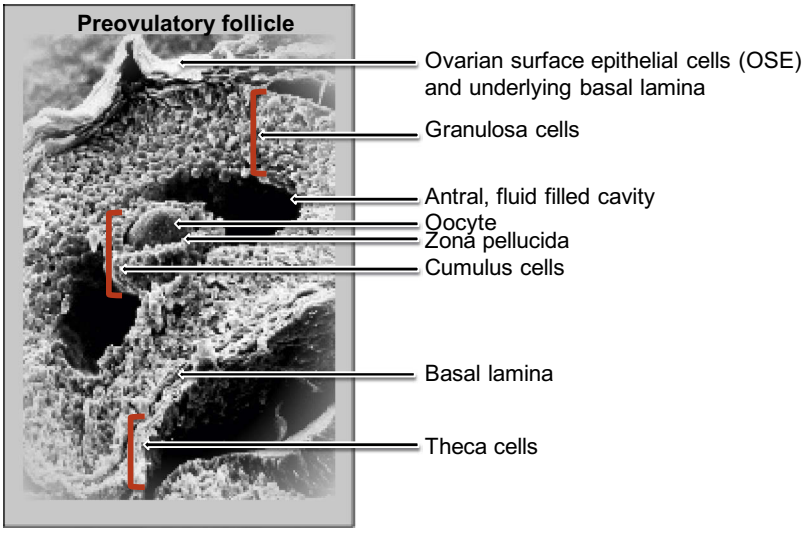

FIGURE 22.2 Cell types and organization within the preovulatory follicle. The preovulatory, antral follicle is composed of several cell types. The ovarian surface epithelium is composed of mesoepithelial cells that face the peritoneal cavity and are separated from the ovarian stroma by a basal lamina. The theca cells are the outermost layer of the follicle and produce androgens. The theca cell layer is separated from the granulosa cells by another extracellular basal lamina. The granulosa cells of preovulatory follicles express receptors for FSH and LH and aromatase (*Cyp19a1*) that converts theca cell-derived androgens to estradiol. The antral cavity is filled with fluid that contains serum components as well as factors secreted from the granulosa cells, cumulus cells, and the oocyte. The cumulus cells are connected directly to the oocyte by gap junctions (Connexin37; GJA4) that permit the transfer of small molecules, such as cGMP, from the cumulus cells to the oocyte. Factors that are produced by oocytes, such as GDP9, BMP15, and FGF8, are secreted from the oocyte into the antral fluid and modify cumulus and granulosa cell functions. The extracellular matrix between the oocyte and the cumulus cells is the zonal pellucida that is composed of specific proteins involved in follicle formation as well as fertilization. The cumulus cell–oocyte complex (COC) is a specific niche in the preovulatory follicle. (See text.)

layer of cells in the preovulatory follicle and is composed of the theca externa and theca interna. The theca externa contains fibroblasts that generate extracellular collagen to provide a semirigid, supportive structure around the follicle. The theca externa is also endowed with an elaborate vascular network that supplies nutrients and oxygen to the follicle. The granulosa cell layer is separated from the theca layer by a thin collagen/laminin-rich basal lamina. This matrix provides an attachment surface for the outermost layer of granulosa cells, the mural granulosa cells. The remaining granulosa cells form a syncytium in which they are interconnected by specialized gap junctions, composed primarily of connexin 43 (GJA1).[40] The cumulus cells, the inner layer of somatic cells, surround the oocyte, forming the cumulus cell–oocyte complex (COC). The cumulus cells are separated from the oocyte by the zona pellucida, a matrix of specific glycosylated zona proteins that serve to protect the oocyte and to provide structure and function during fertilization. The zona also allows for the attachment of cumulus cells and their connections with the oocyte via gap junctions, comprised exclusively of connexin 37 (GJA4), in the COCs that are critical for oocyte development.[41,42] The OSE is derived from cells of a distinct origin from that of the mesenchymal cells or germ cells within the ovary.[43] These OSE cells lay external to a basal lamina and thus face outward toward the peritoneal cavity. The role of these mesoepithelial cells in ovarian function and ovulation is not entirely clear but appears not to be essential for ovulation.[44,45] However, they respond to hormones and can lead to OSE cell cancer, often referred to as "ovarian cancer".[43]

In order for the oocyte and its surrounding somatic cumulus cells, the COCs, to be released from the surface of the ovary and hence ovulated, specific, highly organized, and sequential morphological, biochemical, and molecular changes occur within the preovulatory follicles in response to the LH surge. The major morphological changes that occur in follicles at the time of ovulation have been described in detail previously[3] and therefore will not be elaborated here. However, it is important to note that there are five key events that ultimately permit ovulation to be successful. These are (1) COC expansion, (2) breakdown of gap junctions, (3) resumption of meiosis in the oocyte, (4) release of the COC complex from the surface of the ovary, and (5) luteinization (Figures 22.1, 22.3, 22.4 and 22.5).

COC Expansion

In brief, the compact COC complex present in the preovulatory follicle undergoes the process of expansion also known as mucification (Figure 22.3). In this process, the cumulus cells make an extracellular hyaluronan-rich matrix, migrate outward from the oocyte to fill the antral cavity, and become dissociated from each other. The process of COC expansion and matrix formation is obligatory for successful extrusion of the oocyte from the surface of the ovary, as reviewed recently and outlined briefly below.[1,7,46]

Although the precise mechanisms by which extrusion of the COCs from the ovary is accomplished remain to be determined, the process of COC expansion is dependent on LH induction of selected genes (Figure 22.4(A); step (1), highlighted in red). Specifically, the LH surge rapidly induces expression of hyaluronan synthase 2 (*Has2*), which generates long polymers of hyaluronan. These polymers form the backbone of the COC matrix that is stabilized by a scaffold of hyaluronan-binding proteins and proteoglycans (Figure 22.4(B)).

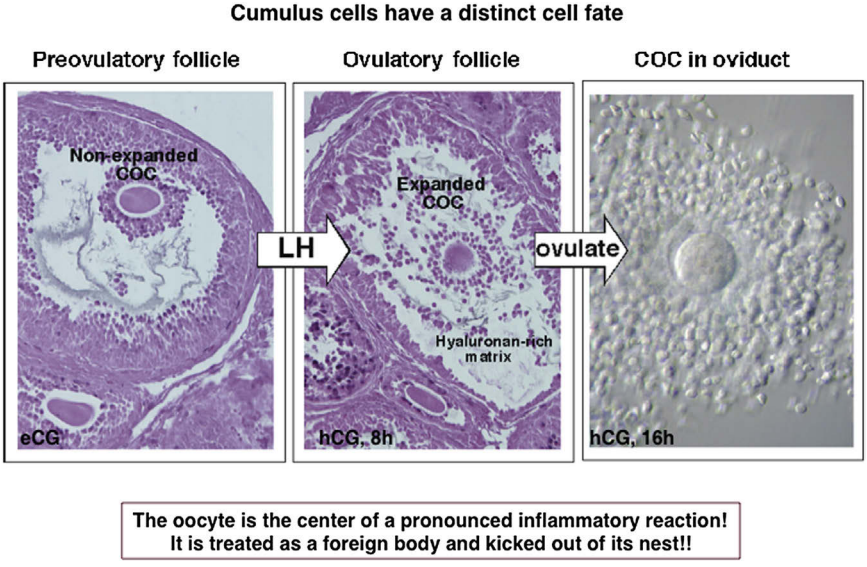

FIGURE 22.3 The LH surge induces expansion of the cumulus cell-oocyte complex (COC). This figure is reproduced in color in the color plate section. Expansion is dependent on the biosynthesis of long polymers of hyaluronan by HAS2. The hyaluronan polymers are stabilized by specific hyaluronan-binding factors including the proteoglycan versican and inflammatory-related factors such as TNFAIP6, IαI, and PTX3. COC expansion is obligatory for release of the enclosed oocyte from the surface of the ovary into the oviduct. (See text.)

LH also rapidly induces expression of the epidermal growth factor-like factors (EGF-like factors), amphiregulin (*Areg*), epiregulin (*Ereg*), and betacellulin (*Btc*). These factors bind the EGF receptor, leading to the induction of prostaglandin synthase 2 (*Ptgs2*) and increased intrafollicular PGs, principally PGE1/2. The EGF-like factors regulate the expression of genes involved in the stabilization of the COC matrix: tumor necrosis factor alpha-induced protein 6 (*Tnfaip6*), pentraxin 3 (*Ptx3*), and the proteoglycan versican (*Vcan*). TNFAIP6 delivers a serum factor IαI to the hyaluronan backbone. PTX3 binds exclusively to TNFAIP6. Versican binds hyaluronan and is the preferred substrate for the protease ADAMTS1. The scaffolding of proteins and the proteoglycan, versican, that bind hyaluronan, act to stabilize the matrix that surrounds the oocyte (Figure 22.4(B)). This matrix is essential for extrusion of the oocyte from the surface of the ovary and its subsequent transit down the oviduct (Figure 22.1).

Gap Junctions and Meiosis

Downregulation and disruption of gap junction proteins facilitate the resumption of meiosis in oocytes by regulating intraoocyte levels of cGMP and cAMP (Figure 22.4(A); steps (2) and (3)) and will be reviewed below.

Ovulation

The LH surge also induces expression of the PGR that, as mentioned, preferentially impacts the process of follicle "rupture" and extrusion of the oocyte more than it impacts COC expansion (Figure 22.4; step (4), highlighted in green). The induction of PGR facilitates the induction of other specific genes encoding the protease ADMATS1, a factor involved in protein secretion, synaptosome-associated factor 25 (SNAP25), cGMP-dependent protein kinase 2 (PRKG2), and endothelin 2.

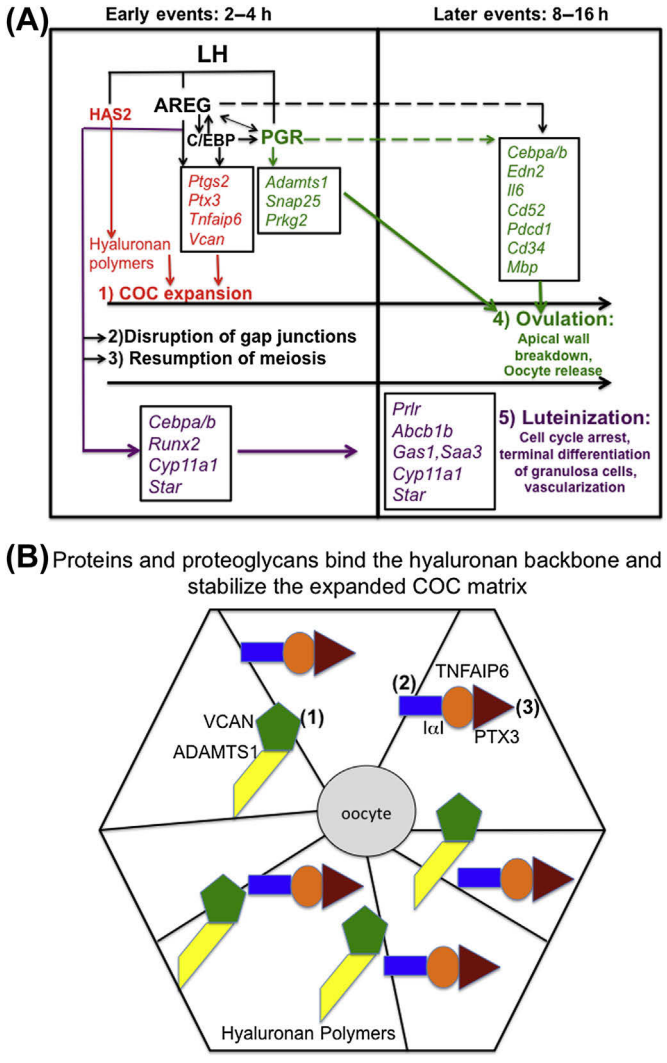

FIGURE 22.4 (A) Early and later events induced by the LH surge. Successful ovulation depends on several sequential events. (1) COC expansion must occur. This is regulated by LH induction of EGF-like factors (AREG), activation of C/EBPα/β, and the induction of specific matrix-stabilizing factors. (2) Gap junctions between granulosa cells and cumulus cells and between the cumulus cells and the oocyte must be disrupted to reduce intraoocyte levels of cGMP. (3) Meiosis is resumed in the oocytes. (4) Release of the oocyte from the surface of the ovary ("ovulation per se") is dependent on proteolytic activity and cytokines. (5) Luteinization is the process by which the granulosa cells terminally differentiate to nondividing luteal cells and begin to produce copious quantities of progesterone. This is dependent on the neovascularization of the avascular granulosa cell layer and occurs following ovulation. (B) Components that control COC expansion. COC expansion is dependent on the production of a hyaluronan-rich extracellular matrix. The long polymers of hyaluronan are stabilized by (1) the binding of the proteoglycan versican (VCAN) and associated ADAMTS1, (2) the TNFAIP6-dependent delivery of IaI, and (3) the binding of PTX3 to TNFAIP6. This scaffold of factors prevents the breakdown of hyaluronan.

Genes that are induced at later times after the LH surge and closer to the time of actual extrusion of the oocyte from the surface of the ovary include cytokines and chemokines as well as other genes whose functions remain to be defined.

At the ovarian surface, the morphological events associated with ovulation involve the dissolution of collagen fibers in the theca layer and the consequent thinning of the surrounding stromal tissue. The vascular network in the theca cells of ovulating follicles becomes highly hyperemic and dilated, indicative of the inflammatory-like activities that are occurring in the somatic cells. The PGs, cytokines, and chemokines that are being released alter vascular functions and appear to recruit immune cells. Ultimately, the basal lamina of the OSE that separates the apex of the follicle from the peritoneal cavity (human and other species) or bursa (mouse, rat) loosens and permits the release of the expanded COCs. The COCs are then picked up by the ciliated cells of the fimbria and transported to the oviduct, where fertilization occurs. Successful release of the oocyte must occur before luteinization; otherwise the oocytes are trapped with the corpora lutea.

Luteinization

The LH surge and the EGF-like factors also induce genes that regulate the process of luteinization (Figure 22.4(A); step (5), highlighted in purple) and terminate the expression of genes regulated by the FSH program. The genes associated with luteinization include the induction and activation of transcription factors C/EBPα/β and RUNX2, steroidogenic enzymes (*Cyp11a1* and *Star*), as well as the prolactin receptor (*Prlr*) and others whose functions remain to be determined. Luteinization occurs following ovulation and is associated with (1) the marked neovascularization of the granulosa cell layer, (2) terminal differentiation of the granulosa cells to nondividing luteal cells, and (3) enhanced steroidogenesis related to increased mitochondrial growth and activity. This rapid and profound development of the vascular network in the newly developed corpus luteum is essential for the delivery of progesterone and other factors needed to support uterine development and implantation.

SETTING THE STAGE: GRANULOSA CELL FUNCTIONS IN PREOVULATORY FOLLICLES

It is now axiomatic that only preovulatory follicles are capable of ovulating in response to the ovulatory surge of pituitary LH. This has been experimentally established in most (all) mammals studied by the evidence showing that granulosa cells in preovulatory follicles selectively express elevated levels of LH receptors that bind LH or hCG.[1,7,47] Thus, preovulatory follicles are the only follicles in the ovary that actually "see" and respond to the LH surge (Figure 22.5). The induction of LH receptor (designated the LH and chorionic gonadotropin receptor, LHCGR) protein and mRNA in granulosa cells of preovulatory follicles depends on (1) the increased sensitivity of granulosa cells to FSH[48,49]; (2) increased expression of *Cyp19a1* (aromatase), production of estradiol, and enhanced activation of the estradiol receptor β (ESR2)[50]; and (3) expression and/or action of activin, a member of the TGFβ family that enhances FSH-induced transcription of the *Lhcgr* gene in granulosa cells but may suppress *Lhcgr* expression in luteal cells.[51,52] In addition to the induction of the LH receptor, granulosa cells of preovulatory follicles produce elevated levels of cAMP in response to LH (and FSH), thereby enhancing activation of the protein kinase A signaling cascade, the canonical pathway downstream of the LH receptor and adenylyl cyclase.[49] This enhanced production of cAMP appears to be critical for initiating the processes of ovulation and luteinization. This is supported by evidence that high levels of FSH or LH or the pharmacological agent forskolin that activate adenylyl cyclase, do not induce ovulation-related genes

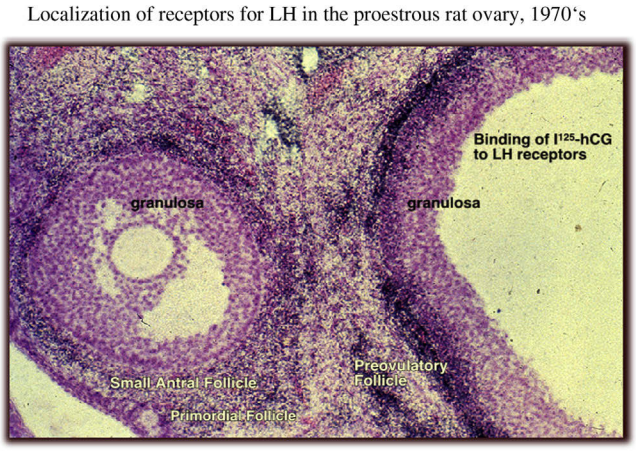

FIGURE 22.5 Induction of LH receptors (LHR; LHCGR) in granulosa cells is the key distinguishing hallmark of preovulatory follicles. This figure is reproduced in color in the color plate section. The presence of LHR in granulosa cells of preovulatory follicles permits them (but not small follicles lacking LHR in granulosa cells) to respond to the LH surge and initiate the molecular programs required for ovulation, COC expansion, resumption of meiosis, and luteinization. This image shows the uptake of radiolabeled hCG (LH) into the theca cells and mural granulosa cells of a preovulatory follicle (right) but only in theca cells of small follicles (left). Primordial follicles do not exhibit detectable uptake of the hormone. Uptake reflects the presence of receptors.

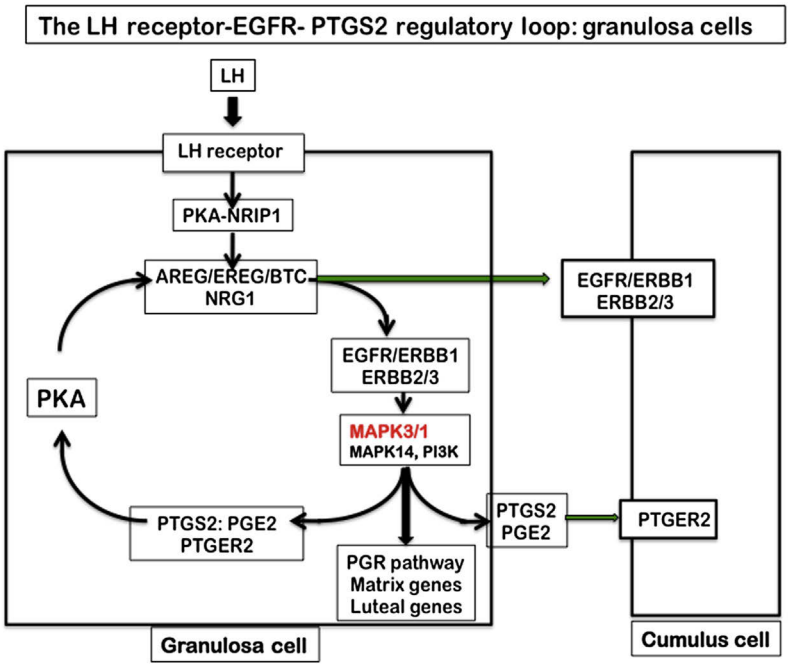

FIGURE 22.6 The LH-EGFR-PTGS2 regulatory loop in granulosa cells. The LH receptor induces expression of the EGF-like factors (*Areg*, *Ereg*, *Btc*, and *Nrg1*) that bind the EGFRs (ERBB1 or ERBB2/3) to activate the MAPK3/1 and PI3K pathways, respectively. Activation of MAPK3/1 leads to (1) the induction of PTGS2, (2) the production of PGE2, (3) activation of the PTGER2 (EP2) receptor, (4) activation of PKA, and (5) further expression of the EGF-like factors. The EGF-like factors and PGE2 produced by this regulatory loop also act by paracrine mechanisms to stimulate similar pathways in cumulus cells (See text and Figure 22.7).

in granulosa cells or cumulus cells of preantral or small antral follicles.[53] Conversely, depletion of phosphodiesterase 4B in granulosa cells and cumulus cells leads to premature elevation of cAMP and luteinization but not ovulation,[54,55] indicating that the level and timing of cAMP production are of the essence in permitting ovulation to occur.

ON-STAGE ACT I: LINKING THE LH RECEPTOR TO OTHER SIGNALING PATHWAYS IN GRANULOSA CELLS

The LH–EGF Receptor Connection

The LH surge not only activates the adenylyl cyclase, cAMP, protein kinase A pathway in granulosa cells but also leads to the activation of other critical signaling cascades (Figure 22.6). Major milestones in our understanding of the molecular events controlling ovulation came when (1) expression of the EGF-like factors (amphiregulin, AREG; epiregulin, EREG, and betacellulin, BTC) and type III neuregulin 1 (NRG1) was shown to be rapidly induced by LH in vivo and in follicle, granulosa cell, and COC cultures[56–58]; (2) expression of hypomorphic alleles or conditional disruption of the EGF receptor (*Erbb1*) pathway in granulosa cells impaired ovulation, oocyte maturation, and luteinization[46,59]; and (3) conditional disruption of the mitogen-activated protein kinases (MAPK3/1) (also known as ERK1/2) blocked ovulation, oocyte resumption of meiosis, and luteinization.[60] The induction of EGF-like factors has been verified in other species, including humans, bovine, porcine, and equine follicles.[61–63] In addition, mice null for the transcriptional co-regulator molecule nuclear receptor interacting protein 1, *Nrip1* (also known as RIP140), are infertile, fail to ovulate, and express low levels of EGF-like factor (*Areg*, *Ereg* and *Btc*) mRNAs.[64] These data suggested that RIP140/NRIP1 might act upstream to regulate the expression of the *Areg* gene.[65] Indeed, recent studies have shown that NRIP1 binds to the *Areg* promoter and enhances forskolin-mediated activation of its promoter activity.[65] The transcriptional effects of NRIP1 are dependent on the recruitment and binding of CREB/JUN factors to a CREB response element in the *Areg* promoter. Importantly, AREG can restore COC expansion in *Nrip1* null mice in vivo but does not restore ovulation, indicating that NRIP1 regulates other factors required for follicle rupture.[65]

Collectively, the data from these mouse models, as well as results from numerous pharmacological studies using selective inhibitors of receptor-kinase (EGFR, MAPK3/1, protein kinase A, PKA) pathways, allow us to link activation of the LH receptor, cAMP, and PKA pathway directly to the induction of the EGF-like factors AREG, EREG, and BTC. These factors, in turn, bind the EGF receptor (ERBB1) and ultimately activate the RAS and MAPK3/1 pathway. The sustained activation of the MAPK3/1 for at least 4 h is critical for COC expansion and expression of *Ptgs2*[66] and may involve the generation of reactive oxygen species that occurs during inflammatory responses.[67] This prolonged activation also appears to be

dependent, at least in part, on the delayed increase in the MAPK3/1-specific dual phosphatase (DUSP6/MKP3).[68] In cumulus cells, the effects of the EGF-like factors are enhanced by oocyte-derived factors (growth differentiation factor 9, GDF9 and bone morphogenic protein 15, BMP15) that increase the expression of the EGF receptor (ERBB1) by a SMAD2/3-dependent pathway.[69]

Another EGF-like factor, type III NRG1, is also induced by LH/hCG, binds to and activates other EGF receptors (ERBB3/ERBB2), and preferentially stimulates the PI3K pathway rather than the MAPK3/1 pathway.[58] However, when NRG1 is combined with AREG, the phosphorylation and activation of MAKP3/1 in granulosa cells is markedly enhanced above that with AREG alone, indicating that these pathways together control distinct events during ovulation. Defining how LH induces the EGF receptor pathways and how they interact has been a major leap forward in our understanding of the molecular and biochemical events that initiate the first steps leading to successful ovulation (Figure 22.6).

Targets of the LH–EGF Receptor Pathway

The LH surge leads to the expression of specific genes that are associated with ovulation, COC expansion, oocyte maturation, and luteinization; and suppresses many genes mediating FSH action in preovulatory follicles (Figure 22.7). Genes associated with ovulation and COC expansion are induced rapidly but are expressed transiently. In the mouse, the expression of many critical genes peaks at 2–4 h and declines by 8 h after the administration of an ovulatory dose of hCG; others are induced between 8 and 16 h.[70] Genes that initiate luteinization occur early, but those that control the formation of the corpus luteum, its vascularization, and its maintenance occur later and are sustained.[71] Once these LH-induced ovulation and luteinization programs are set in motion and the follicle program is turned off, these molecular events cannot be reversed. Thus, in a sense the LH surge is a unique hit-and-run reaction.

Some of the downstream targets of LH and EGF receptor signaling pathways have been identified by gene expression profiles obtained from the *Nrip1*,[64,72] *Mapk3/1*,[60] and *Cebpa/b* mutant mouse models[71]; gene profiling of ovulating follicles by differential display technology[73,74]; gene profiling of mouse COCs during the ovulation process[70]; a rat genome database[75]; a primate genomic database[76]; and the relative expression levels of mRNAs in granulosa cells of the *Nrip1*, *Erbb1*, *Mapk3/1*, and *Cebpa/b* mutant models compared to wild-type controls. Genes whose expression is reduced by disrupting *Nrip1*, *Erbb1*, or *Mapk3/1* include *Pgr*, *Ptgs2*, *Has2*, *Tnfaip6*, *Adamts1*, *Ptx3*, *Prkg2*, *Runx1*, *Runx2*, *Snap25*, and *Nrg1*. Some of these genes, such as *Areg*, *Ereg*, *Btc*, *Adamts1*, and *Snap25*, are also specific targets of *Pgr* as documented in the *Pgr*-null mouse model where ovulation is blocked but luteinization proceeds.[33,35,57,77] Disruption of *Adamts1* also reduces fertility[78,79] (discussed below). By contrast, the expression of versican (*Vcan*), a major extracellular matrix proteoglycan that binds hyaluronan and is the preferred substrate of ADAMTS1, is reduced in the *Nrip1*-null mice but not

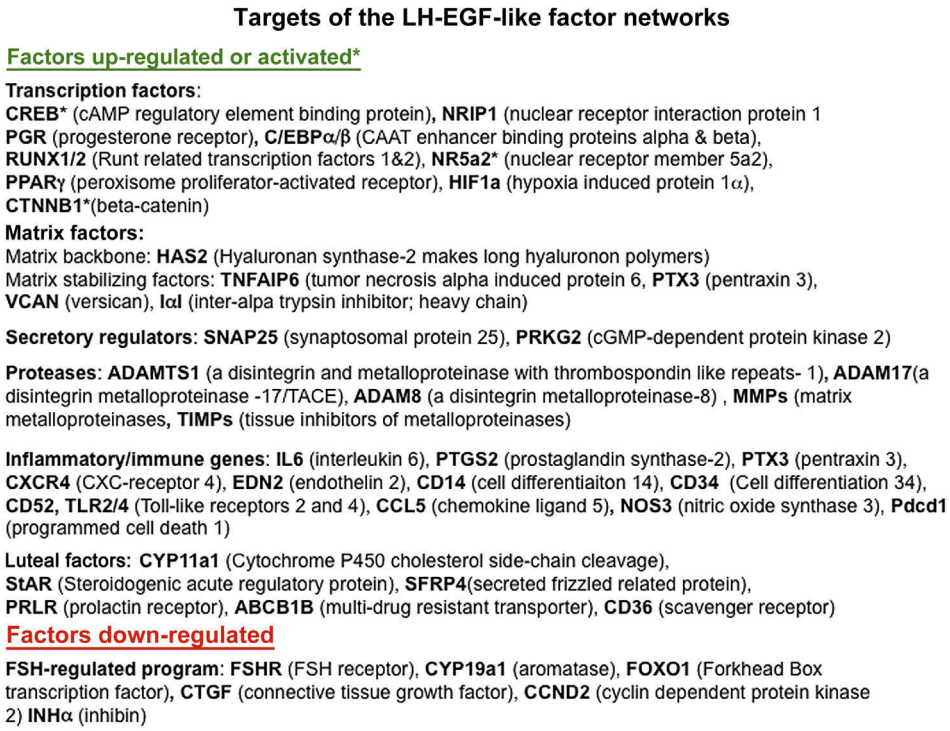

FIGURE 22.7 **Targets of the LH and EGF-like factors in ovulation.** Genes that are induced in granulosa cells and cumulus in response to the LH surge include (1) transcription factors (see also Figure 22.11); (2) components of the COC matrix; (3) factors controlling secretion of peptides, such as cytokines and chemokines; (4) proteases involved in follicle rupture; (5) inflammatory/immune factors that impact COC expansion, ovulation, and fertilization; and (6) genes that maintain luteal cell functions. Factors that are downregulated in granulosa cells by the LH surge are components of the FSH response network that control granulosa cell proliferation and differentiation (including the induction of the LHR) preceding the LH surge.

in the *Pgr* or *Mapk3/1*-null mice.[64] Thus, NRIP1 appears to regulate the expression of *Vcan* and likely additional genes by mechanisms other than, or in addition to, its role in the induction of *Areg*. This may help explain why AREG can restore COC expansion, but cannot induce ovulation, in the *Nrip1* mutant mice in vivo.[65]

Recent studies indicate further that *Nrip1* expression is low in ovaries of immature mice but is increased in response to eCG and is localized selectively to cumulus cells and the inner layer of granulosa cells. This increase likely facilitates the induction of *Areg* in COCs of ovulatory follicles. Conversely, low levels of *Nrip1* in cumulus cells of small antral follicles may be controlled by oocyte-derived factors GDF9 and FGF8, thereby reducing their competence to express *Areg* prematurely.[80] However, this remains to be verified.

The Central Role of ERK1/2 (MAPK3/1)

The expression of the *Lhcgr* gene is not altered in granulosa cells of *Pgr, Nrip1, Erbb1, Mapk3/1*, or *Cebpa/b* mutant mouse models, indicating that it is upstream of these genes. Many genes that are expressed at high levels in granulosa cells of preovulatory follicles and that are normally downregulated as a consequence of the LH surge, remain high in the *Mapk3/1*-mutant mice.[60] These include *Fshr, Cyp19a1, Foxo1, Ctgf, Ccnd2*, and *Inhba*, as well as *Lhcgr* itself.[81] Thus, activation of the MAPK3/1 pathway by LH induction of the EGF-like factors is essential not only *for turning on* genes that regulate ovulation and luteinization but also *for turning off* genes that establish and maintain the preovulatory granulosa cell phenotype. Importantly, this appears to involve activation of C/EBPα/β.[60,81] It is impressive to observe that healthy preovulatory follicles remain present as long as 48 h after administration of hCG to eCG-primed *Mapk3/1*-mutant mice, whereas corpora lutea are fully formed in the wild-type control mice similarly treated. Thus, activation of MAPK3/1 is critical for both ovulation and the terminal differentiation of granulosa cells. It is also important to note that disruption of *Mapk3/1* in the pituitary causes infertility in female (but not male) mice by blocking the LH surge but not basal levels of LH.[82] Thus, the MAPK3/1 pathways in the pituitary and ovary are critical and tightly integrated to control ovulation.

The Multiple Roles of RAS

The selective timing of the RAS/MAPK3/1 activation by LH and EGF-like factors in granulosa cells of preovulatory follicles, but not by FSH in small follicles, appears to be functionally critical for the timely progression of follicular development in vivo. Specifically, when a mutant active form of RAS ($KRAS^{G12D}$) is expressed prematurely in granulosa cells of small follicles, follicle growth is totally derailed. Granulosa cells cease dividing, do not undergo apoptosis, and fail to differentiate. As a consequence, the ovary becomes filled with abnormal follicle-like structures that are devoid of oocytes.[68,83] Thus, activation of the RAS/MAPK3/1 pathway is highly deleterious, if activated prematurely. This illustrates how elegantly this signaling cascade must be orchestrated and controlled to ensure ovulation occurs only in preovulatory follicles and that follicular growth is not disrupted.

ON-STAGE ACT II: SIGNAL CONNECTIONS BETWEEN GRANULOSA CELLS AND THE CUMULUS CELL–OOCYTE COMPLEX DURING OVULATION

COC expansion and the composition of the expanded matrix are critical for successful ovulation (Figures 22.3 and 22.4). Targeted disruption of matrix-related genes *Ptgs2, Ep2, Has2, Adamts1, Tnfaip6, Ptx3*, and *IaI* in mice or in culture impairs COC expansion and the mice are infertile or subfertile.[24,78,79,84–89] If the COC matrix is not made appropriately and lacks the hyaluronan backbone (made by HAS-2) or is not stabilized by the scaffolding of proteins that bind the hyaluronan polymers directly (IαI heavy chain and versican) or to each other (IαI-TNAIP6-PTX3), COCs are not released, and as a consequence the oocytes are trapped inside the nonovulated, luteinized follicles.

The EGF Receptor Loop in COCs

One question that has plagued reproductive endocrinologists for many years is how the LH surge can mediate cumulus cell–oocyte complex expansion. This query was posed because, in most species studied (including humans),[47] LH receptors are highly and selectively expressed in the outer layer of mural granulosa cells but are either absent or low in cumulus cells (Figure 22.8). This perplexing puzzle was resolved relatively quickly after reports by Espey et al.[73], Conti et al.[56], and Shimada et al.[57] showed that the LH surge or exogenous hCG induces the EGF-like factors, *Areg, Ereg*, and *Btc* in granulosa cells of ovulatory follicles. These in vivo observations supported previous in vitro studies showing that EGF itself could impact cumulus cell functions and oocyte maturation in several species. However, the physiological relevance of EGF was difficult to explain because this ligand is not expressed in granulosa cells.

The induction of the EGF-like factors by LH provided the first impressive physiologically relevant evidence showing that endogenous ligands for the EGF receptors were induced and expressed in ovulating follicles.

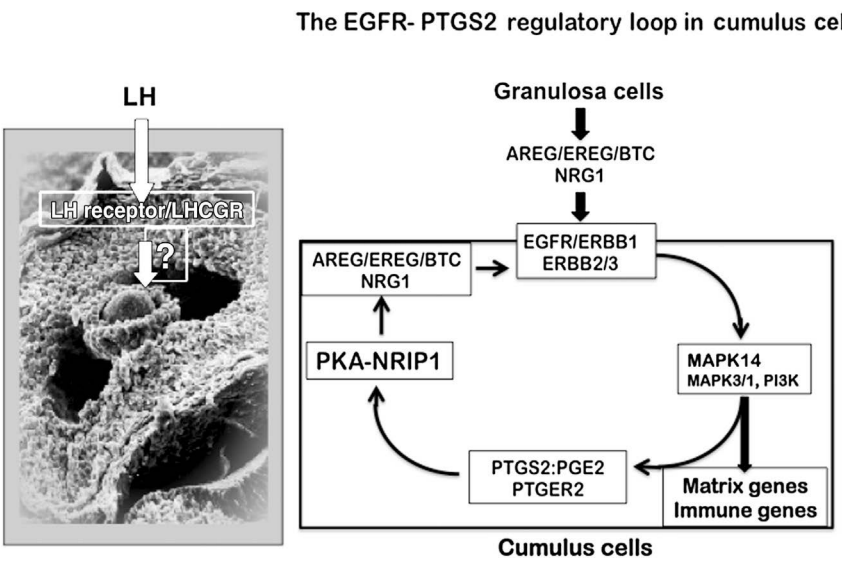

FIGURE 22.8 The EGFR-PTGS2 regulatory loop in cumulus cells. Once the EGF-like factors are secreted from the granulosa cells in response to the LH surge, they bind to EGF receptors present on the surface of cumulus cells and initiate an autocrine regulatory loop in the cumulus cells. The EGF-receptors activate MAPK14 (and MAPK3/1), leading to the induction of PTGS2 and the production of PGs (PGE2). PGE2 binds the PG receptor PTGER2 (EP2) and stimulates the production of cAMP, which activates protein kinase A (PKA). This in turn leads to the induction of the EGF-like factors within the COC. NRG1 activates the PI3K pathway in cumulus cells that impact the resumption of meiosis (See text).

Cleavage enzymes, such as TACE/ADAM17, that activate the EGF-like factors are also induced and critical for EGF-like factor functions.[90] The rapid induction of AREG, EREG, and BTC as well as type III NRG1 by LH (or by its analog hCG) functionally links activation of the LH receptor in granulosa cells to LH-mediated actions in cumulus cells where LH receptor levels are low[47,70] (Figure 22.8). When these EGF-like factors are added to follicles and COCs in culture in the absence of LH, they stimulate COC expansion and thereby convincingly bypass the need for LH or other cAMP-inducing agents.[57,91,92] Data from several laboratories show that AREG stimulates COC expansion in cultures of preovulatory follicles and in intact COCs by inducing genes known to be obligatory for the COC expansion process and ovulation.[46,57]

The EGF-Like Factor PTGS2 Regulatory Loop

Genes that are induced by the EGF-like factor AREG include *Ptgs2*, *Tnfaip6*, *Adamts1*, *Ptx3*, and *Pgr*. Furthermore, mice expressing a hypomorphic allele for the EGF receptor are subfertile, and mice in which the *Erbb1* gene is disrupted selectively in granulosa cells using *Cyp19*-Cre mice are infertile.[46,59] Both of these *Erbb1*-mutant mouse models exhibit impaired COC expansion and oocyte maturation. Type III NRG1 alone does not induce COC expansion, likely because it does not activate MAPK3/1.[58] However, when AREG and NRG1 are combined, expansion is enhanced, and the expression of *Tnfaip6* is significantly increased. Conditional disruption of *Nrg1* also impairs fertility by altering the onset of oocyte maturation and reducing embryo development, but the phenotype is less severe than that of *Erbb1*-mutant mice (Shimada, unpublished data).

Of further critical importance to successful ovulation is the establishment of an autocrine regulatory loop between AREG and PTGS2 in COCs (Figure 22.8). AREG induces *Ptgs2*, leading to increased production of PGs.[57] PGE2, by binding to its cognate EP2 G-protein coupled receptor, activates adenylyl cyclase and cAMP production, leading to transactivation of *Areg*, *Ereg*, and *Btc*.[57,93] This regulatory loop allows the COCs to function independently of LH and the LH receptor to control genes obligatory for matrix formation and matrix stabilization such as *Has2*, *Tnfaip6*, *Ptx3*, and *IaI*.[57,87,88,94] This regulatory loop in COCs also appears to be dependent, in part, on the oocyte and oocyte-derived factors such as GDF9 and BMP15 and the SMAD2/3 pathway.[69,95] This same autocrine regulatory loop also may be operative in granulosa cells, where activin acting via SMAD2/3 may substitute for GDF9 and BMP15, thereby maintaining AREG production in these cells where genes controlling luteinization are preferentially induced.

PGs (PGE2) can also directly impact mouse and human oocytes by binding to EP2 (PTGER2) and EP4 (PTGER4) receptors present in these germ cells, increasing cAMP levels and delaying oocyte maturation.[96,97] Although PTGS2 (COX-2) inhibitors have been found to block ovulation in rats, results of their effectiveness for contraceptive use have been variable and timing is critical.[98,99]

The MAPK14-PTGS2 Connection in COCs

Another kinase, *Mapk14* (p38MAPKα) (Figure 22.8), plays a modulatory role in regulating COC expansion.[100] Targeted disruption of *Mapk14* in granulosa and cumulus cells does not impair fertility, but COCs lacking *Mapk14* fail to expand in culture in the presence of PGE2 or FSH, and expression of *Areg*, *Ereg*, *Ptgs2*, *Tnfaip6*, and *Ptx3*

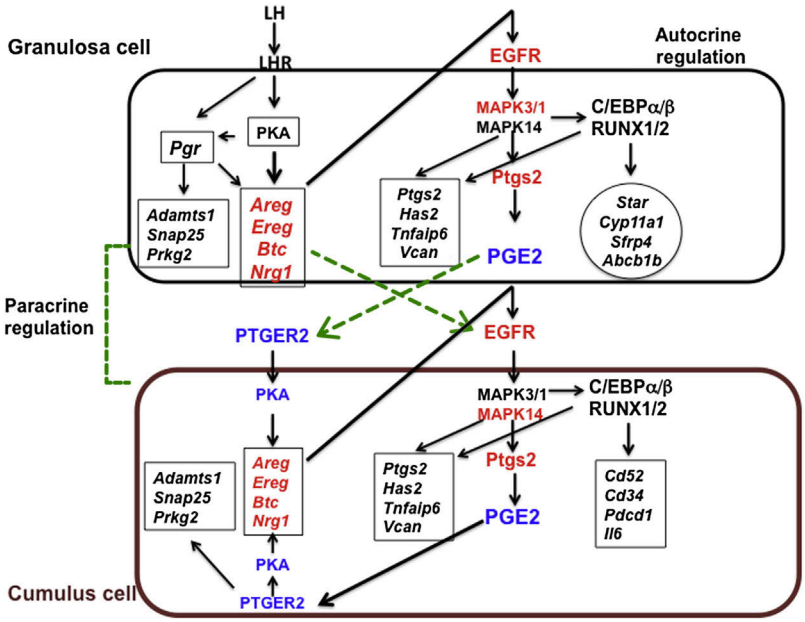

FIGURE 22.9 Schematic of the autocrine and paracrine networks that are initiated by the LH surge and coordinate the functions of granulosa cells and cumulus cells. The LH surge activates its cognate receptor leading to the production of cAMP and activation of PKA. This leads to the induction of specific genes including PGR and the EGF-like factors. The EGF-like factors activate their receptors and MAPK3/1 leading to the induction of matrix and inflammatory genes including PTGS2. The PGE2 that is produced following the induction of PTGS2 by the MAPK3/1 pathway and the EGF-like factors then act in a paracrine manner (dashed arrows) to stimulate an autocrine regulatory loop in cumulus cells that leads to the induction of matrix and immune-related genes.

mRNAs is markedly reduced. Expansion can be restored in the *Mapk14*-mutant COCs by adding AREG. Therefore, MAPK14 is required for mediating PGE2 and FSH induction of *Areg*, and hence genes that are downstream of AREG, in cumulus cells.[100] Confirming the importance of MAPK14, MAPK14 inhibitors block the induction of COC expansion by PGE2 in wild-type COCs.

On the other hand, *Areg* expression is *increased* in granulosa cells lacking *Mapk14*, suggesting that in these cells MAPK14 may suppress the cAMP-PKA pathway.[100] Thus, granulosa cell production of AREG appears to compensate in vivo for the lack of AREG production in the *Mapk14*-mutant cumulus cells.

The autocrine and paracrine signaling networks that are induced by the LH surge and control both granulosa cell and cumulus cell functions are summarized in Figures 22.8 and 22.9.

Nongenomic Processes that Control COC Expansion

COC expansion involves the migratory activity of cumulus cells.[101] This activity is mediated by nongenomic events that are regulated by (1) the EGF receptor-MAPK3/1 pathway and (2)[101] an EGF receptor-calcium dependent mechanism. This has been elegantly demonstrated in studies that examined the mechanisms by which cumulus cells detach from each other and migrate within the matrix and away from the oocyte.[102] Specifically, the EGF receptor-MAPK3/1 pathway and EGF receptor-calcium pathways act coordinately to activate specific proteases known as calpains. These proteases disrupt cell–cell adhesion by cleaving and degrading specific components of focal adhesion complexes, such as paxillin and talin 1. Inhibition of calpain activity significantly reduces COC expansion by impairing cumulus cell migration in vivo and in culture. Thus, cumulus cells, like cancer cells, exhibit migratory behavior that is facilitated by the calpain-mediated loss of cell–cell adhesion.

Other nongenomic events also occur during ovulation. These include the disruption of functional gap junctions between granulosa cells and between cumulus cells and the oocyte.[103] The inactivation of gap junctions is mediated, at least in part, as a consequence of MAPK-mediated phosphorylation of connexin 43 in granulosa cells and connexin 37 in cumulus cells.[46,59,104] This prevents the transfer of substances such as cGMP from cumulus cells to the oocyte. This transport system is critical because cGMP prevents oocyte maturation by inhibiting the specific phosphodiesterase PDE3A, thereby keeping oocyte levels of cAMP elevated.[104–107] As a consequence, oocytes remain arrested in meiotic prophase I.

The cGMP Regulatory Pathway in COCs

The cGMP present in oocytes is generated by the combined functions of granulosa cells and cumulus cells (Figure 22.10). This pathway is comprised of the natriuretic peptide precursor C (NPPC) and the guanylyl cyclase receptor 2 (NPR2). NPPC that is produced and secreted by granulosa cells binds NPR2 that is present primarily in cumulus cells.[108–110] The cGMP that is produced in cumulus cells is then transferred to oocytes. The LH surge not only disrupts gap junctions but also reduces the expression of *Nppc*[111] and NPR2,[109] leading to decreased activation of guanylyl cyclases (NPR2) and reduced levels of cGMP in cumulus cells and the

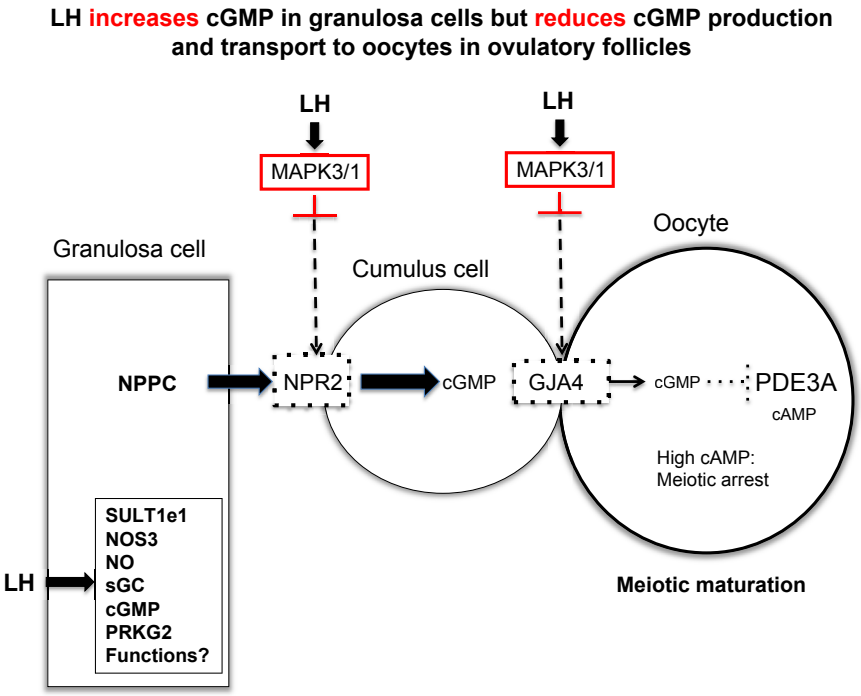

FIGURE 22.10 Regulation of cGMP production in granulosa cells and cumulus cells. In preovulatory follicles, the natriuretic peptide precursor C (NPPC) activates the natriuretic receptor 2 (a receptor linked guanylyl cyclase), leading to increased cGMP production in cumulus cells. cGMP produced by cumulus cells is transported by GAP junctions (GJA4) to the oocyte, where it inhibits the phosphodiesterase 3A, leading to high intraoocyte levels of cAMP. High cAMP prevents the resumption of meiosis. In response to the LH surge and activation of MAPK3/1, expression of NPR2 is reduced and GAP junctions are phosphorylated and inactivated. As a consequence, cGMP levels in the oocyte decrease, PDE3A activity increases, cAMP levels decline, and meiosis resumes. By contrast, the LH surge increases cGMP in granulosa cells by inducing nitric oxide synthase 3, production of nitric oxide (NO), and activation of soluble guanylyl cyclases in the granulosa cells. The coordinate induction of cGMP-dependent protein kinase 2 (PRKG2) suggests that this pathway controls specific functions in granulosa cells.

oocyte.[112] Reduced levels of cGMP in oocytes leads to increased activity of PDE3A and lower levels of cAMP. This then permits the resumption of meiosis of ovulatory follicles (Figure 22.10) (See Chapters 1, 2).

In granulosa cells, another pathway can generate cGMP (Figure 22.10). This pathway is comprised of nitric oxide synthase 3 (NOS-3) that is induced by the LH surge and generates nitric oxides that activate soluble guanylyl cyclases and produce cGMP[104] (see below). cGMP-dependent protein kinase II (cGKII or PRKG2) is also induced by LH in a PGR-dependent manner.[34] Thus, PRKG2 may play a critical role in granulosa cells of ovulatory follicles by mediating the effects of cGMP; however, the precise functions of PRKG2 in ovulatory granulosa cells remain to be resolved.

New Roles for Progesterone

Nongenomic actions of progesterone may also impact somatic cell and oocyte functions during ovulation and oocyte maturation, and these effects of progesterone may be mediated by specific membrane-related receptors that have been identified and localized to preovulatory follicles.[113–115] However, the exact functions of these proteins remain to be determined.

ON-STAGE ACT III: THE OOCYTE REIGNS AT CENTER STAGE

The oocyte itself impacts the function of the surrounding somatic cells during all stages of follicular development and thus is the central player in the follicle. By releasing GDF9, the oocyte in primary follicles organizes the stromal precursor cells to form the theca cell layer.[116,117] In preovulatory follicles, GDF9, BMP15, and FGF8 modulate the functions of cumulus cells by suppressing the expression of the LH receptor and steroidogenesis.[118] However, GDF9 and BMP15 are also essential for facilitating proper formation and stabilization of the matrix during COC expansion. Specifically, GDF9 and BMP15 modulate the expression of *Ptgs2*[95] as well as the innate immune-like factor *Ptx3* that binds and stabilizes TNFAIP6.[88,119] The oocyte also regulates the metabolic functions of cumulus cells to ensure that proper nutrients are supplied to the oocyte.[118,120] Thus, the oocyte is not a passive passenger in COCs prior to or during transport to the oviduct. Rather the oocyte is an active player that helps to direct its own fate throughout follicular development.[121]

ON-STAGE ACT IV: KEY TRANSCRIPTION FACTORS THAT IMPACT OVULATION

Ovulation involves dramatic changes in granulosa cell and cumulus cell functions. Therefore, specific transcription factors are likely to be the targets of the hormone, cytokine, and kinase-activated pathways that coordinate the critical events controlling ovulation (Figures 22.9 and 22.11). As already discussed, the nuclear PGR and the receptor co-regulator NRIP1 play essential roles in ovulation; their disruption causes infertility and ovulation failure.[33,65] *Pgr* is induced by the LH surge by

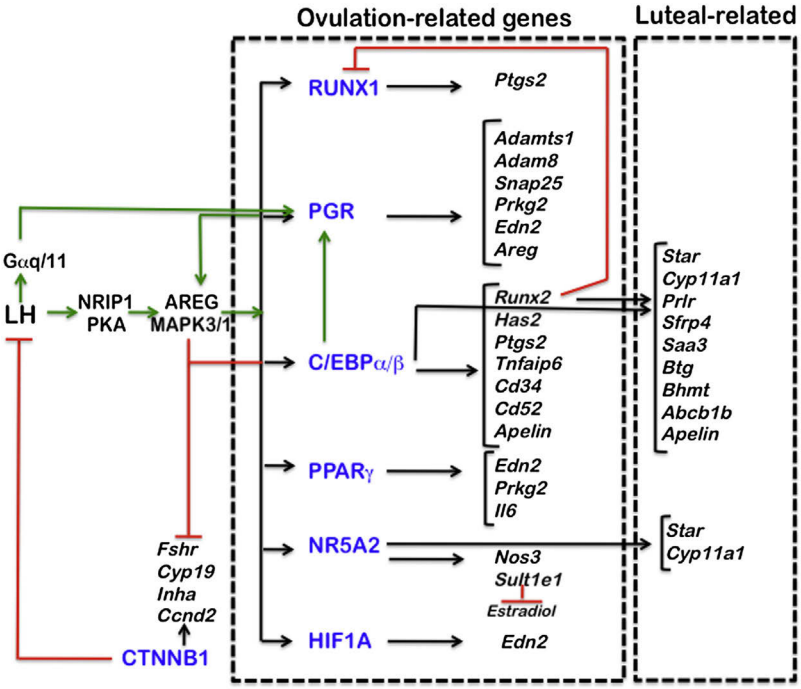

FIGURE 22.11 Transcription factors that mediate LH actions in ovulation and luteinization. The LH surge induces and activates (*) specific transcription factors in granulosa cells. These include (1) RUNX1, which impacts the expression of *Ptgs2*; (2) the nuclear progesterone receptor (PGR), which regulates the expression of the EGF-like factor *Areg*, proteases (*Adamts1, Adam8*), secretory factors (*Snap25, Prkg2*), and endothelin 2 (*Edn2*); (3) C/EBPa/b, which enhances the expression of matrix factors (*Has2, Tnfaip6*), inflammatory factors (*Il6, Cd34, Cd52*), and factors related to luteinization (*Runx2, Star, Prlr, Cyp11a1, Sfrp4*), and suppresses genes mediating the FSH program; (4) RUNX2, which suppresses RUNX1 and regulates genes associated with luteinization, and PPARγ, which regulates genes overlapping with those regulated by PGR; (5) NR5A2, which regulates cGMP production in granulosa cells, and estradiol levels, and also impacts genes associated with luteinization; (6) CTNNB1, which facilitates expression of *Fshr* and aromatase but blocks expression of the LH receptor; and (7) HIF1α, which regulates genes associated with vascularization.

the activation and binding of SP1 to the *Pgr* promoter.[122] Recent studies also indicate that LH induction of PGR requires not only the PKA pathway but also the activation of Gαq/11 pathway.[123] These results support the synergistic actions of forskolin (PKA) and PMA (PKC) in the induction of *Pgr*,[122,124] *Adamts1*,[36] and *Prkg2*.[34] Thus, the LH surge appears to activate not only Gαs and adenylyl cyclase but also Gαq/11 and the inositol phosphate-PKC pathway.

PGR regulates specific target genes, most notable of which are *Adamts1*,[33,36] *cathepsin l*,[33,125] *Adam8*,[126] *Snap25*,[77] *Prkg2*,[127] *Pparg*,[127] and *Edn2*.[128] PGR regulates these genes by interacting with other transcription factors. For example, PGR interacts with C/EBPβ, NF1, and SP1/SP3 to activate the *Adamts1* promoter,[36] and interacts with SP1 to regulate the *Snap25* promoter.[77] In this context, PGR acts more like a transcriptional co-regulatory factor than a transcription factor binding to PGR consensus DNA response elements. NRIP1 appears to be an essential co-activator of the *Areg* gene by binding to CREB/JUN factors on the *Areg* promoter.[65] One would therefore predict that targeted disruption of CREB and specific members of the AP1 family using *Pgr-Cre* mice would also exert detrimental effects on the induction of *Areg* and hence the ovulation process.

C/EBPα and C/EBPβ

Several other transcription factors impact ovulation. Notable among these are the CCAAT enhancer-binding proteins alpha and beta (C/EBPα/β) that are phosphorylated and activated by MAPK3/1.[71,129] Sterneck et al. showed originally (1997) that mice null for *Cebpb* are infertile and do not ovulate.[130] However, these mice suffer from many other maladies. Therefore, the *Cebpb* and *Cebpa* genes were conditionally disrupted in granulosa and cumulus cells using *Cyp19-Cre* mice.[71] The *Cebpa/b* double mutant mice are infertile and anovulatory, whereas either mutant alone is fertile or subfertile. Gene profiling of granulosa cells obtained from the *Cebpa/b* mutant mice revealed a novel set of genes that are mostly downstream of MAPK3/1 and are involved in ovulation and luteinization.[71] Genes that may control the neovascularization of the ruptured, ovulated follicle appear to be major targets, along with *Runx2*, specific transporters, the prolactin receptor *Prlr*, and the acute-phase marker serum amyloid A, *Saa3*.[131] The betaine–homocysteine S-methyltransferase *(Bhmt)* gene was highly downregulated in the *Cebpa/b*-mutant mice, suggesting that methionine metabolism might be critical for ovulation or luteal cell function. Although pharmacological disruption of BHMT reduced progesterone biosynthesis in luteal cells of wild-type mice, the *Bhmt* null mice are fertile.[132] Thus, the functional significance of this gene, and other novel C/EBPα/β-regulated genes remains to be determined.

Induction and activation of C/EBPα/β are also critical for mediating LH/ERK1/2-mediated suppression of genes regulating the FSH-driven program. For example, C/EBP activation suppresses expression of genes encoding *Fshr, Ccnd2, Cyp19a1*, and *Inha*.[60,81]

RUNX1 and RUNX2

The Runt-related transcription factors 1 and 2 (*Runx1* and *Runx2*) are induced rapidly in granulosa cells and

cumulus cells prior to ovulation and luteinization.[70,75,133] Although[134] targeted disruption of these genes in mice has not yet been reported, siRNA for *Runx2* transfected into rat granulosa cells causes the levels of *Runx1* and *Ptgs2* to increase.[135] Because RUNX1 increases the expression of *Ptgs2*, *Ptgs2* appears to be a specific target of RUNX1 but not RUNX2 in vitro. Conversely, RUNX2 regulates the expression of *Runx1* and other genes, some of which are also targets of C/EBPα/β.[136] RUNX2 also induces BTG, a gene that may regulate granulosa cell proliferation during the transition to nondividing luteal cells. That *Runx2* is reduced in the *Cebpb*-null mice and *Cebpa/b*-mutant mice[71] indicates that C/EBPα/β regulate the expression of the *Runx2* gene and may coordinate with RUNX2 to control expression of luteal-related specific genes such as *Abcb1b, Btg*, and *Spp1*.The importance of these genes in ovulation and luteinization remain to be determined.

The Orphan Nuclear Receptor NR5A2

Targeted disruption of the nuclear receptor *Nr5a2* gene also impairs ovulation and luteinization.[137] NR5A2 (also known as liver receptor homolog1, LRH1; Steroidogenic factor 2, SF2; Fushi tarazu F1, FTF) is a close relative of NR5a1 (also known as Steroidogenic factor 1, SF1). NR5A2 is expressed at elevated levels in granulosa cells of growing and antral follicles,[138] whereas NR5A1 is preferentially expressed in theca and stroma cells as well as luteal cells.[138] That disruption of *Nr5a2* impairs ovulation and luteinization more than follicular growth is somewhat surprising and indicates that the functions of NR5A2 in preovulatory follicles are distinctly different from those in growing follicles or the embryonic gonad.[139] Because NR5A2, like C/EBPβ, is phosphorylated by MAPK3/1[140] and MAPK14,[138] the functional activity of NR5A2 may be altered such that it is recruited to, and activates, different target genes in preovulatory granulosa cells following the LH surge. Ovulatory follicles in *Nr5a2*-mutant mice exposed to LH/hCG exhibit impaired expression of matrix-related genes *Ptgs2, Tnafip6*, and *Cd44*.

In addition, NR5A2 regulates transcription of nitric oxide synthase 3 (*Nos3*), which produces nitric oxide (NO). NO activates soluble guanylyl cyclase, leading to increased levels of cGMP. The expression of NOS3 and NO appear to negatively regulate expression of aromatase (*Cyp19a1*) and reduce estradiol production in ovulating follicles.[137] The mechanisms by which NO blocks *Cyp19a1* expression are not known, but may involve NO activation of soluble guanylyl cyclase, cGMP, and PRKG2, which represent a functional signaling pathway in ovulatory follicles.[34,104] The loss of *Nos3* in the *Nr5a2*-conditional knockout mice is also associated with reduced expression of estrogen-specific sulfotransferase (*Sult1e1*), which inactivates estradiol.[137] These combined events lead to prolonged, elevated levels of estradiol and appear to contribute to the impaired ovulation in the *Nr5a2*-mutant mice.[137] The critical role of reducing estradiol in ovulating follicles is supported by the evidence that total loss of *Sult1e1* in mice leads to elevated levels of estradiol, reduces expression of *Ptgs2* in cumulus cells, reduces COC expansion, and impairs ovulation.[141] Estradiol also promotes the expression of NRP2, which leads to increased cGMP, thereby blocking oocyte maturation.[142]

NR5A2 is also critical for the induction of luteal-specific genes, including *Cyp11a1* and *Star*, that control progesterone biosynthesis.[137]

Peroxisome Proliferator-Activated Receptor Gamma

Peroxisome proliferator-activated receptor gamma (*Pparg*) appears to be a target of the PGR in ovulatory follicles. Conditional disruption of the *Pparg* gene in granulosa cells of preovulatory follicles in vivo using *Pgr-Cre* impairs fertility, reduces ovulation, and lowers the expression of specific genes (*Edn2, Prkg2*, and *Il6*) that are also targets of PGR.[143] Of note, however, PPARγ does not regulate the expression of *Adamts1*, a highly specific target of PGR in vivo and in culture. Thus, PGR and PPARγ share some overlapping and coordinate functions as well as some distinct functions in ovulating follicles. The precise mechanisms by which PPARγ regulates ovulation remain to be more clearly documented.

Hypoxia-Related Events

Hypoxia is presumed to occur at the time of ovulation, leading to the increased expression and activation of the transcription factors HIF1α and HIF1β.[143,144] These factors rapidly and transiently induce the expression of specific genes including endothelin 2 (*Edn2*). EDN2 is presumed to bind one of the endothelin receptors EDNR1 or EDNR2 present in theca cells to stimulate smooth muscle contractions, leading to release of the expanded COCs.[128,145] Although EDNR1 and EDNR2 are expressed in granulosa cells, EDNR2 is not required for ovulation. Rather, disruption of the EDNR2 genes leads to increased numbers of corpora lutea.[146] However, disruption of *Edn2* does impair ovulation.[147]

The WNT/FZD/CTNNB1 Pathway

The canonical WNT/Frizzled (FZD) pathway activates beta catenin (CTNNB1) and modulates embryonic gonadal sex differentiation, follicle growth, and ovulation.[148] These results indicate that the expression and regulation of WNT ligands, FZD receptors, and

CTNNB1 are precisely controlled in ovarian follicles at multiple stages of development. Of relevance to ovulation, mice expressing a constitutively active form of CTNNB1 lacking exon 3 (*Ctnnb1*^{ex3}) are subfertile.[149,150] In preovulatory follicles of these *Ctnnb1*^{ex3}-mutant mice, FSH-mediated expression of selected target genes, *Fshr, Cyp19a1*, and *Ccnd2*, is enhanced, indicating that CTNNB1 promotes the preovulatory granulosa cell phenotype. Despite these positive actions of CTNNB1^{ex3}, the *Ctnnb1*^{ex3}-mutant mice exhibit ovulatory defects that are associated with reduced expression of the LH-induced, ovulatory-related genes *Areg, Ptgs2, Tnfaip6*, and *Ptx3* as well as *Lhcgr*.[149] The mutant stable CTNNB1 appears to act, in part, by reducing the binding of CREB to the *Areg* promoter. However, the mechanism by which this is mediated remains to be determined. By contrast, conditional disruption of the *Ctnnb1* gene in granulosa cells does not impair fertility despite the fact that expression of *Cyp19a1* is reduced and of *Lhcgr* is enhanced.[150]

ON STAGE ACT V: KEY PROTEASES IN OVULATION

Ovulation involves and requires the breakdown of the basal lamina separating mural granulosa cells from theca cells as well as the dissolution of the basement membrane underlying the OSE.[3,8] This "thinning" of the ovulatory follicle wall and the surface epithelium ultimately permits the extrusion of the COCs through the ovulation pore. This latter event appears to depend, in part, on EDN2 and smooth muscle contractions within the theca layer[128] (see above). The former events appear to involve various proteases and tissue protease inhibitors, the list of which is long and the functions of which are complex.[151] Despite much research, data from knockout mice lacking various proteases have shed little insight into which ones might be the key players close to or at the time ovulation. However, protease inhibitors can block ovulation, as shown recently in primates.[152] An outstanding and comprehensive review has covered this topic recently; therefore only one protease will be discussed here.[151,153]

As indicated above, *Adamts1* is rapidly and markedly induced in granulosa cells of preovulatory follicles by the LH surge and in a PGR-dependent manner. Not only does the temporal expression of ADAMTS1[36,154] and its control by PGR[33] and possibly CTGF[155] suggest its key role in ovulation, but also the functional activities of ADAMTS1[156,157] indicate that it is a key protease related to ovulation. Mice null for *Adamts1*, as well as mice in which *Adamts1* has been conditionally disrupted in granulosa cells, are subfertile.[79] The proteoglycan versican is one of the preferred substrates for ADAMTS1 and is a key component of the extracellular matrix in expanded COCs and in the follicle wall. In the absence of ADAMTS1, both the invasion of the theca cell layer into the granulosa cell layer as well as the structure of the COC matrix are abnormal. How these defects ultimately cause subfertility and reduce release of COCs remains to be more clearly defined.[158]

ON STAGE ACT VI: CUMULUS CELLS HAVE IMMUNE-LIKE FUNCTIONS AND A DISTINCT FATE

Cumulus cells are distinct from granulosa cells in many ways. As indicated, they are in close physical contact with the oocyte and thereby are exposed to high levels of oocyte-derived regulatory factors that control their function. The oocyte-derived factors, such as GDF9, BMP15, and FGF8, act singly or in combination to suppress cumulus-cell expression of the LH receptor (*Lhcgr*) and steroidogenic genes and promote the expression of other genes in cumulus cells.[120,159] Cumulus cells also have a distinct fate (Figure 22.3). During COC expansion, they are embedded within the expanded extracellular matrix, produce many cytokines and inflammatory factors, and are released from the ovary along with the oocyte at the time of ovulation.[70,160] Importantly, factors within the matrix also control cumulus-cell functions.[161,162] Thus, each COC is a highly specialized microenvironment with inflammatory-like responses that control the formation and stabilization of the matrix.[1,7,163] Hence, during ovulation, the oocyte is the center of a pronounced inflammatory reaction and is essentially treated as a foreign body and kicked out of the nest (Figures 22.3 and 22.12).

The Expression and Functions of Cytokines

In cumulus cells, AREG induction of *Ptgs2* and the production of PGs represent key mediators of inflammation. AREG also leads to the induction of genes (*Alcam, Il6, Cd34, Cd52, Pdcd1*) that are associated with inflammation.[70] In addition to IL6, other cytokines (*Ccl2, Ccl4, Ccl5*) are expressed in cumulus cells, raising the possibility that cytokines and their receptors play distinct roles in the functions and fate of COCs prior to and after ovulation.[164] IL6 alone can stimulate COC expansion and induce genes required for this process by activating the MAPK3/1 pathway and JAK/STAT pathways.[165] IL6 also enhances embryo development.[165] However, *Il6*-null mice are fertile, indicating that other cytokines being released from COCs may act in a redundant manner during ovulation to facilitate COC expansion and expulsion as well as to recruit immune cells to the ruptured ovulation pore. *Cd52* is expressed in ovulating mouse and human COCs, but the functions remain to

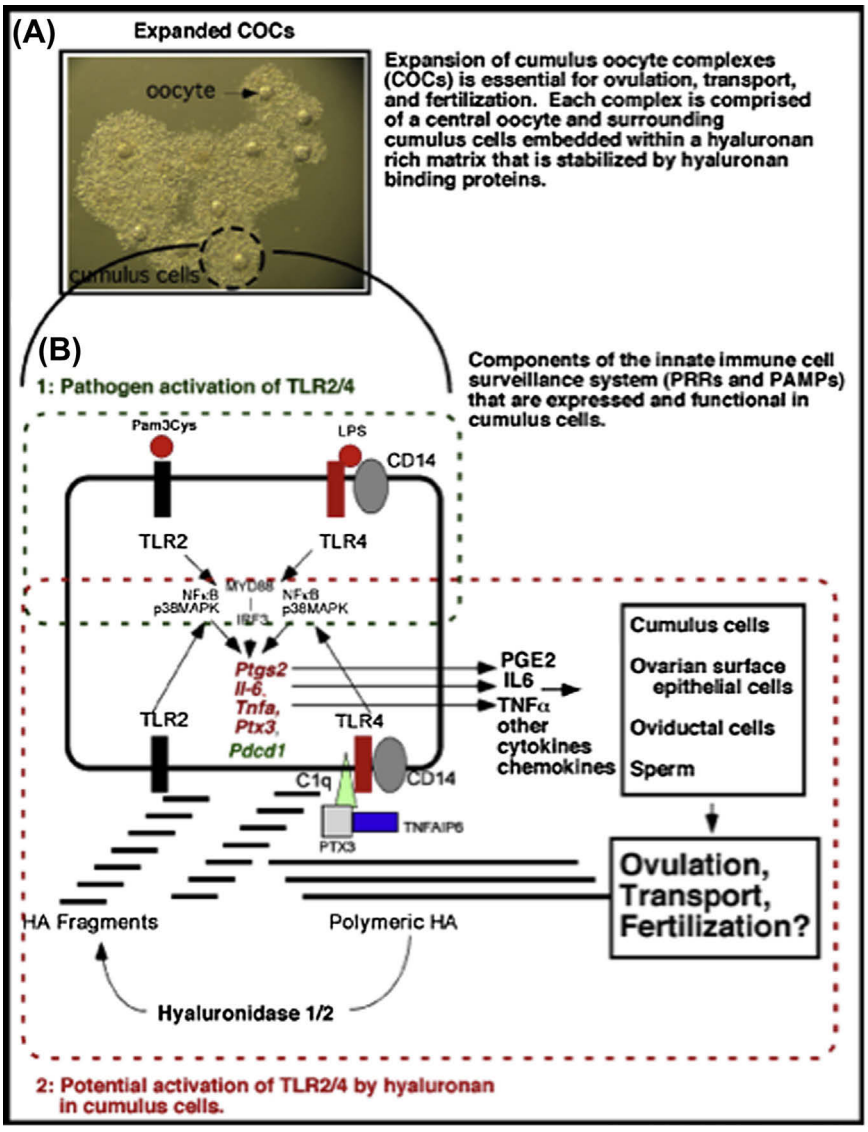

FIGURE 22.12 Schematic of TLR pathway activation and functions in cumulus cells during COC expansion, ovulation, transport and fertilization. This figure is reproduced in color in the color plate section. (A) In response to the ovulatory surge of LH, cumulus cell–oocyte complexes (COCs) undergo expansion. This process requires the synthesis of a hyaluronan (HA)-rich matrix and factors that bind HA to stabilize the matrix. This process is critical for ovulation. (B) Cumulus cells express members of the Toll-like receptor (TLR) superfamily and can respond to specific ligands (1: pathogen-derived or 2: matrix-derived), leading to the induction of inflammation- and innate immune-related genes. These include: *Ptgs2, Il6, Tnfaip6, Tnfa*, and *Pdcd1*. Prostaglandins (PGE2) synthesized by PTGS2, IL6, and TNFα, as well as other cytokines and chemokines, are released from cumulus cells and can impact the function not only of the cumulus cells but also oviductal cells during transport and sperm during fertilization. The degradation of polymeric HA by hyaluronidases is presumed to lead to the generation of HA fragments that activate TLR2 and TLR4. *Source: Ref.160.*

be determined.[166,167] *Pdcd1*-null mice are fertile (Liu and Richards, unpublished observations).[168] Targeted disruption of genes encoding other cytokines is needed to further define their roles in ovulation.

The Role of Immune-Related Factors

Components of the innate immune system are an evolutionarily conserved receptor recognition system that includes the pattern-recognition receptors (*Cq1a, Cd14, Trl4, Tlr2*). In immune cells these receptors are used to discriminate self from nonself and bind such factors as bacterial lipopolysaccharide, LPS/Pam3Cys.[169] These receptors are also expressed in nonimmune cells including cumulus cells.[70,134,170] In cumulus cells they are functional and bind LPS as well as fragments of hyaluronan[91,169] (Figure 22.11). Specifically, LPS itself induces marked induction of *Il6* and *Ptgs2* in cumulus cells. Furthermore, fragments of hyaluronan that are generated by hyaluronidase that is released from cumulus cells or sperm also bind to these receptors and increase *Il6* and *Ptgs2*.[91,164] Thus, cumulus cells have the potential to monitor their environment within the follicle and the oviduct.[160]

Once the COCs are in the oviduct, cytokines released from the cumulus cells may impact the function of oviductal cells. For example, COCs interact with the ciliated cells of the oviduct during transport and cluster in a region where the oviduct is "ballooned" and hence appears to be responding to the presence of the COCs. Although the extent to which factors from cumulus cells regulate these events is not entirely clear, transport and oviductal swelling are not observed in *Ptx3*-null mice in which the matrix disappears rapidly following ovulation.[88,119] The Toll-like receptors may also be involved in fertilization.[164] Specifically, IVF assays have shown that

sperm induce cumulus cells to release specific cytokines and chemokines. Certain chemokines then bind chemokine receptors on sperm and enhance fertilization. These events are dramatically reduced in the presence of TLR2- and TLR4-blocking antibodies.[164] Importantly, recent studies show that not only cytokines and chemokines but also antibacterial factors are released from the ovulated COCs and activate sperm,[171,172] providing evidence that the inflammatory and immune factors may participate in the fertilization process as well.

Recent studies have also proposed that there is a pituitary–ovary–spleen axis associated with ovulation that promotes the trafficking of immune cells to the ovulating follicle.[173] Because many cytokines and chemokines are made in response to the LH surge, they likely recruit immune cells that then further contribute to the inflammatory-like functions in the ovulatory follicle.

OFF-STAGE AND BEHIND THE SCENES: FOLLICLE ATRESIA AND GRANULOSA CELL APOPTOSIS

As mentioned in the introduction to this chapter, one of the most amazing aspects about ovarian follicular development in mammals is that less than 1% of the follicles present in the ovary at birth ovulate successfully. This means that 99% of all growing follicles are eliminated from the ovary by the process of atresia in which granulosa cells undergo apoptosis (programmed cell death). Thus, apoptosis profoundly regulates the number of follicles ovulating and the number of eggs that can be fertilized. That so many follicles undergo atresia underscores the critical importance of this process and apoptosis in controlling the growing follicle pool; hence the number of follicles capable of ovulating.[174]

Recent studies indicate that the forkhead boxO transcription factors FOXO1 and FOXO3 are key mediators of metabolism and tissue homeostasis in all vertebrates.[175,176] In the mouse and human ovary, *Foxo1* and *Foxo3* are expressed at high levels in granulosa cells and luteal cells, respectively[177,178]; appear to regulate granulosa cell metabolism, proliferation, and apoptosis[179–181]; and can functionally interact with steroid hormone receptors.[182] Conditional depletion of *Foxo1* and *Foxo3* in murine granulosa cells using *Amhr2-Cre* or *Cyp19-Cre* mice reveals that these two factors control critical genes and metabolic pathways in ovarian granulosa cells by interacting with the activin and BMP2 pathways.[183] Whereas activin and FOXO1 are expressed in granulosa cells of growing follicles, BMP2 and higher levels of FOXO1 are selectively expressed in granulosa cells of follicles undergoing atresia. By interacting selectively with the activin pathway, FOXO1/3 control genes involved in follicle growth. These include *Ctgf*, *Lox*, *Irs1*, *NrOb1*, and *Amh*. These interactions of activin and FOXO1/3 occur independently of FSH. In addition, activin enhances FSH induction of *Cyp19a1* and *Ccnd2* but impairs FSH-mediated induction of *Lhcgr*. By interacting with the BMP2 pathway, FOXO1/3 induce genes controlling responses to metabolic stress, granulosa cell apoptosis, and follicle death, including *Jnk3*, Bim(*Bcl2l11*), and caspase 3. Thus, it is proposed that a switch from growth to apoptosis in granulosa cells is mediated by FOXO1/3 swapping its interactions from activins to BMP2. What controls this switch remains to be determined but is obviously of utmost importance in the fate of growing follicles.

FOXO1/3 also regulate pituitary expression of *Fshb* by controlling a regulatory loop between the ovary and the pituitary.[183] In the *Foxo1/3*-mutant mice, serum levels of FSH and pituitary expression of the *Fshb* gene are severely suppressed even though serum levels and tissue expression of inhibin mRNAs remain within the normal range. Serum FSH and pituitary expression of *Fshb* can be restored in the mutant mice by removing the ovaries, indicating that the inhibitory factor is an ovarian-derived substance. This regulatory loop therefore also controls the growing follicle pool and ultimately the number that can ovulate.

FOXO1/3 are targets of the PTEN-PI3K-AKT pathway, and when phosphorylated by AKT are generally excluded from the nucleus and degraded. Targeted disruption of *Pten* in granulosa cells increases the number of ovulating follicles and the presence of corpora lutea,[184] perhaps related to decreased activity of FOXO1 but increased levels of FOXO3. Likewise, targeted disruption of another component of the PI3K pathway, tuberous sclerosis complex 1 (*Tsc1*), also leads to increased accumulation of corpora lutea.[185] Although the mechanisms are not known they may involve changes in the activity of mammalian target of rapamycin complex 1 (mTORC1), target of TSC1 and also possibly FOXO1/3.

TRANSLATIONAL CLINICAL CONSIDERATIONS

Many similar signaling cascades and molecular mechanisms control ovulation in mammals. Therefore, the transfer of information obtained from studies in mouse, pig, bovine, and primate models to clinical studies in women is relatively direct. However, understanding the genetic and molecular basis for infertility and anovulation in women is much more difficult to determine. Moreover, ovarian studies in women are particularly challenging because of the lack of available tissue for mechanistic and molecular analyses.

Incidence and Causes of Anovulatory Infertility

Infertility affects at least 10–15% of women in the United States during their reproductive years, and in many cases the underlying mechanisms of infertility remain poorly understood. Endometriosis is often associated with infertility. Although the underlying causes of ovarian dysfunction in this disease are not clearly defined, excess cytokines produced as a consequence of chronic inflammation that is characteristic of endometriosis may be contributing factors. Clearly, cytokines such as IL6 can impact granulosa cell functions, stimulate COC expansion, and modify oocyte quality.[165] Therefore, excess IL6 and other cytokines may interfere with the normal functions of the ovary.

PCOS at the Ovarian Level

PCOS is the most common endocrine defect and cause of *anovulatory infertility* in women in their reproductive years. PCOS afflicts more than 5–10% of women in the United States, costs more than $4 million per year to manage, and is becoming increasingly prevalent. A PubMed search of "ovulation" lists scores of papers that are predominantly related to current clinical studies describing ways to improve treatment of infertile women, especially those with anovulatory PCOS. The number of basic research papers on ovulation pales in comparison. Although some molecular aspects of theca cell androgen production have been determined in PCOS, our understanding of the molecular consequences of PCOS in granulosa cells and cumulus cells is less well defined.

Although elevated androgens (hyperandrogenemia) are one defining characteristic of PCOS, it is also frequently associated with metabolic defects related to insulin resistance and a pro-inflammatory state that may contribute to insulin resistance. Thus, understanding the consequences of endocrine, cytokine, and metabolic defects at *the ovarian level* are critical for improving ovulation, IVF procedures, and oocyte quality in PCOS patients.[38,39] PCOS is often, but not always, associated with obesity, suggesting that cytokines or other factors coming from adipose tissue likely impact the hypothalamic–pituitary–ovarian axis. Two major cytokines derived from adipose tissue are leptin and adiponectin. Whereas leptin regulates appetite, adiponectin has been shown to alter steroidogenesis, genes involved in ovulation, and those involved in apoptosis.[186–189] That adiponectin enhances oocyte and embryo development in mice indicates that this may be a "good" cytokine.[189] Furthermore, expression of adiponectin receptors is correlated positively with oocyte maturation in samples obtained from IVF patients.[189] That levels of adiponectin are reduced in PCOS patients may indicate that it plays some role in optimal ovulation and oocyte quality.[190] Other cytokines released from adipose tissue or immune cells include CRP and TNF alpha, which cause pro-inflammatory reactions in cells.

Ovaries in women with anovulatory PCOS contain numerous small antral follicles that are characterized by high levels of androgens. However, these follicles also produce estradiol. Successful ovulation can be achieved frequently in PCOS patients by decreasing estradiol or its actions and by judiciously increasing endogenous or exogenous FSH. These results indicate that anovulation is related not only to ovarian problems but also to hypothalamus–pituitary events. Ovarian hyperstimulation[191] syndrome (OHSS), in which the ovary produces excessive amounts of estradiol and progesterone and ovarian blood vessels become highly leaky, is frequently associated with hormonal stimulation of IVF patients and complicates IVF outcomes.[191] Therefore it is important to understand what factors contribute to PCOS and to OHSS, including what functions are altered in PCOS ovaries, including the ovarian vasculature[39,191] (see Chapter 29).

Restoring Fertility with IVM, IVF, and ICSI

IVF and intracytoplasmic sperm injection (ICSI) are the most frequent methods used for treating infertile couples. However, the effectiveness of IVF/ICSI procedures is compromised by the transfer of multiple embryos and multiple births. Now that we know many of the genes regulating COC expansion, these genes might be used as markers to identify healthy versus compromised oocytes during IVF.[192] In vitro maturation (IVM) of oocytes provides promise as an alternative to IVF, but oocyte quality remains an issue,[193–198] and better techniques need to be developed in the years ahead.

LH Receptor Mutants and Infertility

Although rare, women with LH receptor insufficiency/mutations exhibit impaired ovulation.[199,200] Based on current information, these defects might be overcome by treating these patients with FSH and EGF-like factors to bypass the need for LH receptor activation.

CONCLUSION

Ovulation is a complex process essential for the reproductive success of every species. Although we have learned a great deal about how LH initiates this process in mice and other mammals, there are still many blank spaces on the canvas and in the script. We know some of the transcription factors that are essential for ovulation, but the regulatory networks that they control remain incompletely defined.

World population continues to soar, and therefore the need to regulate population growth remains critical in many areas of the globe. Conversely, rescuing fertility has a major impact on allowing infertile couples to have the children they desire. Therefore, understanding what regulates ovulation and oocyte quality is of prime importance for the development of new contraceptive approaches as well as for designing improved procedures for IVF of an oocyte and IVM of follicles and oocytes. Although the transfer of some of our current knowledge to clinical issues is occurring, much still remains to be applied to IVF and especially IVM where conditions are less than optimal.

New Contraceptives?

Although the pharmaceutical industry has almost virtually closed the door on research related to reproductive hormones and ovarian function and contraceptive development, the wealth of new knowledge that is now available may one day provide alternative avenues for controlling (blocking or enhancing) ovulation, as well as for improving IVM of follicles and oocytes. Perhaps even microRNAs could be used effectively.

A Role for MicroRNAs?

MicroRNAs (miRNAs) have emerged as a powerful post-transcriptional gene regulatory mechanism for globally changing cell functions. Specifically, long primary microRNA transcripts are processed to mature miRNAs, ~22 nucleotides in length, by specific ribonuclease-splicing enzymes. Drosha along with its RNA binding cofactor (DGCR8) cleaves primary transcripts to precursor transcripts in the nucleus. Once in the cytoplasm, Dicer1 cleaves pre-miRNAs to mature miRNAs. The miRNAs then bind and act on specific sequences to regulate messenger RNA (mRNAs) cleavage and translational repression. Our understanding of which microRNAs control ovulation (or other ovarian functions) remains in its infancy.[201–203] However, mice in which *Dicer1* has been conditionally disrupted in granulosa cells using *Amhr2-Cre* are infertile.[204] The mice exhibit reduced ovulation rates and impaired oocyte and embryo development[204] associated with altered expression of specific genes and miRNA-503.[205] Based on the prediction that Dicer1 regulates the formation of all mature miRNAs in a cell, it is remarkable that the effect of disrupting *Dicer1* is not more severe. This may indicate that miRNAs do not globally affect the granulosa cell mRNA landscape at all stages of follicle development or other ribonucleases that are critical and serve as alternative miRNA regulators. Perhaps when the mRNAs and genes that are altered in the *Dicer1*-mutant granulosa cells are identified, the roles of Dicer1 will be more completely understood in this context. Even though miRNAs that are induced by the LH surge (miR-21, -132, and -212) have been identified, their specific functions and the genes they control during ovulation remain to be clearly defined.[202] Therefore, more studies are needed to determine the roles of miRNAs in ovulation and their possible use as contraceptives.

Identifying Gene Markers of Healthy Oocytes

Many genes that are critical for the function of COCs and oocyte maturation are now known. Some of these may be useful for improving IVM of oocytes, a procedure that currently remains suboptimal[193–206] and for determining the identity of "good" versus "not so good" oocytes used for IVF and intra-cytoplasmic sperm injection (ICSI) procedures.[74,141,206,207] For example, the key roles played by the EGF-like factors in ovulation, as demonstrated in mutant mouse models, is supported by the increased levels of AREG and EREG in follicular fluid of human, porcine, bovine, and primate (Rhesus macaque) ovulatory follicles. Furthermore, when small follicles of the macaque are cultured with gonadotropins to stimulate in vitro follicle and oocyte maturation, the addition of AREG at low levels enhances oocyte maturation and embryo development.[208] Although the effectiveness of AREG in the maturation of human oocytes for IVF/ICSI procedures has not yet been thoroughly analyzed, it would likely enhance human oocyte maturation as well.[209] One of the major obstacles is optimizing the culture conditions that foster oocyte quality, including metabolic factors such as pyruvate and glutamine (not present in some studies)[209] as well as cytokines. For example, secreted factors, including IL6, might also eventually serve to improve IVF/ICSI procedures, if given at the right time and dose.

Small, immature ovarian follicles can now be grown in culture to the preovulatory stage; oocytes from these follicles can be retrieved and fertilized; and the embryos can develop into normal offspring.[210,211] These major advances provide another system in which to analyze the mechanisms of ovulation strictly associated with the follicle in a defined culture system that is devoid of surrounding stromal tissue and the OSE. This approach is being developed to provide a way to restore fertility in women who are infertile due to cytotoxic drugs used for cancer therapies. Implants of ovarian sections have also been effective in restoring fertility in women. In light of these developments, the concept of "oncofertility" has been coined and is being avidly pursued.[212]

CHAPTER

23

Structure, Function, and Regulation of the Corpus Luteum

Richard L. Stouffer, Jon D. Hennebold

Division of Reproductive and Developmental Sciences, Oregon National Primate Research Center, Oregon Health and Science University, Beaverton, OR, USA

INTRODUCTION

"Although much is known, much still remains to be discovered, and much of what has been discovered needs to be uncovered." R.V. Short[1]

The corpus luteum is an endocrine gland within the adult ovary that forms from the follicle wall after ovulation.[2,3] It is associated with four unique features. The first is its ephemeral nature, as the corpus luteum exists for a limited lifespan, which in many species depends upon the fate of the oocyte released by the antecedent ovulatory follicle. Second, its primary, if not sole essential, function is to synthesize and secrete the steroid hormone, progesterone. Progesterone has numerous biological effects on target tissues,[3] but particularly acts in the reproductive tract to permit implantation of the early embryo in the uterine endometrium and to support a maternal environment that sustains intrauterine pregnancy. Thus, the third feature of the corpus luteum is its physiologic connection to viviparity.[2] All mammals, many reptiles, and a few fishes that produce live young exhibit corpora lutea, although the essential connection between the corpus luteum and viviparity is less obvious in nonmammalian species. In some of these species, luteal function may be related to final oocyte maturation, egg movement in the oviduct, or oviposition, since the corpus luteum exists in some oviparous reptiles, amphibians, and birds as well.[4] The latter serves as a preface to the fourth key feature of the corpus luteum, i.e., the tremendous species diversity in the mechanisms that evolved to control the structure and function of the corpus luteum. Although the mammalian corpus luteum seems similar to the steroidogenic adrenal cortex[2] and develops from the steroidogenic ovarian follicle, the latter endocrine tissues display relatively minor differences in regulation of development and function across mammalian species. In contrast, the differences in endocrine and local control of the development, function, and lifespan of the corpus luteum are remarkable. Limitations prevent addressing many individual species in this chapter, but the reader is encouraged to peruse other comparative reviews to marvel at the challenges facing ovarian biologists and their attempts to promote or control fertility in domestic and wild animals, endangered species, and human beings. This review will focus on selected species of traditional laboratory (rodents and rabbits) and domesticated (sheep, cow, and horse) animals, plus primates (Old World macaques and humans), where the majority of research activity occurred over two decades since the publication of the chapter on the corpus luteum by Niswender and Nett[3] in the second edition of *The Physiology of Reproduction*.

Historical Perspective

An interesting reference on the discovery and study of the corpus luteum was provided by R.V. Short in 1977.[1] Existence of the corpus luteum as a structure within the ovary was noted by several renowned anatomists in the sixteenth and seventeenth centuries, such as Fabricius,[5] who provided the first illustrated accounts of the comparative anatomy of the female reproductive tract, including ovaries in the pregnant pig containing "numerous little glands". Although Regnier de Graaf is chiefly remembered for his description of the antral Graafian follicle, he provided the first detailed descriptions of the "globular bodies" (corpora lutea; Figure 23.1) that formed in

place of the "ova" (follicles), which gave an indication of the number of fetuses present[6] (as translated by Jocelyn and Setchell). His appreciation of the diversity of colors (pink, red, purple, and yellow) associated with the gland in various species did not lead him to name the structure the "corpus luteum" (yellow body), which is attributed to Malpighi's observations of cow ovaries. Nevertheless, Malpighi speculated correctly on the corpus luteum's "glandular nature" and stated that its structure closely resembled the suprarenal (adrenal) gland.[7] During this era, the ovaries and their structures were described, but their functions and regulation were not appreciated.

Although de Graaf and the Scottish anatomists William and John Hunter[8] recognized the positive correlation between the number of corpora lutea and the number of offspring arising from pregnancy, and clinicians such as Pott[9] recognized that ovariectomy resulted in cessation of menstruation in women, the importance of these relationships remained unclear.[10] Many scientists remained thoroughly indoctrinated in the prevailing views of Aristotle's "seed and soil" concept that the male provided the "seed" and the female played a passive role by providing the "soil" in which the seed could grow (as recounted by Thompson).[11] The soil was the uterine fluids, and women menstruated because their nature resulted in periodic repletion with excess blood that was removed by menstruation. There was some belief that the ovarian follicle was the egg, but it was not until the 1800s that the egg was first described within the mammalian follicle[12] and that the processes of ovulation and formation of the corpus luteum from the follicle wall were identified.[13] Nevertheless, the general opinion was that corpora lutea were just scar tissues formed after ovulation. Only after Knauer[14] definitively proved that the ovary was a gland of "internal secretion", through classic ablation replacement studies in various mammals, did investigators such as Beard[15] and Prenant[16] hypothesize that the corpus luteum had specific functions in uterine development and gestation due to its secretion of one or more products into the bloodstream. Studies by Fraenkel[17] and Magnus[18] confirmed the endocrine actions of the corpus luteum, but the search to isolate the luteal hormones only began in earnest after suitable bioassays, such as the maternal deciduoma response,[19] were devised. In 1929, Corner and Allen[20] prepared an alcoholic extract from pig corpora lutea that mimicked luteal actions in the uterus and maintained pregnancy in ovariectomized animals. Hisaw[21] also established that similar luteal extracts produced the full secretory-phase development of uterine endometrium in a primate, the rhesus monkey. By then, it was recognized that menstruation in primates did not correspond to the period of "sexual excitement" or estrus in other species (i.e., it was not the time of ovulation and optimal fertility).[22] Rather, it marked the end of the cycle and the absence of ovulation—a wiser basis for the "rhythm method" of contraception.

The modern era of research began in 1934 with the isolation and characterization of the steroid progesterone from luteal extracts by four independent groups.[23–26] Investigators quickly established that this progestin (see Parkes, Ref. 27, for an explanation of how the name was agreed upon) mimicked many of the roles of the corpus luteum. With the development of reliable radioimmunoassays[28] to replace bioassays, attention turned to understanding the processes controlling the functional lifespan of the corpus luteum in various species. After the discovery that hypophysectomy eliminated cyclic ovarian function in adult mammals, particular attention focused on identifying the pituitary gonadotropins[29] and established the vital roles of luteinizing hormone (LH) and prolactin (PRL) as "luteotropic hormones" in the development and steroidogenic function of the corpus luteum in various species.[30] Also, the report that hysterectomy prolonged

the lifespan of the corpus luteum led to investigations into the role of the uterus,[31] and the subsequent discovery that the arachidonate metabolite prostaglandin (PG)-$F_{2\alpha}$ is the uterine "luteolytic hormone" terminating the lifespan of the corpus luteum in nonfecund ovarian cycles of various species.[32]

The discovery of the luteal hormone, progesterone, also had pronounced effects on clinical approaches to assure sufficient luteal support during pregnancy, to control fertility, and to prevent undesirable effects of menopause in women. Although major ovarian pathologies (e.g., ovarian cancers and polycystic ovarian diseases) do not emanate from the corpus luteum, there are situations of deficient luteal function in natural ovarian cycles (short or insufficient luteal phases) or controlled ovarian stimulation cycles (short luteal phases) that may be associated with subfertility.[33] Therefore, a synthetic progestin or, more recently, progesterone supplements can be administered to replace or assist in luteal functions during the menstrual cycle.[34] Also, after the discovery that exogenous progesterone could inhibit ovulation in mammals,[35] researchers formulated the idea that administration of a combination of estrogen and progestational agents would block ovulation and thus prevent conception in women while preserving the semblance of normal menstrual cycles in women. This work was facilitated by the success of chemists (e.g., R. Marker, see Ref. 36) in generating inexpensive, abundant supplies of steroid analogs from plant sapogenins, which are steroids that structurally resemble cholesterol. The basic[37] and clinical testing by G. Pincus, M-C. Chang, J. Rock, and E. Rice-Way proved that the combinational steroid "pill" provided virtually complete protection from pregnancy. The oral contraceptive pill introduced in 1960 had a profound impact on every aspect of society, and it gave women for the first time the opportunity to control their reproductive status. Likewise, the discovery of molecules with antiprogestin activity (e.g., RU486 at Rossel Uclaf) demonstrated the molecular basis of luteal ablation on uterine function and pregnancy, resulting in the availability of a nonsurgical protocol for pregnancy termination or contragestation.[38] The use of progestins, antiprogestins, and, more recently, selective progestin receptor modulators (which may have agonist or antagonist actions at specific target tissues[39]) continues to be of great interest for such purposes as birth control, treatment of disorders of the reproductive tract (e.g., persistent or irregular menstruation), and cancer therapy.

As discussed in this chapter, recent advances in cell and molecular biology are contributing greatly to our understanding of the mechanisms of action of luteotropic and luteolytic factors, the intracellular pathways controlling steroidogenesis, and the cell-to-cell interactions that are critical for the development, function, and normal lifespan of the corpus luteum. Unlike in earlier eras, investigators of the corpus luteum are faced with a tremendous increase in scientific information on a daily basis. In this century of information overload and short information "sound bites" or "abstracts", the scholar is urged to rediscover the major breakthroughs, prevailing controversies, and dogmas of eras that provided the groundwork of current concepts that have yet to stand the test of time. This review attempts to build on prior chapters[3,40] and coalesce ideas from recent reviews of leaders in this field, as referenced in the following sections and cited in the Acknowledgments section.

CLASSIFICATION OF TYPES OF CORPORA LUTEA

Due to its transient nature, one can typically discern a developing phase, a functional phase, and a regressing phase in the lifespan of the corpus luteum. These phases are usually associated with increasing levels, elevated levels, and then declining levels of progesterone in the circulating blood.[2] As adapted from Rothchild and others,[2,41] mammals can be divided into three major categories (Figure 23.2) based on how long the corpus luteum functions after ovulation in the nonfecund ovarian cycle and how the luteal lifespan is affected by pregnancy onset and gestation.

Long-Lived Corpora Lutea

There are some monestrous species (i.e., animals with estrous cycles that occur only at long intervals, such as every 6–12 months) in which a fully functional corpus luteum develops after ovulation and its functional lifespan does not differ remarkably regardless of whether the corpus luteum originates during a fertile or nonfertile cycle.[2] This category, which includes mammalian carnivores (e.g., dogs, wolves, foxes, cats, ferrets, and skunks[42,43]) and other animals such as the roe deer, armadillo, and marsupials,[44–46] contains corpora lutea that last from less than 2 weeks to as long as 6 months. In the domesticated dog,[47,48] for example, the length of the luteal phase in pregnant and nonpregnant animals is ~65 days. At the end of pregnancy, which typically occurs in each cycle of monestrous animals, there is rapid luteolysis. However, if pregnancy does not occur, the loss of luteal structure and function is very protracted; the mechanisms of this are unclear. Many marsupials can be included in this category because, even though the luteal lifespan may last only about 14 days, it is not altered by the occurrence or lack of pregnancy. This category of corpora lutea also illustrates the evolution of mechanisms whereby the corpus luteum's lifespan can be modified by the addition of a *quiescent* interval after ovulation

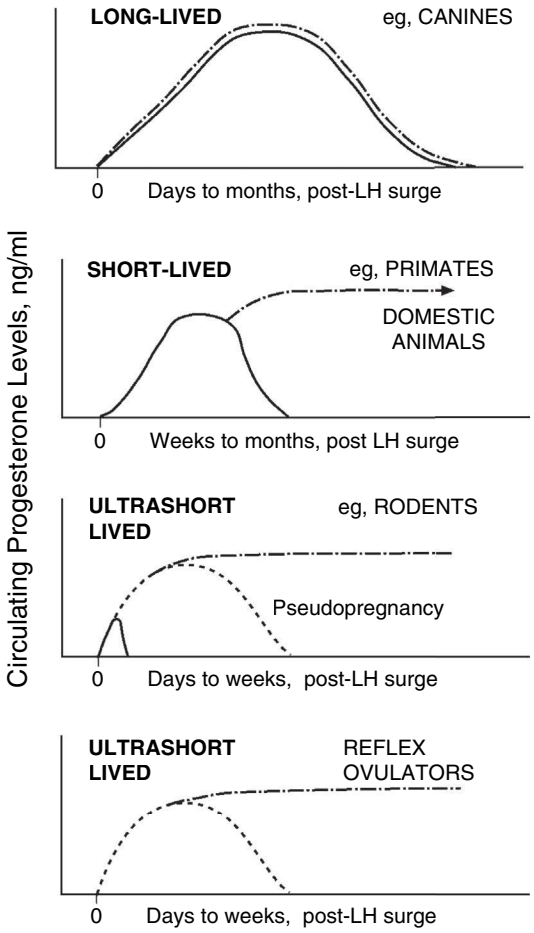

FIGURE 23.2 Types of mammalian corpora lutea based on their functional lifespan (long, short, or ultrashort) during the nonfecund ovarian cycle (solid lines). The effects of nonfertile mating on ultrashort-lived corpora lutea (pseudopregnancy; dotted line) and of pregnancy in all three categories (dashed lines) are demonstrated. Reflex ovulators, such as rabbits and ferrets, can also be categorized as having ultrashort-lived corpora lutea since they have no luteal phase due to the absence of an LH surge unless mating occurs.

before luteal function begins. This can be related to seasonal cues (e.g., in the skunk and badger[49]) or both lactation and season (e.g., in the wallaby[50]).

Short-Lived Corpora Lutea

In many polyestrous species (i.e., animals with frequent ovarian cycles), the corpus luteum develops and functions for a finite interval during the ovarian cycle, but the luteal lifespan is markedly increased if pregnancy ensues. This category includes the primate species of monkeys, great apes, and humans,[51–53] wherein a functional corpus luteum forms rapidly after ovulation and functions for a sufficient interval (~2 weeks) to permit timely movement of the early embryo through the oviduct and to prepare the uterus for implantation. If pregnancy does not occur, the corpus luteum regresses after 2 weeks. However, if pregnancy occurs, the functional lifespan of the corpus luteum is extended for a finite interval[54] until its critical activities (i.e., progesterone production) are assumed by the developing placenta. The time of the luteal–placental shift, after which the corpus luteum is no longer essential for pregnancy, varies between primates (3 and 7 weeks of gestation in rhesus macaques and women, respectively). It is not clear if the processes of luteal regression around the luteal–placental shift are comparable to those during luteolysis in the nonfecund cycle. However, there is intriguing evidence that after a quiescent interval at midgestation, the corpus luteum in primates rejuvenates by term pregnancy and is again a progesterone-secreting gland,[55] but its importance as an endocrine gland is unclear considering the massive steroidogenic activity of the term placenta.

Many of the ungulates, such as the domesticated farm animals, also display short-lived corpora lutea. For example, in sheep and cattle, the corpus luteum forms rapidly after ovulation and functions until day 17 and 21 post estrus, respectively.[56,57] Again, if pregnancy does not occur, the corpus luteum undergoes rapid luteolysis; however, if intrauterine gestation begins, the functional corpus luteum is sustained for several months until the luteal–placental shift or even until the end of pregnancy (e.g., in the pig[58]). However, there are important differences between primates and ungulates with short-lived corpora lutea in the activities and processes controlling the length of the ovarian cycle and the luteal phase, plus maternal–ovarian recognition of pregnancy. First, the ungulate corpus luteum permits waves of antral follicle growth during the luteal phase,[59] and hence the interval of the follicular phase after luteolysis to development of the next ovulatory follicle is very short (2–3 days). In contrast, in many primates, the ensuing follicular phase is relative long (~2 weeks) due to the "dominance" of the corpus luteum, which prevents further development of small antral follicles until after luteolysis.[60,61] Second, luteolysis in ungulates requires the presence of a nonfecund uterus, leading to the concept that in the absence of implantation, a uterine luteolytic signal promotes the regression of the corpus luteum of the cycle.[62] In contrast, hysterectomy does not alter the functional lifespan of the corpus luteum in primates exhibiting menstrual cycles (e.g., macaques and women[63,64]), indicating the absence of a uterine luteolytic signal. Third, whereas ungulates evolved a mechanism that apparently blocks the synthesis and/or secretion of the uterine luteolytic signal in early pregnancy, higher primates utilize an embryonic hormone that acts directly on the corpus luteum to rescue it from impending regression and promote luteal structure and function in early pregnancy.[65] Again, there are exceptions or additions to these concepts. For example, some primates (e.g., New World monkeys and Prosimians[66]) do not menstruate and may produce a uterine luteolytic signal.[67] The horse also produces a

fetal hormone after the first month of gestation that may stimulate the function of existing corpora lutea, but also induces ovulation of large antral follicles and the formation of "secondary" corpora lutea that assist in progesterone secretion for 5 months until the luteal–placental shift.[3]

Ultrashort-Lived Corpora Lutea

Species with this feature[2] do not form a functional corpus luteum (e.g., polyestrus rodents and perhaps some insectivores) or indeed any corpus luteum during the ovarian cycle unless mating results in ovulation (reflex ovulators, e.g., rabbit[68]) and/or pseudopregnancy or pregnancy (e.g., rat and mouse). In rodents such as the laboratory rat or mouse,[69,70] the estrous cycle lasts 4–5 days and lacks a true luteal phase. After ovulation, the ruptured follicle takes on some of the characteristics of a corpus luteum, but the luteal gland is not well developed and is considered nonfunctional since it does not secrete sufficient progesterone to stimulate a uterine response (i.e., decidualization) to implantation cues. Progesterone produced within the corpus luteum is rapidly metabolized to 20α-hydroxyprogesterone, an inactive progestin that will not support pregnancy. Mating or a facsimile (cervical stimulation) during estrus that does not result in pregnancy results in development of functional corpora lutea that secrete progesterone for 12–14 days. This interval of luteal function, known as pseudopregnancy, is an unusual artifact since mating in the natural environment typically results in pregnancy. However, pseudopregnancy is a valuable means of distinguishing mechanisms initiated by the neuroendocrine reflex arc in response to cervical stimulation that promote luteal development in animals with ultrashort-lived corpora lutea. If mating initiates pregnancy, continued progesterone secretion by the corpus luteum is required throughout gestation. Continued luteal structure and function are achieved by a combination of maternal (uterine decidual) and fetal (trophoblast) hormones or hormonal precursors that act on or are converted to essential factors by the rodent corpus luteum of pregnancy.[71] Regression of the corpus luteum at the end of gestation, and perhaps at the end of pseudopregnancy, is controlled by a uterine luteolytic factor.[69]

Thus, mammalian species have developed diverse means (Figure 23.2) to ensure that ovarian cyclicity returns in the event of a nonfecund cycle (to restore fertility potential), yet provide adequate progesterone support if pregnancy ensues (to support intrauterine gestation until delivery of offspring). The simplest case is in animals with a "long-lived" corpus luteum, where gestation lasts no longer than the normal lifespan of the corpus luteum in the ovarian cycle. However, many animals have evolved means for keeping the functional lifespan of the corpus luteum "short" (i.e., less than necessary for successful pregnancy) in the ovarian cycle to increase reproductive efficiency. Therefore, processes evolved for preventing the development of a functional corpus luteum (an "ultrashort" lifespan), for uterine control of luteolysis in the nonfecund cycle (a "short" lifespan), and for uterine–placental extension of luteal function in the event of pregnancy initiation. Detailed discussion of these processes and the factors that control luteal structure and function are included in the following sections.

LUTEINIZATION

The corpus luteum forms from the cells comprising the wall of the ovulatory follicle. Luteal formation (i.e., luteinization) begins prior to ovulation but proceeds in earnest after follicle rupture and continues for a species-specific number of days until the fully formed corpus luteum is present. As reviewed by Murphy,[72] luteinization is a remarkable event involving cell proliferation, cell differentiation, and tissue remodeling that is unparalleled in the adult mammal. It is composed of two major processes: (A) eventual cessation of proliferation plus rapid hypertrophy and differentiation of the steroidogenic cells of the follicle into the luteal cells of the corpus luteum; and (B) the rapid growth of blood vessels (i.e., angiogenesis) and, in some species, the lymphatics (i.e., lymphangiogenesis)[73] into the previously avascular granulosa layer of the follicle to form the extensive microvascular bed of the corpus luteum (Figure 23.3). Although luteinization is often referred to as "terminal differentiation" of the follicle, it should be recognized that in many species, from rodents to primates, further differentiation may occur in luteal tissue in response to pregnancy. The angiogenic process in the corpus luteum is remarkable, even in comparison to the rapid vascular development in tumors or the placenta, and offers a unique model for studying microvessel development, maintenance, and regression in normal adult tissue. As adapted from Murphy[72] and others,[3,74,75] this section will discuss the processes and regulation of luteinization resulting in a fully developed, progesterone-secreting corpus luteum.

Morphologic Events

A common event during collapse of the follicle antrum at ovulation is the infolding of the follicle wall, with breakdown of the basement membrane separating the granulosa and theca layers of the follicle. This is followed by invasion of microvascular cells into the avascular granulosa layer, as well as other cells associated with the vasculature (e.g., perivasculature support cells, or pericytes,[77] and migrating cells of the immune system). In a few species, such as the dog,[78] this process starts

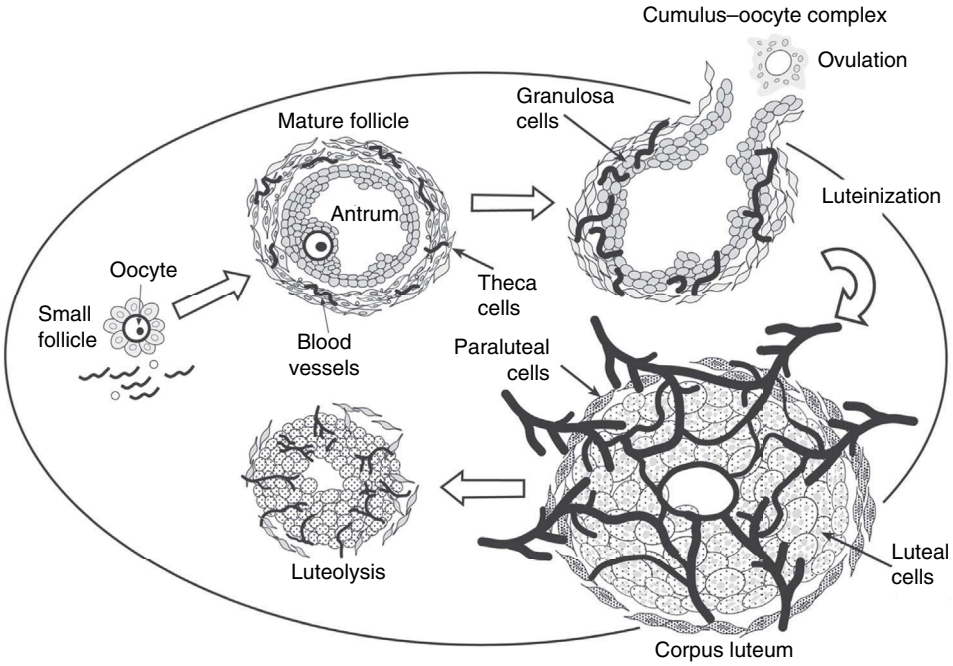

FIGURE 23.3 Development of the corpus luteum from the mature (Graafian) follicle. Folliculogenesis results in a large antral follicle in which vascularization (black blood vessels) is limited to the outer somatic (theca) cell layers. A basement membrane separates the theca from the avascular somatic (granulosa) cell layer, which encloses the gametogenic (oocyte) cell and a fluid-filled antrum. Near the time of ovulation, the basement membrane breaks down and angiogenesis occurs in the granulosa layer. Granulosa cells hypertrophy, and in many species luteinized granulosa and theca cells intermingle within the luteal tissue. In other species (e.g., primates), some compartmentalization remains as theca-derived paraluteal cells are found around the periphery and along infoldings in the corpus luteum. At luteolysis (see the Section Luteolysis), both the luteal cells and microvasculature degenerate. *Source: From Ref. 76, with permission.*

well before ovulation. But in most mammals, it follows rupture of the follicle. The follicular infolding and vascular invasion also transport theca cells toward the center of the follicle cavity. In many species, including rodents and various domestic animals, theca-derived luteal cells appear to disperse throughout the parenchyma of the corpus luteum.[75] Thus, unlike in the antecedent follicle, there is no apparent compartmentalization of theca- and granulosa-derived cells in the corpus luteum of these species. However, in some primate species, such as Old World macaques and humans, areas of the theca-derived compartment remain discrete from the remainder (including granulosa-derived) of the luteal tissue throughout its lifespan, even into pregnancy.[79] The fate of the theca interna versus theca externa is controversial; they may degenerate or be absorbed into the surrounding stroma, become incorporated into the luteal parenchyma as thecal–luteal cells, and/or remain as paraluteal cells clustered along the periphery or along infoldings of the luteal gland. The fate of thecal cells may depend upon their differentiated state or proximity to luteinizing granulosa cells at ovulation. Certainly, their destruction is documented in some species, such as the horse,[80] and there is speculation that they degenerate and are absent from the corpus luteum of a New World monkey, the marmoset.[81]

In addition to the dramatic increase in vascularity, the large increase in mass of the corpus luteum is due to hypertrophy of the luteinizing granulosa cells.[82] The granulosa cell with a high nuclear–cytoplasmic ratio is converted into a luteal cell with a low nuclear–cytoplasmic ratio, at a volume increase of up to 10-fold.[83] Even before ovulation, there are significant cellular changes as the nuclear chromatin disperses and the nucleolus forms concomitant with the increase in number of polyribosomes.[82,84] Intracellular connections (e.g., gap junctions) between granulosa cells (as well as theca cells) disappear, presumably as a prelude to tissue remodeling.[85] The amount of smooth endoplasmic reticulum increases and the characteristics of the mitochondria change, as they become rounded and their cristae convert from lamellar to primarily tubular form. The luteal cells may also contain well-developed Golgi complexes, as well as lipid droplets and protein-secretory granules. These changes are consistent with a cell that is very active in steroidogenesis, as well as peptide–protein secretion. However, again the characteristics (e.g., lipid droplets and protein-secretory granules) and the stage at which they develop (e.g., early after ovulation in domestic animals or primates versus midpregnancy in rodents[82]) vary between species.

It appears that marked changes in the cytoskeleton play an important role in optimizing cell size as well as

steroidogenic function.[75] Limited research to date suggests that luteinizing granulosa cells transiently alter their expression of microtubule components (e.g., tubulin) around ovulation, as well as acquire the ability to express smooth muscle actin, cytokeratin, vimentin, and desmin.[86,87] Again, there are likely differences between granulosa- and theca-derived luteal cells, as theca-derived cells only express large amounts of vimentin, at least in some species.[86]

Also, it is likely that changes in the extracellular matrix (ECM) and cell–ECM interactions are critical in the tissue remodeling and function within the developing corpus luteum. Prior to ovulation, theca cells are separated from the granulosa cells via a basal lamina composed of collagen type IV; laminin α, β, and γ chains; nidogens; and the proteoglycan perlecan.[88,89] Aggregates of a novel basal lamina–like matrix, named "focimatrix" for focal intraepithelial matrix,[90] are scattered in between granulosa cells. After ovulation, focimatrix and the follicular basal lamina undergo degradation.[91] In the nascent corpora lutea, a basal lamina of similar composition restricted to capillary or subendothelial basal laminas appears as new blood vessels develop. In the bovine corpus luteum, the type IV collagen in the basement membrane of the follicle is replaced by the fibrillar (type I) collagen, which remarkably comprises one-sixth of the mass of luteal tissue.[92] Not only are there qualitative and quantitative changes in the ECM during luteal development, but also cell surface–associated glycoproteins, such as the integrins, expressed on resident luteal cells appear to be critical in the developing corpus luteum. For example, there is speculation that removal of alpha 6, beta 1 integrin-mediated ECM binding following ovulation permits functional luteinization.[93] Restoration or expansion of other cell–ECM interactions may be critical as well (e.g., integrin beta 3 expression is upregulated in the mouse corpus luteum).[94] In human luteinized granulosa cells, alpha 5, beta 1 and alpha 5, beta 3 integrin expression facilitated cell adhesion to fibronectin as well as cellular migration, and prevented apoptosis, which in turn may promote the motility and survival of granulosa cells during luteal development.[95] Fibronectin also induces the expression of secreted protein, acidic, cysteine-rich (SPARC) in bovine luteal cells, a proteolytic fragment of which promotes endothelial network organization and progesterone synthesis.[96] Creative approaches using in vivo and in vitro models remain essential for dissecting the roles and interactions between cell populations and the ECM during the lifespan of the corpus luteum.

A number of proteases are implicated in luteal remodeling in various species,[97] including serine proteases (e.g., the plasminogen–plasmin system[98]), the matrix metalloproteinases (MMPs) and their endogenous tissue inhibitors (TIMPs) (for a review, see Ref. 99), as well as those proteases belonging to the **a** **d**isintegrin **a**nd **m**etalloproteinase with **t**hrombo**s**pondin-type repeats family (ADAMTS).[100] The roles of the plasminogen (PLG)–plasmin system and metalloproteinases in luteal development are uncertain, however, plasminogen null-mutant mice ($Plg^{tm1Dco}/Plg^{tm1Dco}$) treated with the broad-spectrum metalloproteinase inhibitor Galardin formed functional corpora lutea following the establishment of pseudopregnancy.[101] While the corpus luteum appeared normal morphologically, plasminogen deficiency was associated with a 50% reduction in the level of circulating progesterone. Injection of Galardin into the macaque follicle at the time that animals received an ovulatory stimulus (e.g., human chorionic gonadotropin (hCG)) prevented ovulation but did not affect subsequent levels of circulating progesterone or luteal lifespan.[102] Such findings indicate that protease activity after an ovulatory stimulus, while necessary for follicle rupture, is not required for luteinization and luteal development in primates. Moreover, additional complexity is evident from rodent studies demonstrating that TIMPs, endogenous MMP inhibitors, may serve to regulate luteal development and function through both MMP-dependent and independent mechanisms.[103] Thus, although there are reports of marked differences in protease expression between cell types comprising the corpus luteum and between species,[104–106] the exact roles that ECM remodeling and proteolytic activity play in luteal development remain uncertain and warrant further study. Recent genomic studies determined that the mouse and human genomes contain 628 and 553 protease-encoding genes, respectively.[107] Although limited information exists with regard to their biochemical and cellular activities, additional studies are needed to characterize the repertoire of ECM and ECM-remodeling proteases and their potential functional activity in the developing corpus luteum.

Regulation and Role of Luteal Neovascularization

The changes in vascularity associated with the development of a functional corpus luteum are remarkable (for a review, see Ref. 108). Prior to ovulation, the primary follicular layer destined to form the corpus luteum (i.e., the granulosum) is avascular, whereas after luteal development each steroidogenic cell is adjacent to a microvascular element[109] and cells associated with the microvasculature comprise about 50% of the total cell population.[110] However, the precise mechanisms whereby angiogenesis[111] and possibly vasculogenesis (from local[112] or circulating[113] vascular progenitor cells) form the dense network of capillaries in the developing corpus luteum are not well defined. There is evidence of early migration of microvascular cells into the luteinizing granulosa cell layer,[79] but much of the capillary

expansion appears caused by endothelial cell proliferation. Cell proliferation is greatest in the corpus luteum during early development, and evidence suggests that the vast majority (up to 95%) of the dividing cells are vascular endothelial cells.[109] The interval of angiogenesis varies between species, but in primates the capillaries reach the central cavity by day 4 and venules appear along the cavity border that lead back through the luteal tissue to large veins outside the corpus luteum by day 6 of the luteal phase.[79] Nevertheless, there is evidence for some continued microvascular cell proliferation after luteal development. For example, the vascular space with the corpus luteum of domestic animals and primates increases from the early to midluteal phase, and the number of nonsteroidogenic cells (i.e., primarily associated with the microvasculature) increases to the late luteal phase.[110] This may be associated with further maturation of the microvessels (as they acquire endothelial support cells, or pericytes[77,114]), but this important feature has received limited attention to date.[108]

Since the discovery that follicular fluid and ovarian extracts contained "angiogenic activity",[115] investigators have strived to identify the factors that control vascular events (e.g., endothelial cell proliferation) in the developing corpus luteum. Many of the earlier candidates (e.g., fibroblast growth factor 2 (FGF2), also referred to as basic FGF) were pleiotrophic factors that stimulated proliferation or migration of various cell types. Although some of these factors, including FGF2, may[108] or may not[75] have a role in luteal angiogenesis, major progress occurred when researchers determined that newly discovered endothelial-specific growth factors[116] associated with vasculogenesis in the developing embryo and angiogenesis in pathologic conditions (e.g., tumor growth) were also present in the ovary. Ongoing studies support the hypotheses that such factors play key roles in physiologic angiogenesis in the corpus luteum, that their regulation may be different from that observed in other tissues, and that cell–cell interactions via these factors are critical for the normal development, function, and perhaps lifespan of the corpus luteum.

Vascular Endothelial Growth Factor (VEGF)

VEGF,[116] also discovered as a vascular permeability factor (VPF), specifically acts on vascular endothelial cells to promote proliferation, migration, tube formation, and vessel permeability. Five molecular forms of VEGF (with 121, 145, 165, 189, and 205 amino acids) can be produced by alternative splicing, and differ in solubility and heparin-binding ability.[116] Recent evidence from other tissues indicates that the isoforms may have different physiologic functions. Also, the VEGF family continues to expand to include newly discovered, structurally related proteins that share homology with VEGF (now called VEGFA), including VEGFB, VEGFC, and c-fos-induced growth factor (FIGF, previously known as VEGFD)[116] that may well be expressed in the ovary.[117] In addition, researchers have identified high-affinity receptors that include kinase insert domain receptor (KDR, also known as VEGFR), fms-related tyrosine kinase 1 (FLT1, also known as VEGFR2), and fms-related tyrosine kinase 4 (FLT4, also known as VEGFR3), as well as proposed co-receptors (neuropilin 1 and 2) on endothelial cells that mediate or facilitate VEGF action.[118,119]

Collective evidence suggests that all the necessary components of the VEGFR system are present and dynamically expressed in the corpus luteum of several species (for reviews, see Refs 120,121). Although primarily based on mRNA data, luteinizing granulosa cells appear to express high levels of *VEGFA*,[117] with *VEGFA* expression remaining high in the corpus luteum during luteal development and in the developed corpus luteum.[108] Experiments localized VEGF mRNA and protein to the steroidogenic luteal cells[122] and, in one report, to endothelial support cells.[77] Also, FLT1 and KDR were localized to microvascular cells and, intriguingly in a few reports, to luteal cells.[123,124] There are few studies to date on specific cell types[125,126] to directly evaluate the production, regulation, and actions of VEGFA isoforms, VEGF types, or VEGFRs and co-receptors in the corpus luteum. Limited evidence, however, suggests that one isoform (VEGFA 165b[127]) may be anti-angiogenic in some species.

Limited studies suggest that regulation of VEGF expression in the ovulatory follicle and corpus luteum differs from that in many tissues. It is generally believed that a decline in local oxygen concentrations (hypoxia) is a primary stimulator of VEGF production and angiogenesis in normal and pathologic conditions.[128] Indeed, a similar scenario was proposed for the follicle.[129] However, Martinez-Chequer and colleagues[130] observed that hypoxic conditions did not increase VEGFA production by nonluteinizing granulosa cells from the preovulatory follicle or luteinizing granulosa cells from the periovulatory follicle in Old World monkeys. Rather, evidence from several species indicates that gonadotropin, notably the midcycle LH surge, promotes VEGF production[130] via transcriptional and/or posttranscriptional[131] actions in the luteinizing granulosa layer and developing corpus luteum. In addition, local factors such as insulin-like growth factors 1 and 2 (IGF1 and IGF2) may modulate or synergize with LH to control VEGF expression in luteinizing granulosa cells.[130] However, reports suggest that LH action on luteal tissue is less or not important in controlling VEGF production per se (except as a general luteotropin for maintaining luteal structure and function), and that local regulators including hypoxia predominate.[132,133]

A critical role for VEGFA in luteal angiogenesis and corpus luteum development and function is now established.[108,134] Since homozygous and heterozygous

null mutations for *Vegfa* (*Vegfa*^{tm1Gn}/*Vegfa*^{tm1Gn}) were embryonically lethal in mice (due to vascular malformations[135,136]), more classical ablation approaches were required, including protocols that prevented potential antecedent effects during follicle development. Administration of VEGFA antagonists (e.g., VEGF antibody and soluble VEGFR chimeras) to mice or monkeys either at the time of ovulation (i.e., during luteinization) or at midluteal phase (i.e., after luteal development) markedly inhibited subsequent luteal structure and function.[134,137] The suppression of luteal endothelial cell proliferation, endothelial cell area, and circulating progesterone levels, plus evidence that direct injection of VEGFA antagonist into the periovulatory follicle blocks its rupture and impairs luteal architecture,[138] suggests that VEGFA: (1) acts primarily through local effects in the follicle and corpus luteum, not via indirect actions on other tissues controlling ovarian function (e.g., via the hypothalamus–pituitary to alter gonadotropin secretion[139]); (2) is essential for ovulation of the mature follicle and normal development of the corpus luteum; and (3) remains important in the developed corpus luteum to maintain luteal structure and function. Nevertheless, there are few studies to date on the mechanisms of action or direct effects of VEGFA, or other VEGF family members, on luteal cell types. There is one report that VEGF stimulates proliferation of endothelial cells isolated from the monkey corpus luteum.[140]

Other Angiogenic and/or Angiolytic Factors

The angiopoietins (ANGPTs), unlike VEGFs, are not endothelial cell mitogens, but nevertheless are essential for normal vascular development.[141] Four different ANGPTs were identified in the mouse or human, and they all bind to the receptor tyrosine kinase, endothelial (TEK, also known as Tie-2), as either an agonist (ANGPT1, plus ANGPT4 in the mouse) or antagonist (ANGPT2, plus ANGPT3 in humans). An evolving model proposes that interactions between VEGF and ANGPT agonists and antagonists are critical for vessel development and maturation during embryogenesis and tumorigenesis.[142] Whereas VEGFA promotes angiogenesis to the stage of capillary tube formation, the local tissue ratio of ANGPT (1:2) appears critical for capillary growth, maturation, or degeneration. ANGPT2 may loosen cells from the ECM, allowing VEGFA to stimulate endothelial cell events, whereas ANGPT1 recruits periendothelial cells (i.e., pericytes) to stabilize and mature capillaries. In the relative absence of VEGF or other angiogenic factors, ANGPT2 may destabilize vessels and cause capillary degeneration, especially of those not supported by pericytes.

One can hypothesize that a similar scenario is important for vascular events occurring during the development, maintenance, and regression of the corpus luteum. Both ANGPT1 and ANGPT2, plus *TEK* mRNA or TEK protein, were detected in the luteal and endothelial cells, respectively, of several species. Limited reports on (1) the different temporal expression patterns for ANGPT1/2 and VEGFA during the luteal lifespan,[122,143] and (2) the preponderance of immature vessels (not supported by pericytes) in the ovine corpus luteum,[114] are consistent with this model. However, further research is needed on the cellular sites of ANGPT expression and action in the corpus luteum. Preliminary evidence that intrafollicular injection of the antagonist ANGPT2, but not the agonist ANGPT1, destroys the periovulatory follicle and resets the ovarian cycle in monkeys portends a vital role for ANGPTs in follicle–luteal structure and function.[144] Likewise, little is known about the regulation of ANGPT expression, except that the ovulatory gonadotropin surge stimulates ANGPT1 (but not ANGPT2) expression in luteinizing granulosa cells,[131] and chorionic gonadotropin (CG) exposure and early pregnancy promote ANGPT expression in the corpus luteum[143] of primate species. However, given the in vivo approach of these studies and the delayed response (36 h) of the ovulatory follicle,[131] it remains to be determined if these are direct or indirect effects of gonadotropin.

To date, VEGFA and its hypothesized interactions with ANGPTs have received the most attention regarding the development and maintenance of the vasculature in the corpus luteum. But future research must also resolve the role of other emerging factors that may synergize with VEGFA either to promote neovascularization or maturation of blood vessels, or to serve as a check on VEGFA action. One such factor is prokineticin 1 (PROK1), also named endocrine gland (EG)-VEGF due to having similar biologic actions as VEGF,[145] which is highly expressed in steroidogenic tissues, including the corpus luteum.[146] However, the different expression patterns for VEGFA and PROK1, which is molecularly distinct from VEGF and a member of the AVIT family, in the primate[147] and bovine[148] corpus luteum suggest complementary or diverse actions. Likewise, it appears that members of the SLIT-ROBO ligand–receptor family involved in angiogenesis[149] are expressed in the corpus luteum.[150] The concept of negative-feedback regulation of VEGF was advanced following the recent discovery of vasohibins (VASHs[151]) and the subsequent hypothesis that VASH1 is a negative regulator of VEGF's angiogenic action in the bovine corpus luteum.[152] Also, the discovery that the delta-like ligand 4 (DLL4)–Notch receptor system negatively regulates VEGF-mediated angiogenesis led to experiments in monkeys showing that DLL4 neutralization during luteal development increased angiogenesis but markedly suppressed the steroidogenic function and lifespan of the corpus luteum.[153] Studies on these and other potential regulators (e.g., the apelin–apelin receptor system[154]) are warranted. A scenario seems to be emerging that proposes a dynamic balance between factors that promote the development, maturation and function, and degeneration of the microvasculature that

is critical for the normal functional lifespan of the corpus luteum (Figure 23.4).

Finally, with the validation of specific markers for lymphatic cells, investigations recently characterized the robust lymphatic system in the corpus luteum, especially in larger animals such as primates[73] and domestic animals.[155] Moreover, these reports indicate the lymphangiogenic VEGFC and FIGF and their receptor FLT4 are dynamically expressed in these corpora lutea. The lymphatic vasculature plays a number of important roles, including maintaining fluid balance and transporting immune cells, in the body. Understanding the roles of the "second circulatory system—the lymphatics" in the ovulatory follicle[156] and corpus luteum will also be critical to systems analyses of ovarian function.

Differentiation of Steroid-Secreting Cells

Suppression of Steroidogenic Cell Proliferation

It is proposed that further differentiation of follicular steroidogenic (i.e., theca and granulosa) cells into primarily progesterone-secreting (i.e., luteal) cells is associated with cessation of proliferation.[72] Based on limited studies in a few species, primarily during superovulation protocols wherein the LH surge is replaced with a bolus of the LH-like hormone hCG, this appears to be the case. In rodents, cell mitotic activity generally ceased by 7 h after administration of the hCG bolus, and before the occurrence of ovulation at 12 h.[157] However, cell proliferation may continue in the cumulus cell compartment[158] and in follicles of species with a long LH surge-to-ovulation interval. Chaffin and colleagues propose that a secondary rise in cell proliferation occurs after the gonadotropin surge,[159] and numbers of dividing cells do not decline until 24 h after the hCG bolus[160] in monkeys. A small percentage (10%) of cells continued cell cycle activity up to the time of ovulation (36 h post hCG[161]). Indeed, there is evidence that proliferation of granulosa–luteal cells persists through ovulation[72] and in the developed corpus luteum.[109,162,163] However, the percentage of dividing cells is small, may decline with advancing age of the corpus luteum, and remains to be shown to have biologic relevance. For example, in primates there is little evidence of increased proliferation of steroidogenic, or even nonsteroidogenic (microvascular[164]), cells in species where the luteal lifespan is prolonged in actual or simulated pregnancy.[109,165]

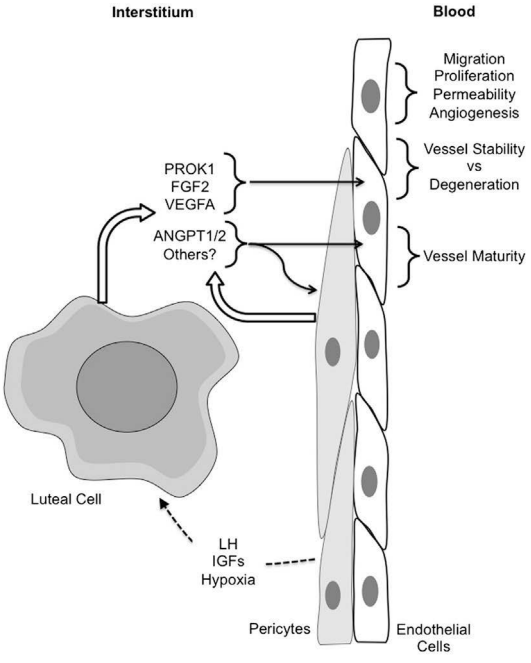

FIGURE 23.4 Schematic of the proposed interactions between luteal cells, capillary endothelial cells, and (in some species) periendothelial support cells (pericytes) for the production and action of angiogenic factors that control the development, maintenance, and regression of the microvasculature in the corpus luteum during the ovarian cycle. White arrows denote synthesis and release of vascular endothelial growth factors (VEGFs), prokineticin 1 (PROK1), basic fibroblast growth factor (FGF2), and/or the angiopoietins (ANGPT1 and 2). The dotted arrows indicate known regulators of VEGF–PROK1–ANGPT expression. The black arrows denote sites of action leading to the indicated effects on the microvasculature. See the text for further details. *Source: Adapted from Stouffer,[74] with permission.*

Considerable information has accrued in understanding how follicle–luteal cell progression through the cell cycle, or its cessation, is controlled by the intracellular proteins called cyclins,[72] their interaction with specific cyclin-dependent kinases (CDKs, e.g., CDK2), and inhibition of cyclin–CDK activity by cyclin-dependent kinase inhibitors (CDKNs). Studies in rodents indicate that cyclins D2 and E, plus Cdk2, which promote cell passage through the G1 and G1-S transition phases of the cell cycle, are downregulated in granulosa cells following the ovulatory hCG bolus.[72,166] Cyclin D2 is rapidly suppressed, whereas cyclin E does not change until 48 h post hCG. Although the mechanisms regulating cyclin expression require further investigation, there is some evidence for dephosphorylation of proteins (i.e., retinoblastoma proteins (RB)[72]) during luteinization in mice and women that could suppress cyclin D and E activity. The importance of the cyclin D system in controlling follicle growth is supported by evidence that granulosa cells from cyclin D2 null-mutant mice ($Ccnd2^{tm1Wbg}/Ccnd2^{tm1Wbg}$) are unable to proliferate, but they do luteinize following a gonadotropin bolus.[167] However Cdk4 null-mutant mice ($Cdk4^{tm1Kiyo}/Cdk4^{tm1Kiyo}$) demonstrated normal follicular development and granulosa cells exited from the cell cycle after ovulation, suggesting that another Cdk (possibly Cdk6) complexed with cyclin D2 regulates proliferation.[168] Again, there may be important species differences at this control point since Chaffin et al.[161] did not observe a decrease in cyclin D2 or E mRNA expression in the granulosa cells of monkey preovulatory follicles during the decline in cell proliferation initiated by an hCG bolus. Rather, the levels of cyclin B1 mRNA are reduced

in macaque granulosa cells within 12 h of exposure to a gonadotropin bolus. Also, phosphorylated RBs are present in the developing corpus luteum in primates.[169]

Unlike cyclin expression or activity, evidence suggests that the expression of CDK inhibitors is more consistent among species during luteinization. A similar profile of a transient increase in cyclin-dependent kinase inhibitor 1A (CDKN1A, or CKIp21), followed by a later rise in cyclin-dependent kinase inhibitor 1B (CDKN1B, or CDKp27), occurs in granulosa cells of rodents[170] and primates[161] after an ovulatory hCG bolus. The early rise in CDKN1A is associated with the marked decline in cell mitosis, but the later rise in CDKN1B may be critical for sustained cell cycle arrest. Studies in *Cdkn1b* null-mutant mice (*Cdkn1b*^{tm1Ako}/*Cdkn1b*^{tm1Ako}) indicate that follicles grow normally, but luteal cells do not stop proliferating following an ovulatory stimulus.[171] Subsequent generation of the *Cdkn1a*$^{-/-}$, *Cdkn1b*$^{-/-}$ double null-mutant mouse provided evidence that both cyclin-dependent kinase inhibitors (CKIs) cooperate to control exit of granulosa cells from the cell cycle.[172] Interestingly, despite continued proliferation, they differentiated into luteinized cells. Further studies are needed to understand the dynamics of cyclin–CDK–CDKN pathways in the follicle and corpus luteum, and their roles in controlling cell proliferation and differentiation. It is also likely that other pathways, such as the MYC–MAX–MXD1 family of transcription factors and TP53 (i.e., p53)-regulated $Mg2^{+}$–$Mn2^{+}$-dependent protein phosphatase 1D (PPM1D), also regulate cell proliferation[159] via or independent of the cyclin system.

To date, little is known about the gonadotropin actions that inhibit follicle cell proliferation. Gonadotropin surge levels could act directly or via LH–CG-stimulated intermediates, such as local growth factors or steroids (e.g., progesterone[173]), to control early and late (periovulatory) events in the cell cycle. Likewise, there is little information on proliferation or its control in luteinizing theca cells.[72]

Enhancement of Progesterone Production

One of the hallmarks of luteinization is the switch from the principal steroid product of the maturing follicle (i.e., estrogens) to that of the developing and mature corpus luteum (i.e., progesterone). This is both a qualitative and quantitative change, as the mammalian corpus luteum produces up to 100-fold greater amounts of steroid than the follicle. Thus, circulating levels of estradiol originating from the preovulatory follicle reach the picomolar range, whereas progesterone levels produced by the corpus luteum can reach the nanomolar range. The human corpus luteum, for example, is estimated to secrete up to 40 mg of progesterone per day during the menstrual cycle.[174] To achieve such steroidogenic activity, it appears that at least two major pathways are enhanced in luteal cells: (1) cell-specific amplification of steps in the steroidogenic pathway converting cholesterol to progesterone; and (2) increased ability to sequester bloodborne sources of cholesterol and to store cholesterol-rich lipid deposits.[175]

Circulating progesterone levels increase within the first half-hour to 2 h in several species, including primates and rodents, after exposure to a gonadotropin surge or bolus.[158,176] This suggests that a basal level of LH-sensitive progestogenic activity can be in place, but is relatively inactive until the LH surge. Indeed, nonluteinized granulosa cells from monkey preovulatory follicles appear to possess substantial levels of the enzyme 3 beta-hydroxysteroid dehydrogenase (HSD3B1 in nonprimate species; HSD3B2 in primates), since they readily convert pregnenolone to progesterone.[176] However, these cells cannot readily convert cholesterol analogs or cholesterol sources such as low-density lipoprotein into progesterone. Evidence from some species suggests that luteinization is associated with a marked increase in expression and/or activity of the cytochrome P450 side-chain cleavage enzyme ($P450_{scc}$ or CYP11A1) responsible for converting cholesterol to pregnenolone in the inner mitochondrial membrane, but there may be a divergence in CYP11A1 expression and enzyme activity as there are reports that *CYP11A1* mRNA initially declines following the onset of the LH surge.[177] Since CYP11A1 is required for androgen synthesis in the theca layer of the follicle,[178] its enhancement during luteinization may be primarily in the granulosa cells. Moreover, a further increase in HSD3B expression, and a decrease in 17α-hydroxylase, 17-20 lyase ($P450_{17\alpha}$ or CYP17A1, which catalyzes androgen production from progesterone), and aromatase ($P450_{arom}$ or CYP19A1, which converts androgen to estrogen) may facilitate the cellular emphasis on progestin production. Detailed genomic studies revealed that steroidogenic gene expression in the macaque follicle shortly after ovulation and through the initial stages of the corpus luteum is, in fact, associated with a preferential upregulation of key progestogenic enzymes (e.g., *CYP11A1* and *HSD3B2*) and reduced expression of enzymes involved in androgen (e.g., *CYP17A1*) and estradiol (e.g., *CYP19A1*) synthesis.[179,180]

Since initial steroidogenesis (i.e., CYP11A1 activity) occurs inside the mitochondria, the mechanism by which cholesterol is transported from outside to the inner mitochondrial membrane has been an area of important investigation.[181,182] Although recognized for years as the rate-limiting step in steroidogenesis, and the site of acute regulation via synthesis of a short-lived protein, it wasn't until the mid-1990s that this protein was identified, characterized, and named steroidogenic acute regulatory protein (STAR).[183] Mutations of the *Star* gene in mice (*Star*^{tm1Klp}/*Star*^{tm1Klp})[184] or that occur spontaneously in humans[182] are characterized by the inability

to synthesize adequate amounts of steroids. However, placental steroidogenesis in some species (e.g., humans) does not appear to involve STAR, but possibly a related protein, STARD3,[185] that possesses STAR-related lipid-transfer (START) domains. The critical role of STAR in cholesterol transport in adrenal and gonadal cells is established, but the mechanism of action awaits resolution. Although targeted to the mitochondrial membrane by specific amino acid sequences, STAR does not appear to require a receptor-type molecule for cholesterol transfer once it reaches the mitochondria. STAR has been postulated to act as an intermitochondrial shuttle[186] that interacts with other proteins on the outer mitochondrial membrane such as the translocator protein (TSPO; also known as the peripheral benzodiazepine receptor), voltage-dependent anion channel 1, and phosphate carrier protein. Each molecule of STAR transfers hundreds of molecules of cholesterol before undergoing a cleavage or inactivation event.[186] Notably, the expression of STAR is markedly upregulated in the granulosa layer during luteinization in many species.[187,188]

In several species, there is a transient peak in STAR expression occurring early after the LH–CG bolus, followed by a decline,[180,187–189] before returning to high levels in the corpus luteum. Biphasic patterns were also reported for expression of the steroidogenic enzymes CYP11A1 and HSD3B2.[180,188] These patterns could be related to transient downregulation of LH–CG receptors or desensitization of the receptor-stimulated pathways,[3] which is known to occur in rodents at ovulation,[190] but this awaits investigation in other species. Alternatively, the renewed expression could reflect the end of tissue-remodeling activities essential for follicle rupture and the emergence of steroidogenic activities in the developing corpus luteum. Nonetheless, high levels of expression of STAR, CYP11A1, and HSD3B2 immediately after follicle rupture ensure uninterrupted and increasing levels of progesterone synthesis through the initial period of luteal development in primates.[179,180] Such a similar pattern of expression for STAR, CYP11A1, and HSD3B2 could stem from shared (NR5A1–NR5A2 and GATA4–GATA6) and gene-specific transcription factors (e.g., NE5A1–NR5A2 and GATA4–GATA6).[191] Finally, the renewal of expression of the steroidogenic enzymes (CYP17A1,[190,192] or CYP19A1[179,193,194] after the development of the corpus luteum in various species, e.g., rodents and primates) likely reflects the unique ability of their corpus luteum to also synthesize androgens and/or estrogens. It is intriguing that the compartmentalization of the luteal tissue in Old World monkeys, baboons, and women retains the distribution of androgen- and estrogen-producing enzymes observed in the follicle. Immunocytochemical localization of CYP17A1 to the paraluteal and thecal–luteal cells and CYP19A1 to the granulosa luteal cells implies the continuation of a two-cell model for estrogen production in the corpus luteum of higher primates.[195,196]

To produce large quantities of progesterone, a major increase in availability of the steroid precursor, cholesterol, is required. The process of de novo synthesis of cholesterol by cells is well established.[175] However, de novo synthesis by luteal cells appears to be a minor source for cholesterol steroidogenesis, since expression of 3-hydroxy-3 methylglutaryl CoA (HMG–CoA) reductase (the enzyme catalyzing the rate limiting in cholesterol synthesis from two carbon precursors) appears constant in the corpus luteum.[197] Moreover, pharmacologic blockage of this enzyme does not alter circulating progesterone levels in women[198] or progesterone secretion by human luteinized granulosa cells.[199] Rather, most species use bloodborne sources of cholesterol esters, either in the form of high- or low-density lipoproteins (HDLs or LDLs), for luteal steroidogenesis. Notably, marked increases in the expression of receptors for and binding of HDL (scavenger receptor B1, SCARB1) and/or LDL (LDLR) occur during luteinization[200–204]; that may actually precede cell exposure to circulating substrate after ovulation. The relative contribution of the two lipoproteins varies between species, with the rodent corpus luteum relying primarily on HDL and the primate corpus luteum requiring LDL.[205] The preferential use of one lipoprotein type over another can occur, again depending on the species, despite the fact that both SCARB1 and LDLR are coexpressed in the corpus luteum. In luteinizing macaque granulosa cells, LDL primarily serves to support progesterone synthesis,[200,206] although both SCARB1 and LDLR expression increase after gonadotropin stimulation.[200] Further confirmation of the preference for LDL as a source of cholesterol in the corpus luteum comes from studies whereby patients that lack circulating LDL due to phenotypic abetalipoproteinemia have reduced levels of luteal progesterone synthesis.[207,208] Although receptor-dependent lipoprotein uptake is critical for sustained steroidogenesis, sufficient intracellular quantities of stored cholesterol esters exist to support the initial rapid increase in progesterone synthesis post LH and hCG (i.e., within the first few minutes to hours).[200]

Despite clear evidence demonstrating that LDL is the preferential source of cholesterol esters for primate luteal steroidogenesis, recent studies support a critical role for SCARB1 as a regulator of cholesterol uptake and progesterone synthesis within the primate corpus luteum. Using the human granulosa cell line HGL5, which can be induced to synthesize progesterone in response to increased intracellular cyclic adenosine monophosphate (cAMP) levels, a small interfering RNA (siRNA)-mediated reduction in SCARB1 levels significantly reduced the expression of CYP11A1, HSD3B2, and STAR.[209] Also, several *SCARB1* gene variants that alter function have been identified, and certain alleles are

associated with differences in circulating lipid levels, especially in women younger than 50 years of age.[210] One such SCARB1 variant (small nucleotide polymorphism, or SNP rs4238001) results in a glycine-to-serine substitution at position 2, which in turn leads to an increased rate of SCARB1 turnover and reduced cell surface expression.[211] This receptor variant was associated with lower follicular progesterone levels in women undergoing infertility treatments than those who possessed the wild-type allele. Of nine women possessing this variant, none had a viable pregnancy after embryo transfer, which is in contrast to the 30% pregnancy rate in control women without that particular variant. These studies parallel the findings from mice lacking SCARB1 that exhibited a 50% reduction in circulating progesterone levels relative to wild-type animals.[212] Although the molecular mechanisms require characterization, these studies suggest that SCARB1 action extends beyond its capacity to serve solely as a cholesterol–HDL uptake protein.

Relative to the mechanisms involving cholesterol uptake in luteal cells, its intracellular movement and processing are not as well characterized. Current evidence suggests that apolipoprotein A1 (APOA1) binds to SCARB1 and facilitates transfer from HDL-derived cholesterol ester.[213] Also, the Niemann Pick C1 protein (NPC1), which mediates transfer of LDL-derived cholesterol from the endosome to the Golgi apparatus,[214] is upregulated during luteinization.[215] Deficiencies in these components in rodents (e.g., APOA1[216]) or women (NPC1[217]) will diminish circulating progesterone levels and impair fertility. In human luteinizing granulosa cells, disruption of the NPC1-dependent cholesterol transport pathway blocks progesterone synthesis that is induced in response to LDL supplementation.[218] Reduced progesterone production by these cells was associated with excessive free cholesterol accumulation in large granules, suggesting a block in the movement of cholesterol from the lysosome to smaller storage vesicles or mitochondria.[218] However, when mice bearing a spontaneous mutation in the *Npc1* gene (*Npc1*^{m1N}/*Npc1*^{m1N}) receive exogenous gonadotropins, or their ovaries are transplanted into wild-type recipients, follicles ovulate and form corpora lutea.[219] Further investigation of *Npc1* mutant mice revealed that the reproductive defect likely stems from abnormal pituitary function. Moreover, *Npc1* null-mutant mice (*Npc1*^{tm1Mbjg}/*Npc1*^{tm1Mbjg}) that were unable to utilize LDL cholesterol as a substrate for steroid synthesis and that possessed preantral and antral follicles with highly vacuolated granulosa cells still generated circulating progesterone concentrations that were similar to those in wild-type mice.[220] Thus, it is likely that redundant pathways (e.g., Niemann Pick C2) are critical in allowing for continued luteal steroid synthesis when spontaneous or engineered mutants arise in individual genes encoding NPC1 or other cholesterol handling and transport proteins.

Following uptake from LDL or HDL or de novo synthesis, reserves of cholesterol available for steroidogenesis are stored in lipid droplets in the form of cholesterol esters. The synthesis of esterified cholesterol is dependent on the action of acyl coenzyme A–cholesterol acyl transferase (ACAT1) in the rough endoplasmic reticulum.[175] Free cholesterol must then be liberated by the actions of one or more lipase enzymes. Thus, another mechanism whereby luteal cells can acutely increase the availability of substrate for steroidogenesis is by hydrolysis of intracellular stores of cholesterol esterase in lipid droplets. The enzymes catalyzing this process belong to the lipase family, with hormone-sensitive lipase (LIPE) and lysosomal acid lipase (LIPA; also referred to as cholesterol esterase) being expressed in the corpus luteum of different species at luteinization.[221,222] Moreover, hepatic lipase (*Lipc*) null mutants (*Lipc*^{tm1Unc}/*Lipc*^{tm1Unc}) produce significantly less progesterone than their wild-type counterparts following the administration of an ovulatory bolus of hCG.[223] As the lipase family is composed of 12 different members, a complete characterization of which enzymes are critical for supplying the cholesterol needed for steroid production in the developing corpus luteum remains to be determined. Once free cholesterol is available, it is then transported intracellularly via sterol carrier proteins (e.g., SCP2 in rodents[224]) and cytoskeletal elements such as vimentin.[225] Figure 23.5 provides a schematic of progesterone biosynthesis in a "generic luteal cell", as adapted from Niswender, Ho, and colleagues.[182,226] However, there are many molecular and cellular events in this complex pathway, plus their regulation, which remain poorly understood and display species diversity.

It is likely that other mechanisms ensure that an adequate supply of cholesterol is available for steroid synthesis within the corpus luteum. The aforementioned description of cholesterol uptake and release from cellular stores is just one aspect of this complex system. Recent data from primates strongly suggest that increased steroid production by luteinized granulosa cells is also dependent on a reduction in the active efflux of cholesterol out of the cell, otherwise known as reverse cholesterol transport (RCT). RCT is mediated primarily by the cholesterol transport proteins such as ATP-binding cassette transporter 1 (ABCA1), which shuttles intracellular cholesterol to extracellular HDL lipoprotein acceptors. Expression of ABCA1 and the lipoprotein acceptor APOE are upregulated by the nuclear receptors NR1H3 and NR1H2 (also known as liver x receptor (LXR) alpha and beta, respectively), which are critical for maintaining cellular cholesterol homeostasis.[227] In luteinized human granulosa cells, which express both isoforms, treatment with synthetic agonists that activate both receptor subtypes increases the expression of the RCT system.[228] Consequently, increased RCT activity markedly reduced granulosa cell cholesterol levels and their progesterone-synthesizing capacity. In rhesus

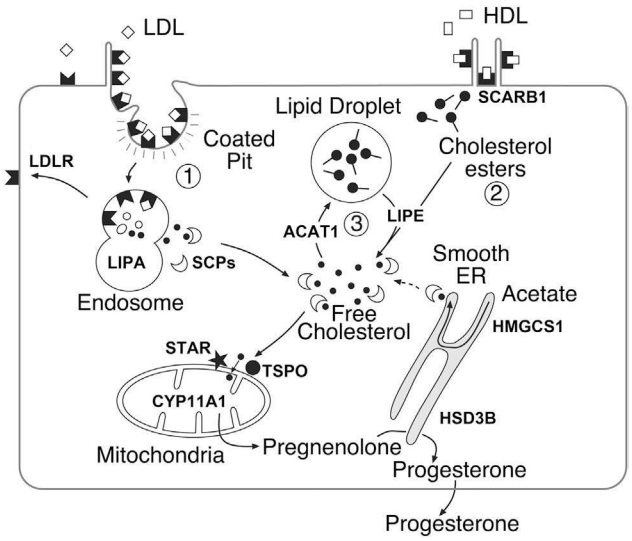

FIGURE 23.5 Simplified illustration of the three major sources of intracellular, unesterified (i.e., "free") cholesterol for progesterone synthesis in luteal cells. (1) The LDL-receptor mediated pathway leading to internalization of coated pits, and fusion with lysosomes to form endosomes, where lysosomal acid lipase (LIPA) generates free cholesterol (·). (2) The HDL receptor (SCARB1) pathway wherein hormone-sensitive lipase (LIPE) generates free cholesterol. (3) The storage and turnover of free cholesterol in lipid droplets via ACAT1-catalyzed cholesterol ester formation and LIPE-catalyzed ester hydrolysis. Intracellular transport of hydrophobic free cholesterol appears actively directed by various proteins, including NPC1 protein and sterol carrier proteins (e.g., SCP2). Cholesterol transport to the inner mitochondrial membrane involves the steroidogenic acute regulatory protein (STAR), possibly in close association with TSPO–peripheral-type benzodiazepine receptor and an endogenous ligand (e.g., diazepam binding inhibitor (DBI)). Cholesterol is enzymatically catalyzed to pregnenolone by the CPY11A1 complex. After moving to the smooth endoplasmic reticulum (ER), pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase-Δ^{5-4} isomerase (HSD3B). Progesterone then exits the cell. Except under certain pathologic conditions where it may serve as a compensatory pathway,[194] de novo synthesis of cholesterol from acetyl CoA–acetate by 3-hydroxy-3 methylglutaryl CoA (HMG–CoA) synthase and reductase (dotted line) appears minimal in luteal cells.

macaque granulosa cells obtained from animals undergoing a controlled ovarian stimulation protocol, NR1H3 and NR1H2 as well as ABCA1 expression decreased within 3 h of an ovulatory stimulus. Incubating these cells with an LXR agonist also significantly reduced their ability to produce progesterone[229] due to increased RCT activity and direct suppression of the expression of key steroidogenic enzymes (e.g., STAR, CYP11A1, HSD3B2, and SCARB1). Whether the RCT system and its regulation is a common feature in controlling the corpus luteum in other species awaits investigation.

Steroid- and/or Peptide-Secreting Cells

Although the primary hormone produced by the corpus luteum is the steroid progesterone, it is clear that luteal cells synthesize and secrete many peptides–proteins that can serve in a species-dependent manner as local (paracrine or autocrine) or endocrine factors. Three types of hormones have been identified: oxytocin, relaxin, and inhibin–activin.

As reviewed by Sherwood and Fields[230] and Ivell,[231] following discovery of a "contractin factor" in cow luteal extracts that stimulated uterine contractions, 70 years passed before it was identified as molecularly homologous to oxytocin in the posterior pituitary.[232] Subsequent studies confirmed that oxytocin is synthesized in large luteal cells in much the same way as pituitary cells; first as a precursor protein that contains the nonapeptide sequence for oxytocin plus its carrier protein neurophysin I, followed by packaging of the prohormone into secretory granules[233] where it undergoes a series of enzymatic steps to release oxytocin.[231] The factors promoting luteal oxytocin mRNA expression, protein synthesis, and secretion are not well understood.[230,231] In the cow, oxytocin–neurophysin mRNA increases markedly in luteinizing granulosa cells after ovulation, but production of luteal oxytocin is markedly delayed and does not peak until well into the luteal phase (days 8–12). The delay appears due to a lag in the availability of peptidyl glycine α-amidating monooxygenase, which is the terminal enzyme in post-translational processing. Moreover, oxytocin secretion and action in the late luteal phase may occur when its mRNA levels are reduced or virtually absent; this paradox can be explained by posttranscriptional regulation and oxytocin stores in granules that are released in response to a secretagogue (e.g., a $PGF_{2\alpha}$ pulse). In domestic animals, such as cows, sheep, goats, and pigs, there is evidence that luteal oxytocin plays a role in luteal regression at the end of the nonfertile cycle[41] (see the section Luteolytic Factors on $PGF_{2\alpha}$). The release of oxytocin at midcycle may upregulate its own receptors in the uterus, and the subsequent pulses of Ca^{2+}-dependent oxytocin release provide a positive-feedback loop for promoting $PGF_{2\alpha}$ release from the uterus at luteolysis.

Luteal oxytocin is detectable in other species, including primates, but at 1000-fold lower levels; more sensitive techniques (e.g., real-time polymerase chain reaction) are required to detect oxytocin mRNA, and oxytocin concentrations in ovarian venous blood are typically not high enough to have an endocrine effect on nonovarian tissues.[231] A physiologic role for oxytocin in such species is perhaps limited to a local action, especially at luteinization. In many species,[234] including primates,[235] there is evidence that the LH surge promotes expression and production of oxytocin, and its receptor,[231,235] in luteinizing cells of the ovulatory follicle. Generally, data from a variety of species support a pro-luteinization action of oxytocin (e.g., to promote progesterone production and secretion).[235,236] Ivell[231] speculates that the paracrine luteotropic action of oxytocin during development of

the corpus luteum occurs in various species, only to be usurped by an endocrine role as a luteolytic factor during regression of the corpus luteum in domestic animals. Further studies are needed to establish the physiologic importance of oxytocin in periovulatory events and luteinization.

Although reports[237,238] suggest that relaxin (RLN) or a relaxin-like factor (RLF, or INSL3) are expressed by the ovulatory luteinizing follicle, and could play a role in ovulation,[239] relaxin has generally been considered a hormone of pregnancy and parturition.[230] Although discovered by F. Hisaw in 1926,[240] until recently the molecular nature of relaxin family members and their receptors proved elusive (for a review, see Ref. 241). Three genes encoding relaxins were identified in humans, which belong to the superfamily of structurally related hormones, including insulin, IGFs, insulin-like peptides (INSLs), and relaxin-like factor (RLF or INSL-3). RLN1 is typically produced and secreted by rodents (rat and mouse) and domestic animals (pig), whereas RLN2 is found in the circulation of primates (human). RLN3 is expressed in the brain, but its physiologic significance remains undefined. Recently, orphan receptors belonging to the leucine-rich guanine nucleotide-binding (G-protein) coupled receptors were identified as RLN family peptide (RXFP) receptors.[242]

The corpus luteum of many species produces and secretes RLN in a stage-dependent manner.[241] In species such as the rat, mouse, pig, and human, the corpus luteum is the sole source of RLN throughout pregnancy. However, the dynamics of RLN production and resultant levels or patterns in the circulation during pregnancy vary between species.[241] In the pig, *RLN* mRNA and protein increase at midluteal phase, particularly in the fertile cycle. The protein then progressively accumulates in membrane-bound cytoplasmic granules in large luteal cells throughout gestation, until about 2 days before delivery when degranulation occurs, luteal RLN levels markedly decline, and circulating RLN levels surge 12–24 h before delivery. A similar prepartum surge occurs during late gestation in rats and coincides with the decline in progesterone levels that is required for onset of parturition. In contrast, in primates, including women, the levels of RLN are detectable but much lower in the corpus luteum, and it does not appear this protein accumulates in membrane-bound granules. Also, circulating RLN levels are higher during early pregnancy, compared to the second or third trimester, and there is no evidence of a prepartum surge.[243,244] In nonprimates,[241] data suggest that RLN serves as a hormone during pregnancy to promote growth of the lower reproductive tract (cervix and vagina); facilitate rapid, successful delivery (cervical softening); and contribute to development of mammary gland alveoli (pig) or nipples (rat). In primates, limited studies have not demonstrated a physiologic role for RLN, but abnormal patterns of circulating RLN have been associated with early pregnancy loss in women.[245] Nevertheless, there is reason to suspect that it does not play a critical role in women since sole use of sequential estrogen and progesterone treatment in assisted reproductive technology protocols to mimic ovarian function results in normal gestations with timely delivery of offspring and successful lactation.[65] This does not, however, rule out a local ovarian action,[246] or actions on the embryo[247] in nonhuman primates. Clearly, the parturitional and lactational activities of RLN vary between species, as effects of relaxin deficiency are more dramatic in rats or pigs[241] than mice (i.e., $Rln^{tm1Wint}/Rln^{tm1Wint}$ or $Rxfp1^{tm1Jgo}/Rxfp1^{tm1Jgo}$ mutants).[248] An extreme example is the sheep corpus luteum, which does not produce RLN.[249]

Inhibin and activin are members of the transforming growth factor beta (TGFβ) superfamily of ligands initially identified based on their ability to inhibit and stimulate pituitary FSH, respectively.[250] The sequential expression of inhibin B (αβB) and inhibin A (αβA) as antral follicle growth proceeds is well documented.[251] Although inhibin production typically ends following the LH surge in many species, the corpus luteum of Old World monkeys[252] and women[253] continues to synthesize and secrete significant amounts of inhibin A and its α subunit. Investigators have localized the inhibin subunits primarily to granulosa luteal, but not theca luteal, cells[254]; these may also produce the binding proteins follistatin and follistatin-related gene products,[255] which neutralize inhibin–activin activity. However, follistatin is highly expressed in luteal tissue of other species (e.g., rat[256]) that do not produce inhibin–activin. Thus, these proteins may bind other factors, such as bone morphogenic proteins (BMPs), which could have local actions during luteinization and luteolysis.[256] Although the major source of inhibins and activins after early pregnancy in primates is the fetal–placental unit,[257] the corpus luteum secretes appreciable amounts of inhibin A in early gestation.[258] However, an endocrine role for luteal inhibin or activin remains unclear.[250] Immunoneutralization studies employing inhibin antisera suggest that testicular inhibin B plays a critical role in regulating circulating FSH levels in male primates,[259] but such studies failed to establish a similar role for ovarian inhibin A in females during the luteal phase of the menstrual cycle.[260] Proposed local actions to modulate luteal structure and function await delineation.[250]

LUTEOLYSIS

The corpus luteum typically ceases function and structurally involutes at one of three stages: (1) near the end of a nonfecund ovarian cycle; (2) at the point in

gestation where its progestogenic function is no longer needed to maintain intrauterine pregnancy, or if the corpus luteum is required throughout pregnancy; and then (3) at term delivery of the offspring. This loss of luteal structure–function is often referred to as luteolysis. As elegantly reviewed by Davis and Rueda,[261] the area is not without controversy as some investigators have used the terminology of functional luteolysis versus structural luteolysis and debated whether these events are independent, dependent, or interdependent. This issue is again related to species differences, such that in some species (e.g., the hamster[262]) the corpus luteum undergoes loss of function and essentially involutes within one ovarian cycle, whereas in others (e.g., the mouse and rat) the corpus luteum no longer functions but three or more generations of corpora lutea may be evident in the ovary during the cycle.[263] Likewise, the corpus luteum of primates may cease function 3–4 days before menstruation at the end of the cycle,[51] but residual luteal mass is evident into the next follicular phase and can even respond in a limited manner to exogenous gonadotropin (LH/CG) treatment.[264] Another level of complexity may be added when comparing luteolysis at the end of the ovarian cycle versus that in pregnancy. There are reports that structural involution can occur at a slower rate following pregnancy compared to the end of the ovarian cycle.[265] Such differences may be due to exposure to different milieus of luteotropic or luteolytic factors (see the section Regulation of Luteal Structure and Function) and/or reliance on different cell processes for destruction.[266] For example, although there is little evidence for a significant role of prolactin in promoting the structure and function of the primate corpus luteum during the menstrual cycle, this hormone may delay the luteolytic process in the "rejuvenated corpus luteum" after parturition, especially during lactation.[51] To date, for various reasons, many researchers investigated the process of luteolysis near the end of the nonfecund cycle, and often used the model of $PGF_{2\alpha}$-induced luteolysis once this prostaglandin was established as the uterine luteolytic factor in rodents and domestic animals. The hallmark of early luteal regression is declining progesterone production, clearly demarcated by the fall of circulating blood levels of this steroid hormone.[267] In species not utilizing a uterine luteolytic ($PGF_{2\alpha}$) process, however, the mechanisms and cellular events involved in loss of luteal function and structure remain poorly understood.

With considerable interest in recent years in the events that control cell death during tissue development and homeostasis, investigators began to apply advances in this field to studies on germ cell depletion, follicle atresia, and luteolysis in the ovary. While six different forms of cell death have been described,[268] the majority of studies conducted to date have focused primarily on the type of programmed cell death termed apoptosis.[269] Apoptosis describes the coordinated collapse of the cell, protein degradation, and DNA fragmentation, followed by rapid loss of dead cell fragments (e.g., by engulfment by immune cells).[270,271] Key characteristics include cell shrinkage (not swelling, as noted in necrosis), cytoplasmic "blebbing", chromatin condensation, and internucleosomal DNA cleavage that yields a "ladder" of 180 bp incremental sizes of genomic DNA that can be discerned by gel electrophoresis.

Increasing evidence supports the theory that apoptosis is an important mechanism controlling involution of the corpus luteum. Apoptotic indices, either morphologic or biochemical, were observed during structural involution of the corpus luteum in rodents[270,271] domestic animals,[272–274] and primates.[275–277] There is increasing evidence that the pro-apoptotic members of the death receptor family and their ligands are involved in luteal regression, including early disruption of progesterone production and structural involution. Notably, luteal expression of tumor necrosis factor (TNF) receptor superfamily (TNFRSF) members and corresponding ligands, which also include FAS ligand (FASL) and its receptor FAS, is associated with luteolysis in several species.[275,278,279] TNF can cause death of endothelial cells derived from the corpus luteum[280,281] and augment interferon gamma-induced death of luteal cells[282] from domestic animals (see the section Luteolytic Factors). Moreover, pseudopregnant mice treated with a TNF-neutralizing antibody and *Tnfrsf1a* null-mutant animals were refractory to $PGF_{2\alpha}$-mediated suppression of luteal progesterone production and luteal regression.[279] The pro-apoptotic actions of TNF appear to be dependent on its ability to elicit the synthesis of ceramide through the action of acid sphingomyelinase.[279] Evidence for a possible role of this superfamily in luteolysis is further derived from *Tnfrsf1a*-deficient mice ($Tnfrsf1a^{tm1Imx}/Tnfrsf1a^{tm1Imx}$), who fail to progress through the luteal (diestrus) phase of the cycle.[283] Exposure to FASL or FAS-activating antibody causes apoptosis of luteal cells in several species,[284,285] as well as luteinized granulosa cells from women.[286] The functional importance of the FASL–FAS system during luteolysis in the mouse is supported by evidence that: (1) FAS-activating antibody causes premature luteal regression[287]; whereas (2) mutants lacking FASL ($Fas^{gld/gld}$ mice) or FAS ($Fas^{lpr/lpr}$ mice) have irregular ovarian cycles attributed to defects, including aberrant luteolysis.[287] While such evidence supports a role for the TNFRSF family in regulating apoptosis, other pathways involved in determining luteal cell fate are likely involved as well. For example, it was recently discovered that expression of select SLIT proteins (e.g., SLIT2 and SLIT3) and an associated receptor (e.g., ROBO2), which promotes apoptosis and inhibits cell migration,[149] peak in the human corpus luteum during the period of luteal regression. Upon luteal rescue with exogenous

hCG administration, SLIT2, SLIT3, and ROBO2 expression was significantly lower, approaching early luteal and midluteal phase levels. By treating primary cultures of luteal cells with a recombinant ROBO1–Fc chimera that inhibits SLIT–ROBO signaling, cellular migration was increased while apoptosis decreased significantly,[150] suggesting an important role for this autocrine–paracrine pathway in primate luteolysis.

There is considerable evidence that members of the B-cell chronic lymphocytic leukemia (CLL)–lymphoma 2 (BCL2) family of apoptosis-regulatory proteins are present in the mammalian ovary, including the corpus luteum. It is possible that the prevailing theory[268] suggesting the balance between pro-apoptotic (e.g., BCL2-associated X protein, or BAX; and BCL2-antagonist/killer 1, or BAK1) and anti-apoptotic (e.g., BCL2; and BCL2L1, commonly known as BCL-X) factors, perhaps modulated by stimulus-sensitive BH3-only proteins (e.g., BNIP3, BAD), which controls cell death, also applies to follicle and corpus luteum turnover. The evidence is strongest for follicle atresia, where BAX protein levels are elevated[288] and *Bax*-deficient mice ($Bax^{tm1Sjk}/Bax^{tm1Sjk}$) accumulate abnormal follicles as their granulosa cells atrophy but presumably fail to undergo apoptosis during attempted atresia.[289] However, there is less evidence on the dynamics and role of BCL-like proteins in the corpus luteum; indeed, whether the ratio of pro (e.g., BAX)-to-anti (e.g., BCL2) apoptotic proteins changes in association with apoptosis in the primate corpus luteum during the menstrual cycle[290,291] or early pregnancy[292] is controversial. In human corpora lutea that were undergoing regression, as determined by declining levels of circulating progesterone, the antiapoptotic protein BCL2 was significantly lower, which correlated with increased cellular apoptosis. In contrast, expression of the pro-apoptotic proteins BAX and BAK1 remained constant, supporting the concept that the ratio of pro- and anti-apoptotic factors is critical in determining luteal cell survival.[277]

Although some progress has occurred in evaluating local death ligands and apoptotic regulatory proteins in the corpus luteum, there is little information on the molecular pathways that execute apoptosis and degrade cellular targets. In mammals, at least 13 different **c**ysteine **as**partate-specific prote**ases** (caspases or *CASP* genes) have been identified that serve as either "initiator" caspases (i.e., activate other caspases or initiate early mitochondrial changes) or "effector" caspases (hydrolyze a broad spectrum of proteins, including protein kinases, cytoskeletal components, and inhibitors of DNAses). Initial reports identified several caspases in luteal tissue,[293,294] and limited evidence supports a key role for the effector CASP3 in luteolysis. Notably, the uterine luteolytic factor, $PGF_{2\alpha}$, activates CASP3 during luteal regression in rodents[295] and sheep.[296] Also, *Casp3* null mice ($Casp3^{tm1Flv}/Casp3^{tm1Flv}$) exhibit delayed onset of luteal involution in gonadotropin-stimulated ovarian cycles.[297] However, there may be CASP3-independent mechanisms that are dependent upon the stage of the corpus luteum.[298] A complex interplay between inhibitors and activators of caspase activity also appears critical. The CASP8 and FADD-like apoptosis regulator protein (CFLAR, also known as cFLIP), which prevents CASP8 activation, is downregulated during structural luteal regression.[299]

While evidence to date supports a role for apoptosis in luteolysis, numerous issues remain to be resolved. There is evidence that pharmacologic methods of induced luteolysis (e.g., GnRH antagonist–induced LH deprivation versus $PGF_{2\alpha}$-induced luteolysis) can result in different patterns of cell death.[300] Studies are needed to compare processes of cell death during luteolysis in the ovarian cycle, pseudopregnancy, and pregnancy. Likewise, the physiologic stimuli and cellular pathways that result in cell death in the corpus luteum await clear definition. Extensive research in invertebrate and vertebrate systems established that deprivation of critical survival-promoting "growth factors" or expression of "death ligands" is used in normal tissue turnover to eliminate cells by apoptosis.[268] One can hypothesize that removal of or reduced sensitivity to luteotropic factors and/or additional or increased sensitivity to luteolytic factors promotes apoptosis in the corpus luteum. However, whether these factors act directly or indirectly (e.g., via regulation of local death ligands[268]) and how cellular processes are temporarily activated are not clear.

It also remains unclear whether the cell death during luteolysis occurs solely via apoptosis. For example, there is some controversy as to whether luteal cells in primates are dying by apoptosis[163,276] or by autophagy.[300,301] Autophagy is the process whereby cytoplasmic macromolecules and organelles (e.g., mitochondria and endoplasmic reticulum) are enveloped within vesicles (autophagosomes) that subsequently fuse with lysosomes, resulting in the degradation of their contents.[302] Certain characteristics of primate luteal cells during regression are indicative of autophagy rather than apoptosis, including cytoplasmic vacuolization and the appearance of prominent lysosomes in the absence of nuclear degeneration.[300,301] Nonetheless, recent evidence suggests that the relationship between autophagy and cell viability is more complex. While under certain circumstances autophagy serves to initiate cell death independently from caspase activation and apoptosis, it can also facilitate cell viability by allowing for the recycling of damaged or nonfunctional macromolecules or organelles.[303] Reportedly, both apoptotic cell death and autophagy occur in the human corpus luteum following natural and induced (GnRH antagonist) luteolysis, whereas hCG supplementation blocked apoptosis but was without any effect on autophagy.[277] The expression of

Beclin 1 (BECN1), a key upstream initiator of autophagosome formation, is highest in the human corpus luteum during its development, peak function, and during early pregnancy, whereas BECN1 expression was absent during luteolysis.[304] Thus, the significant levels of BECN1 and autophagosomes during periods of peak progesterone production[277,304] support a role for autophagy not necessarily in cell death, but in maintaining luteal cell viability in primates. In contrast, markers of autophagy peak in the rat corpus luteum only as it undergoes spontaneous or $PGF_{2\alpha}$-induced luteolysis during pseudopregnancy.[305] Moreover, pharmacologic inhibition of autophagosome degradation increased rat luteal cell death in vitro, while in contrast, blocking autophagosome formation inhibited luteal cell death. Whether autophagy promotes luteal cell death or survival may be yet another example of a species-dependent process. Further research is needed to identify the forms of cell death and their regulation during luteal regression in a species-specific manner.

REGULATION OF LUTEAL STRUCTURE AND FUNCTION

It is well established that the ovulatory LH surge initiates many of the early events in luteinization; indeed, the LH-induced early rise in progesterone synthesis appears essential for a number of hormonal as well as local actions of progesterone ranging from controlling the strength and duration of the LH surge[306] to ovulation,[307] respectively. However, the luteinizing ovulating follicle rapidly becomes dependent on additional luteotropic support for development and maintenance of luteal structure and function, as evidenced by: (1) the undeveloped corpus luteum and ultrashort luteal phase following the LH surge in unmated, nonfecund rodents; and (2) the ability of LH antagonists to quickly suppress luteal development and function within 24 h after the LH surge in species with a short luteal phase (e.g., primates).[308] A widely accepted concept is that the functional lifespan of the corpus luteum after the LH surge is dependent upon a balanced, and often sequential, exposure to factors that either promote (luteotropins) or inhibit (luteolysins) luteal structure and function.[309] Again, species have evolved various mechanisms for controlling the corpus luteum. Thus, luteotropic or luteolytic factors may originate from within the ovary or corpus luteum, as well as from classical or nonclassical endocrine glands, such as the pituitary, uterus, and placenta.

Luteotropic Factors

The primary luteotropic hormones vary between species, but generally include PRL-[310] or LH-like[311] hormones from the pituitary or uterine–placental unit. However, vital complementary roles may be played by local factors such as ovary- or luteal-derived steroids or growth factors.

Prolactin-Like Luteotropic Hormones

As recently reviewed by Stocco, Telleria, and Gibori,[75] either PRL secreted by the anterior pituitary or PRL-like hormones from the uterine decidua and placenta are the essential luteotropins in rodents, such as the rat, depending upon the stage of the corpus luteum following ovulation (Figure 23.6). Their critical role is evident from *Prl* ($Prl^{tm1Hmn}/Prl^{tm1Hmn}$) or Prl receptor ($Prlr^{tm1Cnp}/Prlr^{tm1Cnp}$) null-mutant mice, in which ovulation and early luteinization occur, but progesterone levels are subnormal and the corpora lutea regress rapidly, resulting in sterility.[312,313] However, the defect in uterine decidualization, implantation, and early embryonic development

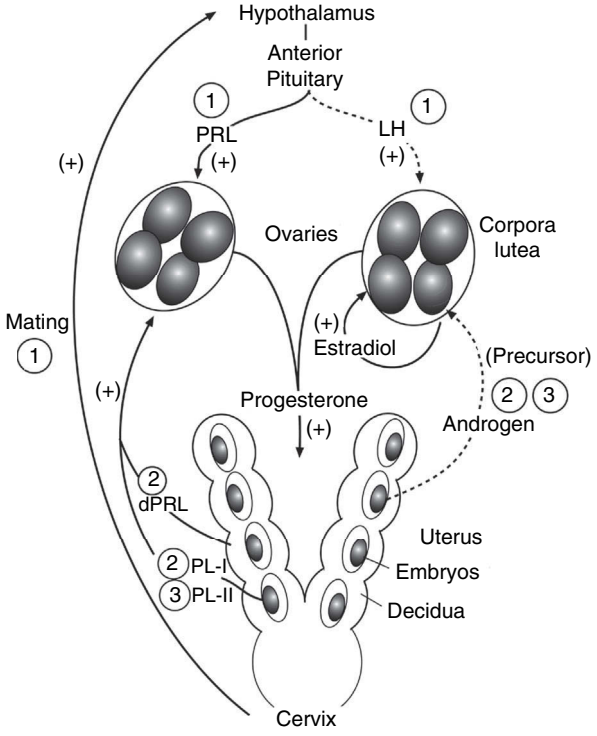

FIGURE 23.6 Diagram of the neuroendocrine, endocrine, and local mechanisms promoting luteal structure–function during early (1), mid- (2), and late (3) pregnancy in the rat. Three different sources of prolactin (PRL)-like hormones provide luteotropic support as gestation proceeds: (a) a neuroendocrine reflex arc activated by mating results in PRL release from the anterior pituitary; (b) by the second week of pregnancy, decidual prolactin (dPRL) can provide support; and (c) by mid- to late pregnancy, placental lactogens (PRL3D1, or PL-I; and then PRL3B1, or PL-II) are the primary luteotropins. Also, in early pregnancy, LH promotes production of the local luteotropin, estradiol. By mid- to late pregnancy, LH is no longer required because androgen from the placenta serves as a precursor for luteal estrogen production. Prolactin-like hormones and estradiol combine to maintain the functional corpus luteum throughout pregnancy, which is essential since the rat placenta is not a significant source of progesterone.

can be overcome by exogenous progesterone. Progesterone replacement does not, however, prevent fetal death at midpregnancy, suggesting additional vital roles for PRL within the uterus and placenta. Mating at estrus (i.e., stimulation of the cervix) activates a neuroendocrine loop that results in PRL secretion from the pituitary in two daily surges (one nocturnal, one diurnal) for 10–12 days.[70] It is experimentally established that pituitary PRL secreted during the first week of pregnancy or pseudopregnancy is solely capable of supporting luteal development and sustaining normal levels of progesterone secretion.[75] However, by day 7, pituitary PRL is no longer essential due to the expression of PRL-like luteotropins by the decidua and placenta.[75] From days 7 to 11, this activity appears to be a "decidual luteotropin", which according to recent data is identical in sequence and biologic activity to pituitary PRL.[314] Although capable of compensating for pituitary PRL, its role is probably comparable for decidual-derived PRL in primates (i.e., as a local "growth factor").[315] Nevertheless, by day 12, as pituitary PRL surges end and decidual PRL production declines, the pituitary is no longer essential for pregnancy maintenance.[75] Remarkably, the corpora lutea of pregnancy increase in mass, vascularity, and steroidogenic capacity due to secretion of other PRL-like factors, termed chorionic somatomammotropin hormones and known as prolactin family 3, subfamily d, member 1 (*Prl3d1*; commonly known as placental lactogen I), and prolactin family 3, subfamily b, member 1 (*Prl3b1*; commonly known as placental lactogen II).[316] Rat PRL3D1 is a glycosylated, 36–40 kDa protein produced by trophoblast giant cells that is only detectable in the circulation at midpregnancy. Rat PRL3B1 is a nonglycosylated, 25 kDa protein with a much shorter half-life that is also produced by the trophoblast giant cells. Onset of PRL3B1 precedes the decline in PRL3D1 expression in these cells, and circulating PRL3B1 levels rise from midpregnancy until parturition. It is now believed that both rat and mouse PRL3D1, as well as PRL3B1, bind to the PRL receptor and are sequentially responsible for maintenance of luteal structure and function in late pregnancy (as reviewed by Refs 75,317).

Thus, in rodents, such as the rat and mouse, PRL or PL binding to PRL receptors promotes luteal structure and function. Experiments in hypophysectomized rats suggest that between days 6 and 11 of pregnancy, LH also acts in concert with PRL to promote progesterone secretion.[318] However, subsequent studies suggest that the actual luteotropin is locally synthesized estradiol,[319] which results from LH-stimulated production of androgen by the ovary and corpus luteum that is aromatized to estradiol.[75] This absolute requirement for estradiol develops after the first week of pregnancy and it remains until parturition. But by midpregnancy, pituitary LH is no longer required because placental androgen production by trophoblast cells increases markedly and serves as a substrate for estrogen production by the ovary.[320] Although the rodent decidua and placenta produce PRL-like hormones, much like in primates,[315] there is no conclusive evidence that the former produces LH-like hormones, analogous to CG in monkeys or women.

The mechanisms of PRL action in the rodent corpus luteum are an area of active investigation.[321] The expression of species-specific numbers of long and short isoforms of the PRL receptor (PRLR-L and -S), is induced by luteinization,[321] and PRL itself may stimulate its own receptor's expression.[322] Until recently, PRL regulation of the rodent corpus luteum was thought to primarily involve PRLR-L.[321] But recent experiments on mice expressing only PRLR-L suggest that the short from is also required; critical defects in tissue matrix (collagen IV), angiogenic factors (VEGF), and microvascular endothelial cell organization were associated with the lack of luteinization.[323] Thus, as in the follicle,[321] PRLR-S as well as PRLR-L may impact the functional lifespan of the rodent corpus luteum.

Although the PRLR isoforms have identical extracellular domains, differences in the lengths and sequences of their intracellular domains lead to different signaling properties.[321] PRL-receptor signaling activates a number of signal transduction pathways, but most information to date originates from studies on PRLR-L activation of the Janus kinase 2 (JAK2)–signal transducer and activator of transcription 5A (STAT5) signal transduction system.[321] The importance of this pathway was established from dual *Stat5a* (*Stat5a*^{tm1Jni}/*Stat5a*^{tm1Jni}) and *Stat5b* (*Stat5b*^{tm1Jni}/*Stat5b*^{tm1Jni}) null-mutant mice that exhibit inadequate luteal function and infertility.[324] Several kinase pathways activated by PRL in other tissues warrant further evaluation (e.g., phosphatidylinositide 3-kinase (PI3)–protein kinase B (AKT), mitogen-activated protein kinase, C-Src,[75] and especially PKCdelta, which appears essential for PRL-stimulated relaxin expression in the rat corpus luteum).[325] PRL signaling through the short form of PRLR is poorly understood, but it is hypothesized to act as an inhibitor of PRLR-L function or to have other isoform-specific actions.[321]

PRL directly stimulates progesterone production in luteal cells by several mechanisms (for a review, see Ref. 75). First, PRL promotes steroidogenesis by upregulating enzymes involved in progesterone (CYP11A and HSD3B) and estradiol (CYP19A1) synthesis, as well as preventing progesterone degradation by inhibiting 20α-HSD activity through the reduced expression of the *AKR1C3* gene that encodes this enzyme.[326,327] Since the enzymes involved in progesterone production (i.e., CYP11A and HSD3B) are generally expressed in excess and are not rate limiting, the primary action of PRL appears to be total suppression of *AKR1C3* mRNA–20α-HSD activity, thereby preventing progesterone catabolism to the inactive progestin,

20α-dihydroprogesterone. Another enzyme that is regulated, notably by stabilization without affecting mRNA transcription,[328] is 17βHSD-7 (HSD17B7), which is involved in estradiol synthesis. This enzyme isoform was originally identified in the rodent corpus luteum at midpregnancy and term pregnancy as prolactin receptor–associated protein (PRAP) because of its association with the short form of PRLR.[329] A second and probably lesser mechanism of PRL action is to promote cholesterol availability from extracellular and intracellular stores, while promoting intraluteal cholesterol stores.[330] PRL increases the expression of HDL receptor (SCARB1), hormone-sensitive lipase, and sterol carrier protein 2 (SCP2),[331] and many of these effects appear mediated at the transcriptional level. Microarray experiments also identified new gene targets for PRL, which differ from those of LH, in the rodent corpus luteum.[331,332]

Less is known of the mechanisms where PRL regulates other luteal activities, thereby maintaining luteal structure and function. Since PRL promotes luteal expression of LH receptors,[333] enzymes involved in estradiol synthesis (as discussed here), and both ESR1 (ERα) and ESR2 (ERβ),[75] some of the effects are likely indirect and mediated by LH (e.g., STAR expression) or estradiol (e.g., angiogenesis[75]). Alternatively, some PRL effects may be direct, such as stimulation of proteases or their endogenous inhibitors (e.g., α2-macroglobulin[334]) or enzymes that scavenge oxygen-free radicals (e.g., superoxide dismutase[75]). Such actions may be important for stage-specific tissue remodeling and stability during luteal development and function, respectively. PRL may also influence cell hypertrophy either directly (e.g., via the induction of eukaryotic elongation factor 2 (EEF2), which promotes protein translation events[335]) or indirectly (e.g., via local synthesis and action of growth factors, such as IGF1, on large luteal cells[336]). However, much remains to be understood regarding the actions of PRL and PL in the corpus luteum at the physiologically relevant stages during the luteal lifespan of rodent species, as well as in other species where the corpus luteum is PRL dependent and sensitive.

Luteinizing Hormone (LH)-Like Luteotropins

Despite considerable controversy that extended into the 1980s, it is now generally accepted that following ovulation, the corpus luteum of many species, including domestic animals (e.g., sheep, cow, and horse[3]) and primates (monkeys to humans[337]), is primarily dependent upon LH from the anterior pituitary for the development and maintenance of luteal structure and function. Hypophysectomy,[338] administration of LH antisera,[339] or suppression of endogenous LH secretion[308] inhibits the corpus luteum, whereas co-administration of LH with such treatments can restore the normal functional lifespan of the corpus luteum during the nonfecund ovarian cycle. LH depletion and neutralization beginning within 1–2 days of ovulation can prevent the normal development of the corpus luteum, whereas treatment at midluteal phase will cause premature regression of the developed corpus luteum (for a review, see Ref. 307).

Nevertheless, there are likely differences in LH support of the corpus luteum between primate and nonprimate species, including acute regulation of progesterone secretion. In monkeys and women, pulses of secreted LH are entrained to increase progesterone secretion by midluteal phase, with steroid levels at baseline in the lengthening intervals between LH pulses by the late-luteal phase of the nonfecund cycle.[340] This, plus evidence that GnRH antagonist treatment rapidly and completely suppresses circulating progesterone levels (and causes early menstruation[308]), demonstrates the absolute requirement of primate luteal cells for LH exposure to maintain and stimulate progesterone secretion. In contrast, Diaz and colleagues[341] review evidence from cows and sheep that LH pulses are not entrained to progesterone secretion and that GnRH antagonist treatment only modestly (50%) decreases circulating progesterone levels in a stage-specific manner. Such findings suggest that a portion of luteal function in these domestic animals is not dependent on LH and is consistent with the concept that the developed corpus luteum contains a cell type (i.e., large luteal cells) that constitutively produces progesterone. The purported role of "constitutive" versus "LH-dependent" stimulation of luteal progesterone production between cell types during the luteal lifespan and between species warrants further evaluation (see the section Small versus Large Luteal Cells).

Despite this "constitutive activity", the corpus luteum in many domestic animals requires continual LH support until luteal function is no longer required to maintain pregnancy.[3] This interval in gestation may be relatively short (30 days in sheep), long (200 days in cow), or until term delivery (115 days in pig). In contrast, in many primate species, pituitary LH secretion is only required until late in the luteal phase of the fecund cycle. Thereafter, the LH-like hormone CG is secreted by trophoblast cells of the developing placenta, which extends the functional lifespan of the corpus luteum in early pregnancy.[54] CG is synthesized for a species-specific interval during gestation in primates, including throughout pregnancy in women.[65] The primary, although not sole (e.g., local uterine–placental[342]), action of CG is to sustain luteal structure and function for several days to weeks in early pregnancy until progesterone production is pronounced in the placenta. After this time (i.e., the luteal-placental shift), the ovary and corpus luteum is not required to maintain pregnancy in primates. Domestic animals do not typically produce a placental LH-like hormone, but the horse is a unique example. Although not likely the initial sustainer of luteal function in early pregnancy (see the section Small versus Large Luteal Cells), the mare placenta

begins to secrete large quantities of an LH-like hormone, originally termed pregnant mare serum gonadotropin (PMSG) and now referred to as equine CG (eCG).[3] The eCG induces ovulation of additional follicles that grow in intervals during early pregnancy and promotes the function of these secondary corpora lutea.[343] The corpora lutea secrete progesterone until eCG disappears from the circulation at 150 days of gestation, but luteal-derived progesterone is only essential until about day 70. Thereafter, progesterone support from the fetal–placental unit is sufficient to sustain pregnancy in mares.[344]

Pituitary LH, placental CG, and equine CG are members of the glycoprotein family of hormones that includes the pituitary follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH). Containing noncovalently linked α and β subunits with distinct glycosylation patterns (see a review in Ref. 311), the luteotropic LH–CG moieties bind with high affinity to one receptor (i.e., the LH–CG receptor), but not the FSH or TSH receptors. However, there is species specificity of the receptor, as primate LH–CG receptors (like primate GH receptors) have a much higher affinity for human LH or hCG than nonprimate gonadotropins.[345] Since the cloning of the LH–CG receptor,[346] considerable information has accrued on this member of the seven-transmembrane domain, rhodopsin-like, G protein–coupled receptor family.[347] LHCGR expression and hormone binding correlate with luteal function and circulating progesterone levels, as activity increases during luteal development and decreases during luteal regression in various species.[3] However, whether LHCGR levels directly influence luteal structure and function is less clear, in part because *Lhcgr* null-mutant mice (*Lhcgr*^{tm1Hht}/*Lhcgr*^{tm1Hht}),[348,349] as well as inactivating *LHCGR* gene mutations in women,[350] cause follicular defects and anovulation, which preclude analysis of luteal function. Also, the observation that few of the LHCGR need to be occupied for maximal steroidogenesis in the corpus luteum led to the concept of "spare receptors" for this luteotropin (see Ref. 3 for a review). Whether these receptors are really spare is unclear since signal transduction (e.g., cAMP production) continues to increase even though acute steroid production is maximal. There is speculation that this level of receptor occupancy and cAMP signaling is important for other aspects of luteal structure and function, especially in conditions of higher luteotropic support such as CG exposure in pregnancy.

G protein–coupled signaling though the LHCGR receptor involves activation of adenylate cyclase, production of cAMP, and activation of cAMP-dependent protein kinases (C kinases), which can have profound acute (steroidogenic) and chronic (structure–function) effects on the corpus luteum (see Refs 72,347 and Chapter 20 for reviews of signal transduction pathways). Although LH–CG can activate cAMP-independent pathways (e.g., phospholipase C–mediated synthesis of inositol-1,4,5 triphosphate (IP_3) and diacyl glycerol (DAG), leading to activation of protein kinase C (PKC) and intracellular calcium fluxes),[351,352] many of the effects of LH on steroidogenesis can be mimicked by exogenous cAMP and appear similar to those described here for PRL in rodent luteal cells (i.e., enhancement of lipoprotein (LDL) receptors and uptake, metabolism of stored cholesterol esters to free cholesterol, and promotion or maintenance of key enzymes such as CYP11A1 and HSD3B). However, there are two major differences between PRL–placental lactogen and LH–CG action in luteal cells of relevant species: (1) LH–CG does not regulate circulating progesterone levels by inhibiting its rapid metabolism by 20α-HSD; but, rather; (2) LH–CG action to acutely promote progesterone secretion involves rapid increases in STAR activity (via PKA-mediated phosphorylation), followed by a transcriptional effect to promote STAR expression. This mechanism, which remains an area of intense investigation, may be a critical site of LH–CG action in luteal cells of various species. Notably, STAR expression as well as that of key steroidogenic enzymes is sustained during prolongation of primate luteal function by CG treatment mimicking pregnancy initiation.[353,354]

There is much less known regarding the physiologic actions of LH via cAMP-independent pathways[347] or the nonsteroidogenic actions of LH to maintain luteal structure and function. Recent evidence suggests that the cAMP–PKA pathway is associated with morphological changes and regulation of apoptosis, whereas additional pathways (e.g., AKT- and ERK1/2) are also involved in LH–CG-regulated cell proliferation, differentiation, and survival.[355] Other pathways, including cAMP–PKA-dependent regulation of the pathways GSL3β–β-catenin[356] and MTOR–S6K1,[357] appear critical for various LH–CG actions. LH regulates a number of processes and proteins in luteal cells, including proteases and their inhibitors (i.e., MMPs, ADAMTS, and TIMPs[99,100,106]), cell–cell communication via gap junctions,[358] pro- and anti-apoptotic factors (e.g., MCL1[359]), and expression of other local (e.g., angiogenic[360]) or hormonal (e.g., relaxin[361]) factors. Investigators using differential display techniques or cDNA microarrays[354,362,363] are discovering novel or underappreciated LH-regulated pathways, such as the corticotropin receptor–binding protein (CRF–urocortin-R_1–R_2-BP) system in the monkey and human[364] corpus luteum, which are dynamically expressed and may regulate luteal structure and function.[365] Rigorous investigations of these genes and gene families and their proteins in the corpus luteum will increase our understanding of the complex systems controlling luteal structure, function, and lifespan.

Other Luteotropic Factors

There is growing evidence that the primary luteotropic hormones, PRL or LH, exert their actions, at least in part, through local synthesis and secretion of tropic

factors. These factors include steroids, peptide–proteins, and arachidonate metabolites.

Estradiol is an essential luteotropin for the maintenance of luteal structure and function in the rabbit (for a review, see Ref. 366), and also at a specific interval during pregnancy (days 7–11) in the rat.[75] Indeed, the corpus luteum of many species contains the classical nuclear estrogen receptor ESR1 and/or the recently discovered ESR2 (i.e., ERβ) form.[75] Experiments in gene-mutant mice suggest that estradiol can act via either ESR1 or ESR2 to influence luteal structure and function, but one cannot rule out effects predetermined by loss of estrogen action in the antecedent follicle.[367] Also, one cannot rule out the local actions of high estrogen levels on putative membrane receptors.[368,369] Estrogen's actions within the corpus luteum are not well defined, but there are limited reports that it enhances STAR expression and mitochondrial cholesterol transport in rabbit luteal tissue,[370] and SCARB1 expression, sterol content, and cholesterol transport (SCP2) capacity in rat luteal tissue.[75,371] One can hypothesize that estrogen synergizes with LH or PRL action to promote luteal structure and function. For example, LH-stimulated estrogen increases eukaryotic translation elongation factor 2 (EEF2) expression in rat luteal cells, and EEF2 is then activated by PRL, leading to a significant increase in luteal cell protein content.[335,372] Estrogen may also regulate luteal angiogenesis, notably at midpregnancy in the rat.[75] There is evidence for ER expression in endothelial cells[373] and estrogen regulation of angiogenic factors and their receptors,[123,374] such as that found in other vascular beds.

Since Rothchild[2] first proposed that progesterone itself is a local luteotropin in the mammalian corpus luteum, evidence (for a review, see Ref. 307) has accumulated for LH-induced transient expression of progesterone receptors (PGRA and PGRB) in the ovulatory, luteinizing follicle of many species, and continued PGR expression in the developed corpus luteum of many species with short- and long-luteal phases (from dogs to cows and primates). Studies in null-mutant mice established an essential role of *Pgra* ($Pgr^{tm1Omc}/Pgr^{tm1Omc}$), but not *Pgrb* ($Pgr^{tm2Omc}/Pgr^{t21Omc}$), in ovulation, but progesterone's role during luteinization appeared minimal.[375] Nevertheless, there are reports of progestin and antiprogestin effects in the rodent corpus luteum despite the absence of nuclear PGR.[376] Progesterone inhibited the expression of AKR1C3–20α-HSD (and hence suppressed progesterone metabolism) in rat luteal cells, and evidence was presented for this action via progestin binding to the glucocorticoid receptor.[377] Progestins may also have actions via plasma membrane receptors proposed to exist in granulosa and luteal cells[378] that prevent apoptosis and hence promote survival, but do not regulate progesterone secretion.[379] However, in species other than rodents, there are data suggesting that progesterone acts as a local luteotropin to promote luteal development and sustain luteal structure and function during the ovarian cycle and perhaps in pregnancy (for a review, see Ref. 307). In vitro and in vivo studies employing antiprogestins (e.g., RU486[380]) or progesterone synthesis inhibition and replacement (e.g., a HSD3B inhibitor with and without a progestin, R5020[381]) demonstrate a critical role for progesterone in controlling luteal structure and function as well as ovulation. Specific progesterone actions to control luteal tissue remodeling (e.g., protease expression[106]), health (suppression of apoptosis[380]), and sensitivity to other local factors (e.g., via ESR expression[382]) have been reported. Again, one can hypothesize that LH effects that are independent of progestin action and those that are mediated by LH-stimulated progesterone action synergize to control the development or structure–function of the corpus luteum in a species-dependent manner (Figure 23.7). Recent genome-wide analyses of the effects of LH ablation–replacement versus steroid ablation and progestin replacement in the corpus luteum (e.g., in primates[363]) are providing valuable databases for clarifying the roles of gonadotropins and steroids in luteal development and function. Further studies are needed to discern the role of progesterone and its potential receptor–signal transduction pathways in controlling the functional lifespan of the corpus luteum in species with short versus ultrashort luteal phases.

Direct effects of growth hormone (GH) on the ovarian follicle and corpus luteum were reported (see a review in Ref. 383), and there is some evidence that GH may be required for optimal luteal development. For example, both LH and GH were needed to obtain normal luteal weight and development in hypophysectomized ewes, although LH alone supported normal progesterone levels in the circulation.[226] Although there is some evidence for receptors for the metabolic hormones GH and insulin in luteal tissues, there is speculation that many of their effects pertain to GH-induced elevations in circulating IGF1 or IGF2, or local IGF production in response to luteotropic hormones.[384,385] There is evidence that IGF1 or IGF2 stimulates progesterone secretion by luteinizing granulosa cells or luteal cells from various species,[130,385,386] but the cellular mechanisms of IGF action in luteal cells have received little attention.[385,387] In the human, LH stimulation of STAR expression is enhanced by IGFs.[388] There are limited reports of IGF stimulating peptidergic activity (oxytocin production), production of angiogenic factors (VEGF), or expression of luteotropin receptors (e.g., ERβ in rat luteal cells), often in synergy with LH or PRL action. Significant advances have occurred in our understanding of gonadotropin control and dynamic expression of components of the IGF-R-BP (insulin-like growth factor binding protein 3) system within the follicle, and its integral role in influencing steroidogenesis and growth versus atresia of the maturing antral follicle.[389] It

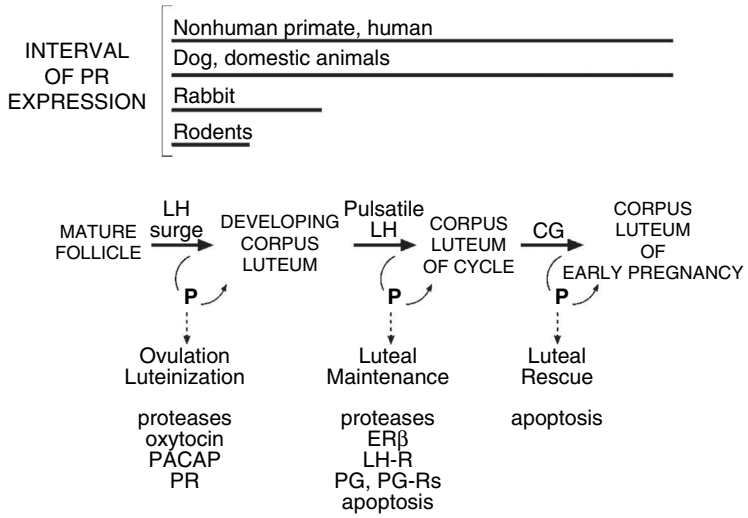

FIGURE 23.7 Schematic of the duration of "classical" progesterone receptor (PGR) expression in the corpus luteum of various species during its functional lifespan in the ovarian cycle and early pregnancy (top), with the hypothesis that LH–CG-stimulated synthesis of progesterone (P) generates a critical luteotropic factor essential for ovulation (in all species examined to date), development of the corpus luteum (except in rodents), maintenance of the corpus luteum during the ovarian cycle (in cows and primates), and extension of luteal structure and function in pregnancy (in cows and primates). Some of the gene products and processes identified as P-regulated pathways are listed. Growing evidence supports the concept of P as a local luteotropin.[2] Proteases include ADAMTS1, cathepsin L (rodent), and MMP1 (nonhuman primate). ADCYAP1: adenylate cyclase activating polypeptide 1 (pituitary). See text and other reviews[307] for further details.

is possible that similar dynamics of the IGF system play a role in the development and functional lifespan of the corpus luteum.[384] Further studies are needed to discern similarities and differences in the regulation and role of the species-specific IGF (e.g., IGF1 in rodents and IGF2 in primates)-R-BP system in the corpus luteum.[389]

Although investigations on eicosanoids have focused primarily on the luteolytic action of prostaglandin (PG) $F_{2\alpha}$ (see the section Vascular Endothelial Growth Factor), there is growing evidence that other PGs and arachidonate metabolites can have luteotropic or luteoprotective effects on the corpus luteum of various species. Notably, PGs of the E, I, and D series stimulate cAMP and progesterone by luteal preparations in vitro,[390,391] and can prevent spontaneous and/or $PGF_{2\alpha}$-induced luteolysis during local intrauterine or intraluteal administration in monkeys[392] and domestic animals (see Ref. 393). The concept of a balance between luteotropic versus luteolytic PGs controlling luteal development, structure and function, and lifespan[309] is supported by recent evidence from the bovine[393] and primate[394] corpus luteum such that components involved in PGE synthesis, transport and signaling (e.g., PGE synthase, PG transporter, and PGE receptor subtypes 2 and 3), are activated during luteal development and maintenance, whereas the PGF system (PGF receptor, or PTGFR) is activated at luteal regression. These data may explain the puzzling observation that infusions of a PG synthesis inhibitor can decrease circulating progesterone levels.[395,396] Further studies are needed on the putative luteotropic role of PGs (e.g., PGI[397] as well as PGE), the role on other arachidonate metabolites,[398,399] and their relationship to the luteolysin $PGF_{2\alpha}$ in controlling luteal structure and function. To date, the best evidence for a physiologic role of luteotropic PGs is the purported role of PGE_2 during early pregnancy in domestic animals (after interferon tau (IFNτ) declines and luteal resistance to $PGF_{2\alpha}$ is lost[400]; see the section Domestic Animals).

Luteolytic Factors

As elegantly reviewed by Niswender[3] and McCracken,[41] the concept of physiologically important luteolytic factors (i.e., those that promote the loss of function and structural involution of the corpus luteum) began with the observation by Loeb in 1923[31] that removal of the uterus (i.e., hysterectomy) lengthened the lifespan of the corpus luteum in guinea pigs. Subsequently, investigators reported that the timely demise of the corpus luteum was also delayed following hysterectomy in many species during pseudopregnancy (e.g., rat,[401] mice,[402] and rabbit[403]), or in other species that develop a functional corpus luteum during the nonfecund ovarian cycle (e.g., cow and sheep,[404] pig,[405] and horse[406]). There is variation among such species in the length of time that corpora lutea survive after hysterectomy, but luteal tissue will generally retain both structure and function for at least the duration of normal pregnancy. Nevertheless, the extended luteal function may be at a lower level than that achieved earlier in pseudopregnancy (rabbit) or the luteal phase of the estrus cycle (horse). In many, but not all,[3] such species, the luteolytic effect of the uterus

appears to be exerted locally. Removal of one of two uterine horns in many domestic[407] and laboratory[408] animals does not prevent timely luteal regression in the ovary adjacent to the intact horn, but prevents luteolysis on the other ovary. Therefore, it appears unlikely that the luteolytic factor is transported from the uterus to the ovary through the systemic circulation. Studies by Ginther[409] and others[41] suggest that the uterine luteolytic factor passes directly from the uterine vein into the ovarian artery in sheep and cattle, not through direct connections but a countercurrent mechanism that permits transfer between regions of extensive contact between these two vessels. Throughout the broad ligament, the vessels have thinner walls where they are in contact, they share a common tunica adventitia, and the ovarian artery is very tortuous on the uterine vein—all features consistent with venoarterial exchange.[409] However, in some species such as primates (Old World monkeys[63] and humans[64]) and dogs,[410] hysterectomy does not alter the normal lifespan of the corpus luteum. In such species, as well as those where the uterine luteolytic effect is not exerted locally, there is less contact between the uterine vein and ovarian artery.[411,412] Nevertheless, once the concept developed of a uterine luteolytic signal near the end of the nonfecund ovarian cycle, pseudopregnancy, or parturition in many species, investigators found it very difficult to elucidate the bioactive agent. It was not until the late 1970s, after considerable controversy, that there was general agreement that the uterine luteolytic factor was not a protein, peptide, or steroid, but rather $PGF_{2\alpha}$.[32]

Prostaglandin (PG) $F_{2\alpha}$

As reviewed by Sirois et al.,[413] prostaglandins (PGs) are lipid molecules that belong to the eicosanoid family, which also includes prostacyclin, epoxyeicosatrienoic acids, thromboxanes, leukotrienes, and lipoxins. They are derived from 20-carbon (C) polyunsaturated fatty acids, typically arachidonic acid. The various classes of PGs are synthesized through the intermediate PGH_2, which is generated via the action of prostaglandin synthase (PTGS) activity. There are two PTGS enzymes (PTGS1 and PTGS2), with the PTGS2 enzyme being the predominant isoform responsible for PG synthesis in the ovary. $PGF_{2\alpha}$ synthesis can occur via different routes, including: (1) direct conversion from PGH_2; (2) through the 9-keto reduction of PGE_2; and (3) through PGD_2 via 11-keto reductase activity. The enzymes responsible for the formation of $PGF_{2\alpha}$ from such varied substrates belong to the aldo-keto reductase (AKR) superfamily, primarily the 1C and 1B group.[414] AKR1B5, which is highly expressed in the bovine uterus, appears to be a major source of $PGF_{2\alpha}$ synthesis.[415] However, the level of contribution by other AKR family members is unclear, as their role in PG metabolism in the corpus luteum has not been studied in detail.

A major breakthrough occurred with the discovery that $PGF_{2\alpha}$, but not other PGs, caused premature luteolysis in pseudopregnant rats.[416] This observation was followed by evidence that: (1) exogenous $PGF_{2\alpha}$ had luteolytic effects in every species tested that depended on uterine control of the corpus luteum, except only to a limited extent in pigs[417]; and (2) $PGF_{2\alpha}$ synthesis and secretion are elevated in endometrial tissue during luteal regression,[418,419] plus pulses of $PGF_{2\alpha}$ release into the uterine vein (often detectable in the circulation) increase in frequency and amplitude during the onset of luteolysis in several species.[41,267] Critical evidence for a causal role of endogenous $PGF_{2\alpha}$ was derived from studies wherein nonsteroidal anti-inflammatory drugs that inhibit PG synthesis, such as indomethacin, or active or passive immunization to $PGF_{2\alpha}$, blocked spontaneous luteolysis during the estrous cycle and prolonged pseudopregnancy and pregnancy in domestic animals and rodents.[420,421] Evidence that null-mutant mice lacking the $PGF_{2\alpha}$ receptor ($Ptgfr^{tm1Aic}/Ptgfr^{tm1Aic}$)[422,423] do not display a timely preparturitional decline in circulating progesterone and fail to deliver, plus that this can be overcome by ovariectomy, supports a critical role for $PGF_{2\alpha}$ in signaling luteolysis.

The molecular and cellular mechanisms involved in controlling the synthesis and release of uterine $PGF_{2\alpha}$ during luteolysis remain to be fully defined. The endocrine action of $PGF_{2\alpha}$ between the uterus and the ovary, however, is clearer. As posited by McCracken[41] from studies in sheep (Figure 23.8), the following model emerged whereby changes in steroid sensitivity toward the end of the luteal phase: (1) stimulate the hypothalamic oxytocin pulse generator to increase the frequency of oxytocin release from the posterior pituitary; and (2) upregulate oxytocin receptors in the uterine endometrium. These combined effects lead to the release of low (subluteolytic) pulses of $PGF_{2\alpha}$ from the uterus, which are sufficient to cause release of oxytocin stores from the corpus luteum via $PGF_{2\alpha}$–PTGFR signal transduction. The supplemental release of luteal oxytocin amplifies the release of uterine $PGF_{2\alpha}$, resulting in large (luteolytic) pulses of $PGF_{2\alpha}$ that cause luteal regression. Moreover, Wiltbank and colleagues[424] proposed another amplification system in the corpus luteum, wherein small amounts of uterine $PGF_{2\alpha}$ stimulate intraluteal production of $PGF_{2\alpha}$ via induction of PTGS2. The positive-feedback loops between the uterus and corpus luteum, and within the corpus luteum, lead to sufficient $PGF_{2\alpha}$ action causing luteolysis. A similar amplification loop was also reported to be active in the corpus luteum of pseudopregnant rabbits.[425] It is noteworthy that luteal tissue in domestic animals acquires the ability for $PGF_{2\alpha}$-induced PGF synthesis at the stage when the corpus luteum first develops the capacity for $PGF_{2\alpha}$-mediated luteal regression (day 7 in cows and day 13 in pigs[424,426]).

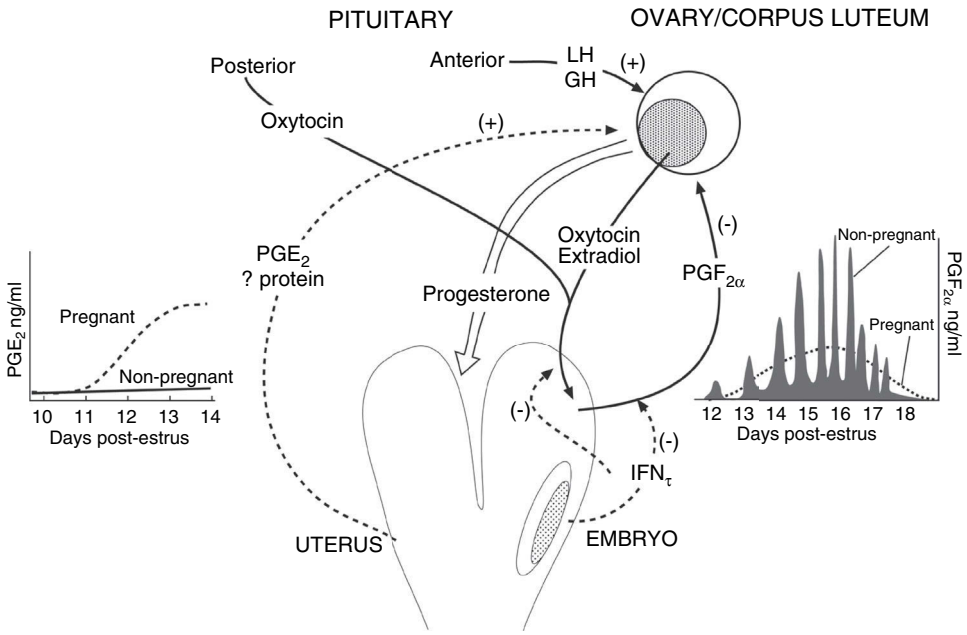

FIGURE 23.8 Model of the neuroendocrine, endocrine, and local mechanisms controlling the functional lifespan of the corpus luteum during the estrous cycle (solid lines) and during early pregnancy (dotted lines) in ruminants, such as sheep. During the cycle, the corpus luteum is controlled by luteotropic factors (luteinizing hormone (LH) and growth hormone (GH)) from the anterior pituitary and a uterine luteolytic factor ($PGF_{2\alpha}$) whose timely pulsatile release (right inset) is influenced by pituitary (oxytocin) and ovarian (steroids and oxytocin) hormones. Following implantation, embryo-derived interferon tau (IFNτ) prevents the pulsatile release of $PGF_{2\alpha}$, thereby preventing luteolysis in the fertile cycle. Also, secretion of PGE_2 (left inset) or unknown proteins from the uterus may promote luteal function during pregnancy. Hence, the corpus luteum continues to produce progesterone, which sustains intrauterine pregnancy. *Source: Adapted from Refs 3,428, with permission.*

The potential for $PGF_{2\alpha}$ to promote luteolysis is dependent on the responsiveness of several genes that are critical effectors of luteal function and luteolysis after a certain point in the luteal phase, including genes encoding angiogenic (i.e., *VEGF*, *VASHs*, and *FGF2*) and vasoactive factors (i.e., endothelin 1, angiotensin-converting enzyme, and endothelial nitric oxide synthase; discussed further in this chapter).[427] Since many other substances, including gonadotropins, progesterone, and cytokines, are proposed modulators of luteal or uterine $PGF_{2\alpha}$ production,[41,424] the precise manner in which the luteolytic signal is controlled remains incompletely defined.[424]

PTGFR, the receptor for $PGF_{2\alpha}$, is a G protein–coupled cell surface receptor with seven transmembrane domains.[413] It is one of the group 2 contractile PG receptors, which also includes PGE (PTGER1) and thromboxane A_2 receptors, thought to signal through $G_{\alpha q}$ and the phospholipase C pathway to increase intracellular Ca^{2+} levels. Although many studies in the 1970s reported specific $PGF_{2\alpha}$ ligand binding to luteal tissue preparations,[41] there have been relatively few studies on the expression and activity of PG receptor subtypes in luteal tissue since their discovery. The regulation of PTGFR expression in the corpus luteum through the luteal phase is species dependent,[261,394] but is generally present and capable of inducing luteolysis late in the ovarian cycle. There is evidence that PTGFR is expressed in the corpus luteum of many species,[429,430] including those lacking a uterine luteolytic mechanism.[394] Regarding the latter, a comprehensive analysis of the rhesus macaque transcriptome at different stages of the natural luteal phase revealed that PTGFR expression is dynamically regulated, wherein its expression is minimal during luteal development and the interval of peak progesterone synthesis, but then increases dramatically just prior to and during the period of luteolysis.[179,394] The level of change in mRNA expression in the macaque corpus luteum was greater for *PTGFR* than for any other gene. Likewise, rescue of rhesus macaque luteal function through the administration of increasing daily doses of hCG (i.e., in a simulated early-pregnancy model) prevented the spike in *PTGFR* mRNA levels that were routinely observed prior to and during luteolysis (NCBI Geo Accession GSE25335[354]). Collectively, these findings support the need for additional studies to establish the role that PTGFR signaling plays in the internal "self-destruct" mechanism proposed for primate luteolysis.[431]

The number of reports linking the Ca^{2+}–protein kinase C pathway to $PGF_{2\alpha}$ action in the corpus luteum is growing,[432] particularly in relation to antisteroidogenic effects and cell death.[261,433] Through the PKC-dependent activation of RAF1, $PGF_{2\alpha}$ stimulates the extracellular signal-regulated kinase (ERK) family of MAPKs,[434] which

in turn results in the phosphorylation and activation of ribosomal protein S6 kinase 1 (RPS6K1) signaling in steroidogenic luteal cells.[435] Inhibition of the mammalian target of rapamycin (MTOR) with rapamycin prevented $PGF_{2\alpha}$ stimulation of RPS6K1 and downstream mechanisms involved in cellular protein synthesis.[435] Other reports suggest that Ca^{2+}-dependent $PGF_{2\alpha}$ signaling via ERK interferes with gonadotropin upregulation of STAR expression and progesterone secretion through the activation of the transcription factor Yin Yang 1 (YY1), which inhibits STAR transcription through the recruitment of histone deacetylase 1.[436] $PGF_{2\alpha}$-dependent activation of ERK signaling was also reported to diminish the responsiveness of bovine luteal cells to IGF1 through the phosphorylation of insulin receptor substrate 1 (IRS1), a key intermediate in the insulin–IGF1 pathway,[387] and to increase the expression of the nuclear receptor NR4A1 (Nurr77), a transcription factor that is critical for increasing 20α-hydroxysteroid hydrogenase activity attributed to AKR1C3.[437] There is also evidence that $PGF_{2\alpha}$ increases expression of SOCS3, a member of the suppressor of cytokine signaling family, which can limit PRL–PL action by inhibiting the JAK2–STAT5 pathway.[438]

While the mechanisms responsible for PGFTR signaling are becoming more defined, the effector mechanisms of PTGFR stimulation in regulating luteolysis remain unclear, with several avenues proposed that range from reducing luteal blood flow to blocking the action of luteotropic factors, inhibiting steroidogenesis, and promoting cell destruction and tissue dissolution. Again, however, the effects may vary between species and differ between in vivo (e.g., intact tissue) and in vitro (e.g., dispersed, cultured cells) experimental systems. Based on its potent vasoconstrictor activity in various vascular beds, and evidence that exogenous $PGF_{2\alpha}$ can markedly decrease luteal blood flow in sheep,[439] it was originally proposed that one of the early, important actions of the luteolytic $PGF_{2\alpha}$ signal was to limit the influx of bloodborne nutrients and the like to the luteal tissue and the efflux of metabolic byproducts, thereby causing tissue damage and dissolution. However, other investigators did not observe early changes in total or regional (luteal) ovarian blood flow during spontaneous or $PGF_{2\alpha}$-induced luteolysis in rodents,[440] rabbits,[366] or domestic animals[41] when progesterone levels were first declining (up to 50%). Moreover, when blood flow is assessed soon (i.e., within an hour) after administration of a $PGF_{2\alpha}$ bolus or a $PGF_{2\alpha}$ agonist, an increase in blood flow was reported.[441] Studies were recently performed that allowed for a detailed characterization of the endogenous $PGF_{2\alpha}$ pulses that occur before, during, and following luteolysis in domesticated animal species.[442,443] More rigorous studies providing exogenous $PGF_{2\alpha}$ that mimic such endogenous pulses near the end of the luteal phase, however, had no effect on acute changes on luteal blood flow, suggesting that a single, large bolus of $PGF_{2\alpha}$ may elicit nonphysiological effects. There is little doubt that later decreases in blood flow, potentially initiated through the loss of capillaries and small vessels,[444] are associated with continued reduction in luteal function and tissue destruction. However, in vivo and in vitro evidence that $PGF_{2\alpha}$ can suppress progesterone production and antagonize luteotropic hormone action preceding the later reduction of blood flow points to other major actions in luteal tissue.

Current evidence suggests that $PGF_{2\alpha}$ induction of luteolysis can also occur via multiple, nonvascular effects. $PGF_{2\alpha}$ increases the percentage of steroidogenic cells progressing through the cell cycle, which is a prerequisite for the induction of apoptosis.[445] $PGF_{2\alpha}$ can also rapidly decrease luteal progesterone synthesis by inhibiting the intracellular transport (e.g., by decreasing the mRNA levels and activity of SCP2 in rodents[446]) and entrance of cholesterol into mitochondria (e.g., by decreasing the activity and expression of STAR in domestic animals and rodents[436,447]). It now appears that previous observations that $PGF_{2\alpha}$ inhibited lipoprotein-supported progesterone production by luteal cells[440] were not due primarily to lesions in cholesterol uptake or storage,[448] but rather to lesions in cholesterol delivery to CYP11A1.[440] Reports that transport-independent hydroxylated cholesterol substrates enhance steroid production by luteal tissue during spontaneous or $PGF_{2\alpha}$-induced regression support this concept. Nevertheless, there is evidence that $PGF_{2\alpha}$ causes a similar reduction in mRNA expression of some steroidogenic enzymes (e.g., *HSD3B* in the corpus luteum of sheep[449]). Moreover, in the rat corpus luteum, $PGF_{2\alpha}$ rapidly induces the transcription of the progesterone-degrading enzyme *AKR1C3*/20α–HSD.[75]

Although the ability of $PGF_{2\alpha}$ to serve as the luteolytic signal and cause of early loss of luteal function in many species is generally accepted, $PGF_{2\alpha}$ effects on individual cell types and their interactions with one another leading to the loss of luteal structure and cell death are less clear. The separation of actions on function and structure is obvious from in vitro studies where addition of $PGF_{2\alpha}$ suppresses steroidogenesis without reducing cell viability.[450] Morphometric and biochemical studies of cellular constituents also suggest that cell–cell interactions are important in luteal regression.[451] When steroidogenic cells (i.e., large and small luteal cells) isolated from the bovine corpus luteum are incubated without other luteal cell types (i.e., immune and endothelial cells), $PGF_{2\alpha}$ failed to inhibit progesterone production.[452] When endothelial and immune cells are included, $PGF_{2\alpha}$ reduced progesterone production and induced the synthesis of nitric oxide (NO) and other arachidonic acid–derived mediators (e.g., leukotrienes). In addition to the evidence suggesting that the "large" luteal cells are the predominant target for $PGF_{2\alpha}$,[453] there are reports that the

numbers of "small" luteal cells and microvascular cells decrease before any loss of large cells at luteolysis.[454] Evidence of apoptosis in small luteal cells and endothelial cells before large cells[62,433,455] supports this concept.

While the direct actions of $PGF_{2\alpha}$ on subsequent changes in luteal structure and function, such as induction of cell-signaling and effector pathways (e.g., PKC, death receptor family members, caspases, etc.), is of considerable interest in terms of mechanisms of $PGF_{2\alpha}$ action, it is likely that $PGF_{2\alpha}$ promotes the production of local luteolytic factors that also contribute to the functional and structural demise of the corpus luteum. The following are examples that serve as potential intraluteal mediators of a luteolytic program.

Vasoactive Factors: Endothelin and Nitric Oxide

Research conducted mostly over the past two decades, involving primarily domesticated animal species, supports an essential role for vasoactive substances in luteolysis. As reviewed by Miyamoto et al.,[456] several vasoactive pathways, including endothelin–endothelin receptor and nitric oxide systems, appear to be critical intraluteal factors involved in luteolysis. Moreover, endothelin and nitric oxide serve as effectors of the luteolytic program induced by uterine $PGF_{2\alpha}$.[427,457]

Endothelins (EDNs) are a peptide family consisting of three different members (EDN1, EDN2, and EDN3) and sarafotoxins, which were originally defined by their vasoconstrictive actions.[458] However, EDN1 has also emerged as a local modulator in regulating luteolysis, whereas EDN2 is implicated in control of ovulation and luteinization.[459,460] Research by Milvae, Meidan, and colleagues[460,461] suggests that EDN1 is an important factor controlling luteolysis in domesticated animal species. There is evidence that endothelial cells within luteal tissue are the primary sites of *EDN1* mRNA expression. However, *EDN1* is transcribed as a "prepro EDN1" molecule, and the active peptide is ultimately formed from the intermediate "big ET1" by the action of endothelin-converting enzyme (ECE1) on endothelial cells and luteal cells. Several reports indicate that the EDN1 receptor (EDNRA and EDNRB) system is present in the corpus luteum,[462] with the expression and differential regulation of each receptor subtype through the luteal phase being species dependent. At the time of luteal regression, the ovine and porcine corpus luteum expresses predominantly EDNRA,[463,464] whereas the pseudopregnant rabbit corpus luteum possesses both EDNRA and EDNRB.[465] EDNRA expression is consistently observed in luteal endothelial cells, whereas expression in both small and large luteal cells or only in small luteal cells is species dependent.[463,464] Thus, the microvasculature synthesizes precursor and big EDN1, but both luteal and endothelial cells can produce bioactive EDN1 and transduce EDN1 signals via receptor-mediated pathways. Moreover, Meidan and Levy[460] proposed that increased expression and activity of the EDN1 synthetic (ECE)–EDNRA system at the time of luteal regression explains the sensitivity of the corpus luteum to the luteolytic actions of $PGF_{2\alpha}$ during the latter half of the luteal phase. From a functional standpoint, there are reports that addition of EDN1 inhibits basal and/or LH-stimulated progesterone production by mixed or purified preparations of cells from the corpus luteum.[462] Notably, preincubation with an EDNRA antagonist not only prevented the effects of exogenous EDN1 but also blocked the antisteroidogenic effect of $PGF_{2\alpha}$ in luteal tissue slices.[466] In sheep receiving intraluteal EDNRA antagonist infusion via osmotic minipump, a luteolytic bolus of $PGF_{2\alpha}$ induces an acute (<24 h) reduction in serum progesterone concentrations that then recover to levels equal to those observed in saline-treated control animals.[463] Thus, inhibition of EDNRA-mediated signaling had no effect on the short-term actions of $PGF_{2\alpha}$, but inhibited its long-term luteolytic activity. Intraluteal infusion of an EDNRB selective antagonist, however, was unable to block $PGF_{2\alpha}$-mediated reduction in luteal progesterone synthesis. In vivo administration of the same EDNRA antagonist in cattle also prevented a drop in circulating progesterone levels and delayed functional luteolysis,[467] further supporting a role for EDN1 and EDNRA in regulating ruminant luteal lifespan.

Nitric oxide (NO) is another potent vasoregulatory substance that recently emerged as an important luteolytic factor. NO can be synthesized by three different nitric oxide synthase (NOS) enzymes (neuronal NOS1, inducible NOS2, and endothelial NOS3) that utilize L-arginine as a substrate.[468] Both NOS1 and NOS3 genes are viewed as constitutive, resulting in a level of NO synthesis that regulates vascular tone. In contrast, NOS2 is expressed in many cell types following an inflammatory stimulus in response to cytokines or prostaglandins, leading to the generation of large amounts of NO.[468] As reviewed by Shirasuna,[469] NO synthesis and participation in luteolysis were reported in rat, rabbit, cow, sheep, and human. In general, intraluteal NO is synthesized by inducible NOS2 and/or endothelial NOS3, depending on the species being studied. For example, NOS2 and NOS3 protein levels in the bovine and pseudopregnant rabbit corpus luteum increased from the early to late luteal phases, with expression being localized to both endothelial cells and luteal cells.[470] In the human and equine corpus luteum, however, NOS3 expression increased at the end of the luteal phase, while inducible NOS2 remained relatively constant.[471,472] *NOS2* and *NOS3* mRNA levels declined in the pseudopregnant rabbit corpus luteum toward the end of the luteal phase, whereas NOS3, but not NOS2, protein levels increased two fold through this interval.[473] Subsequent analysis of NOS3 expression revealed a heterogeneous pattern of

expression in bovine luteal tissue that appears when the corpus luteum becomes sensitive to the luteolytic action of $PGF_{2\alpha}$. In the early luteal phase, NOS3 was homogeneously distributed throughout the corpus luteum but became localized primarily to the periphery at the mid- to late luteal phases.[474] The redistribution of NOS3 to the periphery may be responsible for the increased localized blood flow in the same region noted shortly (<1 h) following the administration of a luteolytic bolus of $PGF_{2\alpha}$.[469] However, whether such an NO-dependent increase in peripheral luteal blood flow occurs during spontaneous luteolysis or when $PGF_{2\alpha}$ is administered to reflect its endogenous pulsatility remains to be determined.

$PGF_{2\alpha}$ is a key inducer of NO production in the corpus luteum of several species,[475–477] where resident endothelial cells appear to serve as the major site of synthesis.[457,469,478] The ability to recapitulate in vitro the induction of NOS activity following $PGF_{2\alpha}$-induced luteolysis in vivo is dependent on the presence of multiple cell types. Co-cultures of bovine aortic endothelial cells, smooth muscle cells, and luteinized granulosa cells synthesized significantly higher levels of NO in response to $PGF_{2\alpha}$ relative to those cultures that did not include luteinized granulosa cells.[476] Moreover, both NO and $PGF_{2\alpha}$ production in cultured luteal cells is induced in response to EDN1 stimulation, suggesting that an amplification loop exists between these three luteolytic factors.[479] Further support for a positive-feedback loop comes from rodent studies whereby the induction or inhibition of NO production resulted in increased or diminished synthesis of $PGF_{2\alpha}$, respectively.[475] As NO synthesis is known to occur in response to an inflammatory stimulus, it is not surprising that pro-inflammatory cytokines (e.g., TNF and IFNγ)[480,481] and arachidonic acid–derivied leukotrienes (e.g., leukotriene C_4)[482] also induce luteal NOS expression and NO production. NO synthesis increases in response to both TNF and IFNγ in isolated bovine endothelial cells, which, in turn, could be blocked by also including progesterone.[481] TNF- and IFN-mediated increases in NO production are associated with elevated *NOS2* mRNA levels.

Compounds that block NOS activity (or, in contrast, act as NO donors to increase NO concentrations in vitro or in vivo) have been valuable in terms of defining the functional aspect of NO involvement in luteolysis. Administration of an NO synthesis inhibitor during spontaneous and $PGF_{2\alpha}$-mediated luteolysis extended the functional interval or progesterone- and oxytocin-producing potential of the bovine corpus luteum.[470,483,484] The ability of a systemic dose of TNF, one that increases luteal $PGF_{2\alpha}$ synthesis, to reduce circulating progesterone levels and estrus cycle length can be inhibited by the co-administration of an NOS inhibitor.[485] As opposed to inhibiting NOS activity, injection of an NO donor into the bovine corpus luteum increased luteal blood flow in its periphery and reduced circulating progesterone levels as well as luteal phase length.[484] In cultured luteal cells, increased levels of NO through the addition of an NO donor resulted in elevated levels of intracellular Ca^{2+} as well as stimulated *FAS*, *BAX*, and *CASP3* mRNA levels.[486] A corresponding increase in CASP3 activity and apoptosis was observed following luteal cell culture with elevated NO levels, suggesting a role for NO in structural regression. Moreover, a similar increase in luteal cell apoptosis was observed in slices of human corpus luteum cultured in the presence of the exogenous NO substrate L-arginine.[487] While the majority of evidence to date supports a role for NO in both functional and structural luteolysis, conflicting reports by Weems and colleagues suggest a luteotropic role for NO. When an NOS inhibitor was infused via an intrauterine route ipsilateral to the ovine ovary possessing the corpus luteum, there was no delay in the loss in progesterone-producing potential or luteal weight during the ovine estrous cycle.[488] Moreover, the NOS inhibitor reduced the capacity of the uterus to convert PGE_2 to $PGF_{2\alpha}$, leading the authors to speculate that NO may be luteotropic in sheep.[489]

Further studies are warranted to determine if these conflicting results are due to differences between species, the route of administration, or the timing of administration. Moreover, little is known regarding the signaling mechanism through which NO affects luteal regression. In other cell types, NO functions by diffusing through target cell membranes, binding and activating soluble guanylate cyclases (e.g., GUCY1A2, GUCY1A3, and GUCY1B3), which in turn leads to elevated cyclic guanosine monophosphate (cGMP) levels. Increased levels of intracellular cGMP subsequently regulate phosphodiesterases, ion-gated channels, or cGMP-dependent protein kinases.[490] It is currently unclear which, if any, of these NO targets are activated in responsive luteal cells.

Collectively, data suggest that the EDN1 and NO systems, through their regulation by luteotropic and luteolytic hormones, play a local inhibitory role in the corpus luteum (Figure 23.9) and mediate, at least in part, $PGF_{2\alpha}$ actions during luteal regression.[460,462] However, key experiments remain to be performed, including investigations discerning whether modulating endogenous EDN1 and NO synthesis or action alters the function or lifespan of the corpus luteum during the natural cycle. Although limited evidence suggests that the EDN1–NO system is present in other species, including rodents and primates,[471,487,491–493] further studies need to address its importance beyond domestic animals. Finally, clarification is needed on the relative importance of $PGF_{2\alpha}$ action on luteal versus endothelial cells, and on the local amplification of $PGF_{2\alpha}$[341] versus EDN1 and/or NO[460] in the cascade of events leading to loss of luteal structure and function during luteolysis (Figure 23.9).

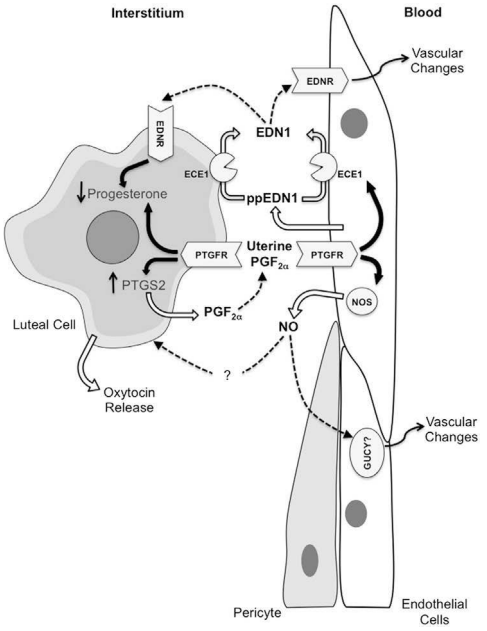

FIGURE 23.9 Diagram of proposed interactions between luteal cells and microvascular cells for the production and actions of local endothelin (EDN), nitric oxide (NO), as well as $PGF_{2\alpha}$ in response to the uterine luteolysin $PGF_{2\alpha}$. It is hypothesized that the initial $PGF_{2\alpha}$ signal is amplified or mediated by positive-feedback loops to increase intraluteal levels of $PGF_{2\alpha}$,[341] EDN1,[494] and NO,[457,469,478] which then alters luteal and endothelial cell function and causes tissue regression. Heavy black arrows: cellular responses to uterine $PGF_{2\alpha}$ through the activation of the $PGF_{2\alpha}$ receptor (PTGFR), including induction of the enzymes EDN-converting enzyme 1 (ECE1), nitric oxide synthase (NOS), and PG synthase 2 (PTGS2); white arrows: uterine $PGF_{2\alpha}$–induced luteal synthesis of preproEDN1, NO, $PGF_{2\alpha}$, and oxytocin; dotted lines: action of EDN1 and NO on luteal and endothelial cells (EDNR: EDN receptor; GUCY: guanylate cyclase, NO receptor); thin black arrows: possible luteolysis-promoting effects. *Source: From Ref. 74, with permission.*

Immunomodulators: Cytokines and Chemokines

Increasing attention has been directed at the cells of the immune system that, whether residing throughout or attracted at specific stages, comprise a significant portion of the luteal tissue (for reviews, see Refs 495,496). All types of leukocytes, with the exception of B cells, appear present with their relative numbers changing during the lifespan of the corpus luteum, sometimes in a species-specific manner. For example, neutrophilic granulocytes are at their highest density during luteal development in the rat (i.e., early pregnancy or pseudopregnancy), with considerable numbers also present at luteal regression.[497] In contrast, few neutrophils were detected in the pig corpus luteum,[498] and although they are present in the human corpus luteum, no differences in density were noted at luteolysis.[499] Eosinophilic granulocytes are relatively sparse in the rat corpus luteum,[497] yet infiltrate the ovine corpus luteum in large numbers after ovulation and are suspected to have a luteolytic role in sheep.[500] Likewise, the numbers of lymphocytic subtypes in luteal tissue, such as cytotoxic T cells ($CD8^+$), helper T cells ($CD4^+$), and natural killer (NK) cells, vary markedly between species. T cell subset distribution in the corpus luteum throughout its lifespan is best characterized in cattle. By using quantitative flow cytometry, Poole and Pate[501] observed a greater percentage of $CD8^+$ T cells than $CD4^+$ T cells in the corpus luteum, opposite of what is found in peripheral blood. Following the administration of a luteolytic $PGF_{2\alpha}$ dose, a significant increase in a subset of $CD8^+$ T cells ($CD8\alpha\alpha^+$) that possess greater immunoregulatory activity than cytotoxic potential was observed. The proportion of $CD8^+$ cells increased in the corpus luteum of early pregnancy relative to the corpus luteum of nonpregnant animals.[501] Moreover, the number of regulatory T cells (T_{reg} and forkhead/winged helix transcription factor 3 expressing cells ($FOXP3^+$) cells) that secrete immunosuppressive TGFβ1 dramatically declined following $PGF_{2\alpha}$ induction of luteolysis. In the human corpus luteum, B cells and NK cells were sparse to nondetectable,[499,502] although $CD4^+$ cells were abundant in several species, especially at luteolysis.[497,503] Macrophages are the cell type most consistently detected in the corpus luteum; these cells reportedly comprise more than 10% of all cells in human luteal tissue.[502] Moreover, an increase in macrophage density was detected in a number of species during luteal regression.[495,504]

In general, the changes in leukocyte cell density during the early and late luteal phases correlate with the tissue reorganization occurring during development and dissolution of the corpus luteum, respectively. Investigators related these events to an acute inflammatory response and tissue repair during ovulation and luteinization,[505] and an immune reaction and tissue elimination at luteolysis.[506,507] Major histocompatibility complex (MHC) class II proteins are expressed on the surface of bovine[508] and primate[509] luteal cells, which can be further enhanced by $PGF_{2\alpha}$.[508] In the rhesus macaque corpus luteum, levels of mRNA encoding both MHC class I and class II proteins increase significantly at the time of functional and structural regression.[179] Indeed, the increased expression of MHC class I and class II mRNAs and proteins is consistent with the induction of an immune response during luteolysis. However, limited evidence to date supports the physiologic relevance of local immune cells in controlling luteal function or lifespan, and MHC-II molecules could serve in alternate roles (e.g., as receptors triggering apoptosis).[510] This is due in part to difficulty in specifically modulating leukocyte numbers or action in the corpus luteum in vivo. One early approach to suppress macrophages and T lymphocytes with glucocorticoid administration yielded equivocal results in rabbits and rats.[511,512] Such approaches may be confounded by direct actions of glucocorticoids in luteal tissue via receptor-mediated pathways.[513] In an opposite approach, Bagavant and colleagues[514] noted that an exaggerated pro-inflammatory response and elevated cytokine levels in mouse ovaries

elicited through T helper cells were compatible with normal ovarian cyclicity, ovulation, and fertility.

Nevertheless, it is well established that leukocytes express a cell-specific array of cytokines, enzymes, and reactive oxygen species that promote the destruction of cells and ECM during tissue remodeling.[500,515] Alternatively, cytokines may act to stimulate or inhibit steroid synthesis, at least as demonstrated in numerous in vitro experiments.[516,517] Also, macrophages reportedly serve to eliminate dying luteal cells or cell fragments (apoptotic bodies) by phagocytosis.[518] Brannstrom and Friden[500] provide a useful schematic of potential luteotropic versus luteolytic actions of cytokines on cell types of the corpus luteum.

Numerous studies established that the cytokine TNF, a 17 kDa polypeptide, is produced in the ovary[519] and can have luteotropic or luteolytic effects depending upon the species, stage of the luteal phase, and local milieu.[261] Although perhaps produced by nonimmune cells, including endothelial and luteal cells, detailed studies in the pig[520] indicated that the luteal macrophage population secretes up to 100-fold greater quantities of bioactive TNF than other luteal cell types. In the bovine corpus luteum, TNFα and its receptors, TNFRSF1A (TNFR-I) and TNFRSF1B (TNFR-II), all increase during luteolysis.[521] TNF mRNA and protein, as localized by in situ hybridization and immunohistochemistry, respectively, are expressed in large and small steroidogenic cells as well as immune cells in the bovine corpus luteum.[278] TNFRSF1A and TNFRSF1B expression was also noted in the steroidogenic and immune cells, as well as endothelial cells, suggesting that TNF acts as a paracrine–autocrine mediator of luteolysis. In primate species, *TNF* gene expression peaks in the rhesus macaque corpus luteum during the period of functional regression,[275] which also is the interval of the luteal phase when isolated human luteal cells produce the most TNF.[522] Reports suggest that TNF inhibits luteal cell response to luteotropins, as judged from progesterone production in vitro, by the mid- to late luteal phase in rodents, domestic animals, and primates.[261] Moreover, TNF reportedly induces the death of microvascular endothelial cells from the bovine corpus luteum in vitro,[280] causes regression of blood vessels in the rabbit corpus luteum,[523] and augments IFNγ-induced death of luteal cells, including isolated endothelial cells.[282,524] Experiments on TNFR null mice ($Tnfrsf1b^{tm1Imx}/Tnfrsf1b^{tm1Imx}$)[283] suggest that *Tnfrsf1b* (TNFRII; lacks a death domain and is generally thought to mediate TNF's tropic functions, e.g., cell proliferation) deletion does not markedly alter ovarian function or reproductive capacity. However, *Tnfrsf1a* (TNFRI; possesses a canonical death domain) deletion caused numerous female reproductive defects, including early onset of puberty and premature cessation of ovarian cyclicity, with those that continued to cycle having prolonged diestrus intervals (see the section Luteolysis for an overview of TNFR-related family members and involvement in apoptosis). The prolonged diestrus may indicate a role of the TNFRSF1A system in luteolysis, but other defects in the antecedent follicle or hypothalamic–pituitary function cannot be ruled out. Nevertheless, evidence that exogenous TNF can cause functional as well as structural luteolysis[523,525] led investigators to propose that TNF interacts with $PGF_{2\alpha}$, as well as with EDN1 and NO,[472,526] to promote regression of the corpus luteum. Although TNF's signal transduction pathways in the corpus luteum remain to be resolved,[261,352] its effects include the suppression of luteotropic action and steroidogenesis.[283]

Chemokines, defined as a family of small cytokines with two adjacent cysteine residues (the C–C motif family), two cysteines with an intervening amino acid (the C–X–C motif family), or those that possess a single cysteine (the C motif family), exhibit selective chemoattractant and activating properties on leukocyte populations and are differentially distributed within the ovary.[527] For example, evidence suggests that interleukin 8 (IL8) promotes neutrophil accumulation and activation (e.g., elastase activity) and plays a critical role in gonadotropin-induced ovulation[528] and perhaps luteal development (e.g., angiogenesis).[529] The chemokine receiving the most attention to date, however, is chemokine (C–C motif) ligand 2 (CCL2, commonly known as monocyte chemoattractant protein 1, or MCP1), which attracts and activates T lymphocyte subtypes and monocytes–macrophages.[530] Increased *CCL2* mRNA and protein expression occurs in the corpus luteum of rodents, domestic animals, and primates during luteolysis.[531–534] Also, luteolytic agents such as $PGF_{2\alpha}$ increase CCL2 expression in luteal tissue either directly or indirectly via production of other cytokines.[535] $PGF_{2\alpha}$-mediated upregulation of CCL2 expression occurs in corpora lutea obtained at the end of the luteal phase[536,537] or in functional corpora wherein progesterone synthesis was inhibited.[537] The cellular sources of CCL2 are unclear, and there are conflicting reports regarding the ability of luteal cells to synthesize CCL2.[538,539] Isolated luteal endothelial cells cultured in the presence of peripheral blood mononuclear cells expressed significantly higher levels of CCL2 than when each cell type was cultured by itself.[540] Although $PGF_{2\alpha}$ did not affect the level of CCL2 expression in individual cell cultures or cocultures, these findings support a synergistic role of both cell types in the synthesis of CCL2 in the corpus luteum. Nevertheless, the data are consistent with the hypothesis that CCL2 promotes the influx of macrophages that occurs in aging luteal tissue and that these cells then play a role in the structural, if not earlier functional, demise of the corpus luteum. As proposed by Penny,[535] chemokines such as CCL2 may prove to be a paracrine link between hormonal and cellular events within the corpus luteum involving

steroidogenic luteal, microvascular endothelial, and immune cell types. While the chemokine CCL2 has received the most attention with regard to its potential role in luteolysis, there are in total 24 CC, 13 CXC, and 2C motif-containing family members that have yet to be studied in detail regarding their role in luteal biology, including luteolysis. Luo and colleagues recently analyzed the expression of the chemokines IL8, CXCL2, CCL2, CCL8, CCL4, and CCL11, as well as the chemokine receptors CCR1, CCR2, CXCR2, and CCR5 in the early- and late-stage ($PGF_{2\alpha}$-sensitive) porcine corpus luteum.[537] $PGF_{2\alpha}$ increased mRNA levels for all but *CXCL2* and *CCL11* genes in the late- but not early-stage corpus luteum. Thus, a careful examination of recently obtained genomic databases is warranted to fully characterize the scope of chemokine involvement in luteolysis in different species.[179,541–543]

Transforming growth factor β1 (TGFB1) is a multifunctional secreted protein that generally regulates immune function,[544] as well as cell survival and migration, through the Sma- and Mad-related proteins (SMAD) signaling pathway.[545] In addition to being synthesized by follicular cells,[546] luteal cell cultures produce high levels of TGFB1.[547] The transcription factor early growth response gene 1 (*EGR1*) mRNA and protein were induced in response to $PGF_{2\alpha}$ in bovine luteal cells in vivo and in vitro, which led to EGR1 binding to the TGFB1 promoter. $PGF_{2\alpha}$-induced EGR1 activation was associated with increased *TGFB1* mRNA and protein expression, which could be blocked by adenoviral-mediated expression of an EGR1 binding protein (NAB2) that inhibits its transcriptional activity. Moreover, luteal cells treated with TGFB1 displayed reduced progesterone secretion.[548] Through the classical SMAD signaling pathway, TGFB1 disrupted the potential of isolated bovine microvascular endothelial cells to migrate and form capillary-like structures when cultured on Matrigel.[549] Moreover, TGFB1 caused loss of cell–cell contacts and increased the permeability of confluent cells. Treatment of fibroblasts isolated from bovine corpora lutea with TGFB1 also induces laminin, collagen I, and MMP1 expression.[550] Collectively, these results suggest that TGFB1 promotes structural regression of the corpus luteum by destabilizing blood vessels, as well as by inducing fibroblast-mediated remodeling of the ECM. However, in other species such as the rhesus macaque, expression of TGFB1 and its receptor is highest in the corpus luteum of early pregnancy, suggesting a role in supporting luteal function.[551] Thus, further studies are needed to clarify the role that TGFB1 plays in luteolysis of other species.

Extension of Luteal Function in Early Pregnancy

Mammals have developed diverse means for ensuring that ovarian cyclicity returns in the event of a nonfecund cycle, yet providing adequate progesterone support if pregnancy ensues. In the simplest case (e.g., many carnivores and marsupials), gestation lasts as long as or is shorter than the normal lifespan of the corpus luteum in the ovarian cycle (see the section Long-Lived Corpora Lutea). In these animals with "long-lived corpora lutea", there is no need for the conceptus or mother to alter luteal function because the developed corpus luteum is destined to provide the necessary progestational support. However, most animals have evolved a means for keeping the functional lifespan of the corpus luteum "short" (i.e., less than necessary for successful pregnancy) in the nonfecund cycle to increase reproductive efficiency. The most extreme cases (see the section Ultrashort-Lived Corpora Lutea) are the reflex ovulators (e.g., the rabbit), which do not even ovulate unless mating occurs, and the spontaneous ovulators that do not form fully developed, functional corpora lutea unless mating occurs (e.g., mouse and rat). Earlier in this review, emphasis was placed on the complex and sequential roles of maternal and decidual PRL, placental PL, and ovarian–placental steroids (i.e., estrogen) in promoting the functional lifespan of the rodent corpus luteum during pseudopregnancy and/or pregnancy. However, other animals that develop a functional corpus luteum during the ovarian cycle evoked processes for extending luteal function if pregnancy ensues, by circumventing the luteolytic signal at the end of the cycle and/or by providing additional luteotropic support to maintain luteal structure and function. The mechanism whereby the developing conceptus (implanting blastocyst) extends luteal function is the critical event in "maternal recognition of pregnancy".[54,65] The corpus luteum may be a critical source of progesterone throughout pregnancy, or become unnecessary after the "luteal–placental shift" when the placenta replaces the corpus luteum as the primary source of progesterone. Domestic animals (notably the ruminants, such as sheep and cattle) and primates with short-lived corpora lutea provide excellent models for illustrating different approaches to extending luteal function in early pregnancy.

Domestic Animals

It is generally regarded that uterine exposure to progesterone during the 10–12 days following ovulation not only prepares the endometrium for implantation but also primes the mechanisms for production of the uterine luteolytic signal, $PGF_{2\alpha}$, if pregnancy does not occur. The proposed interaction between the posterior pituitary, uterus, and ovary to control the release and action of oxytocin and $PGF_{2\alpha}$ was alluded to earlier (see the section Luteolytic Factors). It is now well established that extension of the functional lifespan of the corpus luteum in the fertile cycle is due to production of an antiluteolytic factor from the developing conceptus. In sheep,

embryos transferred to synchronized recipients as late as day 12 post estrus will prevent timely luteolysis.[552] Hence, the critical period for maternal recognition of pregnancy in the sheep is days 12–13 of the cycle.[3] Evidence indicates that the conceptus secretes antiluteolytic activity, which is not an LH- or PRL-like luteotropin,[553] beginning around day 10, increasing through day 16, and becoming nondetectable by days 21–22. An important advance was the discovery by Bazer, Roberts, and colleagues[554,555] that the antiluteolytic substance in ewes is IFNτ produced by mononuclear cells in the embryonic trophectoderm.

Ovine IFNτ was originally called trophoblastin[556] or trophoblast protein 1 (TP1) because it is the first major protein secreted by the trophectoderm of the peri-implantational conceptus. This protein was subsequently identified as a type 1 IFN with potent antiviral, antiproliferative, and immunomodulatory activities.[554] There is a high sequence homology of IFNτ across ruminant species, where it apparently has a unique role in pregnancy initiation. There are multiple IFNτ isoforms that arise from multiple genes; however, their functional significance remains unclear since all IFNτ isoforms tested to date extend luteal function when injected into the uterine lumen at the appropriate time in ewes, cows, and goats.

The mechanisms of paracrine action of IFNτ to prolong the function of the corpus luteum is an area of intense research (Figure 23.8). It is well established that the high-amplitude pulses of luteolytic $PGF_{2\alpha}$ coming from the uterus in nonpregnant ewes are absent in fertile cycles.[41] IFNτ appears to act locally to prevent and/or alter the pattern of $PGF_{2\alpha}$ secretion.[557] Although basal secretion of uterine $PGF_{2\alpha}$ is higher in early pregnancy, the high-amplitude, episodic pulses of $PGF_{2\alpha}$ release do not occur. There is also evidence from some species that $PGF_{2\alpha}$ secretion may be directed into the uterine lumen rather than the bloodstream. IFNτ appears to interact with type 1 IFN receptors in the endometrium to block expression of estrogen and oxytocin receptors, and this action prevents estrogen and oxytocin responses and may be the primary event preventing uterine-induced luteolysis.[558] Although the primary action of IFNτ to prevent luteal regression may be at the uterus, there is evidence of an endocrine action to promote luteal resistance to $PGF_{2\alpha}$ and prolong the function lifespan of the corpus luteum.[559] Recent reports identified IFNτ-stimulated genes[560] and IFNτ-promoted lymphangiogenesis[561] in luteal tissue.

Since intrauterine, as well as venous, infusions of IFNτ alone can extend the lifespan of the ruminant corpus luteum,[560,562] some investigators believe that this is the only pregnancy recognition factor produced by the conceptus. However, others noted that the sensitivity of the corpus luteum to the luteolytic action of $PGF_{2\alpha}$ is reduced in early pregnancy.[563] Since the uterine endometrium secretes another PG, PGE_2, in greater amounts during early pregnancy[564] and PGE_2 infusion delays luteolysis,[565] it was suggested that this PG suppresses the luteolytic actions of $PGF_{2\alpha}$.[400] Further studies are needed to establish the potential endocrine roles of IFNτ versus PGE, perhaps via IFNτ promotion of intraluteal PGE and PGE receptor (PTGER) synthesis,[566] to prevent $PGF_{2\alpha}$ action in the corpus luteum and hence promote establishment of pregnancy. Again, species differences in maternal recognition of pregnancy exist even between domestic animals. Although the critical role for IFNτ appears valid for sheep, cows, and goats, the mechanisms are clearly different in pigs and horses.[567,568] The corpus luteum in the pig is required throughout pregnancy,[58] and it is hypothesized that PGE and/or estrogens (not IFNτ) secreted by the porcine conceptus prevent the luteolytic actions of uterine $PGF_{2\alpha}$.[568] A similar mechanism may occur in the mare, except the fetal trophoblast also begins to secrete an additional luteotropin (eCG; see the section Luteinizing Hormone (LH)-Like Luteotropins) that sustains the function of secondary corpora lutea until the time of the luteal–placental shift around day 150 of gestation.[344]

Primates

In primates, such as Old World monkeys and women, it is clear that the demise of the corpus luteum near the end of the nonfecund menstrual cycle is not due to a uterine luteolytic factor. Nevertheless, the factors responsible for luteolysis in primates remain an enigma. As reviewed by Zeleznik and Benyo,[337] research has focused on either a relative loss of luteotropic support (LH) or intraovarian luteolytic factors (estrogen or $PGF_{2\alpha}$). Although the frequency of LH pulses declines by midluteal phase,[340] subsequent studies demonstrated that this apparent reduction in luteotropic support does not cause luteolysis since the length of the luteal lifespan was unaltered if pulse frequency was not allowed to decline.[569] Nevertheless, considerable evidence suggests that luteal cell sensitivity to LH, including LH receptors or receptor isoforms,[570–572] LH-stimulated cAMP production, and cAMP signaling,[573] declines as the lifespan of the primate corpus luteum progresses; and incremental increases in LH are needed to sustain the normal functional lifespan of the corpus luteum in the menstrual cycle.[574] However, the intracellular mechanisms controlling LH sensitivity and its role in onset of luteolysis are unclear.

The lack of a uterine or pituitary role in signaling luteolysis led investigators to propose "self-destruct" mechanisms[51] whereby local factors that are synthesized in the ovary or corpus luteum lead to loss of luteal structure and function. Based on the ability of the primate corpus luteum to synthesize estrogen, plus reports that systemic or local delivery of estradiol induced premature

luteolysis, it was proposed that estrogen was the local luteolytic factor.[51] However, further studies investigating endogenous[575] and exogenous[576] estrogen actions did not support its physiologic or local luteolytic role. Difficulty in detecting appreciable levels of the classical estrogen receptor, ESR1, in primate luteal tissue further reduced enthusiasm for this scenario. However, the discovery of the β isoform of ER (ESR2) in primate luteal tissue[577,578] plus evidence that progesterone downregulates luteal ESR2 expression, which is highest at luteolysis in the monkey,[382] suggest that the issue of local estrogen action in the primate corpus luteum warrants reevaluation. Because primate luteal tissue synthesizes PGs,[579,580] a self-destruct scenario involving $PGF_{2\alpha}$ was also envisioned. Early in vivo studies yielded variable results, in part due to rapid metabolism, stage-specific sensitivity of the corpus luteum, or high levels of endogenous PGs in luteal tissue. A recent comprehensive analysis of individual mRNAs or proteins involved in PG synthesis, metabolism, and signaling[394] indicates that PGE_2 synthesizing (e.g., microsomal PGE_2 synthase 1) and signaling (PGE_2 receptor 3) peak during development and maintenance of the primate corpus luteum, whereas $PGF_{2\alpha}$ signaling (PTGFR) increases during functional luteolysis. The data support the concept that there is a shift from luteotropic (PGE) to luteolytic (PGF) PG action near the onset of luteal regression. Intraluteal administration of $PGF_{2\alpha}$ analogs induces premature luteolysis in monkeys and women.[392,581] Evidence of $PGF_{2\alpha}$ binding and PTGFR receptors in luteal tissue, plus antigonadotropic effects of $PGF_{2\alpha}$ on primate luteal cells in vitro,[582] support a direct action of this PG in the corpus luteum of the menstrual cycle. Nevertheless, without specific agonists and antagonists of individual PGs, it has been difficult to substantiate a physiologic role for endogenous $PGF_{2\alpha}$ in primate luteolysis. Following recent advances in our understanding of PG metabolism and action,[413] and the production of more selective inhibitors of PG synthesis and PG receptors, further studies are warranted to define the putative roles of luteotropic (PGE and PGI) versus luteolytic (PGF) PGs, and other arachidonate products, in the primate corpus luteum.

The causes of luteolysis in primates remain unclear, but it is generally believed that secretion of another LH-like hormone, CG, by the implanting blastocyst and the syncytiotrophoblast cells of the placenta is responsible for "rescuing" the primate corpus luteum near the end of the fertile cycle and extending luteal function in early pregnancy.[54,65] Administration of hCG to mimic the patterns and levels of endogenous CG elicits changes in the corpus luteum that are characteristic of maternal recognition of pregnancy: (1) the functional luteal lifespan is prolonged, and timely menstruation does not occur; (2) circulating levels of progesterone increase transiently and then decline as the time of the luteal–placental shift approaches; and (3) nonsteroidogenic activities, including relaxin and inhibin A production, also increase. Notably, passive or active immunization of nonhuman primates and women against CG produces infertility despite normal ovulatory menstrual cycles.[583,584] Thus, CG independent of any other embryonic factors appears capable of rescuing the corpus luteum of the menstrual cycle and converting it into that of early pregnancy.

Although CG secretion appears characteristic of pregnancy in all primates, the patterns and peak levels vary among humans, apes, and Old World and New World monkeys.[65] Peak CG concentrations circulating in women are 100–1000 higher than in baboons, macaques, or marmosets. Although CG is first detected in utero–ovarian venous and then peripheral blood around the time of implantation in all primates, the duration of placental production varies. In humans and apes, CG levels peak in the first trimester, then decline but remain at substantial levels throughout gestation. However, in baboons and macaques, CG levels decline to near or below the limits of detection by midpregnancy. In marmosets and squirrel monkeys, CG levels do not peak until midpregnancy and decline just before parturition. In addition, the forms of CG secreted by the implanting blastocyst and developing placenta may vary. There is evidence from assisted reproductive technology (ART) protocols in women that free βhCG was first detectable about 2 days before intact α-βhCG,[585] and that by the later stages of the first trimester and again at term pregnancy there is a relative excess of free αhCG when CG levels are declining. Research on the control of CG expression and secretion is limited by the difficulty of obtaining early primate embryos or placental tissue.[54] However, such studies are needed to understand the control of pregnancy initiation and early pregnancy loss in women.

CG is an LH-like glycoprotein hormone that shares the same α subunit (glycoprotein hormones, alpha polypeptide (CGA)) with pituitary LH (and FSH and TSH[311]). However, chorionic gonadotropin, beta polypeptide (*CGB*) genes are distinct from the LH beta gene (*LHB*), and it is proposed that the primate *CGB* gene evolved from an ancestral *LHB*-like gene through a single base pair (bp) deletion in exon III and a 2 bp insertion that extended the translated region of the C-terminal region. Thus, human LHB and CGB demonstrate remarkable similarity (85% homology) in the first 114 amino acids, but CGβ is unique from other glycoprotein hormone β subunits due to its 24–31 amino acid extension at the C-terminus. Also, their glycosylation with N-linked complex carbohydrates and sulfation vary between pituitary gonadotrophs and placental trophoblast cells. Consequently, hCGA and hCGB (but not LH subunits) contain terminal sialic acid residues, and are not sulfated like oligosaccharide termini on LH. These differences markedly influence the molecule's size and charge, as well as circulating half-life and bioactivity.

Again, for ethical and practical reasons, there have been few studies on the cellular and molecular changes during CG rescue of the human corpus luteum in early pregnancy. However, in every primate species studied,[54] evidence supports the concept that pituitary LH and placental CG share a common receptor that regulates luteal cells at least in part through stimulation of adenylate cyclase, to form cAMP and activate cAMP-dependent pathways (e.g., C kinases). Models simulating early pregnancy in monkeys and women via exogenous CG exposure provide some insight.[54,586] Morphologically,[587] there are rapid changes in granulosa luteal cells suggestive of rapid use of steroid precursors (fewer lipid droplets) and increased production of secretory proteins (more membrane-bound granules). In contrast, the theca luteal cells display changes suggestive of increased steroid precursor accumulation (more lipid droplets) and steroidogenesis (more agranular endoplasmic reticulum). However, the increased mass and steroidogenic (both progesterone and estrogen) activity are not apparently accompanied by a renewal of angiogenesis in the corpus luteum. There is little evidence that the marked decline in microvascular cell proliferation that occurs as the corpus luteum ages in the menstrual cycle is altered by CG exposure.[109,165] However, this does not rule out CG effects on the luteal vasculature either directly or via vascular-specific factors (e.g., ANGPT1 or ANGPT2[164]) to influence vessel structure and function (e.g., vascular permeability).

CG exposure results in divergent changes in luteal expression of mRNAs and proteins involved in steroid and peptide hormone production. In the monkey corpus luteum,[588] 7 days of CG exposure transiently stimulates progesterone production by enhancing the uptake and availability of cholesterol stores (e.g., LDL) for steroidogenesis, not by stimulating key enzymatic steps (e.g., CYP11A1 or HSD3B2). In contrast, CG markedly increases the expression and/or enzyme activity for androgen (CYP17A1) and estrogen (CYP19A1) production in primate luteal tissue.[588,589] Remarkably, although relaxin secretion by the primate corpus luteum increases in early pregnancy, it remains unclear whether CG directly or acutely exerts transcriptional or posttranscriptional control over relaxin expression from the *H2* (not H1) gene.[54] In a detailed analysis of changes in the macaque luteal transcriptome following 1–9 days of hCG exposure simulating maternal recognition of pregnancy,[354] levels of more than 1000 gene products (mRNAs) changed significantly compared to pretreatment control tissues. Further studies on such databases (transcriptomes and proteomes) are needed to clarify the direct versus indirect effects of CG exposure that transiently prevent luteolysis and extend the structure and function of the primate corpus luteum in early pregnancy. Consideration of the direct versus indirect effects of CG action must take into account the dynamics of LHCGR–effector systems in primate luteal tissue. Unlike in rodent systems, where a large bolus of LH or CG results in "downregulation" of gonadotropin receptors, the scenario in primate luteal tissue to high, rising levels of CG appears different. Although many of the LHCGRs became occupied, there was a remarkable constancy in the total receptor population as the duration and level of CG exposure increased.[54,590] Nevertheless, homologous desensitization of adenylate cyclase became apparent, as cAMP production in response to LH or CG (but not PGE_2 or forskolin) became severely impaired.[591,592] It is possible that uncoupling of LH–CG receptor–signal transduction via cAMP is important for the transient progestational response of the corpus luteum to continued CG exposure in early pregnancy. However, the continued response to local luteotropic factors, notably PGE_2[592] or progesterone,[593] may promote luteal structure and function.

Given that LH continues to circulate in the late luteal phase of the menstrual cycle, it remains unclear why or how another LH-like hormone (i.e., CG) rescues the primate corpus luteum in early pregnancy (for a review, see Ref. 54). Based on studies on cells and membranes from nonprimate species, it was initially proposed that there were differences in receptor movement or turnover following binding of human CG versus ovine LH that prolong CG action (e.g., progesterone production) by luteal cells. That LH–CG receptors in monkeys and women demonstrate a unique specificity for primate gonadotropins[345] emphasizes the need for further studies in relevant species.

Although initial studies employing macaque granulosa cells did not support the concept of different kinetics for hLH versus hCG promotion of progesterone production,[594] recent reports using human cell systems suggest that LH and CG differ in their potency and chronic ability to stimulate cAMP and progesterone secretion[355] and the activation of signaling pathways.[355,595] For example, hCG appears more potent in cAMP production (and hence steroidogenesis), whereas hLH is more potent in ERK and AKT activation to promote cell proliferation or survival during luteal development. However, Zeleznik[596] presented data suggesting that administration of increasing amounts of recombinant hLH, as well as hCG, around the expected time of implantation increased progesterone levels and prevented timely luteolysis during the menstrual cycle in macaque monkeys. These data are consistent with the concept that CG's ability to rescue the primate corpus luteum is due to qualitative and quantitative differences in the circulating gonadotropin support between LH (intermittent pulses with intervals of gonadotropin deprivation) and CG (continuous, increasing levels) near the end of the nonfecund versus fertile cycle. Further studies are needed to discern how CG prevents timely luteolysis in the fertile cycle and whether luteal regression after the

luteal–placental shift involves similar processes as in the nonfecund cycle.

LUTEAL CELL TYPES AND THEIR REGULATION

Small versus Large Luteal Cells

Many years ago, investigators proposed that the corpus luteum consisted of at least two types of luteal cells based on differences in size, morphology, and staining properties.[597] In domestic animals, the "large" luteal cells contain more smooth and rough endoplasmic reticulum, mitochondria, extensive Golgi apparati, and secretory granules than "small" luteal cells—features that are consistent with greater steroid and peptide–protein hormone production by large cells (for a review, see Ref. 3). The often-stated opinion is that the large cells are derived from the granulosa layer, whereas the small cells originate from the theca layer of the luteinizing follicle. This concept has not been definitively tested, although Meidan and colleagues[598] report that pharmacologically induced luteinization of granulosa and theca cells in vitro results in many of the characteristics of large and small luteal cells, respectively. However, limited evidence suggests that this concept is an oversimplification. Using monoclonal antibodies (Abs) to granulosa and theca cell surface antigens, Alila and Hansel[599] determined that small luteal cells bound theca-specific Abs, whereas large luteal cells bound either granulosa-specific or theca-specific Abs. Moreover, the percentage of large luteal cells that bound granulosa-specific Abs declined, whereas those that bound theca-specific Abs increased, as the bovine corpus luteum aged. This evidence suggests that small luteal cells become large luteal cells as the lifespan of the corpus luteum progresses. But whether this scenario: (1) implies further cell differentiation as well as hypertrophy, within discrete large cell subtypes; or (2) is conceptually relevant to other species, including primates with compartmentalized theca–luteal and granulosa–luteal cells in luteal tissue, is not clear.

Studies in several species indicate that the number and size of luteal cells change during the lifespan of the corpus luteum. In general, the numbers and sizes of steroidogenic luteal cells increase as the corpus luteum develops (e.g., during the early to mid-luteal phases in domestic animals and primates; for a review, see Ref. 600), whereas their numbers and size decline during luteal regression near the end of the cycle. It is likely that increases in luteal cell number and size along with vascular development (increased endothelial cells; see the section Luteinization) influence corpus luteum activity after ovulation, as these events parallel the rise in circulating progesterone levels. Moreover, the removal of granulosa cells from the preovulatory follicle markedly reduced luteal mass and serum progesterone levels (but not luteal lifespan) in domestic animals[601] and primates.[602] These studies established the critical importance of granulosa-derived luteal cells in the progestogenic function of the corpus luteum during the ovarian cycle.

However, it appears that marked changes in function occur in luteal cells before changes in cell number or size at luteolysis. Moreover, morphometric evaluations of cellular constituents in a limited number of species suggest that cellular destruction does not occur simultaneously in all cell types during luteal regression. For example, small luteal cells and endothelial cells were the first cell types to decrease in the sheep corpus luteum, followed by the loss of large luteal cells.[454] However, because luteolysis also involves a decline in cell size (e.g., as a result of loss of lipid droplets or apoptosis), it is difficult to establish whether large luteal cells actually disappear or no longer meet the size criterion. Again, differences appear evident in species with compartmentalized luteal tissue. In primates, notably the human, it was suggested that luteolytic changes first occur in the granulosa-derived luteal tissue. Sasano and Suzuki[603] observed that the number of granulosa luteal cells decreased, whereas the paraluteal region of theca luteal cells remains prominent and steroidogenically active in the corpus luteum near the end of the menstrual cycle.

Function and Regulation of Luteal Cell Types

Despite the caveats of identifying luteal cells on the basis of size, which clearly varies between species and during the lifespan of the corpus luteum (for a review, see Ref. 600), considerable progress in characterizing luteal cell types was made by Niswender,[454] Hansel,[604] and others[341,494] when they separated cells from luteal tissue of domestic animals based on differences in cell size and density. Consistent with fine structural analyses of cellular organelles, the large luteal cells (≥20 and 30 μm diameter in sheep and cows, respectively) secrete 10- to 30-fold more progesterone than small luteal cells (<20 and 17 μm diameter), but the presence of cholesterol precursor (e.g., LDL) is required to sustain this difference during longer term incubation in vitro. The higher progestogenic activity of large luteal cells in sheep is associated with greater expression of CYP11A1 and HSD3B enzymes, and mitochondrial cholesterol transport is elevated. The mechanisms responsible for maintaining this high steroidogenic activity are not well defined; Bogan and Niswender[605] suggest that it is due to tonically active protein kinase A and phosphorylated STAR in ovine large luteal cells. Other reports indicate that the large luteal cells of various species are the primary, although not necessarily exclusive, producer of relaxin and/or oxytocin.[230] This research suggests that large luteal cells can produce more than one hormone (e.g., they are dual secretors of steroid

and peptide–protein hormones). Taylor and colleagues[606] identified four subpopulations of large luteal cells in the pig by combining chemical and hemolytic plaque assays to detect steroid and relaxin production.

Small and large luteal cell preparations that differ in steroidogenic activity were also prepared from the corpus luteum of other species (e.g., rodents, rabbits, and primates; for a review, see Ref. 600). In monkeys, the 30- to 40-fold greater level of basal progesterone production by large luteal cells compared to small luteal cells is similar to that observed in other species. However, small three- to fourfold differences were generally observed between small and large cells from the human corpus luteum.[607] A critical unanswered question is how these large and small luteal cell preparations in primates compare to the compartmentalized luteal and paraluteal cells observed in situ.[195,196] Evidence indicates that basal estrogen production by all luteal cells is low, with only the large cells having the capacity to convert exogenous androgen to estrogen. Thus, the large cells contain aromatase (CYP19A1), which is also localized to the true luteal cells in the tissue parenchyma. One might expect the small luteal cells, which in other species are thought to be of thecal origin, to correspond to the exteriorized paraluteal cells that contain $P450_{C17}$ (CYP17A1) for androgen synthesis. However, androgen synthesis was 10-fold greater in large versus small cells from the monkey corpus luteum,[608] with reports on human luteal cells yielding conflicting data.[609,610] These data and histologic observations[587] suggest that size alone cannot distinguish between luteal and paraluteal cells in the primate corpus luteum. Rather, the large cell population may be composed of highly steroidogenic (both progestogenic and either androgenic or estrogenic) cells of both granulosa and theca origin (as proposed from the original work of Alila and Hansen in sheep[599]). The origin and ultimate fate (e.g., to differentiate further into large cells as the corpus luteum ages) of small luteal cells in the primate corpus luteum remain speculative.

There are also marked differences between small and large luteal cells in their responsiveness and receptor levels for luteotropic and luteolytic factors.[611] For example, ovine large cells are minimally responsive to gonadotropin (LH), cAMP, or other activators of the protein kinase A pathway, whereas small cells respond with up to a 10-fold increase in progesterone production.[341] Related observations and calculations led to the proposal that in sheep, the chronically elevated steroidogenic activity of large cells is "constitutive" (i.e., minimally regulated by ongoing hormone exposure) and responsible for 80% or more of the secreted progesterone. LH exposure may increase progesterone levels somewhat through acute actions on small luteal cells, but may also sustain levels through the conversion of small "less active" to large "high steroidogenic" luteal cells.[612] However, $PGF_{2\alpha}$ appears to have early luteolytic actions through the large luteal cells. In domestic animals, such as sheep and cows, large luteal cells express much greater levels of PTGFR receptors than small luteal cells.[341] It appears that $PGF_{2\alpha}$ activates the phosphatidyl inositol (PI) pathway, with both branches of PI signaling (i.e., elevated intracellular CA^{2+} levels and protein kinase C (PKC) activation) occurring primarily in large cells.[341] A scenario is proposed by Hoyer[433] and Niswender[611] that uterine $PGF_{2\alpha}$ reduces progesterone secretion and increases oxytocin and $PGF_{2\alpha}$ production by large luteal cells. The decline in intraluteal P levels permits oxytocin action on small luteal cells to increase intracellular Ca^{++} levels and subsequent apoptosis. Luteal-derived $PGF_{2\alpha}$ also activates Ca^{++} channels in large luteal cells that may result in apoptosis. Thus, the interplay between uterine $PGF_{2\alpha}$ and locally produced oxytocin and $PGF_{2\alpha}$ on different luteal cell types may be critical for timely functional and structural luteolysis.[611,613]

Although the sheep and cow are excellent large-animal models for preparations of luteal cells, important species differences in the hormone responsiveness of luteal cell types are likely with rodents and primates. For example, although small luteal cells typically respond to LH-like hormones, there are reports that large luteal cells also respond (e.g., in rats[614] and women[615]) or are more responsive (e.g., in rhesus monkeys[616]) than small luteal cells. This issue requires further investigation. Some differences may be technique related, for example the human corpus luteum is difficult to disperse into cell preparations, such that the prevalent use of harsh proteases (e.g., trypsin) likely alters cell responsiveness or causes cell damage. This may explain why steroid production in vitro by large versus small cells from women is reportedly much less than that of other species. However, Brannian and colleagues[617] used similar techniques to isolate cell types from the sheep and monkey corpus luteum and confirmed species differences. As expected, small cells from the ovine corpus luteum were much more responsive to LH than large cells; however, the opposite was observed for the monkey—large luteal cells were more responsive to LH. This difference, if validated (detailed studies on LH–CG receptors and gonadotropin-activated signaling pathways in primate luteal cell types are limited), could relate to the apparent differences in the luteotropic roles of LH-like hormones in ruminants versus primates. Although elimination of endogenous LH support (using a GnRH antagonist) only modestly reduces (up to 50%) circulating progesterone levels in cows[618] or sheep[619] depending on the stage of the luteal phase, it causes complete and rapid suppression of progesterone levels and early luteolysis at all stages of the luteal phase in primates.[574,620] Likewise, the entrainment of LH pulses to progesterone secretion by the midluteal phase of the menstrual cycle, with steroid levels at baseline in the lengthening intervals between LH pulses by the mid- to late luteal phase,[340] demonstrates: (1) the continued absolute requirement of primate luteal

cells for LH-like hormone; and (2) the absence of any luteal cell type that constitutively produces progesterone. These findings would suggest that both small and large luteal cells in the primate corpus luteum respond to LH and CG during the menstrual cycle and at recognition of early pregnancy, respectively.

The effects of other luteotropic or luteolytic factors, and the possible dynamics of cell responsiveness or receptor signaling during the luteal lifespan, have received less attention. It was proposed that LH-stimulated estradiol production in the rabbit corpus luteum leads to estrogen action on both small and large cells to promote progesterone production.[621] There are limited reports of different steroidogenic responses of small and large luteal cells from rodent corpora lutea to PRL,[622] notably PRAP (HSD17B-7)[75]; it is exclusively expressed in large luteal cells. Large luteal cells in sheep have greater numbers of GH receptors than small cells,[341] whereas small, but not large, luteal cells from women responded to GH with enhanced progesterone production.[607] There is also evidence that luteal cell responsiveness to LH, but not the local luteotropin PGE_2, decreases in large (as well as small) cells as the monkey corpus luteum ages.[616] Whether or how such changes assist in regulating the functional lifespan of the corpus luteum in various species requires further investigation. After considerable effort to isolate and characterize luteal cell types in the 1980s through the mid-1990s, this research area received less attention in recent years in part because of: (1) the vagaries in arbitrarily defining cell types based on a variable (i.e., size or diameter), which changes during the lifespan of the corpus luteum and in response to luteotropic or luteolytic factors; and (2) the lack of established markers (e.g., cell surface proteins) to identify and separate luteal cell types. Nevertheless, new information on differences between "small and large"[181] or granulosa- versus theca-derived[623,624] luteal cells, as well as endothelial, immune, and stromal-like cells,[385,625] continues to increase our understanding of the cell heterogeneity within the corpus luteum. As global gene and epigenetic[626] protein expression or novel tissue micromanipulative techniques (e.g., laser capture microdissection) are applied to the corpus luteum, a better perspective will be obtained on the origins, dynamics, and interactions between luteal cell subpopulations that are important for the functional lifespan of the corpus luteum during the ovarian cycle and pregnancy (Figure 23.10).

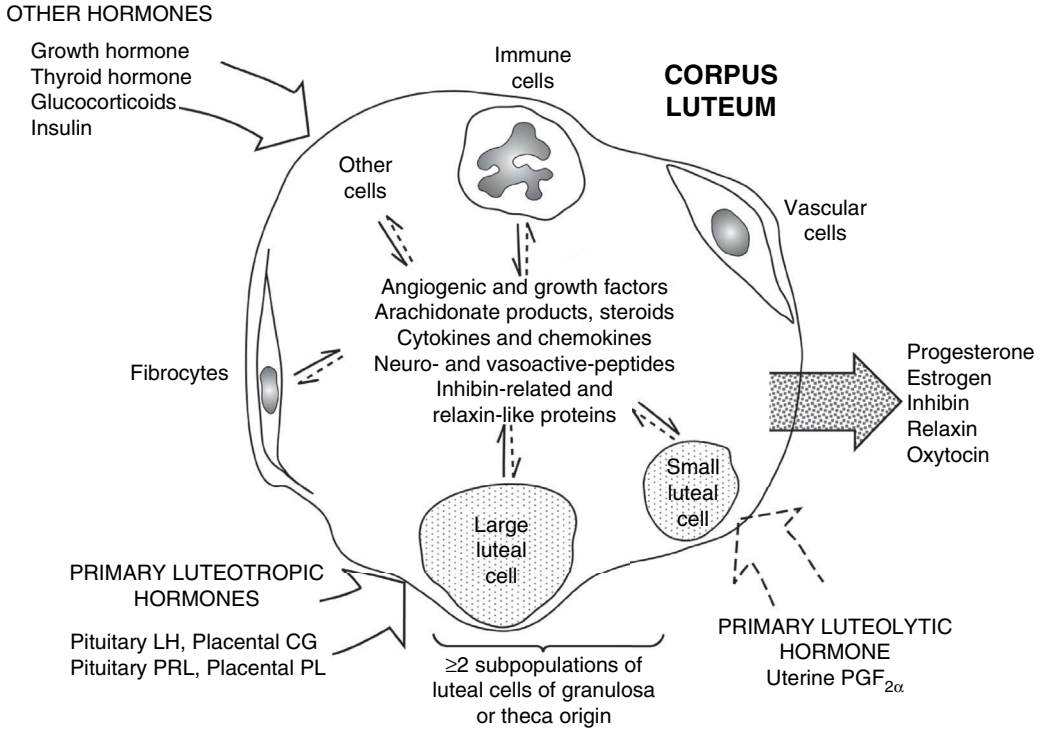

FIGURE 23.10 Conceptual summary of the multiple cell types in the corpus luteum, the luteotropic and luteolytic hormones regulating luteal structure and function, and the categories of products that may serve as autocrine or paracrine regulators of the corpus luteum as well as secreted hormones. Solid open arrows denote hormones from the pituitary, placenta, and other endocrine glands that promote the development, function, and/or lifespan of the corpus luteum, whereas the dotted open arrow depicts the uterine luteolysin $PGF_{2\alpha}$. Line arrows denoted secretion (solid) by or action (dotted) on cell types within the corpus luteum. The gray open arrow denotes hormone secretion from the corpus luteum. As evident from the text, this composite corpus luteum does not exist in nature, as species evolved mechanisms relying on various hormones and local factors for their specific niche in reproduction. *Source: Adapted from Ref. 76.*

CONCLUSION

The past two decades provided major increases in our knowledge of the processes that promote luteal development, the cellular components and control of steroidogenesis, and the mechanisms involved in extending luteal function in early pregnancy (Figure 23.10). Likewise, information has accrued on the cellular actions of luteotropic hormones and luteolytic $PGF_{2\alpha}$, and the possible role of local factors in controlling luteal structure and function. Nevertheless, many issues need to be resolved at the systemic, cellular, and molecular levels to understand the activities of the corpus luteum and its regulation by endocrine and local factors. The identification of genes that are exclusively or preferentially expressed in ovarian compartments at specific stages of the reproductive cycle,[627] and the initial results from global gene microarray analyses,[628] portend rapid advances in identifying novel or underappreciated processes in the corpus luteum. Because of the corpus luteum's origin from the follicle, traditional gene deletion techniques may be difficult to interpret; however, advances in acute, conditional, and tissue-specific gene knockout approaches, as well as "knockdown" approaches using antisense oligonucleotides or siRNAs, should provide valuable tools for analyzing the roles of genes and gene products in the corpus luteum. Likewise, the advent of basic and clinical proteomics will impact ovarian biology in the near future. Recognizing the myriad of species differences in the control of the corpus luteum, a comparative database will be essential for future applications to improve or control fertility for such purposes as preserving endangered species, controlling species with burgeoning populations, improving the efficiency or quality of food (meat) production, and treating ovarian disorders in women's health. The ovarian biologist will continue to find a plethora of intriguing problems and hypotheses for testing to understand this unique gland, the corpus luteum, which is essential for intrauterine pregnancy.

Acknowledgments

Appreciation is expressed to those who kindled the author's interest in this field—Drs David Schomberg, Gary Hodgen, Harold Behrman, Ernst Knobil, Gordon Niswender, and Irv Rothchild. Also, the input of other outstanding scientists, especially through their recent, timely reviews as cited in the text, is noted, including Drs Roger Short, John McCracken, Geula Gibori, Bruce Murphy, Rena Meidan, Jerome Strauss III, David Sherwood, Richard Ivell, Bo Rueda, Jonathan Tilly, Tony Zeleznik, Milo Wiltbank, Mats Brannstrom, and Fuller Bazer. Due to space limitations, many appropriate references could not be included; the reader is encouraged to read other timely and historical reviews plus the relevant literature for an in-depth appreciation of the advances and issues in this field. The scientific and intellectual contributions of the students, fellows, and collaborators to Drs Stouffer's and Hennebold's program are gratefully acknowledged. Support for Drs Stouffer and Hennebold during preparation of this review was provided by the Oregon National Primate Research Center (P51 OD011092). A special thanks to Ms. Traci Lea for her assistance in preparing this manuscript.
