Carbon tetrachloride, beta-naphthol, hexylresorcinol, niclosamide, dichlorophen, and (primarily) tetrachloroethylene were the drugs used for the treatment in the early days.

Praziquantel at dosages of 40, 25, and 15 mg kg^{-1} was given to school-age children heavily infected with *F. buski* for the first time in central Thailand. Even administered at the lowest dose of 15 mg kg^{-1}, it showed to be highly efficient. As no side-effects occurred, a single praziquantel dose of 15 mg kg^{-1} at bed time was recommended for children. Praziquantel treatment was also highly effective in school-age children with severe fasciolopsiasis in Taiwan. In Indonesia, infection in children was treated with 30 mg kg^{-1} of praziquantel with minor side effects. However, this drug could not save the life of a heavily infected 20-year old woman.

A single dose of praziquantel at 15 mg kg^{-1} is, therefore, the treatment of choice nowadays. The pharmacological termination of *F. buski* infections are both effective and low-cost. A single-dose of the broad-spectrum anthelminthic praziquantel is given to school-age children in endemic areas, which together with the prevention of reinfection, is aimed at improving the children's health at a crucial time in their growth and development.

The efficacy of triclabendazole, oxyclozanide, and rafoxanide was recently evaluated in naturally infected pigs, based on fecal egg count reduction tests and clinical improvement. On the 28th day after the treatment, triclabendazole showed the highest efficacy (97.12%), followed by oxyclozanide (93.27%) and rafoxanide (83.17%). None of these anthelmintics exhibited any side-effects in the treated animals.

Detection and Management for Food Safety

Attention should be focused on the metacercarial stage. Metacercarial cysts on plants are visible to the naked eye. The cysts average 3.9/2.1 mm. Up to 200 cysts may be found on the skin of one water caltrop, but the usual number is approximately 15–20.

Dried aquatic plants are not dangerous because dessication kills the metacercariae. Metacercariae are very sensitive to dryness, which causes death of metacercariae in 19 h at 27 °C. Metacercariae are killed by direct solar radiation in 20–30 min. People need to be instructed not to soak the fruits in water every once in a while to preserve their freshness. There should be sufficient time between the time the fruits are harvested to the time they are sold in the market to make them safe.

Prevention of infection might also be accomplished if the aquatic plants and their fruits are immersed in boiling water for a few minutes. Aquatic plants such as water chestnut should be boiled for 1–2 min before eating to kill the encysted metacercariae on the plants. Moreover metacercariae are killed after 1 min in boiling water, in 1% HCl in 18 days, by 2% acetic acid in 9 days, by 3% acetic acid in 6 days, by 5% salt solution in 3 h, by soybean sauce in 30 min, and by 10% cane sugar in 3 days.

Peeling the plants and fruits and washing in running water to wash away the freed metacercarial cysts should also be considered as a preventive measure.

Disease Control

The control of *F. buski* infections is theoretically very simple and the most practical method is to avoid eating raw, water-derived food. However it is extremely difficult to enforce such a simple method in face of century-old traditions. Such measures demand fundamental changes in the eating habits, customs, and economic conditions of the people. Infections with *F. buski* follow a familial trend, as food preparation and eating habits are passed from one generation to the next. In addition, water plants are common food source because they are cheap and readily available (**Figure 9**).

The nature of fasciolopsiasis does not justify the establishment of a separate control program, because it can be controlled along with other food-borne parasitoses for which there are sustained control programs, such as those launched by the World Health Organization (WHO). Control of fasciolopsiasis by blocking or interruption of the parasite life-cycle can be achieved through proper diagnosis followed by pharmacological treatment of people and their livestock, and by preventing reinfection. In countries where eating raw plants is customary and treated water is not available, the prevention of reinfection relies on consistent educational propaganda stressing the importance of thoroughly cooking all aquatic plants and boiling all water.

The most easy way to control fasciolopsiasis is by pharmacological treatment and the implementation of modern pig farming. Control measures include prevention of pollution of the ponds where water caltrop, water chestnut, and other aquatic plants are cultivated. Pollution of the ponds happens in different ways in the various endemic areas. Human excreta are used as fertilizer in China, promiscuous

Figure 9 Uncontrolled food plant markets in city streets contribute to the dissemination of the disease to people who do not necessarily live in the countryside.

defecation takes place in the bodies of water near the houses in Thailand, and excreta of pigs are washed into neighboring bodies of water in Taiwan.

Pigs easily acquire this disease because they are often fed with infected raw vegetables. Thus, the plants must always be checked for the presence of metacercariae, the greatest numbers being found from May to October. The use of fermented silage to feed pigs instead of fresh aquatic green fodder has been suggested to prevent infection in the animals.

Eggs cannot survive anaerobic conditions but may resist low temperatures and be maintained at 4 °C for 3–4 months.

Educational efforts should be directed primarily toward school-age children because they are less entrenched in their food and eating habits, behavior, and customs. Significant changes in the control of intestinal helminthiasis rely on the development of effective broad-spectrum anthelminthics and the implementation of control programs in school-aged children with strong community therapy programs.

In Taiwan, fasciolopsiasis was highly endemic in the past, but in the 1980s the number of human cases decreased. The aggressive education programs in Taiwan included lectures and demonstrations of *F. buski* flukes in primary schools and during home visits. Although the reduction in the number of cases was recognized in their endemic regions, this tendency was not stable, because many cultures, particularly in China, still enjoy eating raw food products. In addition, there is a belief that cooking food destroys the flavor and nutritional value. The simplest control measures in endemic areas should include boiling water, thorough cooking or steeping of aquatic plants in boiling water, restraining pigs from having access to ponds and canals, eliminating intermediate host snails, and prohibiting the use of unsterilized "night soil" as fertilizer and aquatic green fodder for pigs. Unfortunately, despite WHO control programs implemented and sustained in the communities, fasciolopsiasis still remains a public health problem in endemic areas. Furthermore, in areas where it was thought to be fully controlled, as in Uttar Pradesh, India, where no case was detected since the 1990s, there are reports of a re-emerging infection in recent years.

Fasciolopsiasis, together with other food-borne trematodiases, have been very recently added to the list of priority helminthiases and food-borne zoonoses with high impact on human development, within the so-called neglected tropical diseases (NTDs) by WHO. This decision assures targeted action against this disease in endemic Asian countries for the years to come.

HELMINTH-TREMATODE

Heterophyes heterophyes

J-Y Chai, Seoul National University College of Medicine, Seoul, Korea

Glossary

Cellophane thick smear technique A method of fecal examination to detect helminth eggs. Approximately 60 mg of feces is placed on a glass slide and a cellophane paper soaked with glycerin and malachite green is put on the feces. The feces under the cellophane are compressed to become flat and dried before microscopic examination.

Kato-Katz thick smear technique A method of fecal examination to detect helminth eggs. The feces are sampled by filtering through a fine mesh and used to fill a small premade hole on a plastic plate which is placed on a glass slide. The plastic plate retaining the feces (41.7 mg) on the slide is carefully removed. A cellophane paper soaked with glycerin and malachite green is used to cover the feces. The feces under the cellophane are compressed to become flat and dried before microscopic examination.

Niclosamide An anthelmintic drug used for the treatment of a wide spectrum of helminth infections, including many species of trematodes and cestodes.

Praziquantel An anthelmintic drug used for the treatment of a wide spectrum of helminth infections, including almost all species of trematodes and many species of cestodes.

Background

The trematode family Heterophyidae (=heterophyids) includes a number of minute intestinal trematodes (or flukes) infecting humans and animals. The genus *Heterophyes*, one of the members, was created by Cobbold in 1866. The adult flukes of *Heterophyes*, together with *Heterophyopsis*, have a peculiar genital apparatus which is called a 'genital sucker,' and this character is comparable with and distinct from other genera of the Heterophyidae. Within the genus *Heterophyes*, at least 17 species or subspecies have been reported (Table 1). However, only eight species, including *Heterophyes aequalis*, *Heterophyes bitorquatus*, *Heterophyes chini*, *Heterophyes dispar*, *Heterophyes heterophyes*, *Heterophyes nocens*, *Heterophyes pleomorphis*, and *Heterophyes superspinatus*, are acknowledged as valid species. The species known to infect humans include *H. heterophyes*, *H. nocens*, and *H. dispar*. Heterophyiasis is a disease caused by infection with species of *Heterophyes*. The disease is prevalent in the Far East, the Middle East, Egypt, Sudan, and southeastern Europe.

Characteristics

Morphologic Characters of *Heterophyes*

Heterophyes flukes are characterized by their minute body (0.4–2.7 mm long), a large and median located ventral sucker, presence of a genital sucker armed with gonotyl, and two adjacent testes near the posterior extremity (Figure 1). *Heterophyes* flukes are morphologically distinguished from other heterophyids, including *Heterophyopsis*, *Metagonimus*, *Pygidiopsis*, *Centrocestus*, *Stellantchasmus*, *Haplorchis*, *Procerovum*, and *Stictodora*, by various features. *Heterophyes* differs from *Heterophyopsis* in that the latter has an elongated body and also two obliquely tandem testes. *Heterophyes* differs from *Metagonimus* in that the latter has a smaller submedian located ventral sucker and the genital sucker is absent. *Pygidiopsis* differs from *Heterophyes* in that the former has a small ventral sucker connected anterolaterally to a ventrogenital apparatus but lacks the genital sucker. *Centrocestus* is armed with small circumoral spines around the oral sucker and lacks the genital sucker. *Stellantchasmus* has a small laterally deviated ventral sucker and an elongated sac-like seminal vesicle connected to a muscular expulsor at the opposite side of the ventral sucker and lacks the genital sucker. *Haplorchis* and *Procerovum* have only one testis, whereas *Heterophyes* and other heterophyids have two testes.

Important Species

H. heterophyes

H. heterophyes was first discovered by Bilharz in 1851 at an autopsy of an Egyptian in Cairo, and is now known to cause human infections along the Nile Delta of Egypt and Sudan, the Middle East, and southeastern Europe. *H. heterophyes* adults are 0.4–2.7 mm long and their unique morphology includes the presence of two side-by-side testes near the posterior end of the body, a large ventral sucker which is located median, and a large submedian genital sucker armed with 70–85 chitinous rodlets on its gonotyl. *H. heterophyes* differs from *H. nocens* in the number of rodlets on the gonotyl; 50–62 in *H. nocens* versus 70–85 in *H. heterophyes*. The adults of *H. dispar* (0.4–1.4 mm) are slightly smaller in body size and

Heterophyes indica	No	India	Rao and Ayyar (1931)
Heterophyes inops	No	Egypt	Looss (1902)
Heterophyes katsuradai[c]	Yes	Japan	Ozaki and Asada (1926)
Heterophyes pallidus	No	Egypt	Looss (1902)
Heterophyes persicus	No	Egypt	Looss (1902)

[a]Human infections were reported from Koreans who traveled to Saudi Arabia or Sudan.
[b]Human infections were reported from inhabitants of Egypt, the Middle East, and the Mediterranean, and also from several Koreans who traveled to Saudi Arabia or Sudan.
[c]Regarded a synonym of *H. nocens*.

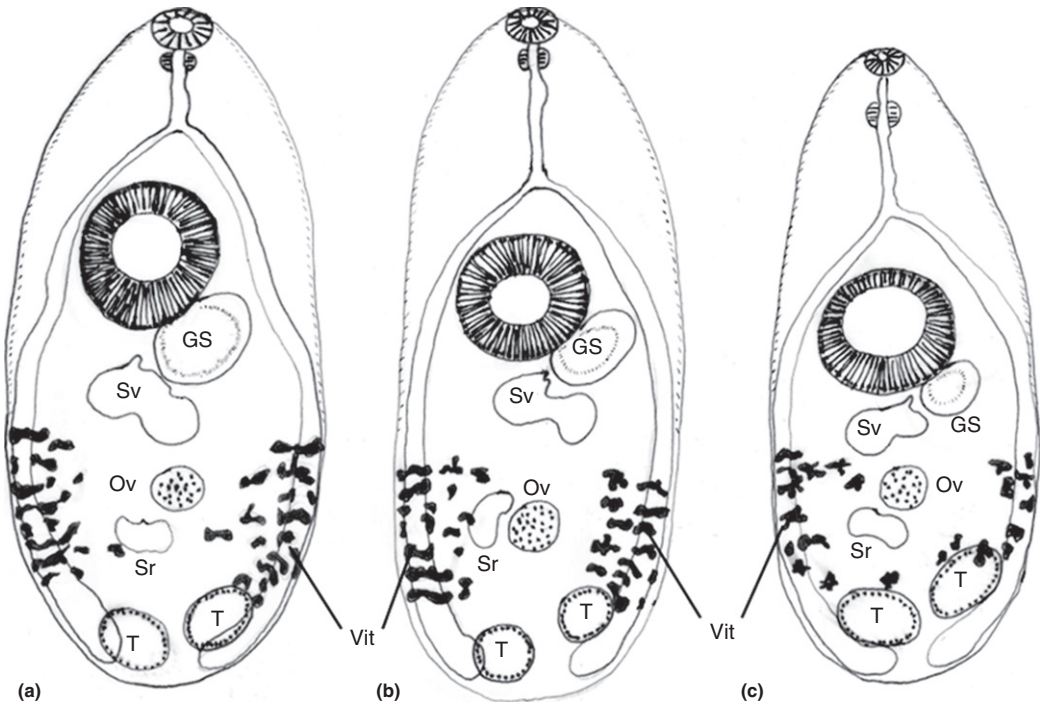

Figure 1 *Heterophyes* spp. infecting humans. (a) *Heterophyes heterophyes*; (b) *Heterophyes nocens*; (c) *Heterophyes dispar*. GS, genital sucker; Ov, ovary; T, testis; Sv, seminal vesicle; Sr, seminal receptable; Vit, vitelline follicles.

have smaller sizes of the genital sucker and smaller numbers of rodlets on the gonotyl (22–33) than *H. heterophyes*. The eggs of *H. heterophyes* are slightly larger (0.024–0.029 mm long) than those of *H. dispar* (0.021–0.023 mm long).

The life cycle of *H. heterophyes* is elucidated in Figure 2. The molluscan intermediate host is a kind of brackish water snail, *Pirenella conica*, in the Mediterranean and Red Sea, and *Cerithidea cingulata* (= *Tympanotonus microptera*) in India. In some

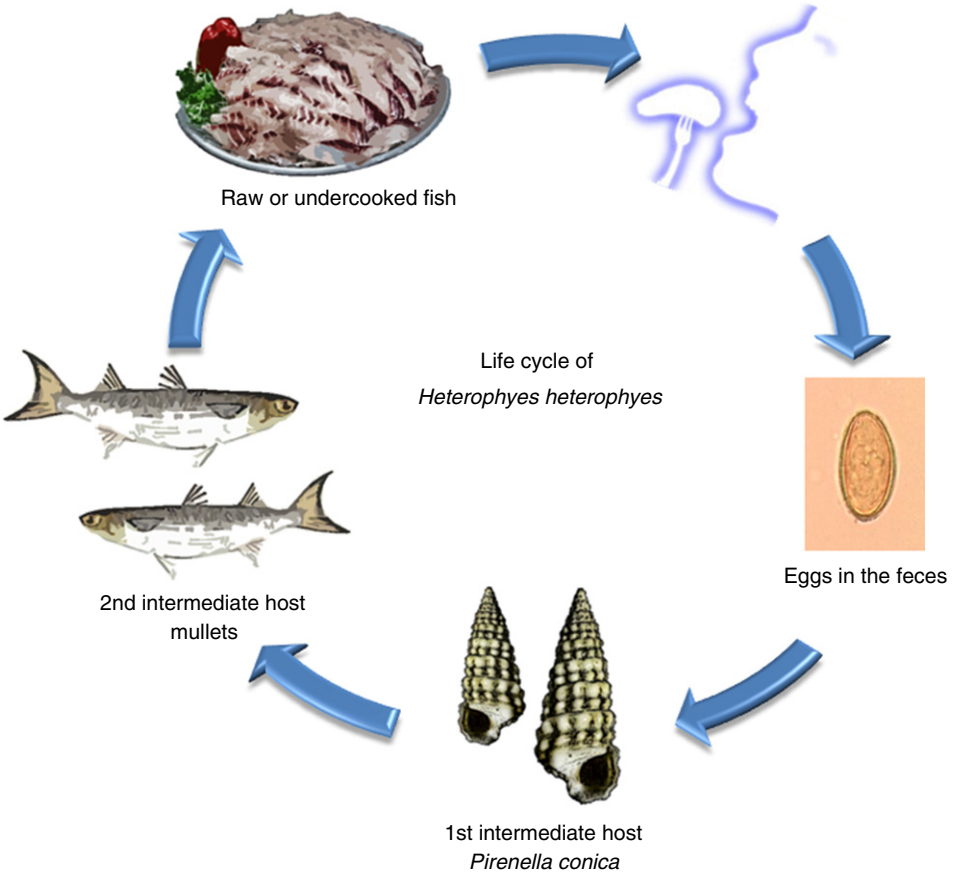

Figure 2 The life cycle of *Heterophyes heterophyes*.

areas, up to 38% of *Pi. conica* shed the cercariae of *H. heterophyes*. The cercariae shed from the snails, swim in water, find fish hosts, and quickly enter between the scales of the fish. They encyst in the muscle of the fish. Brackish water fish, including *Mugil cephalus*, *Mugil capito*, *Mugil auratus*, *Mugil saliens*, *Mugil chelo*, *Tilapia nilotica*, *Tilapia zilli*, *Aphanius fasciatus*, *Barbus canis*, *Sciaena aquilla*, *Solea vulgaris*, and *Acanthogobius* spp., are important fish hosts. Metacercarial cysts are globular or slightly oval, 0.13–0.26 mm in diameter, and usually found in the fish muscles. The larva inside the cyst is usually folded on itself showing the oral sucker, ventral sucker, genital sucker with gonotyl spines, and excretory vesicle filled with refractile globules. The longevity of metacercariae in the fish is unknown, but they may be able to survive for several years or throughout the life span of the fish hosts. In salted fish, they can survive only up to 7 days. A variety of mammals and birds, including dogs, cats, wolves, bats, rats, foxes, sea gulls, and pelicans, take the role of the reservoir hosts. Rats, dogs, cats, foxes, badgers, pigs, macaques, and gulls can be used as experimental definitive hosts. The life span in the canine or feline host is 1–4 months but may be longer in humans.

H. nocens

H. nocens was first reported in Japan by Onji and Nishio in 1916 based on worms recovered from experimental dogs and cats fed with the metacercariae encysted in the mullet, *Mu. cephalus*. The adult flukes are 0.9–1.6 mm long and morphologically close to *H. heterophyes*. Therefore, this species was for sometime called a subspecies of *H. heterophyes*, i.e., *H. heterophyes nocens*. However, *H. nocens* is now acknowledged as a distinct species because it has a consistent morphologic feature, in particular, the smaller number of rodlets (50–62) on the gonotyl in comparison to *H. heterophyes* (70–85). This species is now known to occur as human infections in Korea, Japan, and China. In China, the species described as *H. heterophyes* by Xu and Li in 1979 is presumed to be *H. nocens*. The eggs of *H. nocens* are similar in size (0.024–0.029 mm long) compared with *H. heterophyes* but slightly larger than those of *H. dispar*.

The first intermediate host is a brackish water snail, *C. cingulata* (= *Ty. microptera*). The cercariae are of the ophthalmo-pleuro-lophocercous type and shed from the snails into water. They can survive for as long as 42–54 h in sea water. When the fish hosts are available nearby them, they quickly attach to the fish skin, penetrate between the scales, and enter into the muscles. Important fish hosts include brackish water fish species, including *Mu. cephalus*, *Acanthogobius flavimanus*, *Lateolabrax japonicus*, *Therapogon oxyrhynchus*, and *Liza menada*. Metacercarial cysts are globular or slightly oval, 0.16–0.20 mm in diameter, and usually found in the fish muscles (Figure 3). The larva inside the cyst characteristically reveals its oral sucker, ventral sucker, genital sucker with

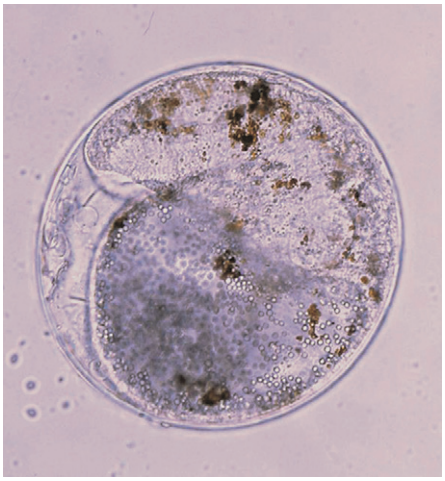

Figure 3 An infectious stage larva (= metacercaria) of *Heterophyes nocens* isolated from the muscle of a mullet, *Mugil cephalus*, slightly flattened. The cyst size is 0.17 mm in diameter.

gonotyl spines, and excretory vesicle filled with refractile granules. The longevity of metacercariae in the fish is unknown, but they may be able to survive for several years or throughout the life span of the fish hosts. In salted fish, they can survive only up to 7 days. Domestic or feral cats, dogs, and rats are natural definitive hosts. Mice and rats are experimental definitive hosts. The life span in animal host is 1–4 months but may be longer in humans.

H. dispar

H. dispar was first discovered in the intestines of dogs and cats in Egypt by Looss in 1902, and then in mammals, including the fox and wolf in northern Africa and the eastern Mediterranean. The geographic distribution is similar to that of *H. heterophyes*. The size of *H. dispar* adults is approximately three-quarters of that of *H. heterophyes* and *H. nocens*. The internal structures are almost the same as *H. heterophyes*; however, the most striking difference is the much smaller number of rodlets on the gonotyl (22–33) in *H. dispar*. There was a debate on the possible synonymy of *H. dispar* with a closely related species, *H. aequalis*. However, *H. aequalis* differs from *H. dispar* in the smaller number of rodlets on the gonotyl (14–25) and short ceca, i.e., ending before the anterior margin of two testes in *H. aequalis* but extending down to the posterior margin of two testes in *H. dispar*.

The whole life cycle is similar to that of *H. heterophyes*. Brackish water snails, *Pi. conica*, serve as the first intermediate hosts, and brackish water fish, including *Mugil* spp., *Tilapia* spp., *So. vulgaris*, and *Sc. aquilla* are the important second intermediate hosts. Metacercariae are morphologically similar to those of *H. heterophyes*. They usually encyst in the fish muscles. The larva shows its oral sucker, ventral sucker, genital sucker with gonotyl spines, and excretory vesicle filled with refractile granules. The longevity of metacercariae in the fish is unknown, but they may be able to survive for several years or throughout the life span of the fish hosts. Natural definitive hosts include dogs, cats, wolves, jackals, foxes, and kites. Pups and rabbits were used as experimental definitive hosts.

Clinical Manifestations

The most frequent clinical manifestations in heterophyiasis patients are mild to moderate degrees of abdominal pain, diarrhea, lethargy, anorexia, and weight loss. However, the severity of symptoms may vary and depend on host-side factors. One factor is the intensity of infection in each patient, i.e., the number of infected worms. Heavier infection cases tend to suffer from more severe illnesses. Another factor is the immune status of the patient, i.e., immunocompetent or immunodeficient. A third factor is the history of previous exposures to infection that can confer acquired immunity of individual patients. A new visitor to an endemic area may suffer from severe illnesses after a primary infection, whereas residents in endemic areas generally complain of milder symptoms. In immunocompromised patients, severe clinical manifestations, including erratic parasitism (= extraintestinal heterophyiasis) in the heart, brain, and spinal cord, may occur as in other heterophyid species infections. *H. heterophyes* and *H. nocens* (presumed) infections are suspected as the causes of cerebral manifestations, including epilepsy, brain abscess, or brain cyst.

Virulence Factors and Pathogenesis

The virulence of *Heterophyes* flukes might be different for different species of parasites. However, there have been no studies supporting this hypothesis. Two principal factors related to virulence are mechanical and chemical irritation by the flukes. Mechanical irritation is chiefly caused by the movement of worms which can have harmful effects on the intestinal mucosa, in particular, the villous and crypt layers of the small intestine. Chemical substances produced by the flukes, which include excretory–secretory proteins (ESPs), can play the role of not only antigens but also toxins to the host. Immune responses of the host against the flukes or their ESPs may be too strong (hypersensitivity) that the host immunity can damage the host itself. The affected mucosa may undergo hypersensitive and allergic reactions, including severe catarrhal inflammation and loss of villi. Pathogenicity is also related to other host–parasite relationships, including the intensity of infection; heavier infections generally undergo severer illnesses.

In human or animal hosts, adult flukes of *Heterophyes* parasitize the middle part of the small intestine, and invade the crypt of Lieberkühn by day 2–3 postinfection, and localize between villi or in the intestinal lumen during later stages. At the site of attachment in the host intestinal mucosa, *Heterophyes* adults can cause mechanical and chemical irritation and elicit inflammatory reactions, ulcers, and superficial necrosis of the mucosa. Villous atrophy and crypt hyperplasia may be the two major histopathologic features, accompanied by inflammatory cell infiltrations. In avian hosts, like sea gulls, the flukes frequently invade extraintestinal or somatic tissues and organs, in particular, the liver, pancreas, and bile duct. Also in

humans, eggs of *H. heterophyes*, and presumably *H. nocens*, were found encapsulated in the brain of patients with neurological symptoms. Therefore, erratic parasitism, as reported by Africa and coworkers in 1940 in *Stellantchamus falcatus*, *Haplorchis* spp., and *Procerovum* spp., seems to occur in patients infected with *Heterophyes* flukes.

Epidemiology

H. heterophyes

The principal mode of human infections with *H. heterophyes* is consuming raw or improperly cooked flesh of fish intermediate hosts, notably mullets and gobies. Endemic areas are scattered along riverside areas of Egypt, Sudan, Iran, Greece, Turkey, Italy, and Tunisia. Also in Asia, several endemic foci were reported but the parasites seem to have been actually *H. nocens*. In Egypt, human infections are prevalent in the northern part of the Nile Delta, particularly around Lakes Menzaleh, Burullus, and Edco, where fishermen and domestic animals frequently consume salted or insufficiently baked fish. In these areas, 36–90% of school children and 22% of adults were infected with this fluke during the 1930s–1950s; however, the prevalence among these people declined to 2.5–10.0% in the 1980s. The population at risk in these areas is approximately 1 million. In Iran, the prevalence in villages of Khuzestan was 8% on average and ranged from 2% to 24%. In postmortem examination of carnivores in the same areas of Iran, 14.2% of jackals, 33.3% of foxes, and 2.5% of dogs were infected with heterophyid flukes, including *H. heterophyes*, *Metagonimus yokogawai*, and *Heterophyes katsuradai* (a synonym of *H. nocens*). Imported human infections were reported in Korea and Japan, among people who returned from Egypt, Saudi Arabia, or Sudan.

H. nocens

After the discovery of *H. nocens* in Japan, the existence of this fluke in Korea was also confirmed by recovery of adult flukes from experimental mice and rats fed the metacercariae in mullets, *Mu. cephalus*. Human infections occur in various parts of Japan and Korea, where mullets and gobies are consumed raw or under improper cooking conditions. In Korea, more than 40% prevalence were noted among residents in southwestern coastal areas, including Jeonranam-do and Gyeongsangnam-do (Provinces). In the coastal village of Muan-gun, Jeonranam-do, 75% of the inhabitants were positive for heterophyid eggs; they were mixed-infected with *H. nocens* (all of 20 worm-recovered cases) and *Pygidiopsis summa* (18 of 20 worm-recovered cases). In these areas, individual worm burdens of *H. nocens* ranged from 3 to 1338 (average 237 worms per person). Many coastal islands in the western and southern seas of Korea were added to the list of endemic areas. In Japan, human infections occur in Kochi, Chiba, Yamaguchi, Chugoku, and Hiroshima Prefectures. Lakeside villages of Mikkabi-cho, north end of Hamana Lake, and Shizuoka Prefecture are new endemic areas with prevalence rates of 7.5% and 10.5% among the people.

H. dispar

Human infections can occur when fish intermediate hosts, including *Mugil* spp., are eaten raw or are inadequately cooked. However, human infections were unknown before 1986 when two Korean men who returned from Saudi Arabia were found to be infected with this fluke together with *H. heterophyes*. Human infections possibly exist in Thailand.

Analytical Methods

Conventional Methods

The detection of heterophyiasis patients is usually based on recovery of eggs in the feces. Smear techniques, including the direct smear, cellophane thick smear, and Kato-Katz thick smear, are applied in field studies. Concentration techniques, including formalin–ether sedimentation and brine flotation, are performed in laboratories equipped with centrifuges. However, in areas of mixed infections with other heterophyid species, specific diagnosis is problematic. In addition, detecting eggs in the feces is often unsuccessful in light infection cases and it is necessary to use immunological or molecular detection techniques.

Heterophyes eggs can be differentiated from those of *Clonorchis*, *Opisthorchis*, and other heterophyid species. However, it is difficult and needs experience. Eggs of *H. heterophyes* and *H. nocens* are similar and characterized by their length of 23–27 and 24–29 mm, respectively, ellipsoid to ovoid shape with length/width ratio of 1.5–2.1, clean shell surface, less prominent operculum, no shoulder rims, and yellowish brown color. The eggs of *H. dispar* are similar to those of *H. heterophyes* or *H. nocens*, with the exception of smaller egg size. There can be false egg-negative results among light infection cases, for example, with less than 100 worms in an infected person. The number of eggs produced per day per *H. heterophyes* or *H. nocens* may be less than 100 in the human host, so the probability of detecting eggs in the feces from such a case is almost negligible. In such cases, serological tests, including ELISA, and genetic techniques, including polymerase chain reaction, may be helpful. The diagnosis of erratic parasitism in the heart, brain, or spinal cord is impossible unless a biopsy or necropsy is done on the affected lesion. In this case, serological diagnosis may be helpful.

Serologic, Molecular, or Numerical Taxonomy Studies

Few studies have been performed in these areas. In dogs, three immunodiagnostic methods, including counter current immunoelectrophoresis, intradermal test, and indirect fluorescent immunoassay, to detect serum antibodies against *H. heterophyes* were attempted. The intradermal test revealed 100% sensitivity and 90% specificity. Molecular studies are not yet available.

Control/Preventive Measures

To control heterophyiasis in endemic areas, detection and chemotherapy of infected people are critically important.

The drug of choice for individual treatment is praziquantel, and the efficacy of a single oral 10–20 mg kg^{-1} dose of praziquantel is satisfactory, with a more than 95% cure rate. Niclosamide can also be used. Proper disposal of human or animal feces can reduce the infection source (*Heterophyes* eggs) to the snail intermediate host. However, control of the snail host is hardly practicable or feasible. Also, prevention of wild fish, including the mullets, from infection is impractical because fish-eating birds and mammals in nature, i.e., reservoir hosts, are implicated in the life cycle. One of the most efficient preventive methods is to persuade people to cook fish before eating. However, public health workers have experienced how difficult it is to persuade people in endemic areas to change their long-held food traditions of eating raw or undercooked fish. Because of this strong food tradition, prevention of heterophyiasis at the consumer level is very difficult.

There are reports that heating fish for 10–15 min at 70 °C could inactivate metacercariae; however, the extent of research and available data are insufficient to determine the exact time–temperature treatment required. A review by WHO in 1995 of available data on processing conditions identified some parameters for heating, pickling, salting, freezing, and irradiating fish for inactivation of parasites. Similar treatment conditions are also expressed in regulatory requirements of the US (FDA) and the EU. For example, freezing and storing at −20 °C or below for 7 days, or freezing at −35 °C or below until solid and storing at −35 °C or below for 15 h, or freezing at −35 °C or below until solid and storing at −20 °C or below for 24 h is sufficient to kill parasites. The FDA's Food Code recommends these freezing conditions to retailers who provide fish intended for raw consumption. Further, heating of fish flesh to a temperature sufficient to kill bacteria is also considered adequate for parasites. Brining and pickling may reduce the parasite hazard in a fish; however, some zoonotic trematode metacercariae require up to 8 days in 30% brine to be killed, as reported by WHO in 1995. The effectiveness of smoking to a temperature of 65 °C is considered to be effective for parasitic nematodes in fish, but there is little research on this process for intestinal trematodes, including *Heterophyes*.

Research Needs

Further studies are required to draw firm conclusions regarding the phylogenetic relationships of different *Heterophyes* species. Clinicopathological significance of *Heterophyes* flukes should be investigated in detail. The diagnostic procedures other than the conventional fecal examination techniques should be investigated further. Further research is needed to determine the exact time–temperature relationships to kill metacercariae in fish for prevention of heterophyiasis.

Metagonimus yokogawai

J-Y Chai, Seoul National University College of Medicine, Seoul, Korea

Glossary

Cellophane thick smear technique A method of fecal examination to detect helminth eggs. Approximately 60 mg of feces are placed on a glass slide and a cellophane paper soaked with glycerin and malachite green is put on the feces. The feces under the cellophane are compressed to become flat and dried before microscopic examination.

Crypt hyperplasia Pathological feature in the small intestine of humans or animals characterized by marked proliferation and increase in the number of crypts.

Kato-Katz thick smear technique A method of fecal examination to detect helminth eggs. The feces are sampled by filtering through a fine mesh and then used to fill a small pre-made hole on a plastic plate, which is placed on a glass slide. The plastic plate retaining the feces (41.7 mg) on the slide is carefully removed and the feces are covered by a cellophane paper soaked with glycerin and malachite green. The feces under the cellophane are compressed to become flat and dried before microscopic examination.

Praziquantel An anthelmintic drug used for treatment of a wide spectrum of helminth infections, including almost all species of trematodes and many species of cestodes.

Villous atrophy A pathological feature in the small intestine of humans or animals characterized by shortened, blunt, edematous, inflammatory, and congestive villi.

Background

The trematode family Heterophyidae (=heterophyids) includes a number of minute intestinal trematodes (or flukes) infecting humans and animals. The genus *Metagonimus*, one of the members, was created in 1912 by Katsurada based on adult flukes recovered from dogs experimentally fed with sweetfish, *Plecoglossus altivelis*, and also from humans who consumed sweetfish raw in Taiwan. Several other *Metagonimus* species have subsequently been reported; *Metagonimus takahashii*, *Metagonimus miyatai*, *Metagonimus katsuradai*, *Metagonimus minutus*, and *Metagonimus otsurui*. Among them, *Metagonimus yokogawai*, *M. takahashii*, and *Metagonimus miyatai* are the major species occurring as human infections. *M. katsuradai* and *M. minutus* are listed among the possible human-infecting species; however, no evidence of natural infections has been demonstrated. Metagonimiasis is caused by one or more species of the genus *Metagonimus* and is prevalent in the Far East, including the Republic of Korea (Korea), China, Japan, and far eastern Russia.

Characteristics

Morphologic Characters of *Metagonimus*

Metagonimus flukes are minute (0.5–1.5 mm in length) and characteristically have a laterally deviated (submedian located) ventral sucker without a ventrogenital apparatus or a genital sucker and two testes near the posterior extremity (Figure 1). *Metagonimus* flukes are morphologically distinguished from other heterophyids, including *Heterophyes*, *Heterophyopsis*, *Pygidiopsis*, *Centrocestus*, *Stellantchasmus*, *Haplorchis*, *Procerovum*, and *Stictodora*, by various features. *Heterophyes* and *Heterophyopsis* differ from *Metagonimus* in that they have a bigger median-located ventral sucker and a prominent genital

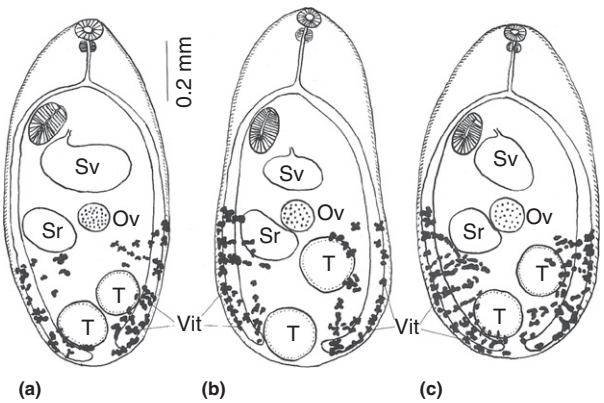

Figure 1 *Metagonimus* species infecting humans in Korea and Japan. (a) *Metagonimus yokogawai*; (b) *Metagonimus miyatai*; (c) *M. takahashii*. Ov, ovary; Sr, seminal receptable; Sv, seminal vesicle; T, testis; Vit, vitelline follicles. Reproduced with permission from Figure 9 in Chai *et al.* (1993) *Korean Journal of Parasitology* 31: 99.

 doi:10.1016/B978-0-12-378612-8.00157-8

sucker. *Pygidiopsis* differs from *Metagonimus* in that the former has a median located ventral sucker connected anterolaterally to a ventrogenital apparatus. *Centrocestus* has a median located ventral sucker and is armed with small circumoral spines around the oral sucker. *Stellantchasmus* is similar to *Metagonimus* in that it has a small, laterally deviated ventral sucker but differs in the presence of an elongated sac-like seminal vesicle connected to a muscular expulsor at the opposite side of the ventral sucker. *Haplorchis* and *Procerovum* have only one testis, whereas *Metagonimus* and other heterophyids have two testes. *Haplorchis, Procerovum,* and *Stictodora* have an armed gonotyl superimposed on a slightly submedian ventral sucker.

Important Species

Metagonimus yokogawai

Metagonimus yokogawai was originally described by Katsurada first reported in 1912 in Taiwan and Japan, and is currently the most prevalent species of *Metagonimus* in the Far East. This species has been reported to be distributed in Japan, Korea, China, Taiwan, Russia, Rumania, Israel, the Balkan states, and Spain. Some of the old literatures on *M. yokogawai* actually dealt with *M.takahashii* or *M. miyatai*. The unique morphologies of *M. yokogawai* include the presence of two testes closely adjacent to each other near the posterior end of the body, whereas in *M. takahashii* and *M. miyatai*, two testes are more or less separated. Another character of *M. yokogawai* is the distribution of vitelline follicles in lateral fields between the level of the ovary and the posterior portion of the posterior testis, whereas *M. takahashii* has abundant distribution of vitellaria beyond the posterior testis, and *M. miyatai* has no vitellaria distribution beyond the posterior testis. In *M. yokogawai*, the uterine tubule does not overlap or cross over the middle portion of the anterior testis, whereas it crosses over and overlaps the whole anterior testis in *M. takahashii* and *M. miyatai*. The eggs of *M. yokogawai* are smaller (0.0260–0.0300 mm long) than those of *M. takahashii* (0.0300–0.0360 mm long) and *M. miyatai* (0.0285–0.0315 mm long), though there are some overlaps. The adults are slightly smaller in *M. yokogawai* (0.800–1.320 mm long) compared with *M. takahashii* (0.863–1.193 mm long) and *M. miyatai* (0.998–1.300 mm long). The adults of *M. yokogawai*, *M. takahashii*, *M. miyatai*, and *M. minutus* differ from those of *M. katsuradai* and *M. otsurui* in that they have a larger ventral sucker than the oral sucker. *M. minutus* differs from *M. yokogawai*, *M. takahashii*, and *M. miyatai* in its smaller body (0.457 mm long) and smaller egg sizes (0.023 mm long).

The life cycle of *M. yokogawai* is elucidated in Figure 2. The molluscan first intermediate host is a kind of freshwater snail, *Semisulcospira coreana* or *Semisulcospira libertina*. The cercariae are ophthalmo-pleuro-lophocercous type and are shed from the snails. They swim in water and infect freshwater fish, the second intermediate host. The sweetfish, *P. altivelis*, is the most important fish host but the dace *Tribolodon hokonensis* or *Tribolodon taczanowskii* and the perch *Lateolabrax japonicus* can also serve as the second intermediate hosts. Metacercarial

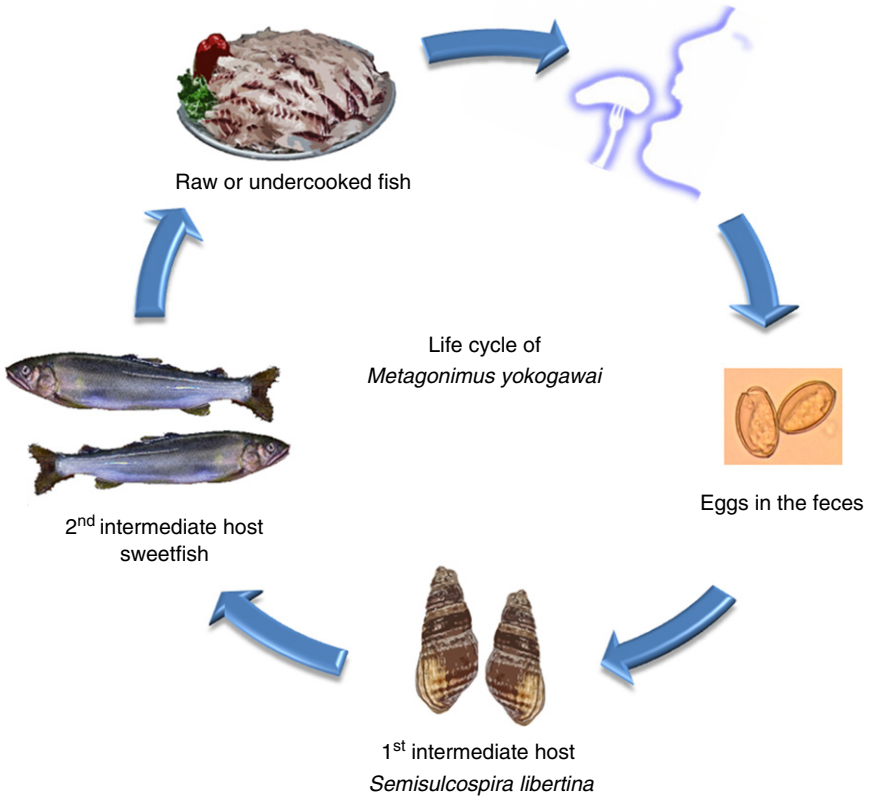

Figure 2 The life cycle of *Metagonimus yokogawai.*

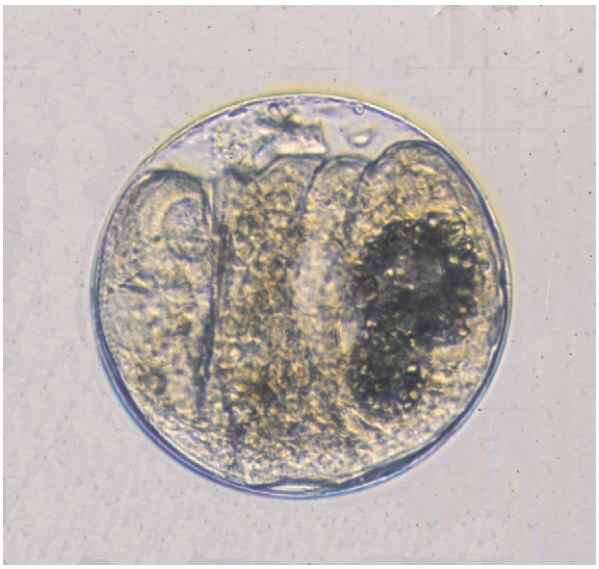

Figure 3 An infective stage larva (metacercaria) of *Metagonimus yokogawai* isolated from the muscle of a sweetfish, *Plecoglossus altivelis*. The cyst size is 0.15 mm in diameter.

cysts are round or slightly elliptical (Figure 3), 0.14–0.16 mm in diameter, and are usually found in the fish muscles. The larva inside the cyst is usually folded on itself showing the oral sucker, ventral sucker, and excretory vesicle filled with refractile granules. The longevity of metacercariae in the fish is unknown, but they may be able to survive for 2.5 years or throughout the life span of the fish hosts. Natural definitive hosts include dogs, rats, cats, and foxes, and birds including kites. However, the significance of each animal host as the source of human infection (i.e., as reservoir hosts) has not been well verified. Mice, rats, cats, and dogs can be experimentally used as the definitive hosts.

Metagonimus takahashii

Metagonimus takahashii was first reported in Japan by Takahashi in 1929 and named by Suzuki in 1930. The worms were recovered in the small intestine of mice and dogs fed with metacercariae encysted in various species of freshwater fish, excluding the sweetfish, which is a principal host for *M. yokogawai*. These worms were initially called a large egg-type *Metagonimus*, but a year later they were reported as a new species. The validity of *M. takahashii* as a distinct species was questioned for some time, and the name was compromised as *M. yokogawai* var. *takahashii*. However, recently, its taxonomic significance became strongly supported not only by the morphology of larval and adult stages, but also by different specificities to fish intermediate hosts. *Metagonimus takahashii* differs from *M. yokogawai* and *M. miyatai* in the position of the two testes, the distribution of vitelline follicles, and the egg size, and from *M. katsuradai* and *M. otsurui* in that the latter two have a smaller ventral sucker than the oral sucker. *Metagonimus takahashii* differs from *M. minutus* in its larger body and larger eggs. The Koga type of *Metagonimus*, which encysts in the dace *T. hokonensis*, is regarded a synonym of *M. takahashii*.

The snail host includes *S. libertina*, *S. coreana*, and *Koreanomelania nodifila*, and freshwater fish, including the crucian carp *Carassius carassius*, carp *Cyprinus carpio*, dace *T. taczanowskii*, and perch *L. japonicus*, harbor the metacercariae. Metacercarial cysts are slightly elliptical or disk shaped, 0.15–0.17 mm in diameter, and usually found inside the scales of the fish. The larva inside the cyst shows the oral sucker, ventral sucker, and excretory vesicle filled with refractile granules. They remain alive in the fish hosts for several months to years. Pelicans, kites, and other species of birds have been reported to be natural definitive hosts. Dogs, cats, mice, and rats are experimental definitive hosts.

Metagonimus miyatai

Metagonimus miyatai flukes were first found in 1941 in Japan but its taxonomic significance had long been questioned. Thus, it had been designated as the *M. yokogawai* Miyata type. A numerical taxonomy study report suggested that *M. miyatai* could be a subspecies of *M. takahashii*. However, its validity was acknowledged in 1997 by Saito and co-workers. The new species description was based on adult flukes from dogs and hamsters experimentally fed with metacercariae encysted in the sweetfish, dace, common fat-minnow *Morocco steindachneri*, pale chub *Zacco platypus*, and dark chub *Zacco temmincki*, and also on specimens from naturally infected humans in Japan and Korea. *Metagonimus miyatai* is morphologically different from *M. yokogawai* and *M. takahashii* in the position of the posterior testis, which is markedly separated from the anterior testis, the distribution of vitelline follicles that never cross over the posterior testis, and the intermediate size of eggs between *M. yokogawai* and *M. takahashii*. *Metagonimus miyatai* differs from *M. katsuradai* and *M. otsurui* in that the latter two have a smaller ventral sucker than the oral sucker, and from *M. minutus* in its larger body and egg size. *Metagonimus miyatai* is genetically distinct from *M. yokogawai* and *M. takahashii*.

Freshwater snails, *Semisulcospira globus*, *S. libertina*, and *Semisulcospira dolorosa*, are the first intermediate hosts. Freshwater fish, *Z. platypus* and *Z. temminckii*, are the important second intermediate hosts. Other freshwater fish, including *P. altivelis*, *T. hokonensis*, *T. taczanowskii*, *Opsariichthys bidens*, and *Morroco steindachneri*, also serve as the second intermediate hosts. Metacercarial cysts are round or slightly elliptical, 0.15–0.18 mm in diameter, and are usually found inside the scale of the fish hosts. The larva inside the cyst shows the oral sucker, ventral sucker, and excretory vesicle filled with refractile granules. The longevity of metacercariae in the fish is unknown, but they may be able to survive for several months to years. Natural definitive hosts include the dog, red fox, raccoon dog, and black-eared kite. Mice, rats, hamsters, and dogs are experimental definitive hosts.

Clinical Manifestations

The most frequent clinical manifestations in metagonimiasis patients are mild to moderate degrees of abdominal pain, diarrhea, lethargy, anorexia, and weight loss. However, the severity of symptoms may vary and depend on host-side

factors. One factor is the intensity of infection in each patient, i.e., the number of infected worms. Heavier infection cases tend to suffer from more severe illnesses. Another factor is the immune status of the patient, i.e., immunocompetent or immunodeficient. A third factor is the history of previous exposures to infection that can confer acquired immunity of individual patients. A new visitor to an endemic area may suffer from severe illnesses after a primary infection, whereas residents in endemic areas generally complain of milder symptoms. In immunocompromised patients, severe clinical manifestations, including erratic parasitism in the heart, brain, and spinal cord, may occur as in other heterophyid species infections. In one patient, multiple intracerebral hemorrhages and diabetes mellitus occurred, though it is unclear whether the patient was immunocompromised or not.

Virulence Factors and Pathogenesis

The virulence of *Metagonimus* flukes might differ for different species of parasites. However, there have not been sufficient studies to support this hypothesis. Two principal factors related to virulence are mechanical and chemical irritations by the flukes. Mechanical irritation is chiefly caused by the movement of worms which can give harmful effects to the intestinal mucosa, in particular, villous and crypt layers of the small intestine. Chemical substances produced by the flukes, which include excretory-secretory proteins (ESPs), can play the role of not only antigens but also toxins to the host. Immune responses of the host against the flukes or their ESPs may be too strong (hypersensitivity) that the host immunity can damage the host itself. The affected mucosa may undergo hypersensitive and allergic reactions, including severe catarrhal inflammation and loss of villi. Pathogenicity is also related to other host–parasite relationships, including the intensity of infection; heavier infections generally lead to severer illnesses.

In animal hosts, adult flukes of *M. yokogawai* parasitize the middle part of the small intestine, and invade the crypt of Lieberkühn by day 2–3 postinfection, and localize between villi or in the intestinal lumen during later stages. The worms can cause mechanical and chemical irritation to the mucosa and the affected mucosa reveals inflammatory and allergic reactions. Villous atrophy and crypt hyperplasia are the two major histopathologic features, accompanied by inflammatory cell infiltrations. The infected villi show blunting and fusion, edema at their tips, congestion and inflammation, and decreased villus/crypt height ratio. In immunocompetent hosts the location of worms is generally confined to the intestinal mucosa. However, in immunosuppressed hosts the worms may invade a deeper mucosal layer and even the submucosa. Immunosuppression also enhances survival of worms and prolongs their life spans. Poor absorption of intestinal secretions from the secretory crypt cells is thought to be an important mechanism of diarrhea. In *M. miyatai* infection, the intestinal histopathology of experimentally infected mice is similar to that seen in *M. yokogawai* infection, although the degree of mucosal damage is less severe. In other species of *Metagonimus*, pathogenicity and intestinal histopathology have not been studied.

It has long been a question whether *Metagonimus* worms parasitize only the intestine of the hosts. In other heterophyid flukes, *Stellantchamus falcatus*, *Haplorchis* spp., and *Procerovum* spp. can invade the submucosa and muscle layer of the intestine. This can cause erratic parasitism in man, which is often fatal, based on reports of Africa and co-workers in 1940. The heart valve, brain, and spinal cord are the three most frequently affected sites, where eggs and adult flukes, originating from the intestinal mucosa, embolize in the blood vessels. Such erratic parasitism may occur in immunocompromised patients due to lowered capacity of immune function against foreign stimuli. With regard to *Metagonimus* spp., no direct evidence of erratic parasitism in humans has been reported. However, in a patient infected with *M. yokogawai*, intracerebral hemorrhage was noticed and this could be an acute complication of metagonimiasis. In experimental mice, *M. yokogawai* adults were found to have invaded the submucosa of the small intestine when the mice were immunosuppressed by prednisolone injection.

Epidemiology

Metagonimus yokogawai

The principal mode of human infection with *M. yokogawai* is consuming raw flesh of the fish intermediate hosts, notably the sweetfish and the dace in the Far Eastern countries. Endemic areas are widely scattered along the riverside where people traditionally eat raw fish dishes. In Korea, approximately 240 000 cases infected with *M. yokogawai* are estimated along the rivers and streams running through the eastern and southern coastal areas. The prevalence of the infection in villagers in these areas can sometimes reache 60–70%. In China, human infections have been found in Guangdong, Anhui, Hubei, and Zhejiang Provinces. Taiwan is also included among the endemic areas. In Japan, a lakeside area around the Hamamatsu Lake, Shizuoka Prefecture, showed a 13.2% egg-positive rate among 4524 lakeside people examined. In Russia, the prevalence among ethnic minority groups in the Amur and Ussuri valleys of Khabarovsk Territory was between 20% and 70%. In the north of Sakhalin Island, the infection rate among Russians was 1.5% and that among ethnic minorities was 1.0%. Sporadic cases were also reported from the Amur District and the Primorye Territory.

Metagonimus takahashii

After its discovery in Japan, the existence of *M. takahashii* was also confirmed in Korea through recovery of adult flukes from experimental rabbits fed with the metacercariae in fish. The presence of human infections was noticed in the riverside people of the Hongcheon River, Gangwon-do, in 1988, and the upper reaches of the Namhan River, Chungcheongbuk-do, in 1993. The inhabitants were mixed-infected with *M. takahashii* and *M. miyatai*, with an egg-positive rate of 9.7% for both species. *Metagonimus takahashii* is now presumed to be prevalent in many small rivers and streams in inland areas of Korea. The major source of human infection is the crucian carp, *C. carassius*.

Metagonimus miyatai

Human infections are known in Korea and Japan. In Korea, it was reported as an undetermined species of *Metagonimus* by detecting eggs that are slightly larger in size than those of *M. yokogawai*. Later, adult worms were recovered from the riverside people living along the Namhan river in Umsong-gun (mixed-infected with *M. takahashii*) and Yongwol-gun (infected only with *M. miyatai*). In Yongwol-gun, the egg-positive rate among 77 riverside people was 48.1%. Adult worms were also recovered from inhabitants along the Hantan River, Chorwon-gun, Gangweon-do and Talchon River, Chungwon-gun, and Chungcheongbu-do. In Japan, the Hiroi River basin, Nagano Prefecture, and many small rivers of Shizuoka Prefecture are endemic areas of *M. miyatai* infection.

Analytical Methods

Conventional Methods

The detection of metagonimiasis patients is usually based on recovery of eggs in the feces. Smear techniques, including the direct smear, cellophane thick smear, and Kato-Katz thick smear, are applied in field studies. Concentration techniques, including formalin–ether sedimentation and brine floatation, are performed in laboratories equipped with centrifuges. However, in areas of mixed infections with different species of *Metagonimus*, specific diagnosis is problematic. In addition, detection of eggs in the feces is often unsuccessful in light infection cases and it is necessary to use immunological or molecular detection techniques.

Metagonimus eggs can be differentiated from those of *Clonorchis, Opisthorchis*, and other heterophyid species. However, it is difficult and needs experience. Eggs of *M. yokogawai* are characterized by their length of 26.9–31.6 mm, elliptical shape with length/width ratio of 1.5–2.1, clean shell surface, less prominent operculum, no shoulder rims, and dark yellow or brown in color. The eggs of *M. takahashii* and *M. miyatai* have similar morphology to those of *M. yokogawai*, with the exception of their larger egg sizes. There could be false egg-negative cases among the light infection cases, for example, with less than 100 worms in an infected person. The number of eggs produced per day per *M. yokogawai* worm is 14–64 eggs in the human host, so the probability of detecting eggs in the feces from such a case is almost negligible. In such cases, serological tests, including enzymze linked immuno sorbent assay (ELISA), are helpful.

Molecular Methods

Adult flukes of *M. yokogawai, M. miyatai,* and *M. takahashii* can be genetically differentiated by the polymerase chain reaction-based restriction fragment length polymorphism (PCR-RFLP) patterns. The target genes are internal transcribed spacer 1 (ITS1) site of ribosomal RNA and mitochondrial cytochrome *c* oxidase I (mCOI). PCR analyses based on random amplification of polymorphic DNA (RAPD) technique also show distinguishable banding patterns between *M. yokogawai* and *M. miyatai*. Analyses of the chromosome number and karyotype are also helpful to discriminate genetic differences between *M. yokogawai* and *M. miyatai*. The sequence comparison of 28S ribosomal DNA and mitochondrial cytochrome *c* oxidase subunit I can support *M. miyatai* as a distinct species. Application of genetic techniques to discriminate eggs of *Metagonimus* species in the human feces has not yet been successful.

Control/Preventive Measures

To control metagonimiasis, the detection and chemotherapy of infected people are critically important. The drug of choice for individual treatment of *Metagonimus* infection is praziquantel, and the efficacy of a single oral dose of 10–20 mg kg^{-1} praziquantel is satisfactory, with up to 95–100% cure rate. Proper disposal of human or animal feces can reduce the infection source (*Metagonimus* eggs) to the snail intermediate host. Control of the snail host is hardly possible or feasible. Also, control of the fish host, including the sweetfish, is impractical. One of the most efficient preventive methods is to persuade people to cook fish before eating. However, public health workers have experienced how difficult it is to persuade people in endemic areas to change their long-held food traditions of eating raw or undercooked fish. Because of this strong food tradition, prevention of metagonimiasis at the consumer level is highly difficult.

There are reports that heating fish, for example, sweetfish, for 10–15 min at 70 °C could inactivate metacercariae; however, the extent of available data is insufficient to determine the exact time–temperature treatment required. A review by World Health Organization (WHO) in 1995 on processing conditions identified some parameters for heating, pickling, salting, freezing, and irradiating fish for inactivation of parasites. Similar treatment conditions are also expressed in the regulatory requirements of the US (FDA) and the EU. For example, freezing and storing at −20°C or below for 7 days, or freezing at −35 °C or below until solid and storing at −35 °C or below for 15 h, or freezing at −35 °C or below until solid and storing at −20 °C or below for 24 h is sufficient to kill parasites. FDA's Food Code recommends these freezing conditions to retailers who provide fish intended for raw consumption. Further, heating of fish flesh to a temperature sufficient to kill bacteria is considered also adequate for parasites. Brining and pickling may reduce the parasite hazard in a fish; however, some zoonotic trematode metacercariae require up to 8 days in 30% brine to be killed as reported by WHO in 1995. The effectiveness of smoking to a temperature of 65 °C is considered to be effective for parasitic nematodes in fish, but there is little research on this process for intestinal trematodes, including *Metagonimus*. The infectivity of metacercariae can be controlled by gamma-irradiation of the fish at 200 Gy but the feasibility of the irradiation technique in the field conditions is low.

Research Needs

Further studies are required to draw firm conclusions regarding the phylogenetic relationships of different *Metagonimus* species.

Clinical significance of *Metagonimus* flukes and diagnostic procedures other than the conventional fecal examination techniques should be further investigated. Further research is needed to determine the exact time–temperature relationships to kill metacercariae in sweetfish for prevention of metagonimiasis.

Geographical Distribution

Current estimated total number of fishborne liver fluke infections is 45 million people in Asia and Europe, of which 9 million are infected with *Opisthorchis viverrini*, 1.2 million with *Opisthorchis felineus* and 35 million with *Clonorchis sinensis*. As many as 680 million people worldwide are at risk of infection. Infection hot spots for *O. viverrini* are northeast Thailand, Lao PDR, Cambodia and to a lesser extent, south Vietnam (Figure 1). As many as 67 million people in Southeast Asia are at risk of infection. *Clonorchis sinensis* is found in North Vietnam, China, Taiwan, and Korea, and previously in Japan. To date, *O. felineus* has been reported to occur in all European countries except Great Britain, Ireland, Finland, and Scandinavian. Among the republics of the former USSR, it is present in the Ukraine, Belarus, Baltic countries, Moldova, and Kazakhstan (Figure 2).

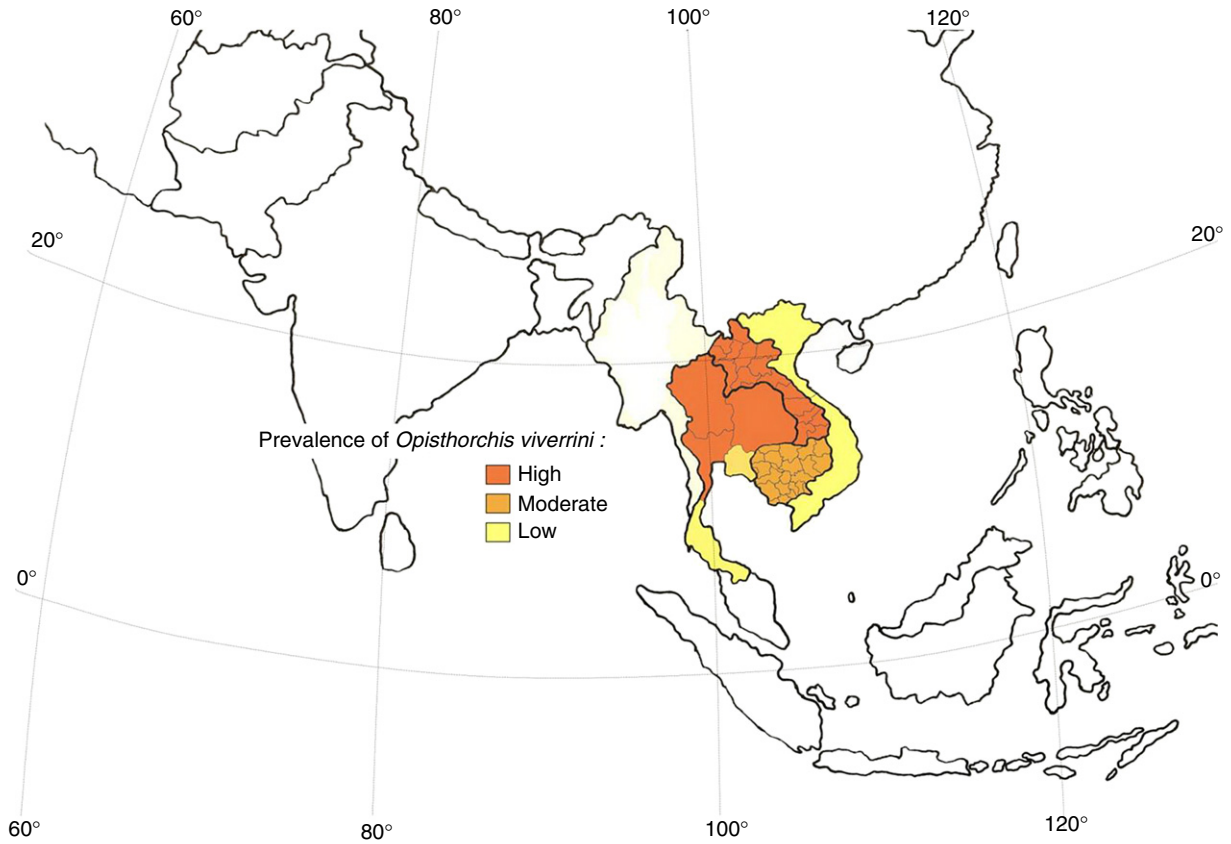

Figure 1 Geographical distribution of *O. viverrini*.

 doi:10.1016/B978-0-12-378612-8.00158-X

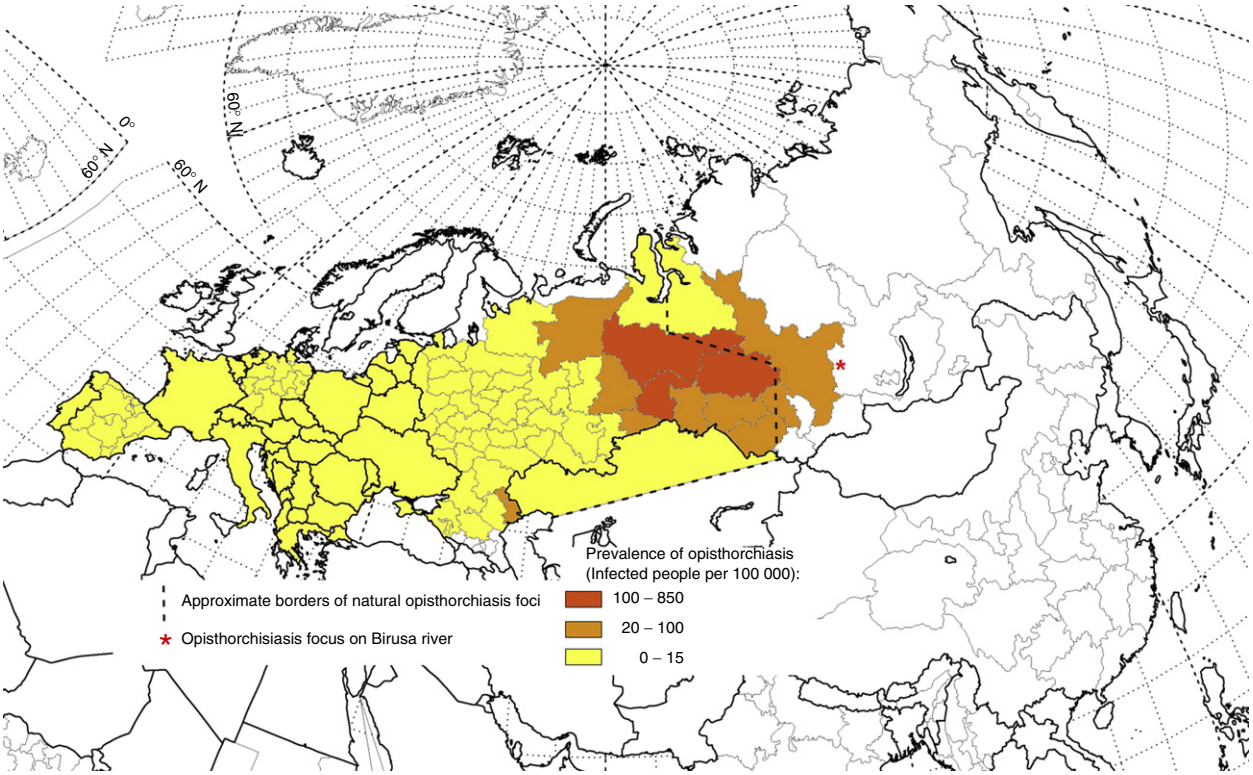

Figure 2 Geographical distribution of *O. felineus*.

It is believed that the presence of suitable snail intermediate hosts dictates the geographical distributions of these liver flukes. However, because of human population migration and extensive traveling plus growing importation of freshwater aquaculture products from endemic countries, it is now increasingly common to detect infected people in nonendemic areas. For example, cases of opisthorchiasis in nonendemic areas, such as USA and Europe, have been reported in immigrants from Asia. The cause of infection was due to the consumption of imported raw or undercooked freshwater fish containing metacercariae.

Taxonomy and Morphology

It is assumed that *O. felineus* was originally discovered and described in 1831 as *Distomum conus*. However, this and a subsequent description in 1836 as *Distomum lanceolatum felis cati* were not valid. In 1884, *O. felineus* isolated from cats and described as a valid species, *Distomum felineus* adhering to rules of zoological nomenclature and in 1895 *O. felineus* was included into the new genus *Opisthorchis*. The first discovery and description of *O. viverrini* was in 1915 from humans in Chiang Mai Thailand and subsequently from a fish-eating cat.

The three liver flukes are morphologically very similar. *Clonorchis sinensis* was isolated into a separate monotypic genus where the main distinctions from the *Opisthorchis* species are the branched shape of its testes (vs. lobed testes in *Opisthorchis*) and the position of testes and vitelline glands. There is, however, an alternate point of view that argues that *O. viverrini* and *C. sinensis* are more closely related to each other than to *O. felineus*. This is based on the number and arrangement of protonephridia (excretory formulae) of cercariae and metacercariae, namely, for *O. viverrini* and *C. sinensis* $2[(3+3)+(3+3+3)]=30$, versus $2[(5+5)+(5+5+5)]=50$ for *O. felineus*. It is generally believed that this character is constant for the representatives of a single genus in trematodes. Another argument is the number of the penetration glands in cercariae: 14 in *O. viverrini* and *C. sinensis* versus 20 in *O. felineus*. In addition, the *O. viverrini*/*C. sinensis* relationship versus *O. felineus* has been supported by phylogenetic molecular genetic analyses.

The liver flukes are hermaphroditic, dorso-ventrally flattened, and leaf like in shape. Adult worms (maritae) of *O. felineus* have a lancet-shaped body narrowed at the front end with a rounded tail. The size of adult flukes measures 5.5–10 × 0.77–1.65 mm with *C. sinensis* largest (10–25 × 3–5 mm) and *O. felineus* smallest (7–12 × 2–3 mm). The body size varies depending on the definitive host species. The body is armed with two muscular suckers, the oral sucker situated anteriorly and the ventral sucker at the mid-body. All three species of liver fluke eggs have distinct opercular shoulders surrounding the operculum at one end and a small knob or comma shape appendage at the abopercular end.

The ovary is smooth-edged or, more rare, weakly lobed, and occurs in front of the testes in the middle of the body. The uterus spans from the ovary to the front edge of the ventral sucker but does not overlap it. The vitelline glands form bunches located in the middle body third behind the ventral

sucker. The seminal receptacle is located somewhat behind the ovary. The testes have four or five lobes and are located diagonally one after another. The genital pores appear at the anterior side of the ventral sucker. The egg shell surface is rough and irregular or seen as musk-melon patterns by electron microscopy. Eggs of the three species of liver flukes share similar morphologies and are difficult to differentiate.

Recent systematic analyses of *O. viverrini* in Southeast Asia has shown that it is in fact a species complex in which adult worms show identical and indistinguishable morphologies but they are genetically very different, hence cryptic species. Whether this is the case for *O. felineus* and *C. sinensis* remains to be determined.

Life Cycle

Adult worms inhabit bile ducts, gall bladder, and to a lesser extent the pancreatic duct. Once sexually mature adult worms cross-fertilize and produce eggs that are discharged with bile fluid into the intestine and the feces and passed into the environment (Figure 3). The number of eggs produced per worm depends on the worm burden. In humans each worm can on average produce 50 egg g^{-1} feces. A common characteristic of all opisthorchiids is high specificity toward the first intermediate host, with usually one snail species or a few closely related species involved. Different species of *Bithynia* snails serve as the first intermediate hosts of *O. viverrini*, namely *Bithynia goniomphalos*, *Bithynia siamensis siamensis*, and

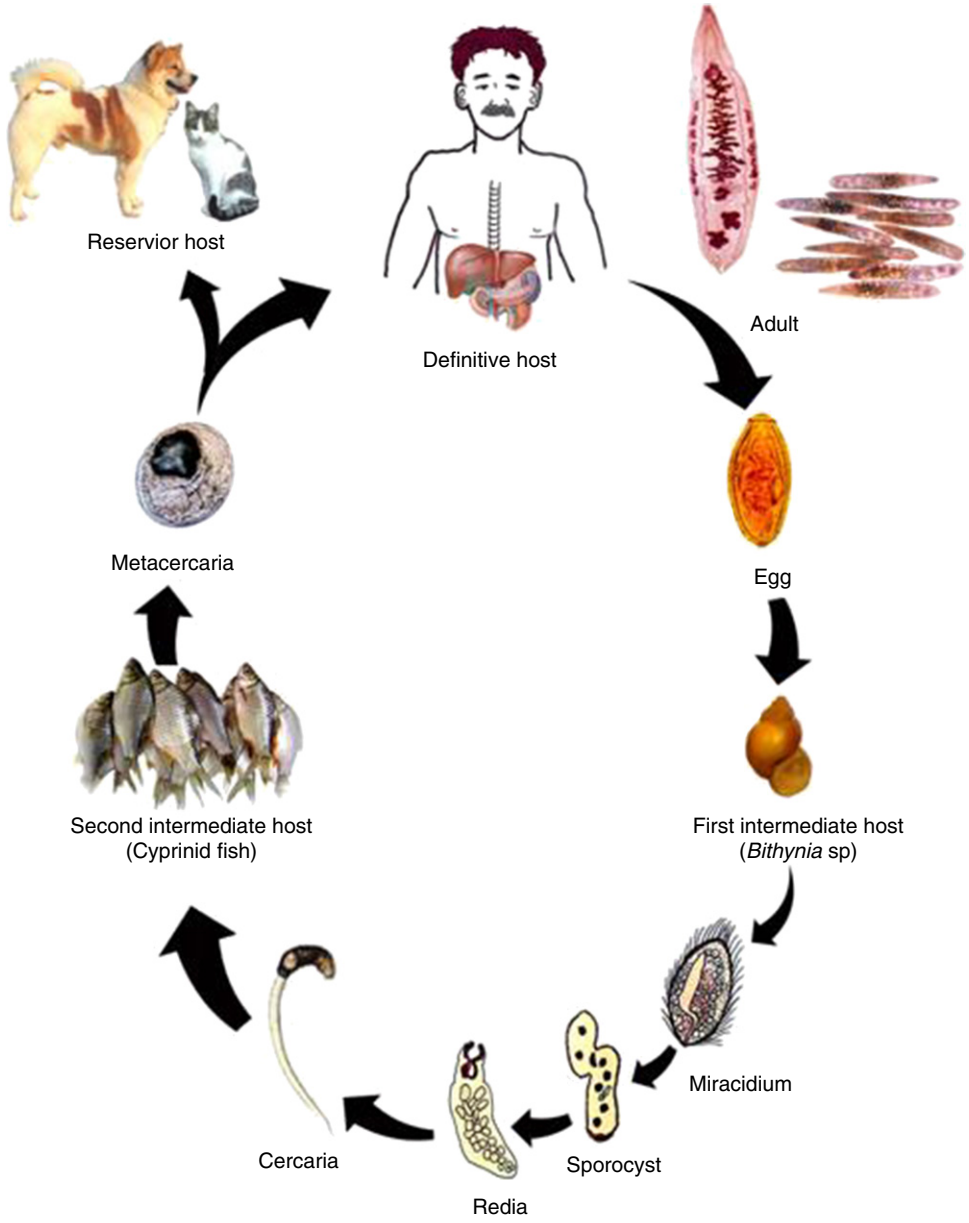

Figure 3 Life cycle of the liver flukes.

Bithynia funiculate. Until the middle of the twentieth century, *Bithynia leachi* was considered the first intermediate host of *O. felineus*. Subsequently, it was divided into four species *B. leachi*, *Bithynia troscheli*, *Bithynia inflata*, and *Bithynia sibirica*. The first three species are susceptible to *O. felineus* as well as *Bithynia tentaculata* and *Boreoelona linholmiana*. When eggs reach a body of freshwater, i.e., small ponds, streams, and rivers, or flooded rice fields and are ingested by specific *Bithynia* spp., miracidium hatch and develop into sporocysts and rediae. The rediae gave rise to cercariae that are released daily approximately 2 months after infection.

Once exposed to appropriate fish intermediate hosts, the free-swimming cercariae shed their tails, penetrate into the tissues or the skin of freshwater fish. Metacercariae penetrate subcutaneous adipose and muscle tissues to a depth of no more than 1–2 mm. Several unusual sites for clustering of metacercaria are known, such as pectoral fins, gills, and gut walls. Development of cercaria into metacercaria takes from 3 weeks to 2 months depending on the fish species and water temperature.

Humans become infected by ingesting the metacercariae in uncooked or partially cooked fish. The ingested metacercariae excyst in the duodenum, enter the common bile duct and migrate to the distal bile duct. Development of juveniles requires approximately 2 months to become the sexually mature stage. In the case of the closely related liver fluke, *C. sinensis*, it has been reported that they can survive up to 26 years in a human host. Based on the pattern of age-intensity profiles, it is anticipated that *O. viverrini* may survive in humans for approximately 10–20 years, which may also be the case for *O. felineus*.

The prevalence of *O. viverrini* infection in *Bithynia* snails is typically less than 1%. Snail population density exhibits strong seasonality and is dependent on rainfall, being highly abundant in the rainy season and distributed extensively in shallow water and rice fields; but disappearing rapidly in the dry season.

Prevalence of infection in fish intermediate hosts is much higher. As high as 90–95% prevalence of *O. viverrini* metacercariae has been recorded in several species of cyprinid fish. The most common species are in the genera *Puntius*, *Cyclocheilichthys*, and *Hampala*. Host finding mechanisms of cercariae is a complex process. Free-swimming cercariae are very efficient in locating the appropriate species of fish in a large volume of water. The intensity of liver fluke infections in fish varies by season, species, individuals, and types of water bodies. Most metacercariae are distributed throughout the body of fish and some are found in the head of the fish. For *O. viverrini*, metacercarial burdens peak in winter (October–February) and become low in the rainy season and summer thus transmission of the parasite from fish to humans is probably seasonal. This seasonal pattern may also occur in *O. felineius*.

In Thailand and Lao PDR, 18 species of fish from seven genera have been reported to serve as intermediate hosts of *O. viverrini* (**Table 1(a)**). Of these, *Cyclocheilichthys apogon*, *Cyclocheilichthys armatus*, *Cyclocheilichthys repasson*, *Puntius leiacanthus*, and *Hampala dispar* are considered to be the most important. The number of metacercariae reported in fish varies from between one to hundreds. The frequency distribution of *O. viverrini* metacercariae in fish is highly dispersed with most fish having few metacercariae whereas a few fish harbor a heavy metacercarial load. Recent findings of trematode metacercariae other than *O. viverrini* in cyprinid fish in Thailand have indicated that the occurrence of mixed species of trematodes in a given fish species is common. **Table 1(b)** lists 23 cyprinid fish that can act as second intermediate hosts for *O. felineus*. Ide is the host most susceptible to *O. felineus* and the most important source of infection, followed by common bream, whereas carp has low infection.

Dogs (*Canis familiaris*) and cats (*Felis catus*) are reservoir hosts in the life cycle of *O. viverrini* but the prevalence of infection in these animals is relatively low. The animal reservoir hosts of *O. felineus* are domestic dog and cat and wild fish-eating animals such as wolf (*Canis lupus*), red fox (*Vulpes vulpes*), corsac fox (*Vulpes corsac*), Arctic fox (*Alopex lagopus*), raccoon dog (*Nyctereutes procyonoides*), brown bear (*Ursus arctos*), raccoon (*Procyon lotor*), ermine (*Mustela erminea*), weasel (*Mustela nivalis*), Siberian weasel (*Mustela sibirica*),

Table 1 Fish intermediate hosts of the liver flukes

(a) Opisthorchis viverrini

Latin name	*Local name*
Cyclocheilichthys apogon	Sai Tan Ta Daeng
Labiobarbus leptocheilus	Sa
Puntius brevis	Taphian Jut
Barbonymus gonionotus	Taphian Khao
Henicorhynchus siamensis	Soi Khao
Henicorhynchus ornatipinnis	Soi Peek Daeng
Hampala dispar	Kra Sup Jut
Hampala macrolepidota	Kra Sup Khit
Osteochilus hasselti	Soi Nokkhao

(b) Opisthorchis felineus

Latin name	*Common name*
Leuciscus idus	Ide
L. cephalus	Chub
L. leuciscus	Dace
Rutilus rutilus	Roach
Blicca bjorkna	Silver bream
Carassius carassius	Crucian carp
C. auratus gibello	Silver crucian carp
Abramis brama	Common bream
A. ballerus	Blue bream
A. sapa	White-eye bream
Chondrostoma nasus	Nase
Scardinius erythrophtalamus	Common rudd
Pelecus cultratus	Ziege
Cyprinus carpio	Common or European carp
Tinca tinca	Tench
Gobio gobio	Gudgeon
Alburnus alburnus	Bleak
Phoxinus phoxinus	Minnow
Ph. chekanowskii	Chekanovsky minnow
Aspius aspius	Asp
Barbus borysthenicus	Barbel
Leucaspius delineatus	Sunbleak
Cobitis taenia	Spined loach

steppe polecat (*Mustela eversmani*), European mink (*Mustela lutriola*), sable (*Martes zibellina*), wolverine (*Gulo gulo*), Eurasian badger (*Meles meles*), and otter (*Lutra lutra*). Chipmunks (*Eutamias sibiricus*) have been found infected as well as beaver (*Castor fiber*), Eurasian water shrew (*Neomys fodiens*), Caspian seal (*Phoca caspica*), wild boar (*Sus scrofa*), domestic pig (*Sus scrofa domestica*), and muskrat (*Ondatra zibellina*). Although fecal contamination from infected animals undoubtedly contributes to parasite transmission to snails in the environment, its actual importance is unclear. Where fecal contamination from humans is reduced or eliminated by mass treatment and/or improved sanitation, infection among domestic cat and dog reservoir hosts could maintain the source of parasite and play a critical role in transmission and viability of the life cycle.

Pathogenesis, Pathology, and Morbidity

Pathological changes in liver fluke infection are confined mainly to bile ducts, liver, and gall bladder in both humans and in animal models. The magnitude of the pathology depends on the intensity, duration, and susceptibility of hosts. For light infections, the liver appears grossly normal, whereas, in heavy infections localized dilation of the thickened peripheral bile ducts can be seen on the surface beneath the fibrotic capsule of the liver. Major microscopic changes are confined to the large- and medium-sized bile duct where the flukes are found. The gross and microscopic characteristics of human opisthorchiasis are well established within 7–15 years after *O. viverrini* infection. Clinical manifestation is infrequent and often nonspecific and related to abdominal discomfort as a result of indigestion. Community based morbidity rates are approximately 5% among infected people. However, preclinical pathology can be detected by ultrasonography which has revealed various hepatobiliary abnormalities as a result of chronic opisthorchiasis. This chronic infection condition leads to bile duct inflammation and may eventually induce cholangiocarcinoma (CCA). Although pathogenesis of opisthorchiasis is complex, recent studies have revealed that the pathogenenic features in opisthorchiasis are largely a consequence of immunomodulation during the acute and chronic phase of infection. For pathogenesis of CCA, chronic inflammation plays a central role in carcinogenesis through oxidative and nitrative DNA damage which initiates tumorigenesis. While CCA is fatal and curative treatment is not forthcoming, opisthorchiasis is effectively cured by treatment with praziquantel. Praziquantel treatment eliminates not only *O. viverrini* but also reduces associated morbidities and risk of CCA.

Liver Flukes and Cancer

CCA accounts for 15% of liver cancers worldwide. In the absence of flukes or endemic infections, development of CCA is quite rare although incidence is increasing in many high-income countries for unknown reasons. The northeast of Thailand has the highest CCA incidence in the world. At present, *O. viverrini* and *C. sinensis* have been classified as type 1 carcinogens. A recent study suggested that host genetic background may play a role in the development of CCA and may help explain the high incidence of CCA in northeast Thailand. Additionally, past exposure to infection in terms of elevated *O. viverrini* antibody levels may be a risk factor for CCA development. Liver cirrhosis, chronic infection with the Hepatitis C virus, heavy alcohol consumption, high fluke egg density in stools, obesity, consumption of nitrate-containing foods, history of familial cancer, and gallstones may also be risk factors.

Epidemiology

Opisthorchiasis due to *O. felineus* in humans was first discovered in Tomsk, Siberia in 1881. A subsequent study of 1535 corpses revealed a high prevalence of opisthorchiasis in Tomsk of 6.91% (106 cases). This was the first time showing that opisthorchiasis presented a major health problem. As limited detailed records and studies are available it is not clear whether *O. felineus* represents a significant health problem in European countries. It apparently does not present an evident health problem in all of these countries except Kazakhstan, where it used to be a significant problem in the northern regions of the country, especially in Pavlodar. Unfortunately, no recent statistics on opisthorchiasis in Kazakhstan are available. It is generally believed that the prevalence of *O. felineus* both in humans and in animals increases from west to east. Opisthorchiasis represents a significant medical problem in the Ob-Irtysh basin, where the prevalence of opisthorchiasis in humans increases dramatically (see **Figure 2**).

Dashed lines in **Figure 3** represent the approximate borders of *O. felineus* geographical range, which is believed to be limited by its first intermediate host. No natural opisthorchiasis foci are believed to be present east of the Ob River, except for a small focus on the Birusa River in Irkutsk oblast (represented by the asterisk in **Figure 2**). Note that the foci of human opisthorchiasis extend further eastwards, with a high prevalence in Krasnoyarsk krai, which is due to high human migration rate and to the marketing of infected fish from Ob River.

It is difficult to make accurate estimates of the number of people infected with *O. felineus*, because as with *O. viverrini* the early stages of infection are asymptomatic in the majority of cases, and the clinical symptomatology in chronic cases is nonspecific and is often diagnosed as a consequence of other diseases. Hence, actual levels of opisthorchiasis prevalence would be considerably higher than currently recorded. It is estimated that the number of people infected with *O. felineus* is 1.5 million.

This is not the case in Southeast Asia where extensive study has shown that *O. viverrini* posses a significant health problem. For example, the pattern of infection in endemic communities is that prevalence and intensity increases with age of the population, thus middle aged people (>20 years) tend to have high prevalence and intensity of infection. Consequently, associated hepatobiliary morbidity also frequently occurs in this age group. The frequency distribution of worm burden in human hosts is not uniform, since the majority of parasites are harbored by a small group of people. In addition, there is evidence of predisposition to heavy infection in which heavily infected individuals have a tendency to return to their

pretreatment infection levels after treatment. These epidemiological characteristics have important implication for control programs.

Role of Aquaculture

Because of the growing fishery export trade from endemic areas of foodborne trematodes to nonendemic areas, both the World Health Organization and Food and Agriculture Organization are aware of the importance of an integrated, multidisciplinary approach to food safety and quality. This should encompass the entire food chain. In the case of aquaculture, the food chain approach required is a responsibility that the fish supplied are safe for human consumption by all involved with the production, processing, trade, and consumption of fish. Development and implementation of good aquaculture practice (GAP), good hygienic practice (GHP), and hazard analysis critical control point (HACCP) are recommended for fish farming in order to reduce snail contamination in fish ponds and hence metacercarial contamination in fish. These measures are possible in intensive, industrial aquaculture practices but for small-scale subsistence fish farming a balance between the operational costs and potential profits should be considered.

A recent investigation in fish farms in Lao PDR supported by the Food and Agriculture Organization demonstrated that some carp species commonly cultured in fish ponds contained *O. viverrini* metacercariae. This preliminary result suggested that apart from captured fish, culture fish can provide an additional source of infection to consumers and thus urgently needs attention.

Source of Infection for Human and Animals

Within the life cycle of *O. viverrini* and *O. felineus* infective metacercariae are found only in specific fish intermediate hosts. Mostly cyprinid species serve as the source of infection to humans and animal hosts. Food preparation methods of these fish are the main issues regarding viability of the metacercariae and hence risk of human infection. In Southeast Asia, particularly in Thailand and Lao PDR, the undercooked fish dishes as source of the liver fluke infection can be grouped into three categories (Figures 4(a)–(c)). Fresh or raw fish dishes without heating is called 'koi pla' and pose a high risk of infection. Of moderate risk is a short fermented dish (1–2 day) known as 'pla som' in which the metacercariae are viable. The last dish is fermented fish known as 'pla ra', which normally requires long-term fermentation, but short term and variable ingredients may provide favorable environments for metacercarial survival. Pla ra is a common ingredient for cooking in Southeast Asia for example in papaya salad ('som tum'). In Lao PDR, the fermented fish is known as 'pla dak.' In other countries such as Cambodia raw fish are prepared as pla hoc that is similar to pla som and these may serve as sources of

Figure 4 (a) Cyprinid fish in Thailand, (b) pla ra (fermented fish), (c) pla som (marinated fish), and (d) koi pla (raw fish preparation).

Figure 5 (a) Salted cyprinid fish in Russia and (b) stroganina (frozen sliced raw fish).

infection. The usual sources of *O. felineus* infection in Russia are dried or salted fish (Figure 5(a)). Other dishes include sliced raw fish ('stroganina,' Figure 5(b)), which is popular among native Siberians, and fish pickled in vinegar.

Diagnosis and Detection

The most widely used methods of opisthorchiasis diagnostics are traditionally based on the detection of *O. viverrini* and *O. felineus* eggs in feces and duodenal contents under the microscope. The eggs of the parasite become detectable during the fourth week after infection. Various fecal examination techniques are employed for diagnoses of liver fluke infection such as the formalin–ether concentration technique, the Kato thick smear and Stoll's dilution egg count technique. Other standard techniques such as direct smear or sedimentation techniques are also used in certain situations according to available facilities. Single examination by these techniques seems to have a high false-negative rate, especially with light infections or those with a history of recent treatment. Repeated stool examinations are necessary to improve the sensitivity of examination. Although repeated examination, yields increased sensitivity, repeated or multiple stool sample collections is difficult in practice, particularly in rural communities. Another complicating factor in accurate detection and diagnosis is that several species of trematodes belonging to the Opisthorchiidae, Heterohyidae, and Lecithodendriidae have eggs and life cycle stages that are similar morphologically.

Since the main factor in liver pathology is changes in duodenocholedochopancreatic organs, diagnosis of opisthorchiasis utilizes clinical and instrumental tools used to diagnose gastroenterological diseases. The most widespread methods are X-ray diagnostics (cholecystocholangiography), ultrasonic examination, and computer tomography. Immunological methods for opisthorchiasis diagnostics are currently available; however, they are nonspecific and lack sensitivity, and they are used as an addition to parasitological methods. Detection of *O. felineus* in fish and snails is also performed by microscopy.

More accurate, yet still infrequently used in clinical diagnostics, are modern molecular diagnostic methods such as polymerase chain reaction (PCR) or specific DNA probe hybridization. They have advantages over conventional methods in higher sensitivity and specificity and they can detect all life cycle stages. There are disadvantages; however, including high costs and the requirement of specialist expertise and facilities. Nonetheless, these diagnostic tools are potentially useful not only for monitoring parasite transmission but also in food inspection and safety.

Prevention, Treatment, and Control

Prevention

The campaign for reduction of raw fish consumption in Thailand to date has proven ineffective and difficult to implement in practice. The difficulty of detecting infected cases that invariably have light infection (egg g^{-1} feces < 1000) and the problem of reinfection are two of the many difficulties facing health workers. However, the millions of people infected and at risk of infection, in addition to the direct and indirect economic losses resulting from liver fluke infection, require the devotion of time and resources to development and implementation of prevention and control measures. Ideally, improvements in hygiene and sanitation practices prevent transmission of eggs from feces, which disrupts the cycle of fluke maturation and transmission. To be successful and long-lasting, prevention programs require broad community acceptance and participation.

The easiest and most promising way of preventing opisthorchiasis is decontaminating fish, as metacercariae are the only source of infection for humans. A multitude of studies have examined the viability of metacercariae under various environmental conditions and it is known that they remain viable when frozen at $-20\,^{\circ}C$ for up to 1 month. Temperatures of $>50\,^{\circ}C$ kill metacercariae in a few minutes, however, to ensure that metaccercariae are killed in frozen pieces of fish they must be cooked for a long time. It is generally recommended to cook fish in boiled water for more than 30 min.

Very popular fish dishes of dried and salted fish are not safe for consumption. Salted fish is generally considered ready in a day or 2. It has been proven that metacercariae remain viable under high salt concentrations for up to 2 weeks. The popular dish in Russia and eastern Europe of slightly salted fish is not safe at all. The same is true for dried fish where greater

than 12 days of drying are required to kill 99% of metacercariae. Given that the weight of fish and the temperature of drying are not constant even at fish plants or after 12-day period, dried fish remain dangerous for consumption.

Hot smoking is a reliable method of fish decontamination. A period of 2–2.5 h at 70–80 °C kills all metacercariae. Alternatively, cold smoking has similar effects to those of drying and salting. The same is true for treating fish with vinegar where it has been shown that 100% of metacercariae remain viable and infectious after 24 h.

Treatment

The acute stage of opisthorchiasis involves desensitizing and detoxication therapies, with the chronic stage usually determined by the affect on the duodenocholedochopancreatic zone. Therefore, treatment involves an integrated therapy following general principles for treating gastroenterological diseases. The drugs of choice are those commonly used in gastroenterology and hepatology, (choleretics, enzymes, and the drugs influencing gastrointestinal tonus and motility) in combination with nutrition therapy. From the 1920s until before the introduction of praziquantel into clinical practice, the standard therapeutic was antimony potassium tartrate, a highly toxic drug requiring long-term administration. The situation changed with praziquantel availability in the mid-1970s. Praziquantel is marketed under many brand names depending on the manufacturer, for example Biltricide and Droncid from Bayer for clinical and veterinary uses, respectively. The doses and course duration depend on the disease stage and age and body weight of patients. Recommended daily doses are 45–70 mg per kg body weight but a single dose of 40 mg kg^{-1} is also used. Treatment programs vary according to local situation and constraints in each country. In Thailand, a control program was implemented via selective treatment approach as opposed to mass treatment. Although the efficacy of praziquantel is relatively high (90–95%) and to date no evidence of drug resistance has been reported, reinfections are a common phenomenon. Therefore, control by chemotherapy alone may not be successful. Chemotherapeutic treatment with praziquantel has proven very effective yielding efficacy of more than 90% in some cases. However, when using higher sensitivity methods such as PCR, the actual treatment efficacy could be lower and this clearly deserves more detailed investigation. This treatment often leads to the resolution of infection and reversal of disease-related abnormalities.We recommend that a multidisciplinary treatment, sanitary improvement and health education approach be implemented. In addition to chemotherapy, health education to avoid eating raw or undercooked fish is essential to reduce and prevent infection. This eating behavior, which is deep rooted, a part of culture and tradition for decades in endemic areas of *O. viverrini*, is not easy to change. Thus, the health education message should be culturally sensitive for an endemic community. For the current population of adults who have been exposed to the infection and are at risk of having hepatobilairy disease and CCA, health education may need to be focused on the importance of reinfection which can further increase the risk of CCA. Another approach for control is targeting the young generation such as school children hence realize the future goal of a parasite-free generation having low or no risk of CCA.

Control

Interrupting the life cycle of the parasite has always been regarded as a promising way of disease control, for example application of molluscicides (drugs that kill snails) to control snail populations. Low concentrations of certain molluscicides (e.g., phenasal and niclosamide) are lethal for infected snails, sublethal for uninfected ones, and presumably nontoxic for other animals. Application of molluscicides was practiced for some time in Russia before the discovery of praziquantel antihelminthic activity. The biggest case against this approach is that it is a huge interference in biocenosis that can have dramatic consequences. Economical factors also negate its usage as the application of molluscicides is practical only for small water bodies since the costs of treating big areas are extremely high. Additionally, it has been shown that snail populations are restored in about 5 years, hence repeated treatments are necessary. Therefore, decontamination of aquatic bodies has been abandoned in Russia.

Control efforts are primarily focused on the reduction and elimination of parasite transmission by ensuring proper food preparation, promoting the development of improved diagnostic techniques, providing chemotherapy, and improving sanitation. A combination of health education, mass treatment, and governmental aid could significantly reduce liver fluke infection. Emphasis on health education should be placed on the younger generation in school as a part of the conventional curriculum.

To aid control measures, the possibility of developing a vaccine against liver fluke is a challenging task. Researchers have been pursuing this approach but it is still at rudimentary stage and none has been generated thus far. The recent development of gene catalogues for both *O. viverrini* and *C. sinensis* should facilitate vaccine development and tests for liver fluke control.

To ensure the success of liver fluke control programs, collaboration with different sectors in society are required, that is, with fisheries and aquaculture institutions and industries, with food production and distribution industries, education sectors and nongovernment organizations. An initiative of the Food and Agriculture Organization (FAO) has stressed the need to assess the relative importance of aquaculture *vis-à-vis* capture fisheries as a source of foodborne trematode infection. The need for food safety assurance and products from aquaculture for both domestic consumption and international trade is needed. The principle of HACCP approach are available for effective control of food risk at the production stage. However, more studies are needed to optimize additional production costs against food safety to meet local conditions and constraints in applying the HACCP approach.

Conclusions and Future Perspectives

Opisthorchis viverrini is a foodborne trematode, which is an important health problem because of the massive numbers of

people infected and its serious morbidities such as hepatobiliary diseases and CCA. Although infections are identified throughout Southeast Asia, the epi-center are northeast Thailand and Lao PDR, where high prevalence coexists but a high incidence of CCA is known in Thailand. Such information in nearby endemic countries, that is, Laos and Cambodia is currently lacking. Despite lower recorded cases of *O. felineus* in certain parts of Europe, recent outbreaks of opisthorchiasis have been documented and further investigation on its current distribution range and intermediate hosts are required.

Metacercariae of *O. viverrini* and *O. felineus* can only be reliably killed by high temperature. They are resistant to drying, high salt concentration and low temperatures (see section 'Prevention, Treatment, and Control'). Even boiled and fried fish is often not safe, as it takes a long time before all metacercariae are killed. A desirable approach for prevention of infection by *O. viverrini* is by the consumption of cooked fish, but the campaign for changes in the eating habits of people appears to have met with little success.

Diagnosis of opisthorchiasis for appropriate treatment is therefore essential to prevent morbidity and disease complication. The standard conventional diagnosis is the parasiotological method of demonstrating eggs in faeces or bile specimens. Several immunological diagnostic methods by antibody or antigen detection are available but careful interpretation of the test result is required. Molecular diagnostic methods have been introduced as alternative methods for diagnosis with the advantage of high specificity and sensitivity. Diagnosis by detection of parasite DNA in fecal specimens is a promising method since it identifies positive tests even in a considerable number of egg-negative specimens and equally sensitive in egg positive cases. The ability to discover positive cases in apparently egg-negative cases as determined by the conventional method, has demonstrated that this PCR-based diagnostic approach is useful for both individual and mass screening diagnosis. It also provides an additional tool for evaluation of the chemotherapy program. With fish aquaculture playing vital role in international aquaculture trade, this PCR-based method serves as a tool for fish inspection for metacercariae, as a significant issue of food safety. The disadvantage of molecular diagnostic methods for detection of the parasite DNA is the requirement of specific molecular instrumentation, thus the development of the detection system into a simplified kit format for routine field and laboratory use is required.

Glossary

Cercaria (plural: cercariae) One of the larval stages of a trematode. Large numbers of cercariae develop by asexual multiplication in the first intermediate snail hosts. Most have a tail for free-swimming in the water after emerging from the snail. Except for the schistosomes, cercariae usually do not infect humans directly.

Definitive host The host in which the trematode becomes sexually mature.

Eosinophilia Increase in the number of eosinophils: more than 500 μl^{-1} in peripheral blood is considered as eosinophilia. Eosinophilia is not only suggestive of helminth infections but also common in various allergic diseases and autoimmune diseases.

Helminth Eukaryotic multicellular parasites. Medically important helminths are categorized into three principal taxonomic groups: trematodes (flukes), cestodes (tapeworms), and nematodes (roundworms).

Metacercaria (plural: metacercariae) The encysted stage of a trematode in its second intermediate host prior to transfer to the definitive host, usually representing the stage infective to the definitive host.

Paratenic host This is a host in which a parasite can survive for longer periods without maturing. Usually a paratenic host is not essential for the completion of the life cycle of the parasite. In *Paragonimus westermani*, the larvae (excysted metacercariae) can infect and survive in the muscles of wild boars that have eaten crabs. Humans as well as dogs can be infected by ingesting raw wild boar meat.

Pleurisy Pleurisy (pleuritis) is an inflammation of the pleura. In the case of paragonimiasis, pleurisy is often associated with the retention of much exudate fluid (pleural effusion) or air (pneumothorax) in the pleural cavity.

Background

Paragonimiasis is subacute to chronic lung disease caused by the infection of lung flukes of the genus *Paragonimus*. *Paragonimus westermani* is the best known of the lung flukes, but several additional species are now known to develop in human hosts. Infection occurs mainly via consumption of uncooked/undercooked freshwater crabs/crayfish contaminated with metacercariae, an infective larval stage of the fluke. In addition, consumption of raw/undercooked meat of wild boar, which is a paratenic host that can harbor juvenile worms, is an important route of infection especially in Japan. Clinical features of the disease, such as chronic cough, hemoptysis (rusty colored sputum), chest pain, abnormalities by chest radiographic findings, etc., are somewhat similar to those of pulmonary tuberculosis or lung cancer. Even in the paragonimiasis-endemic areas, physicians often do not pay much attention to this disease because of its relatively low mortality and morbidity in comparison with the other two common pulmonary diseases. However, paragonimiasis misdiagnosed as pulmonary tuberculosis or lung cancer can cause enormous socioeconomic loss and create a mental/physical burden for the patient due to unnecessary hospitalization, laboratory examination, surgical operation, and long-term medication. In terms of epidemiology and disease control as well as food safety, identification of *Paragonimus* species is critically important because only a few out of approximately 50 nominal species are infective to humans. Current problems of taxonomy of *Paragonimus* species in relation to their infectivity to humans will be discussed.

Characteristics

Morphology

Adult *Paragonimus* worms are approximately 1 cm in diameter, having oral and ventral suckers, and look like a coffee bean in shape, size, and color while they are alive. They are hermaphroditic but usually live as a pair in a capsule in the lungs of the mammalian definitive hosts (Figure 1). Identification of species using morphological characters can be difficult. The shape, size, and proportion of oral and ventral suckers are, together with the shape of cuticular spines and the size, shape, and positions of the testis and ovary, the main characters used. The size and shape of metacercariae are also commonly used for the identification of the species.

Life Cycle

Like most other digenetic trematodes (flukes), *Paragonimus* species require two intermediate hosts, freshwater snails as the first intermediate host and freshwater crustaceans as the second intermediate host (Figure 2). Adult worms reside in the lungs of the definitive mammalian hosts, as a pair, in the cavity of a granulomatous lesion, called a worm cyst, where they lay eggs. The eggs are coughed up, swallowed down, and voided from the host either in sputum or in feces. In fresh water, a miracidium emerges from each egg and swims to find the first intermediate snail host. In the snail, asexual multiplication through sporocyst and rediae stages yields large numbers of cercariae. The cercariae emerge from the snail hosts and enter a crustacean (freshwater crab or crayfish) second intermediate host, where they encyst and grow to become infective metacercariae. Snail hosts are critically important for the maintenance of the life cycle of *Paragonimus* species, but the various developmental stages in snail hosts are not infective to humans: ingestion of snails does not lead to infection.

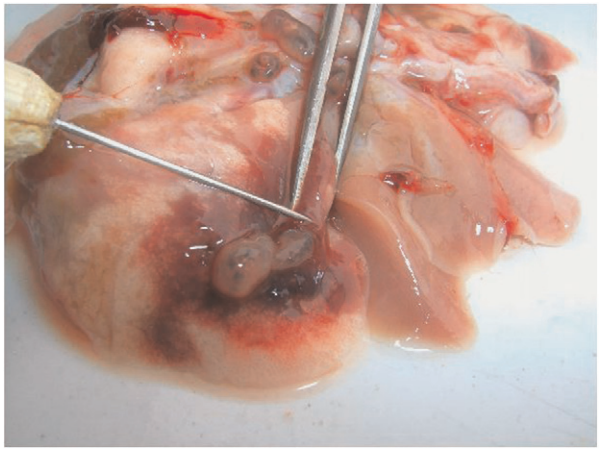

Figure 1 A pair of *P. heterotremus* adult worms squeezed out from a worm cyst in the lung of experimentally infected cat.

Paratenic Host

In Japan, approximately 25 years ago, small-scale outbreaks of paragonimiasis were found among local people living in a mountainous area who dined together on uncooked wild boar meat. Eventually, juvenile *P. westermani* worms were found in the muscles of hunted wild boars. Experimental infections revealed that worms of this species could not mature in wild boars, but could persist as juveniles in this animal, utilizing it as a paratenic host. According to a recent survey, seroprevalence of *P. westermani* infection among wild boars in southern Japan remains as high as 75%. Moreover, approximately 70% or more of human cases of *P. westermani* infection in Japan nowadays are thought to be infected by ingesting raw or undercooked wild boar meat. Recently in Kyushu, Japan, Horii and colleagues revealed that more than 60% of boar-hunting dogs were seropositive against *P. westermani* antigen and active infection was confirmed in many of them by fecal egg examinations. Those seropositive dogs had been allowed free access to, or intentionally fed with, uncooked wild boar meat (Figure 3).

Clinical Manifestations

When metacercariae of *Paragonimus* species are ingested by the definitive mammalian hosts, they excyst in the upper part of the small intestine, penetrate across the intestinal wall, then migrate into the abdominal wall where they grow for a while.

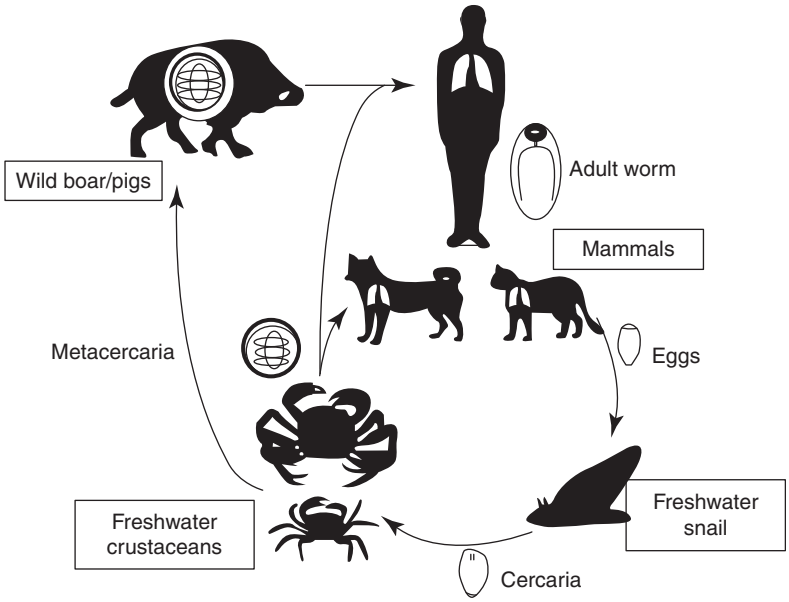

Figure 2 Life cycle of *Paragonimus* species. Reproduced from Nakamura-Uchiyama F, Mukae H, and Nawa Y (2002) Paragonimiasis: A Japanese perspective. *Clinics in Chest Medicine* 23: 409–420.

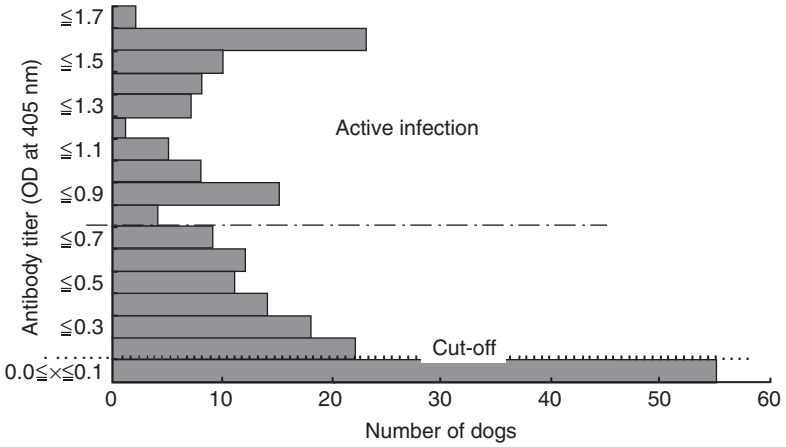

Figure 3 Paragonimiasis seroprevalence of boar-hunting dogs in Kyushu, Japan. The *P. westermani*-specific antibody titers in the sera of 224 dogs were measured by ELISA and the frequency-distribution of ELISA OD values plotted. Out of 224 dogs, 147 (65.6%) were seropositive, when the arbitrary cut-off value (.....) was set at OD = 0.100. Among 147 seropositive dogs, 83 (56.5%) were identified to have active infection because their OD values were more than 0.700 (— - — -). Reproduced from Kirino Y, Nakano N, Doanh PN, Nawa Y, and Horii Y (2009) A seroepidemiological survey for paragonimosis among boar-hunting dogs in central and southern Kyushu, Japan. *Veterinary Parasitology* 161: 335–338.

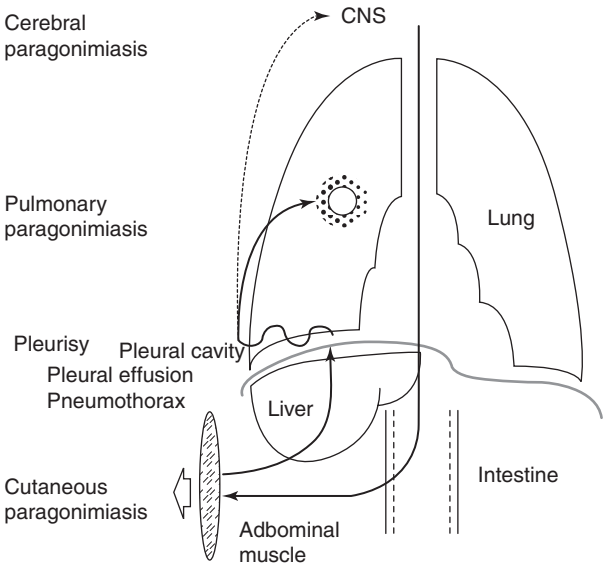

Figure 4 Migration route of *Paragonimus* species in humans. Paragonimasis patients express various symptoms depending on the location of the worms in the body and the stage of worm maturation. Reproduced from Nakamura-Uchiyama F, Mukae H, and Nawa Y (2000) Paragonimiasis: A Japanese perspective. *Clinics in Chest Medicine* 23: 409–420.

Then they come back to the peritoneal cavity, penetrate the diaphragm to reach the pleural cavity where they seek a mate, and then enter the lung parenchyma. Thus, signs and symptoms of the patients should be analyzed depending on the localization of the parasites and their maturation stages (Figure 4).

During the migration period, due to the small size and relatively rapid movement of the worms, patients rarely complain about abdominal symptoms. Acute eosinophilic peritonitis has been reported as a rare form of extra-pulmonary paragonimiasis. While migrating, a larva or juvenile worm may reach the subcutaneous tissue of the abdomen or chest to cause cutaneous paragonimiasis. Experimental infection in laboratory animals revealed that the juvenile worms often migrate through the liver before reaching the pleural cavity. There are a few case reports of eosinophilic liver abscess and hepatic capsulitis due to *Paragonimus* infection.

Once the worms reach the pleural cavity, they induce eosinophilic pleural effusion with/without pneumothorax, which are common features of the early stage of pulmonary paragonimiasis. Patients often complain of fever and chest pain but the degree of those symptoms is rather mild in comparison with those seen in bacterial pleuritis. The worms further migrate from the pleural cavity to the lung parenchyma, where they mate and start to produce eggs. At this stage, nodular lesions associated with scattered minute periovular inflammatory lesions can be seen in chest X-ray examination, computed tomography (CT), or magnetic resonance imaging (MRI). As a consequence of host–parasite interactions, the nodular lesion within the lung turns into a cavitating lesion with a communication into airways. This is now the chronic stage of pulmonary paragonimiasis during which patients show typical signs and symptoms of pulmonary paragonimiasis, namely, chronic cough and rusty colored sputum.

Related to the route of migration of worms, lung lesions are often seen in the lower to middle part of the lung and are frequently connected with the visceral pleura in chest imaging pictures. Because pulmonary tuberculosis lesions are mainly seen in the middle to upper lungs, the localization of lung lesions is suggestive, but not definitive, of the presence of lung flukes.

Juvenile and adult worms may reach the central nervous system (CNS) to cause neuro-paragonimiasis. The major routes of invasion of the CNS are surmised to be direct migration via the soft tissue around the jugular vein, or direct migration from the intervertebral foramina. In the acute stage

of neuro-paragonimiasis, patients are often present with eosinophilic meningoencephalitis. In chronic CNS-paragonimiasis, focal seizure with calcified lesions in the radiogram of brain is a typical form.

Pathology and Pathogenesis

Owing to the complexity of the migratory route of worms from the gut to the lungs, pathological changes in the hosts should be segregated into the tissue migratory phase and the lung phase. During migration, the lesions are mainly acute to subacute eosinophilic inflammation/abscess. As rare cases, eosinophilic peritonitis or eosinophilic liver abscesses have been reported. Before reaching the lung, worms pass through, or reside in, the pleural cavity causing pleurisy associated with eosinophilic pleural effusion, sometimes more than 90% eosinophils. Related to this, high levels of IL-5, a crucial Th-2 cytokine for eosinophilopoiesis and taxis, are detected in the pleural effusion of paragonimiasis patients. Peripheral blood lymphocytes of the patients produce high levels of Th-2 cytokines such as IL-5 and IL-13 on *Paragonimus* antigen stimulation. Peripheral blood eosinophilia of more than 30% is not rare in the early acute pleuropulmonary stage of paragonimiasis. At the extreme, a total white blood cell count of 100 000 mm^{-3} with more than 90% eosinophils was recorded in a child infected with *P. westermani*.

Once adult worms succeed in pairing in the lungs, the initial acute stage of eosinophilic inflammation in the lung parenchyma is followed by gradually progressing fibrotic encapsulation associated with numerous granulomatous lesions around eggs. Although host animals react to encapsulate parasites by immune/inflammatory responses, parasites tend to keep their living space and maintain a communication from the lesion to the respiratory tract of the host to allow eggs to reach the outside environment. For this purpose, parasites produce/release various proteinases in their excretory/secretory products. As a result, a cavitating lesion with a fistula to the airway is formed in the lung parenchyma. Along with the progression of the disease toward the chronic stage, peripheral blood eosinophilia becomes rather reduced and sometimes normalized, rendering recognition of possible parasitic disease in the differential diagnosis more difficult.

Among the common species of *Paragonimus* that can infect humans, *Paragonimus skrjabini* (including *Paragonimus miyazakii*) rarely mature in humans. Instead, they remain as immature worms to cause pleurisy and nodular skin lesions in the anterior chest wall.

Epidemiology of Human Paragonimiasis

Although lung flukes occur widely in tropical and subtropical regions, human cases have been seen only in limited areas of Asia, West Africa, and South and Central America where people have a custom of eating uncooked/undercooked freshwater crustaceans or wild boar meat. According to the World Health Organization in 1995, approximately 20 million people are infected with lung flukes and approximately 300 million people are at risk. The vast majority of the paragonimiasis patients as well as those at risk are in mainland China. Although paragonimiasis used to be endemic nation-wide in Japan, Korea, and Taiwan, the prevalence drastically decreased by the 1980s. Re-emergence of the disease, however, has been reported in Japan. North-eastern India, northern Vietnam, and central to northern Lao PDR were recently added as endemic areas of paragonimiasis.

Among more than 50 named *Paragonimus* species, only a few have been identified as human pathogens. *P. westermani* is the most important species in Asia, followed by *P. skrjabini* (and its Japanese subspecies, *Paragonimus skrjabini miyazakii*) and *Paragonimus heterotremus*, but the infectivity to humans of many other *Paragonimus* species recorded in Asia remains unknown. Human infection with *Paragonimus kellicotti* has been reported in the USA. In Central to South America, *Paragonimus mexicanus* is the species proven to cause human disease. Several other species recorded in this area are now considered as synonyms of *P. mexicanus*. In West and Central Africa, two species, *Paragonimus africanus* and *Paragonimus uterobilateralis*, are known to infect humans.

Paragonimus westermani is widely distributed in the Indian subcontinent (including Sri Lanka), east to Siberia, China, Korea, Japan and Taiwan, and south to the Philippines, Indonesia, and Malaysia. However, its ability to infect humans is variable among different geographical populations. Human cases of *P. westermani* infection have been found in China, Korea, Japan, Taiwan, and the Philippines, but proven/confirmed cases have never been reported from other countries, where this species is endemic in wild animals. Even in experimental infection in laboratory animals, *P. westermani* in Fareast Asian populations can mature in dogs and cats, but those of Southeast and South Asian populations hardly become adults in dogs. In Vientiane province in Lao PDR, *P. westermani* metacercariae were found along with metacercariae of several other *Paragonimus* species in the same crab hosts, but only *P. heterotremus* adults or eggs were detected in human cases in this area. Similar selective infection of *P. heterotremus* in humans was recorded in northern Vietnam where metacercariae of *P. heterotremus*, *Paragonimus vietnamensis*, and *Paragonimus bangkokensis* were concurrently found in the same crab hosts. These experiments of nature clearly indicate that the virulence to humans or other mammalian hosts is variable among *Paragonimus* species or even among the geographical populations of the same species.

Molecular Phylogeny and Biogeography

Of the more than 50 nominal species of *Paragonimus*, most occur in eastern Asia. There are more than 30 nominal species in China alone. Recent molecular phylogenetic analyses revealed that there is often enormous genetic variation within and between species and populations in *Paragonimus*. Molecular work has also demonstrated that morphological variants may not differ from one another in DNA sequences of the markers used. An updated molecular phylogenetic tree based on the ITS2 sequences of some *Paragonimus* species from Asia is shown in Figure 5. This clearly demonstrates the presence of four main groups of species, with *P. vietnamensis* and *Paragonimus macrorchis* standing distinct. Geographic distribution

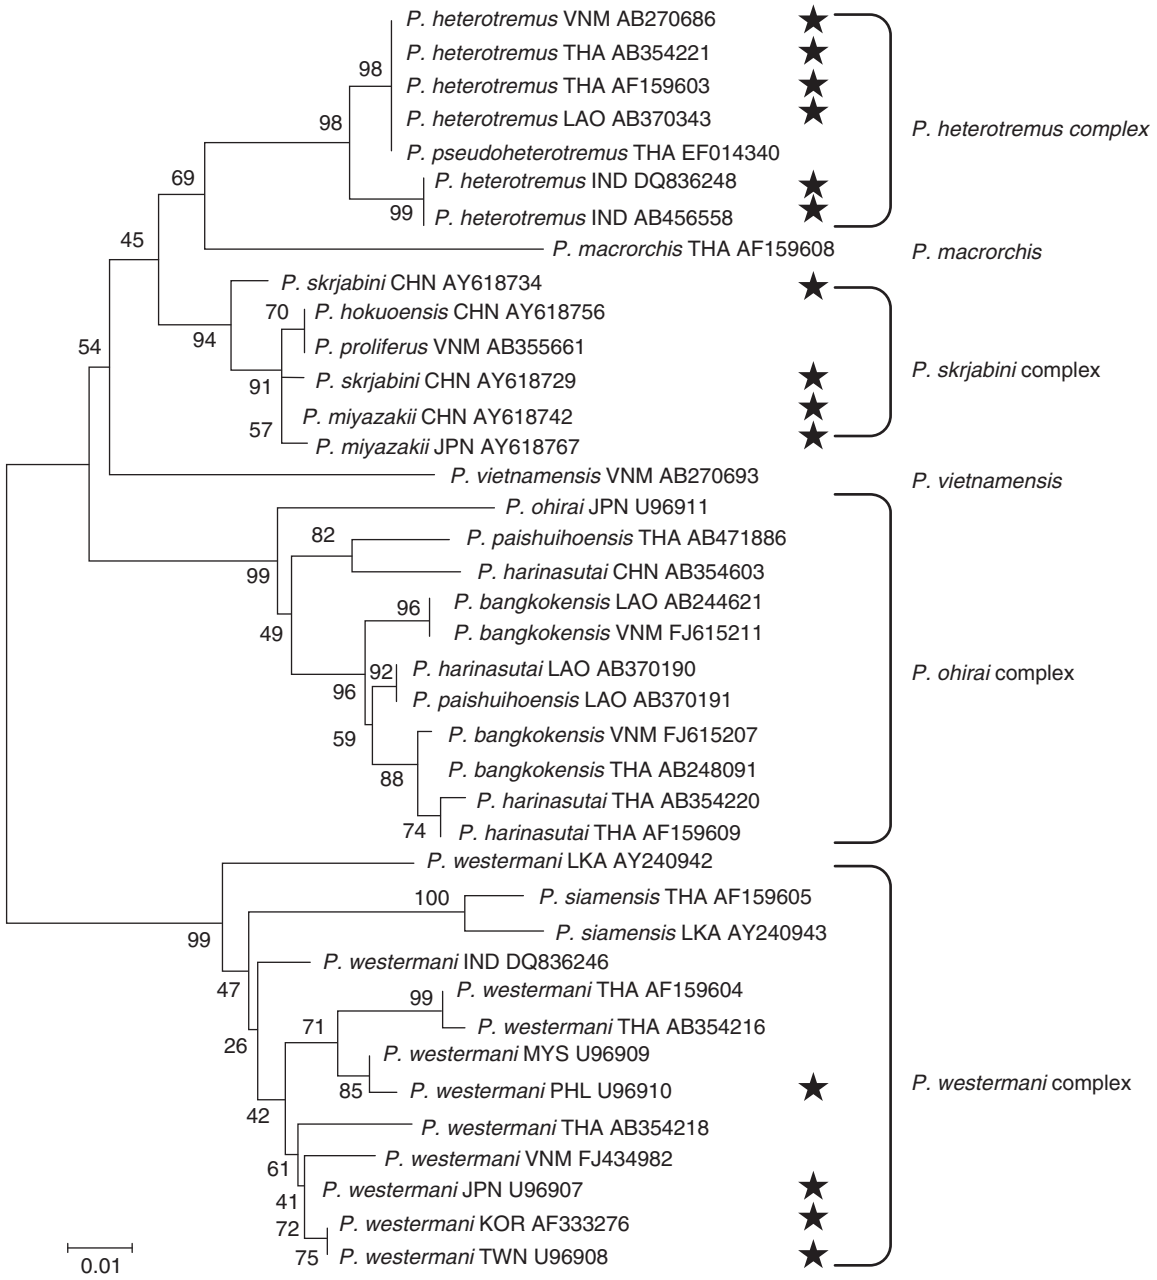

Figure 5 A midpoint-rooted neighbor-joining tree reconstructed from ITS2 sequences of *Paragonimus* species in Asia. The sequence data were obtained from GenBank (http://www.ncbi.nlm.nih.gov/). The three letter country code and the GenBank accession number are given after the species name. CHN, China; IND, India; JPN, Japan; KOR, Korea; LAO, Lao PDR; LKA, Sri Lanka; MYS, Malaysia; PHL, the Philippines; THA, Thailand; TWN, Taiwan; VNM, Vietnam; * sequence from a population known to infect humans. The numbers on the nodes are bootstrap values.

of the four major species complexes is illustrated on the map (Figure 6).

Considerable variation is apparent within *P. westermani* that is consistent to some extent with the differences in infectivity to humans as mentioned above. *Paragonimus siamensis*, although distinct from *P. westermani* in details of cuticular spination, is clustered within the *P. westermani* complex. It may be noted that *P. westermani* found in central Vietnam (FJ434982) and southern Thailand (AB354218) was clustered with Far East populations (Figure 5), but their infectivity to humans is undetermined.

Paragonimus skrjabini miyazakii, a human pathogen in Japan, was proven to be a synonym or sister species of *Paragonimus skrjabini skrjabini*, which is a human pathogen in China. These clustered with *Paragonimus hokuoensis* from China and also with Chinese and Vietnamese populations of *Paragonimus proliferus* to form a species complex. Metacercarial morphology differs greatly among members of this complex. For example, the metacercaria of *P. proliferus* is a gigantic excysted one (2.0–2.4 mm in length) whereas that of *P. hokuoensis* was reported to be within a cyst approximately 350 μm in diameter. Nevertheless, both ITS2 and CO1 sequences derived from both

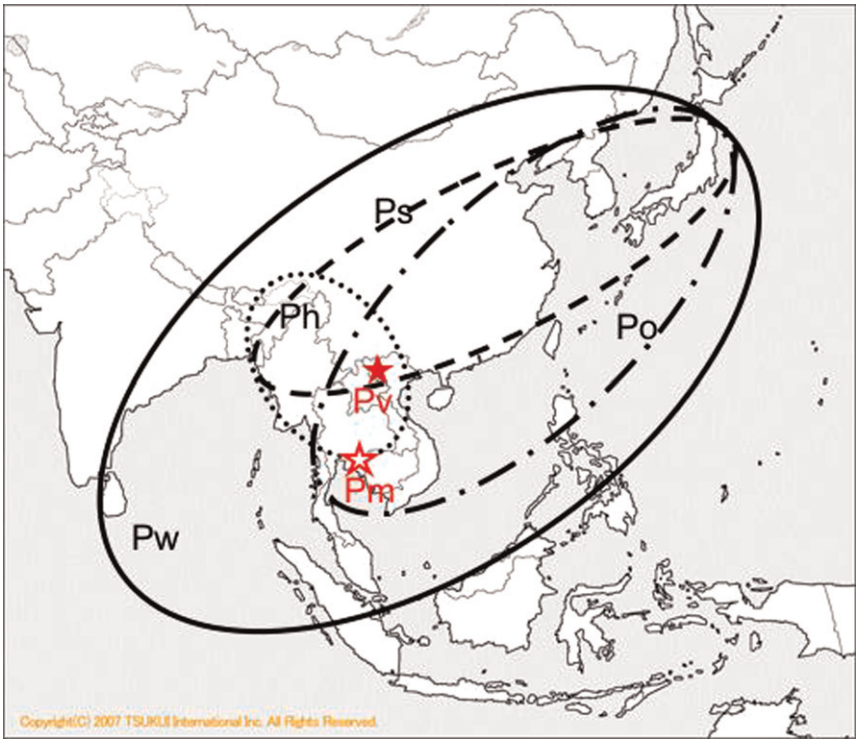

Figure 6 Geographical distribution of *Paragonimus* species complex in Asia: ——— *P. westermani* complex; — - — - *P. ohirai* complex; – – – – – *P. skrjabini* complex; ..... *P. heterotremus* complex; ★: *P. vietnamensis*; ☆: *P. macrorchis*.

kinds of metacercariae were almost completely identical. Furthermore, although the data were not included in Figure 5, several *Paragonimus* species recorded in China, such as *Paragonimus szechuanensis*, *Paragonimus hueitungensis*, *Paragonimus veocularis*, and *Paragonimus fukienensis*, are probable synonyms of *Paragonimus skrjabini* despite considerable variation among them in metacercarial morphology.

Paragonimus heterotremus, the most important human pathogen in Southeast Asia, is clustered with *Paragonimus pseudoheterotremus*, a recently proposed new species, and more distantly with *P. macrorchis*, but the infectivity of the latter two species to humans is not known. The ITS2 sequence of *P. pseudoheterotremus* is almost identical (only one base difference) with that of *P. heterotremus* and the CO1 was very similar to that of *P. heterotremus* from an Indian population (data not shown). *P. pseudoheterotremus* should, thus, be a synonym of *P. heterotremus*.

The *Paragonimus ohirai* complex, named after its oldest named member, also includes *Paragonimus bangkokensis*, *Paragonimus harinasutai*, and *Paragonimus paishuihoensis*. No members of the *P. ohirai* complex (Figure 5) are known to regularly infect humans. This is a large and diverse group containing a number of nominal species and some taxonomic puzzles. *Paragonimus bangkokensis* and *P. harinasutai* were both first found in Thailand and are easily distinguishable by morphological characteristics. Nevertheless, their ITS2 sequences showed extremely high similarities, suggesting they are not distinct species. There is a geographical variation in the sequences of these two nominal species (Figure 5).

Paragonimus vietnamensis was found in northern Vietnam as extremely large (approximately 800 μm in diameter) metacercariae. Molecular phylogenetic analyses revealed that this species is distinct from any other known *Paragonimus* sp. (Figure 5). *Paragonimus sheni* was discovered in Wuyishan, Fujian Province, China, between 1978–1983. Its validity as a distinct new species should await molecular phylogenetic data.

Analytical Methods

In terms of food safety, detection of the infective stage of any parasite is critically important. Metacercariae, the infective larvae of *Paragonimus* species, reside in freshwater crustaceans (crabs, crayfishes). The prevalence and the intensity of metacercarial infection in crabs can be determined by classical parasitological examination. The entire process is shown in a series of photographs (Figure 7). All the necessary equipments is shown in Figure 7(a1), and dissecting microscope is needed for searching the metacercariae and an ordinary light microscope for their morphological identification.

The first step (Figure 7(a)) is to manually remove the hard shell (carapace) of the crab (Figure 7(a2)) and take off the gills (Figure 7(a3)), which are then pressed between two glass plates (Figure 7(a4)) and examined under the microscope.

The second step (Figure 7(b)) is to take the hepatopancreas tissue out (Figure 7(b1)), mix well inside the carapace (Figure 7(b2)), and transfer the mixture into a cup (Figure 7(b3)). Tap water is added to the mixture (Figure 7(b4)), the sediment is allowed to settle for 5 min, and then the supernatant is decanted off. This washing by sedimentation/decantation is repeated until the supernatant fluid

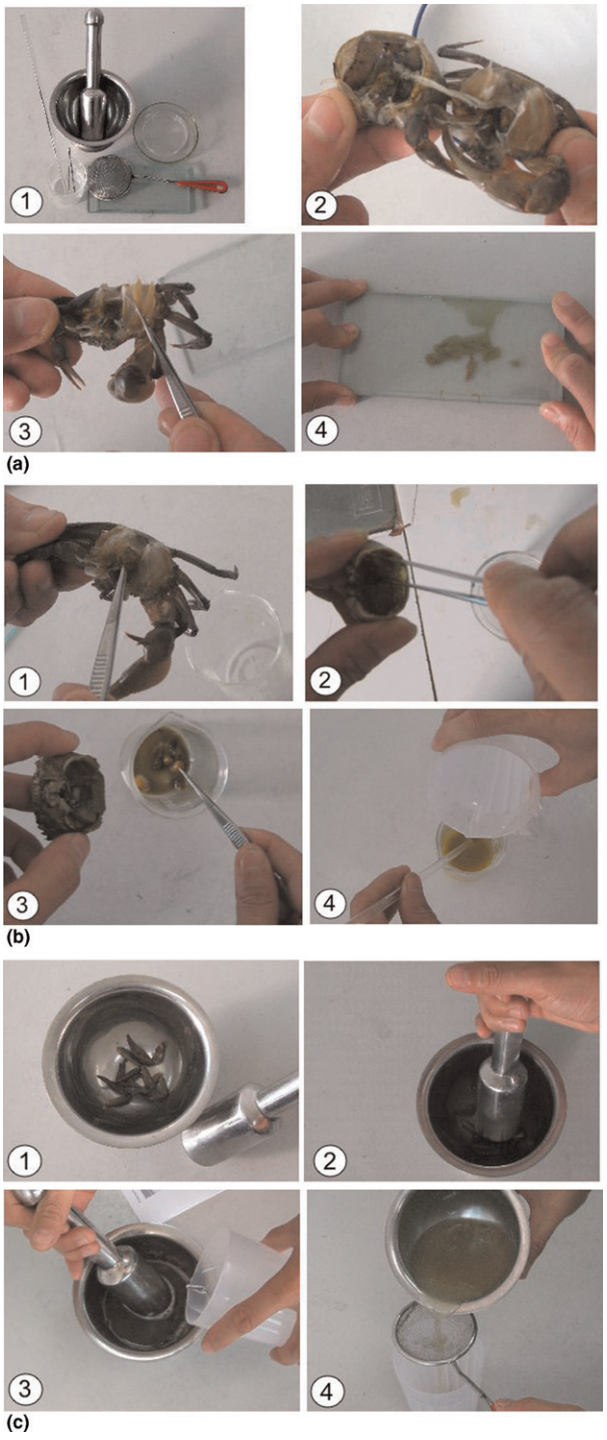

Figure 7 Methods for collecting metacercariae from freshwater crab hosts: (a) examination of the gills; (b) examination of hepatopancreatic tissue; (c) examination of the residual carcass of crabs.

becomes clear. The sediment is transfered to a Petri dish and examined under a microscope for the presence of metacercariae.

Finally (Figure 7(c)) the legs and the body are chopped into fine pieces (Figure 7(c1)) and smashed with a mortar and pestle (Figure 7(c2)). Tap water is added to the mortar and mixed well (Figure 7(c3)). The homogenate is then transferred through a stainless mesh strainer into a cup (Figure 7(c4)). The sedimentation/decantation process is repeated until the supernatant becomes clear, and the sediment is examined under a microscope.

Some of the typical *Paragonimus* metacercariae are shown in Figure 8. Remember that crabs are sometimes infected with metacercariae of more than one species of *Paragonimus* or other trematodes. Morphological and morphometric records are critically important for further identification. Polymerase chain reaction (PCR)/sequencing of some genes like ITS2 and CO1 is extremely useful for confirmation of the identification of species. If sufficient numbers of metacercariae can be obtained, experimental infection of mammalian hosts (dogs, cats, and rodents) is recommended to obtain adult worms for both morphological and genetic identification.

For the examination of the meat of paratenic host animals like wild boar, press thin slices of meat between two glass plates and examine under a microscope. After examination, put the meat slices into artificial gastric juice (pepsin/HCl solution) and incubate at 37 °C overnight. Transfer the digested materials and fluids through the mesh and clear the sediments by sedimentation/decantation; examine the sediment under a microscope.

For the mammalian definitive or paratenic hosts, serological screening by enzyme-linked immunosorbent assay (ELISA) can be used to determine the seroprevalence.

Diagnosis

Diagnosis of paragonimiasis can be made by detecting *Paragonimus* eggs in the sputum or feces by microscopic examination. However, the egg detection rate is not very high, especially in areas of low endemicity like Japan (less than 50%). Even in heavily endemic areas, egg-positive cases are just the tip of the iceberg (Figure 9).

Where egg-positive cases are found, there must also be egg-negative, symptomatic, and seropositive cases as well as egg-negative, asymptomatic, and seropositive cases. Therefore, diagnosis of human paragonimiasis is mainly based on clinical features with the supporting evidence of chest X-ray and immunological tests together with the history of eating intermediate/paratenic hosts. In the classic textbooks, it is often said that nodular/cavitating lesions are the typical radiological findings of *P. westermani* infection, whereas pleurisy is common in *P. skrjabini* (including *P. miyazakii*) infection. However, pleurisy is frequently seen in *P. westermani* infections nowadays in Japan, possibly due to earlier diagnosis and low density infections. Pleurisy was reported to be a good indicator for *P. heterotremus* infection in Lao PDR.

Differential diagnosis for ectopic paragonimiasis is more problematic than in pulmonary cases. Clinical features of cutaneous paragonimiasis are somewhat similar to those caused by other parasites such as *Gnathostoma* or *Sparganum*. The majority of cutaneous parasitoses cases have been diagnosed by postoperative identification of surgically extirpated worms. Because mobile cutaneous lesion(s) with eosinophilia are the suggestive indicators of cutaneous parasitoses, an immunological screening test such as multiple-dot ELISA is helpful to avoid unnecessary surgery. The acute phase of

Figure 8 *Paragonimus* metacercariae of various shape and appearances: (a) *P. heterotremus*; (b) *P. bangkokensis*; (c) *P. westermani*; (d) *P. skrjabini miyazakii*; (e) *P. vietnamensis*; (f) *P. harinasutai*; (g) *P. proliferus*. Scale bar = 200 μm.

cerebrospinal paragonimiasis also needs to be differentiated from other CNS-parasitoses, such as angiostrongyliasis, cysticercosis, gnathostomiasis, etc. In the chronic stage, epileptic seizure is the most common clinical manifestation of cerebral paragonimiasis, and again, differential diagnosis from neurocysticercosis or brain tumor is necessary. Immunoserological tests are helpful, but antibody might not be detected in chronic cases of more than several years duration. Reliable serological tests have been applied for immunodiagnosis of human paragonimiasis; these include ELISA and immunoblotting-based methods. Immunoblotting for the detection of IgG4 antibody to excretory and secretory (ES) products of adult *P. heterotremus* provides a sensitive and specific test. Recently, purified or recombinant proteins of *P. westermani* cysteine proteinases or recombinant egg antigen have been tested as an ELISA antigen with high sensitivity and specificity in serodiagnosis. Nevertheless, none of the immunological diagnosis systems can identify the pathogen to species. A PCR assay for detection of DNA from *Paragonimus* eggs in sputum or in histopathological sections has a potential in clinical epidemiological studies to provide species/geographical population identification.

Treatment

The anthelminthic drug, praziquantel (PZQ), is recommended as the drug of choice for the treatment of *Paragonimus* infection. According to the manufacturer's instruction, 40 mg kg^{-1} body weight should be taken per day, for two days. However, this dose sometimes resulted in incomplete cure for *P. westermani* patients who subsequently required additional doses. A dose of 75 mg kg^{-1} body weight per day for 2–3 days is recommended in Korea and Japan. This regimen gives an

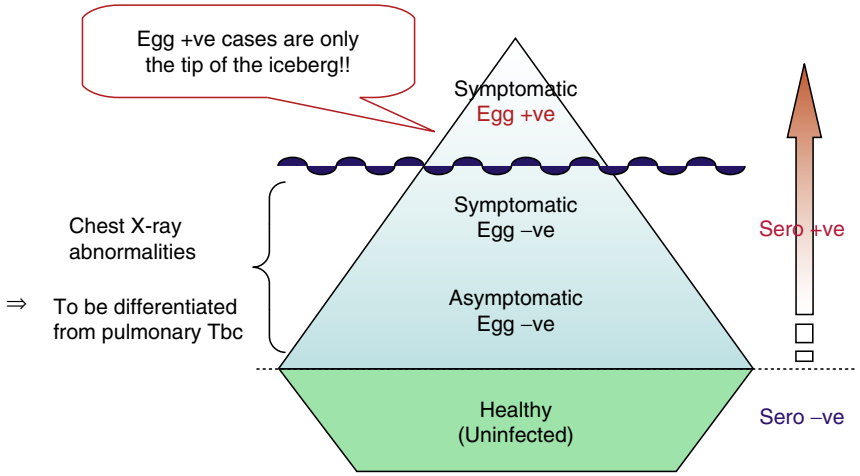

Figure 9 Sputum and fecal egg-positive patients are only the tip of the iceberg! Symptomatic egg-negative or asymptomatic egg-negative cases can be detected only by immunoserological methods Tbc, tuberculosis.

almost 100% cure rate but still a few cases showed resistance. A dose of PZQ 25 mg kg^{-1} of body weight for 1–3 days produces a cure rate of 70–100% for *P. heterotremus* infection in Thailand.

As an alternative to PZQ, field trials of triclabendazole (TBZ), which is a drug of choice for fascioliasis (WHO), was conducted in Cameroon for *P. africanus* infection, and in Ecuador for *P. mexicanus* infection, with reasonably satisfactory results by a single dose of 10 mg kg^{-1} of TBZ . The efficacy of TBZ against *P. skrjabini* was evaluated in experimental infections in dogs and five human cases in China with satisfactory results. However, the efficacy of TBZ against *P. westermani* is not quite satisfactory; in the Philippines, the cure rate of 10 mg kg^{-1} TBZ single dose for *P. westermani* was 18/24 (76%) by sputum egg detection at 90 days after a treatment. Similarly, the cure rate of a single dose of 10 mg kg^{-1} of TBZ for *P. westermani* cases was 3/5 (60%) in Japan. In both countries, the efficacy of 75 mg kg^{-1} day^{-1} PZQ for 3 days treatment for *P. westermani* infections was nearly 100%. The efficacy of TBZ seems to be variable depending on *Paragonimus* species.

Prevention and Control

Theoretically the most effective way to control paragonimiasis is to cure patients or to interrupt the life cycle. However, *Paragonimus* species exploit snail first intermediate hosts and crustacean second intermediate hosts, and a variety of mammalian definitive hosts. Therefore, elimination of the parasite or the interruption of the life cycle would require serious environmental destruction and have significant effects on the biodiversity in the endemic areas. Diagnosis and treatment for mammalian definitive hosts except for humans are practically impossible. The only possible and practical way is to change the habit of consuming raw crabs and crayfishes by education campaigns. Again, this seems to be effective only temporarily, as the re-emergence of paragonimiasis has been occurring in highly developed countries like Japan and the US.

Early diagnosis with effective treatment would be the only practical measure of control. In this regard, repeated education concerning paragonimiasis and other food-borne diseases is critically important and necessary not only for the residents, but also for the clinicians in endemic areas.

Research Needs

1. Identification of natural definitive mammalian hosts to confirm the natural life cycle.
2. Identification of factors determining the infectivity to humans (host specificity).
3. Phylogenetic and biogeographical relationships within and among African, Asian, and American *Paragonimus* spp.
4. Establishment of immunodiagnosis system to discriminate/identify the pathogen at the species level.
5. Development of more effective drugs.

SPIROCHETES

Leptospira

AJ Rodriguez-Morales, Universidad Tecnológica de Pereira and Office of Scientific Research, Pereira, Risaralda, Colombia
DM Castañeda-Hernández, Fundación Universitaria del Área Andina, Pereira, Colombia

Glossary

Surveillance In public health and epidemiology, the discipline of continuously gathering, analyzing, and interpreting data about diseases, and disseminating conclusions of the analyses to relevant organizations, to intervene in their patterns in order to control and prevent them.

Zoonosis Any infectious disease that can be transmitted between species (by different ways, by a vector or by their products and food) from animals to humans or from humans to animals (less common).

Introduction

Leptospirosis (also known as Weil's syndrome, canicola fever, canefield fever, nanukayami fever, 7-day fever, rat catcher's yellows, Fort Bragg fever, black jaundice, pretibial fever, and Stuttgart fever) (tenth International Classification of Diseases A27) is caused by infection with bacteria of the genus *Leptospira*, and affects humans as well as other mammals, birds, amphibians, and reptiles. It has been reported in more than 150 mammalian species.

History of Disease

The disease was first described by Adolf Weil in 1886, when he reported an acute infectious disease with enlargement of spleen, jaundice, and nephritis. *Leptospira* was first observed in 1907 from a postmortem renal tissue slice. In 1908, Inada and Ito first identified it as the causative organism and in 1916 noted its presence in rats.

The Pathogen

Though recognized among the world's most common diseases transmitted to people from animals, leptospirosis is nonetheless a relatively rare bacterial infection in humans. The infection is commonly transmitted to humans by allowing water contaminated by animal urine to come in contact with unhealed breaks in the skin or eyes, or with mucous membranes. Rodents can contaminate water as well as food, thus becoming an important source of infection for human beings. Outside of tropical areas, leptospirosis cases have a relatively distinct seasonality with most of them occurring in spring and autumn.

Before 1989, the genus *Leptospira* was divided into two species, *Leptospira interrogans*, comprising all pathogenic strains, and *Leptospira biflexa*, containing the saprophytic strains isolated from the environment. *L. biflexa* was differentiated from *L. interrogans* by the growth of the former at 13 °C and growth in the presence of 8-azaguanine (225 μg ml^{-1}) and by the failure of *L. biflexa* to form spherical cells in 1 M NaCl. Additional to these 2 species 19 other species are described and reported at the National Center for Biotechnology Information (NCBI) taxonomy bank (Table 1).

Both *L. interrogans* and *L. biflexa* are divided into numerous serovars defined by agglutination after cross absorption with homologous antigen. If more than 10% of the homologous titer remains in at least one of the two antisera on repeated testing, two strains are said to belong to different serovars. More than 60 serovars of *L. biflexa* have been recorded, although up to 2012 at the NCBI taxonomy bank only serovars Ancona, Andamana, Canela, Jequitaia, Monteralerio, and Patoc have been recognized. Within the species *L. interrogans* more than 200 serovars have been described and 84 are recognized at the NCBI taxonomy bank for 2012 (Table 2); additional serovars have been isolated but are yet to be validly published. Serovars that are antigenically related have traditionally been grouped into serogroups. Although serogroups have no taxonomic standing, they have proved useful for epidemiological understanding.

There are at least five serovars of importance in the United States of America (USA) and Canada, all of which causes disease in dogs (Icterohaemorrhagiae, Canicola, Pomona, Grippotyphosa, and Bratislava) (Table 2).

There are other (less common) infectious strains (Table 2). Genetically different *Leptospira* organisms may be serologically

identical and *vice versa*. Hence, an argument exists about the basis of strain identification. At present, the traditional serological system seems more useful from a diagnostic and epidemiologic standpoint (which may change with further development and spread of technologies like polymerase chain reaction (PCR)).

Transmission

Leptospirosis is transmitted by the urine of an infected animal and is contagious as long as the organisms are still moist. Although rats, mice, and moles are important primary hosts, a wide range of other mammals including dogs, deer, rabbits, hedgehogs, cows, sheep, raccoons, opossums, skunks, and certain marine mammals are able to carry and transmit the disease as secondary hosts. Dogs may lick the urine of an infected animal, off the grass or soil, or drink from an infected puddle. There have been reports of 'house dogs' contracting leptospirosis apparently from licking the urine of infected mice that entered the house. The type of habitats most likely to carry infective bacteria are muddy riverbanks, ditches, gullies, and muddy livestock rearing areas where there is regular passage of either wild or farm mammals. There is a direct correlation between the amount of rainfall and incidence of leptospirosis, making it seasonal in temperate climates and year round in tropical climates.

Leptospirosis is also transmitted by the semen of infected animals. Slaughterhouse workers may contract the disease through contact with infected blood or body fluids.

Humans become infected through contact with water, food, or soil containing urine from these infected animals (secondary hosts). This may happen by consuming contaminated food or water, or through skin contact. The disease is not known to spread from person to person and cases of bacterial dissemination in convalescence are extremely rare in humans. Leptospirosis is common among water-sport enthusiasts in specific areas as prolonged immersion in water is known to promote the entry of the bacteria. This situation was particularly highlighted in 2000 after an outbreak among 'Eco-Challenge' athletes, in Malaysian Borneo. Surfers and whitewater paddlers are at especially high risk in areas that have been shown to contain the bacteria, and can contract the disease by swallowing contaminated water, splashing contaminated water into their eyes or nose, or exposing open wounds to infected water. Occupations at risk include veterinarians, slaughterhouse workers, farmers, sewer workers, and people working on

derelict buildings. Rowers are also sometimes known to contract the disease. Farmers working closely with cattle, particularly during milking, are mostly at risk. Infection can be acquired during milking through urine splashes or by breathing in an aerosol of urine droplets. The risk of infection is greatest in 'herringbone' parlors where the milkers are below the level of the cows. Infection can also be acquired from discharges after calving or abortion. Milk can be contaminated with *Leptospira*. Leptospirosis can be transmitted via breast milk.

In the past century, many outbreaks related to food contamination were internationally reported. However, most recent outbreaks are associated with occupational and recreational contaminated water exposure. In some countries, however, cans have been contaminated with rats' urine. This highlights the need and relevance of pest management in the warehouses of food industry.

Biological Hazards

Leptospira is considered among the group of viruses and bacteria that cause only mild disease to humans, or are difficult to contract via aerosol in a lab setting, such as hepatitis A, B, and C; influenza A; Lyme disease; *Salmonella*; mumps; measles; scrapie; dengue fever; and human immunodeficiency virus (HIV). This corresponds to biohazard level 2 (mild risk for humans).

Epidemiology

Leptospirosis has a worldwide distribution. This pathology remains one of the most common and dreaded zoonotic infections. Traditionally related to certain socioeconomic or climatic conditions that favor endemicity in animal vectors and human exposure, it is generally confined to the developing parts of the world, particularly in islands of Asia and the Caribbean where incidence can reach figures as high as 432 cases per million population. The incidence is higher in the tropics than temperate regions. This zoonosis is randomly reported from industrialized countries often as an imported disease following international travel to exotic destinations. In both developing and developed countries, leptospirosis is an important public health problem related to poor housing conditions. In recent years, a new trend in human leptospirosis outbreaks has been observed related to recreational activities among the wildlife (a form of tourism that is becoming increasingly popular) and army expeditions, either for training or for combat-related purposes in similar environments. Thus, leptospirosis has become an important infectious agent to take into account when preparing for such expeditions, and this is reflected in efforts to define and utilize successful preventive antibiotic administration policies. Leptospirosis has become an important foodborne zoonosis in travelers.

The disease is seasonal, with peak incidence occurring in summer or fall in temperate regions. Extensive flooding and seasonal rainfall are significant risk factors for exposure to water contaminated with leptospires. A report from Brazil described a relationship between rainfall and human leptospirosis. Much of the resurgent international interest in leptospirosis stems from several large clusters of cases which have occurred in Central and South America following flooding as a result of El Niño-related excess rainfall. However, the occurrence of large outbreaks of leptospirosis following severe floods is not a new phenomenon and not restricted to tropical regions.

Leptospirosis was formerly considered to be primarily an occupational disease associated with agriculture, mining, livestock farming, and military maneuvers.

Eradication of the disease involves not only the attention of veterinarians but also adequate health and surveillance networks in the developing world; awareness of the evolution of the global incidence of human disease is important for acknowledging the relative risks in international travel and highlighting world areas that should move at the epicenter of enhanced disease surveillance and attempts at control from international health organizations.

According to the Office International des Epizooties, data available from the World Animal Health Information System, which is coupled with the World Animal Health Information Database interface (Handistatus), during 2004, 20 countries in the Americas reported human leptospirosis (Barbados, Brazil, British Virgin Islands, Chile, Colombia, Costa Rica, Cuba, Dominican Republic, El Salvador, Guadeloupe (France), Guyana, Jamaica, Mexico, Nicaragua, Panama, Paraguay, Saint Vincent and the Grenadines, USA, Uruguay, and Venezuela). For that year such reports totalize more than 4200 cases (Table 3). This represents a significant burden of disease in this region.

Recent data from serological studies indicated that in some areas of Latin America (e.g., Coffee triangle, Colombia), as many as 33% of cattle can be reported positive. In humans, some studies in Latin America have recently reported figures of 37% (e.g., Madre de Dios department, Peru) or up to 68% (e.g., Córdoba, Colombia), using microscopic agglutination test. In Peruvian Amazon, so far this year (2012), in the Loreto Regional Hospital (HRL) alone, five patients have been treated with severe pulmonary leptospirosis (with pulmonary hemorrhage) who recovered in the intensive care unit; a probable fatal case referred from a private clinic awaiting confirmation of the diagnosis; and a current patient who is in critical condition in the intensive care unit of HRL (22 April 2012). In addition, a man from Nauta with febrile icteric syndrome (confirmed by PCR, died on 22 April 2012) with a diagnosis of severe leptospirosis and renal failure, and two young men with lung injury remained in hospital but they were in stable condition owing to the timely diagnosis and medical attention. In Fiji, Pacific Ocean, in 2012 (from January to April), 279 people have contracted leptospirosis, which is attributed to the January floods.

Clinical Presentation

Leptospirosis has been described as a zoonosis of protean manifestations. In any case, expert consensus is that leptospirosis occurs as two recognizable clinical syndromes: anicteric and icteric leptospirosis.

Anicteric leptospirosis is a self-limited disease similar to a mild flu-like illness. Icteric leptospirosis, also known as Weil's

+, Reported present or known to be present; –, no information available.

disease, is a severe illness characterized by multiorgan involvement or even failure. Two distinct phases of illness are observed in the mild form – the septicemic (acute) and immune (delayed) phases. In icteric leptospirosis, the two phases of illness are often continuous and indistinguishable. At disease onset, clinically predicting the severity of disease is not possible. Subsequent sequelae depend on the serovar involved and the health, nutritional status, and age of the patient, as well as the rapidity of definitive and supportive treatment.

A third syndrome of asymptomatic infection is more controversial, but has been reported and some studies indicated that more than 10–15% of the population in endemic areas would show positive to serological test although not presenting any clinical symptom.

The spectrum of symptoms is extremely broad; the classical syndrome of Weil's disease represents only the most severe presentation. Formerly, it was considered that distinct clinical syndromes were associated with specific serogroups. However, this view was questioned by some authorities, and more intense study over the last 30 years has refuted this hypothesis. An explanation for many of the observed associations may be found in the ecology of animal hosts' maintenance in a geographic region. A region with a richly varied fauna will support a greater variety of serogroups than a region with few animal hosts. In humans, severe leptospirosis is frequently but not invariably caused by serovars of the Icterohaemorrhagiae serogroup. The specific serovars involved depend largely on the geographic location and ecology of local maintenance hosts. The Icterohaemorrhagiae and Canicola serovars are supposed to be present worldwide, but the rest are mostly localized in certain areas of the world. Thus in Europe, serovars Copenhageni and Icterohaemorrhagiae, carried by rats, are usually responsible for infections, whereas in Southeast Asia, serovar Lai is common. In South America, in 2005 serovar Buenos Aires was described and isolated from an aborted dog fetus in Argentina.

The clinical presentation of leptospirosis is biphasic, with the acute or septicemic phase lasting for approximately a week, followed by the immune phase, characterized by antibody production and excretion of leptospires in the urine. Most of the complications of leptospirosis are associated with localization of leptospires within the tissues during the immune phase and thus occur during the second week of the illness.

Prevention

Prevention of leptospirosis can be achieved either by elimination of the environmental risk, by preemptive development of protection through vaccination (in animals) or by prophylactic administration of antibiotics in susceptible populations. Prevention may be also achieved through the use of protective clothing or by changes in animal husbandry, as well as by avoiding food and water contamination with *Leptospira*-infected sources.

As already noted, environmental control of leptospirosis is a futile target because the ecology of the species and serovars continually evolves, partly owing to animal vaccination strategies. Animal vaccination is sufficient to control endemically infected herds. Annual booster vaccination should be carried out in spring in order to boost immunity before summer, which is the time when maximum spread of the infection occurs. However, it is recommended that vaccination should be completed at least 3 weeks before the breeding season begins as vaccination during the breeding season may impair fertility.

Risk factors for the disease include natural disasters such as floods following excessive rain. This is a trend extensively recognized in most endemic areas and can provide a framework for disease, or at least outbreak, prevention. Yet shortcomings of the public health sector in such impoverished endemic areas often preclude such interventions. Similarly, implementation of protective measures to minimize exposure to infected soil and water is subject to public health sector adequacy.

The utility of doxycycline in preventing disease in susceptible populations was excellent in a study done in USA troops stationed in Panama. Administration of doxycycline was also widely used for prophylaxis in subjects exposed during an international outbreak related to recreational activities. In the latter case, however, the doxycycline benefit might actually refer to a percentage of exposed subjects who would not have developed clinical disease anyway. Other efforts to implement doxycycline prophylaxis in endemic settings have not proved as statistically significant. At present, doxycycline administration appears a logical preventive measure on potential exposure to leptospirosis. Moreover, it may serve preventively both for other zoonoses with a common environmental distribution and for other tropical infections that may pose risks for travelers.

In many countries leptospirosis is included in epidemiological surveillance, however, in many other places it is not. This should be enhanced particularly in those developing countries where there is still lack of regular control programs for leptospirosis, foodborne, and zoonotic diseases. Additionally, further development of the prevention strategies is also required to support zoonosis risk reduction impact on disease.

Countries with leptospirosis ought to establish public health programs for its prevention and control, as a part of building a comprehensive initiative for the control of all important infectious diseases. After establishing disease surveillance and laboratory support service, the disease burden must be monitored before and during interventions for control.

Conclusion

Leptospirosis remains as one of the most important hemorrhagic bacterial zoonotic diseases in the World. The last decade has been linked to new epidemiological settings, such as its occurrence in travelers and people practicing recreational activities in aquatic places. Even more, natural disasters, particularly flooding appears to increase disease risk, especially in developing countries, where there is a lack of effective control programs. Contamination of water and food from different sources still make leptospirosis an important foodborne disease particularly in developing countries. Thus, further actions in research and public health control are required to improve its epidemiological burden and significantly reduce its occurrence that as has been shown can lead even to fatal cases.

VIRUSES

Contents

Hantavirus

PJ Padula, National Institute of Infectious Diseases INEI, Buenos Aires, Argentina

Glossary

Cross-immunity One agent causes immunity against other serogroups or serotypes.
Immunoglobulin A protein that acts as an antibody to help the body fight off disease. There are 5 classes: IgG, IgA, IgD, IgM and IgE.
Pathogenesis The natural evolution of a disease process in the body without intervention or treatment.
Platelet Blood cells that are essential to clotting.
Prodrome An early or premonitory sign or symptom of a disorder.
Reservoir A passive host that harbors pathogenic organisms without injury to itself and serves as a source from which other individuals can be infected.
Viremia The presence of viruses in the blood.
Virus A group of infectious agents characterized by their inability to reproduce outside of a living host cell.
Zoonoses Diseases that may occasionally be transmitted from animals to people.

Characteristics

Hantaviruses are named after the Hantaan River in Korea, where the Hantaan virus was shown to be the cause of a deadly disease in soldiers stationed there in 1951. Over the next few years, several other etiologic agents of a similar renal syndrome were discovered across Europe and Asia. At the end of the twentieth century a new pulmonary disease caused by these viruses was discovered in USA.

Hantaviruses are enveloped viruses with a negative-stranded RNA genome composed of three segments (family Bunyaviridae and genus *Hantavirus*). These viruses are distributed worldwide and in nature are hosted by wild mammals, such as persistently infected rodents and shrews, without apparent signs of disease manifestation but secrete virus for prolonged periods. Hantaviruses are transmitted to humans by inhalation of virus-contaminated urine, feces, and/or saliva. It is yet not known if human infection of shrew-borne hantavirus may be possible.

They are associated with two severe diseases:

- Hemorrhagic fever with renal syndrome (HFRS), (5–10% case-fatality rate). It is caused by viruses of the Old World hosted by rodents of two subfamilies, Murinae and Arvicolinae.
- Hantavirus pulmonary syndrome (HPS), or also known as hantavirus cardiopulmonary syndrome, (20–50% case-fatality rate) is caused by viruses confined to the New World and is distributed by Sigmodontinae rodents, thus, due to the distribution of these rodents, HPS is confined to the New World (Table 1).

Treatment is mainly supportive; there are no agents available to eliminate the virus or to avoid a disseminated infection. The drug ribavirin has been effective in HFRS, but not HPS.

The development of vaccines against these diseases has been hampered by the lack of animal models of the disease. None of the Old or New World hantaviruses cause illness or death in any animal model, with the exception of Andes virus (ANDV), which causes a lethal disease in hamsters that is very similar to human HPS. An ideal candidate as a vaccine would be one that protects against the two types of disease.

Clinical Manifestation

The two mainly different clinical forms of the disease are HFRS, which includes diseases such as Korean hemorrhagic

 doi:10.1016/B978-0-12-378612-8.00125-6

fever, epidemic hemorrhagic fever, and nephropathia epidemica (fever and renal syndrome) and HPS. However, increasing evidence suggests that the boundaries of these two diseases are no longer perfectly separated, and for this reason it was recently proposed to join the denomination as hantavirus disease (HVD).

Renal Syndrome

The symptoms can be split into five phases:

- The incubation period is 12–16 days (range 5–42).
- The disease begins with a febrile phase characterized by flu-like symptoms: fever, chills, headache, nausea, abdominal and back pain, respiratory problems like dizziness that is accompanied by diarrhea and proteinuria and lasts for 4–7 days.
- There is a leukocytosis and a thrombocytopenia that lead to the formation of petechiae (blood spots) on the buttocks and soft palate, usually called the hypotensive phase. The development of a capillary leakage syndrome leads to a loss of blood pressure at approximately the fifth day. The drop may be small and short lived or large enough to cause shock, and symptoms can lead to tachycardia and hypoxemia. This phase can last for 2 days.
- The disease enters a renal phase, that lasts for 3–7 days and is characterized by the onset of renal failure and proteinuria occurs, affecting the kidneys characterized at first by oligouria then polyuria which can last for a couple of days up to weeks, bleeding of the mucous membranes and edema of the lungs.
- The convalescent phase is when recovery occurs and symptoms begin to improve.

Pulmonary Syndrome

The symptoms can be split into four phases:

- The incubation period is 16–24 days (range 12–35).
- The clinical disease is manifested by a viral prodrome of 1–8 days. The symptoms, which are similar to HFRS, include fever, myalgias, headache, vomiting, and diarrhea; tachycardia and tachypnea generally do not develop until approximately day 6, followed by the precipitous onset of pulmonary edema. Such conditions can lead to a cardiopulmonary phase, where cardiovascular shock can occur. A characteristic of the disease is that it progresses very rapidly, and hospitalization and ventilation of the patient is required.
- Once the cardiopulmonary phase begins, patients can develop a pulmonary capillary leak syndrome leading to respiratory distress symptoms characterized by shortness of breath as the fluid fills the lungs. During this phase, thrombocytopenia is very marked; the decrease in platelets is rapid even when measured 8 h apart. The cardiopulmonary phase persists for up to 1 week, followed by spontaneous diuresis.
- A convalescent phase is characterized by weakness and exertional dyspnea for 3–4 weeks in almost all survivors.

Pathogenesis

Common features of both HFRS and HPS are:

- increased vascular permeability and decreased blood pressure due to endothelial dysfunction,
- syndromes are accompanied by myocardial depression and hypotension or shock,
- diseases appear to be immunopathologic, and inflammatory mediators are important in causing the clinical manifestations, and
- endothelial cells are susceptible to hantavirus infection; however, virus does not cause cytopathic effects, to explain increased endothelium permeability.

In HFRS, the most dramatic damage is seen in the kidneys which can cause fluid overload; the retroperitoneum is a major site of vascular leak and the kidneys suffer tubular necrosis where as in HPS, the lungs, spleen, and gall bladder are most affected. In the case of HPS, pulmonary capillary endothelial cells express high densities of infection; capillary leak is centered in the lungs leading to fulminant noncardiogenic pulmonary edema and may progress quickly to cardiogenic

shock. As in other viral systems, it appears that pathogenic hantaviruses possess mechanisms to antagonize the innate immune system including tumor necrosis factor-α, interleukin 1β, and interferon γ, though this has yet to be clarified. Although antibody-mediated protection is probably the key, cytotoxic T cells may play a role in both protective immunity and pathogenesis of the diseases.

Hantavirus infection in rodents is characterized by an acute phase of peak viremia, viral shedding, and virus replication in target tissues, followed by a persistent phase of reduced, cyclical virus replication despite the presence of high antibody titers.

Epidemiology

The geographic distribution and epidemiology of human cases of the diseases caused by hantaviruses have been considered a consequence of the distribution and natural history of their primary rodent hosts. The precise number of identified hantavirus species is a matter of debate; because the International Committee on Taxonomy of Viruses (ICTV) classification guidelines have not yet demarcated viruses below the species level, and only the main representative viral species pathogenic for humans were summarized in Table 1.

Four hantaviruses are known to cause HFRS:

- Hantaan virus (HTNV), which causes the most severe form of HFRS and is present primarily in Asia.
- Dobrava virus (DOBV), which causes serious HFRS and has been identified in the Balkans.
- Puumala virus (PUUV), a milder form of HFRS which causes a higher proportion of sub clinical infections and is prevalent in Europe.
- Seoul virus (SEOV), which results in a less severe form of HFRS and has a worldwide distribution.

China and Russia have the highest annual incidence of HFRS; most cases are attributable to the SEOV, with the Hantaan virus playing a minor role.

Genetic characterization of the first African hantavirus (Sangassou virus) detected in an African wood mouse (*Hylomyscus simus*) in Guinea was shown to be very closely related to the DOBV clade of hantaviruses, whose members cause the most severe cases of HFRS in Europe. Reports originated from serologic surveys of human populations demonstrated antibodies against this virus although its pathogenicity is unknown.

Since HPS was first recognized it has been identified throughout nearly all American countries. The Sin Nombre (SNV), the cause of the majority of HPS cases in USA and the ANDV of South America, cause the most severe disease, although the number of confirmed annual cases is low (100 cases per country) related to HFRS (approximately 10 000 cases per country).

High rodent population densities and special human activities can result in increased cases of rodent-borne disease. Several rodent species are associated with additional hantaviruses that have not been implicated in human disease. Also, the role of several European and American hantaviruses in transmission of infected nonreservoir rodents (spill-over) is not very clear. Based on a large panel of fragments of the N- and GPC-encoding American strain sequences, phylogenetic studies reported molecular evidence that pathogenic hantavirus in America is represented by different genetic lineages associated in most of the countries with *Oligoryzomys* species according with the geographic distribution.

Person-to-person transmission is rare and has been reported with ANDV in Argentina and Chile, primarily associated with close and prolonged contact, and occurred early in the respiratory phase of the disease. In addition, SEOV was found in several sites in USA, Argentina, and Brazil but was not associated with typical HFRS.

Analytical Methods

Seroprevalence is the first test to do when investigating hantavirus infection, performed principally with an enzyme-linked immunosorbent assay or immunofluorescence assay, to detect immunoglobulin M (IgM) antibodies to hantavirus. The hantavirus-infected patients showed an early and strong IgM, immunoglobulin G, and immunoglobulin A serum antibody response, in most of the cases as early as 1–4 days following the onset of symptoms.

Although native hantavirus antigens are being widely used as diagnostic reagents, their production requires expensive containment laboratory conditions for virus propagation. Recombinant protein technology is less expensive and proteins are generated in larger amounts.

Hantaviruses may be present in clots, lymphocyte fractions, and plasma from patients with acute HPS or HFRS and also in the blood, autopsied tissues, saliva, feces, or urine of infected rodent reservoirs. The difficulty in isolation of hantaviruses has constrained efforts to detect viral genetic material by RT-PCR and sequencing. Real-time RT-PCR offers significant improvements to the quantitation of viral load and in the reduced risk of carry-over contamination into the laboratory.

According to CDC, Biosafety Level 2 (BSL-2) facilities and practices are recommended for laboratory handling of sera from persons potentially infected with hantavirus. Potentially infected tissue samples should be handled in BSL-2 facilities in accordance with Biosafety Level 3 (BSL-3) practices.

Control and Preventive Measures

Most cases of human illness associated with hantaviruses have resulted from prolonged exposure to aerosols from infective saliva or excreta of naturally infected wild rodents, particularly within a closed, poorly ventilated area. Rodent control in and around the home remains the primary strategy for preventing hantavirus infection. Hantaviruses are heat labile and are susceptible to lipid solvents, detergents, and disinfectants like dilute hypochlorite solutions.

The possibilities of infection associated with ingestion of food contaminated with the virus, contact with mucous membranes, or contamination of breaks in the skin barrier have not been clearly evaluated. Hantavirus survival through the digestive tract is unlikely to occur. Very few viruses can survive exposure to saliva because of the potency of antiviral compounds in the saliva like several proteins as secretory

leukocyte protease inhibitor. If it survives, hantavirus must pass through acid condition of the stomach and avoid destruction by enzymes like pepsin, which are designed to disassemble protein or lipid coats of most viruses. But the source of disease instead of being contaminated food could be breathing in air surrounding food, garbage, and food stores contaminated by relatively fresh mouse droppings. *Ex vivo* stability of hantaviruses has been shown to persist much longer in a humid as compared to a dry environment.

The prevention is done primarily by sealing cracks and holes of the food storage area for possible mouse entry with materials that will be resistant to gnawing. The cartilage in rodent's heads allows them to go through a hole as small as 1/4 in. Besides, packaged food must be placed in metal containers, glass bottles, and heavy plastic containers with tight fitting lids, all of them resistant to rodents.

Rodents are the animal species most frequently included in the human diet; in the temperate world, they serve only as a supplement to the regular diet, however in the tropical world, they are widely accepted as a popular source of protein. Consuming rodents in pesticide-treated areas and handling rodents with potential zoonoses like hantavirus are two possible risks. Pesticide materials may be retained in meat. Exposure to zoonoses from ectoparasites, blood, and urine while handling rodents to be used for food is another possible risk that deserves attention.

Research Needs

An integrated investigation at the landscape scale will allow a better understanding of interactions between changes in climate, land use, and human behavior, together with the ecology of animal hosts of hantavirus agents. Further analyses are needed to provide a better knowledge of the serotypes circulating in America because studies on cross-protective immunity among them are hindered by difficulties to propagate virus in cell culture and isolation. Although efforts are continuing to develop safe and effective hantavirus vaccines, viral therapies are not thriving. A finite number of viral agents cause respiratory tract disease in the intensive care unit; some of them like hantavirus are rare but have an immense public health impact. Recognizing these viral etiologies becomes important in treatment, infection control, and public health measures. In many regions, it is still necessary to implement education programs for primary and infectious disease physicians to early suspect hantavirus infections. Wild animals, including rodents, should be taken into account in the national programs for food safety.

Hepatitis A Virus

A Rzeżutka, National Veterinary Research Institute, Puławy, Poland
N Cook, Food and Environment Research Agency, York, UK

Glossary

Cytopathic effect The cell damage caused by viruses.
Genotype Genetic type of microorganism determined on the basis of the genome sequence using typing techniques.
Hepatitis A A liver disease caused by a picornavirus.
Immunofluorescence A detection technique used for microscopy utilizing target-specific antibodies conjugated to a fluorescent molecule.
Infectivity Ability to produce an infection.
Molecular epidemiology The study of the occurrence and transmission of a disease within populations using molecular methods.
Molecular methods Techniques used for detection or identification of microorganisms at the genome level.
Strain An isolate of the same type of microorganism possessing different properties.
Viral capsid The protein shell that surrounds a virus particle.
Viremia The presence of viruses in the blood of an infected host.

Historical Background

A contagious disease with characteristic symptoms of jaundice, probably viral hepatitis, was first recognized in ancient times. In the twentieth century, the viral etiology of 'infectious hepatitis' was proven by isolation of the agent from stools of infected patients. In due course, hepatitis A has been recognized as an infection that is acquired through ingestion of viruses showing tropism to liver tissue.

Characteristics of Hepatitis A Virus (Taxonomy, Structure of the Virus, Genome Organization, and Virus Strains)

Hepatitis A virus (HAV) is classified into *Hepatovirus* genus within the Picornaviridae family. Mature virions are approximately 27–32 nm in diameter and can only be visualized under an electron microscope (Figure 1). The viral capsid has an icosahedral symmetry and is composed of 32 capsomers or protein subunits. The lack of lipid envelope makes HAV resistant to inactivation by heat, pH changes, and to many disinfectants, which affect enveloped virus infectivity. Cell-adapted HAV survives pH 1 when treated for 2 h at room temperature, and virus infectivity is still retained after incubation at 60 °C for 1 h. Infectivity can be preserved for at least 1 month after drying and storage at 25 °C with 42% humidity or even years at − 20 °C. The longer a virus can survive outside a host, the greater are its chances for transmission. Like other picornaviruses, HAV has a potential to survive in water environments, soil, foodstuffs, and also on surfaces of inanimate objects for extended periods.

HAV has a linear, uncapped, single-stranded 7.5 kb RNA genome consisting of five segments. The 5′-end of viral RNA is linked to the VPg protein followed by the 5′-noncoding region (NCR) and P1–P3 regions. The genome has a short 3′-poly(A) tail acting as the terminator of translation. The genome has only one open reading frame, translated into a single precursor polyprotein, which is post-translationally cleaved to generate the functional viral proteins. The P1 genome segment encodes four structural proteins of the viral capsid (VP1, VP2, VP3, and VP4), whereas the translation of other genome

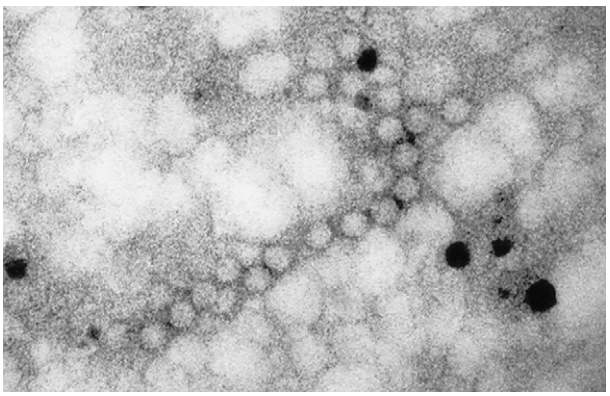

Figure 1 Electron micrograph of HM175 strain of HAV. Reproduced with permission of Albert Bosch and Rosa M. Pintó, Enteric Virus Laboratory, University of Barcelona.

 doi:10.1016/B978-0-12-378612-8.00126-8

segments, that is P2 and P3, results in formation of seven nonstructural proteins necessary for RNA synthesis and virion formation. The VP1 and VP3 capsid proteins act as an antigenic epitope on the viral surface which elicits a neutralizing antibody response. The nonstructural proteins of HAV have also been shown to be immunogenic.

Based on molecular differences and homology across the HAV genome, all virus strains are classified into one out of six genotypes. The genotypes I, II, and III have been isolated from humans, whereas genotypes IV, V, and VI are of simian origin. These isolates are genetically distinct from human HAV strains. Genotype I can be further divided into two subgenotypes, IA and IB, differing from each other at approximately 7.5% of base positions. This genotype is the most prevalent worldwide. Despite observing variations on molecular level, all isolates represent only one virus serotype. Consequently, in vaccinated individuals a single vaccine strain can induce the development of protecting antibodies against human variants of HAV, circulating on different continents.

Course of HAV Infection

HAV is infectious only for humans and primates; however, it cannot produce illness in all primate species. Virus transmission occurs mainly through the fecal–oral route either by direct contact with an ill person or by ingestion of contaminated food or drinking water. Disease development after exposure to the urine or nasopharyngeal secretions of infected individuals can occur but is uncommon and not well documented. A parenteral route of virus transmission has also been reported. After ingestion, viruses pass through the gastrointestinal tract to the liver via the hepatic portal vein. When virions reach the liver, they attach to HAVcr-1 receptors present on the hepatocytes, then enter these cells and replicate there. After virus formation, progeny are secreted into liver sinusoids and bile canaliculi, from where they are transported to the intestines to be finally excreted in feces. Liver cell damage is not entirely associated with virus release, but it appears as a result of immune mechanisms in which virus-specific T-cells are involved. Liver hepatocytes are the primary site of virus replication. Nevertheless, viruses have been shown in Kupffer cells and in the cytoplasm of epithelial cells of biliary ducts. The virus is also able to replicate in extrahepatic tissues like epithelial cells of the small intestine and salivary glands. Despite the presence of the virus in saliva, there is no scientific evidence that saliva-transmitted infection has ever occurred.

The mean incubation period of the disease is approximately 30 days with a maximum time of 50 days. A viremia precedes the development of symptoms by 7–14 days. During active virus replication, infected persons remain generally asymptomatic. When symptoms appear, they usually are mild or nonspecific. In adults, virus excretion in feces can occur 2–3 weeks before the onset of jaundice and lasts for at least 6 weeks after onset of symptoms. During that time, virus is shed via feces, which may contain $> 10^6$ infectious viruses per gram. In some cases, virus shedding has been observed 3 months after the onset of clinical symptoms. Generally, the severity of illness is age-dependent with milder symptoms of the disease reported in children than in adults. In young children, subclinical or anicteric infections are common, whereas in adults, hepatitis A is symptomatic with dark urine, pale stools, and jaundice. Symptoms observed in humans during the course of HAV infection are summarized in Table 1. Anti-HAV neutralizing antibodies, mostly IgM, appear in the serum shortly after the onset of symptoms. However, the major role in protection of individuals against reinfection is attributed to IgG antibodies, which confer lifelong immunity. Apart from IgM and IgG antibodies, the presence of fecal and serum anti-HAV IgA has also been evidenced, though their role of secretory immunity in protection against virus infection is limited. Although the disease is self-limiting, in some cases (3–20% of the patients) relapsing or prolonged hepatitis occurs. During relapse, the HAV virus can reemerge and cause jaundice,

Table 1 A summary of the symptoms reported among patients with hepatitis A

Period of infection	*Duration*	*Symptoms*
Incubation period	10–50 days	Lack of symptoms (active virus replication)
Prodromal (preicteric) phase	Several days to more than a week	General symptoms: fever, fatigue, malaise, myalgia, arthralgia Gastrointestinal symptoms: anorexia with disorders of taste and smell, sore throat, nausea, vomiting, diarrhea, constipation, hepatomegaly, splenomegaly, abdominal discomfort Symptoms from respiratory tract: cough Skin symptoms: rash, urticaria, exanthematous skin eruptions
Acute (icteric) phase	3 weeks	Gastrointestinal symptoms: anorexia, nausea, vomiting, hepatomegaly, hepatic tenderness, splenomegaly pale stools Skin symptoms: yellowish discoloration of the mucous membranes (conjunctivae, sclerae), jaundice, pruritus Other symptoms: dark, golden-brown urine, biochemical and hematological changes
Prolonged or relapsing hepatitis	Lasting up to 6 months after onset of illness	Biochemical changes

despite the presence of anti-HAV antibodies, with virus being detected in feces and serum. In some cases (approximately 1.5–4.7% of hepatitis patients), atypical manifestations of disease such as acute kidney injury have been reported. There is no evidence of chronic liver disease or persistent infection. A serious complication of the infection is a fulminant hepatitis, observed among young children and adults with underlying chronic liver disease. Fulminant hepatic failure is an extensive necrosis of the liver, resulting in disruption of its normal functions. The estimated mortality rate due to HAV infection is low, estimated at between 0.2% and 0.3%, but in patients over 50 years old, it increases to 2.1%. For the majority of patients (approximately 60%), complete clinical and biochemical recovery takes place within 2 months and within 6 months for the remainder.

Epidemiology

Prevalence of HAV Infections

In some parts of the world like North America, Western Europe, and Australia, the number of HAV outbreaks are declining, which is consistent with a low anti-HAV IgG seroprevalence in the population. Although anti-HAV IgG rates remain high or moderate in South America, Africa, Asia, Middle and Southern Europe, a declining trend in HAV seroprevalence is also observed. Seroprevalence rates are highly correlated with socioeconomic status and access to clean water and sanitation. For instance, in the US, the number of acute HAV cases has declined by 92% over a 12-year period, with 1 case recorded per 100 000 of inhabitants. International travel to countries where HAV infections are frequently reported is the most common risk factor for acquiring the disease. Furthermore, sexual or household contact and consumption of contaminated food or water are also indicated. Annually approximately 100 000 cases of HAV with approximately 500 deaths have been reported in the WHO European Region. The real number of food-borne HAV cases is difficult to estimate, due to prolonged virus incubation period and the lack of suspect food items for laboratory testing when the outbreak occurs. According to the European Food Safety Authority, in 2007, only 46 outbreaks of HAV were linked to consumption of contaminated food. Hepatitis A still remains a global public health concern, with approximately 1.5 million clinical cases reported worldwide annually.

Virus Transmission through Contaminated Food

In most HAV cases reported, a definitive virus source is not recognized and often there is a lack of evidence that food was the sole source of infection. In some outbreaks, the virus source and mode of its transmission was successfully identified through testing of the implicated foodstuff as a follow-up to an epidemiological investigation (Table 2). Detection of HAV outbreaks is complicated by the variable length of incubation period, which is dependent on the dose of the virus ingested and the difficulties in linking the illness with the type of food consumed. Food contamination can occur in different stages within a food supply chain. For instance, a common vehicle of virus transmission is sewage contaminated water, used for farming of shellfish or irrigation of food crops. Furthermore, extensive handling of fresh produce by infected field workers either during production or harvesting, processing, or packaging can result in food contamination. For instance, in an outbreak of hepatitis in New Zealand linked to consumption of blueberries, a traceback investigation of the produce indicated that fruit contamination by HAV occurred in the orchard, and an audit visit performed on the field revealed poor sanitary facilities, which did not facilitate proper hand hygiene among the berry pickers.

In addition, food preparation surfaces contaminated by viruses can also serve as an environmental virus route when produce is in contact with them. Viruses transferred to the surfaces of fruit and vegetables can persist sufficiently long between a contamination event and consumption to constitute a significant risk to consumer health. Most food contamination appears as a result of its handling during processing or at point of service. A good example is an outbreak recorded in Belgium, in which 269 individuals were infected by HAV. Raw beef was identified as the vehicle of virus transmission, and the virus source was a food handler working at the meat distribution plant. He was manually preparing beef meat by cutting and peeling it before its distribution to local butcheries. The food handler had contracted hepatitis A infection (confirmed serologically) and was working with bare hands in the days preceding his symptomatic illness. Blood and serum samples collected from infected persons and from the food handler were virus-positive. Subsequent sequence analysis of VP1/2A junction region of isolated HAV from patients confirmed that the infection was caused by the same virus strain. Although meat samples were not tested for the presence of HAV, there was enough evidence to state that consumption of raw beef was a probable source of infection. In these two outbreaks, the mechanism leading to the food contamination was clear. In both the New Zealand and Belgium cases, viruses were transferred to foodstuffs by infected persons working within the food supply chain. Lack of observance in personal hand hygiene among these workers allowed viruses to enter the food chain.

Another mechanism leading to food contamination can be seen with shellfish, that is, growth in polluted water environments. Shellfish are filter-feeding animals which collect nutrients from the surrounding water by passing them over gills in their body. If shellfish are grown in a sewage-polluted environment, in addition to nutrients, they can also concentrate pathogenic bacteria and viruses. HAV can persist in an infectious state in shellfish for more than 3 weeks following contamination, and viral RNA can be detected after 6 weeks post-contamination. Thus, consumption of shellfish harvested from polluted areas can constitute a risk of infection. The largest ever reported outbreak of HAV resulting from eating of virus-contaminated shellfish took place in China in 1988 and affected almost 310 000 persons. Since then, at least a dozen outbreaks of HAV have been recognized, in which shellfish were confirmed to be the vehicle of virus transmission, as recent example occurred in the US. In this case, the outbreak-related oysters were farmed and harvested from two Louisiana harvest areas in the Gulf of Mexico. The oysters were shipped

Table 2 Examples of food-borne hepatitis A outbreaks

Country	*Year*	*Number of infected persons*	*Implicated food/ food source*	*Virus source*	*Outbreak confirmation*	*HAV strain detected*	*Reference*
Canada	2005	16	Ready-to-eat foods, leafy salads/ restaurant	Food handler	Epidemiological investigation, laboratory testing of blood samples	Genotype IIIA	Heywood *et al.* (2007)[a]

to several restaurants where they were eaten in a raw state. Only one person among 38 victims admitted eating baked oysters. None of the case patients reported any other risk factors related to infection than food consumption. Oysters harvested from the same areas at the same time as oysters served to the case patients were collected for laboratory testing from a wholesaler who provided shellfish to the restaurants. Viruses were detected by reverse transcription polymerase chain reaction (RT-PCR) in the oyster meat. Hepatitis A RNA sequences derived from oysters were identical to virus sequences obtained from patients' sera. It was confirmed that all cases were due to infection by a single strain classified as

HAV genotype IA. This outbreak originated from a common source, and it is likely that this source contaminated oysters before distribution, because employees involved in shipment had minimal physical contact with the shellfish and none reported hepatitis symptoms. All implicated oysters have been harvested from approved areas remote from any fixed source of sewage discharge. Contamination of the shellfish beds by harvesters was unlikely, as they met all hygienic requirements. The probable sources of contamination were illegal waste disposal from recreational boats within legal harvest areas or illegal harvesting in closed areas.

Virus Transmission through Contaminated Water

Among other risk factors for acquiring HAV than consumption of contaminated foods is exposure to virus-polluted water. Contamination of drinking water sources can occur via improper disposal of untreated or partially treated sewage to the environment. Contamination can also be attributed to the failure in water treatment processes. Although water-borne transmission of HAV is less common compared to other virus types, there have been several HAV outbreaks documented where fecal-contaminated drinking or recreational water has led to infection and disease. For instance, a water-borne HAV transmission was recently described in China, where the outbreak was traced to a school's dining room. Cooked food was ruled out as a source of the virus, and all kitchen staff were negative for anti-HAV antibodies. The putative virus source was well water used for meal preparation and drinking. Some of the ill students admitted to drinking untreated water from the well. Unfortunately, the water source was not tested for the presence of HAV, but bacteriological analysis has revealed *Escherichia coli* contamination. Fecal contamination of the well may have potentially come from two toilets situated in close proximity to the well. No other event or food could explain the source of the disease. Molecular characterization of the HAV VP1/2A junction region showed that all individuals were infected by the same strain representing the IA genotype. Virus isolates revealed 100% homology of the analyzed sequences.

Analytical Methods for HAV Detection

Detection in Clinical Samples

High virus load in the feces of infected persons ($> 10^6$ virions/g) makes the detection of virus particles by electron microscopy possible. Although it allows identification and visualization of the viral agent in the tested sample, it is not routinely used due to its low sensitivity and labor intensity. Clinical diagnosis of HAV infection is based on serological tests, where the presence of anti-HAV IgM and/or IgG antibodies in serum can be confirmed. The concentration of the virus in blood is low, and viremia is transient compared to fecal virus shedding, so if detection of viral antigen is needed, it is performed on fecal samples using molecular tests. Apart from conventional RT-PCR, real-time RT-PCR is also used for direct virus RNA detection in a broad range of clinical and environmental samples. A novel method based on nucleic acid detection is a DNA microarray technique. It uses specific oligonucleotide probes, which can selectively bind to the target virus sequence during microarray hybridization. This method can allow identification of a single nucleotide polymorphism in the analyzed sequences; thus, virus strain, genotype, or subgenotype can be easily determined. This technique offers an alternative to sequencing of amplified PCR products and also has an advantage of being a potentially high-throughput system. A new approach for detection of hepatitis virus antigen in serum samples is integrated automatic electrochemical immunosensor array, enabling simultaneous detection of multiple viral targets in the same sample. The technology is based on immobilized specific virus antibodies on electrochemical sensor arrays. Viral antigen is captured by antibodies from a sample solution, and subsequently the potential change before and after antigen capture is measured. This assay offers simultaneous detection of five different hepatitis virus antigens in a short time as it requires only few minutes to fully analyze the sample. Moreover, it is both sensitive and cost-effective. Currently, this novel method has not been used in routine screening of clinical samples; however, it has an advantage of high-throughput technology, which could be applied in clinical diagnostics.

Infectivity and Cell Culture

Infection of cultured mammalian cells can be used for detection of HAV in clinical or food samples, but for routine diagnostics, it is impractical and time-consuming. Furthermore, wild HAV strains are difficult to adapt to grow in cell cultures, and virus presence in cells should be confirmed by another method, for example, immunofluorescence or molecular testing. Nevertheless, some strains have been successfully adapted to African green monkey kidney cells (Vero, BS-C-1, and BGMK) and to fetal rhesus kidney cell lines (FRhK-4, FRhK-6, and Frp/3). In addition, human hepatoma (PLC/PRF/5), human fibroblasts, and MRC5 human diploid lung cells may also support virus replication. It has been found that progeny virions can either remain associated with infected cells or released into culture medium without visible cell damage. If a cytopathic effect occurs, it is seen 2–14 days after cell inoculation. Successful adaptation of HAV strains to grow in cell culture is based on acquired mutations within the virus genome during growth. Two mutations are essential; one appearing in an internal ribosome entry site of the 5′-NCR and the second in the 2B and 2C region of the virus genome, coding for nonstructural proteins.

Detection in Foods

Methods to detect viruses in foods are composed of two basic parts: (1) sample treatment (preparation) and (2) detection assay. Within each part, variations can exist in application and approach, and this is reflected in methods, which have been developed and published hitherto. Sample treatment involves separating viruses from food substances. It can be performed using PEG precipitation, ultrafiltration, ultracentrifugation, or by using charged membranes or filters. An immunomagnetic separation can also be employed, where viruses are captured by antibodies coated on magnetic beads followed by their

removal from food extracts by magnetic separation. Subsequent to virus concentration, nucleic acids are extracted and purified. Detection assays are generally based on RT-PCR, with selective amplification of specific virus genomic sequences. RT-PCR has the potential for exquisite sensitivity, theoretically being capable of amplifying one target molecule in a single reaction. Different genes within the HAV genome can be targeted by RT-PCR, although the 5′-NCR region has been shown to be the most conserved among all currently isolated HAV strains and is frequently used as target sequence. A limitation of PCR-based analyses is the lack of indication as to viral infectivity. An alternative to RT-PCR is the nucleic acid sequence-based amplification (NASBA) technique, where amplification of RNA occurs through the simultaneous action of three enzymes at one temperature in a single step. The potential detection limits offered by NASBA are similar to those achieved by RT-PCR. Currently, there is no other alternative to molecular methods for virus detection in foods, offering high sensitivity and speed of analysis, and the resolution of the issue of regarding rapid infectivity may need to wait for new technological solutions.

Detection in Water

As with food samples, molecular methods are applied for the detection of viruses in water. However, water samples have to be substantially concentrated as only a small volume of sample can be used for nucleic aid extraction. There are several published methods for HAV concentration from water samples in which viruses are adsorbed to negatively or positively charged filters, glass powder, or glass fiber. In addition, viruses can be removed from water by filtration. Clogging of filters by particulate material can be a major problem. This can be overcome to some extent in tangential flow ultrafiltration systems, where a continuous flow of suspension is passed across the membrane, and liquid passes through pores with sizes approximately 0.01 μm, whereas larger sized particles are swept across them. The system circulates the suspension, and viruses are retained in a diminishing volume of liquid until the retention volume of the system is reached.

Virus Survival in Food

There are several types of produces which are prone to virus contamination, among which leafy green vegetables, berry fruits, and shellfish are of the most concern. Despite the increasing amount of food-borne outbreaks related to consumption of virus-contaminated food, the viral agent has mostly been detected in infected individuals or clinical samples collected from the person handling the food but rarely in the implicated food produce. This may be attributed to the low virus prevalence in food tested or the low sensitivity of the method used. HAV has demonstrated the ability to survive for a few days on lettuce, strawberries, and spinach stored at refrigeration conditions. This indicates that infectious viruses can persist on vegetables for several days under conditions commonly used for storage in households. Also, the potential of HAV to survive in chilled and frozen shellfish was shown in shellfish-related outbreaks. Furthermore, commonly applied food processes such as washing, freezing, and freeze-drying are ineffective in virus inactivation; thus, if produces are contaminated, they may present a potential health risk.

Control and Preventive Measures for HAV Contamination of Foods

Currently, infection in the community caused by HAV can be efficiently controlled through immunization of susceptible individuals. Mass vaccination against HAV is not routinely conducted; however, when it is performed, it usually follows WHO recommendations. Certainly, vaccine use in some countries and improvement of living conditions in others have resulted in a declining rate of HAV prevalence. But despite that, the virus transmission patterns have not changed, with contaminated food and water still recognized as an important risk factors for acquiring the disease.

Various methods are commonly employed to eliminate microbial pathogens from foods. Heating can inactivate HAV but is not appropriate for use with foods such as soft fruit and salad vegetables. Chlorination is in general use in the fresh produce industry, but the conditions employed may not be completely effective against HAV. Gamma irradiation is effective against HAV and other enteric viruses, but at levels which are higher than those generally permitted for use on foodstuffs. HAV can survive freezing, with little if any loss of infectivity, as demonstrated in outbreaks, which have occurred from consumption of frozen berries. High hydrostatic pressures are effective in eliminating infectious HAV.

It is, of course, better to prevent contamination from occurring in the first place than to try to eliminate it after it has occurred. This can be achieved by adoption of appropriate control procedures in food production. Agricultural industries, such as those involved in the production of soft fruit and fresh vegetables, must be adhere to good agricultural practice in order to minimize the risk of transmission of enteric viruses. Water used for irrigation or washing must be of good sanitary quality. Food handlers should be educated about microbial safety guidelines and rules of good hygiene. Any person with symptoms of acute hepatitis (fever, headache, fatigue combined with dark urine and light stools, or jaundice) should be excluded from handling foods or from being present in areas of food production. Where children can be involved in food production, for example, in countries where hepatitis A is highly endemic, it should be kept in mind that they can be infected with HAV without showing any symptoms. Vaccination of food handlers against HAV would be an effective prevention measure, especially when safe and effective inactivated vaccines are commercially available. Unfortunately, they are not used on a large scale within the food industry. This may be partly due to incompletely justified benefits related to the use of vaccine and its high cost. However, vaccination has been used on several occasions to control outbreaks of HAV in communities. Outwith the food industry, vaccination has been recommended for individuals being at risk of acquiring infection.

With shellfish production, there are various government regulations which specify sanitary controls covering several

areas such as the quality of the shellfish-growing waters, processing, and marketing of the food products; although these have been mainly developed with bacterial contamination in mind, they could be revised to take account of viruses. Depuration is often used to reduce microbial contamination but may not be entirely effective in removing viruses.

As the role of viruses as major agents of food-borne disease is becoming more widely recognized, there are consequent international efforts aimed at tackling the problem of contamination of foods by pathogenic viruses. For instance, the Codex Alimentarius Commission Committee on Food Hygiene is currently developing guidelines on the control of viruses in food. The development of virus-specific hazard analysis and critical control point (HACCP) plans would be welcome, and this is underway in European Commission supported research toward integrated monitoring and control of viruses in food supply chains. As a major food-borne pathogen, HAV is specifically included in all these activities, the outcome of which should help to reduce the threat to public health that contamination of foods with this virus causes.

Glossary

Asymptomatic Displaying no signs of disease.
Autochthonous Indigenous to an area.
Cell culture Animal cells grown *in vitro*.
Endemic A disease found commonly throughout a particular area.
Seropositivity Having antibodies against a specific agent.
Seroprevalence The proportion of individuals in a population that have antibodies to a specific agent.
Zoonotic Capable of transmission from animals to humans.

Introduction

Hepatitis E is a major cause of waterborne acute hepatitis in developing countries. The disease is endemic in parts of the world with poor sanitation and hygiene, where it occurs in large outbreaks. The first reported outbreak of hepatitis E occurred in Delhi, India, in 1955 and 1956, although it was not recognized as such until the 1990s, when advances in molecular diagnostics and immunodiagnostics made it possible to identify the viral agent. In developed countries, the disease was initially thought to be related only to travel in endemic areas. However, over the past few years a number of cases of locally acquired hepatitis E have been reported in Europe, USA, and Japan and evidence of an animal reservoir have been discovered. Routes of transmission of hepatitis E in developed countries are still unclear, but several cases of foodborne transmission have been reported.

Characteristics of Hepatitis E Virus (HEV)

HEV, previously classified as a member of the Caliciviridae family, is currently, due to differences in genome organization and nucleotide sequence, provisionally classified in a separate genus, *Hepevirus*, of the family Hepeviridae. HEV is a non-enveloped, single-stranded ribonucleic acid (RNA) virus. Virion particles are approximately 27–34 nm diameter, with an icosahedral protein shell or capsid, enclosing a linear 7.5 kb RNA genome. All identified strains of HEV have been classified into four genotypes (1–4), which are distributed by geographic region. In contrast to what is seen in endemic areas in Asia and Africa, where the infecting viruses belong to genotypes 1 and 4, indigenous infections observed in the USA and Europe to date are almost exclusively caused by genotype 3 strains. Despite the presence of four different genotypes only a single serotype is recognized.

The infectious dose of HEV is currently unknown. After entry by the oral route, the virus is passed through the intestinal tract, where it probably replicates. The virus then passes to the liver, and after replication it is released into the bile and blood by mechanisms that are not understood. HEV replication in the liver results in damage to that organ, but the pathogenesis and mechanisms of liver injury during HEV infection are not still explained; however, immune mechanisms are probably involved.

The incubation period of hepatitis E ranges from 15 to 60 days. Virus particles can be found in the bile and feces of an infected person during the late incubation phase, and up to 2 weeks after the onset of clinical disease. The clinical symptoms of the diseases in most cases are very similar to those reported during hepatitis A. During acute HEV infection, the case-fatality rate in the general population is 0.2–1%. The case-fatality rate in developed countries is higher, ranging from 8% to 11%. The most susceptible individuals in developing countries are young adults and pregnant women and the case-fatality rate during pregnancy approaches 15–25%. In developed countries the infection seems to be more prevalent in the middle-aged and elderly men, and is normally lethal in patients with underlying chronic liver disease.

Epidemiology

The most common route of transmission of hepatitis E is consumption of contaminated drinking water, whereas person-to-person transmission is rare. The occurrence of hepatitis E is highest in central and southeast Asia, North and West Africa, and Mexico, areas where fecal contamination of water

is common, and seroprevalence in populations from endemic regions ranges between 3% and 26%. Outbreaks involving several thousand cases have been recorded in countries such as India, Myanmar, and China. In North America and Europe, cases of hepatitis E are uncommon, although seroprevalence ranges from 1% to 5%, suggesting circulation of HEV within the populations there. In industrialized countries, most of the cases are related with travel in endemic areas, but several cases of autochthonous hepatitis E have been reported.

Anti-HEV antibodies have been identified in several animals including chickens, pigs, wild boars, deer, cats, dogs, mongooses, horses, cattle, sheep, and rodents. In some of the animal species positive for anti-HEV antibodies HEV RNA has also been identified. Strains circulating in animals show a high nucleotide identity with human strains identified in the same area, although comparisons are related to short regions of the viral genome only. High levels of HEV infection in pigs are reported from several countries all over the world, although the infection appears to be asymptomatic. HEV strains with very similar RNA sequences have been detected in pigs and humans, which prompts concern over the potential extent of zoonotic transmission of the virus through consumption of contaminated pork products.

Outbreaks of Foodborne Hepatitis E

There have been a few reports of foodborne outbreaks of hepatitis E. However, recent studies have indicated that consumption of contaminated and undercooked meats from infected pigs, wild boars, and deer may be a risk factor for acquisition of this disease. Several studies have suggested that consumption of undercooked pig liver and wild boar meat may have been the cause of some cases of hepatitis E in Japan. Wild boar liver is also often eaten raw in Japan, and this has also been linked to some hepatitis E cases. In Bali, raw pig meat or fresh pig blood is consumed, and seropositivity to HEV is relatively high in the human population. In a case of hepatitis E in the UK, which was caused by an HEV strain very similar to pig strains, the patient had admitted to eating raw pork products, although this was not conclusively the cause of the infection. In USA, 11% of the retail livers tested were positive for HEV RNA and, when inoculated into HEV-free pigs they were able to infect the animals, implying the survival of the virus under storage conditions. The Third National Health and Nutrition Examination Survey in the USA showed that HEV seropositivity was associated with consumption of liver and organ meats. Recently, consumption of shellfish has been indicated as a possible cause of an HEV outbreak on a cruise ship, the shellfish possibly being contaminated by filtrating contaminated water. Consuming uncooked shellfish has also been shown as a possible risk factor of acquiring the infection in other studies.

HEV-positive livers have been shown to still be infectious after incubation at 56 °C for 1 h, but they were unable to infect pigs after being stir-fried at 191 °C (internal temperature of 71 °C) for 5 min or boiled in water for 5 min. This demonstrates that normal cooking procedures can inactivate the virus, but that livers need to be cooked thoroughly to decrease the risk of potential foodborne transmission.

An apparent association with eating raw liver sausage (*figatellu*) typical of Corsica has been reported for eight autochthonous hepatitis E cases diagnosed since 2007 in France. In his Promed contribution this author also remarked that genotype 3 HEV sequences were recovered from seven *figatelli* purchased in supermarkets in southeastern France, finding genetic links between these sequences and those recovered from patients who ate raw *figatellu*.

Detection Methods for HEV in Foods

Detection of HEV in foodstuffs is carried out mainly through qualitative or quantitative polymerase chain reaction (PCR). Extraction methods and detection protocols can vary significantly, and no gold standard has yet been defined for HEV diagnosis. PCR-based methods do not give information on the residual infectiousness of the virus in foodstuffs, and often detection of HEV RNA is not associated with the presence of infectious virus particles. Experimental infections have been performed demonstrating that the virus can remain infectious in foodstuffs. Cell culture replication of HEV has been reported, but to date there is no routine method available for the detection of infectious virus. Development of such a routine method would be very useful for detection of infectious virus, and could be established as the gold standard to test foodstuffs.

Lack of Information

The discovery of HEV strains in pigs related to human strains is potentially significant with regard to the possibility of interspecies transfer and zoonotic infection. Pork products are usually thoroughly cooked at temperatures that should inactivate viruses, but a potential for zoonotic foodborne transfer of HEV may lie in environmental contamination via manure from infected pigs. HEV may be widespread in the general pig population, and if so, it is possible that much of the pig manure, which is stored on farms and subsequently spread onto agricultural land as fertilizer, could contain infectious HEV particles. This could result in exposure of the human population. It may be informative to study prevalence and survival of HEV in the environment and on crops and foods, and also to develop methods to detect interspecies transfer at an early stage.

The incidence of HEV infection in developed countries might be underestimated. The serological data available are as high as 16% for the UK blood donor population and 21% in USA population and are not explained by the relatively low number of autochthonous cases of disease reported. It is likely that the cases of hepatitis E are underreported, considering that they can occur either without any or with nonspecific symptoms. It has been hypothesized that HEV causes clinical symptoms in a dose-dependent manner, and probably individuals in developed countries are exposed only to low doses of the virus. Information still needs to be gathered to clarify the routes of transmission of the nonwaterborne cases of HEV, and the extent of the foodborne transmission in developed countries.

Finally, long nucleotide sequences spanning the entire genome of genotype 3 HEV strains of human and animal origin are needed to understand to what extent swine viruses are in fact representing a real risk of hepatitis transmission to humans via either zoonotic or foodborne transmission pathways.

Lassa Fever Virus

O Ogbu, Ebonyi State University, Abakaliki, Nigeria

Glossary

Contamination The introduction or occurrence of a contaminant in food or food environment.
Control measure Any action and activity that can be used to prevent a safety hazard or reduce it to an acceptable level.
Disinfection The reduction by means of chemical agents and/or physical methods of the number of microorganisms in the environment to a level that does not compromise food safety or suitability.
Endemic A temporal pattern of disease occurrence in a population with predictable regularity and only minor fluctuations in its frequency over time.
Hemorrhage Instance of sudden bleeding in large amounts.
Infectious A disease capable of being transmitted from person-to-person with or without actual contact.
Mortality rate The number of deaths in a specific period of time.
Pathogen An organism capable of causing disease.
Virus An intracellular parasite that cannot be seen with the aid of light microscope but only with electron microscope.

Background

Lassa fever virus is a highly contagious level IV pathogen which has been implicated in causing the zoonotic disease commonly called Lassa fever or Lassa hemorrhagic fever. Typical clinical symptoms of Lassa fever were first described in Sierra Leone in the early 1950s, unfortunately, little or no attempt was made then to identify the causative agent. However, barely 20 years later, to be precise, in 1969, a similar disease which claimed the life of two missionary nurses occurred in Nigeria. Laboratory investigations of pathological specimens from victims of the Nigerian episode implicated a virus as the causative agent. The name of the isolated virus was coined after the small village of Lassa in the Yedseram River valley in Borno State, North Eastern Nigeria, where the outbreak of the case that led to isolation and subsequent identification of the virus took place. The virus was identified as an arenavirus and classified into the arenaviridae family. Since then, several other outbreaks have been reported in many towns and villages across various states in Nigeria, including the Plateau State capital Jos 1970. Others with outbreaks are Zonkwua from 1974 to 1977, Abo Mbaise and Owerri, a town and Imo State capital, respectively, in 1985; Ekpoma, a town in the Delta State, during 1990–92 and 2012; Lafiya, Nasarawa State capital in 1992 and 2012 and Abakaliki, Ebonyi State capital in 2005, 2007, 2009, 2011, and 2012, Lagos in 2012, Ondo in 2012, and Port Harcourt, River State Capital, in 2012.

In 1970, outbreaks of Lassa fever were reported in Liberia and Sierra Leone. Epidemics of the disease have also been documented in other West African countries including Senegal, Guinea, and Mali. Other African countries such as Central African Republic and Congo Democratic Republic have had their own share of Lassa hemorrhagic fever outbreaks.

Interborder traffic and international travels have resulted in the export of Lassa fever from endemic areas to other parts of the world. The affected countries are the USA, Canada, UK, Israel, Japan, and Netherlands.

The treatment of Lassa hemorrhagic fever with ribavirin was initiated in 1979. Since then, the drug has been found to be highly effective and used extensively to save hundreds of thousands of individuals infected by the virus across the world.

Characteristics

Lassa virus is spherical in shape and is a medium-sized agent that measures between 70 and 150 nm in diameter (Figure 1). It has been classified into the arenaviridae family. A typical mature Lassa virus particle possesses a glycoprotein envelope with T-shaped spikes measuring 7–10 nm on its surface. The envelope encloses a helically coiled nucleocapsid genome which measures between 400 and 1300 nm in length. The genome of the Lassa fever virus is a single-stranded, bisegmented ribonucleic acid (RNA). As a typical arenavirus, it lacks the conventional negative-strand coding arrangement. The interior part of the virus contains electron-dense granule identified as the host cell ribosome from where the name 'arena' meaning sandy was derived.

The genome consists of a small (s) and a large (l) RNA fragment of 3.4 and 7 kilobases, respectively. The small RNA (sRNA) fragment encodes the viral structural proteins like

 doi:10.1016/B978-0-12-378612-8.00128-1

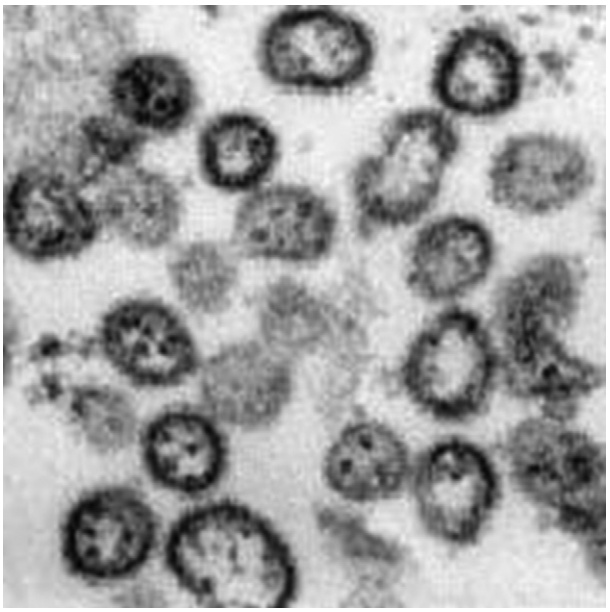

Figure 1 Lassa virus electron micrograph. Image courtesy: C. S. Goldsmith and M. Bowen, Centre for Disease Control and Prevention, Atlanta, USA.

glycoprotein, precursor protein, and the nucleoprotein. The large RNA fragment on its own encodes for nonstructural proteins including viral polymerase and a small zinc-binding (Z) protein. The sequencing of Lassa virus sRNA has enabled the identification and molecular characterization of four Lassa virus strains. These are the Josiah strain from Sierra Leone, two strains from Nigeria, including strain LP and strain Nigeria. The fourth strain designated as AV was exported to Germany by a traveler who had visited Ghana, Côte d'Ivoire, and Burkina Faso. RNA sequencing of the Lassa virus revealed a relatively genetic variation among the circulating strains, however, strain AV appears to be closely related to strain Josiah.

Lassa fever virus can be inactivated by exposure to ultraviolet light, gamma irradiation, or ultrasonic vibration. The effect of these physical factors on the virus depends on the exposure time. Nevertheless, the virus is stable at room temperature and pH range of 5.5–8.5, but heating at 50, 56, 60, and 100 °C inactivates the pathogen within an hour, 30, 15, and 2 min, respectively. Also, the exposure of Lassa virus to acidic and basic solutions above pH 5.4 and 8.6 levels neutralizes its infectivity. Chemical agents like 0.5% sodium hypochlorite, 0.5% phenol, and 10% formalin can kill the virus. This forms the basis of using these agents as disinfectants for cleaning the contaminated surfaces.

Pathogenesis

Rodent rats, particularly the *Mastomy natalensis* sp., commonly found in large numbers in the savannah grasslands and tropical and subtropical forests of West Africa are known to carry Lassa fever virus throughout their life without developing clinical symptoms. Accordingly, the asymptomatic rodent carriers can excrete the virus in their urine, saliva, respiratory secretions, and the exposed blood vessels on anything including uncovered food, food products, meat and its products on contact with any of these.

During the dry period of the year, bush burning usually drives rodents to peoples' homes and grain stores. As the rats search for food, the infected ones among them, can contaminate exposed food, food products, grain, and other materials. Consumption of such food or grains raw, or when not properly cooked causes Lassa hemorrhagic fever.

Eating raw grain, a common practice used for quality testing of stored grains by traders is a possible source of transmission when such products are contaminated.

Hunting and subsequent consumption of rat meat as a source of animal protein for some families is another possible means of contracting the Lassa fever virus. Consequently, the virus has been confirmed to be transmitted in humans through the feco-oral route.

Furthermore, in dirty unhygienic houses infested with rodents, the legs of persons who sleep in such environments are sometimes nibbled by the rats and the infected ones among them can transmit the virus to such persons. Other possible means of contracting Lassa hemorrhagic fever are by inhalation of Lassa virus-contaminated air droplets or sexual intercourse with infected person(s) during the early stage of the infection called the incubation period. In medical practice, use of contaminated medical equipment and needles without adequate sterilization can also transmit the virus.

At the point of entry, the virus undergoes primary replication, before being disseminated through the blood stream, lymph vessels, and other body fluids to multiple organ–system complexes including the reticuloendothelial system for further replication. When the number of virus progeny has approached the infectious dose (population of the virus that can illicit disease), it then causes clinical illness. Infected cells of the intestine, spleen, kidney, liver, myocardium, lungs, and brain are often inflamed, enlarged, ballooned, and the tissues are then infiltrated, resulting in lesions and necrosis.

As a result of this massive destruction of infected cells and tissues, capillary permeability is increased, followed by peripheral vasoconstriction in the presence of disseminated intravascular coagulation that leads to hemorrhagic syndrome. The activities of the virus in the infected cells, tissues, and organs impair their physiological functions which suddenly results in the clinical illness called Lassa fever.

Replication

Replication of Lassa fever virus forms the basis of its pathogenesis. The process starts with adsorption of the virus on widely distributed and highly conserved cell-surface receptor molecules (**Figure 2**). The glycoprotein of the spikes is responsible for the virus–cell interactions. The other steps are penetration, removal of the viral envelope, and liberation of viral RNA into the infected host cell cytoplasm.

Thereafter, duplication of RNA, transcription of mRNA, and translation of proteins take place also in the cytoplasm. During these processes, the cell nucleus provides capped cellular mRNA for priming transcription, whereas the nuclear membrane provides structural support.

Figure 2 Lassa virus adsorption on cell surface. Image courtesy: C. S. Goldsmith and M. Bowen, Centre for Disease Control and Prevention, Atlanta, USA.

The initiation of replication and transcription starts from the terminus of the template. As the RNA polymerase rails on the template to add new nucleotides that will form the polynucleotide of the new strand, the first two slip back on the template to create nontemplate nucleus, a process peculiar to arenaviruses. After the biosynthesis of macromolecules, the viral progenies are assembled through a process yet to be fully understood. Mature viruses are then released through budding from the plasma membrane of acutely infected cells.

Clinical Manifestation

The incubation period of Lassa hemorrhagic fever is between 7 and 21 days. At onset, the infection is insidious with fever, headache, rigors, myalgia, backache, and malaise. The body temperature may increase to 40 °C, which is usually higher in the evenings than mornings. Being a generalized infection, clinical symptoms of Lassa hemorrhagic fever manifest in every system of the infected individual. The symptoms of respiratory tract involvement include: cough, chest pain, dyspnea, pharyngitis, and pleuritis.

In the oral cavity, ulcerated lesions with white or yellow exudates are present in the soft plates and tonsils. Other symptoms of gastrointestinal tract include difficulty in swallowing (dysphagia), nausea, blood-stained vomit which later turns black, bloody and watery diarrhea that may lead to dehydration, abdominal pain, constipation, as well as hepatitis.

In the cardiovascular system, symptoms like pericarditis, tachycardia, bradycardia, hypertension, hypotension, thrombocytopenia, leukopenia, uremia, depressed lymphocyte counts, and platelet function have been reported. Also lymphoadenopathy; elevated aminotransferase; decrease in prothrombine level; distress of blood circulation; and bleeding through the skin, lungs, gastrointestinal tract, and other mucous membranes have been recorded.

Symptoms of the central nervous system being affected are aseptic meningitis, encephalitis, global encephalopathy with seizures, cerebella ataxia, though not very common, and unilateral or bilateral hearing defect or seizure.

The liver and kidney are often inflamed, enlarged, and are painful on palpation of their respective locations.

The neck is swollen due to inflamed lymph nodes. On the skin are generalized maculopapular rashes. Capillary lesions cause hemorrhage in the stomach, small intestine, kidney, lung, and brain. This can be a prediction of the severe case that leads to death as a result of shock and vascular collapse. During the convalescence period, the virus may no longer be found in the blood samples of some patients.

Diagnosis

Accurate diagnosis of Lassa fever requires a complex approach, taking into consideration the clinical manifestation, epidemiological data, and result of laboratory findings.

The clinical symptoms of Lassa fever can easily be mistaken with other common tropical infections such as severe malaria, typhoid fever, yellow fever, Ebola virus infection, hemorrhagic conjunctivitis, and other viral hemorrhagic fever diseases. As a result, epidemiological parameters have to be taken into account, this including presence of rodent in the area, whether the person has traveled to an endemic place, during what period of the year has there been any contact with somebody with similar illness, if yes, when and how, to mention a few.

Laboratory diagnosis is used for definitive diagnosis. Lassa fever is diagnosed in the laboratories by detecting specific Lassa virus antigens or antibodies in pathological specimens. Specimens for laboratory analysis should be collected as soon as possible from the patient suspected of having the infection. Subsequently, manipulation of suspected Lassa fever virus-infected materials from human and rodent is required to be done in highly specialized biosafety level IV laboratory. Unfortunately, such laboratories are rarely available in poverty-stricken endemic countries, nevertheless, efforts have to be made to send collected specimens to laboratories with adequate facilities for processing and testing highly contagious materials.

The specimens to be collected include patients' blood, urine, pleural fluid, cerebrospinal fluid, throat swab, and in case of death, pathological materials from liver, kidney, spleen, and heart. The same samples should be collected from any available rodents.

In the laboratory, the virus can be isolated using laboratory animals including albino mice, guinea pigs, Vero cell culture, or African green monkey kidney cell culture. Albino mice inoculated intracerebrally die between 3 and 5 days after infection. Lassa fever virus causes conspicuous and total cytopathic effects on confluent monolayer derived from Vero cell culture within 96 h after inoculation. Further, the virus can be seen under electron microscope using specimens obtained from infected persons or infected rodents.

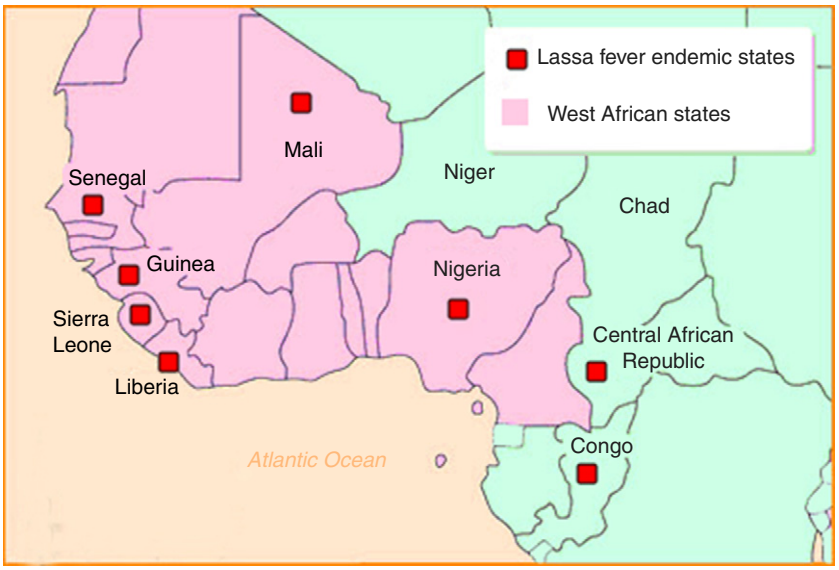

Figure 3 Map of the West African subregion showing Lassa fever endemic countries.

Virus antigens are detectable by enzyme-linked immunosorbent assays (ELISA) using Lassa virus-specific antibodies. The test is easy to handle and rapid, and can be performed with inactivated specimens, which is advantageous in many health institutions where sophisticated equipment is not available.

The indirect fluorescent-antibody (IFA) test has been employed in the laboratory diagnosis of acute Lassa virus infection. The interpretation of IFA results is complicated by the presence of IFA antibodies during both the acute and convalescent stages of infection. The appearance of IFA antibody early in the course of Lassa virus infection is always useful in identifying patients with poor prognosis.

A comparative study of ELISA sensitivity and specificity with a positive reverse transcription-polymerase chain reaction (RT-PCR) test using Lassa virus suspected specimens was carried out. The results proved that the combined ELISA Ag/IgM assay was highly sensitive and specific for the diagnosis of Lassa fever and the antigen detection assay. It therefore offers a unique advantage in providing early diagnosis as well as prognostic information.

Although the RT-PCR assays are higher in sensitivity, their applicability in the West African countries is limited due to the fact that the machines and other facilities are readily available. Further, another valuable diagnostic tool for the detection of Lassa fever virus is the rapid diagnostic immune blot assay but its limitations include low sensitivity and lack of the capacity to provide prognostic information.

Epidemiology

Lassa fever virus was first isolated in Nigeria after an outbreak in a small village called Lassa in Borno State, North Eastern Nigeria. Between 1969 and 2012, several other cases that claimed many lives including those of medical doctors and nurses have been reported in many towns and villages across Nigeria.

In the same vein, series of outbreaks have been recorded in other West African countries including Sierra Leone, Ivory Coast, Liberia, Guinea, Senegal, and Mali. Also the infection has been reported in Central African Republic and Congo Democratic Republic. Documented reports have revealed that between 300 000 to 500 000 cases of Lassa fever resulting in 5000 deaths occur yearly in West African countries (Figure 3).

It has been postulated by the author that the illness may be one of the infectious diseases responsible for many mysterious, uninvestigated, and unreported sudden deaths in many parts of Nigeria and other African countries. Most of the deaths are often believed by many naive individuals to be caused by evil persons (doers) who employ African witchcraft, also called 'African remote control' to kill people, especially those excelling in business and other professions.

Lassa fever has been exported from endemic areas to other parts of the world including USA, Canada, UK, Israel, Japan, and the Netherlands.

The virus is hosted by multimammate rodent rats, specifically the *M. natalensis* sp., which are commonly found in large numbers in the savannah grassland and tropical and subtropical forests of West African. Infected rodents remain carriers of the highly virulent and contagious virus throughout their life without developing clinical symptoms but excrete the virus in their urine, saliva, respiratory secretions, and also through exposed blood vessels. Humans become infected through contact or consumption of food contaminated with infected rodents' excretions or secretions or still eating undercooked or uncooked infected rat meat. Other possible means of contracting the Lassa virus infection are by inhalation of contaminated air droplets containing the virus, use of contaminated medical equipment and needles without adequate sterilization.

Person-to-person transmission of Lassa fever virus can occur through contact with the virus in blood, tissues, secretions, excretions, bruised skin, and sexual intercourse with infected persons. The virus can be isolated in the blood, feces,

urine, throat swab, vomit, semen, and saliva of infected individuals who continuously excrete and secrete the virus for 30 days or more. However, the virus cannot spread through casual contact of intact skin-to-skin.

Outbreak of Lassa hemorrhagic fever can take place at any time of the year. However, in West African subregion, the outbreak is more common during the dry season (from October to early April). During the period, rampant bush-burning practices drive the rodents to people's homes. It is also a time of harvest and as such attracts vector rodents searching for food in grain stores and human habitats. The infected rodent that found itself in the homes can contaminate exposed food, food products, grain, and other materials, as shown in Figure 4. Consumption of such food or grain raw may cause Lassa hemorrhagic fever. Further, eating raw grain, a common practice used for quality testing of stored grain by dealers is also a possible source of transmission. Also, abject poverty among the populace of most West African communities, subjects children between the age of 7 and 15 years and even adults to hunt for rats (a source of animal protein) for family consumption and income generation.

When infected rodents are caught and eaten raw or undercooked, it could cause Lassa fever. Further, a bite from infected rats which share dirty unhygienic houses (common site in endemic environment) with humans can be the source of transmitting the virus to humans.

Lassa virus can always be transported from an endemic area to other Lassa fever-free environments by infected persons during the incubation period or through export of contaminated grains with rodents' excretions and secretions. Still infected persons during periods of viral incubation, who work at food processing industry stand the chance of contaminating food products.

Lassa fever virus infects all age groups and both sex. Individuals at great risk are rural dwellers living in poor sanitation and crowded conditions where the vector rodents *M. natalensis* are usually found. Other persons at risk are close relatives, sympathizers, and care givers who habitually keep close contact with loved ones irrespective of the nature of illness, a common cultural practice in the African setting. Health care workers are not spared if proper barrier nursing and infection control measures are not instituted and maintained.

Figure 4 Rodent rat in food remnants in a typical kitchen. Photo by O. Ogbu and I. Ogbu, Department of Applied Microbiology, Faculty of Biological Sciences, Ebonyi State University, Abakaliki, Nigeria.

Approximately 15–20% of patients hospitalized for Lassa fever die from the illness, whereas, approximately 80% of human infections with Lassa virus are mild or asymptomatic. The prevalence of antibody to Lassa virus varies from 7% in Guinea, 15%, 20%, and more than 20% in Sierra Leone, Liberia, and Nigeria, respectively. Lassa virus causes high mortality in pregnant women and developing fetuses, with mortality rates of 92%, and 75% for fetuses in early pregnancy and third trimester, respectively. Lassa fever has been implicated in 100% mortality in the neonatal period, for full-term babies, whereas mortality rate for gravid women is 7% in the first two trimesters, and 30% in the last trimester, as against average mortality rate of 13% for nonpregnant women. High concentrations of the virus have been found in both fetal tissues and placenta. It has been postulated that maternal T-cells cannot attack Lassa virus in the placenta because of the inability of placental cells to express class I or II major histocompatability complex antigens.

Control and Preventive Measures

In West African towns and villages where there are no facilities for laboratory diagnosis, most Lassa fever infections are treated as malaria. As the patient's condition deteriorates, other supportive medications including fluid replacement, blood transfusion, administration of paracetamol, and broad spectrum antibiotics among other drugs are then initiated. However, very few experienced physicians can empirically start ribavirin therapy while waiting for laboratory results. Early administration of ribavirin is very effective for the treatment of Lassa fever.

Lack of facilities to confirm diagnosis has necessitated that all assays are done in either Europe or the US. By the time the results are sent back to the affected area, irreversible complications might have developed in the first group of patients. Nevertheless, such results are helpful for postprophylactic exposure.

Primary transmission of the Lassa virus to humans can be achieved by avoiding contact with mastomy rodents, especially in disease endemic areas. Food must be kept away from rodents and the premises constantly cleaned to prevent vector rodents from entering homes. Enlightenment campaign against bush burning and rat hunting for eating must be intensified in the endemic areas. Trapping and use of rat poisons are effective in an attempt to reduce rodent populations. Still, storage of grains in modern silos will also help to prevent contamination of stored grain by infected rodents.

Absolute care must be taken while caring for infected patients to avoid further transmission of the disease through person-to-person contact or nosocomial routes. Precautions like isolating infected persons, instituting strict barrier nursing, wearing protective clothing, such as masks, gloves, gowns, and goggles, as well as adequate sterilization of equipment must be maintained until the disease runs its course. Body fluids, excreta, food, and other materials that might have been

contaminated should be handled carefully and disposed properly by burning. All instruments used on the patient, except disposable must be subjected to autoclaving immediately. Absolute care must be taken when collecting and transporting pathological materials to the laboratory for investigations. Correct procedure for the manipulation of materials suspected to contain highly virulent Lassa fever virus have to be observed.

All those who had contact directly with suspected Lassa hemorrhagic fever patients have to be traced, monitored, and specimens from them should be collected for laboratory investigation. Those who test positive have to be isolated and treated as soon as possible with ribavirin.

Overcoming the scientific, political, and economic obstacles in producing a vaccine for human use is very important at this critical period as the outbreak is on the increase. Adequate funding and applications of new vaccine technologies will no doubt stimulate the production of a vaccine for clinical trials.

Conclusion

From this overview, it is unequivocally established that Lassa fever is a very important vectorborne disease that has assumed epidemiological proportions in West Africa where it is highly endemic. The public health implication of the disease cannot be overstated. Apart from possible periodic outbreaks of Lassa fever epidemic within the region, the unprecedented increase in interborder traffic and international travels elevate the chances of introducing the virus to other regions within and outside the African continent.

Nipah Virus

SP Luby, Stanford University, Stanford, CA, USA

Glossary

Date palm sap Sap of the tree *Phoenix sylvestris*. It is collected during winter in Bangladesh by shaving the bark from the top of the tree and directing the sap flow to collection jars overnight. It is either drunk raw or made into molasses.

Ephrin B-2 receptor A transmembrane protein on endothelial cells that Nipah virus G glycoprotein attaches to before entering the cell.

Porcine respiratory encephalitis syndrome The clinical illness associated with Nipah virus infection in pigs characterized by trembling, muscle spasms, leg weakness, uncoordinated gait, and frothy salivation.

Pseudovirus A virus constructed in the laboratory by melding characteristics of natural viruses to permit evaluation of specific viral structures and characteristics.

***Pteropus* bats** Large old world fruit bats, includes 59 recognized species. These bats are important pollinators and seed dispersers, but are also hunted for their meat and in many areas considered as an agricultural pest.

Background

Nipah virus was first identified in a large outbreak in Malaysia from September 1998 through May 1999. On 1 March 1999 Kaw Bing Chua, a medical virologist with the University of Malaya, isolated a novel virus from the cerebrospinal fluid of a patient with fever and mental status changes who lived in Sungai Nipah village. Outbreak investigators ultimately identified 276 human infections and 105 deaths from Nipah virus during this first recognized outbreak.

Characteristics

Nipah virus is a member of the family Paramyxoviradae. It is closely related to Hendra virus, which has caused sporadic infection in horses and persons who come in contact with sick horses. Together, Hendra and Nipah viruses make up the genus *Henipavirus*. Nipah virus is a zoonoses. Its natural reservoir are *Pteropus* bats. These bats are large old world fruit bats. Whenever *Pteropus* bats have been tested, a substantial percentage have antibodies to Nipah virus. The virus has been isolated from *Pteropus* bats in Malaysia, Cambodia, and Thailand. *Pteropus* bats infected with Nipah virus in the laboratory, similar to wild bats that are found to be infected, do not appear clinically ill. Nipah virus is rapidly inactivated by desiccation, but can be recovered after a 60-min incubation in solutions ranging from pH 3 to 11; it can survive for days in bat urine, in fruit juice, or on the surface of a cut mango. Nipah virus can infect a wide range of mammals including pigs, dogs, cats, ferrets, hamsters, African green monkeys, and people.

Clinical Manifestations

In humans, the median incubation period from exposure to virus to onset of illness is 9 days. There are three common acute clinical presentations of human infection with Nipah virus. First, Nipah virus can cause a mild illness with a few days of fever, headache, and rapid complete recovery. Second, most commonly human Nipah virus infection presents as a severe encephalitis with fever, confusion, seizures, and loss of consciousness. Third, human Nipah infection can present as a primary respiratory tract infection with fever, productive cough, and shortness of breath progressing to respiratory failure. The case fatality rate among humans with Nipah virus infection has ranged from 39% in Malaysia where one-half of patients received mechanical ventilatory support to 73% in Bangladesh where mechanical ventilation is largely unavailable. Two-thirds of Nipah patients in Bangladesh presented with cough and developed respiratory difficulty compared with only 14% of patients during the Malaysian outbreak reporting cough on presentation. Eight percent of human Nipah virus infection survivors in Malaysia and 18% in Bangladesh developed recurrent central nervous system infection several months or years after the initial infection. The recurrent encephalitis typically presented with new central nervous system deficits. One-third of survivors of Nipah infection have long-term neurologic deficits. These deficits are more common among patients who suffered symptoms of acute encephalitis.

Virulence Factors

The Nipah virus G surface glycoprotein attaches to the ephrin B-2 and ephrin B-3 receptors and triggers the Nipah virus F

 doi:10.1016/B978-0-12-378612-8.00406-6

surface glycoprotein-mediated fusion with the target cell. The ephrin B-2 and B-3 receptors have remarkably similar amino acid sequence homology among animals susceptible to Nipah virus infection. The receptor is commonly expressed throughout the human body including capillaries, arterial endothelial cells, smooth muscle cells, and neurons including neurons of the brainstem. The ubiquity of the ephrin B-2 receptor explains both the wide species susceptibility to Nipah virus as well as its diffuse access to a wide range of organs including lung, brain, and kidney among the infected persons.

Nipah virus strains isolated in Bangladesh are somewhat different from strains isolated during the Malaysian outbreak. Among four Nipah virus isolates from human Nipah virus cases in 2004, the sequences of the nucleoprotein open reading frames of the isolates differed by 0.9% in nucleotide homology, in contrast to the sequences obtained from all of the human cases in Malaysia which were nearly identical to each other. The overall nucleotide homology between a prototypical Malaysian strain of Nipah virus and a strain of Nipah virus from Bangladesh was 91.8% . One hypothesis to explain the higher prevalence of respiratory symptoms among Nipah virus patients in Bangladesh compared with those in Malaysia is that some strains of the virus may possess unidentified virulence factors that selectively favor human pulmonary infection.

Pathogenesis

Nipah infection in humans leads to a generalized vasculitis of small blood vessels characterized by thrombosis, inflammatory cell infiltration, and parenchymal necrosis, with a particular tropism to the brainstem. Nipah virus invades a wide range of neurological cells, though initial infection is likely through endothelial cells. Pathology specimens and magnetic resonance imaging (MRI) investigations suggest widespread neuronal death from infarcts. Other commonly infected organs in humans include the kidney and lung. Nipah virus has been recovered frequently from throat swabs and respiratory secretions of acutely infected patients.

The mechanism of viral latency and recurrent or late onset Nipah encephalitis is incompletely understood, though other paramyxoviruses including measles and Hendra virus also cause recurrent progressive fatal late-onset central nervous system infection. In late-onset Nipah encephalitis, only neuronal cells are infected with virus; the vascular endothelium is not involved.

Epidemiology

Human Nipah virus infections are most commonly recognized in dramatic outbreaks where several previously healthy people living near each other suddenly developed an acute severe illness with high mortality. Human Nipah virus infections have been confirmed in Malaysia, Bangladesh, and Eastern India (Figure 1). A single large outbreak was recognized in Malaysia with no human cases confirmed since 1999. In Bangladesh, recurrent outbreaks and sporadic cases of human Nipah virus infection have been recognized in most years since the first outbreak was confirmed in 2001. Also, sporadic human Nipah infections and the index case in all

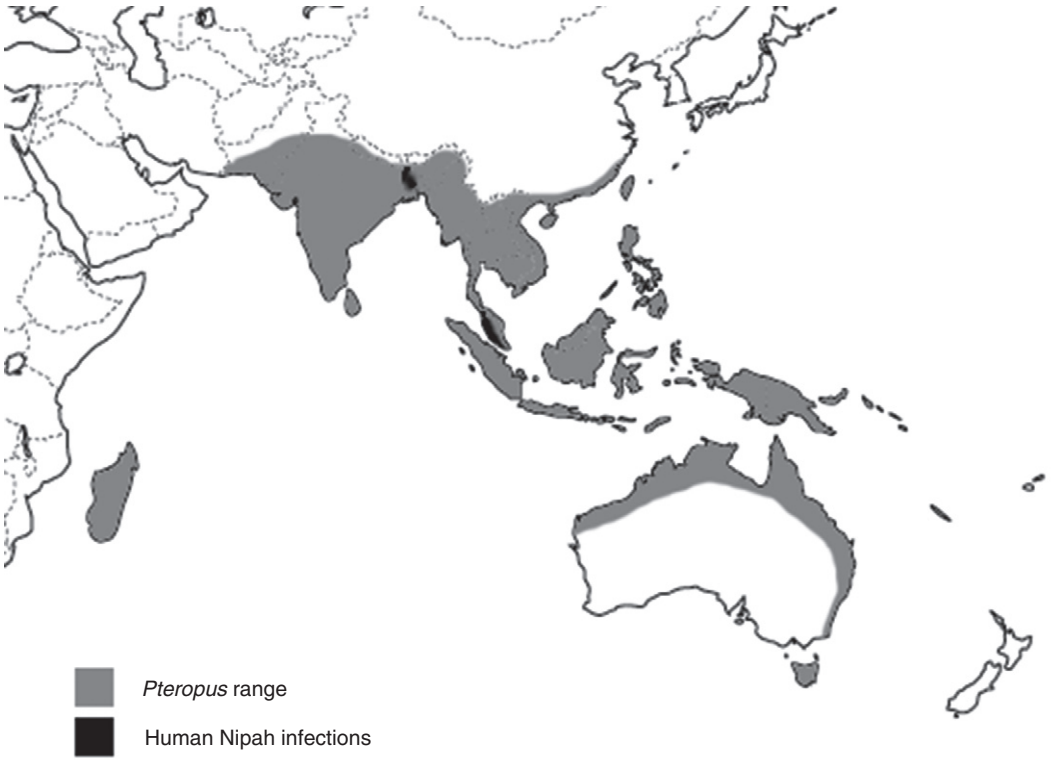

Figure 1 Range of *Pteropus* bats and location of human Nipah infections.

outbreaks had illness onset between December and April. Almost all confirmed human Nipah infections in Bangladesh were among residents of central, western, and northwest Bangladesh. The two outbreaks confirmed in India occurred within 50 km of the Bangladesh border, adjacent to the affected regions of Bangladesh.

Outbreak investigations have identified multiple pathways of transmission of Nipah virus from its bat reservoir to humans. In Malaysia, domestic pigs may have been infected after eating partially consumed fruit contaminated with bat urine or saliva. Compared with people, Nipah causes a more mild illness in pigs, porcine respiratory encephalitis syndrome, with less than 5% mortality. When pigs are infected with Nipah virus, they commonly shed the virus in their saliva, even when they are asymptomatic. The high density of commercially raised pigs in Malaysia allowed the virus to be easily transmitted from pig to pig. The steady introduction of newborn pigs into the piggeries provided a susceptible population that permitted long-term circulation of the virus. Persons who had direct physical contact with pigs including feeding, clipping tails, tagging ears, administering medications, collecting semen from boars and artificially inseminating sows, and handling sick and dead pigs were the primary victims of the Nipah outbreak in Malaysia. Abattoir workers in Singapore who slaughtered Nipah-infected pigs from Malaysia also developed Nipah infection. In Bangladesh, exposure to a herd of pigs was associated with human Nipah infection in a 2003 outbreak in Naogaon. In an outbreak in 2001, illness was associated with contact with sick cattle, and in 2004 one child developed Nipah infection after caring for a sick goat that died following an illness characterized by fever and difficulty in walking.

In Bangladesh, fruit bats commonly feed on date palm sap that is harvested from date palm trees from November through April. Night time infrared photography confirms that *Pteropus giganteus* fruit bats commonly contaminate date palm sap by licking the sap stream during collection. Fresh date palm sap is commonly consumed raw by village residents; it is a popular seasonal delicacy. The only exposure associated with illness in an outbreak in Tangail District in 2005 and in an outbreak in Manikgonj and Rajbari districts in 2008 was drinking raw date palm sap. The time of year when Nipah outbreaks have repeatedly occurred in Bangladesh is the timewhen date palm sap is harvested. The outbreaks have occurred in the regions of the country where date palm sap cultivation is most common.

In Bangladesh and India, extensive person-to-person transmission of Nipah virus infection has been identified in several outbreaks. Most of the care provided to ill patients in Bangladesh is provided by family members and friends, and includes extensive exposure to ill person's saliva including sharing food, sharing a bed, and kissing severely ill patients. People who transmit Nipah virus are more likely to have respiratory symptoms and are more likely to die. Half of recognized cases of human Nipah virus infection in Bangladesh result from person-to-person transmission.

Analytical Methods

Several laboratories including the Centers for Disease Control and the Australian Animal Health Laboratory have developed various enzyme immunoassay (EIA) tests to detect IgG and IgM antibodies to Nipah virus in people and various other animals. Seventy percent of humans who eventually develop antibody to Nipah virus have detectable Nipah virus IgM antibody on their fourth day of illness. Because of the high fatality rate, sole reliance on immunoassay for diagnosis undercounts Nipah infections.

Nipah virus grows readily in cell culture, but because of the high mortality of human infection most countries consider Nipah virus a biosafety level-4 pathogen. Thus, Nipah virus culture and serum neutralization antibody testing requires a high containment facility. Two research groups have developed a recombinant Vesicular Stomatitis Virus which expresses the F and G proteins of Nipah virus. This pseudovirus can be safely used in a biosafety level-II laboratory, has high analytical sensitivity, and provides an alternative more rapid assessment of virus neutralization.

Various polymerase chain reaction (PCR) primers have been developed to identify Nipah virus RNA in the saliva, urine, and cerebrospinal fluid from infected humans as well as in various tissues and fluids from infected animals. Both quantitative real-time PCR and conventional PCR assays have been developed by several research laboratories

Sensitive assay to assess antibodies to Nipah virus G protein using a Luminex microsphere binding assay has been developed for testing Nipah antibodies in a wide range of animals.

Control/Preventive Measures

Limiting fruit bat access to domestic animals and to the human food supply is a first step toward preventing human Nipah virus infection. Separating domestic animals from the immediate environment of trees that produce fruit that are attractive to *Pteropus* bats can reduce risk. Although it is unrealistic to expect animal handlers in regions where Nipah virus circulates to clinically distinguish a domestic animal infected with Nipah virus from much more common infections, encouraging people who handle sick animals to protect themselves from exposure to saliva and to wash their hands with soap after contact with sick animals may reduce the risk of transmission. In Bangladesh, research teams are evaluating programs to encourage the wider use of skirts made from locally available materials that prevent the access of bats to date palm sap intended for raw consumption. The large outbreak in Malaysia ended after widespread deployment of personal protective equipment to people coming in contact with sick pigs, restriction on livestock movements, and culling more than 900 000 pigs. Preventing person-to-person transmission requires developing interventions to reduce saliva exposure among people who care for seriously ill patients. In outbreak investigations of person-to-person Nipah transmission, washing hands with soap after contact with Nipah patients has been associated with a reduced risk of the virus transmission.

Research Needs

As Nipah virus is recently discovered, there are a number of important unanswered research questions in basic science,

diagnostic development, clinical care, epidemiology, and prevention. In the basic sciences, research priorities include understanding the early events of Nipah virus infection and immune evasion, identifying determinants for virulence and host susceptibility and clarifying the mechanism of viral persistence, and reactivation of latent Nipah virus infection. Priorities for diagnostic research include developing a general *Henipavirus* PCR that targets highly conserved genetic targets within the henipavirus and so will detect Nipah virus and other related viruses which may also be human pathogens, and developing recombinant enzyme immuno assay antigens to standardize serological diagnosis.

Research on clinical care should focus on identifying practical interventions for low-income countries that can reduce the very high case fatality rate and rate of neurological sequelae. Priorities for epidemiological research include describing the transmission dynamics of Nipah virus in *Pteropus* bats and the relationship of this transmission to human infections, to identify additional pathways of transmission from bats to humans, and to describe the geographical extent of human Nipah infections and, in the process, to better understand why this pathogen which is widely distributed in bats is observed in humans in more restricted locations.

Priority areas for prevention research include development of a vaccine for domestic animals, development and evaluation of interventions to interrupt transmission from the wildlife reservoir to humans including preventing *Pteropus* bats' access to date palm sap that is destined to be drunk raw, and developing practical approaches and behavior change interventions to reduce the risk of saliva exposure and, therefore, person-to-person transmission for caregivers of severely ill patients.

Norovirus

E Duizer and M Koopmans, National Institute for Public Health and the Environment, Bilthoven, The Netherlands

Glossary

Antigenicity The ability of a chemical structure, referred to as an antigen, to bind specifically with T cell receptors or antibodies.

Infectivity The ability of a pathogen to establish an infection.

Introduction

Human norovirus (NoV) infection is popularly known as winter vomiting disease, gastric flu, or stomach flu and the virus itself as the cruise ship virus and vomiting bug. All these nicknames point at some characteristic features of these viruses: an infection is likely to lead to severe vomiting and diarrhea and the outbreaks follow a pattern of winter-seasonality; outbreaks on cruise ships occur regularly and tend to receive a lot of media attention.

NoV are now recognized as one of the most common causes of foodborne gastroenteritis worldwide. Being small nonenveloped particles, NoV are quite stable outside the host and may persist on inanimate surfaces, in water, and on food. The infectious dose is low and transmission of infection between persons is common. These factors contribute to the best known feature of NoV: the tendency to cause outbreaks of gastroenteritis in settings such as hospitals, homes for the elderly, child daycare centers, military establishments, cruise ships, hotels and restaurants. Foodborne transmission is common, but accurate estimates of the exact proportion of human NoV illness that can be attributed to consumption of contaminated food are not available. Currently, the NoV causing foodborne infections are all thought to be of human origin; in other words, a human NoV infection is the result of person-to-person transmission, for which food is one of the intermediate vehicles. In this article we will review essentials of NoV virology and epidemiology with emphasis on aspects that are relevant to their role as foodborne pathogens. For in-depth reviews on specific aspects references have been given.

Historical Information

The acute epidemic diarrhea that is currently known as NoV infection was described by Zahorsky in a paper in 1929, which eloquently described it as the winter vomiting disease, referring to the seasonality and high percentage of patients vomiting. In the decades that followed, outbreaks with similar features were described and a virus was suspected to be the etiological agent because parasite and bacteria-free filtrates transmitted the disease. In 1972, a 27 nm virus-like particle (VLP) was detected by use of immune electron microscopy in stool filtrate obtained from an outbreak of acute gastroenteritis at an elementary school in 1968 in Norwalk (OH, USA). This morphological identification lent the viruses their initial name as small-round-structured viruses (SRSVs). In 1979, another small particle as etiological agent of an outbreak of acute gastroenteritis in an infant home in Sapporo, Japan, was described: the Sapporo virus. The Norwalk agent and Sapporo virus had subtle differences in surface structure when examined by electron microscopy (EM), but more importantly were antigenically distinct. Further characterization was hampered because the viruses could not be grown in the laboratory. In 1982, Kaplan *et al*. formulated what is now known as the Kaplan criteria to identify NoV outbreaks, and in 1983 Pether and Caul published the first paper of NoV as the cause of foodborne outbreak in which the virus was most probably spread via chicken sandwiches prepared by an infectious member of the kitchen staff. Subsequently, Jiang and coworkers used the original Norwalk virus preparations to clone and characterize the Norwalk virus genome. Since then, molecular tools to detect these viruses have developed quickly and polymerase chain reaction (PCR) assays are currently the gold standard for diagnosis. With the beginning of the molecular era, the genome characterization of these viruses was possible, and this was used in virus taxonomy. The Norwalk agent became the prototype of the genus *Norovirus* in the family Caliciviridae, whereas the Sapporo virus turned out to be a distant relative, placed in a separate genus *Sapovirus*.

Nomenclature, Taxonomy, and Classification

Norovirus and *Sapovirus* are the two genera of the family Caliciviridae with humans as the primary host for several strains. The three other genera are *Lagovirus* (known host species: rabbits, brown hares), *Vesivirus* (known host species:

 doi:10.1016/B978-0-12-378612-8.00123-2

sea lions, other marine animals, swine, cats, dogs, fish, seals, cattle, and primates), and *Becovirus*, identified in cattle. With the development of sensitive and generic molecular techniques new viruses are also being discovered in different animals and two new genera have been proposed and await independent confirmation. The animal caliciviruses have been associated with a range of clinical syndromes, including stomatitis, upper respiratory tract infections, and systemic diseases with severe hemorrhagic syndromes. NoV are known to infect humans, but have also been detected in pigs, cattle, sheep, mice, cats, lions, and dogs. Sapoviruses infect humans, pigs, and mink. In humans, NoV and sapoviruses cause acute gastroenteritis, and asymptomatic infections, whereas in animals they seem to cause mainly asymptomatic infections and mild gastroenteritis. In immunocompromised mice, the murine NoV can cause encephalitis, vasculitis, pneumonia, and hepatitis indicating a broad tissue tropism.

The diversity within the genus *Norovirus* is great, and a first subdivision of the genus in five genogroups (geno group (G) I–V) is made on the basis of phylogenetic analysis of sequences of the capsid protein. So far, strains belonging to GI have been detected in humans, GII strains in humans and pigs, GIII in cattle, GIV in humans, cats and dogs, and GV has been detected only in mice. The genogroups are further divided in genotypes, again based on phylogenetic analysis of sequences of the capsid protein. Currently, GI includes eight different genotypes whereas GII includes 19 genotypes, three of which have swine as their natural host. Despite this diversity, in recent years few strains, primarily those of genogroup II, genotype 4 (GII.4), have been responsible for a majority of the outbreaks worldwide, although a wider diversity is seen when looking at sporadic cases of gastroenteritis. Because the NoV GII.4 viruses seem to be the main epidemic genotype, in the scientific literature especially this genotype is subdivided into subtypes or variants, for example, NoV GII.4-2004 variant. Full naming of NoV is according to a cryptogram that is organized as follows: host species/genus/species (or genogroup)/strain name/year of occurrence/country of origin. For example Hu/NoV/GI.1/Norwalk/1968/US, Hu/NoV/GII.4/Bristol/1993/UK, Sw/NoV/GII.11/Sw918/1997/JP.

Nomenclature

Until recently, there was no international consensus for the nomenclature of NoV, resulting in some confusion in the literature. Recombinant NoV strains are commonly seen and cause naming difficulties, because they cannot be adequately classified with the current nomenclature system, which is based solely on the capsid gene (ORF2). A recent proposal of a consensus nomenclature scheme including both ORF1 and ORF2 typing is the basis of a publicly available genotyping tool.

NoV Morphology

Caliciviruses are small nonenveloped viruses with a linear single-stranded positive-sense RNA genome of 7.4–8.5 kb. The NoV genome has three open reading frames (ORF) and a 3′ poly A tail. The approximately 5.4 kb ORF1 encodes the six proposed nonstructural proteins, including the viral nucleoside triphosphatase, protease, and RNA-dependent-RNA polymerase. ORF2 is approximately 1.6 kb long and codes for VP1 whereas ORF3 is only approximately 0.6 kb and codes for VP2. The virus particles (virions) consist of a single RNA strand, covalently linked at its 5′ end to one copy of viral protein genome-linked (VPg) and the virus capsid. The capsid is made of a few copies of viral protein 2 (VP2) and 180 copies of a single capsid protein (viral protein 1, VP1) folded into 90 dimers, forming 32 cup-shaped depressions that can be seen in EM pictures of the virus, and has led the family name caliciviruses ('calyx' is cup in Latin). This typical structure is, however, less clear for the NoV that have a more fuzzy appearance. Additionally, the NoV belong to the smaller caliciviruses with a genome of 7.5–7.7 kb (**Figure 1**).

The key antigens of the NoV reside in VP1. This main viral protein contains three domains: a shell domain, constituting the body of the capsid, and two protruding (P) domains. Protruding domain 1 (P1) is the domain between the most exterior/protruding domain P2 and the S domain. Currently, the P2 domain is considered to contain the host cell binding site(s) and key antigens.

NoV Replication

NoV, as all viruses, are obligate intracellular organisms. Because they do not have a metabolism of their own, they are obliged to invade host cells and parasitize the subcellular machinery. Owing to the lack of an *in vitro* propagation system for human NoV, knowledge about the replication strategy of this virus is based mostly on analogies with other single-stranded positive-sense viruses such as members of the Picornaviridae family, to which poliovirus and hepatitis A belong, or viruses from the genus *Vesivirus* within the family Caliciviridae. Only after the discovery of the cultivable murine NoV, MNV-1, in 2003 by Karst and coworkers, it became possible to obtain detailed insights into the NoV replication and processing strategies.

The general steps are clear. The virion interacts with the host cell via a virus-specific receptor and then enters the cell by an as yet poorly understood mechanism. The cellular receptor for NoV binding is unknown, but carbohydrates similar to our ABO blood group are thought to be involved. Subsequently, the capsid is removed or altered and the RNA genome is released into the cytoplasm (uncoating). In the next step, the genome, which is itself a messenger RNA, is translated. ORF1 is translated into a polyprotein that is cleaved in at least six nonstructural proteins by the viral protease. These nonstructural proteins are all involved in the replication of the viral RNA genome. This replication is accomplished by synthesis of a small number of antisense (negative) RNA strands from the genomic RNA and subsequent synthesis of two major positive strand RNA species: a full-length genomic RNA and a subgenomic RNA for the synthesis of the structural proteins VP1 and VP2. Interestingly, for viral genome replication, the nonstructural viral proteins, cellular proteins, and cellular membranes from endoplasmatic reticulum, golgi-complex, and endosomes are needed in a productive replication complex, whereas production of the virus capsid seems to require less stringent regulation and cellular involvement. The

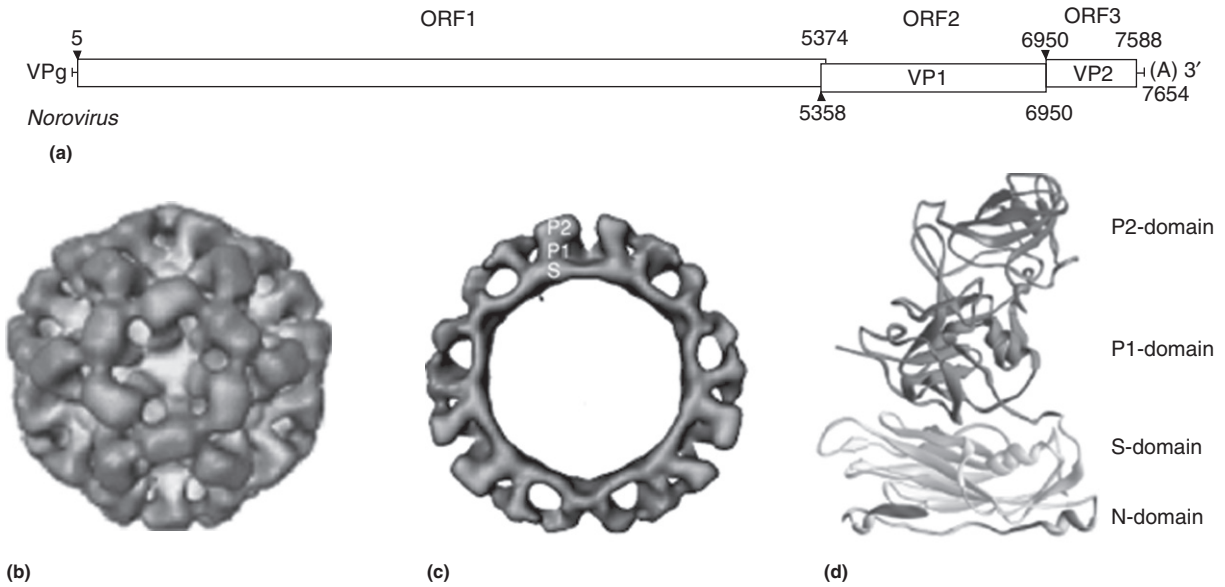

Figure 1 NoV GI genome and virion structure. (a) The genomic organization and reading frame usage (numbers indicate nucleotide position) for Norovirus GI.1 (Hu/NoV/Norwalk/1968/US, GenBank Accession Number M87661). (b) Three-dimensional structure of Norovirus GI.1 recombinant virus-like particles (rVLPs) viewed along the icosahedral threefold axis at approximately 22 Å. An rVLP is made up of 90 dimers of a single protein that form a shell domain from which arch-like capsomeres protrude. (c) A central section of the NoV GI.1 rVLP perpendicular to the icosahedral threefold axis. The arch is composed of the protruding (P) domain (divided into subdomains P1 and P2) and the shell (S) domain. (d) Three-dimensional ribbon representation of an individual subunit from the rNorovirus GI.1 capsomere derived from X-ray crystallography studies of Norovirus GI.1 rVLP at 3.4 Å. Reproduced from Green KY (2007) Caliciviridae: *The Noroviruses*, *Fields Virology*, 5th edn Philadelphia: Lippincott Williams & Wilkins. pp. 950–979.

production of VP1 is efficient in several different expression systems, and when enough copies of this protein are present, self-assembly into VLPs will occur. The next steps in the virus replication cycle are packaging of the viral RNA, maturation of the virus capsid, and subsequent release of infectious viruses.

NoV Pathology

NoV enter the body of their host via the oral route, and after multiplication in the epithelial cells lining the small intestine, leave the body via vomitus (oral) or stool.

The Norwalk virus (GI.1) retain infectivity if stool filtrate is exposed to pH 2.7 for 3 h at room temperature, and no RNA degradation could be measured after 30 min at pH 2, indicating that gastric passage is likely. Based on pathology performed on biopsies of infected symptomatic persons, it is thought that replication occurs in the duodenum and jejunum. Functional and morphological measurements on duodenal biopsies show significantly impaired barrier function during NoV infection: The transepithelial electrical resistance is less than a half that of the control and the passive mannitol leakage is more than doubled. Additionally, there is an increased anion secretion, which can contribute to the diarrhea. Remarkably, no indication for reduced absorption capacity was detected, indicating that the overall function of mature enterocytes was not affected. The functional changes coincide with minor villus blunting, a reduced villus surface area, reduced tight junction protein expression and doubling of the number of apoptotic cells in the villus. Below the epithelium there was a clear infiltration of intraepithelial lymphocytes. Histopathological changes as characterized by villus blunting and infiltration of mononuclear cells were also seen in the jejunum in volunteers during the acute phase of Norwalk virus infection and in the duodenum and jejunum of pigs infected with porcine sapovirus. Concomitant with jejunal pathology, a delay in gastric emptying was observed. If we assume the pathology in the duodenum and jejunum are caused by virus replication, the combination of abnormal gastric function and virus replication so close to the pylorus may explain the projectile vomiting and presence of NoV in the vomitus.

Clinical Manifestation (Disease)

A NoV infection typically results in a mild, short-term, self-limiting illness characterized by (projectile) vomiting and diarrhea, often accompanied by abdominal pain, nausea, and fever. NoV can infect people of all ages and clinical symptoms usually start 12–48 h after exposure and subside for 2–3 days in adults, and approximately 1 week in children. Asymptomatic infections are common. More severe disease has been seen in risk groups such as young infants, elderly, immunocompromised patients, and patients with renal disease and other comorbidities. In hospitalized patients more than 80 years of age, symptoms last longer, and mortality has been observed. Chronic disease has been reported for (severely) immunocompromised patients. Complications are

not common in NoV infections in healthy individuals, but more severe gastrointestinal symptoms and even extraintestinal manifestations have been reported anecdotally. So far, extraintestinal manifestations or viraemia has been rarely reported, but this has not been addressed systematically. Several reports from Japan, Spain, and Italy mention neurological symptoms associated with ongoing NoV infection in children. It remains to be seen if this complication is common around the world.

Asymptomatically infected persons and persons that have gone through a symptomatic phase continue shedding viruses for at least 2 weeks and often longer. Atmar and coworkers showed that for the NoV GI.1 strain (Norwalk virus 8fIIa inoculum) peak levels of shedding from symptomatically infected volunteers occurred after cessation of symptoms, and levels of shedding were as high in symptomatically and asymptomatically infected persons. The median peak amount of virus shedding was approximately 1×10^{10} genomic copies per gram feces, and remained above 1×10^{6} genomic copies per gram feces for up to 2 weeks. Interestingly, in one study (using different quantitative PCR assays) the median viral loads of NoV GI and GII strains in feces was found to be 8.4×10^{5} and 3.0×10^{8} genomic copies per gram feces, respectively: the viral load of NoV GII was more than 100-fold higher than that of GI. This difference is believed to contribute to the higher transmissibility and prevalence of NoV GII strains. The same group also showed that a higher viral load during a NoV GII.4 infection was associated with prolonged diarrhea, something that was not found for NoV GI.1. A straightforward interpretation of these data are hampered because absolute quantification of genomic copies still awaits thorough validation. Furthermore, the detectability and quantification of RNA strands/genomic copies does not necessarily indicate the presence or quantification of infectious viruses.

Shedding of NoV does not only occur via feces, but also via vomitus. The onset of vomiting may be quite abrupt, and has led to contamination of kitchen surfaces and restaurants through aerosols. For several outbreaks the role of vomiting in the spreading of viruses has been described but due to methodological limitations, there are no good data on the level/quantity of infectious NoV in vomitus. Recently, NoV RNA was detected in mouth wash samples from approximately 25% of patients for more than a week after disappearance of symptoms, and even in persons with diarrhea only. The presence of viral RNA in mouth washes might imply that coughing and speaking can contribute to the spread of these viruses but this requires further study.

In addition to the high level of shedding, the infectivity of the NoV is very high. For the NoV GI.1 Norwalk virus it is estimated that the average probability of being infected by a single infectious particle is approximately 0.5: the highest value reported for any pathogen to date. For comparison, this probability is 0.4 for poliovirus, 0.02 for *Campylobacter jejuni*, and 0.000 03 for *Salmonella enterica* (serovar Newport). The probability of becoming ill after exposure to NoV seemed to be dose-dependent and increased to 0.7 at high virus doses ($\sim 10^{8}$ genomic copies). The overall picture is clear: few viruses are needed to cause infection and, with or without symptoms, virus shedding is high.

Most patients with NoV illness do not need treatment. In hospitalized patients, the most common treatment is rehydration. In an experimental replicon system, some effect of antivirals was observed on the level of replication, but this is far from clinical application. Treatment of symptomatic chronic shedders with a range of different approaches has not yet been successful.

NoV Immunology and Genetic Susceptibility

The chance of being infected by NoV after oral exposure to an infectious virus depends on several viral and host factors. The host factors are mainly the immunological status with respect to the virus strain and the genetic susceptibility of the host. In the early volunteer studies it was noted that short-term, strain-specific resistance to disease, not to infection, developed in some volunteers. However, some individuals with high serum-antibody titers could be infected and become sick over 2 years later when exposed to the same virus, whereas individuals without any detectable serum antibodies could not be infected. It is now clear that genetic susceptibility interfered with immunology in these early studies. Just as for *Helicobacter pylori* and *Vibrio cholera* infections, NoV infections depend on the histo-blood group antigens (HBGAs). For NoV, several factors have been shown to correlate with susceptibility to infection by different NoV strains. The first factor is the secretor status, as determined by a functional fucosyl transferase-2 enzyme: secretors are more likely to be infected by NoV than nonsecretors. For example, nonsecretors, constituting approximately 20% of the Europeans, are resistant to infection by NoV GII.4, GII.3, and GI.1, but can be infected by NoV GI.3 and GII.2 strains. The second factor is the Lewis antigens as determined by the fucosyl transferase-3 enzyme. For this factor resistance to infection is far less clear, some strains can infect only Le^{a}, some only Le^{b}. The above implies that the impact of NoV strains on the population may differ greatly, and depends on the ability of a given strain to infect sufficient susceptible individuals for sustained transmission to occur. In the past 10 years, NoV GII.4 have been the most common cause of outbreaks, but these viruses evolve rapidly. Since 2002, when a particularly virulent NoV GII.4 strain emerged, new variants have evolved and spread globally almost every other year. Each of these variants has distinct host binding properties and antigens, making the development of a NoV vaccine quite challenging.

Immunity to NoV is not well understood. Older studies showed that immune responses might be specific and short-term and immunological studies are complicated by the lack of a culture method or a small animal model and differences in host susceptibility for NoV infection. Recent studies do show that on NoV infection antibodies are produced and that these can be measured. Seroprevalence studies have shown that most persons are exposed to a NoV in early life, but disease remains common in people of all ages. This is the first indication of lack of sufficient protective immunity or the true existence of different serotypes. The genetic diversity observed for NoV translates into antigenic diversity. Viruses belonging to different genotypes may induce cross-reactive antibodies, but not those that are directed at the specific host binding, and

thus, influence on the virus infection or disease is doubtful. Studies have shown that even variants within a genotype may have distinct host cell binding properties, due to mutations around the host cell binding domain. This affects antigenicity of the viruses, and thereby escape from herd immunity. This mechanism likely contributes to the success of NoV. However, in mice, cross-reactive T cells may be induced that respond to exposure with viruses from distinct genogroups. These studies show that the immunity to NoV is complex.

Epidemiology

Statistical Data on Prevalence and Incidence of the Disease

NoV are notorious for their ability to cause outbreaks. Outbreaks are very often seen in closed settings with an especially vulnerable population such as hospitals and nursing homes. However, NoV can infect people of all ages and health status, and in several settings attack rates for the patients and staffs are similar. Additionally, cruise ships are also famous for NoV outbreaks , and outbreaks are reported for child daycare centers, schools, concert halls, navy vessels, and scouting camps. Most outbreaks are characterized by person-to-person spread, although introduction of the virus via a point source, such as food or water, could remain unnoticed even if it is common.

Even though outbreaks attract most of the media attention, the number of cases of sporadic infections, or nonreported family outbreaks, is much higher. To estimate the incidence of NoV infection in a population requires costly population-based studies. So far, such studies have been performed only in the US, Australia, the UK, and the Netherlands resulting in burden estimates of viral gastroenteritis varying between 1.3 and 31 infections per 1000 inhabitants. The study in the Netherlands in 1999, estimated the burden of NoV to be 450 disability-adjusted life years (DALYs), with an estimated incidence of 470 000 cases (2.9% of the Dutch population). In another study it was calculated that NoV infections cost the Dutch society 25 million euros in 2004. For comparison, in the same population, the burden of disease for *Salmonella* and *Campylobacter* were estimated to be 8.8 million euros and 19.6 million euros, respectively. We already know the estimates for NoV are likely too low because the incidence of NoV gastroenteritis has increased significantly in recent years, and mortality and hospitalizations due to NoV infections were underestimated.

Geographic Distribution

Reports on NoV outbreaks and studies addressing causes of gastroenteritis in hospitalized children, have demonstrated that NoV is a significant cause of illness around the world. Even though there are large data gaps, particularly in developing countries, NoV are recognized as important pathogens of travelers' diarrhea in various regions of the world. Many of the recent epidemic NoV GII.4 variants have been observed worldwide. Although their impact as cause of outbreaks seems to differ between regions it does show that there are no intrinsic limitations for a global spread of at least some NoV strains.

Reservoirs for NoV, Vehicles for Transmission, and Examples of Implicated Foods

The NoV infecting humans are considered exclusive human pathogens. Even though a huge number of NoV infections and outbreaks have been studied, there is no indication for zoonotic transmission or animal reservoir for human infections. Transmission of NoV is thus per definition person-to-person. What we consider food or waterborne transmission of NoV is actually indirect person-to-person transmission in which food or water is a vehicle for the viruses. This is most clear in food handler transmission. Food handlers can contaminate food with NoV via vomit or via feces. Vomiting as symptom of NoV infections results in widespread dissemination of viruses: viruses contaminate surfaces and fomites in close proximity of the patient by droplets whereas a wider circle and the air is contaminated by aerosols. The viruses are acid resistant and will retain infectivity for at least several days. Contamination via feces occurs through insufficient personal hygiene, especially by persons shedding viruses themselves (e.g., after using toilets), but also by those taking care of infected persons (e.g., changing of diapers) or cleaning toilet areas used by infected persons. Food handlers can also contaminate food by transferring viruses from contaminated surfaces to hands during preparation of ready-to-eat food or by transferring viruses from contaminated food to other ready-to-eat foods. Inanimate surfaces include contaminated utensils, for example, chopping equipment, such as dicers, cutting knives, and serving utensils. Foods reportedly implicated in this route include mostly multiingredient foods such as salads and sandwiches that often require multiple touching for production. Another foodborne route for NoV is via contaminated water, used for drinking or irrigation during cultivation or as production or wash water anywhere in the process. NoV are very stable in water; they will remain infectious for months and virus detection in surface waters is not uncommon. Virus persistence in water is affected mostly by temperature, UV radiation, association and sedimentation with solids, and the microbial flora.

Numerous papers report on NoV infections via drinking water, however reports on NoV in irrigation and process waters are limited for foods other than shellfish. Surface waters that may be used for irrigation or drinking water production can easily be contaminated by human NoV because the virus is shed in high numbers (up to 10^{11} per gram feces) by many people (up to 15% of the population in winter season) and the virus reduction achieved in sewage water treatments plants rarely exceeds 2 log reduction. NoV levels in treated sewage may contain more than 10^3 NoV genomic copies per liter. Interestingly, although in the general population NoV GII infections are much more common than NoV GI infections, in sewage water (influent) NoV GI viruses are regularly detected as often, or even more often, than NoV GII viruses. It is also suggested that removal efficiencies for NoV GI are less than for GII viruses , whereas removal efficiency for bacterial indicators was in general much more.

Peak concentrations of pathogenic viruses occur in source waters used for drinking water production. If seasonal and short-term fluctuations coincide with less efficient or failing treatment, an unacceptable public health risk from exposure to this drinking water may occur. In a recent risk analysis on

the safe use of wastewater in agriculture it was concluded that NoV levels require a 6 log reduction to achieve a WHO accepted risk of infection of 10^{-3} per person per year. In times of water scarcity due to global changes, such as increasing populations and climate change, the use of wastewater for use in irrigation is evaluated but may exceed tolerable risk levels as set by WHO.

Contaminated water can also result in contaminated shellfish. Shellfish are the most common foodborne source of NoV infection, and monitoring systems are established for this product. Often, multiple strains are found, indicating sewage contamination of the growing waters. Because multiple NoV strains are regularly detected in shellfish, there is an added risk of double infections, and consequently a risk of virus recombination, after consumption. Bivalve molluscan shellfish, such as oysters, filter large volumes of water and thereby accumulate and concentrate different types of pathogens. Because bacteria and viruses show differences in terms of accumulation and concentration and are reduced with different efficiencies by depuration from contaminated shellfish, the absence of bacterial contamination does not necessary indicate the absence of viruses. The cells of the digestive tract of at least several oyster species were recently found to present carbohydrate structures that are indistinguishable from the HBGAs that are known to bind several NoV strains. This could mean that oysters can specifically accumulate and concentrate NoV and it might explain the lack of clear effect of depuration on NoV number. NoV GI viruses are detected relatively often in shellfish and shellfish related outbreaks.

Owing to difficulties in detecting viruses in foods, difficulties in linking cases and food in space and time, especially when frozen read-to-eat foods are involved, and the highly efficient person-to-person spreading, the fraction of foodborne outbreaks is hard to establish. However, for Europe it was estimated that ~84% of the outbreaks were reportedly due to person-to-person transmission (including indirect via environmental contamination), and ~16% due to foodborne transmission. From data in a review describing 47 food and waterborne NoV outbreaks from 2000 to 2007, it is estimated that in approximately 40% of the cases a food handler was responsible for the outbreak, followed by fresh produce (28%), bivalve shellfish (17%), and consumed water (15%) (Figure 2).

According to an expert meeting held in 2007, three NoV food commodities were selected as priorities based on scientific proof and epidemiological relevance:

1. NoV in prepared ready-to-eat foods infected by food handlers practicing poor personal hygiene during food preparation and serving.
2. NoV in bivalve mollusks that are consumed raw or lightly cooked: through fecal contamination of waters in which they are growing.

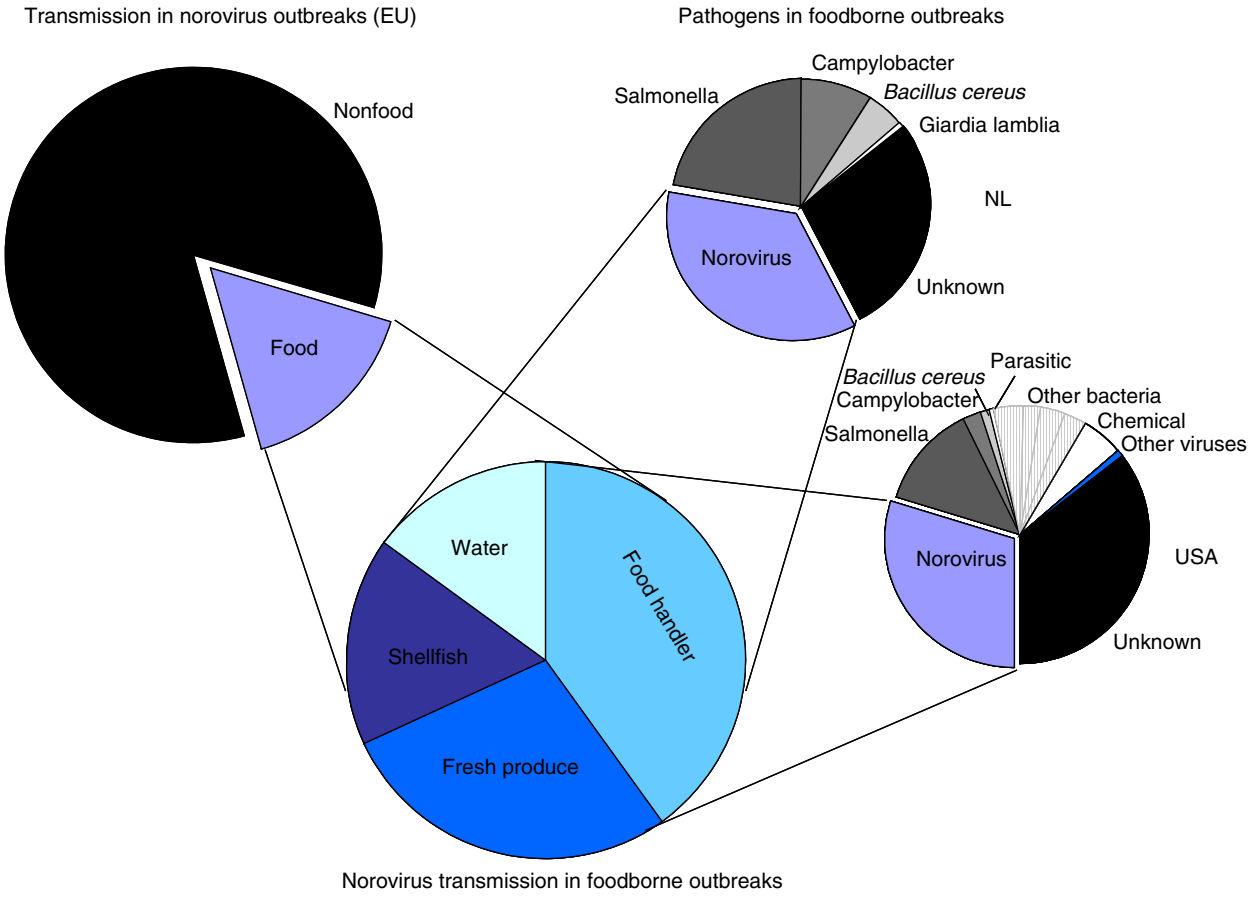

Figure 2 Relative relevance of transmission routes in foodborne NoV outbreaks.

3. NoV in fresh produce: through contaminated water (used for irrigation, or fertilizer application, or wash water) or via contact with contaminated surfaces and contaminated utensils.

Finally, environmental transmission occurs. NoV are very stable outside the human host and may persist in infectious form on surfaces and fomites for weeks and even longer. Environmental transmission has been reported to play a role in NoV outbreaks in hotels, hospitals, food establishments, a concert hall, and on cruise ships. Furthermore, in food establishments associated with NoV outbreaks, widespread environmental contamination has been demonstrated and transfer of viruses from surfaces via fingers and subsequent ingestion is possible.

Methods for NoV Diagnosis and Detection

NoV Diagnosis

Infection with NoV is typically diagnosed by the detection of the virus in patient stool samples, rather than by measuring immune response of the host to the virus. The virus capsids (protein) can be detected by enzyme immune assay (EIA)-like tests and the virus genome by real-time reverse transcriptase-polymerase chain reaction (RT-PCR) assays. Advantages of the RT-PCR method (detection limit of 10–100 viral particles per gram stool) is the high sensitivity and that it can be applied to all kinds of substrates such as feces, vomitus, serum, food matrices, and water. A bottleneck is the high genetic diversity of these viruses. Therefore, generic tests have been developed and no single primer pair can detect all NoV strains. Additionally, generic tests are optimized for the detection of a broad range of viruses, not for the specific and more sensitive detection of one strain. Therefore, false negative tests are relatively common and back-up protocols should be available for additional testing. The sensitivity of EIA-based methods rarely exceeds 70% of that of the RT-PCR assays, indicating that single patient diagnosis by EIA is likely to result in many false negatives. However, most EIA-based tests do show good specificity and they may be used for outbreak diagnosis when at least three samples are tested. When ascertaining possible infection or illness in sporadic cases, validated, and internally controlled PCR-based techniques are preferred. Currently, EIA-based and fast (result within 1 h) point-of-care tests are being developed and validated since early recognition is very important in implementing counter measures to reduce the size of NoV outbreaks. Note that most of the newly developed EIA-based tests seem to have optimized sensitivity for NoV GII.4 viruses, which is a good approach for outbreak diagnosis in general. However, relatively more foodborne outbreaks are caused by NoV GI strains for which sensitivity is often less than the overall 70%. Owing to their higher sensitivity, RT-PCR methods are the method of choice for confirmation of NoV infection in consumers when a food source is suspected epidemiologically.

Because NoV are the most common etiologic agent of foodborne outbreaks of gastroenteritis, diagnostic tests have not been readily available and several clinical and epidemiologic profiles are the characteristic of NoV outbreaks; the Kaplan criteria have been used to distinguish foodborne outbreaks of gastroenteritis caused by NoV from those caused by bacteria. The Kaplan criteria as reevaluated by Turcios and coworkers included: vomiting in $>50\%$ of patients, mean incubation period of 24–48 h, mean duration of illness of 12–60 h, and no bacterial pathogen detected. Using these criteria resulted in a sensitivity and specificity of 68% and 99%, respectively in discriminating the NoV outbreaks form bacterial outbreaks.

NoV Detection in Food and Water

Detection of NoVs in food and water relies mostly on (real time) RT-PCR methods. Owing to the variety of food matrices, there is a challenge in the first stage of the RT-PCR protocol: the extraction of the viral RNA from the matrix. Many studies have focused on the method development to extract viral RNA from shellfish, which has resulted in a variety of methods. Common features of these are dissection of the digestive tract and hepatopancreas and subsequent homogenization, followed by variable (partial) purification and RNA extraction methods. Other matrices such as fresh produce and fruits are often contaminated by an infected food handler or via irrigation or wash water. In such cases viral contamination will be primarily at the surface and protocols are based on elution of the virus particles from the surface of the product, followed by a concentration step (mostly ultra-centrifugation or -filtration) and RNA extraction from the concentrate.

For NoV detection in water a variety of methods are available. Here too, the challenge exists in obtaining concentrates with a detectable level of viral RNA, but a low level of RT-PCR inhibitors. Many protocols varies on a general method which, in short, entails concentration by adsorption to a filter (e.g., a positively charged membrane, glasswool), subsequent elution from the filter and further concentration using a microconcentrator or precipitation step. Immunoaffinity concentration and purification protocols have also been developed for application in water. State-of-the-art detection limits for NoV in water are approximately 10 and 300 genomic copies (RT-PCR units) of NoV G1 and GII, respectively, per 1.5 l water.

Currently, methods for standardized detection of NoV (and hepatitis A virus (HAV)) in soft fruits, leafy greens and bottled water are being validated in the CEN/TAG4 committee of the European Union and Health Canada has listed select validated methods in its Compendium of Analytical Methods for virus detection in foods. Note that all NoV detection methods are based on detection of the presence of NoV RNA (or capsid protein) and that these are not direct measures for infectivity. However, the infectious dose for NoV is extremely low and the presence of NoV RNA does indicate contamination with human feces. At the moment is not clear if there are safe levels of contamination by NoV. As was mentioned before for shellfish, in general there are no indicator organisms (or chemical indicators) for which we know they reliably predict the absence or presence of human NoV in foods, water or environmental samples. Owing to all the difficulties described above, it is unlikely that prospective batch testing of foods to show virus absence will be a reliable and cost-effective strategy.

Prevention of Contamination of Foods

NoV are primarily transmitted directly from person to person. Control of person-to-person transmission and of food handler transmission of NoV relies mostly on strict personal hand hygiene. Proper use of gloves and adequate hand washing, using soap, running water, and disposable towels are keys to prevent contamination of food. Alcohol-based hand sanitizers can be used to supplement the standard hand washing routine. Laboratory data show that the reduction of virus load or infectivity is less, or variable, when alcohol-based hand sanitizers are used instead of washing with water and soap; therefore, the use of only hand alcohol is not recommended.

Foods can also be contaminated by accidents of vomiting in areas where food is being prepared or stored. In a room where a person has vomited all the food items can be contaminated through droplets or via aerosols and these items should be disposed of or consumed only after virucidal treatment. In general, food handlers should not be allowed at the workplace when symptomatically infected with NoV and should only be allowed to return to work after a period of, for example, 48 or 72 h without symptoms. However, because shedding of NoV can continue for 4 or even 8 weeks and asymptomatic infections are common, persons should comply with strict hand hygiene instructions at all times.

Prevention of shellfish contamination relies on the use of clean water for production. Attempts to reduce viral contamination by relaying has proven to be unsuccessful or at best unreliable. The water quality in the growing areas is assessed by continuous monitoring for fecal contamination as measured by quantification of *Escherichia coli*/fecal coliforms/total coliforms. This has proven to be effective in reducing the number of shellfish-consumption related infections due to bacterial and parasitic pathogens. However, viruses may be present in water and shellfish in the absence of *E. coli*/fecal coliforms/total coliforms. To control viral safe production of shellfish, a sanitary survey of the sources and types of fecal contamination (human and animal) in the vicinity of production areas can be helpful. Additionally, methods to detect low levels of NoV in shellfish and growing waters are available and may contribute to a monitoring program with more relevance for viral food safety than mere detection of *E. coli*/fecal coliforms/total coliforms.

Prevention of contamination of fresh produce requires all of the above because contamination can occur by contaminated water or by food handlers applying suboptimal hand hygiene. It is the key to use only clean water (and soil) for the production of food and appropriate sanitary and hand washing facilities should be in close vicinity.

Viral Inactivation in Foods

Virus-infectivity reducing treatments are either treatments that lead to reduction of the virus load or treatments that inactivate the viruses. There are currently no effective, realistic, and validated virus infectivity reducing treatments for food except cooking adequately. The effects of heat treatment on virus infectivity in foods are highly dependent on virus (sub)-type and food matrix. This complicates the assessment of virucidal activity for human NoV. The human NoV cannot be grown *in vitro* yet, information on inactivation rates are based on model viruses such as the feline calicivirus, murine NoV, or HAV, sometimes in combination with reduction in genomic copies of the human NoV. Nonetheless, commonly used cooking procedures for rice, pastas, or potatoes are considered adequate treatments to destroy viral infectivity. Conventional pasteurization (e.g., 63 °C for 30 min, or 70 °C for 2 min) is more effective than high-temperature short-time (71.7 °C for 15–20 s) pasteurization, but NoV are unlikely to be completely inactivated at those treatments. For shellfish, it has been shown that HAV can be inactivated when an internal temperature of 90 °C is reached for at least 90 s. This could also be true for NoV.

The effects of washing on (murine) NoV infectivity are limited. Washing of fresh produce with just water resulted in approximately 1 log reduction of MNV on the produce, addition of 200 mg l^{-1} sodium hypochlorite or 250 mg l^{-1} peroxyacetic acid gave approximately 1 log additional reduction. However, both supplements were successful in preventing cross contamination from spiked fresh produce to clean fresh produce washed in the same washing water. Seven commercial disinfectants were shown to be ineffective at the FDA-permitted concentration when tested for the inactivation of feline calicivirus on strawberries and lettuce. Similar results were found for sodium bicarbonate, chlorine bleach, peroxyacetic acid, and hydrogen peroxide at FDA-approved concentrations.

Because viruses never grow outside their host, preservation methods aimed at preventing or reducing growth of bacteria or fungi will not contribute significantly to viral food safety: freezing, cooling and drying, vacuum packaging, or packaging under protective atmospheres will result in little reduction in viral infectivity. For example, calicivirus infectivity is reduced less than 1 log after five cycles of freezing and thawing and less than 1 log after storage at refrigerator temperatures for 1 week. Outbreak reports show that NoV infectivity will outlast the shelf life of most fruits and vegetables, and NoV infectivity remains at a sufficient level to cause disease after cooled or frozen storage. Furthermore, NoV are very stable at low pH and more than 3 log inactivation may occur only at pH <3, a pH that is often unacceptable for the sensorial quality of foods. Information on virus infectivity after long-term storage, or cooling or freezing in combination with acidification is lacking.

The effects of high hydrostatic pressure (HPP) on human NoV infectivity in foods are unknown, but tests with the cultivable MNV have been performed. Approximately 4 log reduction of MNV was demonstrated in oyster tissues at a treatment 5 min, 400 MPa, at 5 °C. Although only 0.8 log infectivity reduction was found for MNV at homogenization pressures of 300 MPa at 75 °C in PBS (relative to 3 log for MS2). Clearly, virucidal effects depend on the food matrix but HPP may be a measure to reduce viral infectivity.

Studies on the effect of irradiation (gamma or UV) on NoV (calicivirus) infectivity in foods are limited. UV irradiation does reduce virus infectivity but its effectiveness is highly dependent on the presence of the virus on the surface of the food, the food matrix and perhaps even the NoV genotype. It cannot be considered an effective generic measure to reduce

viral infectivity on or in food. UV irradiation can be effective for the inactivation of viruses in water and aerosols.

Virus Infectivity Reducing Treatments for Surfaces

For surface disinfection, many disinfectants recommended for use in food establishments are not effective against the nonenveloped viruses, such as NoV. One effective method is the use of sodium hypochlorite, for which the effectiveness is determined by the availability of free chlorine and the exposure time. The recommended treatment for clean surfaces uses solutions of ≥ 1000 ppm free chlorine for at least 5 min to inactivate HAV, and presumably also NoV.

Feline calicivirus was not efficiently inactivated on environmental surfaces or in suspension by 1% anionic detergents, quaternary ammonium (1:10), hypochlorite solutions with <300 ppm free chlorine, or less than 50% or more than 80% alcohol preparations (ethanol or 1- and 2-propanol). Varying efficacies of 65–75% alcohol are reported, however, short contact times (<1 min) rarely result in effective inactivation. Moreover, the presence of fecal or other organic material reduces the virucidal efficacy of many chemicals tested. MNV was reported to be sensitive to 60% alcohol, alcohol hand rubs, bleach, and povidone iodine-based disinfectant in suspension tests using very low level interfering substances. This was remarkable, because this would suggest a higher sensitivity of MNV than of feline calicivirus for commercial disinfectants and most likely higher sensitivity to hypochlorite of MNV compared to human NoV, because the RNA of human NoV was much better protected during hypochlorite inactivation than the RNA of feline and canine caliciviruses. Overall, human NoV seems to be the most resistant calicivirus tested so far.

Regulatory Measures

Viruses such as NoV have several features that make them behave differently in the food chain than classically recognized foodborne bacteria. It is clear that hazard analysis and critical control point (HACCP) systems and good manufacturing practice (GMP) should be in place and the appropriate guidelines for production of safe foods should be followed. Because it is now recognized that this will not automatically result in virus safe foods, a new CODEX guideline is being drafted. These Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food aim to minimize the risk of illness arising from the presence of human enteric viruses, more specifically from NoV and HAV, in foods. The guidelines are supplemented with two annexes: Control of hepatitis A virus (HAV) and norovirus (NoV) in bivalve mollusks and Control of hepatitis A virus (HAV) and norovirus (NoV) in fresh produce and could be published as early as 2011.

Foot-and-Mouth Disease Virus

C Carrillo, Plum Island Animal Disease Center, Greenport, NY, USA

Glossary

Acute infection A presentation of a disease with a rapid onset and/or short course of symptoms and disease evolution.

Amino acids These are critical-to-life molecules, which contain an amine group, a carboxylic acid group, and a side chain that varies among different amino acids. They have many functions in metabolism and are the building blocks of proteins.

Carrier An infected individual that carries an infectious agent despite a healthy appearance.

Chronic infection A long-lasting course of a disease in which there is clear presentation of symptoms related to such disease.

Epitope Also known as antigenic determinant, it is the part of an antigen that is recognized by the immune system.

Muller's ratchet effect The process by which the genomes of an asexual population accumulate deleterious mutations in an irreversible manner.

Nucleotide The molecules that join together in chains to make up the structural units of ribonucleic acid and deoxyribonucleic acid.

Peptides or polypeptides Short polymers of amino acids linked by peptide bonds.

Persistent infection The remaining infection after recovery from the disease during which it is still possible to isolate the infectious virus from the individual despite the absence of disease symptoms.

Quasispecies A large group or cloud of related genotypes that exist in an environment of high mutation rate, where a large fraction of offspring are expected to contain one or more mutations relative to the parent.

Background

Foot-and-mouth disease (FMD) was the first viral animal disease identified. The oldest recollection of data describing a disease like FMD was in cattle by Eraclito in ancient Greece (*ca.* 500 BC). The first description of an FMD virus (FMDV) epizootic was recorded in 1514 by Girolamo, in Northern Italy, and in 1546 by Frascastorius, in Venice. In 1764, Michel Sagar individualized the infection identifying it under the name of *Aphthis pecorinis*. But it was not until the experimental studies carried out by Loeffler and Frosch in 1897 that the etiologic agent of FMD was identified and defined as a filterable infectious agent smaller than bacteria. This was the first description of a virus causing an animal disease. In 1922, Vallee and Carre reported the existence of different serotypes, identifying only serotypes A and O. Subsquently, in 1926, serotype C was described by Waldmann and Trautwein; the Asia 1 and South African Territories (SAT) 1, SAT 2, and SAT 3 were described in 1936 by Lawrence. Thus, FMDV exists in seven well-defined serotypes, namely A; O; C; Asia 1; and SAT 1, SAT 2, and SAT 3. However, a large number of subtypes have evolved within each serotype group, making its classification a difficult issue. In fact, the seven original serotypes have been defined based on the lack of cross-reactivity among each virus and the antibodies in sera from the heterologous serotypes. Later, based on the comparisons of VP1 sequence data, it was confirmed that the distribution of FMDV isolates occurs not only in serotype-related groups, but also in genotypes with less

than 15% differences in nucleotide (nt) sequence, which coincide with the geographic origin of the isolates and have been defined as topotypes.

Etiology, and Characteristics of FMDV

The etiologic agent of FMD is a ribovirus of the Picornaviridae family. Within the ribovirus of positive-sense ribonucleic acid (RNA), the family Picornaviridae includes very important pathogens, such as *Enterovirus* (polioviruses and coxsackieviruses), *Cardiovirus*, and several other genera. *Aphthovirus* is one of these 12 genera of the Picornaviridae family comprising the *Equine rhinitis A virus*, the *Bovine rhinitis B virus*, and the FMDV. The diameter of any intact picornaviral particle is approximately 22–23 mμ long and consists of a nonenveloped outer protein coat or capsid with icosahedral symmetry. The protein capsid is composed of 60 capsomeres, each one of them containing a copy of each of the four capsid proteins: VP4, VP2, VP3, and VP1, also known as 1A, 1B, 1C, and 1D, respectively. A single-stranded RNA genome of positive polarity is enclosed in each mature capsid. The FMDV particle is highly labile and rapidly loses infectivity at pH values of less than 6 and greater than 9. However, it is stable at low temperatures, surviving for at least 1 year at 4 °C. Survival times at 37 °C and 56 °C are 10 days and less than 30 min, respectively. In fact, the process of pasteurization of contaminated milk at 72 °C for 15 s does not inactivate FMDV. It must be heated at 100 °C for more than 20 min for virus inactivation. In the environment, the virus can survive in the soil for at least 3 days during winter; in urine, it can persist up to 39 days; and in dry fecal material, it can persist infective up to 14 days in summer and 6 months in winter conditions. For its inactivation, sodium hydroxide 2%, sodium carbonate 4%, and citric acid 0.2% are effective. But it is resistant to iodophores, quaternary ammonium compounds, and hypochlorite and phenolic compounds, especially in the presence of organic matter. FMDV survives in lymph nodes and bone marrow at neutral pH but is destroyed in the muscles due to the acidification process that accompanies the rigor mortis of the carcasses.

Genomic Organization

The approximately 8500-nt long viral RNA consists of a single open reading frame (ORF), flanked by two noncoding regions (NCRs), both predicted to display complex secondary structures, which play a critical role in viral replication and gene expression. A small viral protein (VPg) is covalently linked to the 5′ end of the molecule. A poly-C tract divides the 5′NCR in a small RNA (S) fragment of approximately 400-nt long and a large RNA (L) fragment, which contains the remaining 5′NCR, the unique ORF, and the 3′NCR. Little is known about the function of the Aphthovirus poly-C tract, except that it is also present in only *Cardioviruses*. The picornavirus internal ribosome entry site (IRES) element provides cap-independent translation function. Its length varies among isolates and has been indirectly and inconclusively related with viral virulence. The translation initiation of the FMDV RNA starts at two AUG codons separated by 84 nt, following ribosome recognition of the upstream IRES. The viral ORF encodes a single polyprotein, which is cleaved by viral proteases to yield different viral products. A highly ordered structure is also predicted at the 3′NCR of FMDV genome of approximately 90 nt long, which precedes a long poly-A tail. The viral ORF encodes a single polyprotein, which will be cleaved into a number of intermediate subproducts and 12 final mature proteins. This processing will yield nonstructural proteins (NSPs) known as Lpro, and precursors P2 and P3, plus the capsid or structural proteins (SPs) 1A, 1B, 1C, and 1D, all of them contained in the precursor protein P1. The NSPs are involved in the critical functions of the virus life cycle in infected cells and will result in eight different final products that catalyze the processes of proteolysis, shut-off of host proteins, evasion of host immune system, cytopathic effects, etc.

Viral Structure and Antigenicity

The structure of FMDV capsid has been thoroughly analyzed by X-ray crystallography and was mostly found to contain the combination of four SPs (1A, 1B, 1C, and 1D) in higher structures, as previously described as capsomeres (see Characteristics). One of the important characteristics of the SP is that they contain the most important antigenic structure of the viral particle. Probably, the best known is the antigenic site located in the G–H loop of 1D (also known as VP1), which has been repeatedly related with the generation of neutralizing antibodies. Not all the antigenic sites are linear epitopes, but several conformational or discontinuous epitopes have been described in proteins 1B (VP3) and 1C (VP2).

A second critical function of the capsid proteins is to provide cell recognition factors that make possible the entry of the virus into the host cell. Several studies have determined that the G–H loop of protein 1D contains an arginine–glycine–aspartic acid signal peptide. This motif is critically involved in virus interaction with cell surface integrin receptors. There are also indications of other mechanisms of cell recognition, probably used as alternative routes for infection, such as the capacity to interact with heparan sulfate glycosaminoglycan residues on the cell surface, which is used as a pathway for FMDV variants adapted to cells in culture. The capacity of FMDV to develop and to use multiple pathways for entry into the host cell illustrates the importance of the genetic plasticity of FMDV that results in the evolution of viral antigenicity throughout the action of determined selective pressures. Evolution of FMDV in cell culture can reduce the constraints in an important antigenic site and may allow the virus to explore new antigenic structures.

Variability and Evolution

Many studies have already provided important experimental support to the fact that due to the high mutation rates of replication, RNA viral populations consist of a composite of multiple genetic variants, termed as quasispecies, in which the predominance of special features is the result of the equilibrium between the competitive fitness of each genetic variation in response to the selective pressures acting in each

occasion. This property allows RNA viruses to easily adapt and survive in every different environment. But at the same time, it produces uncontrollable number of spontaneous mutations with detrimental effects that constantly debilitates the population on passages, known as the Muller's ratchet effect. There are enough experimental results to infer that some strains of FMDV may die out if they are restricted to a small contained population of susceptible hosts. However, genetic and antigenic variability of FMDV populations even in the absence of immune pressure are a real challenge for vaccination and control of this disease, and has to be considered for the epidemiology of FMD.

Clinical Manifestation in Animals

FMDV usually produces an acute, systemic vesicular disease. In natural infections, the main route of virus entry is the respiratory tract, and as few as 1–10 infective particles can produce the disease. The initial virus multiplication usually takes place in the pharynx epithelium, producing primary vesicles or 'aphthae.' Within 24–48 h after the epithelium infection, fever and viremia start and the virus enters the blood to spread out and produce secondary vesicles, preferentially in the mouth and feet. Early signs of the disease are fever, prostration, lack of appetite, and lameness. Later, FMD is characterized by the formation of vesicles on the mucosa of the mouth, tongue, lips, cheeks, and palate. Also, vesicles are usually found on the skin between the claws of the feet, coronary band, teats, and udder. Besides farm animals, FMD also affects more than 70 species of wild ruminants. The acute phase of disease lasts approximately for 1 week and declines gradually coinciding with the appearance of a strong humoral response. On infection, FMDV elicits a rapid and broad spectrum of immune mechanisms, including humoral and cellular responses that induce efficient protection against reinfection with homologous and antigenically related viruses. Neutralizing antibodies against B-cell epitopes located on the viral capsid can be detected as early as 4 days after infection and peaks at approximately 10–14 days postinfection. Although FMD does not result in high mortality in adult animals, the disease has debilitating effects, including weight loss, decrease in milk production, and loss of draught power, resulting in a loss in productivity for a considerable amount of time. The recent outbreaks of FMD in a number of FMD-free countries, such as Taiwan in 1997; UK, France, and The Netherlands in 2001; Uruguay and Argentina in 2001; Japan 2002; and others have significantly increased public awareness of its highly disruptive effects from a socioeconomic point of view, as well as its possible use as a terrorist weapon. Despite low mortality rates, FMD severely decreases the livestock production and introduces important trade restrictions on animals and livestock products. In some cases, mortality can be observed among young animals, associated with lesions in the myocardium. In ruminants, an asymptomatic, persistent infection can be established during which the virus can be isolated from the esophagus and throat fluids of the animals. Although the mechanisms that mediate persistence are unclear, both naïve and vaccinated animals can become persistently infected or 'carriers' following acute or chronic, unapparent infection. However, the epidemiological role of these carriers as origin of outbreaks of acute disease is still unknown. Similarly, the genetic determinants for virulence, viral neutralization and host-specificity are yet to be defined.

Under certain circumstances, including the strain and host characteristics, FMD infection can be subclinical, with unapparent symptoms of disease that leads to unnoticed disease, mostly common between sheep and goats. The mechanisms for this kind of resistance to FMDV infection are not well understood and can also occur in animals exposed to the virus after either acute disease or vaccination. Unequivocal evidence of transmission from carrier or unapparent infected animals to susceptible hosts has neither been demonstrated under experimental conditions nor in the field.

Epidemiology and Risks of Transmission to Humans

The disease is enzootic in most parts of the world, with disease-free countries being Australia, New Zealand, North America, and Europe. The global distribution of FMD is clearly associated in areas with lower levels of economic development and it contributes to severe economic problems of many developing countries. The World Health Organization does not consider that FMDV can be transmitted from animals to humans (known as zoonosis). Only few cases, less than a hundred, have been somehow linked to manipulation of heavily infected animals or highly concentrated viral suspensions in laboratories. However, there is no proof of human infection with the animal virus and epidemiological data indicates that potentially contaminated products do not present food safety risks for humans. Long-distance airborne transmission has been documented. FMDV can be mechanically disseminated by animals, farmers, farming equipment, and during animal transport. There is no real proof of FMDV infection in humans; however, records from 1880s show that at least 2 people died of FMD and more than 200 suffered painful symptoms, with 'raw red' mucous membranes and chronic ulcers lined by 'thick puckered edges.' Also, 'the enlarged cervical (neck) glands remained tender, red, and swollen long after the throat symptoms had subsided, resembling, in this respect, scarlet fever; and in some instances, the feet of those who suffered were swollen and painful, simulating rheumatism,' but given the high incidence of the disease in animals across all continents, its occurrence in humans is strikingly rare. The last human case reported in Britain in 1966 was described as mild and self-limiting, mainly causing uncomfortable tingling blisters on the hands, feet, and in the mouth, including the tongue; fever; and sore throat. It has been demonstrated that after contact with FMD-infected livestock, virus can be recovered from nostrils, throat, and saliva; but till date, no implications for human health has been reported, and it is suspected that it might have been mistaken with the HFMD induced by the viruses from the *Enterovirus* group.

FMD is highly contagious and affects artiodactylous, mostly cattle, swine, sheep, and goats. FMD is one of the most communicable of all animal infections; it spreads by direct or indirect contact with infected animals, from their excretions

and secretions, or from contaminated materials and persons. The feeding of uncooked garbage containing infected meat scraps or bones is one of the most common means of spreading. Treatment to limit secondary bacterial pneumonia and mastitis are recommended only where FMDV is endemic, followed by local quarantine and revaccination with the most appropriate vaccine type for the outbreak. Otherwise, in FMD-free countries, the policy of stamping out used to be the choice, the measures taken are killing and disposal of all susceptible livestock on the infected farms and also their immediate contact farms, followed by a thorough disinfection and cleaning of the premises and its equipment, and quarantine with sentinel animals before repopulating the premises. After the 2001 outbreak in UK, in view of the dramatic situation that the stamping-out policy had created, public opinion questioned the need for large-scale slaughter of susceptible animals, particularly the slaughter of healthy animals that were just vaccinated to create a buffer zone around the outbreaks. The culls of healthy animals represent a human tragedy and a traumatic experience for the acting veterinarians, the farmers and their families, and the operators who have to deal with thousands of repeated killings.

Diagnostic Methods

Initial diagnosis is usually made on the basis of clinical symptoms, history of contact between the herd and an infected animal, report of FMD in neighboring farms, visit to market places or fairs, new livestock acquisitions in the farm, and other epidemiological data. In a fully susceptible herd, the clinical signs are frequently severe and pathognomonic. However, in endemic regions, in cattle that have partial natural or vaccine immunity, or in small ruminant's species, clinical signs may be mild and may be missed. Always a differential laboratory diagnostic is needed to rule out FMD from other vesicular diseases, such as swine vesicular disease, vesicular stomatitis, and vesicular exanthema of swine. Currently, FMD is confirmed by reverse transcription polymerase chain reaction (RT-PCR; usually real-time RT-PCR (rRT-PCR)), antigen capture enzyme-linked immunosorbent assay (AgELISA), and virus isolation (VI). Both, the rRT-PCR and conventional RT-PCR take less than 3 h to show results. Meanwhile, ELISA can be obtained in 3–4 h after the sample is received by the laboratory, but a negative result must be confirmed by inoculation of the sample into sensitive cultures (VI) followed by confirmation of the virus by RT-PCR and the virus serotype by AgELISA. These assays can take up to 4 days. RT-PCR methods are much faster and hence, more compatible with the need to rapidly detect disease and initiate an appropriate disease control strategy. Most interesting is the portable onsite diagnosis properties of the rRT-PCR. The assay is specific and as sensitive as VI, and viral RNA can readily be detected in oral and nasal samples, blood, milk, and organs from experimentally infected animals 24–96 h before the onset of clinical signs. In 1966, Cowan and Graves identified a highly immunogenic FMDV-NSP antigen, called the virus infection-associated antigen (VIAA, which was subsequently identified as the viral RNA polymerase), which reacted with the sera from convalescent animals but not with the sera from vaccinated animals and could be used in an agar gel immunodiffusion test to differentiate infected from vaccinated animals (DIVA). However, in later studies, it was seen that sera from vaccinated animals were reactive against VIAA when they had received multiple doses or when the vaccines did not have enough quality and were contaminated with NSPs. The concept of using NSPs as a DIVA test deserved further work to improve the reliability of this diagnostic assay. ELISA-based assays with various NS 3AB, 2C, 3C, and 2B, their respective peptides, the products from recombinant baculovirus, *Escherichia coli*, or synthetically produced peptides to NSPs have been developed and are currently being validated. Whole and clotted blood samples and probang samples may also be sent.

Antibodies to FMDV can be detected in the milk of cattle that have recovered from FMD, using either the liquid-phase blocking ELISA or a specific isotope assay for bovine immunoglobulin G1.

Control/Preventive Measures

FMD control in endemic areas is implemented by regular vaccination, which has resulted in the eradication of the disease in some areas of the world. Conventional vaccines based on chemically inactivated viruses are widely used. They elicit a consistent humoral response, albeit generally weaker than that induced in infected animals. This response correlates with a solid lymph proliferative response and with considerable, although short-lived, protection. However, they do not prevent the persistent infection of protected animals with FMDV and despite the fact that the inactivated virus do no replicate in the vaccinated animals, vaccines might be contaminated with viral NSPs, making the distinction between vaccinated and infected animals impossible. During the past decades, FMD-free countries have started policies of holding strategic reserves of FMD vaccines in the event of an outbreak, storing concentrated antigens indefinitely on liquid nitrogen, which can be rapidly formulated into emergency vaccine in the case of an outbreak (for instance, the North American Vaccine Bank and the European Union Vaccine Bank).

Another concern related with FMD vaccines is the fact that vaccinated animals can become long-term carriers following contact with active FMDV. It does not mean that the vaccine produces a carrier state in the animal, on the contrary, vaccination reduces the amount of FMDV that is released into the environment during an outbreak, but there is always a window of susceptibility between the vaccination and the appearance of protection against infection that will help the establishment of persistent unapparent infections.

Finally, it has to be considered that vaccine production and vaccinated animals have both been frequently associated with emergence of viral escapes and induction of carrier animals. Conventional vaccines against FMD are concentrated with cell culture supernatants from FMDV infected cells that require high technology containment barriers to be handled with reasonable degree of safety against an accidental release. They are the product of the best possible guaranties of inactivation with chemical products and require the use of adjuvants,

$Al(OH)_3$/saponin, and oil-based formulations to enhance the immune response to the FMDV antigen. Most often, more than one serotype is included in the same vaccine formulation allowing protection for a limited spectrum of viral variants. Therefore, it is a strong need of genetically engineered immunogens that provide lower risk of escape and allow DIVA strategy.

All these concerns have inclined the FMD-free countries toward a nonvaccination, stamping-out policy. This nonvaccination policy implies slaughtering of all infected and contact animals, associated to animal movement restrictions, increase of the importation of animals and animal subproducts from the nonaffected areas, and total paralysis in trade and export business. These strict control measures also affect other industries related with products and subproducts, such as products for feeding animals, industries of food complements, leather industry; even tourism is affected due to the restrictions in movements of people across the sanitary barriers. Although effective in maintaining an area free of FMDV, the control of the disease is difficult by several socioeconomic as well as technical factors. The wide range of antigenic diversity of the virus does not help either in making the control an easy task. Our current level of understanding of antigenicity and cross-neutralization factors for FMDV is not enough for the preparation of a universal vaccine. Perhaps most importantly, vaccination with inactivated antigens as is currently done does not allow differentiation between vaccinated and convalescent or FMD-recovered animals. Hence, current control and eradication measures consist of vaccination and stamping-out policies.

FMDV RNA behaves as a messenger; in fact, it is infectious when transfected into susceptible cells. This property of direct translation in the cytoplasm of the infected cell allowed the construction of infectious cDNA clones that can be manipulated and used as a tool for studying functional motives and critical features of the virus, which will help in the development of rational and secure new immunogens that allow DIVA strategy.

ORGANISMS OF CONCERN BUT NOT FOODBORNE OR CONFIRMED FOODBORNE

Classical Swine Fever Virus

C Carrillo, Plum Island Animal Disease Center, Greenport, NY, USA

Glossary

Acute infection A presentation of the disease with a rapid onset and/or short course of symptoms and disease evolution.

Amino acids Critical to life molecules that contain an amine group, a carboxylic acid group, and a side chain that varies between different amino acids. They have many functions in the metabolism and are the building blocks of proteins.

Carrier An infected individual that carries the infectious agents despite a healthy appearance.

Chronic infection Long-lasting course of a disease in which there is a clear presentation of symptoms related with such disease.

Epitope Also known as antigenic determinant, this is the part of an antigen that is recognized by the immune system.

Kbp Kilobase pairs; 1 kilobase contains 1000 pair bases.

Nucleotide Molecules that join together in chains, to make up the structural units of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA).

ORF Open reading frame, the tract of genetic sequence that spans without interruption between a start codon and the stop codon, and that in such a given frame codifies for a unique protein.

Persistent infection Remaining infection after recovery of the disease in which it is still possible to recover infectious virus from the individual despite the absence of disease symptoms.

Positive-strand RNA virus Virus containing positive-sense viral RNA, which is similar to mRNA and thus can be immediately translated by the host cell.

Background and History

Classical swine fever (CSF), otherwise known as hog cholera, pig plague (*Schweinepest*), or *Peste Porcina Clasica*, is a specific viral disease of pigs. It does not affect humans or other vertebrates. According to early reports, CSF was a per acute-to-acute disease with a short incubation period and 100% mortality. The disease was first identified in the early 1830s in Ohio, USA, and has since been widely distributed in the Americas, Europe, and Asia for a long time. It was eradicated from North America in 1978 and has also been eradicated from Australia and most countries in Western Europe, but is endemic in Central and South America, the Caribbean, Asia, and Eastern Europe. With the exception of South Africa, CSF has not been reported from the African continent, although its absence does not correlates with the data that supports freedom from disease. It has also been confirmed in the islands of Madagascar. Other regions believed to be free of CSF include Canada (1962), New Zealand, and Scandinavia.

The Virus

The etiological agent known as the CSF virus (CSFV) is an enveloped small virus of the genus *Pestivirus*. Pestiviruses belong to a large family of positive-strand RNA viruses, the Flaviviridae that includes three genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*, plus two groups of viruses that have not yet been classified (GBV-A and GBV-C). Like the rest of the Pestivirus, CSFV are spherical, enveloped particles of 40–60 nm in diameter, which contain a single molecule of RNA of positive sense. Co- and posttranslational processing of the polyprotein encoded by the viral RNA gives rise to the following 11–12 final cleavage products or viral proteins: Npro, C, Erns, E1, E2, p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. Protein C and the glycoproteins Erns, E1, and E2 represent structural components of the virion. E1 and E2 are anchored to the envelope by their carboxy termini, with Erns loosely associated with the envelope. Erns and E2 are present as homodimers linked by disulfide bridges on the surfaces of CSFV virions, whereas E2 is also found dimerized with E1. The genetic basis of CSFV virulence and host range remains poorly understood but recent development of infectious CSFV cDNA clones has enabled genetic approaches for defining mechanisms of viral replication and pathogenesis and identifying viral proteins or protein domains functioning in viral virulence and host range.

The Genome

The CSF genome is a single-stranded RNA molecule of positive sense and approximately 12.3 kb in length. It lacks 5′cap and

 doi:10.1016/B978-0-12-378612-8.00165-7

3′ poly-A tract. Instead, 5′ and 3′-non-translated regions (NTRs) flank a unique open reading frame (OFR), which translates in a single polyprotein of approximately 4000 amino acids long. The NTRs harbor important primary and secondary structural elements that have been shown to be of critical importance for efficient replication of the RNA. Additionally, CSF translation initiation is cap independent and mediated by and internal ribosomal entry site that precedes the AUG start codon downstream in the genome. Thus, the positive-strand RNA genome not only functions as messenger RNA allowing immediate translation of the viral proteinsbut also serves as template for RNA replication.

The RNA is translated in a single polyprotein of more than 4000 amino acids, which is processed in the final viral protein products by a combination of cellular and viral proteases. One of the first translated proteins is the protease, known as N^{pro}, responsible for autocleavage of the polyprotein. Other viral serine proteases and host signal peptidase are believed to be responsible for several other cleavages that will lead to the generation of a total of structural (core, Erns, E1, and E2) and nonstructural viral proteins (p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B).

RNA replication is associated with cytoplasmic membranes and occurs between 6 and 24 h post-infection. CSFV mature in intracellular vesicles and are released by exocytosis.

The Target Host Cell

Cells of the monocyte–macrophage lineage are the natural target cells for viral infection and replication. But other cells from the reticuloendothelial system are also affected. On enterring the natural host, the primary site of replication of CSFV is the epithelial tissue that lines the tonsilar crypts; from there, spreads through the lymphatic vessels to the submandibular and pharyngeal lymph nodes that drain the tonsilar region and later to other lymph nodes. CSFV has direct effect on vascular endothelial cells, which is responsible for the characteristic petechial or echymotic hemorrhages in skin, bladder, kidneys, and serous and mucous membranes. Thymic and bone marrow atrophy and destruction of germinal centers in secondary lymphoid organs are the causes that lead to severe leukopenia and immunosuppression in the infected pigs; B-lymphocytes, T-helper cells, and cytotoxic T-cells are all depleted to different degrees. As a result, CSFV-infected pigs are immunocompromised and susceptible to secondary infections that mask the difficult detection of CSF.

Clinical Signs of the Disease

The main natural route of infection is oronasal by direct or indirect contact with infected pigs or by feeding of virus-contaminated feed. In areas with a high density of pigs, spread of virus easily occurs between neighboring pig holdings. Disease transmission via semen of infected boars may also occur. The incubation period in experimentally infected animals is approximately 1 week to 10 days, but under field conditions clinical symptoms may take up to 2–4 weeks or even more if only adult breeding pigs or mild strains of virus are involved. Highly virulent strains can cause clinical symptoms as early as 2 days postinfection. The clinical signs of CSF are extremely variable and depends both on the virulence of the virus strain, the infectious dose, and the immune response of the pig. Highly virulent strains correlate with acute, obvious disease and high mortality and can cause clinical symptoms as early as 2 days postinfection. Nevertheless, even though pigs of all ages are susceptible, adult pigs often develop less severe disease and have a better chance of survival than piglets. Less virulent strains give rise to subacute or chronic infections that may escape detection, while still causing abortions and stillbirths. In these cases, serological surveillance is critical to confirm the absence of disease. Therefore, CSF clinical forms can be distinguished as acute, chronic, and prenatal.

Acute Course of Classical Swine Fever Virus Infection

Some strains of CSF have an hyperacute course of the disease, characterized by a short incubation period with high fever and death 2–5 days after infection. Mortality rises to 90% or 100% of the infected pigs. In acute presentations, the initial signs are nonspecific such as anorexia, lethargy, and fever; the increased fever may lead to redness of the skin, conjunctivitis, swollen lymph nodes, respiratory signs, and constipation followed by diarrhea. The typical hemorrhages of the skin are not always present, but if so they are usually observed on the ears, tail, abdomen, and the inner side of the limbs progressing toward cyanosis near the terminal stage of disease. Neurological signs are frequently seen, such as a staggering hind limb gait, incoordination of movement, and convulsions, progressing to posterior paresis toward the end of the process. Vomiting, transient constipation followed by severe watery, yellow-gray diarrhea are also frequent in this acute and hyperacute forms. Leukopenia and immunosuppression often leads to enteric or respiratory secondary infections that may mask or overlap the most typical signs of CSF and make difficult the identification of the disease to the farmer or veterinarian. Death occurs usually within 1 month. Recovery with production of antibodies does occur, most often in adult breeding animals that do not display severe clinical signs. Antibodies against CSFV are detectable from 2 to 3 weeks postinfection onward.

Postmortem examination shows pathological modifications in lymph nodes, tonsils, spleen, and kidneys. The predominant lesion of acute CSF is hemorrhage. The lymph nodes become swollen, edematous, and red marmoreal. Hemorrhages of the kidney may vary in size from hardly visible petechiae to ecchymotic hemorrhages. Similar hemorrhages can also be observed in the urinary bladder, larynx, epiglottis, and heart, and sometimes widespread over the serosae of the abdomen and chest. Necrotic foci may also be present on the palatine tonsils. Splenomegaly and spleen infarction occurs sometimes and can be considered pathognomonic of CSFV and African swine fever virus (ASFV) infections. Lesions associated with encephalitis, microgliosis, and focal necrosis in central nervous system can be observed. Lesions due to secondary infections may also be seen, which may mislead the pathologist, such as infarctions and hemorrhages are seen in the lung, pericardial, and peritoneal accumulation of serosous fluids, as well as catarrhal to fibrinous bronchopneumonia and pleuritis as a result of secondary infections.

Chronic Course of Classical Swine Fever Virus Infection

The chronic course of infection starts as any acute infection, with anorexia, depression, intermittent fever, chronic enteritis, and wasting, but is followed by a stage of recovery, characterized by the general improvement of the clinical status of the animal. Later on, a third stage of relapse and deep sickness, often accompanied by death, follows. The typical hemorrhages of the skin are missing, although multifocal and necrotic lesions can occur. Animals can survive more than 3 months before their eventual death. Constipation and diarrhea are alternated, in periods that last for weeks or even months. Poor growth and bad condition are typical (runted pigs).

Pathological changes are similar but less severe than those in acute and hyperacute forms, especially concerning the lack of hemorrhages on organs and serosae. In animals showing chronic diarrhea, necrotic lesion in the ileum, the ileocecal valve, and the rectum are common. Secondary bacterial infections are more common, and cecum and colon can be found ulcerated.

Congenital Course of Infection and Late Onset of Disease

Depending on the virulence of the strain of virus infecting the pregnant sow and the stage of gestation, the outcome of the CSFV infection varies. High virulence strains of CSFV usually results in abortions or early death of the piglets, but infection with moderate and low virulence strains are difficult to detect. In these cases, the disease is subclinical for the sow with a transient fever, slight anorexia, and poor reproductive performance. CSFV is able to pass across the placenta of pregnant animals and infect the fetuses; thus when the infection occurs during early pregnancy may result in abortions and stillbirths, mummification, and malformations. In this case, all that is noticed is a reduction of the fertility index of the herd. When the infection of sows occurs during the first 90 days of pregnancy, healthy-looking, persistently infected piglets are born. These piglets do not show antibodies against CSFV, have persistent viremia, and can excrete large amounts of virus during their short but clinically normal life. Usually after 2–11 months from birth, anorexia, depression, conjunctivitis, dermatitis, diarrhea, and paresis lead them to death.

Prevention and Control

CSF live attenuated vaccines have been in use for a long number of years for controlling and eradicating the disease. The better known are the Chinese (C), the Japanese GPE, the Thiverval, and the Mexican PAV strains. These vaccines have shown to be effective in protecting against clinical signs, virus replication, and virus shedding. Therefore, their inclusion in measures to control CSF can reduce costs and limit spread of CSF outbreaks. The only problem of using vaccination as a control measure is that it is not possible to distinguish between vaccinated and naturally infected serologically positive animals. A general and fruitful effort in all laboratories interested in CSF has been, and still is, the development of new immunogens that allow distinguishing between infected and vaccinated animals. Currently, at least two subunit vaccines based on the use of the protein E2 glycoprotein as the only CSF antigen has been developed. Also, an infectious clone of bovine viral diarrhea virus (BVDV) has been used to prepare deletion of genetic mutants that protect against challenge with virulent strains, but do not produce either clinical signs when inoculated or viral shedding or persistent infection of the inoculated and/or challenged pigs. Natural infection induces strong immunity, but 10–12 days after infection there are circulating neutralizing antibodies, and survivor pigs develop long-lasting humoral immunity.

Regulatory measures, restriction trade policies, and periodic clinical inspections in critical points of commerce and production of pork products are significant tools for prevention. Additionally, CSF prevention has a strong component that can only be achieved through effective communication between veterinary authorities, veterinary practitioners, and pig farmers; effective disease reporting and animal identification system; a strict import control of live pigs, fresh, and cured meat; prohibition of feeding pigs with waste food; and biological and serological surveillance. Finally, the importance of serious rules of on-farm biosecurity cannot be overestimated. The ban on commercial slaughter and sale of pigs meant that all of these pigs had to be destroyed in such a way that they do not enter the food chain, creating a massive problem of disposal. The conclusion is that although the control strategy applied was effective and the costs were justified when compared to that of control failure, they could have been greatly reduced if good biosecurity had been implemented during the outbreak.

To achieve eradication of CSF after an outbreak, stamping out of infected and in-contact pig herds with destruction of the carcasses is traditionally considered to be the best option. Protection areas of infected, surveillance, and control around each outbreak, with restrictions on pig movements should be established as soon as possible. Then, an epidemiological investigation for tracing the source and spread of infection should be carried out. And an emergency vaccination program around the outbreak can also be used to limit disease spread and reduce the number of slaughtered animals. Because vaccine-produced antibodies are indistinguishable from antibodies originated after infection with the virus, all vaccinated animals should be eliminated later on. However, following the control and resolution of the outbreak, the vaccinated animals can be used in commercial slaughter. After an outbreak has been eradicated, it is necessary to put in place a monitoring and surveillance system to demonstrate, at an acceptable level of confidence, that the eradication was successful and the area or country is free of CSF infection. Such surveillance systems need to be maintained for a sufficient period to be sure that eradication has been accomplished, and on-going systems designed to ensure early detection of CSF.

Public Health

Humans are not susceptible to CSF infection. CSF persists infectious in uncooked pork and processed pork that has not been heated to high temperatures for long periods, including salted, smoked, and fresh chilled pork (months and even years depending on the conditions of preservation); however, no cases of disease or seroconversion have ever been reported in CSF endemic countries. On the contrary, feeding pigs uncooked

swill that may contain pork products is extremely dangerous, illegal introduction of meats from CSF endemic countries, vehicles used to transport pigs between high-risk or endemic and free of CSF areas are all extremely dangerous practices because it has been demonstrated that CSF can be transmitted that way. In summary, CSFV is relatively stable in moist excretions of infected pigs, pig carcasses and fresh pig meat, and some pig meat products but is readily inactivated by detergents, lipid solvents, proteases, and common disinfectants.

Diagnosis

CSF is often difficult to recognize because of the wide range of clinical signs and lesions reported according to the amount and virulence of the virus and the age, breed, and immune capability of the pig. Besides, most of the general symptoms can be confused with other diseases, in particular not only ASF, but also porcine reproductive and respiratory syndrome (PRRS) and bacterial septicemia or pneumonia. Acute CSF needs to be differentiated from erysipelas, PRSS, cumarin poisoning, purpura hemorragica, postweaning multisystemic wasting syndrome, porcine dermatitis and nephropathy syndrome, *Salmonella* or *Pasteurella* infections, or any enteric or respiratory syndromes with fever, which do not respond to antibiotic treatment. When present, hemorrhages on the skin and ears are quite easy to detect and lead to the suspicion of acute ASF or CSF, because few other diseases cause similar lesions, but in chronic cases, the multifocal and necrotic skin lesions can be confused with those seen in porcine dermatitis and nephropathy syndrome and erysipelas. Reduced fertility and abortions can be caused by CSFV as well as parvovirus infection, PRRS, Leptospirosis, and Aujeszky's disease. Materials aborted due to CSF infection cannot be distinguished grossly from abortions due to other diseases. In case of an infectious disease of the reproductive tract, investigation for CSF must be immediately carried out in case that the holding in question can be considered at risk for CSF (e.g., due to location of the holding in an area where CSF occurs in feral pigs) and, in any case if more common infectious diseases of the reproductive tract have been excluded.

Therefore, laboratory diagnosis and confirmation of the infectious agent is of paramount importance for CSF. Despite all, the close genetic and immunogenic relationships between all pestiviruses (BVDV and border disease virus) make difficult even the laboratory discrimination of CSFV. Samples of choice for detection of CSFV are tonsillar tissue, lymphoid tissues (lymph nodes and spleen), and the distal ileum. A recent experimental study demonstrated that the nictitating membrane (third eyelid) provides a useful source of virus in pigs that have undergone autolysis, because this organ is much less affected by autolysis than the internal organs. Whole blood samples, nasal swabs, tonsillar scrapings, and tonsillar swabs may be taken from live pigs. Because the disease may run a chronic course, with animals in different stages of postinfection, samples should be taken from as many animals as possible.

Isolation of the virus remains an essential element of the laboratory tools to diagnose CSF, although this is made difficult by the fact that it is a noncytolytic virus and indirect methods are needed to detect it in cell cultures. Pig kidney cell cultures followed by immunofluorescence or immunoperoxidase staining are performed using anti-CSFV polyclonal or monoclonal antibodies as conjugates. It can also be confirmed using reverse transcriptase polymerase chain reaction (PCR) and/or sequencing the nucleic acid product obtained from the infected cell culture. Enzyme-linked immunosorbent assay (ELISA) technology is also used to detect viral antigen in blood or organ samples and offers a rapid way of screening large numbers of samples, but is less sensitive than the PCR. Direct immunofluorescence detection of virus in histological cuts is widely used. A variety of polyclonal and monoclonal antibodies are available for detection of CSFV antigens in frozen tissues, impression smears, and bone marrow aspirates. The assay based on avidin–biotin complex monoclonal antibody is highly sensitive and successful for working with frozen tissue sections.

For detecting antibodies in sera of suspicious or surveillance animals, the indirect immunofluorescence test, virus neutralization test are available. ELISA is also used to detect antibodies in sera, but only some of the tests available distinguish between antibodies produced in response to CSFV and those elicited by related viruses.

Finally, the use of sequencing and molecular genetic studies of the CSFV virus provides important insights on the relationships of viruses isolated from different outbreaks. This analysis can help to point out the possible origin of outbreaks, and demonstrates whether in a particular area all the outbreaks of CSF are likely to be due to a single or multiple introduction of the disease.

Epidemiology

The potential of this disease to spread over long distances and cause outbreaks in areas previously free is widely demonstrated. CSFV transmission takes place through direct contact of susceptible swine with excretions, secretions, semen, blood, saliva, or other contaminated substances from infected animals. Acutely infected pigs that are shedding large amounts of virus in their saliva, as well as lesser amounts in urine, feces, ocular, and nasal secretions, are a potent source of infection for other pigs. Pigs start to shed virus for a few days before clinical signs develop, and continue to do so until antibodies develop, which usually happens approximately 11 days after infection. Congenitally infected piglets may be persistently viremic and may shed the virus for months. These piglets may play a crucial role in spreading the disease and in the maintenance of virus persistence within a population as they constantly shed virus until death. Indirect contact through contaminated vehicles, clothes, instruments, needles, pig traders, and farm visitors has also been described as the source of virus. Aerosol transmission over distances of less than 500 m has been demonstrated experimentally, but is not considered important except possibly under unusual circumstances. Investigations have indicated that persistently infected wild boars, either due to transplacental or postnatal infection, are unlikely to play a role in maintaining the virus. Spread from infected wild boar to domestic pigs and vice versa has taken place on several occasions in the past in some areas of Europe. Spread from wild boars to domestic pigs occurs when free-ranging domestic pigs come into direct

contact with infected boars or scavenge the remains of infected boars that have died or been killed by hunters. Experimental infection has demonstrated that the warthog (*Phacochoerus aethiopicus*) and the bush pig (*Potamochoerus larvatus*) are susceptible to infection and can spread disease to in-contact animals of the same species but the degree of its importance in the epidemiology of CSF is still unknown.

ORGANISMS OF CONCERN BUT NOT FOODBORNE OR CONFIRMED FOODBORNE

Bolivian Hemorrhagic Fever Virus (Machupo Virus)

AJ Rodriguez-Morales, Universidad Tecnológica de Pereira and Office of Scientific Research, Pereira, Risaralda, Colombia
DM Castañeda-Hernández, Fundación Universitaria del Área Andina, Pereira, Colombia

Glossary

Anthroponosis An infectious disease in which the etiological agent is carried by humans and is transferred to other humans and animals.
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of contaminated food, including drink.
Organism life cycle A period involving all different generations of a species succeeding each other through means of reproduction, whether through asexual reproduction or sexual reproduction (i.e., a period from one generation of organisms to the same identical point in the next).
Surveillance In public health and epidemiology, it is the discipline of continuously gathering, analyzing, and interpreting data about diseases, and disseminating conclusions of the analyses to relevant organizations, to intervene in their patterns in order to control and prevent them.
Taxonomy The science of classification; in microbiology the arrangement of microorganisms into a classification.
Zoonosis Any infectious disease that can be transmitted between species (by different ways, by a vector or by their products and food) from animals to humans or from humans to animals (less common).

Introduction

Bolivian hemorrhagic fever (BHF) or Machupo hemorrhagic fever (ICD-10 A96.1) was first identified in 1959 as a sporadic hemorrhagic illness in rural areas of Beni department, Bolivia (Figure 1). BHF is a potentially severe febrile illness caused by Machupo virus (a member of the family Arenaviridae). Clusters of BHF patients were noted the same year and by 1962 BHF was recognized as a new epidemic infectious disease. In 1963, the etiological agent, the Machupo virus was first isolated from patients with acute hemorrhagic fever in San Joaquin, Bolivia.

The Pathogen

The etiological agent is a single-stranded ribonucleic acid (RNA) negative-strand virus (Arenaviridae–arenavirus of the New World). The Arenaviridae are a family of viruses whose members are generally associated with rodent-transmitted disease in humans (a zoonotic disease). They are classified as New World arenaviruses and Old World arenaviruses (Table 1). Each virus is usually associated with a particular rodent host species in which it is maintained. Arenavirus infections are relatively common in humans in some areas of the world and can cause severe illnesses. Other family members for the New World include Guanarito virus (etiological agent of the Venezuelan hemorrhagic fever), Junin virus (etiological agent of the Argentine hemorrhagic fever (AHF)) and Sabia virus (etiological agent of the Brazilian hemorrhagic fever) (Table 1).

Ecologic investigations established the rodent *Calomys callosus*, which is indigenous to the disease-endemic region of northern Bolivia (Figure 1), as the reservoir for Machupo virus. This rodent can enter homes in this region, thereby leading to contamination of dwellings, food, and water.

Chapare virus, shown in Table 1, also cause hemorrhagic fever in Beni department, Bolivia (Figure 1). Real time-polymerase chain reaction analysis of the Chapare virus isolates of 2003 and 2004 cases and subsequent analysis of the complete virus S- and L-RNA segment sequences identified the virus as a member of the New World clade B arenaviruses (Table 1), which includes all the pathogenic South American arenaviruses. The virus was shown to be most closely related to Sabia virus, and distinct from Machupo virus, which is the etiological agent of BHF.

Machupo virus infection in *C. callosus* results in asymptomatic infection with shedding of virus in saliva, urine, and feces; 35–50% of experimentally infected *C. callosus* are chronically viremic and shed virus in their bodily excretions or secretions. Although the infectious dose of Machupo virus in humans is not well known, exposed persons may become infected by inhaling virus shed in aerosolized secretions or excretions of infected rodents, by eating food contaminated with rodent excreta (then making it a foodborne disease), or by direct contact of excreta with abraded skin or oropharyngeal mucous membranes. Reports of person-to-person

Figure 1 Map of Latin America showing Bolivia (in yellow), the Beni department (in red) with its provinces (box) and indicating the countries with borders to this country.

transmission are uncommon; however, hospital contact with a patient resulted in person-to-person spread of Machupo virus to nursing and pathology laboratory staff (nosocomial transmission).

Transmission have been more often reported during spring and summer (April–July–September, the so-called dry season, in the upper savanna region of eastern Bolivia, Beni) (Figure 1), and particularly among agricultural workers.

Biological Hazards

Machupo virus, as many other hemorrhagic fever viruses (such as AHFs, dengue hemorrhagic fever, Marburg virus, Ebola virus, hantaviruses, Lassa fever, and Crimean–Congo hemorrhagic fever) is considered among the group of viruses and bacteria that cause severe to fatal disease in humans, and for which vaccines or other treatments are not available. This corresponds to biohazard level 4 (highest risk for humans).

Epidemiology

Close to 2000 cases of BHF have been reported since 1959 until May 2012. Most of those cases occurred during the first years of the history of BHF (1100 between 1959 and 1963). However, the disease is endemic and currently active. The last case (which was fatal) was reported on 20 April 2012. In 2012 three cases (all of them fatal) have been reported in Bolivia, all of them in Beni department (Table 2). As can be seen from the summary of cases, fatal cases and locations where these cases occurred, BHF has a high case-fatality rate, which can be approximately 22.73% (IC95% 20.60–24.48%) (Table 2), although in some outbreaks the rate can be as high as 100%. Besides these cases, more cases probably have occurred, but as a very restricted geographical disease, few additional information is available with international agencies (e.g., *Office International des Epizooties* or World Health Organization).

As can be seen from Table 2, the disease is endemic in the provinces of Mamoré, Iténez, and Yacuma, in the Beni department, Bolivia (Figure 1).

Outside Bolivia, in Panama imported cases of two North American researchers who were working in Beni have been reported. In Brazil, although no cases have been reported, in 1977, studies conducted in rodents (*C. callosus*) reported a high proportion of them with splenomegaly in an area close to the Iténez province, Beni department, Bolivia (Figure 1).

Given the epidemiology of this disease, international interest on research is limited. There are still many aspects of disease to be better defined. In Index Medicus database, using PubMed (http://www.pubmed.com/) there are less than 30 articles directly related to BHF (medical subject heading: 'bolivian hemorrhagic fever [ti]') (1965–2009).

Food contamination

Rodent excretions are the main source of contamination for food that can be ingested by susceptible humans and become infected. Rodents in rural areas can enter homes, contaminating dwellings and food and water. Raw food in endemic areas can contaminated with Machupo virus and become a source and risk for foodborne infection.

Table 1 Viruses included in the Arenaviridae family, showing the New World and Old World arenaviruses characterized and included in the NCBI Taxonomy Browser (showing those classified up to 2012) (http://www.ncbi.nlm.nih.gov/taxonomy)

Clinical Presentation

BHF is clinically similar to AHF, however, neurological signs are more common in AHF, whereas hemorrhagic diatheses are more common in BHF. After an incubation period of 5–19 days, initial symptoms include headache, fever, arthralgia, and myalgia. In the later stages of this illness, patients may develop hemorrhagic manifestations including petechiae, subconjunctival hemorrhage, epistaxis, hematemesis, leukopenia, thrombocytopenia, melena, adenopathy, relative bradycardia, pulmonary edema, and hematuria, as well as neurological signs including tremor, seizures, and coma, and internal hemorrhage may occur. Pulmonary edema is the most common cause of death.

During the BHF epidemics of the 1960s, convalescent-phase immune plasma from survivors of BHF was administered to selected patients infected with Machupo virus. However, there is, at present, a paucity of survivors of BHF who can donate immune plasma and no active program for collection and storage of BHF-immune plasma.

Diagnosis of BHF

Diagnostic tests available for BHF include viral culture (using VERO cells) from biological samples of the suspected cases (blood, urine, and pharynx) and serology (enzyme-linked

[a]%CFR: case fatality rate.

immunosorbent assay, ELISA) to detect antibodies anti-Machupo virus. Limitations to its diagnosis include that owing to its pathogenicity, Machupo virus requires biosafety level 4 conditions, the highest level.

Management, Prevention, and Control

Although no effective treatment is available for BHF, intravenous ribavirin has been used with some favorable results in the management of disease. However, more extensive clinical studies to assess the usefulness of ribavirin for treating BHF are needed.

The standard management of BHF includes strict isolation, use of specific immune plasma, and ribavirin at a dose of 2.0 g intravenous (i.v.), 1.0 g i.v. Q6 h $\times$ 4 days, and 0.5 g i.v. Q8 h $\times$ 6 days.

The main strategy to prevent this disease is to control rodent populations. In San Joaquin, Mamoré province, Beni department (**Figure 1**), Bolivia, a study has shown the importance of using rodent traps and rodenticides that destroyed more than 3000 specimens of *C. callosus* in 60 days. As rodents can contaminate food and water, rodent control is fundamental to avoid foodborne disease transmission.

A vaccine developed for the genetically related Junin virus causing AHF has shown evidence of cross-reactivity to Machupo virus and may, therefore, be an effective prophylactic measure for people at high risk of infection. Postinfection (and providing that the person survives the infection), those who have contracted BHF are usually immune to further infection from the disease.

Conclusions

BHF is a highly fatal disease, also known as black typhus or Ordog fever, that still needs and deserves further research in many aspects. More published research on BHF has been focused on epidemiological, viral, and molecular diagnoses; however, understanding of its importance and impact as a zoonotic foodborne disease is still very limited.

ORGANISMS OF CONCERN BUT NOT FOODBORNE OR CONFIRMED FOODBORNE

African Swine Fever Virus

C Carrillo, Plum Island Animal Disease Center, Greenport, NY, USA

Glossary

Acute infection A presentation of the disease with a rapid onset and/or short course of symptoms and disease evolution.

Carrier An infected individual who carries the infectious agents despite a healthy appearance.

Chronic infection Long-lasting course of a disease in which there is clear presentation of symptoms related with such disease.

Persistent infection Infection that remains after recovery from the disease where it is still possible to recover infectious virus from the individual despite the absence of symptoms.

Background and History

African swine fever (ASF) is also known under the following names: *Peste Porcine Africaine, Peste Porcina Africana, Pestis Africana Suum, maladie de Montgomery,* warthog disease, *Afrikaanse Varkpes,* and *Afrikanische Schweinepest.*

ASF virus (ASFV) was first described as a disease in 1909 when it infected domestic pigs of European origin in Kenya. It is thought that ASF has existed for many years as an inapparent infection in warthogs, bush pigs, and giant forest hogs in endemic areas of Africa. For a long time it was confined to Africa, but in 1957 it was discovered in Portugal. This first incursion in the European continent was eradicated in 1958. Outbreaks occurring along the Spanish border in France in 1964, 1967, and 1974 were also eradicated by slaughtering infected and exposed animals. Since the mid-1960s, outbreaks have occurred in Italy, Spain, Malta, Sardinia, Belgium, and the Netherlands. In the western hemisphere, ASF first appeared in Cuba in 1971, and later in Brazil, the Dominican Republic, Haiti, and again, Cuba. Finally, during the 1990s, the disease was eradicated by depopulation everywhere except in Africa, with the only exception being the island of Sardinia in the Mediterranean Sea. The most recent outbreak of ASF outside Africa started in early 2007 in Georgia, and has since spread to the countries of Armenia, Azerbaijan, Iran, and Russia. Major outbreaks of ASF in Africa are regularly reported to the World Organisation for Animal Health (OIE).

The Virus

The virus responsible of this disease (ASFV) is the only known animal virus with a deoxyribonucleic acid (DNA) genome that is transmitted by arthropods. Ticks of the *Ornithodoros* genus become infected by feeding on infected warthogs and bush pigs, and transmit to other hosts. Direct transmission of ASF has been proved to occur between domestic pigs, while indirect transmission through ticks is the most common way of transmission in wild swine species. ASF manifests itself in several forms, ranging from highly virulent forms that kill most pigs to subclinical forms that result only in seroconversion. Currently, there is no vaccine and the control of the disease is made by animal quarantine and slaughter.

ASFV is a large, enveloped, double-stranded DNA virus that replicates in the cytoplasm of the infected cell. Is the only member of the Asfarviridae family despite the fact that it shares many similarities with other DNA families like Poxviridae and Iridoviridae. In terms of replication strategy and genome structure, the ASFV genome shows enough genetic divergence relative to the other large DNA families as to be considered apart.

ASFV particles have a complex multi-layered structure that includes a nucleoprotein core or nucleoid that contains the viral genome, surrounded by a core shell or matrix which contains several different proteins that is itself surrounded by two lipid bilayers, also known as the inner membrane or internal envelope, which likely derives from the cellular endoplasmic reticulum. Surrounding the matrix is the capsid, assembled by capsomers of structural proteins that provides the icosahedral structure to the virion. Finally, although not required for virus infection, there is sometimes an external membrane as a consequence of the budding through the plasma membrane. The viral particle is large and contains enzymes and factors needed for viral replication in the cytoplasm of the infected cells.

The Genome

Contained inside the virion, there is a single molecule of linear, double-stranded (ds) DNA that is cross-linked at the

ends, which is between 170- and 192-kbp long. The DNA contains one left and one right terminal genomic regions characterized for carrying: terminal inverted repeats, terminal cross-links, and multigene families; additionally, there is a long central region with conserved and variable sequences and direct repeats interspersed with unique sequences. There are between 160 and 175 open reading frames (ORFs), that encode for more than 150 different proteins, including among others, homologs of cellular ubiquitin, inhibitor of apoptosis, myeloid differentiation primary response antigen MyD116, lectine- and CD2-like proteins, and components of a base-excision repair pathway.

Recent research on the molecular aspects of ASFV, making use of recombinant viruses that contain complete deletions of the ORF for a given gene, has allowed identification of some of the functions of ASFV genes. There are a number of genomic regions involved in virulence, tropism, cell response regulation, and host-range that have been identified. However, despite the short evidence of those genes functionality, they alone are usually sufficient to completely knock down the virulence of the virus, indicating that more than one viral determinant or genomic region might be involved in the same functions. The targeted deletion of genes which causes a reduction in virulence, altered tropism or reduced viability, and replication ability in cell cultures, though not always, correlate with the total loss of virulence in domestic pigs. This illustrates the complexity of the pathological manifestation of the virus in natural hosts. The information that these techniques have provided to the understanding of ASFV is highly valuable and has provided a solid basis for the future development of an effective vaccine, probably through the sequential deletion of targeted genes.

The Target Host Cell

In common with other viral hemorrhagic fevers, the main target cells for replication are those of monocyte–macrophage lineage. The ability to replicate and kill macrophages appears to be a critical factor of virulence in ASFV. Infection induces a progressive down regulation of host protein synthesis at early times postinfection. Virus replication takes place in perinuclear factory areas, and assembly of the icosahedral capsid occurs on modified membranes from the endoplasmic reticulum, where immature capsids and mature viral particles can be detected after 12–24 h of infection (hours post infection (hpi)). The infection of pigs results in lymphocyte, macrophage, and megakaryocyte apoptosis, which heavily impacts the structure and functionality of lymph nodes, spleen, and thymus, which is reflected in lymphoid cell depletion and immunodeficiency.

Clinical Signs of the Disease

Sudden deaths with few lesions are characteristic of the peracute form and may be the first sign of an infection in a herd. The acute form of the disease is characterized by a short period of incubation, between 5 and 15 days, starting with high fever; anorexia; congestion and cyanosis of the skin (particularly on the ears and flanks); shivering and incoordination; diarrhea, which is initially mucoid and later may become bloody; and death within the 2–9-days period of showing symptoms. At necropsy, there are hemorrhages in lymph nodes, spleen (very enlarged), kidneys, and respiratory and gastrointestinal tracts with severe interlobular lung edema. Pregnant sows abort; in some cases, abortions may be the first signs of an outbreak. The disease spreads through the herd over several days or sometimes more slowly over several weeks and many pigs die.

In subacute presentations, the disease lasts 3–4 weeks with remittent fever, pneumonia, dyspnea, *caquexia*, and swelling of the joints. Some outbreaks of the disease in places where the virus is endemic in the domestic pig population are milder, run a longer course and spread more slowly through a herd, with fewer deaths. Some affected pigs become very thin and stop growing and develop signs of pneumonia, skin ulcers, and swollen joints. In this form of the disease, the death rate is generally lower in adult swine, but may still be very high in very young animals. In subacute disease, fever, thrombocytopenia, and leukopenia may be transient, and affected pigs usually die or recover within 3–4 weeks. Sometimes, animals infected with isolates of low virulence may seroconvert without symptoms, abort, or develop chronic ASF. Persistent infection occurs in warthogs and in domestic pigs surviving the acute or subacute viral infection, and anecdotic reports of sudden reactivation and death with ASF symptoms have been recollected. Under experimental conditions, viral DNA was detected in monocytes more than 500-days post infection by polymerase chain reaction (PCR). However, the infectious virus has never been isolated in samples from those animals.

Prevention and Control

ASF is reportable to the OIE. There is no vaccine available and only homologous (rarely heterologous) protection has been described in infection-surviving individuals. Pigs surviving infection with attenuated or low-virulent strains produce antibodies that protect it from fatal infection with the homologous virus, but the neutralizing value of such immune response is still a matter of discussion for some ASF experts.

Prevention relies on strict regulations on the import of animals and animal products from countries where ASF is known to occur. These regulations are enforced through point-of-entry inspections and the compulsory boiling of waste animal products under licensed supervision before feeding to pigs. In Africa, prevention includes measures to keep warthogs and materials contaminated by warthogs away from the herd. The application of a slaughter policy when the disease is diagnosed is mandatory.

Eradication is based on the slaughter of infected and in-contact animals, and disposal of carcasses, often by burying, rendering, or burning. Rapid diagnosis and the prevention of disease spread to feral or wild pigs are very important. Strict quarantines must be imposed. ASFV can survive for long periods on fomites and in the environment, thus sanitation and disinfection are important in preventing further spread. Disinfectants specifically approved for ASF such as sodium

hypochlorite and some iodine and quaternary ammonium compounds are effective. Potential tick vectors should be controlled with acaricides. In addition, biting insects that may be able to transmit the virus mechanically should be controlled.

Public Health

Humans are not susceptible to ASFV. ASFV remains infectious for 3–6 months in uncooked pig products such as sausage, filet, and dry hams. In 1983, ASF spread from Sardinia to the mainland in boar meat.

Diagnosis

Suspect ASF in the field is based on clinical signs and necropsy findings in affected pigs, and a high death rate in affected herds. However, it will be extremely difficult to identify the disease caused by moderate or low virulence strains, as the clinical signs are variable and very often obscured by other common pathogens acting simultaneously. The clinical symptoms of ASF are very similar to classical swine fever (CSF) and the two diseases normally have to be distinguished by laboratory diagnosis. However, before collecting or sending samples from animals with a suspected foreign animal disease like ASF, the proper authorities should be contacted. Samples should only be sent under secure conditions and to authorized laboratories to prevent the spread of the disease.

At necropsy, bright red hemorrhages in the lymph nodes, kidneys, heart, and linings of the body cavities are common findings. There may also be excess hemorrhagic fluid in the body cavities and gelatinous fluid in the lungs. The spleen may be enlarged, darkened, and crumble on slight pressure.

The sample of choice from live animals for laboratory diagnosis of ASFV are whole blood and serum. From dead animals tonsils, lymph nodes, spleen, kidneys, and distal ileum are best recommended. ASFV is not found in aborted fetuses; in cases of abortion, a blood sample should be collected from the dam.

It is essential to isolate and identify the virus, which may be isolated in primary cultures of pig bone marrow or peripheral blood leukocytes from the blood or lung. Infected cells hemadsorb pig red cells will adhere to them, in what is known as the hemadsorption or 'rosette' test. Most isolates of ASFV induce hemadsorption of pig erythrocytes to the surface of infected cells. However, nonhemadsorbing isolates can be missed with this test. ASFV antigens can also be found in tissue smears or cryostat sections, as well as in the buffy coat, with the fluorescent antibody test. The OIE does not consider this test alone to be sufficient for diagnosis, although it is useful in conjunction with other assays. Nucleic acids can be detected with a PCR assay or by the hybridization of nucleic acid probes to tissue sections. PCR is particularly useful in putrefied samples that cannot be used for virus isolation and antigen detection. A rapid, real-time PCR technique using tonsil scraping samples has recently been published. This test can detect the virus a few days before the onset of symptoms. Antibodies to ASFV persist for long periods after infection and serum antibody titers may be tested in a number of ways. These tests include the enzyme-linked immunosorbent assay (ELISA), immunoblotting, indirect fluorescent antibody, and counter immunoelectrophoresis (immunoelectro-osmophoresis) tests. The ELISA is prescribed for international trade. Finally, in doubtful cases, samples can be injected into experimental pigs, although this test is no longer recommended by the OIE due to humane considerations and the complexity of the test.

The differential diagnosis includes CSF (hog cholera), acute porcine reproductive and respiratory syndrome, porcine dermatitis and nephropathy syndrome, erysipelas, salmonellosis, eperythrozoonosis, actinobacillosis, Glasser's disease (*Haemophilus parasuis* infection), Aujeszky's disease (also known as porcine pseudorabies), thrombocytopenic purpura, warfarin poisoning other generalized septicemic or hemorrhagic conditions, and heavy metal toxicity.

Epidemiology

Outbreaks occur from time to time in domestic pig herds in Africa and even in the large control areas in South Africa where a slaughter policy exists. Herds usually become infected by eating warthog flesh and blood or from tick infestations or from other infected domestic pigs. The main threat to pig herds outside Africa is the introduction of infected pork products in waste food from aeroplanes and ships arriving from the southern half of Africa. This is unlikely to occur in the most developed countries because of the strict rules governing the disposal of such waste, but the rules may not be so strict in some other countries.

The ASFV is highly resistant to environmental conditions. It can survive for a year-and-a-half in blood stored at 4 °C, 11 days in feces at room temperature, and at least a month in contaminated pig pens. The virus will also remain infectious for 150 days in boned meat stored at 39 °F, 140 days in salted dried hams, and several years in frozen carcasses.

ASF can be transmitted by direct contact with infected animals, indirect contact with fomites, and tick vectors. Transmission during direct contact is usually by oronasal spread. Aerosol transmission is thought to be unimportant, as it only seems to occur over short distances when pigs are in close contact. ASFV can be found in all tissues and body fluids, but particularly high levels are found in the blood. Massive environmental contamination may result if blood is shed during necropsies or pig fights, or if a pig develops bloody diarrhea. The virus can also spread on fomites, including vehicles, feed, and equipment. There is evidence that some pigs may become carriers. ASF is also spread through the bite of infected soft ticks *Ornithodoros* spp. In tick populations, transstadial, transovarial, and sexual transmission occur. In Africa, ASFV is thought to cycle between newborn warthogs and the soft ticks (*O. moubata*) that live in their burrows. Individual ticks can apparently remain infected for life, and infected soft tick colonies can maintain this virus for years. *Ornithodoros erraticus* became infected with ASFV when the virus was enzootic in Spain and Portugal, and additional *Ornithodoros* spp have been infected in the laboratory. Other blood-sucking insects such as mosquitoes and biting flies may

also be able to transmit the virus mechanically. Stable flies (*Stomoxys calcitrans*) can carry high levels of the virus for 2 days. Under experimental conditions, these flies could transmit ASFV 24 h after feeding on infected pigs.

ORGANISMS OF CONCERN BUT NOT FOODBORNE OR CONFIRMED FOODBORNE

Spoilage Microorganisms

RA Benner, Jr., US Food and Drug Administration, Dauphin Island, AL, USA

Glossary

Aerobic Bacterial growth in the presence of oxygen.
Anaerobic Bacterial growth in the presence of little or no oxygen.
Mesophile An organism that grows at moderate temperatures (20–40 °C).
Modified atmosphere packaging Packaging of food in a gaseous atmosphere in which the proportions of carbon dioxide, nitrogen, and oxygen are different from air.
Psychrotroph An organism that grows at low temperatures (0–7 °C).
Vacuum packaging Packaging of food in the absence of air.

Introduction

Why is an article dedicated to spoilage microorganisms being included in the *Encyclopedia of Food Safety*? Are spoiled foods necessarily a food safety hazard?

Some spoiled foods present no food safety hazard at all. They are simply objectionable and/or offensive from a sensory perspective. These products contain odor, flavor, and/or textural characteristics that cause most humans to reject them. Other spoiled food products, however, can present a food safety hazard.

Evaluation of spoilage is a culturally subjective decision making process. Some food products may be considered acceptable in one part of the world, whereas in another part these products would be rejected. Spoilage assessment is also based on personal preference. Some humans prefer to eat certain food products, whereas others find the same offensive.

Some nonpathogenic spoilage microorganisms generate chemicals that cause foodborne illness. Histamine- and other biogenic amine-producing bacteria can be predominant spoilage microorganisms in certain fish species when storage conditions are favorable for their proliferation. *Morganella morganii, Enterobacter aerogenes, Hafnia alvei, Raoultella planticola/ornithinolytica,* and *Photobacterium damselae* are capable of producing high histamine levels in time/temperature-abused scombrotoxin-producing fish. Consumption of these fish may result in scombrotoxin (histamine) fish poisoning in humans. Articles elsewhere in this encyclopedia contain in-depth discussions addressing this subject matter.

Food spoilage molds including *Aspergillus* spp., *Fusarium* spp., *Penicillium* spp., *Alternaria* spp., etc., may also produce harmful toxins. The food safety implications of these molds and their toxins are addressed in other articles of this encyclopedia.

Food Spoilage – Overview

Food spoilage results when microbiological, chemical, or physical changes occur, rendering the food product unacceptable to the consumer. Microbiological food spoilage is caused by the growth of microorganisms which produce enzymes that lead to objectionable by-products in the food. This is the most prominent type of food spoilage encountered worldwide. Chemical food spoilage occurs when different components in the food react with each other or with some added component which alter the food's sensory characteristics. Examples of this include: oxidation; enzymatic browning; and nonenzymatic browning. Physical food spoilage results when moist foods are excessively dehydrated or dried foods absorb excessive moisture. This article has been dedicated to spoilage microorganisms and shall, therefore, focus on microbiological food spoilage.

Microbiological food spoilage is dependent on both the intrinsic characteristics of the food product and the extrinsic characteristics of handling and the storage environment.

Intrinsic characteristics include:

1. moisture content (A_w);
2. pH;
3. oxidation–reduction potential (E_h);
4. available nutrients;
5. physical barriers;
6. natural antimicrobial substances.

Extrinsic characteristics include:

1. storage temperature;
2. gaseous environment;
3. relative humidity;
4. numbers and types of microorganisms present.

When the above factors are considered in totality, it is obvious that microbiological food spoilage can progress in a

myriad of ways. Discussing all potential food commodities and storage possibilities would be quite onerous and therefore this article will focus on certain representative fresh food commodity groups and how spoilage progresses for each. The intrinsic and extrinsic characteristics that most prominently contribute to microbiological spoilage of each commodity will be considered. In addition, interactions between pathogenic and spoilage microorganisms that affect the quality and safety of each commodity group will be discussed. The following commodity groups have been included in this article:

1. meat and poultry;
2. seafood;
3. raw and pasteurized milk;
4. minimally processed vegetables.

Meat and Poultry

Fresh meat and poultry products are excellent substrates for microbial growth and spoilage. They have a high moisture content (A_w 0.98–0.99) and a normal pH of 5.4–6.6. An ample supply of nutrients is available to sustain microbial growth, including: carbohydrates (glucose, glycogen, and lactic acid) and nitrogen sources (free amino acids and dipeptides). Physical barriers (i.e., hide and skin) are removed during processing, providing access to the muscle tissue for microorganisms. Natural antimicrobial substances are minimal and have little or no effect on microbial growth.

The muscle tissue of healthy animals is essentially sterile. However, during slaughter and processing, this tissue becomes contaminated with microorganisms that originate from animal surfaces, the gastrointestinal tract, lymph nodes, and the processing environment. After slaughter, microbial counts on muscle surfaces typically range from 10^2 to 10^4 cm^{-2}, depending on the sanitary practices and conditions in the processing plant. The types of microorganisms commonly associated with fresh meat and poultry include mesophilic and psychrotrophic bacteria, yeasts, and molds. Spoilage by the mesophilic and psychrotrophic bacteria will be discussed further because these organisms are most frequently responsible for meat and poultry spoilage.

The initial microflora of fresh meat and poultry generally consists of *Staphylococcus*, *Micrococcus*, coryneforms, *Flavobacterium*, *Pseudomonas*, *Moraxella*, *Acinetobacter*, *Alcaligenes*, and Enterobacteriaceae. *Pseudomonas*, *Moraxella*, and *Acinetobacter* will become the dominant spoilage flora under refrigerated, aerobic storage conditions. These organisms are psychrotrophic and thus grow well at typical refrigeration temperatures ranging from 0 to 7 °C. The mesophilic organisms will not grow at these temperatures and are outcompeted by the psychrotrophs. When fresh meat and poultry products are stored under refrigerated vacuum packaging (VP) or modified atmosphere packaging (MAP), the dominant spoilage microorganisms will be lactic acid bacteria (i.e., *Carnobacterium*, *Lactobacillus*, *Leuconostoc*, and *Pediococcus*) and *Brochothrix thermosphacta*. These organisms grow well at refrigerated temperatures under oxygen-limited conditions and will dominate over mesophiles and aerobic psychrotrophs.

Temperature abuse of fresh meat and poultry products may occur at any point in the distribution chain. When aerobically stored meat and poultry are temperature abused, both mesophilic and psychrotrophic bacteria will be present as part of the spoilage microflora. Under moderate abuse conditions (10–20 °C), *Pseudomonas*, *Moraxella*, and *Acinetobacter* will be dominant with lower levels of Enterobacteriaceae, *Micrococcus*, and *B. thermosphacta*. Alternatively, when severe abuse is encountered (20–30 °C), Enterobacteriaceae and Staphylococci may comprise a larger proportion of the microflora. When meat and poultry products stored under oxygen-limited conditions experience moderate temperature abuse, the microflora is commonly dominated by Enterobacteriaceae with lower levels of lactic acid bacteria, whereas severe temperature abuse results in a microflora consisting principally of *Clostridium* with lower levels of lactic acid bacteria and Enterobacteriaceae.

Seafood

Similar to meat and poultry, fresh seafood products are excellent substrates for microbial growth and spoilage. They have a high moisture content (A_w 0.98–0.99) and a pH ranging from 5.4 for red meat species (e.g., tuna) to > 7.0 for some crustaceans. In contrast to meat and poultry, the nutrient supply in most seafood is very low in carbohydrates with the exception of some mollusks, which may contain glycogen levels as high as 5%. However, seafood products contain high levels of nonprotein nitrogen (NPN) including free amino acids, trimethylamine oxide, and urea. These NPN compounds serve as the primary substrate for microbial growth. Physical barriers (i.e., skin and shells) may be removed during butchering or processing, giving microorganisms access to the muscle tissue. Some seafood, however, is stored whole, which requires microorganisms to invade the muscle tissue before spoilage. Microbial growth on edible seafood tissues is not commonly affected by natural antimicrobial substances.

The internal muscle tissue of healthy seafood species is essentially free of microorganisms. However, during butchering and processing, this tissue becomes contaminated with microorganisms, which originate mostly from the harvest waters that seafood species inhabit. The primary microbial reservoirs for postharvest seafood are the gastrointestinal tract, gills, and skin, as well as the harvest and processing environment. After harvest, microbial counts on muscle surfaces typically range from 10^2 to 10^6 cm^{-2}, depending on the handling conditions during harvest and processing. The types of microorganisms isolated from seafood are determined by the harvest environment (i.e., cold or warm waters, salinity, etc.), harvest method (i.e., trawl, longline, traps, etc.), and postharvest handling. The microflora commonly found include both mesophilic and psychrotrophic bacteria. Spoilage of seafood products by these microorganisms will be discussed below.

The initial microflora of freshly harvested seafood from temperate waters typically consists of *Acinetobacter*, *Aeromonas*, *Alcaligenes*, coryneforms, *Flavobacterium*, *Micrococcus*, *Moraxella*, *Pseudomonas*, *Shewanella*, *Vibrio*, and Enterobacteriaceae. The initial microflora of seafood from warm tropical waters is

similar, but with higher levels of Gram-positive cocci, *Bacillus*, and *Vibrio*. In aerobic refrigerated or iced storage conditions, the dominant spoilage flora will be *Pseudomonas* and *Shewanella putrefaciens*, followed by lower levels of *Acinetobacter* and *Moraxella*. These psychrotrophic organisms grow well at refrigeration temperatures and have faster generation times than other psychrotrophs and mesophiles. When seafood products are stored under refrigerated, VP, or MAP conditions, the dominant spoilage microorganisms will be *Photobacterium phosphoreum* and lactic acid bacteria including the genera *Carnobacterium*, *Lactobacillus*, *Lactococcus*, and *Leuconostoc*. *Shewanella putrefaciens* may also play a role in seafood packed in oxygen-limited conditions. These organisms grow well at refrigerated temperatures under oxygen-limited conditions and will dominate over mesophiles and aerobic psychrotrophs.

Fresh seafood products are highly perishable and tend to spoil rapidly when they are temperature abused. The spoilage microflora of temperature-abused seafood stored under aerobic conditions will comprise both psychrotrophic and mesophilic bacteria. *Pseudomonas* and *S. putrefaciens* may still be present, but members of the family Vibrionaceae become predominant, especially at severe abuse temperatures. In addition, some members of the family Enterobacteriaceae may be detected at lower levels. Seafood products that experience moderate temperature abuse while being stored under VP and MAP tend to be dominated by lactic acid bacteria, primarily *Lactobacillus* and *P. phosphoreum*. Research addressing the spoilage microflora of severely temperature abused VP and MAP seafood is very limited. However, mesophilic lactic acid bacteria, Enterobacteriaceae, Vibrionaceae, and *Clostridium* are likely to be present. The lack of research in this subject area is likely due to the increased potential for toxin production by *Clostridium botulinum* under these storage conditions. Effects of spoilage bacteria on growth and toxin production by *C. botulinum* are discussed in the Interactions between Spoilage and Pathogenic Microorganisms section.

Raw and Pasteurized Milk

Similar to meat, poultry, and seafood, raw and pasteurized milk also readily support the growth of pathogenic and spoilage bacteria. Their high moisture content (A_w 0.99) and pH (6.3–6.6) are ideal for numerous Gram-positive and Gram-negative organisms and carbohydrate (lactose), nitrogen (protein and NPN), and lipid sources are plentiful. In contrast to many other foods, milk contains natural antimicrobial substances that need to be considered with respect to microbial spoilage. These include conglutinin, lactoferrin, lysozyme, and the lactoperoxidase system. Conglutinin inhibits Gram-negative bacteria and lysozyme inhibits Gram-positive bacteria. Lactoferrin binds iron, making it unavailable for microbial utilization. The lactoperoxidase system produces hypothiocyanate, which is inhibitory to Gram-positive and Gram-negative bacteria. Although these inhibitory substances do exist in milk, their concentrations and antimicrobial activity are not sufficient to prevent spoilage.

The microflora of raw milk may originate from the environment, inside the udder, udder and teat surfaces, dairy farm workers, and milking and processing equipment. Bacterial counts range from 10^4 to 10^7 ml^{-1}, depending on handling and storage conditions. As would be expected, it is a diverse flora comprised mainly of Gram-positive and Gram-negative bacteria. Sources of the microflora in pasteurized milk are heat-resistant bacteria, postpasteurization contamination by processing equipment, and the processing environment. Bacterial counts are usually at the 10^3 ml^{-1} level but can be higher if the raw milk used for pasteurization has elevated bacterial counts.

The initial microflora of raw milk may contain *Aeromonas*, *Alcaligenes*, *Bacillus*, *Clostridium*, coryneforms, Enterobacteriaceae, *Flavobacterium*, *Microbacterium*, *Micrococcus*, *Paenibacillus*, *Pseudomonas*, lactic acid bacteria, *Staphylococcus*, and *Streptococcus*. The organisms that are most commonly associated with spoilage of refrigerated raw milk are the psychrotrophs – *Pseudomonas*, *Flavobacterium*, and *Alcaligenes*. *Pseudomonas fluorescens* and other pseudomonads are of particular concern because they produce heat-stable lypolytic and proteolytic enzymes that can degrade pasteurized milk, even in the absence of the living organisms. Temperature-abused raw milk is typically spoiled by mesophilic lactic acid bacteria including *Lactococcus lactis* that outcompete the Gram-negative psychrotrophs.

Pasteurization is a heat process intended to destroy vegetative cells of bacterial pathogens and to reduce the levels of spoilage microorganisms. Immediately after processing, pasteurized milk has an initial microflora comprised primarily of thermoduric bacteria that survive the pasteurization process. These organisms include *Micrococcus*, *Streptococcus*, *Bacillus*, *Paenibacillus*, and *Clostridium*. The psychrotrophic spore formers, *Bacillus* and *Paenibacillus*, are often associated with spoilage of pasteurized milk held at refrigerated temperatures. When postpasteurization contamination occurs, the Gram-negative psychrotrophs, *Pseudomonas*, *Flavobacterium*, and *Alcaligenes* are typically the cause of refrigerated pasteurized milk spoilage. Spoilage of temperature-abused pasteurized milk will likely be caused by *Pseudomonas*, *Flavobacterium*, and *Alcaligenes* after postpasteurization contamination or thermoduric survivors of the pasteurization process when postpasteurization contamination does not occur.

Minimally Processed Vegetables

Fresh minimally processed vegetables are different from other commodity groups being discussed in this article because of their much lower protein content. However, they do have an adequate supply of free amino acids and carbohydrates to support a good growth of pathogenic and spoilage bacteria. Vegetables generally have a pH ranging from 5.0 to 7.0 and an A_w ranging from 0.95 to 0.99, depending on species. Their outer surfaces (i.e., peels and skins) give some protection against bacterial invasion, but inner tissues may harbor bacteria without negative impacts to the living plant. Cruciferous vegetables may release isothiocyanates when they are cut, shredded, or bruised. These chemical compounds possess some antimicrobial activity. However, for the vast majority of fresh vegetables, antimicrobial substances have minimal impact on the spoilage microflora.

The surfaces of fresh vegetables typically have a microflora that originates from water, soil, air, insects, fauna, and

handling practices during harvest. This microflora is highly variable and may change depending on any number of environmental or agricultural factors. The primary flora is comprised of bacteria, but yeasts and mold are also present. Although bacterial counts on freshly harvested vegetables usually range from 10^4 to 10^7 g^{-1}, counts as high as 10^9 g^{-1} have been reported. This microflora consists of Gram-positive and Gram-negative bacteria, which may be psychrotrophic or mesophilic. Minimal processing (e.g., cutting, shredding, and peeling) of fresh vegetables results in release of cellular fluids, which provide water and nutrients that promote growth of spoilage bacteria.

The initial microflora of fresh vegetables consists of *Aeromonas, Bacillus, Clostridium*, coryneforms, *Enterobacter, Erwinia, Flavobacterium, Pantoea, Pseudomonas*, lactic acid bacteria, and *Xanthomonas*. The bacteria most commonly associated with spoilage of refrigerated aerobically stored vegetables are members of the genus *Pseudomonas*, including *Pseudomonas marginalis, P. fluorescens*, and *Pseudomonas viridiflava*. These fluorescent pseudomonads cause a form of soft rot in vegetables, which results from the activity of the enzyme pectate lyase. They are also able to grow well at temperatures of 4 °C and below. If refrigerated minimally processed vegetables are stored in VP or MAP conditions, the spoilage microflora tends to be dominated by lactic acid bacteria, particularly *Leuconostoc mesenteroides*. Refrigeration and reduced oxygen storage conditions give these organisms a competitive advantage over mesophiles and aerobic psychrotrophs.

Microbial spoilage of fresh minimally processed vegetables is greatly influenced by temperature and atmosphere of storage. When these products are stored aerobically and abused at moderate temperatures (10–20 °C), the spoilage flora will most likely consist of fluorescent pseudomonads. Storage at severe abuse temperatures (20–30 °C) results in a microflora that may be dominated by members of the genus *Erwinia*, including *Erwinia carotovora* and *Erwinia chrysanthemi*. *Erwinia* spp. are mesophilic facultative anaerobic bacteria that, like the fluorescent pseudomonads, cause soft rot of fresh vegetables. However, lactic acid bacteria have also been shown to dominate the spoilage flora of fresh minimally processed vegetables stored aerobically at 30 °C. The microflora of temperature-abused fresh vegetables stored under VP and MAP conditions also tend to be dominated by *Erwinia* spp. and lactic acid bacteria.

Microbial Pathogens as Spoilage Microorganisms

Throughout this article, intrinsic characteristics of foods and extrinsic characteristics of the storage environment have been discussed in view of their relationship to the growth of spoilage microorganisms and the resulting progression of food spoilage. For the most part, the spoilage organisms discussed have been harmless bacteria that pose no threat to human health. However, in certain situations, the bacteria responsible for food spoilage may, in fact, be pathogenic. *Bacillus* spp. are frequently present in raw and pasteurized milk and have routinely been identified as milk spoilage organisms. The pathogenic species, *Bacillus cereus*, has been linked to spoilage and human illness in fluid milk products. *Clostridium* spp. and members of the family Enterobacteriaceae can constitute a significant proportion of the spoilage flora in temperature-abused fresh meat and poultry products. *Clostridium perfringens* can comprise a large portion of the spoilage flora under anaerobic storage conditions. In addition, Enterobacteriaceae, including pathogenic *Salmonella* spp. and *Escherichia coli*, can dominate the spoilage microflora under aerobic and anaerobic storage conditions. *Vibrio* spp. are commonly present on seafood products harvested from warm water climates. These organisms tend to dominate the microflora of seafood products that are abused at temperatures more than 20 °C. In particular, the human pathogen *Vibrio parahaemolyticus* has been shown to be the predominant spoilage organism in shrimp held at temperatures of 24 °C or greater.

Interactions between Spoilage and Pathogenic Microorganisms

Microorganisms present in foods (or any other environment) interact with each other. The primary interaction from a food safety perspective is competition. It has been shown that some bacteria proliferate in foods at the expense of others. This is sometimes the case with the interactions between spoilage and pathogenic bacteria. When the spoilage microflora (or a portion of it) is able to inhibit, suppress, or eliminate a microbial pathogen in a food product, that food product has less chance to cause consumer illness. This type of microbial interaction will be discussed in the remaining part of this section.

How do spoilage microorganisms inhibit pathogens? Spoilage microorganisms can inhibit pathogens by numerous mechanisms. These include nutrient limitation, competition for space, production of toxic substances (bacteriocins, acids, antibiotics, etc.), iron sequestration, and nonspecific inhibition. Nutrient limitation occurs when spoilage organisms consume the nutrients available in foods and leave little or none for the pathogens. In competition for space, the spoilage organisms attach to the available surfaces, leaving no room for other organisms to attach. Toxic substances produced in sufficient quantities by spoilage organisms may negatively affect pathogen growth and/or survival. Iron sequestration, resulting from siderophore production, binds to iron making it unavailable for use by pathogenic microorganisms. This is essentially a specialized form of nutrient limitation. Nonspecific inhibition occurs when the presence of background microflora and/or spoilage organisms in foods results in a reduction in the numbers of pathogens, but the mechanism of action is unknown or can only be speculated. Of course, a combination of the inhibitory mechanisms discussed in this paragraph may also be employed.

Foodborne bacterial pathogens that can be inhibited by spoilage microorganisms include *Aeromonas sobria*, *B. cereus*, *Campylobacter jejuni*, *C. botulinum*, *E. coli* O157:H7, *Listeria monocytogenes*, *Salmonella* spp., *Staphylococcus aureus*, and *Yersinia enterocolitica*. The most extensively studied spoilage microorganisms that exhibit the ability to inhibit bacterial pathogens are *Pseudomonas* spp. and lactic acid bacteria. Other naturally occurring bacteria, yeasts, and molds have also been shown to exert inhibitory activity toward pathogens. Some *Pseudomonas* spp. have also been shown to inhibit other

spoilage microorganisms including other pseudomonads and *S. putrefaciens*.

Pseudomonas

Pseudomonas spp. primarily inhibit bacterial pathogens by nutrient limitation and iron sequestration in food stored under aerobic conditions. This has been demonstrated in several studies involving microbiological media, meat, poultry, milk, fish, and fresh vegetables. *Bacillus cereus*, *L. monocytogenes*, *Salmonella infantis*, *S. aureus*, and *Y. enterocolitica* levels were reduced in a minced meat medium when they were inoculated with *Pseudomonas fragi* and *P. fluorescens* after 3 days of aerobic incubation at 6 °C. *Pseudomonas aeruginosa* has been shown to inhibit growth of *S. aureus* in milk. *Pseudomonas fluorescens* produces positive, negative, and no effects on growth of *L. monocytogenes* in microbiological culture media, depending on the pH, salt content of the media, and the incubation temperature. *Pseudomonas fluorescens* isolated from raw pork and chicken has displayed inhibitory activity against *C. jejuni*, *E. coli* O157:H7, *Salmonella enteritidis*, *Y. enterocolitica*, *L. monocytogenes*, and *S. aureus*. Naturally occurring *P. fluorescens* and *P. aeruginosa*, isolated from fresh vegetables, have demonstrated antimicrobial activity toward *E. coli* O157:H7, *L. monocytogenes*, *Salmonella* Montevideo, and *S. aureus*. *Pseudomonas* strains isolated from fish inhibited the pathogens *A. sobria*, *E. coli*, *L. monocytogenes*, and *S. aureus* as well as the spoilage bacteria *P. fluorescens* and *S. putrefaciens*. All inhibitory activities reported for *Pseudomonas* spp. were attributed to iron sequestration via siderophore production, nutrient limitation, or other unreported mechanisms.

Lactic Acid Bacteria

Lactic acid bacteria including the genera *Carnobacterium*, *Enterococcus*, *Lactobacillus*, *Lactococcus*, *Leuconostoc*, and *Pediococcus* may inhibit microbial pathogens by producing organic acids (primarily lactic acid), bacteriocins, hydrogen peroxide, and/or diacetyl. Nutrient limitation may also play an inhibitory role for some lactic acid bacteria. As in the case of *Pseudomonas* spp., this has been demonstrated in numerous studies incorporating microbiological media, meat, poultry, milk, fish, and vegetables. Similar to the discussion presented in the *Pseudomonas* section *B. cereus*, *L. monocytogenes*, *S. infantis*, *S. aureus*, and *Y. enterocolitica* levels were reduced in a minced meat medium when they were inoculated with *Lactobacillus brevis* and *Lactobacillus plantarum* after 3 days of incubation at 6 °C. However, only the lactic acid bacteria *Pediococcus damnosus* has displayed inhibitory activity against *Salmonella*. *Carnobacterium piscicola* has been shown to have inhibitory activity against *L. monocytogenes* in culture media. Besides the incubation temperature, the degree of antimicrobial activity depends on the pH and salt content of the media. *Carnobacterium piscicola* has also been shown to control growth of *L. monocytogenes* in crabmeat, creamed corn, frankfurters, and milk. Growth of this pathogen can be controlled more effectively when the food products are incubated at 5 °C rather than at 19 °C. Three unidentified naturally occurring Gram-positive bacteria isolated from fresh bell peppers displayed inhibitory activity against *E. coli* O157:H7, *L. monocytogenes*, *Salmonella* Montevideo, and *S. aureus*. Bacteriocin production by these isolates was postulated, suggesting that they may have been lactic acid bacteria. *Lactobacillus fuchuensis*, *Lactococcus piscium*, *Leuconostoc gelidum*, and *Carnobacterium alterfunditum* isolated from various seafood products showed antimicrobial activity against numerous bacterial pathogens and spoilage bacteria including *E. coli*, *L. monocytogenes*, *S. enterica*, *S. aureus*, *P. phosphoreum*, *Pseudomonas* Group I, and *S. putrefaciens*. Some of these lactic acid bacteria isolates demonstrated bacteriocin-type activity, whereas others did not. Inhibitory activity of the nonbacteriocin-producing isolates was tentatively attributed to nutrient limitation. The three most common inhibitory activities reported for lactic acid bacteria in the literature are pH reduction, bacteriocin production, and nutrient limitation.

Inhibition of foodborne microbial pathogens by lactic acid bacteria is an important consideration when foods are stored under VP or MAP. As mentioned in the preceding sections, lactic acid bacteria commonly dominate the spoilage microflora in foods stored in this manner, especially under refrigerated conditions. This is due to their psychrotrophic and anaerobic growth capabilities. Lactic acid bacteria are also able to grow when carbon dioxide is present in the gaseous atmosphere of stored foods, which provides them a competitive advantage. *Lactobacillus fuchuensis*, *L. piscium*, *L. gelidum*, and *C. alterfunditum*, mentioned in the previous paragraph of this section, were originally isolated from MAP salmon, MAP sea bream, and MAP roughhead grenadier, and inhibitory activity experiments were conducted under anaerobic conditions. This demonstrates that these lactic acid bacteria have antibacterial activity against *E. coli*, *L. monocytogenes*, *S. enterica*, and *S. aureus* in oxygen-limited storage conditions. The background microflora of ground beef has been shown to control the growth of *E. coli* O157:H7 stored under both aerobic and anaerobic conditions. This background microflora was comprised primarily of lactic acid bacteria and the dominant isolate was *Lactobacillus sakei*. *Lactobacillus sakei* has also been shown to inhibit growth of *E. coli* O157:H7 and *L. monocytogenes* in VP cooked meat and *L. monocytogenes* in VP cooked ham. *Enterococcus mundtii* has shown inhibitory activity toward *L. monocytogenes* in a vegetable-based culture media but not in fresh mungbean sprouts stored under oxygen-limited conditions. *Lactococcus lactis* and *L. sakei* isolated from VP chilled meat inhibited the growth of *L. monocytogenes* and *C. jejuni* in meat-based agar stored under anaerobic conditions.

Clostridium botulinum: Time to Toxin Formation Versus Organoleptic Spoilage Detection

Clostridium botulinum is a bacterial pathogen of major concern in foods packaged under reduced oxygen conditions. These anaerobic spore-forming bacteria are commonly found in nature and may grow and produce toxin in hermetically sealed, VP, or MAP foods. Some strains including *C. botulinum* Type E and nonproteolytic types B and F are able to grow and produce toxin at refrigerated temperatures. One strain of *C. botulinum* Type E has been shown to produce toxin

at temperatures as low as 3.3 °C. *Clostridium botulinum* Type E has routinely been isolated from fish and seafood products and has caused a number of illness outbreaks associated with seafood consumption. This has resulted in an area of research addressing time to toxin formation versus organoleptic spoilage detection for VP and MAP refrigerated fresh fish. The primary goal of this type of research is to determine under what storage conditions will these products display spoilage characteristics (e.g., off odors) before the toxin is detected. Thus, this answers the question – will the natural microflora present spoil the fish before a food safety hazard arises?

When VP and MAP cod, whiting, and flounder were inoculated with *C. botulinum* Type E spores and stored at temperatures ranging from 4 to 26 °C, the flounder spoiled before toxin was produced at low temperatures but did not spoil before the toxin was produced at 26 °C. Whiting and cod did not spoil before the toxin was detected at any incubation temperature or gaseous atmosphere tested. Air-stored, VP, and MAP catfish fillets inoculated with *C. botulinum* Type E spores and stored at temperatures ranging from 4 to 16 °C spoiled before toxin was detected in all atmospheres at 4 °C. However, in all atmospheres with storage at 16 °C, and in VP with storage at 8 °C, toxin was detected on the same day as spoilage. In flounder fillets inoculated with a mixed culture of *C. botulinum* Type E and nonproteolytic Types B and F, sensory spoilage was detected before toxin production for samples stored in oxygen permeable film at 4 and 10 °C. However, at the same storage temperatures, sensory spoilage was detected after toxin production in VP samples. These studies show that strict temperature control is extremely important when raw fish is stored under VP and MAP conditions. It should be noted that in VP and MAP stored fish, a large portion of the spoilage microflora is likely to be lactic acid bacteria.

Clostridium botulinum also is a food safety concern when minimally processed produce is stored in MAP. Research has shown that nonproteolytic *C. botulinum* Types B and E can produce toxin at temperatures as low as 5 °C in fresh MAP vegetables, whereas proteolytic *C. botulinum* Types A and B can produce toxin at 15 °C and higher. Most samples displayed organoleptic spoilage characteristics before toxin was detected. However, butternut squash and onion were not considered to be spoiled before toxin was produced. Fresh mushrooms stored in MAP at 20 °C have also been shown to support toxin production by *C. botulinum*. The mushrooms did not appear to be spoiled at the time toxin was detected (3–4 days). Similar results have been found for fresh cabbage stored in MAP.

In general, organoleptic spoilage cannot be relied on to predict the presence of botulinum toxin in VP and MAP foods, especially those that use refrigerated storage as the only means to control growth and toxin production. Additional control strategies should be considered for refrigerated foods packaged in oxygen-limited conditions. These include reduced moisture content, acidification, food additives, pasteurization, or some combination of 'hurdles' that reliably prevent growth and toxin production.

NATURAL TOXICANTS

Contents

Alkaloids

C Crews, The Food and Environment Research Agency, York, UK

Glossary

Extraction A means of extracting specific compounds (such as alkaloids) from food by treatment (usually shaking) with a solvent.

Gas chromatography (GC) A means of separating volatile compounds by passing in a stream of gas through a very narrow heated glass tube coated with an absorptive phase.

High-performance liquid chromatography (HPLC) A means of separating nonvolatile compounds by passing in a solvent under pressure through a column packed with an absorptive phase.

Mass spectrometry (MS) An instrumental means of detecting, identifying, and measuring compounds by producing and separating ions. Used as a detector for gas chromatography (GC–MS) or for high-performance liquid chromatography (LC–MS).

Solid phase extraction (SPE) A means of extracting specific compounds (such as alkaloids) from a solvent extract of food on to a solid medium as a means of separation from food. Alternatively, unwanted compounds can be removed from the extract.

Alkaloids

Alkaloids are chemical substances having one or more nitrogen atoms, usually contained in a heterocyclic ring system, and they function as amines. Most are naturally produced by plants, and many have a pharmacological activity in the animals and humans that consume them, affecting the nervous system and other essential processes. Some insects are immune to the toxic effects and use the alkaloids for their own defense by making their own bodies toxic to predators. Chemical structures of the major alkaloids discussed in this article are presented in Figure 1.

Plant alkaloids are secondary metabolites in almost all cases, that is, their production is not essential for the plant survival. In fact, their purpose in most plants is poorly understood, but in some cases, is known or assumed to be to deter animal and insect predators. Alkaloids have a bitter taste, and often accumulate in the fresh young growing parts of plants that are most likely to be eaten by predators.

Food Safety Issues

Toxic alkaloids can be present in food for various reasons. They are in some cases found as natural components of some important food plants such as potatoes, and in other cases they can contaminate food that does not itself contain alkaloids. Certain fungi that grow on food crops produce toxic alkaloids either during the growth of the plant or during storage. The most important example of this is the fungus ergot, which infects mainly rye, wheat, and barley, and has achieved notoriety through major poisoning outbreaks.

Toxic weeds or their seeds frequently contaminate cereal grains or animal feed, and can cause human poisoning directly or through animal products such as milk and eggs. Furthermore,, many toxic plants are consumed intentionally for their bioactive effect, where some real or perceived health benefit or effect on the nervous system is desired. These herbal food supplements or medicines are defined as foods in some countries, and as medicines in others.

Alkaloid Excretion in Breast Milk

The transfer of alkaloids from food or feed into the milk of humans is of considerable concern, because newborn babies are very sensitive to toxins, and may derive all of their food from breast milk. Alkaloid transfer into the milk of cows, sheep, and goats can also lead to human poisoning. The rate and degree of alkaloid transfer into breast milk are affected by

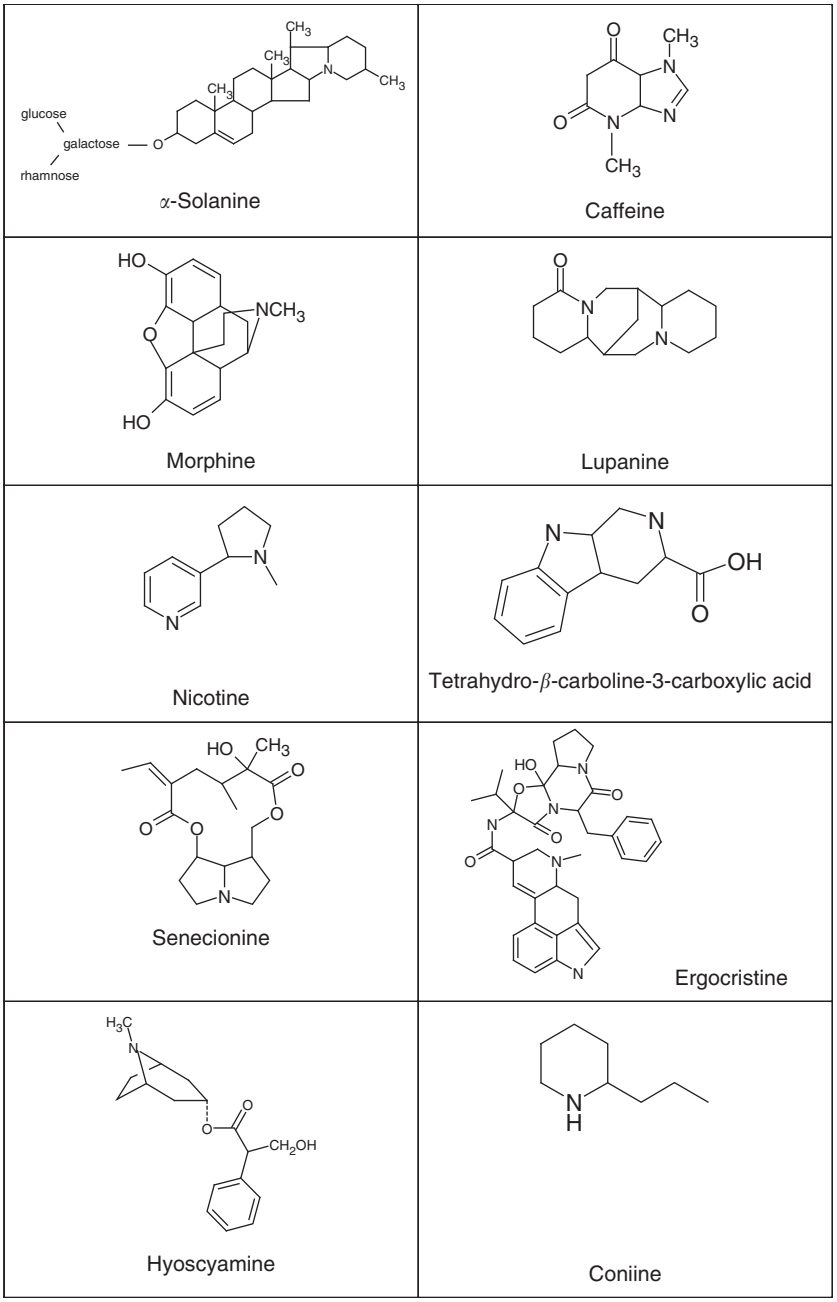

Figure 1 Chemical structures of some common alkaloids.

the solubility of the alkaloid and the fat content of the milk. So, relatively fat-soluble alkaloids will accumulate more in high fat milks.

Some alkaloids can be found at relatively high levels in milk whereas others, notably solanine and ergot alkaloids, remain absent regardless of high ingestion levels. Medicinal morphine has been shown to enter human breast milk and be transferred to babies, but food sources of opiates are unlikely to produce detectable levels in milk.

Experimental doses of caffeine are rapidly absorbed into the blood and pass into breast milk, with ingested doses of approximately 100 mg caffeine producing breast milk concentrations of 2–4 μg ml^{-1}.

The quinolizidine alkaloid anagyrine has been implicated in a human poisoning incident involving the consumption of milk from goats that had grazed on lupins.

Nicotine and cotinine from smoking mothers contaminates milk and can be detected in infants' urine, and so ingestion of these alkaloids in food will presumably also present some risk to babies.

In the paragraphs below the major alkaloids presenting a health risk in food through natural occurrence or contamination

are described. In the analysis of alkaloids in plants and in food, several general approaches apply to almost all situations, thus an overview of these techniques is provided first, with deviations specific to particular alkaloids described in the main text.

Analysis

The determination of alkaloids in food usually takes the form of extracting the compounds with a suitable solvent followed by a detection step that provides either qualitative or quantitative information. Measurement methods vary in complexity from relatively simple techniques that typically produce a color reaction, indicating their presence, to complex instrumental analyse that can identify and quantify individual compounds.

In almost all cases the alkaloids have to be separated from a food matrix, that is, a complex mixture of insoluble fiber and protein, lipids, and water-soluble components. The basic nature of alkaloids aids their extraction considerably. They are mostly soluble in relatively polar organic solvents such as methanol, diethyl ether, or chloroform, but are also soluble in water at acid pH. Typically, alkaloids are extracted into organic solvents and then partitioned into dilute aqueous hydrochloric or sulfuric acid. Alternatively, they may be extracted directly with the acid. The acid solution is then shaken with a nonmiscible organic solvent, such as chloroform, which dissolves and removes much of the coextracted material. The organic layer is discarded and the aqueous extract made strongly alkaline by, for example, the addition of strong ammonia solution. The basic conditions greatly reduce the alkaloids' solubility in the aqueous phase and they can then themselves be extracted into an immiscible organic solvent. This partitioning between aqueous and organic phases can be repeated to produce an extract suitable for alkaloid detection.

Recently, small disposable solid phase extraction (SPE) columns containing a cationic exchange phase have been used for trapping alkaloids from food extracts, and this procedure is likely to dominate future applications.

Alkaloids may be detected in extracts by their reaction with reagents that produce colored products. The reagents include phosphomolybdic acid, iodoplantinate, potassium bismuth iodide (Dragendorff's reagent), and dimethylaminobenzaldehyde (Ehrlich's reagent). The reagents can be used to detect alkaloids on thin-layer chromatography plates, or the colored product may be quantified using spectrometric techniques to give the total alkaloid content. The method has the advantage that another related alkaloid can often be used where specific standards are not available, whereas the major disadvantage is that alkaloid components cannot be quantified individually.

For quantitative analysis of single alkaloids in a mixture, they are usually separated by chromatographic techniques. Most alkaloids are sufficiently volatile to be analyzed by gas chromatography (GC). In some cases, blocking of the polar hydroxyl groups (derivatization) is used. The alkaloids are detected by general purpose detectors such as the flame ionization detector, a nitrogen-specific detector, or more often a mass spectrometer (GC–MS).

Nonvolatile compounds can be separated by high-performance liquid chromatography (HPLC) using normal or reverse phase conditions. Alkaloids can be detected by various means including UV absorbance, refractive index, and mass spectrometry (LC–MS), the choice depending on both the analyte and the solvent used. The most comprehensive information and the best confirmatory evidence are provided by LC–MS.

Alternative techniques include immunoassays that have potential application to inexpensive field-based dipstick tests, and the more expensive nuclear magnetic resonance (NMR) methods that help elucidate chemical structures.

Alkaloids Present Naturally in Food

Solanum Alkaloids

Occurrence

The potato plant (*Solanum tuberosum*) and the aubergine (*Solanum melongena*) are related to some very toxic plants – deadly nightshade, henbane, and tobacco – and themselves contain toxic alkaloids that cause sporadic outbreaks of poisoning in humans. Solanine is present in most of the 1700 species in the genus *Solanum*. Potatoes are a staple part of the diet for very many people, with a worldwide annual production of approximately 350 million tons, and all contain detectable alkaloid glycosides. Therefore, their safety is of considerable concern. Toxic alkaloids were first isolated from potato in 1820 but were not characterized until the 1950s. The major alkaloids in edible *Solanum* species are α-chachonine and α-solanine, which are bound to sugar molecules as glycosides. The alkaloid part of the molecule has a steroidal structure and is attached to a branched trisaccharide or tetrasaccharide.

The glycoalkaloid content of potatoes may increase during storage, particularly when exposed to light (although the greening is independent of toxicity), or as a result of damage during handling (Figure 2). Potatoes can contain up to 350 mg kg^{-1} glycoalkaloids in the fresh tubers with much more being present in the green parts of the plant, including the sprouts. The levels are higher in organically grown plants. The levels are also higher in wild species of potato used in breeding new varieties, and therefore analysis of the progeny

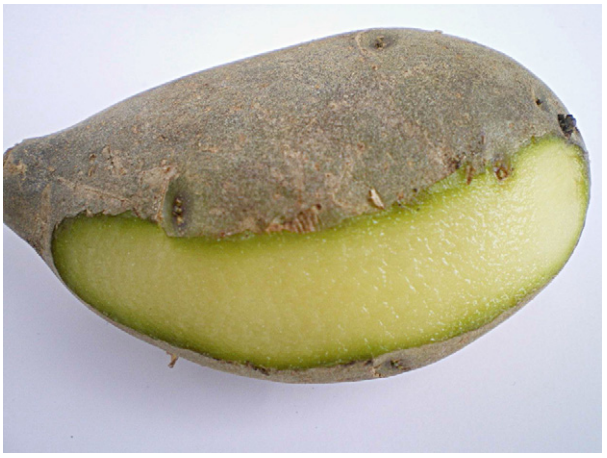

Figure 2 A potato showing evidence of exposure to light.

resulting from breeding trials is required. The glycoalkaloid content is much higher in the potato skin than in the main flesh and can be removed by peeling of the outer 3–4 mm. The alkaloids persist to some extent when potatoes are processed, with potato chips containing up to 100 mg kg^{-1}. Some countries have set limits (typically 200 mg kg^{-1}) for levels of glycoalkaloids in potatoes.

All parts of the aubergine (*S. melongea*, eggplant) contain solanine, however some cooking processes remove the toxin. Potatoes, aubergines, and several other vegetables (tomatoes, cabbage, sweet potatoes, sweet peppers, and chilli peppers), and some fruits (physalis and mulberries), also contain polyhydroxylated nortropane alkaloids called calystegines. Tomatoes contain the related tetrasaccharide glycoalkaloids dehydrotomatine and α-tomatine, but there is no strong evidence of their toxicity.

Toxicity

Solanum glycosides inhibit the cholinesterase enzymes *in vitro*, although clinical cholinergic symptoms are not observed. The toxins cause nerve damage, leading to hallucinations, delirium, and eventually coma. Ingestion of potatoes with high glycoalkaloid content can cause stomach pains, weakness, nausea, vomiting, and breathing difficulties between 2 and 24 h after ingestion, which may persist for several days. Moderately contaminated potatoes (140 mg kg^{-1}) have a bitter taste and higher levels induce a burning sensation. Several outbreaks of potato-related illness have been reported, from which the toxic alkaloid dose has been estimated to be 2–5 mg kg^{-1} body weight.

The glycoalkaloids appear to be more toxic to humans than to other animals. It is believed that they, or their metabolites, suppress fertility, increase infant mortality, and induce neurological defects, including spina bifida. The related potato alkaloids solanidine and salasodine have been shown experimentally to cause teratogenic defects such as craniofacial malformations.

Calystegines are more usually associated with some toxic nonfood plants, but they are potent glycosidase inhibitors, and are therefore of concern, although the degree of human toxicity has not yet been established.

Control

Solanine is not removed by boiling, but it can be destroyed by frying. Solanine poisoning is uncommon as cooks and the public are aware of the problem and tend to avoid green potatoes, in any case, consumption of up to 5 g of green potato per kg body weight per day does not appear to cause acute illness.

Control of solanum glycoside toxins in potatoes is based on careful selection and breeding of seed potato varieties, and attention to handling and processing with a view to reduce mechanical damage and exposure to light. Some chemical treatments, such as the use of sprouting inhibitors, can reduce the formation of the toxins.

Analysis

HPLC with UV detection (HPLC-UV) is, today, the preferred analytical method for glycoside toxins. The presence of the hydrophilic sugar in the molecule means that the toxins are very soluble in water and, therefore, aqueous extraction is used.

Xanthine Alkaloids

Occurrence

The xanthine alkaloids include caffeine, theobromine, and theophylline, and are well-known components of tea (*Camellia sinensis*), coffee (*Coffea arabica*), cola ingredients (*Cola* spp.), and cocoa (*Theobroma cacao*). These are obviously consumed in considerable quantity around the world. Caffeine is the most important xanthine alkaloid. It is a mildly stimulant drug found in tea, coffee, cocoa, and the kola nut and is usually associated with the alkaloids theophylline and theobromine, which are mild cardiac stimulants. Coffee seeds (beans) show considerable variations in caffeine concentration, as do the various brews prepared from the roasted and ground bean. A typical serving of coffee contains between 40 and 100 mg of caffeine. Coffee contains trace amounts of theophylline, but no theobromine. The tea plant contains more caffeine than coffee, however, the brewing process results in the caffeine content of the beverage being rather lower than that of coffee.

The kola nut species *Cola acuminata*, *Cola nitida*, and *Cola anomala* contain theobromine and caffeine. Caffeine is present in *Cola* seeds at levels of approximately 10 000 mg kg^{-1} of the fresh seed. The alkaloids are absent from the related cola plant *Garcinia kola*. Kola nuts are an ingredient of cola drinks, which typically contain approximately 10–50 mg of caffeine per serving, but energy drinks can contain considerably more, often 80–100 mg of caffeine per serving. Guarana is another ingredient of energy drinks that contains caffeine, theobromine, and theophylline. Chocolate (cocoa) contains mostly theobromine and also caffeine and theophylline in low concentrations.

Toxicity

Caffeine is a stimulant of the central nervous system, causing minor enhancement of alertness. This effect contributes to the popularity of beverages prepared from plants such as tea and coffee, and of its use as an ingredient in soft drinks and energy drinks.

Caffeine is metabolized in the liver by the cytochrome P450 oxidase enzyme system which produces the dimethylxanthines, paraxanthine (the major product), theobromine, and theophylline. Paraxanthine increases lipolysis, the process by which fats are split into glycerol and fatty acids. Theobromine has a vasodilatory effect, increasing the oxygen and nutrient flow to the brain and muscles. Theophylline relaxes smooth muscle and increases heart rate and efficiency. The mechanism whereby caffeine causes alertness is unclear, but it might be related to adenosine which is believed to control sleepiness.

Xanthines act as nonselective antagonists of adenosine receptors. Adenosine protects the brain in times of stress by suppressing neural activity and increasing blood flow. Caffeine counteracts this by binding to adenosine receptors without activating them, thus reducing cerebral blood flow. Excesses of caffeine can lead to insomnia, headaches, nervousness,

irritability, anxiety, palpitations, and twitching. The LD_{50} of caffeine in humans is estimated to be approximately 150–200 mg kg^{-1} of body mass, roughly 80–100 cups of coffee for an average adult taken within a limited time frame that is dependent on half-life. Heavy caffeine consumption is believed to increase the risk of miscarriage.

Control

The consumption of caffeine and its content in foods and beverages is not regulated, but government agencies often impose labeling requirements. For example, European Commission regulations call for clear labeling on any beverages containing more than 150 mg l^{-1} of caffeine to state that there is 'high caffeine content' in the product. Because of the risk of miscarriage, the UK Food Standards Agency has recommended that pregnant women should limit their caffeine intake to less than 200 mg of caffeine a day – the equivalent of two cups of instant coffee or a half to two cups of fresh coffee.

Analysis

Caffeine has been determined by gravimetric and spectrophotometric methods, but these are often tedious and unreliable. GC can be used but HPLC-UV is now preferred. The xanthines are typically detected using a photodiode array detector.

Opium Alkaloids

Occurrence

Poppy seeds obtained from the opium poppy (*Papaver somniferens*) are used all over the world for the decoration of baked foods such as bread rolls. The seeds contain a range of morphine alkaloids, but in much lower levels than the parts of the plant used for opium production. The seeds typically contain 5–60 mg kg^{-1} of morphine and 5–50 mg kg^{-1} of codine. These alkaloids can regularly be detected in baked foods that have been decorated with poppy seeds.

In 2005, the opiate content of poppy seeds surveyed in Germany was found to be high enough to cause adverse health effects. Seventy six percent of 110 samples exceeded the guidance level of 4 mg morphine per kg poppy seeds proposed by the Federal Institute for Risk Assessment, but almost 30% contained more than 20 mg kg^{-1}, although these levels would be reduced by processing, especially baking, which has a marked effect on morphine levels. The main interest in morphine is in the analysis of body fluids where it is necessary to distinguish between morphine due to drug abuse and that from legitimate foods.

Toxicity

Morphine appears to mimic the body's endorphins that are responsible for analgesia (reducing pain), causing sleepiness, and feelings of pleasure. Morphine is a phenanthrene opioid receptor agonist which binds to and activates opioid receptors in the central nervous system. Morphine is substantially broken down in the liver, with most being rapidly excreted in the urine. It is metabolized primarily into glucuronides.

Poppy seeds only rarely provide doses of morphine and other opiates that are significant in terms of human health. Ingestion of the seeds is of more importance in terms of verifying opiate abuse indicated by screening tests and distinguishing between innocuous ingestion via food and illegal intake.

Control

Maximum values for morphine in poppy seeds have been set in some countries, for example, a maximum value of 30 mg kg^{-1} in raw poppy seeds sold in Hungary.

Analysis

Opiates are easily determined by GC and GC–MS.

Lupin Alkaloids

Occurrence

Lupin seed is a good potential source of protein as the dry seed contains approximately 40% of protein with a reasonably good amino acid profile (Figure 3). Flour from lupin has been used in the manufacture of products including biscuits and pasta. It has been proposed as a component of infant formula and bread and as a replacement for soya flour. Protein concentrates isolated from lupin have lower levels of alkaloid and improved technical and functional properties, making them more attractive as novel food ingredients.

Lupins and related plants of the Fabaceae family contain alkaloids known as quinolizidines. These secondary metabolites are known to have a defense function against predatory herbivores and microorganisms. The major quinolizidine alkaloid is lupanine, but a number of minor alkaloids are present according to the species, including albine, hydroxylupanine, sparteine, anagyrine, lupinine, and angustifoline.

Lupins that have low alkaloid content are referred to as sweet lupins as opposed to the bitter species or varieties. The most commonly used sweet lupins are *Lupinus albus* (white lupin) and *Lupinus angustifolius* (blue lupin). The mean total alkaloid content of sweet lupin seed is approximately 130–150 mg kg^{-1}, but bitter plants contain approximately four times that amount, with a similar alkaloid pattern. The alkaloid content is affected by geography and climate.

Figure 3 Seeds of lupin (*Lupinus albus*).

Toxicity

Lupin alkaloids are acutely toxic to humans. Quinolizidine alkaloid poisoning causes trembling, shaking, excitation, and convulsion. Lupanine and other lupin alkaloids show a moderate toxicity in vertebrates, whereas α-pyridone alkaloids such as cytisine and anagyrine are strong poisons. It is likely that the molecular target of quinolizidine alkaloid poisoning is the acetylcholine receptor. Lupanine, angustifoline, and 13-hydroxylupanine do not show any mutagenic activity. The lethal dose of lupanine has been determined to be approximately 100 mg kg^{-1} of lupin seeds. It is substantially destroyed by cooking, but if the cooking procedure is insufficient, 10 g of seeds may liberate more than 100 mg of lupanine. Anagyrine causes malformations (crooked calf disease) in young sheep and calves, when their mothers feed on lupins or broom. It has been shown that goats that consume lupin seeds pass anagyrine in the milk, and there has been a single reported case of a child born with limb deformities after maternal ingestion of goat's milk.

Control

Sweet lupin flour may be used to enhance the protein content of foods if the alkaloid content is suitably low. Some countries (Great Britain, France, Australia, and New Zealand) have imposed limits on the quinolizidine alkaloid content of seed or flour, typically at 200 mg kg^{-1}. It is likely that the alkaloid content could be reduced by breeding techniques, but the use of isolates of the protein fraction has been shown to be the safest approach. In most foods prepared from lupin flour, the alkaloid content is slightly changed by the processing, but protein isolates contain only lupanine, at levels below the limit of 200 mg kg^{-1} where the lupin protein isolates used exceeds approximately 15%.

Analysis

Lupin alkaloids can be analyzed by gas chromatography–flame ionization detector (GC–FID) and GC–MS, and also by HPLC.

Nicotine

Occurrence

Nicotine (1-methyl-2-pyrrolidinyl)pyridine, is the major alkaloid of the tobacco plant (*Nicotiana tabacum*). It is present at 2–10% levels in tobacco, and at considerably lower concentrations in other Solanaceae plants including tomatoes, aubergines, peppers, and potatoes. Nicotine has been used as a convenient and inexpensive insecticide and can therefore contaminate food crops. Recently, nicotine has been found in dried wild mushrooms (ceps) from China, which might have absorbed the drug from tobacco leaves used to hold the mushrooms during drying.

Very low levels of nicotine, less than 0.01 mg kg^{-1}, have been reported in fresh potatoes, tomatoes, aubergines, and sweet peppers. There are conflicting data regarding relative levels in the flesh and peel of potatoes. Exposure to nicotine through the diet is much lower than that from even passive smoking, and absorption from ingestion is also much lower by this route. Processing and cooking have little effect on nicotine levels in potatoes.

Toxicity

Low doses of nicotine, for example, from cigarette smoke causes hypertension and respiratory stimulation. There is, however, unlikely to be any detectable physiological effect from ingestion of levels present naturally in food.

Control

The use of nicotine as a pesticide is well regulated. Following the mushroom contamination incident, the European Food Safety Authority (EFSA) proposed the introduction of temporary maximum residue levels (MRLs) of 0.036 mg kg^{-1} nicotine for fresh mushrooms and 1.17 mg kg^{-1} for dried mushrooms (2.3 mg kg^{-1} for ceps).

Analysis

A variety of methods have been used for the analysis of nicotine, but ones based on GC–FID and GC–MS are most popular.

Carboline Alkaloids

Occurrence

Toxic carboline alkaloids are produced during the high temperature cooking of high protein foods. They are neurotoxins and can form mutagenicity promoting derivatives. They have several varied properties and actions including adverse effects on the nervous system and cytotoxicity, but being antimicrobial, antiviral, and antioxidant they also have some beneficial activity.

Carbolines are heterocyclic compounds with an indole ring system joined to a pyridol ring in which the position of the nitrogen molecule can vary. Where the nitrogen is in the 2-position carbon atom, the compounds are called β-carbolines, whereas α- and γ-carbolines have the nitrogen in other positions. In tetrahydrocarbolines, the pyridol ring is saturated.

Tetrahydrocarbolines are formed in food processing by reaction of indolalkyamines such as tryptamine, serotonin, or tryptophan with carbonyl compounds, principally aldehydes. They undergo oxidation to form dihydrocarbolines and ultimately β-carbolines. The highest concentrations of carbolines are found in soy sauce (150–2000 mg kg^{-1} β-carboline) and in coffee (0–12 mg kg^{-1} norharman).

Tetrahydro-β-carboline-3-carboxylic acid (THCA) and methyl-tetrahydro-β-carboline-3-carboxylic acid (MTCA) are isomeric carbolines found in some commercial fruits. Citrus fruits (orange, lemon, grapefruit, and mandarin) have been found to contain 0.15 to more than 8 mg kg^{-1} MTCA with lower levels in other fruits (banana, pear, grape, tomato, and apple). Levels of THCA are lower, usually less than 0.05 mg kg^{-1}. MTCA increases in both pears and bananas as the fruit ripens and softens during storage. Tetrahydro-β-carbolines have also been found in chocolate and cocoa with total levels typically being 1–5 mg kg^{-1}.

Toxicity

The compounds of greatest concern because of their mutagenicity and carcinogenicity are α- and γ-carbolines. *N*-methylcarbolines bioactivated in the liver may act as neurotoxins, and β-carbolines influence the action of neurotransmitters. The tetrahydro-β-carbolines can also act as precursors of *N*-nitrosamines, which are potent carcinogens.

Control

There are no specific approaches to control the intake of carboline alkaloids, however, consumers are occasionally advised not to overcook meat on account of the range of carcinogenic or toxic compounds that are believed to be formed by excessive heating.

Analysis

Carboline alkaloids may be determined by GC–MS or LC–MS, or by HPLC with fluorescence detectors.

Alkaloids that Contaminate Food

Pyrrolizidine Alkaloids

Occurrence

Pyrrolizidine alkaloids are probably the major alkaloidal food contaminants in terms of wide distribution and the degree of economic and health damage caused. They are found worldwide in a very large number of plants. The pyrrolizidine alkaloid content of seeds is often very high (up to 5% dry weight) and the effects can be acute or cumulative. Pyrrolizidine alkaloids not only cause liver damage in the form of veno-occlusive disease, but also have numerous other damaging effects including lung disease and an elevated risk of liver cancer.

Plants containing pyrrolizidines that have been used as food or food supplements include comfrey (*Symphytum*) and a number of vegetables consumed in Japan, including *Petasites, Symphytum*, and *Tussilago*. They are also found in the seed of borage *(Borago officinalis)* and species of *Echium*. These seeds are used in producing specialty oils on account of their beneficial fatty acids, but pyrrolizidine alkaloids are not particularly soluble in oil and reports of its contamination are very limited. However, the major human health problems with pyrrolizidine alkaloids are associated with contamination of food that does not naturally contain the alkaloids.

Bees that feed on plants containing pyrrolizidine alkaloids transfer the toxins into honey and into foods and supplements produced from pollen (Figure 4). This has become a real problem where the plants grow profusely, such as *Echium* in Australia, and guidance has been issued to reduce consumer exposure to contaminated honey. There have also been limited studies indicating that pyrrolizidine alkaloids may be transferred into animal milk and poultry eggs.

Figure 4 *Echium* surrounding beehives in Argentina. Reproduced with permission of Quality Services International, Bremen, Germany.

Toxicity

Pyrrolizidine alkaloids are converted in the liver to highly reactive pyrroles which stimulate proliferation of cells in the liver causing hepatic veno-occlusive disease, hepatic venous thrombosis, ascites, jaundice, and an elevated risk of liver cancer. Acute poisoning causes necrosis of the liver, damage to the lungs, heart, kidney, stomach, reproductive system, and brain, and probably a higher incidence of liver cancer. Pyrrolizidine alkaloids are teratogenic and are transmitted through breast milk.

Most poisonings result from contamination of food grain with seeds of pyrrolizidine alkaloid-containing plants. Pyrrolizidine alkaloids have been responsible for some very serious contamination incidents. In 1975, people in four Indian villages were poisoned by *Crotalaria*-contamination of grain, as a result of which 28 of 67 affected people died from liver disease. Seeds of *Heliotropium*-contaminated wheat in Afghanistan in 1976, causing liver disease in almost 1500 villagers who consumed it. In 1992, *Heliotropium* growing in wheat contaminated the flour, which was consumed because of famine in the area, and this resulted in approximately 4000 casualties. In a more recent outbreak in Afghanistan (2008), more than 150 people were poisoned, and 20 died after consuming pyrrolizidine alkaloid-contaminated wheat flour and goat's milk.

Control

Methods for the control of pyrrolizidine alkaloid contamination are based partly on legislation and advice, and partly on control of the plants responsible.

Most of the plants that produce pyrrolizidine alkaloids have very successfully invaded large area of land in Europe, Asia, Australia, and the USA. Despite the fact that they have

few natural predators, their control by biological means (usually with toxin-resistant insects) is today preferred because of the undesired environmental impact of herbicides.

Acting on government advice, the herbal medicine industries in the UK and in the USA have voluntarily removed preparations containing comfrey root from the market. The German Federal Health Bureau has introduced a limit of pyrrolizidine alkaloid intake from herbal medicines to levels providing less than 1 μg day^{-1}, or to 0.1 μg day^{-1} when used for more than 6 weeks. These limits could be exceeded by consumption of contaminated eggs and honey. The Food Standards Australia New Zealand organization has set a provisional exposure level of 1 μg pyrrolizidine alkaloid per kg body weight per day and has advised consumers not to eat honey from *Echium plantagineum* every day.

Analysis

Pyrrolizidine alkaloids have been analyzed by GC and color reactions, but today LC–MS methods are preferred, especially for food samples. Metabolites of pyrrolizidine alkaloids can be detected in body fluids by this technique.

Ergot Alkaloids

Occurrence

Ergot is the broad term used to describe the infection and toxins produced by the fungus *Claviceps purpurea*, which infects cereal grains. Ergot is most common in rye and triticale, a hybrid of rye and wheat, and it occasionally infects wheat and barley, but rarely oats. Grasses can also be infected and pass spores on to cereal crops. The quantity and pattern of ergot alkaloids vary between fungal strains and the host plant. The fungus produces dark growths known as sclerotia on the grain, which survive milling and baking processes to contaminate bread and other products (Figure 5).

The ergot sclerotia are poisonous, containing alkaloids including ergotamine, ergocornine, ergocryptine, ergocristine, ergoclavine, ergonovine, and ergometrine. These are amide and peptide derivatives of lysergic acid; and tremorgenic indolediterpene alkaloids. Ergot alkaloids containing C9-C10 double bond epimerize to form mixtures of left-hand rotation isomers based on lysergic acid and known by the suffix -ine (e.g., ergotamine) and right-hand rotation isomers based on isolysergic acid known by the suffix -inines (e.g., ergotaminine). In nature, -inines always accompany -ines.

Toxicity

Ergot alkaloid poisoning causes many symptoms including fatigue, burning sensations, muscle spasms, convulsions, and numbness of extremities. In extreme cases, gangrene ensues, leading to loss of extremities, hallucinations, and abortion. Large-scale human poisoning from ergot has been recorded recently in France, India, and Ethiopia.

The ergot isomers differ in toxicity with -ines being biologically active and -inines inactive, thus it is important that analytical methods distinguish between the two.

Figure 5 Ergot (*Claviceps purpurea*) on wheat. Reproduced with permission from D Waylett.

Control

Control of ergot is based on the planting of seed that is free of spores, and from which sclerotia have been removed by seed cleaning equipment or by brine flotation, plowing in of infected seed, and removal of grasses that can carry the fungus. When present in the field, *Claviceps* can be killed by fungicides. Burning of wheat stubble will also reduce the number of viable sclerotia. Cereal cultivars vary in their susceptibility to ergot with those having short flowering periods being less susceptible.

Despite effective cleaning procedures, ergot alkaloids have been detected in surveys of Canadian and European cereals and cereal products at high levels of more than 7000 mg kg^{-1}.

Legislation

Legislative limits have not been set for ergot alkaloids in food as the ergot problem primarily affects animal feed. Ergot alkaloids are usually measured in terms of the weight of sclerotia in a grain sample, with grain having more than 0.05% ergot by weight typically being declared ergoty and unsafe for human consumption. The setting of limits has been hampered by the difficulty in determining the alkaloids and separation of the toxic and nontoxic isomers.

Analysis

The analysis of ergot alkaloids has best been achieved by LC–MS where modern methods can separate the isomeric pairs and give a more accurate picture of exposure. Care is required to minimize the exposure of the samples and extracts to light and heat, in order to avoid epimerization.

Argemone Alkaloids

Occurrence

The seed oil of the plant *Argemone mexicana* contains the toxic quaternary benzophenanthridine alkaloids sanguinarine (approximately 90%) and dehydrosanguinarine (approximately 5%) with lesser quantities of cheletrythrine and coptisine, and small quantities of berberine and protopine, which are isoquinoline alkaloids. The seeds contain 30–35% of oil which itself contains 0.13% alkaloids.

Argemone seed occasionally contaminates cereals, but more frequently its oil contaminates edible oils, especially mustard oil from *Brassica nigra*. Perhaps more commonly in some countries, argemone seed oil is used to adulterate mustard oil.

Toxicity

Consumption of mustard oil contaminated with argemone oil leads to epidemic dropsy. Its effects are dilatation, proliferation, and increased permeability of capillaries, leading to edema of the lower body and limbs, with oxidative stress and death of red blood cells causing anemia and, ultimately, congestive heart failure. The visible symptoms are diarrhea and vomiting, erythema (redness of the skin), coughing, and shortness of breath. Toxicity may be observed following short-term poisoning or cumulative low-dose exposure. Despite these issues, sanguinarine has potential anticancer activity and antimicrobial activity and has been tested as a feed additive for poultry.

Control

Control of argemone poisoning takes two forms. First, yellow-seeded mustard is cultivated, in which the argemone seeds are visible, in mixtures, and the darker oil also shows up. This is encouraged by programs of education for farmers, who are also taught to identify the argemone plant. Second, in countries such as India, official control measures are enforced, including maximum permissible upper limits of argemone oil in edible oils, bans on the sale of unpacked mustard oil, and certification of mustard oils.

Analysis

HPLC-based methods are preferred for all argemone alkaloids, with diode array or mass spectrometric detection.

Mushroom Alkaloids

Mushrooms commonly cultivated or collected for human consumption do not appear to contain toxic alkaloids. The total alkaloid content of the common edible mushroom *Boletus edulis* has been reported as relatively high, but the individual alkaloids have not been identified.

Occurrence

Several mushroom-poisoning incidents are reported every year. The majority are associated with misidentification of toxic species as safe ones by people collecting wild specimens for food. Most serious poisonings are attributable to the fungal genus *Amanita*. Some members of this genus are safe to eat, but others are very poisonous, in particular the Fly Agaric, *Amanita muscaria*, and the Death Cap, *Amanita phalloides*.

Toxicity

The toxins in these fungi are the alkaloids ibotenic acid and related compounds muscarine, muscaridine, and muscimol. Levels of ibotenic acid are typically 300 mg kg^{-1}. It is decarboxylated to the more psychoactive compound muscimol, which produces symptoms on ingestion of 10–15 mg.

Ingestion causes paralysis of the respiratory center and cardiac muscle. There are numerous symptoms, including profuse salivation, sweating, severe colic, vomiting, and purging, often followed by coma and death.

Control

Control of mushroom poisoning can only be provided by education and advice. The most common consumers of these toxins are collectors of wild mushrooms who are aware of the risks and are likely to have identification guides, of which many are available. The major problem appears to be misidentification, especially where the juvenile stages of safe and toxic mushrooms are very similar in appearance.

Minor Alkaloids

Some minor alkaloids rarely contaminate food but have the potential to do so. Tropane alkaloids are a large group of compounds found in some of the Solanaceae, but not in food crops. They have a two-ringed structure characterized by a pyrrolidine and a piperidine ring that share a nitrogen atom and two carbons atoms. The most important tropane alkaloids are (−)-hyoscyamine and (−)-scopolamine (also known as hyoscine). Tropane alkaloids are present at high levels in the Datura species *Datura stramonium* (thorn apple, Jimson weed), *Datura ferox*, and *Datura innoxia*. The highest levels of the alkaloids are found in the seeds, which often contaminate soya beans and linseeds used in the manufacture of animal feeds. Food poisoning by *Datura* occurs occasionally when people mistake the plant for an edible one, for example, the root of *Datura* resembles that of edible burdock.

Tropanes block the muscarine acetylcholine receptors of the central nervous system, preventing the binding of acetylcholine. Poisoning symptoms include tachycardia and mental confusion. High doses (approximately 100 mg in adults) cause coma and death and sometimes lower doses (less than 10 mg) can be fatal.

The hemlock plant (*Conium maculatum*) contains a small number of toxic alkaloids including coniine and coniceine. Hemlock does not normally poison humans as a result of food contamination, but it has been confused with several umbelliferous wild food plants including wild carrot (*Daucus carota*), wild parsnip (*Pastinaca sativa*), and fennel (*Foeniculum vulgare*). It has also been claimed that birds, notably quails, that feed on seeds become toxic and can poison people consuming them.

Summary

Toxic plant exposure is a common cause of poisoning, and although many are caused by alkaloids, the more frequent incidents do not arise through food contamination. Alkaloids

naturally present in important foods such as potatoes can be detected quite readily, and the incidence of their occurrence will increase as analytical methods improve. However, advances in quality control and general awareness can ensure that for virtually all consumers, the dose ingested is well below that likely to cause ill effects.

A more serious threat is accidental or intentional contamination with alkaloids of high toxicity. Large-scale accidental poisonings are still likely to occur occasionally in the poorer countries where the toxic plants are more common, the means of their control are absent, alternative foods are not available, and consumer awareness is poor. Today, there is the modern threat of a moderate-scale intentional contamination of food supplies with poisons, of which the alkaloids are likely agents as they are relatively easier to obtain from natural sources. The answer to this problem lies partly in advances in detection techniques, which are fortunately proceeding at a rapid rate.

NATURAL TOXICANTS

Naturally Occurring Toxins of Plant Origin

C Crews and D Clarke, The Food and Environment Research Agency, York, UK

Glossary

Biosensors These are detectors that incorporate a biological agent such as an enzyme.
Chromatographic methods They are a means of separating chemical compounds in a sometimes complex mixture, usually by high-performance liquid chromatography (HPLC) or gas chromatography (GC).
Colorimetric detection It is a detection based on the absorbance of light of a particular wavelength, usually after producing a colored derivative of the analyte.
Gas chromatography (GC) It is a means of separating volatile organic compounds before detection. The separation is based on the different affinities of compounds for a solid stationary phase and mobile gas phase pumped through a column being heated slowly.
Gas chromatography–mass spectrometry (GC–MS) A combination of GC with a mass spectrometer as a means of identifying and measuring the compounds eluting from a column.
Glycoside It is an active compound bound to a carbohydrate (sugar) molecule.
High-performance liquid chromatography (HPLC) It is a means of separating nonvolatile organic compounds before detection. The separation is based on different affinities of compounds for a solid stationary phase and mobile liquid phase (solvent) pumped through a column.
Liquid chromatography–mass spectrometry (LC–MS) It is a combination of HPLC with a mass spectrometer as a means of identifying and measuring the compounds eluting from a column.
Rapid test kits These are usually portable kits that can be used to measure toxins outside a laboratory, often based on immunoassays.
Reverse-phase high-performance liquid chromatography It is a system of HPLC where the mobile liquid phase is more polar than the solid stationary phase. This is the most common type of HPLC.
Ultraviolet (UV) detection A means of detecting compounds eluting from an HPLC column by detecting their absorbance of UV light of certain wavelengths.

Introduction

Plants regularly cause poisonings on account of certain chemicals they contain. Plant toxins are generally secondary metabolites, that is, they are not essential for the plant to grow but have another function, usually in the plant's defense from animal and insect predators.

Poisonous plants affect nearly all living creatures from insects to humans. Their effects on humans vary from causing individual poisoning to mass outbreaks and from having relatively minor to rare fatal consequences. The means of human exposure varies from direct physical contact and intentional consumption through to accidental ingestion both directly and through contamination of plant- and animal-based foods. Ingestion of toxic plants is almost always deliberate and not accidental. Plants are eaten for food or because they are believed to have health benefits or desirable psychoactive properties. In other cases they may be consumed as an act of suicide.

Some toxin-containing plants are occasionally eaten on account of mistaken identity. Some common bulbs such as daffodils and tulip which are mildly toxic can be mistaken for onions. The fruits of toxic plants such as the very poisonous deadly nightshade appear similar to edible fruits such as blueberries, and the very toxic poison hemlock and hemlock water dropwort resemble wild versions of carrot, parsnip, and chervil.

Food preparation procedures are important in some cases. Lupin seeds need treatment and at home several raw beans need substantial cooking.

Natural herbal remedies have become very popular and can cause poisoning on account of poor knowledge of the plants' properties, misidentification, or lack of awareness of the potential dangers. Today regulation and licensing are addressing these issues in the developed world.

Poisoning can be caused by accidental overdose, overconsumption, or disbelief of the toxicity. Poisons can be transferred from plants to human foods in animal products such as milk, bird's eggs, and honey produced by bees foraging on toxic plants. Toxins can be present in some or all parts of plants including the roots, leaves, fruits, and seeds; and the toxin can be effective when taken internally or through skin contact. Poisonous plants are consumed as found or processed by drying or cooking. These activities affect the toxicity of most

poisonous plants. Many toxins can be deactivated by cooking, but others are concentrated by drying or by extraction into a tea-like beverage.

Some people, such as children and the infirm, are more at risk due to less effective immune systems and form the most important risk group. Very young children are at the highest risk from plant toxins as they regularly put almost anything of suitable size within reach into their mouths, and might find berries and leaves attractive. Poisons affect children more rapidly and severely because their body weight is much lower, thereby increasing the concentration of the toxins.

Some highly toxic plants including water hemlock (*Cicuta* sp.), poison hemlock (*Conium maculatum*), and hemlock water dropwort (*Oenanthe crocata*) contain highly dangerous toxins (cicutoxin, coniine, and oenanthotoxin, respectively). They are not food items but closely resemble edible foods and herbs such as parsnip and dill (**Figure 1**).

Cyanogenic Glycosides

Cyanogenic glycosides are compounds that are chemically bound to sugars and release cyanide in the form of hydrogen cyanide (HCN, prussic acid) under certain conditions, notably in an acid environment or through enzyme action. Many plant species can produce cyanide and over 50 cyanogenic glycosides are known.

Occurrence

In most parts of the world, plants containing cyanogenic glycosides are relatively uncommon dietary items. The major food plants that do contain cyanogenic glycosides are cassava (*Manihot esculenta*), sorghum (*Sorghum* spp.), and corn (*Zea mays*).

The concentration of cyanogenic glycosides in plants varies with many factors such as the organ, plant maturity, time of the year, and growing conditions. Most parts of the plants contain cyanogenic glycosides, with the highest concentrations in the young growth and seeds. The flesh of the ripe fruits remains edible.

The cyanide part of the molecule is synthesized from nitrate as a part of normal plant metabolism, but in competition with amino acid production. The glycosides are present in the vacuoles of the cells and are released when the cell walls are broken by chewing, grinding, or cooking. These processes also release the enzymes that cleave the cyanide–sugar bond, hence releasing the free toxin.

Cassava is a major foodstuff for many people in Africa and South America and is responsible for most cyanide poisoning

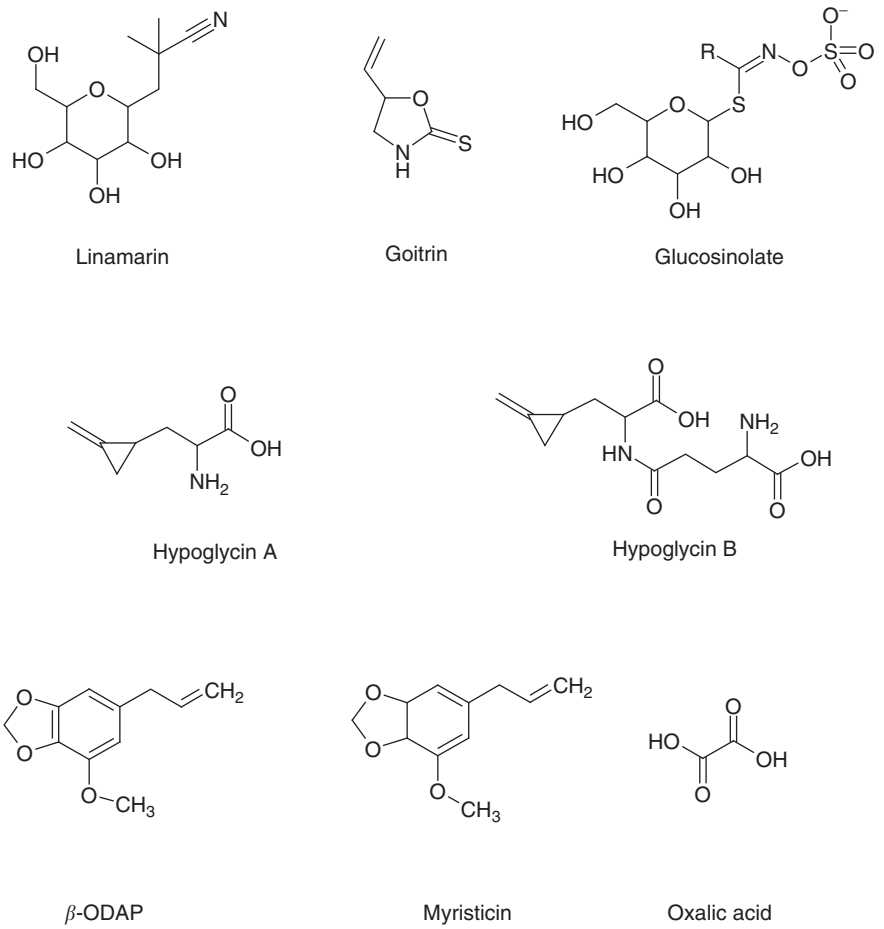

Figure 1 The structure of some important plant toxins.

Figure 2 Cassava root.

in humans. It contains cyanogenic glucosides, linamarin, and lotaustralin that are hydrolyzed by the endogenous enzyme linamarase when the plant is eaten or processed. The root of the cassava plant is eaten (Figure 2).

There have been two large epidemics of cassava poisoning in recent times, in the Democratic Republic of Congo from 1936–37 and in Mozambique in 1981, with many smaller outbreaks in other African countries.

Other food plants well known to be poisonous are several *Prunus* sp. comprising edible fruits such as apricot, cherry, peach, plum, and sloe and *Malus* sp. (apples and crab apples). The edible *Prunus* sp. are usually deciduous trees that are widely cultivated in temperate zones. The toxic glycosides are fortunately contained in the seed kernel, which is usually not consumed intentionally in a large quantity. Flax and white clover contain the glycosides linamarin and lotaustralin, sorghum contains dhurrin, and lima beans contain linamarin.

The cyanogenic glycoside found at high levels in bitter almond (*Prunus amygdalus*) is known as amygdalin or laetrile. In the 1970s, laetrile was popular as a cancer cure but was soon withdrawn on account of its toxicity and lack of evidence of its supposed beneficial properties.

Toxicity

In the body, cyanide released from the hydrolysis of cyanogenic glycosides deactivates cytochrome C oxidase in the mitochondria, disrupting electron transport and stopping aerobic respiration. As a consequence, oxygen is not extracted from the blood and death follows quickly.

Clinical Manifestations

The cyanide ion is readily absorbed from the intestinal and respiratory tracts and has a strong affinity for binding with trivalent iron of the cytochrome oxidase molecule, inhibiting its enzymatic action and preventing cellular respiration. The characteristic cherry red venous blood seen in acute cyanide poisoning results from the failure of the oxygen-saturated hemoglobin to release its oxygen to the tissues because the enzyme cytochrome oxidase is inhibited by the cyanide.

The body can detoxify cyanide quite quickly, so very small doses have no obvious effect. Small quantities of cyanide are detoxified by cellular enzymes and thiosulfates in many tissues to form relatively harmless thiocyanate, which is excreted in the urine. When large quantities of cyanide are rapidly absorbed and the body's detoxification mechanisms are overwhelmed, cyanide poisoning occurs. In most species, the lethal dose of HCN is in the range of 2–2.5 mg kg^{-1} bodyweight.

Low doses of cyanide are goitrogenic in humans and animals. Chronic exposure to low levels of cyanide causes goiter and tropical ataxic neuropathy, a disorder that damages the nerves and makes movements uncoordinated and eventual lameness occurs. Enlargement of the thyroid gland is caused by the formation of thiocyanate, which inhibits the intrathyroidal transfer of iodine and elevates the concentration of thyroid-stimulating hormone.

Moderate poisoning causes headache, tightness in throat and chest, and muscle weakness. Acute poisoning causes more severe effects, notably an irreversible paralytic disorder called Konzo, and sometimes death. Large doses (200–500 ppm) taken at once are often fatal. Konzo and tropical ataxic neuropathy often occur in local epidemics, especially during famines when proper cassava preparation procedures are neglected. Cyanide can also poison workers processing cassava when the HCN fumes are inhaled in enclosed spaces.

Diagnosis and Treatment

The appearance of toxic effects is usually delayed because the glycosides have to reach the gastrointestinal tract before hydrolysis releases cyanide. Tissues lose cyanide very rapidly, so samples must be analyzed quickly or frozen as soon as collected. Cyanide poisoning can be identified by measuring HCN in body fluids by the methods described above.

Treatment for cyanide poisoning consists of binding cyanide in a nontoxic form to reactive compounds. For this purpose intravenous injections of sodium nitrite and sodium thiosulfate are used. Sodium nitrite converts hemoglobin to methemoglobin that reacts with cyanide to form cyanomethemoglobin. This reactivates the cytochrome oxidase system. Sodium thiosulfate combines with cyanide to form sodium thiocyanate, which can be excreted rapidly.

Amyl nitrite is given by inhalation to stimulate respiration. Antidote kits are available containing sodium thiosulfate or hydroxocobalamin and amyl nitrite.

Mitigation

Selective breeding of certain varieties of plant species with naturally low glycoside content has resulted in varieties that are low in cyanogenic glycoside, and has increased their food value for humans and animals. The development of sweet almond varieties with low cyanogenic glycoside content has facilitated the human consumption of almond seeds.

Sorghum varieties low in cyanide have also been developed. Reduction of the enzyme levels can reduce the cassava's toxicity. The genes responsible for linamarin synthesis can be blocked by genetic engineering that can almost completely remove the cyanogenic glycoside content of the roots.

Cassava can be detoxified by chopping and grinding in running water to wash away the glycosides, but long-term consumption of cassava that has been poorly prepared in diets is quite common, resulting in the disease tropical ataxic neuropathy.

Fresh cassava roots rot rapidly and cannot be stored, so detoxification is sometimes neglected. Cassava processing procedures vary depending on the food products being prepared and on local cultural practices. In Africa, cassava is usually boiled or fermented by bacteria and molds in aerobic or fermentation methods. Fermentation and the associated crushing disintegrates the tissues, increasing the rate of glycoside hydrolysis and reducing cyanide by 70–95%. Drying, however, decreases the cyanide content of cassava by only 10–30% and boiling alone does not remove cyanide effectively.

Analysis

In a simple field test, paper strips containing salts of picric acid are used, picrate turns from yellow to red in an atmosphere containing HCN. The measurement of HCN released by chemical or enzyme treatment can also be made using rapid test kits and biosensors based on immobilized cyanidase, usually with colorimetric detection. Cyanogenic glycosides can be analyzed in the intact form by chromatographic methods such as capillary electrophoresis (CE), gas chromatography (GC), and high-performance liquid chromatography (HPLC) or HPLC/mass spectrometry (MS), sometimes with post-column enzymatic cleavage.

Saponins

Saponins are steroidal and triterpene compounds bound to sugar molecules. They produce soap-like foaming when shaken with water, having both a hydrophilic part (glycoside) and lipophilic part (triterpene). Some saponins act as antifeedants, protecting the plant from microbes, fungi, and animals. They may also have beneficial medicinal and dietary effects in humans.

Occurrence

Saponins are mostly associated with the plant ackee (*Blighia sapida*), the fruits of which are a popular food item in Jamaica. *Blighia sapida* is a tall tree found originally in Africa and introduced into the West Indies at the end of the seventeenth century. It also grows in Central America and southern parts of Florida. The fruits are pear-shaped, approximately 10-cm long and weigh approximately 100 g. When ripe, the reddish pericarp opens to reveal the shiny black seeds. The fruits usually contain three seeds, but in 30–50% of the fruits one or two of the seeds are very undeveloped. At the base of the seeds is a fleshy seed mantle (aril) which is cleaned of fibrous material, boiled in water, and eaten. The fruit is usually cooked by baking, or boiling in milk or water to produce a soup (Figure 3).

Figure 3 Ackee fruit showing the seeds and mantle.

Toxicity

The unripe fruits of ackee are poisonous, even after cooking. Consumption of the unripe fruits or of water in which the ackee fruit has been cooked may cause rupturing of the red blood cells (erythrocytes), technically known as hemolysis, leading to epidemics of hypoglycemia (lowered blood glucose). The plant mainly poisons young children who might be unaware of its effects. In Jamaica the condition is well known as 'Jamaican vomiting sickness.' Approximately 270 cases of poisoning were reported in Jamaica between 1980 and 1991.

The ackee fruit toxins are amino acids hypoglycin A and dipeptide hypoglycin B and the γ-glutamyl peptide of hypoglycin A. Hypoglycin A is 2-amino-4,5-methanohex-5-enoic acid or L-(methylenecyclopropyl)-alanine, and is the most toxic compound in the ackee fruit. It is found in the unripe seeds at a level of approximately 0.95% by weight and in the aril at approximately 0.7% by weight. The flesh of the fruit contains less than 0.04% hypoglycin A. Levels in the seed and aril decrease on ripening of the fruit.

Clinical Manifestations

Symptoms of poisoning often occur rapidly after consumption, beginning with intense thirst, severe and persistent vomiting without diarrhea, thus leading to dizziness, weakness and tiredness with tingling sensations (paresthesia), and twitching of the limbs. In severe cases consciousness is lost and coma and death can follow within a few days. The physiological effects are extreme hypoglycemia (low blood sugar) and hypokalemia (low blood potassium).

Hypoglycin A is metabolized to methylenecyclopropylacetic acid in the body, and it is this compound that is directly responsible for the ackee's toxicity. Methylenecyclopropylacetic acid inhibits the metabolism of fatty acids and affects acylCoA dehydrogenase. This leads to fatty acids accumulating in the blood serum. Glucose synthesis is prevented, and

glucose and hepatic glycogen are therefore depleted, leading to hypoglycemia.

Diagnosis and Treatment

Hypoglycemia can be detected by clinical tests, and further testing of blood electrolytes, kidney, and liver functions are advised, along with computed tomography scanning of the brain. The fatty acid profile shows an overabundant proportion of medium-chain fatty acids. Treatment consists of gastric lavage and attempted adsorption of the toxin on to activated charcoal, and actions to help breathing and correct electrolyte imbalance. Intravenous injections of glucose can correct hypoglycemia.

Mitigation

The fruits are banned in the US.

Analysis

Hypoglycin A can be determined using normal methods for amino acids analysis, such as using automated amino acid analyzers, but problems may be caused by coelution with the beneficial amino acids on chromatographic systems. Another approach is to use reverse-phase high-performance liquid chromatography with ultraviolet (UV) detection, after derivatization of the amino acid with *o*-phthalaldehyde, *o*-phenylisothiocyanate, or phenylthiocarbamate.

Glucosinolates

Glucosinolates are sulfur-containing oximes and glycosides associated with brassicas. They have both toxic and beneficial effects on the body, impairing thyroid function in both humans and animals at high doses, but at subtoxic doses, they act as chemoprotective agents against chemically induced carcinogens by blocking the initiation of tumors in a variety of rodent tissues, such as the liver, colon, mammary gland, pancreas, etc.

Occurrence

There are upwards of 200 individual glucosinolates. These are found in common vegetable foods of *Brassica* species, including cabbage, broccoli, cauliflower, and rapeseed. Spicy condiments such as mustard, horseradish, and wasabi owe their piquant nature to high concentrations of glucosinolates.

Toxicity

When the tissues of brassica plants are macerated or cooked, the glycosides are hydrolyzed to release volatile isothiocyanates or nitriles and thiocyanates. The major toxicity is associated with oxazolidine-2-thiones, such as goitrin (5-vinyloxazolidine-2-thione), which impair thyroid function by inhibiting the formation of thyroxine by binding iodine and suppressing thyroxine secretion from the thyroid.

The oil of the brassica rapeseed is often assumed to have cardiovascular toxicity on account of its high level of erucic acid. Despite evidence for this being rather poor, special varieties of low erucic acid rapeseed are now cultivated for edible oil production.

Nitriles released from glucosinolates depress growth and cause damage to the liver and kidneys in severe cases.

Clinical Manifestations

Exposure to toxic levels is revealed as goiter, liver damage, and stunted growth. However in many cases a swelling in the neck is the only symptom observed.

Diagnosis and Treatment

Diagnosis is by detection of thyroid abnormalities in the absence of physiological causes and a history of brassica ingestion. Treatment beyond withdrawal of the glucosinolate source is usually unnecessary

Mitigation

Ingestion of toxic levels of glucosinolates is uncommon and action to prevent exposure is unnecessary.

Analysis

Glucosinolates and derived isothiocyanates in vegetables are normally determined by LC–MS or GC–MS after extraction from plants with polar solvents such as mixtures of water and methanol.

Phytohemagglutinins (Kidney Bean Lectins)

Lectins are proteins that bind to soluble carbohydrates that are parts of glycoproteins or glycolipids. They cause agglutination (clumping together) of certain animal cells, and their function in plants is uncertain.

Occurrence

Red kidney beans (*Phaseolus vulgaris*) and several other beans contain the lectin phytohemagglutinin. This is a lectin that binds to oligosaccharides on the erythrocyte membrane, affecting protein transport across cell membranes and inducing mitosis. It agglutinates mammalian red blood cells causing nausea, vomiting, and diarrhea. It also affects transport systems across cell membranes, and cell permeability to proteins. Red kidney bean poisoning is known as Kinkoti bean poisoning (Figure 4).

Toxicity

Phytohemagglutinin is found in many types of beans, but red kidney beans contain more lectins than other species, typically three times the level found in white beans and ten times that found in broad beans. The toxin content of beans is measured

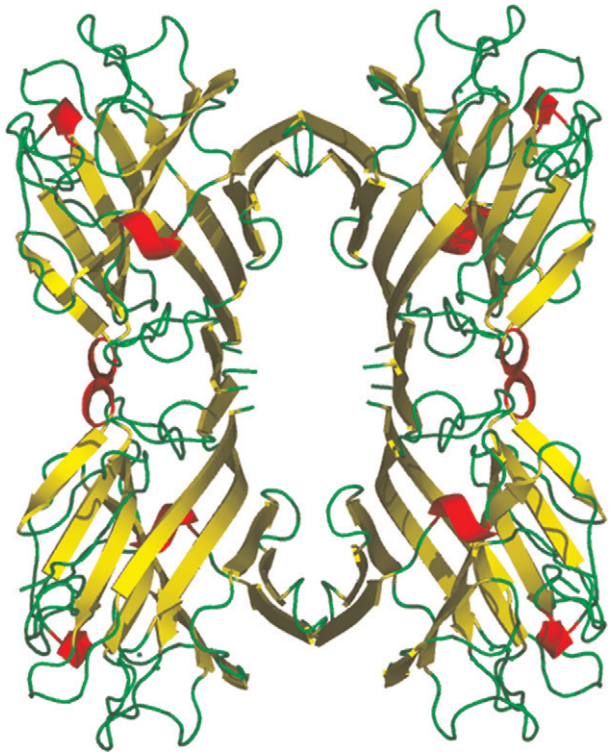

Figure 4 The structure of a phytohemagglutinin.

in hemagglutinating unit (hau), of which the raw kidney beans contain 20 000–70 000 hau. Cooking reduces the hemagglutinin activity levels to 200–400 hau.

Clinical Manifestations

Poisoning can be caused by ingestion of very few beans. Poisoning incidents are not uncommon.

Diagnosis and Treatment

Diagnosis probably often attributes the symptoms to more common causes such as bacterial food poisoning.

Symptoms are apparent between 1 and 3 h of consumption of improperly prepared beans. They begin with extreme nausea, followed by severe gastroenteritis, vomiting, and diarrhea. People affected usually recover very quickly, typically 3–4 h after the onset of symptoms.

Mitigation

Phytohemagglutinin can be deactivated by cooking the beans at 100 °C for 10 min, although much longer times are required to fully cook the beans. It is recommended that the dried beans are first soaked in water for a minimum of 5 h before cooking and then the soaking water is discarded. The cooking procedure is very important and the use of 'slow cookers' or other procedures operating at a relatively low temperature may not destroy the glycoprotein lectin; and warming might increase the toxicity of these foods.

Figure 5 The castor oil plant.

Analysis

Analysis of the toxins is indirect, based on hemagglutination of red blood cells.

Ricin

The castor oil plant (*Ricinus communis*) contains a highly poisonous proteinaceous toxin called ricin. A similar toxin called abrin is found in the plant jequirity (*Abrus precatorius*).

Occurrence and Exposure

The castor plant is a familiar tall annual or perennial with distinctive red stalks and large palmate green–red leaves and fruit pods and a distinctive spiky seed capsule. The attractive seeds, known as castor beans, are very hard, shiny, smooth, marbled, and approximately 17×8 mm in size, with a small protuberance. They contain ricin, which is an extremely toxic water-soluble protein. The seeds contain the highest amounts of ricin and some lesser toxins. Ricin seeds have a hard impermeable seed coat and are generally harmless when swallowed whole, but when chewed or otherwise broken the toxin can be released. Ricin poisoning can occur when broken seeds contaminate cereals, notably soya beans; intact seeds may pass through the digestive tract without releasing the toxin. The lethal dose in adults is considered to be 4–8 seeds (Figure 5).

Castor oil has qualities that gives it numerous industrial uses. In medicine it has famously a strong laxative action but it contains no toxin.

Abrus seeds are very distinctive, being glossy bright red in color and having a single black spot. The seeds are not knowingly eaten by adults but may be attractive to children.

Toxicity

Ricin binds to a specific adenine molecule of the 28S ribosomal ribonucleic acid (RNA) preventing protein synthesis. Poisoning symptoms are gastrointestinal hemorrhage; necrosis of liver, spleen, and kidneys; and a much increased raised white blood cell count.

Clinical Manifestations

If ingested, symptoms may be delayed by up to 36 h but commonly begin within 2–4 h. These include a burning sensation in mouth and throat, abdominal pain, purging, and bloody diarrhea. Within several days there is severe dehydration, drop in blood pressure, and decrease in urine. Unless treated, death can be expected to occur within 3–5 days.

Diagnosis and Treatment

There is no specific treatment beyond supporting care.

Mitigation

Exposure is best reduced by providing education regarding the toxic nature of the plant.

Analysis

Ricin can be detected by the application of tests to measure hemagglutionation. It is difficult to measure on account of its size and proteinaceous nature. It can however be quantified by HPLC with UV detection or by LC–MS applied to tryptic digests.

Ricin is accompanied by ricinine, a small alkaloid that can be determined by GC–MS or LC–MS as a marker of the likely presence of ricin.

Neurotoxic Amino Acids

Legumes of the species *Lathyrus* which grow in Europe, Asia, and Africa contain neurotoxic amino acids which cause large-scale disease epidemics.

Occurrence

The most familiar toxic Lathyrus species is *Lathyrus sativus* (Indian pea) which contains *β*-*N*-oxalylamino-L-alanine acid (*β*-ODAP), *β*-*N*-oxalyl-L-*α*,*β*-diaminopropionic acid, *β*-aminopropionitrile, and dimethylaminopropionitrile. *Lathyrus sativus* is cultivated in large quantities in several countries. The plant can be grown in soils and conditions that do not support safer primary crops. The peas are usually milled to produce flour, which is most often eaten when more preferred foods are unavailable, such as during famines. The concentration of *β*-ODAP in the seed can vary widely, from 0.2 mg to more than 1 mg g^{-1}.

Toxicity

The toxins cause paralysis of the lower body and wasting disease (neurolathyrism) if eaten over a long time. Consumption of the peas has caused major poisoning incidents, most recently in India in 1958 when over 25 000 people were poisoned in one district. *β*-ODAP is a nerve stimulating toxin acting as an agonist of certain nervous system glutamate receptors. It is found together with a nonneurotoxic isomer, *α*-ODAP. *β*-amino-propionitrile inhibits the enzyme lysyl oxidase, affecting the maturation of collagen.

Clinical Manifestations

The disease is manifested after several months of consumption as neurolathyrism. Symptoms of muscle spasms and leg muscle weakness develop, and paralysis ensues.

Diagnosis and Treatment

Diagnosis of lathyrism is based on evidence of consumption and paralysis with no other apparent cause. Lathyrism is treated mainly by withdrawal from the consumption of the peas.

Analysis

β-ODAP can be measured by LC after reaction with amine derivatization reagents such as *p*-nitrobenzyloxycarbonyl chloride. Isomerization of *β*-ODAP to *α*-ODAP should be inhibited where possible when a measure of the toxicity of a plant is required.

Mitigation

The neurotoxic amino acids can be removed from the seeds by soaking in water before cooking.

Oxalic Acid

Rhubarb (*Rheum rhabarbarum* L.) is a common and ,when in season, widely consumed plant in Europe and Asia. It is widely known that the leaves of the plant are poisonous, due to the content of oxalic acid.

Occurrence

Rhubarb is well known and widely found on many continents. The herb sorrel (*Rumex acetosa*) also contains oxalic acid and can cause similar kidney damage.

Toxicity

Serious poisonings are associated with consumption of the leaves of the plant, with the stems (petioles), which are normally the only parts consumed, being much less toxic. Children are poisoned more frequently than adults.

Rhubarb contains oxalic acid and dihydroxyanthracene derivatives. Oxalic acid is nephrotoxic and has a corrosive action, its lethal dose is approximately 10–25 g depending on age. In blood, oxalate binds to calcium to form an insoluble calcium oxalate, which can result in severe hypocalcemia and involuntary muscle contraction. Rhubarb leaves typically contain approximately 0.5% oxalic acid and much higher quantities of the nontoxic malic acid.

Cooking rhubarb with alkaline solutions containing sodium or potassium salts can increase their toxicity by forming soluble salts of oxalic acid.

Clinical Manifestations

Rhubarb poisoning causes abdominal pain, diarrhea, and profuse persistent vomiting, followed by internal bleeding, convulsions, and coma.

Diagnosis and Treatment

The symptoms of rhubarb leaf poisoning show clinical signs such as low production of urine (oliguria), excretion of acetone in the urine (acetonuria), and excessive albumin in the urine (albuminuria). In rare fatalities there are signs of damage to the kidneys.

Mitigation

Exposure can be reduced by warnings of the toxic effects of consuming the leaves and exercising moderation in the consumption of the stems.

Analysis

Treatment consists of gastric lavage with alkali and administration of a laxative (calcium sulfate) rich in calcium which forms an insoluble salt with oxalic acid.

Oxalic acid can be measured in rhubarb by HPLC, CE, or enzymatic methods based on the oxidation of the acid, derivatization, and colorimetric determination.

Minor Plant Toxins

Consumption of several other plants can have an adverse effect on certain individuals but the incidences are so few that they do not warrant the attention given to major plant toxins. Two examples of these are given below.

Avocado

The edible fruits (pears) of the avocado tree (*Persea americana*) are oblong and green with a knobbled green skin and edible greenish-yellow flesh surrounding a single large stone. Avocado is cultivated in many tropical and semitropical areas including Central America, Brazil, the US, and Israel. Avocado has a high content of tyramine which causes hypertension when consumed by patients taking monoamine oxidase inhibitor drugs. Another substance in avocado pears, 1-(acetyloxy)-2-hydroxy-12,15-heneicosadien-4-one (named persin) is known to damage the mammary gland of some animals, and some people are allergic to the fruit.

Nutmeg

The nut of the nutmeg tree (*Myristica fragrans*) contains the compounds myristicin and elemicin that have possible neurotoxic effects and may have psychoactive properties at high dose. The psychoactive effects are rather vague but include euphoria and nausea, and visual hallucinogenic effects are claimed; consequently, most poisoning results from deliberate ingestion of quantities far in excess of culinary portions. The effects last in excess of 24 h.

Conclusions

Our knowledge of plant toxins has improved considerably with the growth in medical and analytical science. The number of toxic plants consumed has probably increased slightly with improvements in the global distribution of foods and the increased awareness of and attraction to foreign diets. Contamination of food with toxic plants has possibly increased slowly with a reversion to 'natural' crop production methods, and the expansion of the geographical spread of plants with global warming. Population growth and climate change have contributed to the most serious plant toxicity problems, with drought and famine driving people to eat plants that are known to have toxicity. Better communications can provide aid, and developments in medicine and plant breeding can mitigate some problems, but the problem of plant toxins is likely to remain for the foreseeable future.

Mushrooms and Toadstools

D Clarke and C Crews, The Food and Environment Research Agency, York, UK

Glossary

Fungal toxin A chemical entity produced by fungi that may cause illness or death when eaten.
Inedible toadstool A fungi that when consumed produces a non-lethal gastric upset, which is not usually assigned to an individual toxin.
Mushrooms The edible fruiting bodies of fungi that are large enough to be picked by hand.
Rhabdomyolysis A rupture of muscles due to toxins or compression. Release of myoglobin leads to renal failure.
Toadstools The fruiting bodies of fungi that are classified as inedible or poisonous.

Introduction

Mushrooms are defined quite simply as the edible fruiting bodies of fungi, which are large enough to be picked by hand. Conversely, toadstools are the inedible, or poisonous, equivalents that are often mistaken for mushrooms.

Approximately 14 000 of the described fungi species from the estimated total of 1.5 million in the world produce fruiting bodies that are large enough to be considered as mushrooms or toadstools. The world market for the mushroom industry in 2005 was valued at more than US$45 billion. During the 1979 production year, button mushroom, *Agaricus bisporus*, accounted for more than 70% of the world's supply of edible mushrooms. The number of individuals engaging in foraging for wild mushrooms will always be unclear; the only solid data are the rates of poisonings.

General Safety

Recently, there has been a rapid change in the pattern of mushroom production in that many species, which were previously considered wild, are now grown commercially for food. This carries no inherent risk in itself as the feedstock cultures are collected from recognized local edible species in the wild and grown under controlled conditions until reproducible and economically viable production processes are established. This includes regular inspection to ensure that the mushrooms in growth are true to type and not outcompeted by any alternative or related species. The result of this is that even the smaller local supermarkets will routinely offer several different species of fresh mushrooms for sale that were previously considered as wild species.

The single biggest food safety aspect associated with mushrooms is basic food hygiene practice rather than chemical intoxication. Wild mushrooms are often contaminated with significant quantities of harmful bacteria. Insects can bore into the mushroom cap to lay their eggs and the burrowing tracks of the resultant larvae introduce bacteria deep into the cap, which cannot be removed by simply peeling and washing. Any unsound mushrooms, such as those with obvious damage and insect larvae, should not be collected and eaten.

The more widely recognized danger of a number of toadstool species is the chemical toxins that are contained within and their often lethal effects. These require oral ingestion of only a modest quantity to cause harm, but they can be handled quiet safety (and so no early warning signal is received) as there is little or no dermal absorption unless the toadstool is waterlogged and the juices are squeezed out onto bare skin. The dangers of eating poisonous mushrooms cannot be overstated. The greatest cause of poisoning is mistaken identity, where a forager assumes they can identify an edible species and collects a common look-alike poisonous species. It is essential to learn foraging skills alongside a trained and experienced professional, normally through a recognized fungal society, where training can be provided in identification of all species of mushroom, irrespective of classification as edible or inedible in locally published field guidebooks. Until a target mushroom and all of its look-alikes can be identified in juvenile, adult, and overripe forms, it is simply not safe to forage unsupervised with the intent to consume wild fungi.

The toxic properties of some mushrooms have been known throughout recorded history. Consumption of fly agaric (*Amanita muscaria*; **Figure 1**) for the ceremonial purpose of ritual intoxication predates written history. *Amanita* poisoning is ascribed to be the cause of the 'poisoning' of at least three Roman emperors and a Pope. More recently, in November 2012, four residents in a California senior-care facility died after consuming mushroom soup prepared by a caretaker, from fungi growing in the grounds of the facility. California alone recorded 1700 cases of mushroom-related illness, of the national total of 5902, with two fatalities during 2009–10.

Figure 1 The death cap mushroom *A. phalloides* (upper) and the fly agaric mushroom *A. muscaria* (lower).

A further potential risk to public safety are wild mushroom dishes in local restaurants. Although many of the species are now produced by safe commercial methods, the presence of a true wild mushroom risotto on a menu implies foraging has taken place. Wise diners would be advised to inquire as to such arrangements, and a manager should welcome the opportunity to reassure that a qualified professional collects and identifies any truly wild produce. A chef in Australia recently caused his own death and that of another diner with a dish prepared with 'mushrooms' he had collected himself.

Identification of fungi is then at the heart of mushroom safety. The fungi of the British Isles are considered the most studied in the world, which, with lichens included, is some 12 000 species. A selection of field guides are listed in the Further Reading section, and relevant local books should be sought, but even the best guides cover only 1000–2400 local species. A new method of fungi identification is the use of a computer-based system named MycoKey. Although recognized as a work in progress, version 4.0 now adequately covers more than 1000 genera that occur in Northern Europe and provides a visual identification system of measuring, drawing, and coloring the fungi to be named and requesting further details to differentiate between look-alikes until the fungus is identified to the genus level and it is clearer what detailed reference texts should be consulted.

Toxicity

Only a few percent of fungi are truly poisonous (2%) and a similarly low percentage are considered as choice edible species (4–5%). It is the species containing toxins and resulting in death that are of the highest degree of public concern. The more poisonous fungi often have appropriately evocative names such as Satan's bolete, yellow sickener, the deadly fiber cap, beechwood sickener, funeral bell, fools mushroom, and false morel.

As the number of individual chemicals identified in fungi that can be considered as harmful is too large to cover in any detail, this work is restricted in scope to those toxins for which there is clear evidence of lethal effect and toxicological data are available documenting the toxin as a lethal dose-50 (LD_{50}), the quantity of toxin required to kill 50% of those humans or animal surrogates who are exposed (Table 1). Individual sections are then given to the most toxic, those with LD_{50} values lower than 10 mg kg^{-1} bodyweight, where a dose of 0.6 g will then have a 1-in-2 chance (50%) of causing death to a 60 kg person, and which poses a real and significant hazard.

Table 1 Summary of mushroom toxins, their source, toxicity, and effects

Toxin class	*Toxin*	*Fungi species*	*LD_{50} mg kg^{-1}*	*Poisoning*
Acromelic acid	Acromelic acid	*Clitocybe acromelalga*		Acroduria – neuroexcitation
Cyanides	Hydrogen cyanide	*Lepista nuda*	3	Cyanosis
Cyclopeptides	Amatoxins	*Amanita phalloides*	0.2–0.5	Hepatic and renal failure
	Virotoxins	*Amanita verna*	2.5	Hepatic and renal failure
Cyclopropanes	Coprinine	*Coprinus atramentarius*	–	Antabuse syndrome
	Prop-2-ene carboxylic acid	*Russula subnigricans*	2.5	Rhabdomyolysis
Hallucinogens	Psilocybin	*Psilocybe semilanceata*	–	Hallucinations
	Bufotenine	*Amanita citrina*	200	Hallucinations
Hydrazine	Gyromitrin	*Gyromitra esculenta*	10–30	Convulsions and GI disorders
Isoxazoles	Muscimol	*Amanita muscaria*	7.5–10	Mycoatropinic and delirium
	Ibotenic acid	*Amanita pantherina*	45	Mycoatropinic and delirium
	Muscarine	*Clitocybe dealbata*	150	
	Tricholomic acid	*Tricholoma muscarium*		
Necatorin	Necatorin	*Lactarius necator*		
Norleucines	Aminohydroxyhexynoic acid	*Trogia venenata*	71	Sudden unexplained death
	Stizolobic acid	*A. pantherina*		Hallucination, spasms, and sleep
Nucleosides	Clitidine	*C. acromelalga*	50	Pain and red coloration of toes
Orellanines	Orellanine	*Cortinarius orellanus*	15–20	Renal failure
Terphenyls	Ustalic acid	*Tricholoma ustale*	Kills mice	Diarrhea, tremors, and death
Trichothecenes	Roridin	*Podostroma cornu-damae*	1	
	Verrucarin	*P. cornu-damae*	0.7	
	Satratoxin	*P. cornu-damae*	0.5	
Triterpenes	Hebevinosides	*Hebeloma vinosphyllum*	66	Paralysis
	Crustulinols	*Hebeloma crustuliniforme*	100	GI disorders and renal failure
	Fasciculols	*Naematoloma fasciculare*	50–168	
Sesquiterpenes	Illudin S	*Lampteromyces japonicus*	5	GI disorders
Lectins	Bolesatine	*Boletus satanas*	3.3	Hemolytic poisoning
	Rubescenslysine	*Amanita rubescens*	0.15–0.3	Hemolytic poisoning
	Phallolysin	*A. phalloides*	0.2–0.7	Hemolytic poisoning

Abbreviation: GI, gastrointestinal.

The actual risk is related to the range and quantities of toxins normally present in any given toadstool. As these are normal metabolic products rather than residual contaminants, the required levels of grams of toxin per kilogram of fresh toadstool are often surpassed in those fungi regarded as poisonous. As an illustration, a total of 500 mg kg^{-1} of amatoxins (LD_{50} 0.2–0.5 mg kg^{-1}) can be found in the death cap (*Amanita phalloides*; **Figure 1**) and this then requires only a 50 g portion of the fresh toadstool to be considered lethally dangerous. The named toxic classes and individual chemicals, a representative fungal source, toxicity, and medical symptoms are summarized in **Table 1**. In reality, some 95% of deaths from 'mushroom' poisoning are due to a single cause – the amatoxins, which are present in species found around the world. Research into medical treatments and supporting analytical chemistry has been heavily weighted toward this single genus–toxin combination as a direct result of the extremely low amount required to be toxic and the likelihood of misidentifying examples of the *Amanita* genus such as 'death caps' and 'destroying angels' with edible *Amanita* and *Volvariella* look-alikes. Nevertheless, new classes of toxins are still being identified after activity guided isolations of 'mushrooms' believed to have caused human deaths (**Figure 2**).

Many mushrooms that are neither choice edible nor poisonous species will often produce undesirable gastrointestinal symptoms that are unrelated to bacteria food poisoning. These symptoms often do not manifest in every consumer, which complicates disease etiology. Individual species in the genera – *Paxillus*, *Agaricus*, *Entoloma*, *Boletus*, *Hebeloma*, *Tricholoma*, *Russula*, *Lactarius*, *Ramaria*, *Chlorophyllum*, *Scleroderma*, and *Laetiporus* – are known to induce nausea, vomiting, abdominal pain, and diarrhea within hours of ingestion. Such symptoms, in the absence of true toxins, can be treated by rehydration but often require hospitalization.

The occurrence, toxicity, clinical manifestations, diagnosis, and treatment for some of the major toxin classes are summarized in **Table 1**. These are provided as illustrative only, and

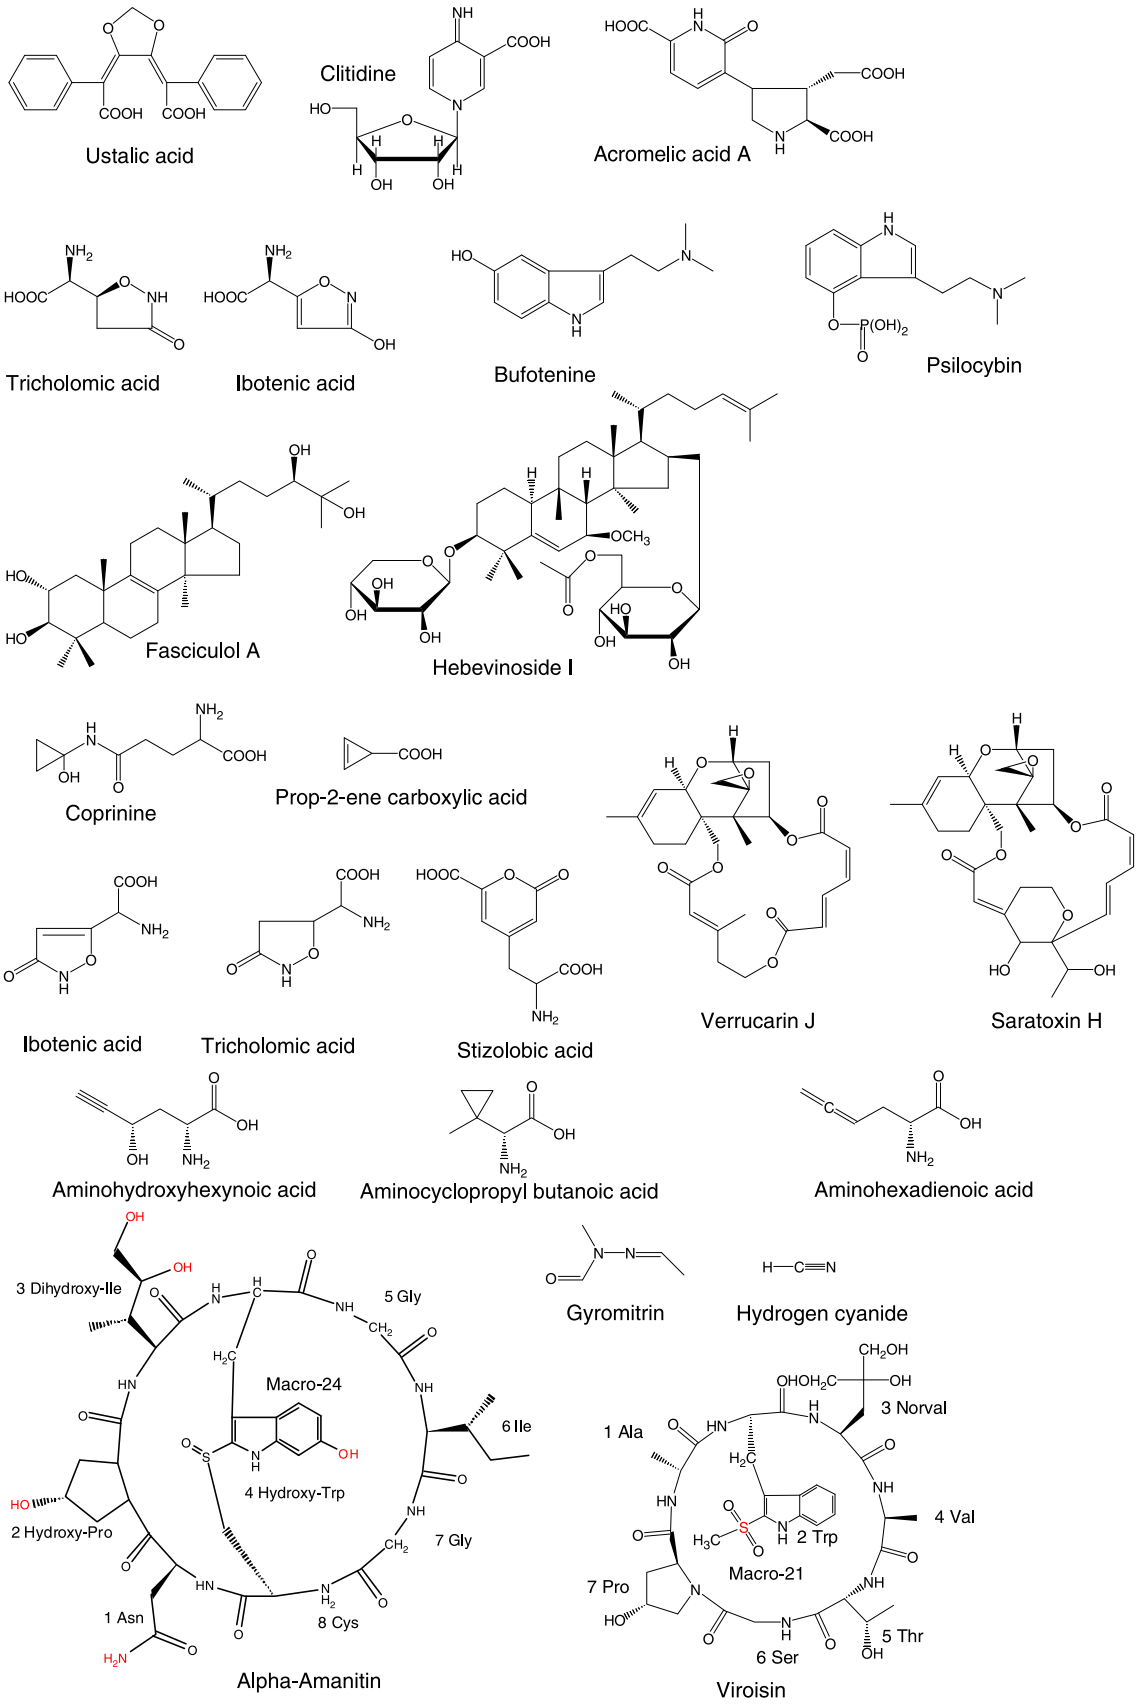

Figure 2 Structures of representative fungal toxins.

of course, expert medical advice and assistance should always be sought in the case of suspected poisoning.

Amatoxin Poisoning

Occurrence

Amatoxins are found in certain fungi in the unrelated genera *Amanita*, *Galerina*, *Lepiota*, and *Conocybe*. Of particular concern are the death cap *A. phalloides*, the European destroying angel (*Amanita virosa*), and the American destroying angel (*Amanita bisporigera* and *Amanita verna*). The sac-like volva from which the fruiting body arises is a distinguishing feature of the genus *Amanita*. A modern overview of the diagnosis and treatment of amatoxins mycosis has been published.

Toxicity

The cytotoxic agents present in these species are amatoxins and virotoxins. These toxins target the liver and inhibit transcription from deoxyribonucleic acid to messenger ribonucleic acid and impair protein synthesis, which leads to cell death.

Clinical Manifestations

The symptoms of severe gastrointestinal distress (stomach cramps, vomiting, and diarrhea) are delayed at least 6–12 h following ingestion. This phase lasts for 1–2 days followed by an apparent remission stage in which the patient feels better as the stomach is emptied. In the third phase, the patient may fall into a coma or die as a result of irreversible liver and kidney failure. The central nervous system deteriorates, and dehydration and exhaustion may impair kidney function, which is further complicated by renal damage.

Diagnosis and Treatment

There is no known antidote. Amatoxin poisoning is particularly dangerous because symptoms are delayed after the mushroom is eaten. By the time the patient feels sick, it is too late for emesis or gastric lavage to be of any use. The stomach can be emptied shortly after ingestion if no more than 2 h have passed. Treatment is on a case-by-case basis and involves careful monitoring of the patient's liver enzyme levels and general condition with supportive care. Charcoal filtration of the blood may be performed in some cases. Even patients who appear to have total remission often subsequently develop chronic active hepatitis. Liver transplantation may also be considered.

Orellanine: *Cortinarius* Poisoning

Occurrence

Orellanine is found in toadstools in the genus *Cortinarius*. This is the largest known fungi genus with 2000–3000 species. The individual species are extremely hard to distinguish and identify visually with any degree of accurately. Most of the lethal species such as *Cortinarius orellanus* and *Cortinarius speciosissimus* are a cinnamon brown color. The distinguishing feature of the genus is the presence of a cobwebby veil (the cortina).

Toxicity

Orellanine is a potent nephrotoxin. A metabolite of orellanine is believed to inhibit protein synthesis in the kidneys.

Clinical Manifestations

Cortinarius poisoning is characterized by an extremely long delay. A minimum of 3 days, or as long as 10 days to 3 weeks, may pass between eating the mushroom and the onset of symptoms. Symptoms include vomiting, diarrhea, loss of appetite, headache, a feeling of coldness, and eventual kidney failure, which may lead to death. Signs of renal impairment are headache, fatigue, thirst, chills, and abdominal, lumbar, and muscle pain.

Diagnosis and Treatment

Cortinarius poisoning is particularly dangerous because of the delay in the occurrence of symptoms. As most foragers simply avoid this genus, it is fortunately quite rare for the mushroom to be associated with the illness. It can be treated as kidney failure, by hemodialysis or peritoneal dialysis. Some patients recover spontaneously; others may require dialysis or kidney transplant.

Monomethylhydrazine Poisoning

Occurrence

Precursor toxins are found in toadstools of the genus *Gyromitra*, particularly in the false morel *Gyromitra esculenta*.

Toxicity

Monomethylhydrazine poisoning is among the most confusing of mushroom poisoning syndromes. The amount of the gyromitrin toxin can vary greatly from toadstool to toadstool, and susceptibility can vary greatly from person to person. The precursor gyromitrin toxin decomposes in the stomach to monomethylhydrazine, which reduces pyridoxine in the central nervous system. The method of preparing the mushrooms makes an immense difference to the toxicity as the toxin is volatile and is destroyed by heating. The 'safest' way to prepare *Gyromitra* species is to parboil the mushrooms (being careful not to inhale any of the vapors, which could contain the volatile toxin), discard the cooking water, and then fry the mushrooms in a clean pan. This removes the majority of the monomethylhydrazine.

Clinical Manifestations

A latent period of 6–8 h is followed by a feeling of fullness in the stomach, then vomiting and watery diarrhea, which may persist for up to 2 days. Headache, lassitude, cramps, and intense pain in the regions of the liver and stomach may be

followed by jaundice. Red blood cells may be broken down. Poisoning can be fatal.

Diagnosis and Treatment

Emesis may help if employed within 2 h after ingestion, but will be ineffective if symptoms have already occurred. Fluid replacement may be necessary if the patient is dehydrated. Patients should be hospitalized so laboratory tests can be performed to detect signs of hemolysis or liver or kidney failure. Glucose infusion prevents hypoglycemia. An infusion of pyridoxine at 25 mg kg^{-1} is generally given in cases affecting the central nervous system.

Antabuse Syndrome

Occurrence

It is caused by the fungi *Coprinus atramentarius*, *Clitocybe clavipes*, other *Coprinus* spp.

Toxicity

Coprinus species produce the compound coprine. This is not itself a poison but interferes with the alcohol detoxification process by inhibiting one of the enzymes (alcohol dehydrogenase) that processes alcohol. Alcohol is then broken down only partially to acetaldehyde. The symptoms of coprine poisoning are due to the build-up of acetaldehyde in the blood. Incidentally, the alcohol antabuse treatment disulfiram operates in the same manner, hence the syndrome being named 'antabuse.'

Clinical Manifestations

Symptoms may occur shortly after the consumption of both the fungus and an alcoholic beverage up to 48 h after the fungi is eaten. Symptoms include a flushing of the face and neck, a metallic taste in the mouth, tingling of the extremities, rapid heartbeat, and a feeling of swelling in the face and hands. The initial symptoms may be followed by nausea and vomiting. Occasionally visual disturbances, vertigo, weakness, and confusion occur.

Diagnosis and Treatment

The symptoms will subside on their own in time, although the patient may be convinced that he or she has been seriously poisoned. Coprine poisoning is unpleasant but will run its course in a couple of hours without treatment. *Coprinus atramentarius* is edible and safe if cooked and if no alcohol is ingested within 2–3 days of eating the fungi.

Tryptamine Hallucinogens

Occurrence

Psilocybin and related tryptamine substances are found in *Psilocybe*, *Stropharia*, *Panaeolus*, and in some species of *Conocybe* and *Gymnopilus*.

Toxicity

These tryptamines are hallucinogenic, and are not toxic themselves, but the hallucinogens often occur with other classes of dangerous toxin. Poisonings often occur when the fungi are used as recreational drugs. These hallucinogens produce pharmacological effects similar to lysergic acid diethylamide (LSD) by stimulation of central serotonin receptors and blocking of peripheral receptors.

Clinical Manifestations

A change of mood usually occurs 20–60 min after ingestion of the mushroom. The patient may experience an altered sense of space and time, fear, excitement, hilarity, hallucinations, vertigo, loss of coordination, anxiety, agitation, headache, nausea, dilation of pupils, seizures, rapid heart rate, or rapid breathing.

Diagnosis and Treatment

Poisoning is rarely serious in adults; moving a hallucinating patient to the hospital when in a disordered state may increase the sense of fear and confusion. Reassurance and time are usually sufficient treatment.

Muscimol and Ibotenic Acid

Occurrence

Primarily found in *A. muscaria* (Figure 1) and *Amanita pantherina*, but similar toxins may occur in *Amanita cothurnata*, *Amanita frostiana*, and *Amanita gemmata*.

Toxicity

Ibotenic acid is metabolized to the toxin muscimol, which causes the symptoms of this poisoning syndrome. The syndrome is produced by the body's efforts to process ibotenic acid. Muscimol is thought to bind to receptors in the brain, causing disordered neurotransmission. Some other *Amanita* spp. are less well studied and have rarely been eaten. Loss of muscular control may be pronounced. Poisonings, including fatal outcomes, are more likely to occur with *A. pantherina*, which contains higher levels of toxin than *A. muscaria*.

Clinical Manifestations

Drowsiness is experienced 30–60 min after ingestion, followed by a state resembling alcoholic intoxication. Following this, a hyperactive state of confusion, muscular spasms, delirium, and visual hallucinations occurs, lasting as long as 4 h. Vomiting usually does not take place. Drowsiness and deep sleep follow.

Diagnosis and Treatment

Recovery is usually quite rapid without treatment, though a fatality rate of 1–5% has been reported.

Muscarine

Occurrence

Muscarine is found in certain members of the genera *Inocybe* and *Clitocybe*. *Inocybe* spp. are often called 'fiber caps.'

Toxicity

The syndrome is not usually particularly dangerous, but is decidedly unpleasant. There are no recorded deaths due to poisoning by this toxin. The toxin attaches to acetyl cholinesterase receptors in the parasympathetic nerves and affects the organs supplied by these nerves.

Clinical Manifestations

The symptoms include perspiration, salivation, lacrymation, urination, defecation, gastritis, and emesis, which occur 30–120 min following ingestion.

Diagnosis and Treatment

Atropine is a specific antidote for muscarine poisoning. Atropine is toxic and should be administered only by a qualified physician. This is the only mushroom poison for which a specific antidote is known.

Unsaturated Norleucine Amino Acids

Occurrence

An undescribed toadstool species *Trogia venenata* has caused 260 deaths over 30 years, known as Yunnan sudden unexplained death (SUD) syndrome. Amino-hydroxy-hexynoic acid, an unsaturated acetylenic acid, has recently been identified as the active poison.

Toxicity

The cause of SUD was tracked epidemiologically to toadstools and a new species *Trogia venenta* was thereby identified and named as the cause. Two new amino acids 2*R*-amino-4*S*-hydroxy-5-hexynoic acid and 2*R*-amino-4*S*-5-hexynoic acid and a known toxin γ-guanidinobutyric acid were implicated. The new toxins have an LD_{50}s of 71 and 84 mg kg^{-1}, respectively. As observations of SUD suggested that cardiac muscle was affected, creatine kinase levels in serum were studied, but they were found not to be elevated as in rhabdomyolysis from cycloprop-2-ene carboxylic acid poisoning.

Clinical Manifestations

SUD may cause profound hypoglycamia within hours. The lack of serum glucose and depletion of adenosine triphosphate lead to neural cell death and a rapid fatal outcome.

Diagnosis and Treatment

Diagnosis is by postmortem determination of 2*R*-amino-4*S*-hydroxy-5-hexynoic acid in the blood of SUD victims. As this is a new syndrome, no treatment is as yet recommended.

Analytical Methods

The presence of toadstool toxins can by definition be established by universal bioassays using rodents to test the lethality of either the intact toadstool or specific fractions of its extract.

Traditionally toadstool toxins have been extremely difficult to measure precisely or accurately. The most powerful tool for identification and determination has hitherto been gas chromatography coupled with mass spectrometry. This technique, however, requires the molecule to be volatile. The few toxins that are volatile are too small for the best use of mass spectrometry and require derivatization to larger structures. Those toxins that are nonvolatile are too polar to chromatograph well and are derivatized to reduce polarity.

The most studied class of toxin has been amatoxins, in which the oligopeptide structures were more amenable to prevailing chromatography and detection techniques. Enzyme-linked immunosorbent assays and simple color-change tests are also used. Amatoxin poisoning is still routinely diagnosed by an acid-catalyzed condensation reaction between the amatoxin indole functional group and lignan-like components in lignan paper. The resultant complex gives a diagnostic blue-colored spot, but this perhaps simple conjugate has not yet been characterized.

Quantitative information on the identity and concentration of toadstool toxins can now be best achieved by modern liquid chromatography and mass spectrometry (LC–MS) techniques. Development of methods to identify and quantify the toxins will allow more effective diagnosis and treatment of poisonings. When working with unknown toxins, this must still be linked to a bioassay to prove the cause and effect.

Modern LC–MS methods are well positioned to help resolve the identification challenges. Development of a universal method to identify and quantify the toxins would allow more effective diagnosis and treatment of poisonings. However, given the diversity of these toxins and their mechanisms of toxicity, the development of such a universal method is not likely in the near future.

There are several more documented poisoning syndromes under study, and it can be expected that further toxins and their diseases will continue to be defined. These include Paxillus syndrome from long-term ingestion of *Paxillus involutus*, encephalopathy after ingestion of *Hapalopilus rutilans* experienced in Germany, and *Pleurocybella porrigens* poisonings in Japan. It is noted that many of the toxins that have resisted identification will be of a more complex chemical structure. In the *P. porrigens* example, a heat-stable high-molecular-weight toxin releases the sugar *N*-glycolylneuraminic acid. In *Amanita smithiana* the novel toxin may be an amino sugar, a conjugate of a norleucine hexadienoic acid and an as yet undefined sugar.

It was noted during the initial work on LSD in the 1960s that further indoles of a similar or greater psychoactive effect than LSD were present in *Boletus manicus*, a mushroom known for its visual and auditory hallucinogenic effects from the Western Highlands of Papua New Guinea. The field of hallucinogenic fungal compounds is an aspect of food safety not receiving great attention.

Conclusions

Many new fungal poisoning syndromes have been described since the early 1990s. This greatly increases the number of classes of potential toxin chemicals in fungi that require consideration when collecting wild fungi, or attempting to diagnose and treat a suspected poisoning.

NATURAL TOXICANTS

Tetrodotoxin

K Campbell and S Haughey, Queen's University Belfast, Belfast, UK

Glossary

Biosensor An analytical tool that detects an analyte through the conversion of a biological response into an electrical signal with a physicochemical detector.

Neurotoxin A toxic component that targets specifically nerve cells or neurons primarily by interacting with membrane proteins such as ion channels.

Regulation A principle, rule, or law designed to control or govern conduct.

Tetrodotoxin Potent neurotoxin produced by bacteria.

Toxicity The degree by which something is poisonous to an organism.

History and Background

Tetrodotoxin (CAS number 4368-28-9) is a powerful, low molecular weight (~319 Dalton (Da)), naturally occurring neurotoxin. It is named from the Teleost fish order Tetrodontiformes from which the toxin was first isolated and described. This fish species received their name because they have four very strong teeth that almost fuse together to form a beak-like structure, which they use to chew and crack shells open to get food. Tetrodontid fish, which include puffer fish or *fugu*, are long established as being toxic (Figure 1).

There is evidence from the early Egyptians (fifth dynasty, *ca*. 2500 BC), Chinese herbal medical writings (*ca*. 200 BC), the logs of Captain James Cook (1774), and other historical texts (e.g., Kaempfer's *History of Japan*) that there was an awareness and knowledge of the toxicity associated with these fish. The first report of formal research into the pharmacology of tetrodotoxin was by Charles Remy in 1883 who described the symptoms of tetrodotoxin poisoning and documented the high concentrations of tetrodotoxin present in the gonads of puffers. Tetrodotoxin was formally named in 1909 by Dr Yoshizmi Tahara who isolated and prepared a crude extract from puffer fish. Pure crystalline tetrodotoxin was not isolated until 1950 when Yokoo isolated tetrodotoxin from the ovaries of *Fugu rubripes* and described it as spheroidine after a genus of puffer fish. The nomenclature of tetrodotoxin was corroborated in 1952 when Tsuda and Kawamura isolated an identical toxin using chromatographic methods. Since the 1960s, the chemistry, pharmacology, and synthesis of tetrodotoxin have been the subject of a voluminous body of work and reviews. The complete low molecular weight (319 Da) structure of tetrodotoxin was first described in 1964 at the Natural Products Symposium of the International Union of Pure and Applied Chemistry by a total of four different laboratory groups including Tsuda, Goto, Woodward, and Mosher. It is important to note that while three of these groups had been working on toxin isolated from puffer fish, the Mosher group was reporting on compound, they named tarichatoxin, isolated from eggs of the newt *Taricha torosa* (Figure 2).

Figure 3 Examples of other species known to contain tetrodotoxin.

Occurence of Tetrodotoxin

Tetrodotoxin now has been found in a wide genre of species. Other marine organisms have been found to store tetrodotoxin and include the Australian blue-ringed octopus (*Hapaloclaena maculosa*, which uses tetrodotoxin as a toxin for capturing prey), parrot fish, triggerfish, goby, angelfish, boxfish (*Ostracion* spp.), tobies, porcupine fish, molas or ocean sunfish, globefish, seastars, starfish (*Astropecten scoparius)*, xanthid crabs (*Eriphia* spp.), a horseshoe crab (*Carcinoscorpius rotundicauda)*, two Philippine crabs (*Zosimus aeneus* and *Atergatis floridus*), a number of marine snails, flatworms, sea squirts, several nemerteans (ribbonworms), and several species of *Chaetognatha* (arrow worms), which use tetrodotoxin as a venom for prey, molluscs (*Nassarius* spp. and the Japanese trumpet shell Boshubora), and marine algae (*Jania* spp.). Terrestrial organisms include the Harlequin frogs (*Atelopus* spp.), Costa Rican frog (*Atelopus chiriquiensis*), three species of California newt (*Taricha* spp.), and members of the Salamandridae (salamanders). The number of species found to contain tetrodotoxin continues to grow (Figure 3).

It is unlikely that these tetrodotoxin-bearers possess a common gene that codes for tetrodotoxin production. The ecologic environments of tetrodotoxin-bearing animals seem to have no common factor other than being closely related to an aquatic system. Bacteria, omnipresent organisms that commonly inhabit the aquatic system, are implicated as the primary source of tetrodotoxin. The bacteria believed to be involved are *Shewanella alga* (Figure 4), *Vibrio* species, *Alteromonas* species, and *Pseudomonas* species and their proposed mechanism of tetrodotoxin accumulation in marine animals was described by Noguchi and Arakawa using the flow chart (Figure 5).

Therefore, the tetrodotoxin of puffer fish is not endogenous (produced by the puffer fish itself), but exogenous (taken from outside and accumulated) via the food chain. It has been suggested that the puffer fish accrue tetrodotoxin as a biological defense agent. There appears to be a symbiotic association between tetrodotoxin-producing bacteria and higher organisms, which offers distinct advantages to both partners. The bacteria have a host as a safe place to live, eat, and reproduce whereas the host uses the toxin for predation or defense or both. The normal visual defense mechanism for slow-swimming and clumsy pufferfishes is their ability to inflate to several times their normal size by swallowing air when threatened, and tetrodotoxin may be an inadvertent weapon. Generally, they are left alone by predators.

Synthesis of Tetrodotoxin

In 1972, the first total synthesis of D,L-tetrodotoxin was described by Yoshito Kishi and co-workers at Nagoya University, Nagoya, Japan. In 2003, Isobe and co-workers at Nagoya University and Du Bois and co-workers at Stanford University, USA, reported the asymmetric total synthesis of tetrodotoxin by two different synthetic approaches. Isobe's synthesis was based on a Diels–Alder approach and Du Bois's synthesis involved C–H bond activation.

Structure and Mode of Action

Tetrodotoxin is known as a guanidinium toxin as it consists of a positively charged guanidinium group made up of three nitrogen atoms incorporated as part of a pyrimidine ring with additional fused ring systems.

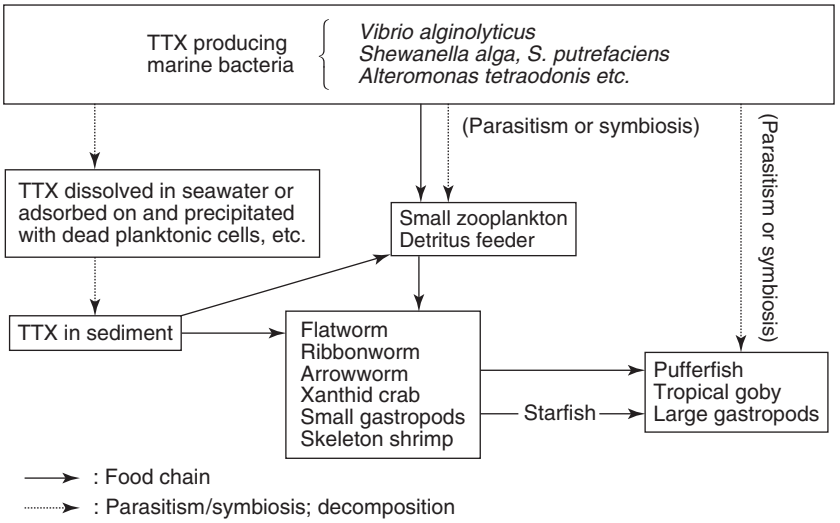

Figure 5 Flow diagram of mechanism of tetrodotoxin accumulation. Reproduced from Noguchi T and Arakawa O (2008) Tetrodotoxin – Distribution and accumulation in aquatic organisms, and cases of human intoxication. *Marine Drugs* 6: 220–242.

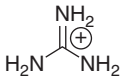

Guanidinium group

The ring systems, of which there are five in total, contain hydroxyl groups. Modifications of the parent compound can occur at five sites designated R_1–R_5 and the main modification at these sites are primarily hydrogen to hydroxyl substitutions. The chemical structure of tetrodotoxin and its derivatives are highlighted (Figure 6).

Tetrodotoxin is an extremely potent neurotoxin, specifically blocking voltage-gated sodium channels on the surface of nerve membranes. The flow of sodium ions into nerve cells is a necessary step in the conduction of nerve impulses in excitable nerve fibers and along axons. Normal axon cells have high concentrations of K^+ ions and low concentrations of Na^+ ions and have a negative potential. Stimulation of the axon results in an action potential, which arises from a flow of Na^+ ions into the cell and the generation of a positive membrane potential. Propagation of this depolarization along the nerve terminal presages all other events. The Na^+ ions flow through the cellular membrane employing the sodium-ion channel, a channel that is selective for sodium ions over potassium ions by an order of magnitude. The sodium channel itself is made up of a single peptide chain with four repeating units with each unit consisting of six trans-membrane helices. The trans-membrane pore is formed when the four units fold into a cluster with the center of the cluster being the pore.

Tetrodotoxin acts by competing with the hydrated sodium cation for the sodium channel. It is proposed that the binding occurs through the positively charged guanidinium group of the tetrodotoxin molecule and negatively charged carboxylate groups on side chains in the mouth of the channel. The guanidinium group fits into the external orifice of sodium channels, but the rest of the molecule is too large to penetrate the channels, acting like a cork in a bottle. This results in plugging the sodium channels from outside preventing the flow of sodium ions into the channel, effectively shutting down sodium movement; thus, the conduction of nerve impulses along nerve fibers and axons ceases. Tetrodotoxin is quite specific in blocking the sodium-ion channel (and, therefore, the flow of sodium ions) while having no effect on potassium ions. Binding to the channel is relatively tight ($Kd = 10^{-10}$ nM). The hydrated sodium ion binds reversibly on a nanosecond time-scale, whereas tetrodotoxin is bound for tens of seconds. The different tetrodotoxin derivatives display different binding affinities to the channel based on the changes in their chemical structure (Figure 7).

The Japanese tiger puffer fish, *F. rubripes*, has been the subject of intensive genetic sequencing studies. A single point mutation in the amino acid sequence of the sodium-ion channel in this species causes it to be immune from being bound and blockaded by tetrodotoxin. Changing the amino acid sequence of any protein alters its structure, and, therefore, its function. Such spontaneous mutations occur frequently in animal populations. Most such changes are neutral or disadvantageous to an organism's survival, but occasionally one confers a selective advantage. In the case of *F. rubripes*, one tiny change enabled the fish to incorporate tetrodotoxin-producing bacteria into its tissues and use the toxin to its own advantage.

Toxicity

The intravenous and oral median lethal doses for mice are reported as 7.3 and 334 μg kg^{-1}, respectively, in mice. On the presumption that these doses are comparable for humans, 0.5 and 25 mg of tetrodotoxin would be expected to kill a 75 kg

	R_1	R_2	R_3	R_4	R_5

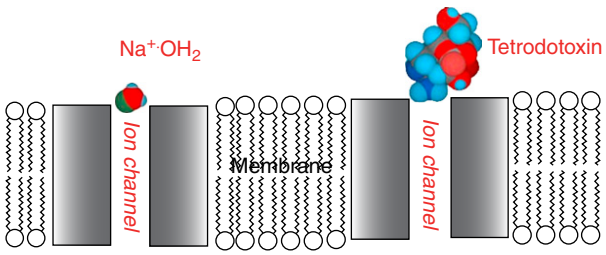

Figure 7 Illustration of tetrodotoxin binding to the sodium ion channel.

person by injection and through consumption. Commonly, reports of a human mortal dose of tetrodotoxin are 1–2 mg with the victim eventually dying from respiratory paralysis.

Tetrodotoxin is 10–100 times as lethal as black widow spider venom (depending on the species) when administered to mice, and more than 10 000 times deadlier than cyanide. It has a similar toxicity as saxitoxin, which causes paralytic shellfish poisoning and also blocks the sodium channel – both are found in the tissues of puffer fish. A recently discovered naturally occurring congener of tetrodotoxin has proven to be four to five times as potent as tetrodotoxin. Except for a few bacterial protein toxins, only palytoxin, a bizarre molecule isolated from certain zoanthideans (small, colonial, marine organisms resembling sea anemones) of the genus *Palythoa*, and maitotoxin, found in certain fishes associated with ciguatera poisoning, are known to be significantly more toxic than tetrodotoxin. Palytoxin and maitotoxin have potencies nearly 100 times that of tetrodotoxin and saxitoxin, and all four toxins are unusual in being nonproteins.

Clinical Manifestations

The first symptoms occur between 15 min and several hours postingestion of tetrodotoxin-containing food. Almost all toxicity is caused by the ingestion of fugu, but other species of animals have been shown to produce tetrodotoxin (e.g., California newt, parrot fish, and blue-ringed octopus). A death from ingestion of tetrodotoxin from a California newt has been documented.

A recent report on toxicity found that initial symptoms may occur up to 20 h after ingestion. Initial symptoms include lip and tongue paresthesias, followed by facial and extremity paresthesias and numbness. Salivation, nausea, vomiting, and diarrhea with abdominal pain develop early. Motor dysfunction with weakness, hypoventilation (may be from dysfunction of central and peripheral nervous systems), and speech difficulties then develop. A rapid ascending paralysis occurs over 4–24 h. Extremity paralysis precedes bulbar paralysis, which is followed by respiratory muscle paralysis. Deep tendon reflexes are preserved early in the course of paralysis. Finally, cardiac dysfunction with hypotension and dysrhythmias (bradycardia), central nervous system (CNS) dysfunction (e.g., coma), and seizures develop. Patients with severe toxicity may have deep coma, fixed nonreactive pupils, apnea, and loss of all brain stem reflexes. Death can occur within 4–6 h. Typically, death occurs from respiratory muscle paralysis and respiratory failure.

Prognosis

Mortality rates are difficult to establish though estimates as high as 200 cases per year with mortality approaching 50% have been reported in spite of good supportive care. Symptoms may last several days even in nonlethal ingestions, but prognosis is reported to be good if the patient survives the first 24 h. Tetrodotoxin is absorbed with activated charcoal. The treatment is symptomatic and supportive with special attention to airway management and cardiac support. Only a few cases have been reported in the US, and outbreaks in countries outside the Indo-Pacific area are rare.

Hazard Characterization

Since 1958 in Tokyo, it is required that specially trained fish cutters or chefs have a license to process and prepare puffer fish. It can take up to 11 years to become a fully competent fugu chef commencing with a 3-year apprenticeship in separating edible and inedible parts. Fugu may be prepared only in kitchens used solely for this purpose. Remarkably, even the waste from fugu preparation must be disposed off in hermetically sealed containers handled by specially trained companies as homeless people may scavenge the bins for food. However, there is no centralized regulation and it is difficult to say for sure who is licensed and who is not with only 19 of Japan's 47 prefectures requiring chefs to pass an exam to obtain a fugu license (Figure 8).

The Food and Drug Administration (FDA) advises consumers in the USA to eat puffer fish (fugu, bok, blowfish, globefish, swellfish, balloonfish, or sea squab) only from two recommended sources. The sources are imported puffer fish that have been processed and prepared by specially trained and certified fish cutters in the city of Shimonoseki, Japan, and puffer fish caught in the mid-Atlantic coastal waters of the US, typically between Virginia and New York. Puffer fish are imported into the US two to three times per year for special occasions, by only one approved New York importer, Wako International, under an FDA/Japanese Government agreement. This is the only acceptable source of imported puffer fish.

Figure 8 Licensed chef in Japan preparing fugu from puffer fish.

A number of the reported poisoning incidences, however, arise from recreational fisherman whereby the fish is mis- or unidentified as being potentially poisonous and consumed by families in rural fishing areas.

Risk Management

Japan is currently the only country to have a regulatory level established for tetrodotoxin in puffer fish at 2000 $\mu g\,kg^{-1}$ of fish. In the USA, it is illegal to import puffer fish but problems do arise due to mislabeling of imported products. The unpublished action limit in other countries for tetrodotoxin is the same as that for paralytic shellfish poisoning toxins, saxitoxin, at 800 $\mu g\,kg^{-1}$ of fish. Below these levels, the fish is deemed fit or safe for consumption. A total of 22 species of puffer fish, all belonging to the Tetraodontidae family, are currently registered as tetrodotoxin poisoning. The levels found in puffer fish vary depending not only on the species but also in the different organs with the dispersal appearing to be species-specific. In marine species, the liver and ovary commonly have the highest toxicity, followed by intestines and skin. Muscles and testis are normally nontoxic or weakly toxic and are regarded as edible by the Japanese Ministry of Health, Labor, and Welfare. The liver generally displays very high toxicity during the year except in the spawning season, at which time the ovary becomes highly toxic through the buildup of tetrodotoxin transferred from the liver. One theory is that tetrodotoxin in the eggs spawned from the ovary could play a role in protecting the eggs from predators. Similarly, when toxic puffer fish are threatened, their bodies swell to two or three times their usual size and tetrodotoxin is postulated to

be excreted from their skin to fend off their attacker. Levels of 160 000 μg kg^{-1} have been reported in the liver.

To reduce poisoning incidents, particularly in Asia, recreational fishermen and consumers should be instructed through food safety campaigns about which puffer fish is edible or inedible. It is believed that this may help official authorities to regulate the capture and consumption of toxic puffer fish species in China in order to avoid the risk of lethal poisoning.

Methods of Analysis

In Japan, puffer fish intended for human consumption are tested using the mouse bioassay. However, the mouse bioassay shows low precision and also requires a continuous supply of mice, which is unethical. Tetrodotoxin can also be tested by high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), capillary zone electrophoresis, gas chromatography–mass spectrometry (GC–MS), and liquid chromatography–mass spectrometry (LC–MS). These methods are accurate, but may be extremely slow as they require extensive sample clean up extraction steps and, therefore, cannot allow rapid screening when large numbers of sample analysis are required and the instrumentation can be expensive.

Biosensors have been highlighted as alternatives to current Regulatory Methods for marine biotoxins including (1) the use of an antitetrodotoxin specific antibody as the biological reporter and amperometric detection with a screen-printed electrode in an indirect competition assay; (2) differential pulse voltametry with screen-printed electrode in the form of a competition immunoassay; (3) a tissue biosensor has been developed with frog bladder membranes, which have a high concentration of Na^+ channels and, therefore, a Na^+ specific electrode measures the transport of Na^+ through the membrane and its dose-dependent inhibition by tetrodotoxin; (4) tetrodotoxin biosensor based on inhibition of cell function has been designed using murine spinal cord neuronal networks cultured on microelectrode arrays where the biological response is monitored as extracellular potentials; and (5) several enzyme-linked immunosorbent assays have been developed as well for the detection of this toxin, some of them preparing the ground for the development of the electrochemical antibody-based biosensors. More recent methods for tetrodotoxin detection have been employed using surface plasmon resonance and fluidic force discrimination that achieve low levels of sensitivity.

MYCOTOXINS

Contents

Mycotoxins – General

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Glossary

Mycotoxicosis A disease caused by a mycotoxin.

Secondary metabolite A chemical compound produced by an organism during growth, but not part of primary metabolism.

Mycotoxins and History

Mycotoxins are fungal metabolites, which when ingested, inhaled, or absorbed through the skin, can cause sickness or death in humans or domestic animals, including birds. By common agreement, toxins ingested when fungi are eaten as food (mushrooms) are excluded, as are compounds that show toxicity only to lower animals, such as insects or plants.

Mycotoxins have been responsible for major epidemics in humans and animals throughout history. The most important epidemics have been ergotism, due to growth of the fungus *Claviceps purpurea* in rye grains, which killed and maimed hundreds of thousands of people in Europe in the past millennium; alimentary toxic aleukia, caused by T-2 toxin produced by *Fusarium sporotrichioides* in grain, which was responsible for the death of at least 100 000 Russian people between 1942 and 1948; and stachybotryotoxicosis, caused by growth of *Stachybotrys chartarum* in hay, which killed tens of thousands of horses in the USSR in the 1930s. With the possible exception of ergotism, these diseases are causing little problem at the present time.

Despite a few excellent studies of disease due to molds in food or feed in the first half of the twentieth century, understanding of the significance of mycotoxins in human and animal health came only more recently. The term mycotoxicosis was first used in 1952 for the diseases resulting from the growth of fungi in foods and feeds. The event that ushered in the modern era of mycotoxin investigation was the discovery of aflatoxins due to the growth of *Aspergillus parasiticus* in a peanut meal, which killed 100 000 young turkeys in the UK in 1960. Laboratory experiments and the investigation of field outbreaks of the disease rapidly led to the discovery that many commonly occurring fungi – both spoilage fungi (the molds) and plant pathogens – are able to produce a staggering array of toxic secondary metabolites, many with chemical structures of types never before encountered in natural product chemistry.

Chemical Characterization

Mycotoxins are secondary metabolites, i.e., they appear to have no role in the normal metabolism concerned with growth of the fungus and they are usually, though not exclusively, produced as the fungus matures. They are frequently bizarre molecules, with structures ranging from single heterocyclic rings with molecular weights of scarcely 50, to groups of irregularly arranged 6- or 8-membered rings with total molecular weights greater than 500 (Figure 1). Some, such as patulin, appear to be relatively isolated compounds, whereas others, most notably the trichothecenes, exist as a family of 100 or more compounds, all fungal metabolites. No particular group of atoms or moiety can be considered to define 'mycotoxin,' as the active groups vary widely among classes of toxins.

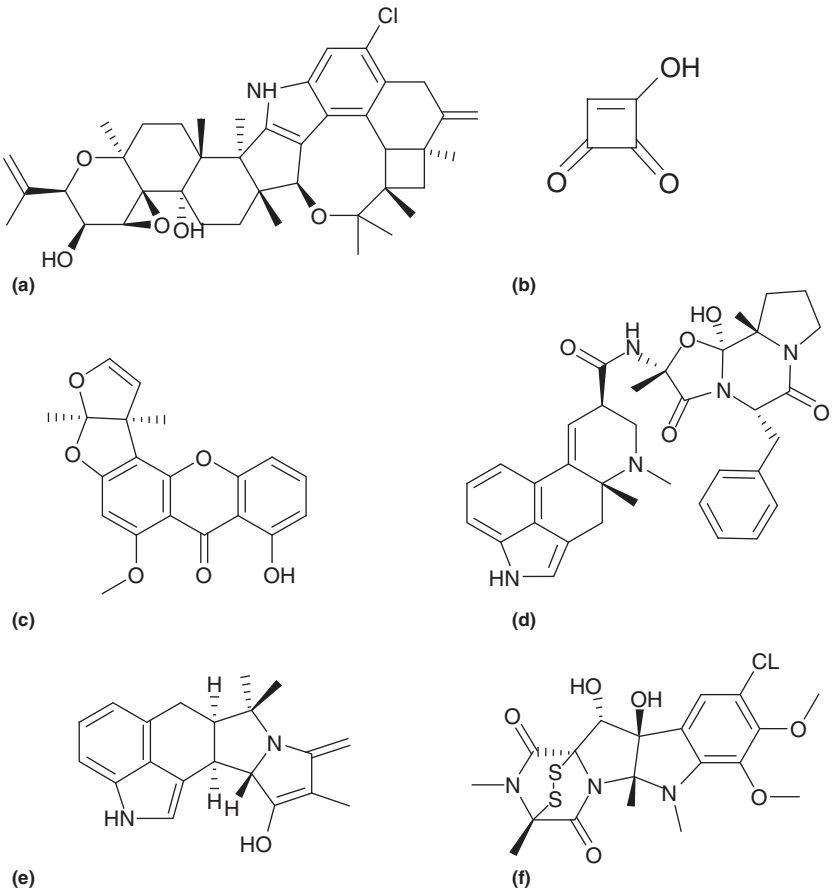

Figure 1 Chemical structures of some mycotoxins. (a) Penitrem A; (b) moniliformin; (c) sterigmatocystin; (d) ergotamine; (e) cyclopiazonic acid; (f) sporidesmin.

Hazard Identification and Characterization

Mycotoxins exhibit four basic kinds of toxicity: acute, chronic, mutagenic, and teratogenic. The most commonly described effect of acute mycotoxin poisoning is deterioration of liver or kidney function, which in extreme cases may lead to death. However, some mycotoxins act primarily by interfering with protein synthesis, and produce effects ranging from skin sensitivity or necrosis to extreme immunodeficiency, which can lead to death from infectious agents. Others are neurotoxins, which in low doses may cause sustained trembling in animals, but at only slightly higher levels, can cause permanent brain damage or death.

Long term effects of low levels of mycotoxin ingestion are also varied. The prime chronic effect of many mycotoxins is the induction of cancer, especially of the liver. Some toxins affect DNA replication, and hence, can produce mutagenic or teratogenic effects.

Unlike bacterial toxins, most mycotoxins are not proteinaceous in character and, being relatively small molecules, are not usually detectable by the immune systems of humans or animals. A major potential danger of mycotoxins in the human diet, therefore, resides in our inability to detect them biologically i.e., in the absence of antibodies.

The symptoms of mycotoxin poisoning are almost as diverse as the chemical structures of the compounds themselves. Some compounds may elicit few symptoms until death results, whereas others may induce severe effects including skin necrosis, leukopenia, and immunosuppression. Doses producing chronic disease are usually far below those responsible for acute effects, and hence long term effects, such as cancer or tumor induction, are undetected at the time of ingestion, and indeed may remain so until the disease is quite advanced. Epidemiological studies on mycotoxins are difficult to conduct and interpret because of uncertainties in the duration and level of exposure. A complication is that mycotoxins in animal feed may in some cases reach detectable levels in edible tissues, such as meat, eggs, and milk. Consequently, the possible presence of mycotoxins in animal tissues may be of importance for hazard identification.

Fungal Sources

Many mycotoxigenic fungi are of widespread occurrence, and indeed in some cases appear to have a strong ecological link with major crops used for human food supplies. The natural fungal flora existing in conjunction with food production is dominated by three genera: *Aspergillus*, *Fusarium*, and *Penicillium*. *Fusarium* species are destructive pathogens on cereal crops and other commodities, and produce mycotoxins before, or immediately after, harvest. Certain species of

Aspergillus and *Penicillium* are also plant pathogens or commensals, but these genera are more commonly associated with commodities during drying and storage. The fungi that produce the major mycotoxins are dealt with in detail under the particular toxins with which they are associated.

After the discovery of aflatoxins, over a period of 20 or more years, searches for these and other toxic compounds led to postulates of relationships of a particular mycotoxin with a wide range of fungi. Many such reports were inaccurate. Only comparatively recently have the major associations between fungi and mycotoxins been firmly established. Most mycotoxins are produced by a single fungus, or a group of closely related species. Only a few mycotoxins are produced by species from more than a single genus.

Categorizing Mycotoxins

Mycotoxigenic compounds can be divided into three broad risk management categories on the basis of both their toxicity and their occurrence in foods and feeds:

1. Major mycotoxins: compounds that have definitely been established to cause sickness in humans or domestic animals, and result in economic problems associated with their presence in food commodities;
2. Minor mycotoxins: compounds with demonstrated toxicity, known to occur naturally in toxic concentrations, and which from time to time may cause sickness or economic loss on a limited scale; and
3. Mycotoxins of less importance: compounds with demonstrated toxicity, but no known disease syndrome, usually due to uncommon occurrence in foods or feeds.

Major Mycotoxins

Five mycotoxins are considered to be of major importance in human or animal health today: aflatoxins, ochratoxin A, fumonisins, deoxynivalenol (and the related trichothecene nivalenol), and zearalenone. Aflatoxins are produced by *Aspergillus* species primarily in cereals and nuts; ochratoxin A is produced by both *Aspergillus* and *Penicillium* species in a range of foods – grapes and products including wines and dried vine fruits, cereals in cool temperate climates, and coffee, cocoa, and chocolate. The remaining major toxins are primarily produced by *Fusarium* species in cereals. These compounds are dealt with in detail in separate articles, together with patulin, considered by some authorities to be important, though no human or domestic animal health issues have ever been ascribed to this compound.

Minor Mycotoxins

A variety of compounds can be considered to be mycotoxins of lesser importance, either because health effects are less pronounced, or because they occur in a limited geographical area. These can be divided between those that occur in pasture or fodder crops, and those produced by *Aspergillus* and *Penicillium* species, which mostly occur postharvest.

Field Toxins

Fungi from the genus *Claviceps* grow on grasses, including cultivated cereals, throughout temperate zones. *Claviceps* species infect the flowers of susceptible hosts, and replace the ovaries with a specialized mass of fungal tissue, a sclerotium, generally known as an ergot. The ergots produced by the most important species, *Claviceps purpurea*, are dark purple to black and are found mostly in rye, but can also occur in barley, oats, and wheat. Ergots of *C. purpurea* contain toxic alkaloids, of which ergotamine (Figure 1d) is the best known. Ergotism, the disease caused by consumption of ergots from rye, may cause convulsions or gangrene. The convulsive symptoms are often accompanied by hallucinations, whereas gangrene, caused by constriction of peripheral blood vessels accompanied by a burning sensation, may result in loss of limbs. This disease syndrome was well known in the Middle Ages, when it was commonly known as 'St Anthony's Fire.' Ergotism has declined in importance with the decrease in use of rye and with increased knowledge of the problem, but outbreaks have occurred in Africa in recent years.

Facial eczema is a disease primarily of sheep in New Zealand, but also known from Australia and South Africa. It is caused by sporidesmin (Figure 1f), produced by *Pithomyces chartarum* as it sporulates on pasture in late summer and autumn. Sporidesmin causes obstruction of the bile duct, liver damage, and photosensitization. The disease known as perennial ryegrass staggers also occurs in New Zealand. *Acremonium lolii*, an endophytic fungus in ryegrass (*Lolium* spp.) interacts with the plant to produce lolitrem, a potent tremorgenic toxin, which causes trembling, staggers, and lack of muscle coordination in sheep, cattle, and horses grazing affected pasture. Death may result in severe cases.

Lupinosis is important in Western Australia, where sheep and cattle are often grazed on lupin stubble after harvest. This disease has also been reported from South Africa and Germany. It is caused by phomopsin A, produced in lupins by the pathogenic fungus *Phomopsis leptostromiformis*. Lupinosis in animals is characterized by jaundice and the development of yellow, fatty livers. Death may occur within a few days. Phomopsin is also produced in lupin seed, and is of concern as lupin seed is increasingly being sold for human consumption.

An important field mycotoxicosis in southern Africa is diplodiomycosis, due to grazing cattle on maize plants that become infected by *Diplodia maydis* after grain harvest. This disease is a neurotoxicosis, characterized in cattle by ataxia, a peculiar walk, incoordination, and often paralysis and death. The chemical cause of diplodiomycosis remains obscure.

In Eastern Europe, stachybotryotoxicosis is a well known disease of domestic animals. It was responsible for the deaths of tens of thousands of horses in the Ukraine in the 1930s, and also affected farm workers when the problem was severe. Symptoms varied, but in horses the most common was necrosis of membranes in the mouth, the result of direct contact with straw infected by *Stachybotrys chartarum*. A general

toxicosis followed, consistent with modern knowledge that the cause was a group of macrocyclic trichothecenes. The same fungus and toxins are one postulated cause of pulmonary distress in US children.

Certain *Alternaria* species grow before harvest in small grain cereals, especially wheat and sorghum. One species, *Alternaria alternata*, produces tenuazonic acid, a well known cause of ill thrift in chickens.

Aspergillus Toxins

Apart from the aflatoxins and ochratoxin A, *Aspergillus* species produce a variety of other mycotoxins. Cyclopiazonic acid (Figure 1e) is produced by several species including *Aspergillus flavus*, with or without simultaneous aflatoxin production. Classical 'turkey X' disease has the characteristics of toxicity due to both aflatoxins and cyclopiazonic acid.

It has recently been shown that *Aspergillus niger* frequently produces fumonisins, until now known exclusively from specific *Fusarium* species. As *A. niger* is of common occurrence in fresh fruits, vegetables, cereals, and nuts, fumonisins are much more widespread than previously believed. The public health significance of fumonisin production by *A. niger* has not yet been evaluated.

Penicillium Toxins

Penicillium species produce a wide variety of toxic compounds, which occasionally cause concern. Penitrem A (Figure 1a) is a potent neurotoxin, responsible for several outbreaks of neurological disorders in horses and sheep, including sustained trembling and brain damage. A number of cases in dogs have also been well documented, where dogs that have eaten moldy food, especially discarded hamburger buns, have exhibited sustained trembling. Fortunately penitrem A appears to have an emetic effect in humans, limiting its toxicity.

As well as *Aspergillus* species, cyclopiazonic acid is produced by several *Penicillium* species, the most important being *Penicillium commune*, a common cheese spoilage mold. As it is water soluble, cyclopiazonic acid appears to have limited mammalian toxicity, but is one cause of ill thrift in birds. A second common water soluble toxin, citrinin, produced primarily by the very common saprophyte *Penicillium citrinum*, has also been implicated in poor growth performance by domestic birds.

Mycotoxins of Less Importance

A wide range of other fungal metabolites have been shown to be toxic to animals in the laboratory or less commonly in the field. Compounds not listed above can be considered to be unimportant in practice, in most cases because the causal fungi rarely grow to a significant extent in foods or feeds.

Less Important *Penicillium* Toxins

Rubratoxins A and B are highly toxic, and were studied quite intensively 20 years ago. However, they are produced by only three known isolates of *Penicillium*, which do not have a recognized name. Rubratoxin was implicated in one poisoning outbreak involving two people, who had eaten homemade rhubarb pie.

Verruculogen is a potent neurotoxin produced by some isolates of *Penicillium simplicissimum* and *Penicillium paxilli*. The rarity of these species in foods and feeds make their practical importance low. The same applies to janthitrems, also neurotoxins produced by *Penicillium janthinellum*, and to viomellein and xanthomegnin, kidney toxins produced by *Penicillium viridicatum* and some *Aspergillus* species. *Penicillium viridicatum* was erroneously believed to be a major source of ochratoxin A until the 1980s.

Citreoviridin falls into a different category. This potent toxin, produced by *Penicillium citreonigrum*, was the likely cause of acute cardiac beri beri, a disease of young healthy Japanese people 100 years ago. As the result of pioneering toxicological work by Sakaki before 1900, Japan banned the sale of yellow rice in 1915, and the disease disappeared. *Penicillium citreonigrum* appears to be a rare species now. However, a recent disease outbreak in northern Brazil suspected to be caused by toxic rice has been attributed to this species. Citreoviridin is also produced by *Eupenicillium ochrosalmoneum* when it infects maize kernels, but the significance of this finding is unknown.

Like *P. citreonigrum*, *Penicillium islandicum* was believed to be common in rice in the nineteenth and early twentieth centuries. It produces four toxic compounds, the skyrins, erythroskyrin and leuteoskyrin, and the cyclic peptides islanditoxin, and cyclochlorotine. It is now an uncommonly isolated fungus.

Less Important *Aspergillus* Toxins

Sterigmatocystin (Figure 1c), produced by *Aspergillus versicolor* is a toxic precursor to the aflatoxins. Its practical importance appears to be low, because it is highly insoluble and it is not clear that ingestion is followed by absorption in either human or animal guts. Also, *A. versicolor* is a slowly growing invader of dried foods, and rarely grows on the large scale necessary for significant toxin production.

Gliotoxin, produced by *Aspergillus fumigatus*, assists this highly pathogenic fungus to invade lung tissue. As *A. fumigatus* primarily occurs in decaying vegetation, it is of low importance as a source of foodborne disease. *Aspergillus clavatus* is of common occurrence in malt houses, growing on malting barley. It is a cause of 'malt workers' lung,' due to the production of patulin as well as a number of other mycotoxins of marginal importance, including kojic acid, cytochalasin E, and tryptoquivalones.

Less Important *Fusarium* Toxins

Like *Penicillium*, *Fusarium* species make a wide range of metabolites with demonstrable toxicity, but which rarely, if ever, are produced at toxic levels in foods or feeds. Moniliformin (Figure 1b) is produced by at least 20 *Fusarium* species and can be expected to be of widespread occurrence in grain crops. Butenolide is produced by several *Fusarium* species, and is

moderately toxic to mice. Fusarochromanone, produced by *Fusarium equiseti*, can cause bone deformities in chickens. Sambutoxin, a metabolite of *Fusarium oxysporum* and *Fusarium sambucinum*, was found to cause hemorrhaging of the digestive tract in rats. None of these toxins has been reliably associated with any disease of humans or animals.

Chemical Analysis

Methodology for analysis of the major mycotoxins is highly developed, and is dealt with under the particular toxins. Specific assays exist for some of the less important toxins mentioned above, but assays are rarely performed outside specialist laboratories with access to standard compounds. Over the past 20 years, numerous papers have described multimycotoxin assays for 50 or even more toxins. However, it is rare for any particular batch of suspect food or feed to have been infected by more than a single mycotoxigenic species, so determining the likely fungus before attempting mycotoxin assays is still the preferred approach to pinpointing the cause of an unknown toxicity. Traditionally, identification of mycotoxigenic fungi is carried out by growth in culture and identification using standard texts. Molecular methods are coming into use at this time, and their utility will increase as more species are molecularly characterized.

Occurrence and Control of Mycotoxins in Foods

Before harvest, mycotoxins are produced in a particular crop only by specific fungi that are pathogens on that crop, or by commensals that have an affinity with that crop. Fitting this category are the production of aflatoxin in peanuts and maize by *Aspergillus flavus*, deoxynivalenol, and related trichothecenes in wheat and sometimes other small grains by *Fusarium graminearum*, and fumonisins in maize by *Fusarium verticillioides*. The major mycotoxin problems in the world's food supply are the result of this type of association. Control of this type of mycotoxin problem has proved to be very difficult. Biocontrol by competitive exclusion has been effective in controlling aflatoxins in some crops and circumstances.

In a slightly different category, *Aspergillus carbonarius* is able to invade grapes before harvest, not because of a specific affinity, but because grapes are frequently damaged at or before harvest. Infection by pathogenic fungi, splitting due to rain, or mechanical damage permit entry of *A. carbonarius*, that thrives in the acid, high sugar environment. Control requires management of these viticultural problems.

By the twenty first century, it is believed that the common species that are responsible for particular toxins are all known, so that the particular crops that needs monitoring, and the climatic conditions that permit fungal growth are well understood.

The other mycotoxins of importance in foods occur after harvest, before crops are fully dry. Here the specificity for formation of a particular mycotoxin appears to be a combination of fungal ecology and climate. Ochratoxin A formation in small grains, only in cool climates, and in coffee, only in warm climates, fits this category – as the result of growth by quite different fungal species. Control here relies on good agricultural practice – dry crops quickly and keeps them dry.

If foods are inadequately dried, badly stored, or incorrectly transported, at too high a moisture content or humidity, or subject to temperature fluctuation, contamination by a wide range of mycotoxins is possible. This problem occurs all too often in tropical countries, but also is a well recognized risk of long distance transport, especially across the tropics. Good agricultural practice, i.e., drying food commodities as soon as possible and keeping them dry, is the only sure defense against mycotoxin formation in stored commodities.

MYCOTOXINS

Aflatoxins

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Glossary

Commensal A fungus which grows in plant tissue without causing discernible damage to the plant, i.e., is not pathogenic.
Conidium (pl. conidia) Microscopic asexual spores produced by molds (filamentous fungi with small fruiting bodies); the main means of propagating many species.
Metabolite Chemical compound produced by a fungus during growth.
Metula (pl. metulae) Microscopic structures sometimes found supporting phialides in *Aspergillus* species.
Phialide (pl. phialides) Microscopic structures bearing conidia in some asexual genera of fungi, such as *Aspergillus*.
Sclerotium (pl. scletoria) Small (less than 1 mm diameter) often hard bodies produced by some filamentous fungi; a resting stage that may or may not lead to the formation of sexual spores (ascospores).

Chemical Characterization

Aflatoxins are highly substituted coumarins, with a fused dihydrofurofuran moiety. There are four naturally occurring aflatoxins of importance. Aflatoxins B_1 (CAS 1162-65-8) and B_2 (dihydroaflatoxin B_1; CAS 7720-81-7), so named because of their blue fluorescence under UV light, are characterized by fusion of a cyclopentenone ring to the lactone ring of the coumarin. Aflatoxins G_1 (CAS 1165-39-5) and G_2 (dihydroaflatoxin G_1; CAS 7241-98-7), which fluoresce greenish yellow, include an additional lactone ring (Figure 1).

When aflatoxin B_1 and aflatoxin G_1 are ingested by lactating animals, small proportions (1–2%) are excreted in milk as aflatoxin M_1 (4-hydroxyaflatoxin B_1; CAS 6795-23-9) and M_2 (4-hydroxyaflatoxin G_1; CAS 6885-57-0), hydroxylated derivatives of the parent compounds.

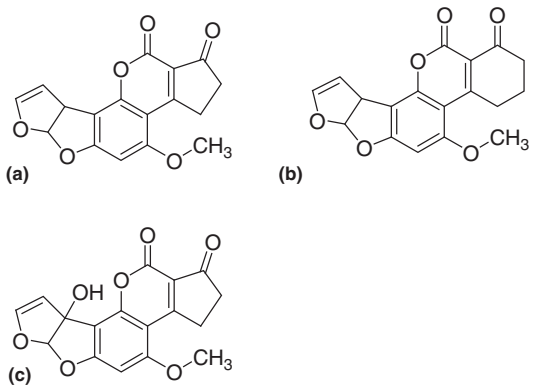

Figure 1 Structures of aflatoxins: (a) aflatoxin B_1; (b) aflatoxin G_1; (c) aflatoxin M_1.

Fungal Sources, Physiology, and Ecology

Aflatoxins are produced in foods, primarily by *Aspergillus flavus* and the closely related species *Aspergillus parasiticus*. On standard identification media, Czapek yeast extract agar and malt extract agar, both species produce rapidly growing colonies characterized by green conidia (asexual spores), under the microscope7 borne on typical *Aspergillus* fruiting structures (Figure 2). The two species differ in small details: *A. flavus* usually bears conidia (asexual spores) on metulae and phialides, whereas in *A. parasiticus* spores are borne on phialides alone. Conidia of *A. parasiticus* exhibit rougher walls than those of *A. flavus*. Isolates of *A. flavus* produce only B aflatoxins, whereas those of *A. parasiticus* produce both B and G aflatoxins.

At least eight other *Aspergillus* species make aflatoxins. Only two of these are of possible importance in foods: *Aspergillus nomius* and *Aspergillus minisclerotigenes*. Both resemble *A. flavus* in culture, but *A. nomius* produces bullet-shaped sclerotia, as distinct from the spherical sclerotia produced by many *A. flavus* isolates, whereas *A. minisclerotigenes* produces small spherical sclerotia. Unlike *A. flavus*, both of these species produce both B and G aflatoxins. Other species are rare, and none is of consequence in foods or feeds.

Detection of these species from foods or soils is facilitated by the use of *A. flavus* and parasiticus agar (AFPA). After 42–48 h incubation on AFPA at 30 °C, colonies of *A. flavus* and *A. parasiticus* exhibit a brilliant orange–yellow reverse coloration.

Physiology

A. flavus will grow from a minimum of 10–12 °C to a maximum of 43–48 °C, and optimally at approximately 33 °C. It

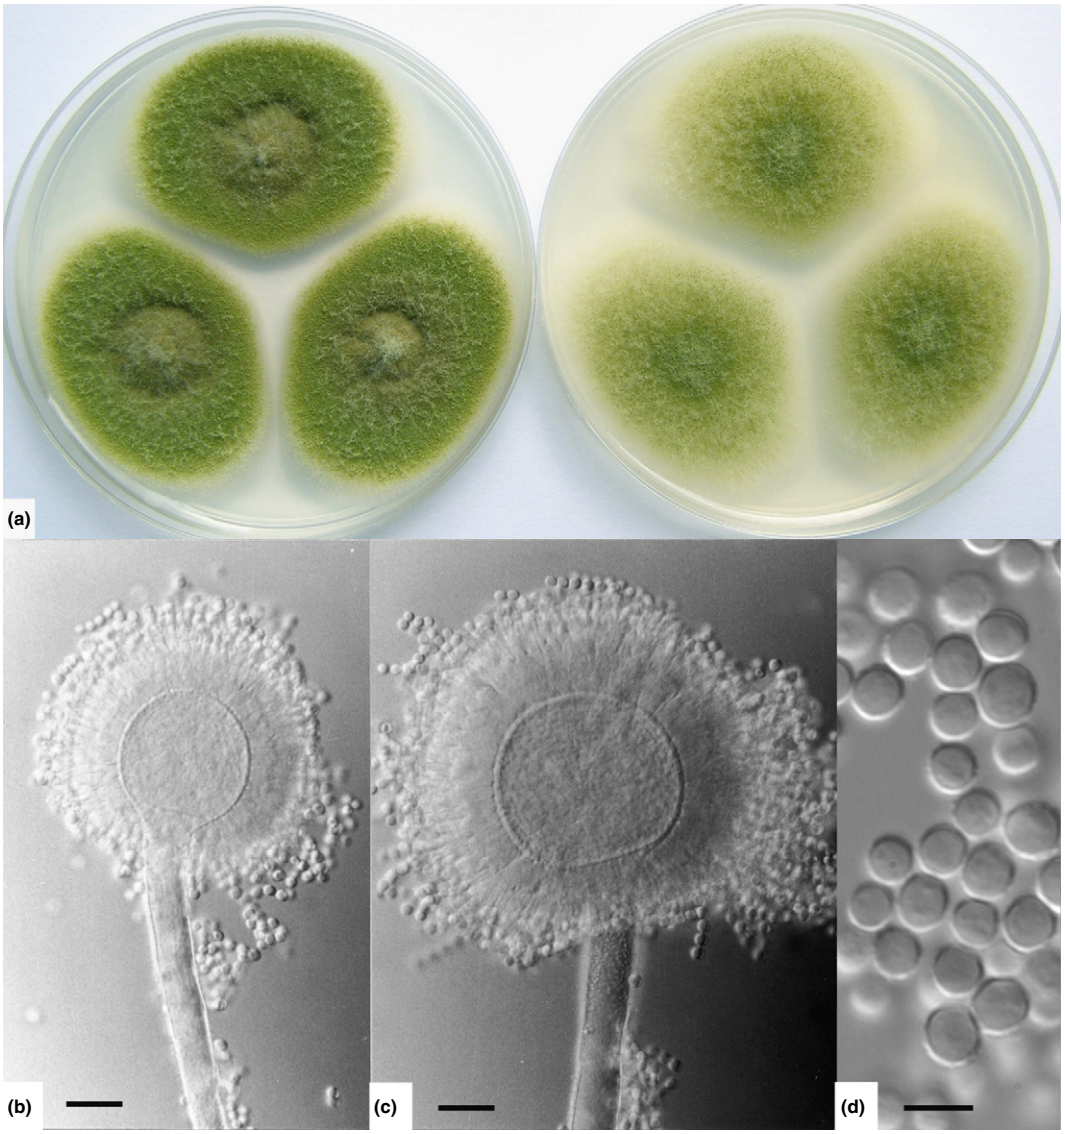

Figure 2 *Aspergillus flavus*: (a) colonies on Czapek yeast extract agar and malt extract agar, 7 days, 25 °C; (b, c) fruiting structures, bar = 10 μm; (d) conidia, bar = 5 μm.

has been shown to grow down to a minimum of 0.82 water activity at 25 °C, 0.81 at 30 °C, and 0.80 at 37 °C. This species will grow in a pH range of, at least, 2.1–11.2 at 25, 30, and 37 °C, with optimal growth near pH 7.5.

The most reliable figures for heat resistance of *A. flavus* conidia indicate a D_{45} value of more than 160 h, a D_{50} of 16 h, a D_{52} of 40–45 min, and a D_{60} of 1 min, at neutral pH and high water activity, with z values ranging from 3.3 to 4.1 °C.

Growth of *A. parasiticus* has been reported over the range 12–42 °C, with an optimum at 32 °C. The effects of water activity and pH on growth are very similar to those described for *A. flavus*. Conidia of *A. parasiticus* have a low heat resistance: D_{55} values of up to 9 min at pH 7 in phosphate buffer have been reported. Values were much higher if water activity was reduced.

Genetics

The aflatoxin biosynthetic pathway in *A. flavus* has been studied extensively and is now quite well understood. The pathway is a single unit on a chromosome within linkage group VII, and includes more than 20 enzymes and gene products. Many of these have now been isolated and characterized. Two regulatory genes, *AflR* and *AflS*, are known. The gene products of *AflR* regulate the biosynthetic pathway at the transcription level, whereas the function of *AflS* appears to be to regulate *AflR* activity.

Ecology

The quest for knowledge about potential aflatoxin problems means that *A. flavus* has been sought in every conceivable kind

of foodstuff. *A. flavus* has become the most widely reported foodborne fungus, reflecting its economic importance and relative ease of recognition as much as its ubiquity. It is especially abundant in the tropics, and it has a particular affinity for nuts and oilseeds as substrates. It grows as a nondestructive pathogen, or commensal, in the tissues of peanuts and cotton plants, and perhaps maize as well, and that is reflected in the widespread occurrence of aflatoxins in those crops. It does not appear to have that advantage in other crops, so that, in commodities apart from nuts and oilseeds, spoilage or unacceptable levels of aflatoxins should not occur in the absence of gross mishandling. Figs are an exception, because of the unique way in which the fungus is able to enter the fruit before harvest.

It is interesting that *A. flavus* is of universal occurrence in tropical and subtropical countries, whereas the closely related *A. parasiticus* is uncommon, indeed almost unknown, in South East Asia. In addition, *A. parasiticus* is not usually found in maize or cotton, but is often dominant in peanuts, even where both species are found together in soils where these crops are being grown.

History

Aflatoxins were discovered in 1960, as the result of an outbreak of a mysterious disease that became known as 'turkey X' disease which killed 100 000 turkey poults in England. It was soon established that peanut meal from Brazil was the cause, and it was subsequently shown that the toxin was produced by the common spoilage fungus *A. flavus.* In the same year, it was discovered that trout fed cottonseed meal while being reared in hatcheries in California frequently had liver tumors: indeed this problem was first reported in 1934. Within 2 years, the toxins had been identified, named aflatoxins after their fungal source, and assays developed using the new technique called thin layer chromatography. By 1970, it had been established that aflatoxins were widespread in tropical and warm temperate commodities, especially peanuts, maize, and cottonseed, and that aflatoxins were potent carcinogens in animals. Indeed aflatoxin B_1 was found to be the most potent liver carcinogen known. During the 1970s, outbreaks of human illness and death showed that aflatoxins can be acutely toxic, and carcinogenicity to humans was postulated. However, in the 1980s, it became clear that the hepatitis B virus caused liver cancer, and the validity of aflatoxin as a cause was questioned. During the 1990s, it was established that both hepatitis B and aflatoxin caused liver cancer, and were synergistic. Equations were developed relating aflatoxin intake to the likelihood of developing liver cancer, in the presence and absence of the hepatitis B virus. In the past decade, it has become apparent that aflatoxins are likely to play an even wider role in human health.

Hazard Identification and Characterization

Aflatoxins have been known to cause acute and chronic toxicity for many years. However, these compounds now appear to have even more diverse effects on human and animal health than believed previously. Aflatoxins have a likely involvement in five toxic effects: acute toxicity, liver carcinogenicity, growth retardation in children, immunosuppression, and liver cirrhosis.

Acute Toxicity – Aflatoxicosis

An outbreak of hepatitis due to aflatoxin ingestion from maize occurred in India in 1974: almost 400 cases were identified, and 106 deaths were reported. Clinical features were jaundice preceded by fever, vomiting and anorexia, with ascites and edema in the lower limbs in extreme cases. Levels in analyzed foods were often extremely high, up to 15 mg kg^{-1}. Given that adults normally consumed more than 300 g of maize per day, estimated daily ingestion was 2–6 mg of aflatoxins. Two outbreaks of aflatoxicosis have been documented from Kenya, in 1981 and 2004. In the latter outbreak, 317 cases and 125 deaths were reported. A smaller outbreak occurred in Malaysia in 1988, where 13 children died from acute hepatic encephalopathy from consumption of commercially prepared noodles contaminated with aflatoxin.

With the exception of the Malaysian incident, aflatoxicosis only occurs when drought or famine causes exceptionally high levels of aflatoxins in the diet, and forces the eating of substandard food. Much more insidious, and more frequent, is liver cancer development from consuming much lower levels of aflatoxin over longer periods of time.

Liver Carcinogenicity

The International Agency for Research on Cancer recognizes aflatoxin B_1 and naturally occurring mixtures of aflatoxins as Class 1 carcinogens, i.e., they are recognized as carcinogenic to humans. Although earlier studies (1970–1990) drew this conclusion, studies in the past 20 years have identified that hepatitis B virus also causes human liver cancer. The two agents provide different histopathology, so it has become evident that both agents are causal and synergistic. In its risk assessment of aflatoxins, the Joint Food and Agriculture Organization of the United Nations (FAO)/World Health Organization (WHO) Expert Committee on Food Additives (JECFA) has derived two potency factors for cancer formation by aflatoxins: for aflatoxin alone, 0.01 cases per 100 000 people per annum per nanogram per kilogram body weight per day, and for individuals carrying hepatitis B infection, 0.30 cases. Thus the two agents together are approximately 30 times as potent as aflatoxin alone.

In the liver, aflatoxin B_1 is converted by cytochrome P450 enzymes to the 8–9 epoxide. This is capable of binding to liver proteins, leading to liver failure, and potentially to aflatoxicosis. This epoxide is also able to bind to DNA, a precursor step to the development of liver cancer.

Stunting in Children

A number of studies have now provided evidence that aflatoxin exposure before birth and in early childhood is associated with stunted growth – defined by WHO as height for age being more than two standard deviations below the average

height for age in a given population. It is apparent from the high numbers of people believed to be consuming uncontrolled levels of aflatoxin, that stunting is an important disease burden, only recently recognized.

Immunosuppression

Aflatoxins have been shown to suppress the cell-mediated immune response in both cell lines and domestic animals. Effects include the impairment of delayed-type hypersensitivity, decreases in the phagocytic activity of macrophages, increased susceptibility to infection, and reduced response to vaccines. Few studies have been reported in humans, but it is apparent that if the effects in humans mirror those in animals even approximately, then the immunosuppressive effects of aflatoxins probably have very wide implications on human health.

Liver Cirrhosis

Direct evidence that aflatoxins are involved in liver cirrhosis is limited, but as death from cirrhosis of the liver is an important cause of mortality, any enhancement by aflatoxin or other factors in causing cirrhosis will have important consequences.

Exposure Assessment

Accurate exposure assessment of aflatoxins in food supplies has proved to be very difficult and is only now being addressed adequately. People in developed economies, with effective regulatory controls, are seldom exposed to levels of aflatoxins that might lead to disease consequences. However, many people in less developed economies are likely to be exposed to deleterious levels. A number of reasons exist. Peanuts are a drought-tolerant crop, and are widely grown in tropical countries, often under conditions of drought stress that promote aflatoxin production. Peanuts are a very valuable source of income to tropical economies. However, because of stringent regulations in developed importing countries, particularly Europe, the best quality nuts are usually exported, whereas poorer batches are consumed locally. If sorting by color is carried out, the nuts of inferior quality are seldom destroyed, but sold to poorer people. Peanuts and maize grown by subsistence farmers in many countries are rarely assayed for aflatoxins, and due to drought or insect damage are frequently of poor quality and contain excessive aflatoxin levels.

Risk Characterization

In general terms, the risk from aflatoxin in developed countries is low. Commodities, especially peanuts, maize, and cottonseed, are closely monitored and sorted to ensure the safety of foods and animal feeds. Foods for meat-producing ruminant animals can contain quite high levels of aflatoxins, up to at least 300 $\mu g\,kg^{-1}$, without effect on the animal or leaving aflatoxin residues in the meat, as ruminant microorganisms detoxify aflatoxins. However, feeds for dairy cows must contain very low levels of aflatoxins to limit the risk of aflatoxin M_1 in milk. Poultry and fish are sensitive to aflatoxins, so feeds must contain only low levels. As a consequence, residues in poultry meat, eggs, or aquaculture products are normally very low.

In many tropical and subtropical areas of the world, peanuts and maize are grown under suboptimal conditions of moisture and insect control, frequently leading to excessive aflatoxin levels. Concentrations of 100–1000 $\mu g\,kg^{-1}$ are not uncommon. Control measures, such as good agricultural practice or sorting of defective grains or kernels, are often neglected. A recent authoritative review has estimated that up to 5 billion people worldwide are at risk from exposure to uncontrolled levels of aflatoxins in their diets.

Chemical Analysis

Analysis of aflatoxin levels in the main commodities in which these compounds occur has become standardized. AOAC International (The Scientific Association Dedicated to Excellence in Analytical Methods) provides such standard methods, used throughout the world. These are briefly summarized below.

Sampling

Aflatoxins are usually very unevenly distributed in commodities, especially peanuts, where it is common for no more than 1 nut in 1000 to be contaminated, but contamination levels in individual nuts are often high, up to 1 $mg\,kg^{-1}$. For this reason, sampling is often the largest source of error in aflatoxin assays. Sampling plans have been developed for continuous lines, for 10 ton lots and for bag stacks. All of the recommended methods use samples sizes of 8 kg or more. Relevant papers should be consulted. For example, Codex has developed sampling plans for several commodities.

Sample Preparation

Entire samples of 8 kg or more should be comminuted in a vertical chopper or similar mill. Subsamples are then further processed.

Extraction

Extraction of subsamples, ideally of 500 g or more, employs a variety of mixed polar and nonpolar solvents, depending on the food matrix being analyzed. Methanol: water (80:20) is recommended for commodities such as maize, peanuts, and cottonseed.

Assays

The traditional methodology of thin layer chromatography is still in use, and is recommended for less developed economies as it is inexpensive and reliable. For acceptable/not acceptable testing, immunochemical methods are most frequently used. For advanced users such as high-volume

analytical laboratories or regulatory authorities, liquid chromatography, sometimes coupled with mass spectroscopy has become a normal practice. Limits of detection are now well below 1 $\mu g\ kg^{-1}$.

Levels in Foods

Levels of aflatoxins in foods are highly variable. However, only a few commodities are at serious risk if good agricultural and manufacturing practices are observed. Peanuts, maize, and cottonseed frequently contain unacceptable levels of aflatoxins, and assays are usually carried out at the wholesale level, and frequently in finished products as well. In developed countries, regulations are generally stringently applied on human foods and animal feeds that contain appreciable amounts of these commodities. Other closely watched commodities are tree nuts, especially pistachios and Brazil nuts, figs, and spices. However, although levels in these commodities may exceed regulatory limits from time to time, such levels seldom pose a long-term risk to human health.

Under inadequate storage conditions, other grains including sorghum and rice may also permit growth of *A. flavus* and aflatoxin production. These commodities have very high consumption levels in many communities, so adequate storage is of great importance.

Management Options – Limits in Foods

Good agricultural practice has been the standard method in developed countries for attempting to control aflatoxin levels in commodities, particularly maize and peanuts. Good agricultural practice involves good farm management, including weed control, optimal row and plant spacing, insect control, adequate water supplies, rapid and complete drying, removal of defects, and effective control of storage conditions. By themselves, these approaches are inadequate: too often drought stress or insect damage results in aflatoxin formation before harvest, out of farmer control, even in developed countries. The only effective control measure for aflatoxins remains end product testing.

Regulation of Aflatoxin Levels

Regulation of aflatoxin levels in foods commenced around 1970, using the then limit of detection, 5 $\mu g\ kg^{-1}$, as the permitted limit. It became clear that peanut producers could not reach that limit, even in developed economies, so higher limits were set up in peanut-exporting countries including the USA and Australia. As analytical techniques improved, with the introduction of liquid chromatography, lower limits were frequently set by importing countries, especially in Europe. Recent clearer understanding of aflatoxin toxicology has produced a compromise safe limit for human consumption of 15 $\mu g\ kg^{-1}$ of peanuts. Levels in most foodstuffs, where aflatoxin is less likely to occur, remain lower, usually 5 $\mu g\ kg^{-1}$ or less.

Although safe levels of aflatoxins have now been established and aflatoxin levels are closely controlled in developed countries, it has been estimated that up to 5 billion people worldwide are at risk from exposure to uncontrolled levels of aflatoxins in their diets.

Reducing Aflatoxin Levels

Reduction in aflatoxin levels in peanuts is accomplished by color sorting of individual kernels after shelling. The process was developed originally to reject commercially unacceptable discolored nuts, regardless of cause: but as fungal growth is a prime cause of discoloration, the process is also an effective nondestructive means of removing most nuts containing aflatoxins. Maize and fig samples are screened for the presence of aflatoxin by the examination of cracked kernels or fruit by ultraviolet light. No effective nonchemical testing techniques exist for cottonseed or pistachios and, as with other commodities, nondestructive chemical assays are not available.

It is a normal practice to assay aflatoxin levels in all consignments of peanuts and maize in major developed producing countries, often repeatedly, from intake to shellers to final product. Such controls rarely exist in less developed countries. Other commodities are similarly screened according to needs and markets.

Interventions

In recent years, several approaches have been put forward to reduce aflatoxin levels in foods and feeds. The most advanced of these is biocontrol by competitive exclusion, for both peanut and cotton crops. The technique, developed independently in the USA and Australia, relies on the fact that only approximately 40% of *A. flavus* strains produce aflatoxins. Selected nontoxigenic strains that are both competitive in the field and unlikely to revert to toxicity are introduced, in high numbers, into soils in fields where peanut or cotton crops are being grown. The nontoxigenic spores compete with the existing toxin producing spores in the soil for infection sites on developing nuts. In sufficiently high numbers, control can be very effective. This process is used commercially in the USA for peanuts and cotton. Pilot scale work is currently in progress on maize crops, and under development for some tree nuts.

Other reported experimental studies have aimed to improve farm efficiency, by providing advice and improved management for farmers in less developed countries. Some success has been achieved.

A different approach has resulted from the discovery that certain clays, among a variety of natural materials including activated charcoal and bentonite, adsorb aflatoxins very strongly. Animal studies have been very effective, and some human trials have yielded promising results. It is too early to say whether this approach will be effective in practice.

Some naturally occurring compounds are believed to be active against chemically induced cancers. Polyphenols from green tea and chlorophyllin, a derivative of chlorophyll, may have application here as dietary supplements.

Deoxynivalenol and Other Trichothecenes

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Glossary

Apoptosis Programed cell death that is a normal component of the development and health of multicellular organisms.

Conidium (pl. conidia) Microscopic asexual spores produced by molds (filamentous fungi with small fruiting bodies); the main means of propagating many species.

Macroconidium (pl. macroconidia) The larger of the two conidial types produced by *Fusarium* species, and characteristic of the genus.

Microconidium (pl. microconidia) The smaller of the two types produced by some *Fusarium* species, but also produced by a number of other related genera.

Chemical Characterization

Deoxynivalenol (DON) belongs to the family of chemicals known as the trichothecenes, sesquiterpenoid compounds characterized by an epoxy ring at the C-12,13 position. At least 100 trichothecene molecules are known, differentiated by hydroxy or acetyl groups and side chains. DON, still sometimes known as vomitoxin in the USA, is 12,13-epoxy-3,7,15-trihydroxy-trichothec-9-en-8-one, CAS number 51481-10-8 (Figure 1). It is the most commonly produced trichothecene in foodstuffs. Nivalenol (NIV), less commonly produced but more toxic, differs from DON by the substitution of a hydroxy group for the hydrogen atom at the C-4 position (Figure 1). The most toxic trichothecene is known as T-2 toxin. It differs from DON in several positions: at C-4, an acetyl ester in place of H; at C-7, H in place of OH; at C-8 an isovalerate ester in place of O; and at C-15, an acetyl ester in place of OH.

Fungal Sources, Physiology, and Ecology

DON and NIV are produced by *Fusarium graminearum* (often listed as *Gibberella zeae*, its sexual stage), *Fusarium culmorum*, and some related species.

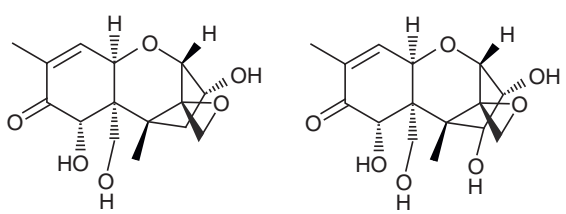

Figure 1 Structures of deoxynivalenol and nivalenol.

Fusarium graminearum grows rapidly on any standard mycological medium including Czapek yeast extract agar (CYA), malt extract agar (MEA), potato dextrose agar (PDA), and dichloran chloramphenicol peptide agar (DCPA). Colonies on CYA and MEA are colored grayish rose, grayish yellow or paler, with reverses orange red to yellowish brown. On PDA, colonies are colored yellowish brown to reddish brown, sometimes with a central mass of red brown to orange areas bearing macroconidia, with the reverse dark red (Figure 2).

Characteristic *Fusarium* conidia, macroconidia, are produced on DCPA or other specialist medium, usually with 5 septa, thick walled, straight to moderately curved, with the basal cell distinctly foot-shaped; microconidia are not produced.

Colonies of *F. culmorum* are similar to those of *F. graminearum*, but colored pale red to pastel red on CYA, MEA, and PDA, the reverse on CYA and PDA is pastel red to deep red, and on MEA brown to reddish brown. Macroconidia are relatively short, wide, and only slightly curved, with 4–5 septa, 30–45 μm long, with basal cells with a slight to definite notch. Microconidia are not produced.

Fusarium graminearum grows from below 5 °C to approximately 35 °C, and optimally at 25 °C. Growth occurs down to 0.90 water activity. *Fusarium culmorum* has a minimum temperature for growth near 0 °C, a maximum approximately 33 °C, and an optimum near 30 °C. It is capable of growth down to 0.87 water activity, lower than most other *Fusarium* species that have been studied. *Fusarium graminearum* occurs in maize, and both *F. graminearum* and *F. culmorum* in small grains, especially wheat and barley. These species are rank pathogens, invading plants and grains by causing diseases, known as Gibberella ear rot in maize and Fusarium head blight in wheat, barley, and triticale. Epidemics of Gibberella ear rot require the congruence of three factors: airborne or insectborne spores, inoculation at the susceptible time, and appropriate moisture and temperature. This disease is

prevalent in north temperate climates especially in wet years, but is much less common in the tropics.

Fusarium head blight affects all commercial cultivars of wheat and barley. *Fusarium culmorum* always produces DON, but whether DON or NIV is produced by *F. graminearum* depends on the geographical origin of the fungal strain.

T-2 toxin is produced mainly by *Fusarium sporotrichioides*. This species grows rapidly on CYA, MEA, and PDA, producing white to pale pink mycelium, with reverse pale on CYA, violet brown on MEA and PDA. Macroconidia are similar to those of *F. graminearum*, but, unlike that species, abundant microconidia are also produced. *Fusarium sporotrichioides* grows under similar conditions to *F. graminearum*, except that its minimum temperature is −2 °C. T-2 toxin is produced on grains, but occurs only under cool conditions.

History

Before 1950, feed refusal in pigs in the US and human toxicoses in Japan and the USSR were separately found to be associated with consumption of small grains. In the USA, pigs became sick and sometimes died. Feeding trials soon established the source as blighted wheat grains and the source of toxicity as *F. graminearum*. This was confirmed by experimental inoculation and feeding. In Japan, it soon became clear the suspect grain – wheat, barley, and rice – was infected with *Fusarium* species, and that the disease, known as Akakabi-byo, had been occurring sporadically for half a century or more. The disease was characterized by nausea, vomiting, diarrhea, and sometimes other symptoms, but was rarely fatal. In the USSR, however, the disease called alimentary toxic aleukia, from the consumption of rye grain that had overwintered in the field due to wartime labor scarcity, killed several hundred thousand people, with symptoms like radiation poisoning.

Identification of the toxin or toxins involved in each of these outbreaks had to wait for improvements in chemical techniques. In the 1970s, the isolation and structural characterization of several trichothecene toxins took place in the USA and Japan. In the USA, DON, then termed vomitoxin, was shown unequivocally to be the cause of the pig disease, whereas in Japan, both DON and NIV were seen as the likely causes of Akakabi-byo. The USSR outbreak was eventually attributed to T-2 toxin produced mainly by *F. sporotrichioides*.

By the turn of the twenty-first century, more than 100 trichothecene molecules were known to occur naturally, produced by a number of plant pathogenic fungal genera. Of these genera, *Fusarium* is by far the most important trichothecene source. At this time, production of DON and

sometimes NIV by *F. graminearum* and *F. culmorum* are the main sources of trichothecenes in foods and feeds, and the main causes for concern.

Hazard Identification

Trichothecenes are potent inhibitors of protein synthesis. DON and other trichothecenes bind to ribosomes, interfering with normal ribosomal function by causing dysregulation of various proteins related to immune function and sometimes apoptosis. Toxicity of the particular molecule varies with conformation that depends on the particular side groups in the molecule. NIV is much more toxic than DON, but is produced in much lower quantities in grains, and so is much less important. T-2 toxin is the most toxic of these compounds when tested in cell lines, and equal to NIV by intraperitoneal injection. T-2 toxin is more than 10 times as toxic as DON by injection, and 70 times as toxic to cell lines. Early studies of DON toxicity used naturally toxic grain. This always included other naturally occurring compounds, providing erroneous results that indicated that DON was more toxic than has been established by assays using the pure compound. Nonetheless, DON is a significant mycotoxin because of its widespread occurrence in cereals and products derived from cereals.

The most obvious syndrome in animals caused by DON is feed refusal in pigs, accompanied by decreased weight gain, gastroenteritis, and effects on heart function and the immune system. DON may cause acute gastroenteritis in humans, where the main symptoms are nausea, vomiting, abdominal pain, diarrhea, and fever. Symptoms can develop within 30 min of exposure and are difficult to distinguish from effects due to bacteria, such as the emetic toxins from *Bacillus cereus*. Recovery is usually complete.

In 2001, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) reviewed the safety of DON and on the basis of a 2-year feeding study in mice concluded that DON was not carcinogenic.

Hazard Characterization

JECFA also evaluated other long-term effects from the same 2-year mice feeding study. Although the mean bodyweight of animals at the lowest dose was lower than that of controls, the difference was considered not to be biologically significant, and no toxicological changes were observed at this dose. JECFA established a provisional maximum tolerable daily intake (PMTDI) of 1 $\mu g\,kg^{-1}$ bodyweight on the basis of the no effect level of 100 μg per kg bodyweight per day in this study and a safety factor of 100. The committee concluded that intake at this level would not result in effects of DON on the immune system, growth, or reproduction.

Consumption of maize containing excessive levels of DON has been associated with numerous incidents of intoxication in China and India. Tens of thousands of people have sometimes been affected. In one episode in India, DON levels in wheat ranged from 0.4 to 8.4 $mg\,kg^{-1}$, whereas in China, intoxication was linked to wheat contaminated with 0.3 to 100 $mg\,kg^{-1}$ DON. In 2010, JECFA derived a group acute reference dose of 8 $\mu g\,kg^{-1}$ bodyweight for DON and its acetylated derivatives using the lowest lower limit on the benchmark dose for a 10% response of 0.21 mg per kg bodyweight per day for emesis in pigs. Limited data from human case reports indicated that dietary exposures to DON up to 50 μg per kg bodyweight per day are not likely to induce emesis.

Exposure Assessment

DON occurs worldwide in maize, wheat, and sometimes other small grains due to growth of *F. graminearum* and related species. JECFA has estimated that the total intake of DON in micrograms per kilogram of bodyweight per day to be 0.78 from the African diet, 1.2 from the Latin American diet, 1.4 from the European diet, 1.6 from the Far Eastern diet, and 2.4 from the Middle Eastern diet. The main source of intake in Europe, Latin America, and the Middle East is wheat (64–88% of total intake), whereas the sources in the other two regions are more varied: wheat, rice, and maize in the African region and wheat and rice in the Far East.

Risk Characterization

The main risk from DON is from chronic exposure, which has been estimated to exceed the PMTDI in many areas of the world. However, the reduction in exposure levels due to processing was not taken into account. For wheat, such reductions can be significant. Regarding acute exposure, the sporadic occurrence of outbreaks of acute gastroenteritis is of public health concern.

A potential risk to farm workers exists from DON inhalation. Grain dusts may contain quite high concentrations of DON. Air samples from Canadian grain elevators contained up to 2.6 $\mu g\,m^{-3}$ of DON. Airborne dust from the same sources contained up to 5.8 $mg\,kg^{-1}$ of DON, plus smaller amounts of T-2 toxin. Some evidence has been reported that grain farming may be associated with midterm pregnancy deliveries in northern Europe.

Chemical Analysis

Analysis for DON usually requires gas chromatography and mass spectroscopy. Modified DON, in the form of the 3-glucoside, is a problem because it is not assayed by the usual techniques. Extraction may use chloroform – ethyl acetate or 70% methanol, and cleanup is accomplished by filtering through a C18 or silica gel column.

Levels in Foods

DON is found in maize and small grains in all areas where these crops are grown, and particularly in wheat, the crop most commonly invaded by *F. graminearum*. It is especially prevalent in cooler areas where rainfall is higher, such as Canada, Europe, and Argentina, but less commonly occurs in drier, hotter areas such as Australia. Levels of DON and other related trichothecenes are usually lower than 1 $mg\,kg^{-1}$ in

foods, but can be much higher, potentially causing intoxication (see Section 'Risk Characterization').

A number of studies have shown that fungal infection rates are higher in crops planted in fields previously planted with maize, particularly when residues from those crops were left in the field. Once grains begin to dry, with the water activity reduced to <0.9, increases in levels of *Fusarium* mycotoxins rarely occur.

Favorable weather conditions are critical for infection to occur in wheat heads. Field observations have confirmed that temperature and moist conditions during anthesis and heading are the major factors of importance.

Management

In 2010, the US Food and Drug Administration issued revised guidelines for DON in foods and feeds as follows: for finished wheat products that may be consumed by humans, 1 mg kg^{-1}; for grains and byproducts for feedlot and dairy cattle, 10 mg kg^{-1}, except that for dairy cattle, the total DON content in feed should not exceed 5 mg kg^{-1}; in feed for pigs, 5 mg kg^{-1}, but not exceeding 20% of the total diet; and for all other animals, 5 mg kg^{-1}, not exceeding 40% of the total diet.

Some success has been achieved in controlling DON formation in wheat by the use of azole fungicides at anthesis. Forecasting systems to advice farmers of the likelihood of DON formation have been developed in Canada and Europe. Otherwise, control relies on reducing levels of *Fusarium* species in the field by good management and crop rotation.

MYCOTOXINS

Fumonisins

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Glossary

Conidium (pl. conidia) Microscopic asexual spores produced by molds (filamentous fungi with small fruiting bodies); the main means of propagating many species.
Macroconidium (pl. macroconidia) The larger of the two conidial types produced by *Fusarium* species, and characteristic of the genus.
Microconidium (pl. microconidia) The smaller of the two types produced by some *Fusarium* species, but also produced by a number of other related genera.
Nixtamalization A centuries old process, used primarily in Central America, in which maize is soaked then cooked with ash or lime high in alkali.
Phialide A cell that produces conidia in basipetal succession, that is, from the tip, with the oldest cell furthest from the formation point, and without change in length of the phialide itself.

Chemical Characterization

Fumonisins are a family of compounds made up of a 19- or 20-carbon chain aliphatic acid backbone with amino or polyhydroxy side groups, two of which are esterified with propane tricarboxylic acid. This provides a hydrophobic/hydrophilic dichotomy unique among the mycotoxins. Fumonisins are structurally similar to the sphingoid base backbone of sphingolipids, important membrane constituents.

The most important fumonisin is known as fumonisin B_1 (CAS 116355-30-0), and has a molecular formula of $C_{34}H_{59}NO_{15}$, with a molecular weight of 721 (Figure 1). Most naturally occurring fumonisins belong to the B series, but some members of the C series, identical to the B series but with the terminal methyl group absent, have also been found in maize. Other much less common fumonisins, designated variously as A and P series, have been isolated from pure fungal cultures.

Fungal Sources, Physiology, and Ecology

Fumonisins are produced by *Fusarium verticillioides* (known in older literature as *Fusarium moniliforme)* and some closely related species, in particular *Fusarium proliferatum*. The principal habitat of these species is maize. It has been shown recently that some fumonisins are also produced by *Aspergillus niger*, an entirely unexpected source.

At 25 °C, *F. verticillioides* grows rapidly on any standard mycological medium including Czapek yeast extract agar, malt extract agar, and potato dextrose agar (PDA). Colonies are white to pale salmon colored, with low and often ropy mycelium and a powdery texture due to production of chains of microconidia. The reverse color on PDA is variable, pale salmon, greyish violet, brownish violet to deep violet. Slow growth occurs at 37 °C on these media (Figure 2).

Characteristic *Fusarium* spores, macroconidia, are produced on dichloran chloramphenicol peptone agar or other specialist media. Macroconidia are long (40–50 μm) and slender,

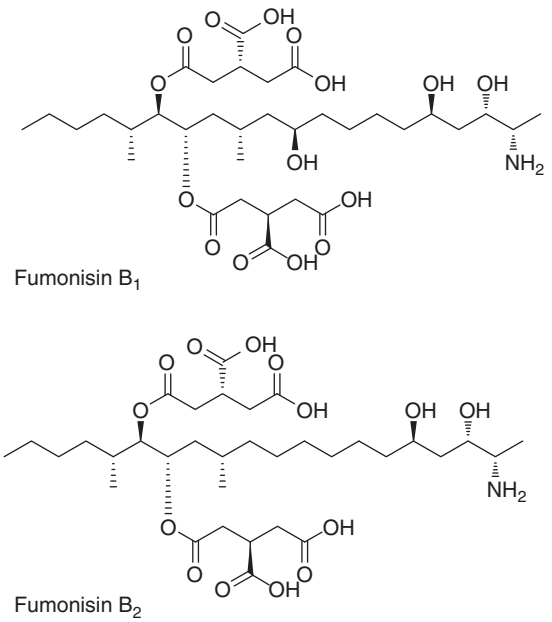

Figure 1 Structure of fumonisins B_1 and B_2.

 doi:10.1016/B978-0-12-378612-8.00192-X

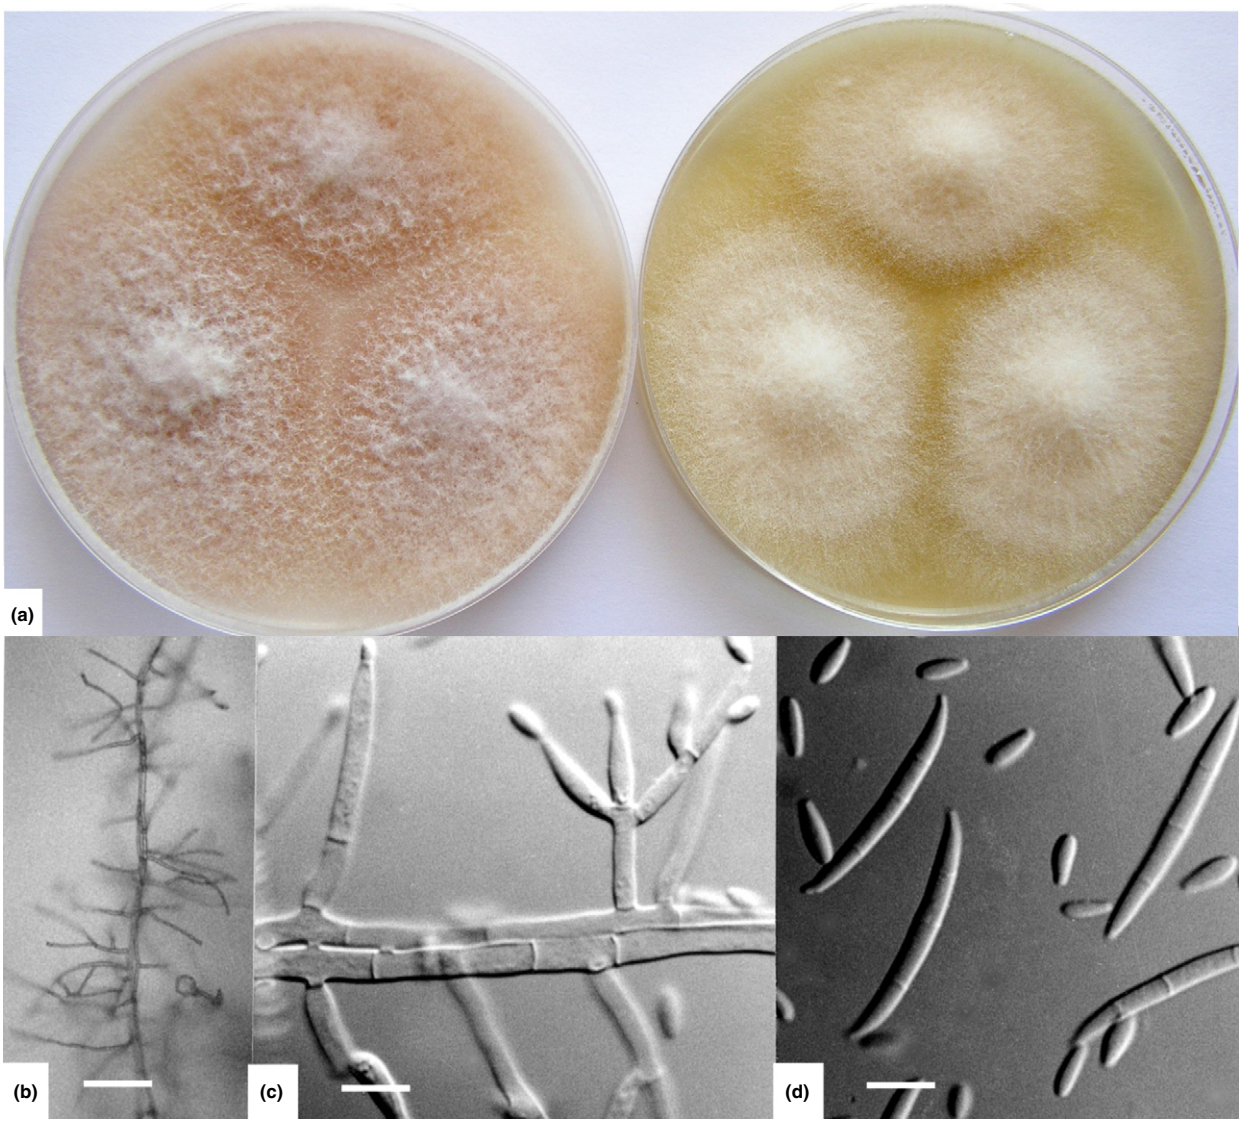

Figure 2 *Fusarium verticillioides*. (a) Colonies on potato dextrose agar and dichloran chloramphenicol peptone agar, 7 days, 25 °C; (b) phialides bearing chains of microconidia, bar = 50 μm; (c) phialides, bar = 10 μm; (d) macro- and microconidia, bar = 10 μm.

almost straight, thin walled, with foot shaped basal cells. Microconidia are pointed at both ends or club shaped, 7–10 μm long, and are produced in chains from long single phialides (fruiting cells). *Fusarium proliferatum* is very similar, but colonies on PDA lack purple colors in the reverse, and microconidia are produced from phialides with more than one fertile neck.

Fusarium verticillioides grows from approximately 3–37 °C, with an optimum near 25 °C. Growth is possible down to 0.87 water activity, but is very slow below 0.90. This species is able to grow under reduced oxygen tension, but not in its complete absence. Fumonisins are produced down to 0.92 water activity. The physiology of *F. proliferatum* is very similar.

Fusarium verticillioides is endemic in maize and grows in all regions, but is less common in cooler areas. It has been isolated from maize kernels wherever it has been sought. It causes both stalk and cob rots, and occurs at all stages in plant development, so it can rightly be considered a commensal in maize. *Fusarium verticillioides* also occurs in sorghum, rice, and millet. Reports exist of the occurrence of this species in many other crops, including causing spoilage of citrus, asparagus, yams, bananas, and pineapples. However, in light of the narrowing of the definition of this species (see Section History), many such claims need to be reexamined before being accepted as authentic.

History

By 1900, it was suspected that a lethal and widespread neurological disease in horses, mules, and donkeys in the US was associated with the feeding of maize. The disease was named leukoencephalomalacia, and was subsequently found

to occur very widely, in countries as far apart as USA, Mexico, South Africa, New Caledonia, and China. However, the cause remained elusive. In the 1970s, South African scientists recognized that the cause was a mycotoxin and, after 20 years of work, were able to isolate and characterize a new class of toxins, the fumonisins. Publication came comparatively recently, in 1998, and was followed by independent publication by scientists in New Caledonia the following year. Both groups of workers were able to demonstrate that fumonisins were directly responsible for the horse deaths by administering or feeding the pure compound to horses.

About 1990, a large scale, often fatal, outbreak of pulmonary disease in southeastern USA pigs occurred. South African experiments in the 1980s had indicated that maize containing fumonisins could cause such a syndrome. Experimental work soon confirmed that fumonisins were responsible.

For many years, the species primarily responsible for fumonisin production was known as *F. moniliforme*. However, due to confusion over the application of that name to a number of distinct species, in 2003 taxonomists agreed to solve the problem by taking up the older name *F. verticillioides* for the major fumonisin producer.

Hazard Identification and Characterization

Fumonisins are remarkable for the wide range of effects caused in animals and possibly in man. Fumonisins act by inhibiting the enzyme ceramide synthase, which causes accumulation of intermediates in the sphingolipid metabolism pathway, and also causes depletion of complex sphingolipids. This inhibition interferes with the binding of folate and some other proteins in cell membranes. The most dramatic effect occurs in horses, where the disease called equine leukoencephalomalacia occurs. This is a rapidly progressing disease that causes equine brains to liquefy. For horses, consumption of feed containing $>10\ \mathrm{mg\ kg^{-1}}$ fumonisin B_1 in the diet (equivalent to $0.2\ \mathrm{mg\ kg^{-1}}$ body weight per day) was associated with increased risk of developing this disease.

In pigs, fumonisins cause pulmonary edema, due to left ventricle heart failure, whereas in rats the primary effect is to cause liver cancer, but they also cause programmed cell death (apoptosis). It is unusual for a single toxin to have such diverse effects in different animal species, but careful investigations have confirmed that to be true in this case. The reasons for such diversity remain unclear.

In humans, fumonisins produced by *F. verticillioides* cause none of these animal syndromes, but are associated with esophageal cancer. Extensive studies in areas of low and high maize consumption in South Africa have suggested this connection. This disease is also prevalent in areas of China and occurs at significantly higher levels than background also in parts of Iran, northern Italy, Kenya, and a small area of the southern USA. In all of those areas consumption of maize and maize products are very high. There is also some evidence that high intake of fumonisins from maize are associated with neural tube defects such as spinal bifida in areas of Guatamala, South Africa, China and a population along the Texas, Mexican border.

Exposure Assessment

The primary source of fumonisins is maize. *Fusarium verticillioides* is endemic in maize, so fumonisins are of universal occurrence wherever maize is grown. Unacceptable levels occur only in plants that are drought stressed near harvest dates or where cobs are extensively damaged by insects. Intake can be high in countries where maize is a dietary staple, notably in Africa, some South and Central American countries and parts of China.

The discovery of fumonisin formation by *A. niger* means that fumonisins occur in many other food commodities, including grapes, wine, dried vine fruits, and probably coffee and cocoa. However, it seems likely that levels in these foods do not add significantly to exposure.

Risk Characterization

For the human population, a provisional maximum tolerable daily intake (PMTDI) of $2\ \mu\mathrm{g\ kg^{-1}}$ body weight per day has been established by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). This PMTDI was maintained by JECFA at a meeting in 2011. The European Commission has established the same tolerable daily intake for fumonisins B_1, B_2, and B_3, alone or in combination.

Chemical Analysis

Analytical techniques have concentrated on the estimation of fumonisin B_1, as it is the most commonly occurring form. Screening methods in foods have been based either on thin-layer chromatography (TLC) after clean up, or more commonly on enzyme-linked immunsorbent assay (ELISA) tests.

The traditional methodology of TLC is still in use, and is recommended for less developed economies as it is inexpensive and reliable. For fumonisins a reversed phase system is preferable. It has been shown that derivatization with fluorescamine before spotting on the TLC plate was more effective than after elution. The preferred developing medium is methanol: 4% aqueous potassium chloride (70:30). A suitable developing solvent is benzene:methanol:acetic acid (18:1:1). Fumonisin B_1 is visualized under long-wave ultraviolet light as a greenish yellow spot with R_f approximately 0.35. Levels down to at least $1.0\ \mathrm{mg\ kg^{-1}}$ can be estimated.

ELISA techniques are also effective for fumonisin analysis. Although antibodies are raised against fumonisin B_1, cross reactivity usually occurs with fumonisins B_2 and B_3 as well. Commercial kits, using a range of methods, are available from several manufacturers.

For analysis by high-performance liquid chromatography, fumonisins lack suitable chromophores, so must be derivatized and detected by fluorescence. The most common derivatization is with orthophthalaldehyde precolumn. Liquid chromatography–mass spectrometry is increasingly being used, as derivatization is not necessary.

Levels in Foods

The occurrence of fumonisins in foods due to growth of *F. verticillioides* and *F. proliferatum* is of significance only in maize. Fumonisins have been detected in a variety of cereals due to other *Fusarium* species, and due to *A. niger* in grapes, wines, and other commodities, but levels are usually low. Excessive fumonisin levels occur when maize plants are drought stressed or suffer extensive insect damage. Maize is a widely consumed cereal, and a dietary staple in many regions of the world, that is, in parts of Africa, South and Central America, and China. Drought stress occurs quite commonly in all of these regions; hence, levels in foods frequently exceed regulatory limits. Maize consumption in parts of Africa has been increasing as this crop replaces traditional crops such as sorghum and millet, often in areas where drought stress occurs, and often outside the geographical regions for which the maize hybrids were developed and to which they are suited. In consequence, consumption of undesirable levels of fumonisins occurs quite frequently in some parts of the world.

Management Options – Limits in Foods

Regulatory Limits

The European Commission has set maximum permitted limits of 4 mg kg^{-1} total fumonisins in unprocessed maize and 200 μg kg^{-1} fumonisins in maize based foods and baby foods after processing. The US Food and Drug Administration has set guidelines for fumonisin levels in processed foods: degermed dry milled maize products, 2 mg kg^{-1} total fumonisins; dry milled maize bran, 4 mg kg^{-1}; and cleaned maize for popcorn, 3 mg kg^{-1}.

Preharvest Control

Fumonisins are produced in maize preharvest. Drought stress is the major factor causing production, though insect damage may also be important. Good agricultural practice, irrigation, and the use of Bt maize cultivars are all important in limiting fumonisin formation. Some progress has been made in breeding cultivars resistant to ear rot due to *F. verticillioides*.

Freshly harvested maize should be rapidly dried to a suitable moisture level, but in practice this is important only in the initial stages of drying because *Fusarium* species grow very slowly below approximately 0.9 water activity, so once the kernel moisture content has been reduced below that figure, fumonisin accumulation ceases. This frequently occurs in field drying before harvest of the cobs. For the same reason, fumonisins will not be produced in storage. Even if very high moisture occurs due to water ingress, competition with other microorganisms at such high water activities will prevent any significant increase in fumonisin levels.

Processing

In most geographical areas, the main methods for controlling fumonisin levels are visual inspection of lots for fungal damage, followed by fumonisin analyses, and rejection of lots that do not meet specifications.

In Central America, the process of nixtamalization is commonly used in preparation of meals based on maize. Nixtamalization is a centuries old process in which maize is soaked then cooked with ash or lime high in alkali. It removes almost all fumonisins, resulting in tortillas and other maize based foods being substantially free of these mycotoxins.

Maize is wet milled to obtain maize starch, germ, and fiber, where as dry milling produces bran, germ, and fractions of decreasing particle size – grits, corn meal, and flour. Fumonisins are not destroyed during these processes and are found in all fractions, with higher concentrations in bran and germ.

Processing at temperatures above 150 °C reduces fumonisin levels. Maize meal production, frying, baking, roasting, and alkaline cooking all have effects, dependent on the temperature actually attained. Extrusion processing is used extensively in the production of breakfast cereal, snack and textured foods based on maize meal. Extrusion temperatures of 160 °C or higher have a significant effect, especially if glucose is included.

MYCOTOXINS

Ochratoxin A

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Glossary

Conidium (pl. conidia) Microscopic asexual spores produced by molds (filamentous fungi with small fruiting bodies); the main means of propagating many species.

Metabolite It is a chemical compound produced by a fungus or other organism during growth, development, or reproduction.

Chemical Characterization

Ochratoxin A (OTA; CAS 303-47-9) consists of a substituted isocoumarin moiety linked to phenylalanine (Figure 1). It is a white crystalline solid with intense ultraviolet (UV) fluorescence, green in acid, and blue under alkaline conditions, due to a closed or open lactone ring, respectively. This reaction is reversible

Fungal Sources, Physiology, and Ecology

OTA is produced by three well-defined groups of fungi. The first group, which may be termed the ocher colored Aspergilli, comprises *Aspergillus ochraceus, Aspergillus westerdijkiae, Aspergillus steynii*, and a few other (much less important) related species. This group is largely responsible for OTA production in coffee, and also in long stored grains. The second comprises two of the black spored Aspergilli, i.e., *Aspergillus carbonarius* and (much less frequently) the closely related and common species *Aspergillus niger*: these species are responsible for most OTA formation in grapes and grape products and, in some regions, in coffee. The third includes two *Penicillium* species, *Penicillium verrucosum* plus the closely related *Penicillium nordicum*. The well documented occurrence of OTA in temperate climate cereals results from the growth of *P. verrucosum*. *Penicillium nordicum* has been reported to produce OTA in cool stored processed meats.

Detection of any of these fungi requires growth on isolation media and identification on standard media, such as Czapek yeast extract agar (CYA) and malt extract agar (MEA) used for *Aspergillus* and *Penicillium* species.

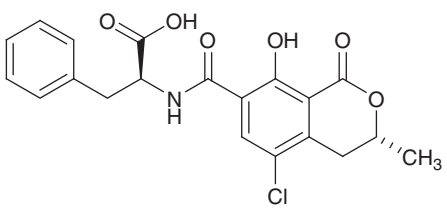

Figure 1 Structure of ochratoxin A (OTA).

Aspergillus ochraceus and Related Species

On CYA, after 1 week at 25 °C, *A. ochraceus* and closely related species produce colonies 40–55 mm in diameter with ocher (light yellow brown) conidia. These characteristics are distinctive for this group of species. *Aspergillus westerdijkiae* (Figure 2) and *A. steynii* are distinguished from *A. ochraceus* by the inability to grow on CYA at 37 °C: *A. westerdijkiae* produces finely roughened, spherical conidia and *A. steynii* smooth walled, ellipsoidal conidia, whereas those of *A. ochraceus* are smooth walled and spherical.

Apart from the difference in maximum growth temperatures, approximately 40 °C for *A. ochraceus* and approximately 5 °C lower for the other species, these three species have similar physiology so far as is known. All are likely to be able to grow down to approximately 0.77–0.80 water activity and over a wide pH range.

Although *A. ochraceus* is the oldest recognized species, recent studies indicate that *A. westerdijkiae* is much more common, and more likely to produce OTA. As *A. westerdijkiae* and *A. steynii* were separated from *A. ochraceus* only recently, studies reporting *A. ochraceus* before 2005 are likely to include all three species.

Ecologically, these three species are most often isolated from stored foods, reflecting their xerophilic nature. However, *A. westerdijkiae* has a major habitat in coffee beans, leading to OTA production.

Aspergillus carbonarius and *A. niger*

These two species produce rapidly growing colonies on CYA, usually 60 mm or more after 7 days at 25 °C, colored black or deep reddish brown. *Aspergillus carbonarius* (Figure 3) produces much larger conidia (6–7 μm in diameter) than *A. niger* (4–5 μm). *Aspergillus carbonarius* grows from approximately 10

 doi:10.1016/B978-0-12-378612-8.00191-8

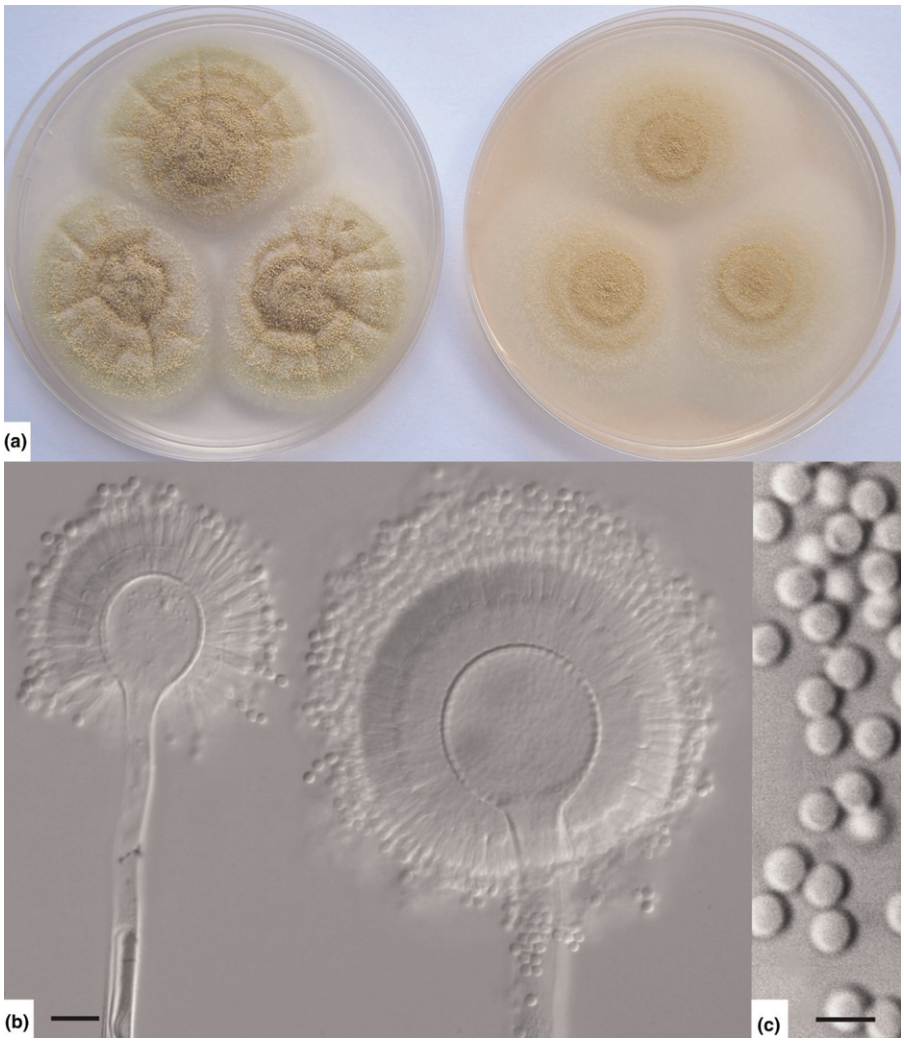

Figure 2 *Aspergillus westerdijkiae*. (a) Colonies on CYA and MEA, 7 days, 25 °C; (b) fruiting structures, bar = 10 μm; and (c) conidia, bar = 5 μm.

to 40 °C, and down to 0.85 water activity, whereas *A. niger* grows from approximately 8–45 °C and down to 0.8 water activity or slightly below.

These species have a major habitat in grapes, producing OTA in dried vine fruits and wines. They also occur in coffee in some growing regions.

Penicillium verrucosum and *P. nordicum*

Penicillium verrucosum (Figure 4) and *P. nordicum* are very similar, slowly growing species, reaching only 15–25 mm diameter on CYA after 7 days at 25 °C, and colored dull green to dark green. Both grow from approximately 0 to 30 °C and down to 0.80 water activity.

Penicillium verrucosum is endemic in European and Canadian wheat, barley, rye, and oats. It is a cold climate fungus, and is rarely isolated outside cool temperate zones or away from cereals. In contrast, *P. nordicum* grows mostly in proteinaceous foods, especially meat and cheese. Reflecting its low temperature profile, it has been isolated from foods cold stored for several weeks or more, but the significance of this for human health is unknown.

History

OTA was originally described as a metabolite of *A. ochraceus* from laboratory experiments on fungal toxicity in 1965, and production was detected from several related *Aspergillus* species soon after. However, natural occurrence, and practical importance, was first linked in 1973 with a *Penicillium* species, *Penicillium viridicatum*, later correctly identified as *P. verrucosum*. OTA was soon characterized as a potent kidney toxin. As a result, it was postulated quite early that OTA was a likely cause of Balkan endemic nephropathy, a kidney disease with a high mortality rate in certain areas of Bulgaria, Yugoslavia, Romania, and Tunisia. However, conclusive evidence of OTA involvement remains elusive, despite much effort. Recent work indicates that this syndrome is likely to result from contamination of wheat grains with seeds of the weed *Aristolochia*

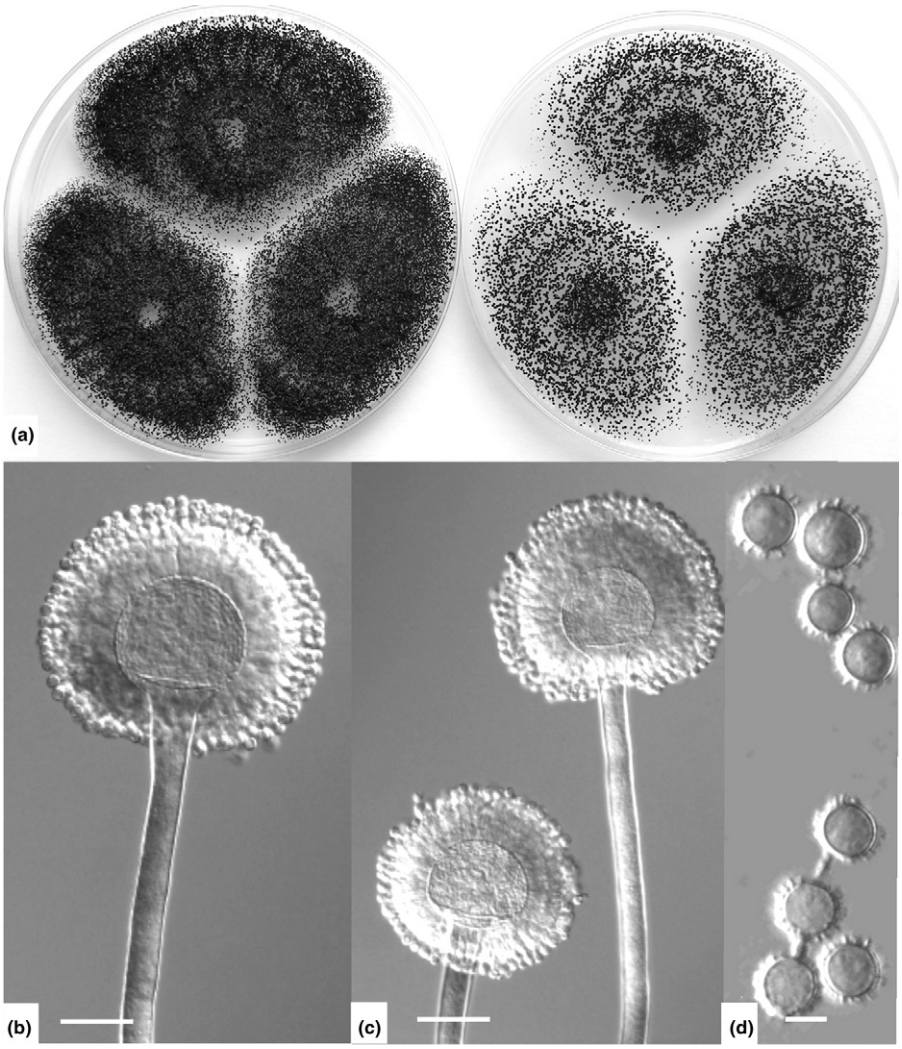

Figure 3 *Aspergillus carbonarius*. (a) Colonies on CYA and MEA, 7 days, 25 °C; (b, c) fruiting structures, bar = 10 μm; and (d) conidia, bar = 5 μm.

clematitis, endemic in affected areas, which commingle with the wheat before harvest.

Hazard Identification and Characterization

OTA is an acute and chronic nephrotoxin affecting kidney function in all animal species tested. OTA is readily absorbed through the intestines and, once it enters the blood stream, has a long half-life, up to 3 weeks in monkeys and 4 weeks or more in human volunteers. As fungi that produce OTA are very widespread in foods, the blood of healthy humans regularly contains detectable amounts of OTA. Because *P. verrucosum* has a restricted distribution, OTA intake as the result of growth of this species is confined almost entirely to Europe and northern North America. The occurrence of OTA in human blood from warmer regions of the world is the result of the growth of *Aspergillus* species in foods.

OTA also has carcinogenic properties, but the mechanism of carcinogenicity remains unknown. Reports by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) indicate that the carcinogenic effects in animals occur at higher doses than nephrotoxicity. Although OTA is demonstrably toxic to animals of all kinds, its effects in humans remain unclear and the subject of debate. Both genotoxic and non-genotoxic modes of action have been proposed. The International Agency for Research on Cancer has classified OTA as a possible human carcinogen (Group 2B), based on sufficient evidence of carcinogenicity in experimental animal studies and inadequate evidence in humans.

Exposure Assessment

People in Europe and Canada are exposed to OTA in barley and wheat and their products, especially bread, and also from offal products derived from animals, especially pigs, fed contaminated feed. OTA also occurs in beer, wine, coffee, cocoa and chocolate, and dried vine fruits, so people everywhere are exposed to this toxin, though exposure from these sources is lower than may

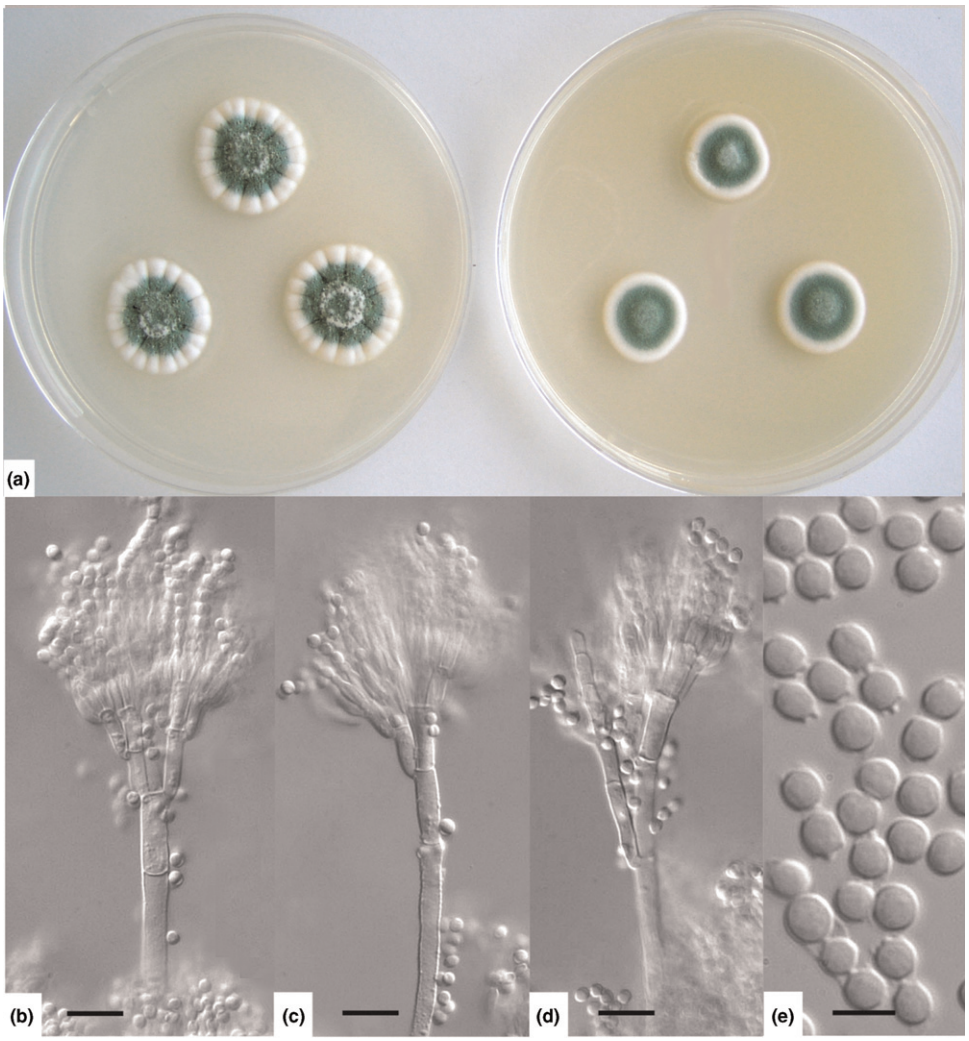

Figure 4 *Penicillium verrucosum*. (a) Colonies on CYA and MEA, 7 days, 25 °C; (b, c, d) fruiting structures, bar = 10 μm; and (e) conidia, bar = 5 μm.

occur from cereals. As wheat and barley crops from warmer climates, such as the US, South Africa, and Australia, are not infected by *P. verrucosum*, OTA intake is often much lower in regions outside Europe and Canada.

A large number of studies have now been published on OTA levels in human blood, although the correlation between blood level and measured food intake is still somewhat uncertain. Blood OTA levels are now considered to be the most reliable measure of human exposure. Published figures are quite variable, with reported levels sometimes exceeding 10 $\mu g\, l^{-1}$ in European individuals. Mean levels around the world commonly range from 0.2 to 1 $\mu g\, l^{-1}$. Often 50–100% of people sampled in any population have detectable levels of OTA in their blood.

Risk Characterization

In a recent evaluation, JECFA has maintained the provisional tolerable weekly intake (PTWI) of OTA at 100 $ng\, kg^{-1}$ of bodyweight based on the lowest observed adverse effect level of chronic toxicity in pigs. The European Food Safety Authority (EFSA) has recommended a PTWI of 120 $ng\, kg^{-1}$ bodyweight.

JECFA has assessed the dietary exposure to OTA in Europe from processed cereals as 8–17 and EFSA as 7–10 ng per kg of bodyweight per week, both well below the PTWI. Even with some additional intake from wines and coffee, the risk from intake of OTA in Europe appears to be acceptable. Intakes in other parts of the world are lower in the absence of appreciable levels in cereals.

Chemical Analysis

Analysis of OTA from foods is complicated by the facts that (1) it is unstable in alkali, which causes lactone ring opening, so any subsequent purification on an immunoaffinity column will be inaccurate and (2) OTA binds to protein, so purification by protein precipitation will also lead to serious inaccuracy.

Extraction

The AOAC International standard method uses phosphoric acid for acidification before extraction with chloroform. Acetonitrile:water is also used.

Purification

In the AOAC method, purification is carried out by absorption on a sodium bicarbonate–diatomaceous earth column, washing with hexane, then chloroform, followed by elution using acetic acid–benzene. Immunoaffinity columns are also recommended.

Assays

The traditional methodology of thin layer chromatography is still in use, and is recommended for less developed economies as it is inexpensive and reliable. A suitable developing solvent is benzene:methanol:acetic acid (18:1:1). OTA may be visualized under UV light. Confirmation is blue fluorescence after exposure to ammonia vapor or spraying with ethanolic sodium bicarbonate.

More modern methods for analysis are based on high performance liquid chromatography, with or without mass spectrometry.

Levels in Foods

The crops and foods affected by fungi producing OTA are quite specific. OTA is produced in temperate climate cereals (wheat and barley) by *P. verrucosum*. It is produced by *A. ochraceus* and related species, and by *A. carbonarius*, during drying or processing of coffee and cocoa, where the dominant causative fungus varies from region to region. Grapes are susceptible to infection by *A. carbonarius* just before or after harvest, due to skin splitting from rain or mechanical damage or infection by pathogenic fungi, especially *Rhizopus stolonifer* or powdery mildews. OTA may be produced just before harvest, during drying of raisins and other dried fruits, or in grape juice before crushing in wine making.

Management Options

Limits in Foods

The Codex Alimentarius Commission presented a recommendation to set a limit of 5 $\mu g\,kg^{-1}$ of OTA in cereals and cereal products, and a number of countries have adopted this limit, though it is still under discussion by Codex. The European Union has set a limit of 5 $\mu g\,kg^{-1}$ of OTA in unprocessed cereals and roasted coffee beans, 3 $\mu g\,kg^{-1}$ in processed cereals, and 10 $\mu g\,kg^{-1}$ in dried vine fruits and instant coffee. In wines and grape juice, the limit is 2 $\mu g\,kg^{-1}$, whereas infant foods must not contain more than 0.5 $\mu g\,kg^{-1}$.

Preharvest Control

Control of OTA levels before processing in foods relies on good agricultural practice. As none of the fungi that produce OTA are known to be systemic invaders or pathogens, the key to low levels in foods is rapid drying, and maintenance of low moisture, regardless of the crop. The problem in cereals in cool moist European climates is to accomplish rapid drying, and then to prevent moisture migration in silos. Coffee is grown under conditions often conducive to mist or rain at harvest, and again effective drying is the key to keeping OTA levels low. Good agricultural practice for vineyards includes disease and insect control, avoidance of mechanical damage before drying, rapid harvest and crushing for wines, and selection of cultivars resistant to splitting in late preharvest rain.

Processing

OTA is largely removed during the wine making process as it is bound to solid fractions and sediment. Some fining agents can also reduce OTA levels in wine. Red wines retain slightly more OTA than white wines, but, overall, the carryover from grapes into finished wine is between 1% and 8%.

Processing of wheat to make flour reduces OTA levels, though the process used greatly influences final levels in bread. Milling hard wheat to produce white flour produced approximately 65% reduction in OTA, and a further 10% decrease occurred during baking. Wholemeal flour and bread showed much less reduction in OTA during processing, as might be expected, because less of the grain is discarded.

Like most mycotoxins, OTA is relatively heat stable. In dry wheat, 50% inactivation at 100, 153, 200, and 250 °C required 707, 201, 12, and 6 min, respectively. In moist wheat, the corresponding inactivation times at 100, 150, and 200 °C were 145, 64, and 19 min, respectively. Complete destruction did not occur even at 250 °C.

Processing coffee beans, including roasting, drink preparation, and instant coffee production all reduce OTA levels in coffee. Dark roasting may remove up to 98% of OTA, but light roasts have much less effect.

MYCOTOXINS

Patulin

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Introduction

Patulin (CAS 149-29-1) is a furopyranone, 4-hydroxy-4H-furo[3,2-o]pyran-2(6H)-one, molecular formula $C_7H_6O_4$, molecular weight 154.12 (Figure 1). Patulin is stable in many kinds of foods, including apple and grape juices and dry maize, but not in wet maize, orange juice, flour, fermented juices, or cheese. Disappearance appears to be due to the reaction with sulfhydryl groups of amino acids or proteins, but that does not necessarily lead to a complete loss in biological activity. Patulin is moderately heat stable, surviving the pasteurization processes.

In the heady days after the discovery of penicillin, extensive searches were conducted for other fungal compounds that might be of therapeutic value. Many metabolites produced by *Penicillium* species were discovered and evaluated. For a short time, patulin was considered to be a possible cure for the common cold, but like most *Penicillium* metabolites apart from penicillin, it turned out to be too toxic to be useful as a drug. Patulin is considered as a mycotoxin.

Patulin is produced by 10 or more *Penicillium* species, including *P. carneum*, *P. paneum*, *P. glandicola*, and *P. griseofulvum*, all of which occur in foods from time to time, and also by the heat resistant spoilage fungus *Byssochlamys fulva*. However, the only patulin producer of significance for food safety is *P. expansum*.

P. expansum can be found in a variety of foods, but its importance lies in its ability to cause destructive rots in apples and pears. Mechanical damage or contact with a rotting fruit permits entry to fruit tissue. *P. expansum* forms brown, circular rots and produces patulin in the damaged tissue. In time, growth becomes visible as a blue colony, with a heaped-up appearance (Figure 2). The rot will consume a fruit in a few days at 25–30 °C.

On standard growth media such as Czapek yeast extract agar or malt extract agar (CYA), *P. expansum* forms moderately quickly growing colonies, 30–40 mm in diameter after 7 days at 25 °C. Conidial production is profuse, dull green, and often heaped in small tufts. The colony reverse on CYA is usually dark brown. The fruiting structures are very small, like little brushes, typical of species in *Penicillium* subgenus *Penicillium* (Figure 3).

P. expansum grows strongly at 0 °C and it has a maximum temperature for growth near 35 °C. The minimum water activity for germination is 0.82. *P. expansum* has a very low requirement for oxygen: concentrations as low as 1% oxygen have little effect on growth.

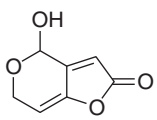

Figure 1 Chemical structure of patulin.

Hazard Identification

Consumers will always avoid rotten fruit, so patulin is not an issue in fresh fruit. However, harvesting for commercial juice manufacture often causes fruit damage, and may involve delays after picking that enable rot development, so apple juice is liable to contain patulin. Poor quality control, i.e., the use of rotting fruit in juice or cider manufacture, can result in high concentrations of patulin in products. For example, levels of up to 350 $\mu g\,l^{-1}$, 630 $\mu g\,l^{-1}$, 1770 $\mu g\,l^{-1}$, and even 3990 $\mu g\,l^{-1}$ have been reported in the literature. The worst results were obtained from apple juice sold at roadside stalls.

Hazard Characterization

Early indications that patulin is carcinogenic or genotoxic have not been confirmed, and effects were only produced at levels much higher than could be expected to occur in foods. However, as many people consume apple juice regularly, chronic toxicity to humans is an area of concern, especially as it is widely consumed by children as well as adults. The FAO/WHO Joint Expert Committee on Food Additives (JECFA) examined evidence for the toxicity of patulin in 1990 and 1995. In agreement with the International Agency for Research on Cancer, JECFA concluded that lack of evidence from studies in experimental animals prevented any evaluation of possible carcinogenicity in humans. However, JECFA noted that in short term studies, patulin could cause gastrointestinal problems, including hyperemia, distension, hemorrhage, or ulceration. The No Effect Level (NOEL) derived from a 13-week study in rats was 0.8 mg kg^{-1} bodyweight per day, based on slight impairment of kidney function and villous hyperemia in mild and high dose groups. The NOEL from a long term study of reproductive toxicity or carcinogenicity in rats was 43 μg kg^{-1} bodyweight per day. Doses above 1.5 mg kg^{-1} bodyweight per day produced maternal toxicity and an increase in the frequency of fetal resorptions, indicating that patulin can be embryotoxic at high dose levels, well above those seen in foods. Patulin also appears to have immunosuppressive properties at high doses. JECFA also concluded that patulin can be genotoxic, though data were variable and differences were observed between bacterial and mammalian cells.

JECFA established a provisional maximum tolerable daily intake (PTDI) of 0.4 μg kg^{-1} bodyweight per day.

Exposure Assessment and Risk Characterization

From the results of the US food surveys in 1994–96, the US Food and Drug Administration examined results from nearly 3000 samples of apple juice, both for sale as fresh juice and as ingredients for other foods. It was found that the mean patulin exposure for all age groups, 1–2 year old children, and children under 1 year was 0.14, 0.80, and 0.21 $\mu g\,kg^{-1}$ bodyweight per day, respectively. At the 90th percentile of exposure, the figures were 0.26, 1.7, and 0.40 $\mu g\,kg^{-1}$ bodyweight per day, respectively. Figures for 1–2 year old children exceeded the PTDI. However, if a limit of 50 $\mu g\,l^{-1}$ of patulin in apple juice was enforced, the figures for the 90th percentile of exposure were 0.10, 0.67, and 0.27 $\mu g\,kg^{-1}$ bodyweight per day, respectively. The figure for young children still exceeded the PTDI, but because of safety factors in that figure, intake levels would still be many times lower than the NOEL calculated by the JECFA.

In consequence, a regulatory limit of 50 $\mu g\,l^{-1}$ for patulin in apple juice and other apple products is recommended by the Codex Alimentarius Commission, and because of that adopted by a number of countries. Many others, including Canada and Australia, have not set limits. Two points are worth noting. First, in contrast to the other major mycotoxins, there have been no reported outbreaks in human or domestic animals associated with the ingestion of apple products containing patulin. Second, patulin intake is highest in temperate zone countries. As apples are a cool climate crop, patulin is more likely to be found in products in temperate zone countries than those in tropical regions.

Chemical Analysis

Although the determination of patulin levels in juices can be carried out by thin layer chromatography (TLC), it is recommended that high performance liquid chromatography (HPLC) be used where possible. TLC methods are imprecise because the recommended extraction by ethyl acetate also extracts other compounds such as 5-hydroxymethylfurfural, and the visualization methods are also relatively insensitive.

Risk Management

Although patulin is produced by a number of fungal species, the only practical concern is that from apple juice. In good commercial practice, rots, which contain nearly all of the patulin, are removed by hand culling, by water flumes or, most effectively, by high-pressure water jets before the apples are crushed. These measures provide effective control. Some patulin migrates from the rots to sound tissue, but residual levels are low. Fermentation of apple juice to produce alcoholic cider has been shown to reduce patulin levels by 90% or more. It is notable that in Australia, regulators use excessive patulin levels as an indicator of the use of poor quality raw materials in juice manufacture, rather than seeking prosecution for excessive levels of the mycotoxin.

MYCOTOXINS

Zearalenone

JI Pitt, CSIRO Animal, Food and Health Sciences, North Ryde, NSW, Australia

Chemical Characterization

Zearalenone (ZEA) belongs to a large family of fungal metabolites described as the resorcylic acid lactone group. It has the formula 6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)-*β*-resorcylic acid lactone, with a molecular formula of $C_{18}H_{22}O_5$ and a molecular weight of 318 (Figure 1). Its Chemical Abstracts Service (CAS) registry number is 17924-92-4.

Fungal Sources

ZEA is produced by the same *Fusarium* species that produces trichothecenes deoxynivalenol (DON) and nivalenol, i.e., *Fusarium graminearum* and *Fusarium culmorum*, and also by *Fusarium crookwellense* and some strains of *Fusarium equiseti* and *Fusarium semitectum*. Generally speaking, its formation occurs under the same conditions as trichothecene production, and the main sources are maize and small grains. As known so far, the conditions for ZEA production seen in these commodities are similar to trichothecene production, i.e., before harvest, mostly at temperatures between 10 and 30 °C and above 0.90 water activity.

History

In the 1950s and 1960s, some US states experienced severe epidemics of maize ear rot. When farmers used contaminated maize as a feed for pigs, a feed refusal and vomiting syndrome became evident, which led to the discovery of DON. Consumption of contaminated maize was also found to be associated with estrogenic effects in pigs. In females, symptoms included enlargement of mammary glands and genital organs, ovary atrophy, infertility, reduced litter size, and reduced piglet weight. In males, contaminated feed was associated with enlargement of mammary glands and atrophy of testes. In 1962, the estrogenic syndrome was reproduced in pigs by feeding maize on which a pure culture of *F. graminearum* had been grown. The syndrome was found to occur in mice also and the pure compound was characterized in 1966.

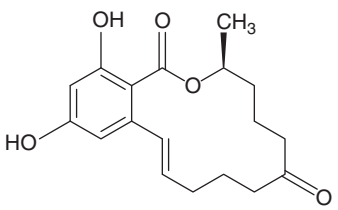

Figure 1 The chemical structure for ZEA. It has the formula 6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)-*β*-resorcylic acid lactone, with a molecular formula of $C_{18}H_{22}O_5$.

Toxicology

ZEA has a low acute toxicity, a 50% lethal dose in rats and chickens exceeding 2 g kg^{-1} bodyweight, administered orally. However, much lower levels of ZEA and its metabolites possess estrogenic activity in experimental and farm animals. The most obvious problems are seen in pigs: doses of ZEA as low as 1–5 mg kg^{-1} can induce vulvovaginitis and vaginal and rectal prolapse in young female pigs. Ruminants, sheep and cattle, are more resistant, and it seems likely that rumen microorganisms are responsible for metabolizing ZEA to compounds of lower toxicity. Chickens are also comparatively resistant, tolerating up to 30 mg kg^{-1} ZEA in feed.

In one set of experiments in mice, ZEA ingestion resulted in an increased incidence of liver and pituitary tumors, consistent with a hormonal carcinogenic action. However, no effects were seen in rats, and the International Agency for Research on Cancer considered the evidence for animal carcinogenicity was limited. No studies on human carcinogenicity have been reported. The nature of its toxicity is not completely understood.

The metabolism of ZEA involves reduction of the 6-keto group, resulting in the formation of α- and *β*-zearalenol. α-Zearalenol has a greater estrogenic activity than ZEA. Some evidence has been put forward that ZEA is associated with the early onset of puberty and advanced growth of girls in Puerto Rico, Hungary, and Italy. However, its importance in human health is still poorly understood.

Both the Joint FAO/WHO Expert Committee on Food Additives and European Scientific Committee for Food have established a provisional maximum tolerable daily intake of ZEA and its metabolites at 0.5 μg per kg bodyweight per day.

Chemical Analysis

As with other mycotoxins, ZEA sampling should be conducted systematically to obtain representative samples. Samples are extracted with aqueous mixtures of methanol, acetonitrile, or ethyl acetate, followed by clean up. ZEA analyses can be

carried out effectively by thin layer chromatography, but high-performance liquid chromatography (HPLC) with fluorescence detection is now widely used. However, because of false positive results, HPLC coupled to mass spectroscopy is used to quantify and confirm the presence of ZEA in commodities. Rapid screening tests based on ZEA antibodies are also commercially available.

Occurrence and Regulation

ZEA occurs in the same situations as DON, i.e., as the result of growth of certain *Fusarium* species on maize and small grains. ZEA occurs in all regions of the world, but is less commonly found than DON. Levels in foods are usually less than 1 mg kg^{-1} in good quality grain, but in moldy material, concentrations of 10 mg kg^{-1} or more may occur. As with DON, levels are higher in crops grown in cooler, damper climates.

No internationally recognized limits for ZEA exist, with country regulations varying from 20 to 1000 μg kg^{-1} of food or animal feed, sometimes even higher.

Management

Control of ZEA in crops is similar to that for DON. However, as DON is the more potent compound, ZEA control is likely to be incidental.

Dioxins, Furans, and Dioxin-like Polychlorinated Biphenyls

M Rose, Food and Environment Research Agency, York, UK

Introduction

Polychlorinated dibenzo-p-dioxins, polychlorinated dibenzofurans, and dioxin-like polychlorinated biphenyls (PCDD/Fs and dl-PCBs, 'dioxins' – Figure 1) are ubiquitously present in the environment and in human tissues even when there is no history of occupational or accidental exposure. Although exposure could occur through inhalation of air, dermal absorption, consumption of drinking water, and consumption of food, there is no doubt that food is by far the most significant input for most of the population where there is no history of occupational exposure. It has been estimated that dietary intake of 2,3,7,8-TCDD accounts for as much as 98% of human exposure. Over the past 15–20 years, many measurements have been made of dioxins in foods, which all lead to the conclusion that over 90% human exposure is normally from food.

Although the original focus was on just the PCDD/Fs, over the past decade or so, it has also become generally recognized that some of the PCBs also bind to the Ah-receptor and elicit dioxin-like biochemical and toxic responses, so that assessment of the health risks of exposure to dioxin-like chemicals must consider these PCBs as well as PCDD/Fs. More recently, attention is being given to other emerging contaminants such as brominated dioxins and biphenyls, polychlorinated (and brominated) naphthalenes, and other compounds which also might elicit dioxin-like toxicity. It is possible that bromine-containing compounds may become more important in time as a result of increased use of bromine in products such as flame retardants, and this use may be linked with increasing amount of bromine-containing chemicals with dioxin-like activity being released into the environment and thereby into our food and bodies.

This section addresses topics such as levels of dioxins in foods, the resulting intakes, geographical variations, trends over time, and the pathways by which PCDD/Fs and PCBs are transferred from the environment to the food chain. Some factors that influence the accuracy and comparability of analytical data are also discussed.

Toxicology and Health Consequences

Dioxins are carcinogenic and can also cause adverse developmental and reproductive effects. Their negative health impacts are linked to their metabolic resistance and lipophilic nature, i.e., their capacity to accumulate in fat tissue in animals and humans. Dioxin-like compounds are known endocrine disruptors. These adverse health impacts have not only been demonstrated by animal studies, but also been observed following accidental and significant short-term human exposure to dioxins. As with other pollutants, the developing fetus and also newborns are most sensitive to dioxin exposure (see World Health Organization (WHO) Fact Sheet No. 225 (2007) on 'Dioxins and their effects on human health').

All humans are faced with a certain 'background' exposure to dioxins. More than 90% of human exposure to dioxins typically occurs through the food supply, mainly fish, meat, and dairy products. Some groups of individuals experience

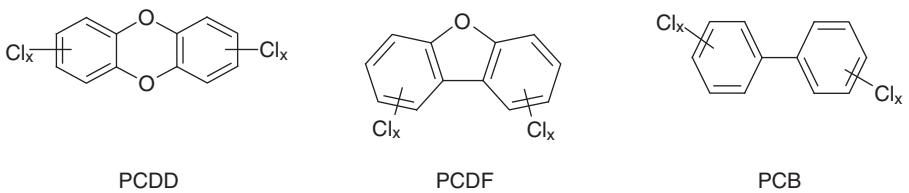

Figure 1 Structures of PCDDs, PCDFs, and PCBs.

higher exposure due to their occupation or because of their diets. Consumers may reduce their own exposure to dioxins by keeping a balanced and varied diet and limiting oily fish, liver, dairy, and other foods of animal origin. Individual strategies are, however, contentious, as oily fish, for example, is not only considered especially important for a healthy diet but also ranks among the foodstuffs most affected by dioxin contamination due to the pollution of the rivers and seas. This has been the subject of risk–benefit analysis, including that done by the UK Scientific Advisory Committee on Nutrition.

Analytical Methods

Analytical methods for dioxins fall into one of two broad categories: screening methods such as the chemically-activated luciferase expression (CALUX) bioassay and confirmatory methods such as gas chromatography coupled to high-resolution mass spectrometry (GC–HRMS). Both need extensive sample extraction and clean-up before they can be used. The CALUX bioassay uses a genetically modified cell line (rat hepatoma H4IIE GudLuc 1.1) that expresses the firefly luciferase on exposure to dioxins or dioxin-like compounds. The amount of luciferase is related to the amount of dioxin-like compounds in the exposure mixture and can be easily quantified with a luminometer. Confirmatory techniques using GC–HRMS involve adding known quantities of standards labeled with stable isotopes to the sample before analysis. Sample extracts are separated using GC and exact ratios of the compounds of interest and the known amount of isotopically labeled standard that was added are measured using HRMS.

Treatment and Interpretation of Analytical Data

Anyone who uses analytical data on dioxin-like chemicals, or the intake assessments derived from them, needs to remain aware of various issues that may influence the accuracy and comparability of the results. Even in some recent studies there are undoubtedly some issues related to the representativeness of sampling and to the accuracy of measured concentrations. Furthermore, interpretation of reported data is complicated by the differing ways in which compounds that are not actually detected and measured are represented in summations or averages.

Toxic Equivalency Factors

Because of the need to assess the risk from complex mixtures of dioxins, an approach has been adopted that assigns a factor relating to the relative potency of each congener, based on a comparison with the toxicity of 2,3,7,8-TCDD. Each chemical is assigned a toxic equivalency factor (TEF) related to the most toxic of the dioxins, 2,3,7,8-TCDD, which is given a TEF of 1. The total toxic equivalency of a mixture is the sum of the TEF-weighted concentration of each compound in the mixture, but there is some variation in the terminology used by different authors; total toxic equivalence (TEQ), summed TEQ, and Σ TEQ are self-explanatory, whereas the unqualified acronym, TEQ, is used by different authors to refer either to the total or to the TEF-weighted concentrations of individual compounds.

$$\text{TEQ} = \text{S}[\text{PCDD}_\text{i} \times \text{TEF}_\text{i}] + \text{S}[\text{PCDF}_\text{i} \times \text{TEF}_\text{i}] + \text{S}[\text{PCB}_\text{i} \times \text{TEF}_\text{i}]$$

Although consideration of total TEQs is essential, it is regrettable that many data are easily available only in this form. As discussed in the Section on PCDDs and PCDFs, total TEQ figures can have deficiencies and their interpretation is greatly facilitated by inspection of the underlying congener-specific data, especially when data from different laboratories are compared. The contribution of specific congeners to the total gives a particular pattern or 'fingerprint' which can be of great value for source identification during specific contamination incidents.

PCDDs and PCDFs

During the 1980s, a number of different TEF schemes were used. International toxic equivalency factors (I-TEFs) for PCDD/Fs were set in 1990 and were adopted by almost all scientists and regulatory authorities. A more recent system of TEFs, including TEFs for the dioxin-like PCBs (see Significance of TEFs for PCBs), set by the WHO in 1997 (WHO-TEFs) has been accepted by most authorities. This system is subject to periodic revision in light of new information about the toxicology of the various congeners, and revised TEFs were proposed in 2005. These have still not been incorporated into legislation. Previous TEFs were assigned in increments of 0.01, 0.05, 0.1, etc., but for this re-evaluation, it was decided to use half order of magnitude increments on a logarithmic scale of 0.03, 0.1, 0.3, etc. Changes were decided by the WHO expert panel for 2,3,4,7,8-pentachlorodibenzofuran (PeCDF) (TEF 0.5→0.3), 1,2,3,7,8-pentachlorodibenzofuran (PeCDF) (TEF 0.05→0.03), octachlorodibenzo-p-dioxin and octachlorodibenzofuran (TEFs 0.0001→0.0003), 3,4,4#,5-tetrachlorbiphenyl (PCB81) (TEF 0.0001→0.0003), and 3,3#,4,4#,5,5#-hexachlorobiphenyl (PCB169) (TEF 0.01→0.03), and a single TEF value (0.00003) was given for all relevant mono-ortho-substituted PCBs. The idea is that TEFs will be subject to periodic review and new candidates with a similar mode of toxic action may be included in the scheme in future.

Significance of TEFs for PCBs

In many food samples, such as some fish, the TEQ contribution made by PCBs may equal or exceed that made by PCDD/Fs. In comparing or interpreting data expressed as TEQs, it is of paramount importance to note whether or not PCBs are included in the total.

It must be remembered that other PCBs have a variety of other biological effects; although consideration of 'dioxins' is incomplete without the inclusion of dioxin-like PCBs, this treatment is certainly not a sufficient response to PCBs in general.

Limits of Detection

In several types of food, it is common for the concentrations of some of the individual dioxins and PCBs to be below the analytical limits of detection (LOD). Inevitably, the sensitivity

of analyses in different laboratories varies, and so does the method of assessing and reporting the LOD. Frequently, quantitative results are reported for any congener giving a GC–HRMS peak with a signal-to-noise ratio (S/N) of, say, 3 or more. If no peak is detected, then an estimate is made of the concentration that would have produced this S/N. LODs so estimated vary between congeners and between different analyses and even between different times. Some laboratories work, instead, to a 'limit of quantitation' (LOQ) which, strictly, should be defined as the lowest concentration at which a specified measurement precision is achieved, as demonstrated in method validation studies, but which is, instead, sometimes taken to be a multiple of the LOD. Alternatively, some data are reported after applying an arbitrary, but consistent, 'reporting limit.' Different laboratories analyzing the same samples, or even interpreting the same raw data, may arrive at differing conclusions about which congeners are present at measurable concentrations, and at quite different LOD values for other congeners, even though their 'positive' results may be in good agreement.

When data include nondetects, then at least three different methods are in use for the calculation of total TEQ concentrations. These are the representation of nondetected congeners in subsequent calculations by: (1) a concentration of 0; (2) a concentration equal to the LOD; or (3) a concentration equal to $0.5 \times$ LOD. Even this may expand to five different methods if LODs and LOQs are differentiated.

The terms 'lower-bound' and 'upper-bound' are generally used to refer to the first two of these methods, which correspond, respectively, to the minimum concentration 'known' to be present and to a larger concentration which 'might' be present. The $0.5 \times$ LOD calculation gives a result which lies midway between these upper and lower bounds, and is sometimes referred to as 'median bound.' This often gives the appearance of better comparability, but if the upper-bound and lower-bound totals are far apart, as is sometimes the case, then the mid-point is not necessarily any closer to the true total TEQ concentration than is either extreme. Use of the $0.5 \times$ LOD convention in calculations from data in which the LOD itself varies between analyses can be particularly misleading.

Further complications may arise when results for specific congeners are averaged across a number of samples, with the total TEQ summation made using the average concentrations. In addition to using all of the above substitution approaches, some workers average only detected values to generate a statistic which is meaningless unless the frequency of detection is also taken into account.

All of these approaches have utility in some circumstances, if applied consistently, but comparisons of total TEQ data representing different detection limits and calculation methods can be extremely misleading.

Analytical Accuracy and Precision

All analytical measurements have, associated with them, a measurement uncertainty. Unfortunately, information on the accuracy and precision of measurements is often absent from reports of data on dioxins. The analysis of these substances in foods is particularly challenging because of the very low concentrations that are involved. Several studies have shown that good agreement can be achieved by highly expert laboratories, but the number of laboratories engaged in these analyses has increased dramatically in the past few years and there is a great variation in the quality of analysis available.

There exist a number of schemes that can be used to assess the performance of a laboratory. The largest of these schemes is the interlaboratory studies organized on an annual basis by the Norwegian Institute of Public Health. It can be seen that over the past decade the scheme has been in operation, the number of laboratories that participate has increased, and performance has generally improved. Samples with low amounts of dioxins represent the biggest challenge. There are also proficiency testing schemes organized by FAPAS (Food Analysis Performance Assessment Scheme) and a closed scheme organized by the EU Reference Laboratory where there is an obligation for National Reference Laboratories within the EU to take part.

Representativeness

The most accurate laboratory analysis can only give a result that represents the sample taken for analysis. How that sample is related to the broad food supply depends on both the quality and the intent of the sampling scheme.

Sampling to assess compliance with limits, whether statutory or guidelines, may not be appropriate for estimation of average intakes. For example, many studies have concentrated on domestic food production and have not included imports, or aim for broad geographical coverage without weighting by food production statistics. Any indication of localized contamination usually leads to more intensive sampling in the same location; small but significantly contaminated locations may, therefore, make a disproportionately large contribution to 'average' concentrations if these are based on all available data. Dietary habits and food consumption patterns may vary regionally and this should also be taken into account, for example, communities near the sea may consume more fish, and this may be caught locally. Some individuals may also have different dietary habits such as vegetarians, those growing their own produce, or those working in an industry giving free or cheaper access to certain food types. Food consumed outside the home, for example, in restaurants or staff canteens also needs to be considered.

For most foodstuffs, achievement of a representative result inescapably necessitates coverage of a large number of samples. However, because of the cost and difficulty of analysis, many studies are based on rather limited numbers of samples. Composite samples formed from many samples of each category of foodstuff are sometimes used; such pooling is usually an integral part of total diet study (TDS) schemes (see The UK TDS). The use of composite samples can be a cost-effective way of obtaining robust measures of average concentrations, but it does not furnish any information on the width and shape of the distribution of concentrations in the individual samples.

A further source of confusion is the varied definition of some terms used in food consumption surveys and databases.

The word 'cereal' in some reports includes simply grain and flour, in others cereal products which may include breads, cakes, and pastries prepared with animal fats, and sometimes various 'breakfast foods.'

Methods for Estimating Dietary Exposure

The most usual method of assessing average dietary intake is to multiply the consumption of each type of food by the concentrations found in corresponding food samples, and to add together the contributions from various components of the diet. For simple population averages, average concentration data can be combined with average food consumption data. For high consumers of particular foods that may be affected by contamination, for example, high fish eaters, then the average concentration data can be combined with high food consumption, for example, at the 95th or 97.5th percentile consumption of particular foods. If high food consumption could also be linked to contamination of hot-spots, for example, high eaters of fish caught locally from polluted waters, then it may be appropriate to combine high concentration data with high percentile consumption data.

A further option is the analysis of duplicate diets, whereby volunteers collect a duplicate portion of all food they consume over a period of time and this is used to produce a composite sample representing the diet.

There is a large amount of data available now for Europe, North America, Australia, and parts of Asia. Gaps still exist for Africa, and parts of Asia and South America, where relatively few studies have been conducted.

Tolerable Intakes

During the 1980s and early 1990s, a number of countries performed risk assessments and derived tolerable daily intakes (TDIs) of dioxins in the range of 1–10 pg kg^{-1} body weight (bw). A TDI is the maximum amount of a contaminant which can be eaten every day over a whole lifetime without incurring appreciable risk to health.

As the data on aspects of the toxicology of PCDD/Fs and PCBs have become more extensive and of better quality, views about the appropriate value of a TDI changed and values resulting from different assessments have become more consistent.

The WHO in 1998 concluded that the TDI was in the range of 1–4 pg TEQ kg^{-1} bw. At the end of May 2001, the Scientific Committee on Food (SCF), an expert committee that advises the European Commission, decided that the tolerable intake should be expressed on a weekly rather than a daily basis and set a tolerable weekly intake (TWI) of 14 pg WHO-TEQ kg^{-1} bw. The WHO/FAO Joint Expert Committee on Food Additives (JECFA) established a provisional tolerable monthly intake (PTMI) of 70 pg kg^{-1} bw per month in June 2001. These values are all of the same approximate value and are consistent with one another.

Legislation

The EU was the first body to set extensive and comprehensive limits for PCDD/Fs, and there is still little other legislation in place world-wide. Regulations came into force in July 2002 and included limits for PCDD/Fs in food and animal feed. Dioxin-like PCBs were later included in 2006. Proposals exist to include nondioxin-like PCBs and these are likely to be regulated later in 2010 or in 2011. This regulation was initially supported by a monitoring plan, which was implemented by all member states. The regulation is supported by strict performance criteria for analytical methods that are used and this is detailed in other legislation. Upper-bound results are used for monitoring purposes and for official control (see Limits of Detection).

The UK TDS

The TDS is a continuous market basket-type survey in which foods representing the average UK diet (based on Defra's Expenditure and Food Survey and trade statistics) are purchased, prepared, and combined into groups of similar foods for analysis. The TDS has been run since 1966 and has been used as a part of the UK monitoring program for chemicals in food. It allows the general UK population's average exposure to nonnutrients (i.e., contaminants such as heavy metals, dioxins, and pesticides), as well as intakes of some nutrients to be estimated. Used in conjunction with the Expenditure and Food Survey, the TDS has enabled trends over time to be established and assessments on the safety and quality of the food supply to be made.

Food samples representative of the UK diet are purchased throughout the year in 24 towns covering the UK, and 119 categories of foods are combined into 20 groups of similar foods (e.g., bread, poultry, milk, etc.) for analysis. The relative proportion of each food category within a group reflects its importance in the average UK household diet. Foods are grouped so that commodities known to be susceptible to contamination (e.g., offal and fish) are kept separate, as are foods which are consumed in large quantities (e.g., bread, potatoes, and milk). The quantities and relative proportions of each food that make up the total diet are largely based on data from the Expenditure and Food Survey and are updated annually to reflect changing eating habits.

Vegetables, Fruits, Pulses, and Grain

Growing plants may be exposed to PCDD/Fs and PCBs via soil, ground-water, and the air. With the exception of the *Cucurbitaceae* family (which includes zucchini or courgette) in which some uptake from soil has been demonstrated, absorption of dioxin-like compounds through plant roots and subsequent translocation does not occur to any significant extent. The outer layers of root crops may become contaminated by direct contact with soil particles, but this will normally be removed by peeling or washing. Contamination of the above-ground part of plants is considered to result largely from retention of airborne PCDD/Fs and PCBs, which

may include absorption from the vapor-phase by the waxy cuticle and retention of particulate-bound contaminants. The highest levels are therefore expected when a convoluted surface of high surface area is combined with a pronounced waxy cuticle.

Although contamination of plant material consumed by food-producing animals is a major part of the pathway from primary source to human dietary exposure, levels in vegetables, fruits, and grains consumed by humans are very low, immeasurably so for many laboratories. Many otherwise broadly based food surveys have omitted analysis of fruits and vegetables, either because of the assumption that their contribution to intake would be insignificant compared with that of fatty foods, or because of the very real analytical difficulties presented by the low concentrations of contaminants present. A number of intake assessments do, however, include quite large contributions for fruits and vegetables.

Data that have been reported need to be viewed with particular care because of issues of representativeness, detection limit, and accuracy. In the latter context, in contrast to animal tissues in which only the 2,3,7,8-substituted PCDD/Fs are found, many other congeners will be present in deposits on vegetation, at higher concentrations than those that contribute to the TEQ, and the concentrations in general will be lower because there is no bioaccumulation. Obtaining the required congener-specificity and sensitivity in the analysis becomes much more difficult in this case.

Animal Products

The main route for exposure of most food-producing animals to PCDD/Fs and PCBs is through their feed. Considerable progress has been made in understanding and modeling agricultural food chain accumulation, in which, for background contamination, the dominant pathway is that of atmospheric distribution and deposition onto vegetation. There is abundant evidence that proximity to point sources of atmospheric PCDD/Fs, such as incinerators operating below recommended temperatures and metal reclamation sites, can lead to markedly raised levels in milk and meat.

There have been a number of recent examples of high levels of contamination in manufactured feeds being carried over into foods. In Europe, much analytical and regulatory attention is now focused on animal feeds but little information is available on the relative importance, under 'background' conditions, of manufactured feeds versus atmospheric distribution.

There is some possibility that the use of sewage sludge for soil amendment could result in increased exposure of livestock, but recent experimental evidence indicates that carry-over of PCDD/Fs entering the feed as a result of sewage sludge fertilization is not significantly different from that for feed containing background levels of PCDD/Fs of atmospheric origin.

The use of pentachlorophenol-treated timber in animal housings has occasionally been found to result in increased levels of PCDD/Fs in cattle, and this was also a possibility for the recent contamination event associated with guar gum produced in India where the product was stored on treated pallets.

Milk and Milk Products

Excretion of PCDD/Fs and PCBs in milk is the main elimination pathway for these compounds in lactating cows. Since the first reports of the detection of PCDD/Fs in cow's milk in 1987, many surveys have been reported and probably more data have been generated on milk than any other foodstuff. Because milk from many animals is usually mixed together in the farm and then mixed with milk from further farms at the dairy, difficulties with representativeness of sampling are less than with other foods, and by sampling individual farms or individual dairies, data representing different sized areas can be obtained.

PCDD/Fs and PCBs are contained entirely in the milk fat. When expressed on a fat basis, milk products contain the same concentrations as the milk from which they were produced. Differences between milk and butter or cheese, reported in several surveys, may arise partly from issues of accuracy and representativeness, but may also occur because milk products are exported and imported to a greater extent and over greater distances than milk itself. Consequently, locally representative data for milk are not necessarily representative of milk products. A number of studies from the late 1980s and early 1990s demonstrated a marked localized influence on levels in milk produced in the vicinity of some incinerators and other point sources.

In terms of contribution to dietary intake, the estimated contribution from milk varies from approximately 15 to 40%.

Butter has been used as an integrative matrix to assess the difference in concentrations between global regions. This can be done because of the way milk is pooled before butter is made. In general, lower concentrations are found in butter from the Southern Hemisphere than in butter from more industrialized regions of the Northern Hemisphere.

Meat

Meat is a more heterogeneous group than milk and milk products and there are considerable differences in the species consumed by different ethnic groups and individuals. The 'meat products' classification included in a number of studies is poorly defined both in terms of the type and the proportion of meat included, and the representativeness of the resulting data is sometimes questionable.

Pork is usually found to have considerably lower levels of both PCDD/Fs and PCBs than beef. There is limited information on meat from other species.

Offal: There is increasing evidence that liver produced from farm animals such as cows, pigs, and sheep may contain elevated dioxin concentrations and exceed limits even when the livestock are given compliant animal feed and are exposed only to normal background levels of dioxin contamination in the environment. The dioxin concentrations in other commonly consumed tissues such as muscle, fat, kidney, etc., from the same animals will typically be well within regulatory limits. Because the limits were set on the basis of excluding the most contaminated foods from entering the food chain rather than on the basis of any health risk, they are under review and may be adjusted in light of this.

Eggs

It has been shown that PCDD/F concentrations in eggs depend on the type of housing; elevated wire cages gave the lowest concentrations whereas access to soil gave higher concentrations. This apparently results from intake of soil and organisms such as insects and annelids in which PCDD/Fs accumulate.

Fish

Although PCDD/Fs and PCBs are usually present in aquatic systems only at very low concentrations, bioaccumulation can result in significant concentrations in fish. As with terrestrial animals, the 2,3,7,8 substituted PCDD/F congeners dominate the pattern found in fish although this is not true of crustaceans and shellfish.

Fish comprise by far the most inhomogeneous food group due to the large number of different species used as food, with widely varying fat contents, different trophic positions, and the great variety of fishing grounds. In general, concentrations of chemicals such as PCDD/Fs and PCBs in fish depend on their fat contents, the extent to which the fish migrate, the number of times they spawn, and their ages, size, and feeding habits. For example, plaice are bottom-feeding fish and therefore may be more exposed to PCDD/Fs and PCBs bound to sediment. Herring has a relatively high fat content and is nonmigratory, which renders it more subject to localized contamination sources.

Consequently, the concentrations of PCDD/Fs and of PCBs are very varied. Because of the large seasonal variation in fat content of most fish, data are often expressed on a whole product basis, but units based on fat are also used, particularly when different species with different average fat contents are to be compared.

Certain fish species originating from the Baltic region are recognized as containing a high concentration of PCDD/Fs and PCBs. A significant proportion of oily fish from this region such as Baltic herring and Baltic salmon are unlikely to comply with the EU limit for PCDD/Fs, and this fish would, therefore, be excluded from the Swedish and Finnish diet. There are indications that such exclusion would have a negative health impact in Sweden and Finland, and consequently there is a local exemption to compliance with the legislation. Sweden and Finland have in place a system which informs consumers about the dietary recommendations for the consumption of fish from the Baltic region in order to avoid potential health risks.

Farmed fish are often fed on feed which contains fish meal. This has led to concerns that there is a possibility of biomagnification of PCDD/Fs and PCBs which are prevalent in fish, and there have been studies conducted that compare concentrations of these contaminants in farmed fish with wild fish of the same variety. Generally small differences have been found although these fall within the range of differences seen between different fish species.

River fish have been subject of more recent investigation partly because rivers are not usually as clean as the sea, and partly because there is an indication that people in some parts of the world are eating more river fish.

Miscellaneous Oils and Fats

Additional intake of fats arises from their use in cooking, or for direct consumption. The PCDD/F and PCB content of vegetable oils, as expected, has been found to be small but not negligible. Animal fats such as butter or lard contain higher concentrations of contaminants.

Food Processing and Cooking

PCDD/Fs and PCBs are stable chemicals that require temperatures far in excess of those encountered in cooking for their destruction. Decreases in concentration in meat during cooking have been observed. Thus in one study, pan-frying hamburger patties were found to reduce the amount of PCDD/Fs actually consumed by 40–50% if the pan fats and juices were discarded. In another, beef with PCDD/F incurred in an animal feeding trial was fried, grilled, barbecued, roasted using conventional and microwave ovens, and stewed in an open pan and pressure cooked. Concentration changes, on a whole product basis, were observed between raw and cooked product. However, in all cases these could be explained simply through changes arising from loss of water and elimination of PCDD/Fs with released fat. The total amounts of PCDD/Fs present in the system (including released fat) remained unchanged. Dietary intake of PCDD/Fs could, therefore, be reduced by the removal of visible fat from meat before cooking and by discarding any fat released from foods during the cooking process.

Reduction in the levels remaining in the tissue has also been reported for fish. It has also been demonstrated that removal of the skin from carp reduces the concentration of PCBs in the carp by approximately 50%.

Time Trends

In view of the great efforts made to identify and control or eliminate sources of PCDD/Fs, it would be both surprising and disappointing if a decrease in levels in foods was not evident, and such a decrease is readily apparent in data from several countries. A reduction, from a peak in the late 1960s to early 1970s, is also evident in human milk and human blood as well as in environmental samples. Levels of dioxin-like PCBs are also declining, but probably at a slower rate than those of PCDD/Fs, so that the proportion of the total TEQ intake attributable to PCBs is increasing. This presumably stems from the fact that PCB production ceased many years before effective control of PCDD/F formation in incineration, pulp bleaching, and other processes was achieved.

A decrease in intake can involve two contributions: first, from a decrease in the amount found in foods themselves, and second, it can arise from a shift in food consumption habits.

Animal Feeding Stuffs

Contamination of feeding stuffs has resulted in several recent 'incidents' which have precipitated considerable regulatory action in the EU.

In 1997, food control laboratories in Germany noticed a reversal of the downward trend in PCDD/Fs levels in milk, with average concentrations increasing over a short period from approximately 0.6 pg TEQ g^{-1} fat to 1.41 pg TEQ g^{-1} fat. An individual sample of milk was found to contain 7.86 pg TEQ g^{-1} fat. This increase was traced back to contaminated feed, and within the compound feed to the incorporation of Brazilian citrus pulp pellets. In the production of these pellets, approximately 2% lime is added and the most probable source of contamination was traced to be the use of a particular lime product formed as a byproduct in a chemical process.

The Belgian incident, which has been described in great detail, gained international notoriety. In March 1999, reduced hatch rates and increased mortality was observed in chickens. Some 2 months later, analysis showed high levels of PCDD/Fs in feeding stuffs and hens. It was eventually discovered that these were a concomitant of PCB contamination of fat. It has subsequently been established that approximately 25 l of PCB-containing transformer oil somehow became a contaminant of approximately 100 t of animal fat that was being recycled. Most of the fat was used to produce poultry feed, and some other to produce animal feeds. After incorporation into feeds, this affected some 20 000 t of poultry feed, 6000 t pig feed, and 400 t cattle feed, the former being contaminated at 811 ng WHO-TEQ kg^{-1} product. In two egg samples, concentrations as high as 266 and 713 pg WHO-TEQ g^{-1} fat were measured.

A further recent example of feed contamination, also discovered in Germany, was traced to the use of PCDD/F contaminated sawdust as a carrier for the incorporation of choline chloride into the feed.

More recently, in September 2008 a feed contamination incident occurred in Ireland, which subsequently led to contamination of pig herds and cattle herds supplied with this feed. The source of contamination was identified to be due to carry over of dioxins and PCBs from contaminated fuel used in a direct drying system in feed production. The animal feed was produced by direct (hot air) drying of raw baker's dough and left over bread products sent for recycling to a licensed feed mill. Two different types of feed materials were produced, bread-crumb, which was produced as pig feed, and biscuit, which was produced as cattle feed. The exhaust from the furnace used for drying, which was fired using contaminated oil, acted as transfer medium and the bread itself acted as filter adsorbing the contaminants from the circulating hot air. The concentrations found on a total TEQ basis ranged from 80 to 200 pg g^{-1} fat in the pork fat samples. Whereas PCBs were the dominant contaminants found, the PCDFs were of most toxicological concern.

Conclusion

PCDD/Fs and dioxin-like PCBs are present in foods throughout the world. Dietary intake is associated primarily with animal fats, offal, and with fish. The spread of concentrations in different examples of most animal products is rather dispersed. However, regionally representative averages are usually somewhat similar.

Most individuals consuming an 'average' mixed diet receive with it an intake of PCDD/Fs and dioxin-like PCBs of approximately 1.2–3.0 pg kg^{-1} bw per day. This is close to the currently recommended TDI, and a proportion of the population exceeds the TDI.

In Europe, the levels of these compounds in food are falling by approximately 50% each decade. It is clear that many adults will have had, for part of their lives, intakes well above current recommendations.

Regulation of primary sources of PCDD/Fs probably accounts for a significant proportion of the gradual decrease in the amount of these compounds in the environment, and the consequent downward trend of concentrations in food. Continued vigilance in the control of these emissions should help to ensure a sustained reduction in exposure.

However, there have been several specific incidents in which PCDD/Fs and PCBs have entered the food supply as a consequence of the use of contaminated animal feed. There could quite possibly have been incidents which have gone unnoticed because of the limited monitoring and surveillance programs that have been in place for these compounds. At the same time, the use of low-grade animal fat in feed can result in the recycling and biomagnification of dioxins and PCBs in food. Regulation of animal feeds, supported by surveillance programs, is therefore of considerable importance if dietary intakes are to be reduced to a minimum.

Individuals who wish to reduce their dietary intake of PCDD/Fs and PCBs can do so by reducing their consumption of animal fat, a choice that can have several health benefits. However, regular consumers of oily fish may receive a considerable part of their exposure to these compounds, possibly most of it, from this part of their diet which also has well-known benefits for health, and it is necessary to put any negative effects from exposure to dioxins and PCBs in context with the health benefits offered by the consumption of fish rich in unsaturated oils.

A holistic approach to food regulation will be increasingly needed in future. Toxicologists, nutritionists, environmental scientists, risk assessors, epidemiologists, analytical chemists, and others must all cooperate to examine the overall picture before decisions on regulation of foods are made.

Environmental Estrogens – Hazard Characterization

PD Darbre, University of Reading, Reading, UK

Glossary

Endocrine disrupting chemicals (EDCs) Exogenous substances that cause adverse health effects in an intact organism or its progeny consequent to changes in endocrine function.

Estrogens Physiological steroid hormones that regulate female reproductive function.

Metalloestrogens Inorganic xenoestrogens that can mimic or interfere in the action of physiological estrogens.

Phytoestrogens Nonsteroidal organic compounds found in plants that can mimic or interfere in the action of physiological estrogens (*phyto*: from the Greek word for plant).

Xenoestrogens Synthetic man-made organic compounds that can mimic or interfere in the action of physiological estrogens (*xeno*: from the Greek word for foreign).

Introduction

Estrogens are essential steroid hormones, which act at low concentrations as chemical messengers to regulate female reproductive function. The main physiological hormones, estrone (E_1), 17β-estradiol (E_2), and estriol (E_3), are synthesized from androstenedione and testosterone by aromatization in the premenopausal woman in the ovary (Figure 1). At the menopause, synthesis of estrogens by the ovary is reduced but production continues at a lower level from peripheral tissues and adrenal glands. Although estrogens act mainly within female reproductive tissues, they have also been shown

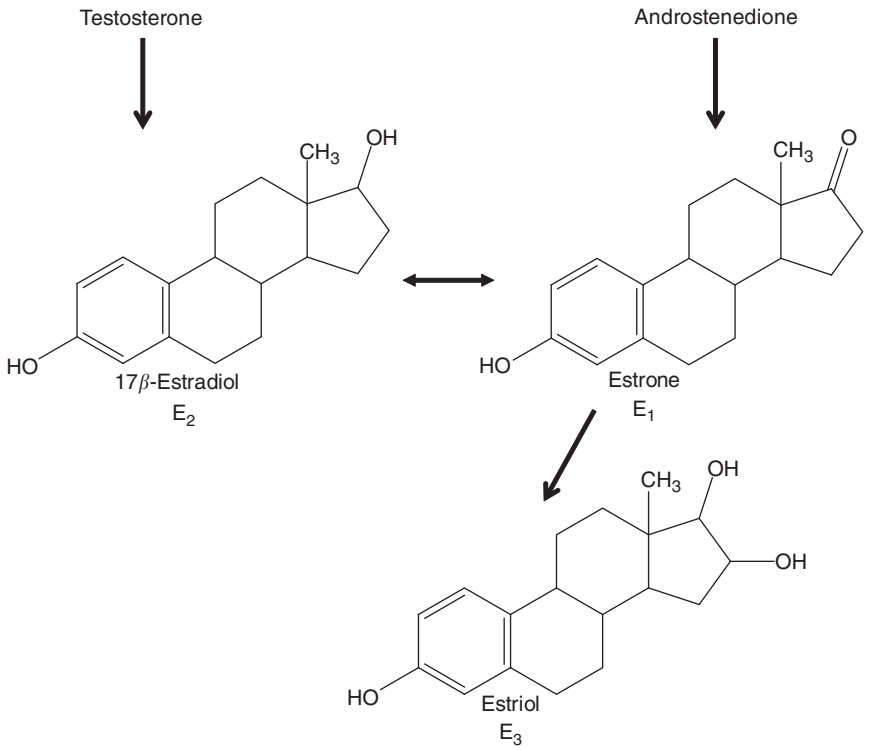

Figure 1 Structures of the physiological estrogens – E_1, E_2, and E_3.

 doi:10.1016/B978-0-12-378612-8.00196-7

to influence bone, brain, liver, and the cardiovascular system and furthermore, may also play a role in hormonal signaling in the male as well as the female. Therefore, compounds ingested in the diet, which can mimic or interfere in estrogen action, have the potential to alter hormonal homeostasis in both women and men. Such compounds have been termed 'environmental estrogens'.

The ability of compounds in the diet to influence reproductive functions was first noted in the 1920s by pig farmers after feeding their animals on moldy grain, and concern was further stimulated in the 1940s by reports that sheep grazing on certain types of clover in western Australia became infertile ('clover disease'). More recent research has identified the estrogenic compounds in the moldy grain to be of microbial origin and these have been termed mycoestrogens. The estrogenic compounds in the clover have been identified as of plant origin and subsequently many other estrogenic compounds have been found in plant material and collectively these have been termed phytoestrogens. Over more recent decades, it has become evident that there are also many man-made chemicals, which can mimic estrogen action and enter the food chain from environmental contamination. Such compounds have been released into the environment from agricultural spraying (herbicides and insecticides) or as by-products of industrial processes and waste disposal (polychlorinated biphenyls (PCBs) and dioxin) and have been termed xenoestrogens. Most xenoestrogens are lipophilic and therefore pass up the food chain partitioned in animal fat where they accumulate at the top of the food chain in humans.

Molecular Basis of Estrogen Action

Binding to Cellular Receptors

Estrogens act in a target cell by binding to intracellular receptors, of which there are two types, estrogen receptor alpha (ERα) and ER beta (ERβ). ERα, for which the complementary deoxyribonucleic acid (cDNA) was cloned in 1985, is the so-called classical ER, but was named ERα after the cloning in 1996 of a second cDNA for a separate ER gene named ERβ. The two ER proteins share close homology, and all three physiological estrogens can bind to both albeit with differing affinities. In the 1990s, the crystal structures of these receptors showed that there was a ligand binding pocket within the ER protein, which is separated from the external environment, and 17β-estradiol was shown to be positioned specifically by hydrogen bonding of its 3- and 17-hydroxyl groups to amino acid side chains and by hydrophobic bonding of the remainder of the steroid ring to other amino acid side chains. Such interactions resulted in conformational changes to the ER protein, in particular to the folding of the helix 12 of the ER protein over the opening to the ligand binding pocket, and these changes in conformation resulted in activation of the ER within the cell.

Regulating Gene Expression

The main mechanism of action of ER within the cell resides in its ability to function as a ligand-activated transcription factor and therefore to regulate gene expression. This is termed the genomic mechanism of action (Figure 2). Binding

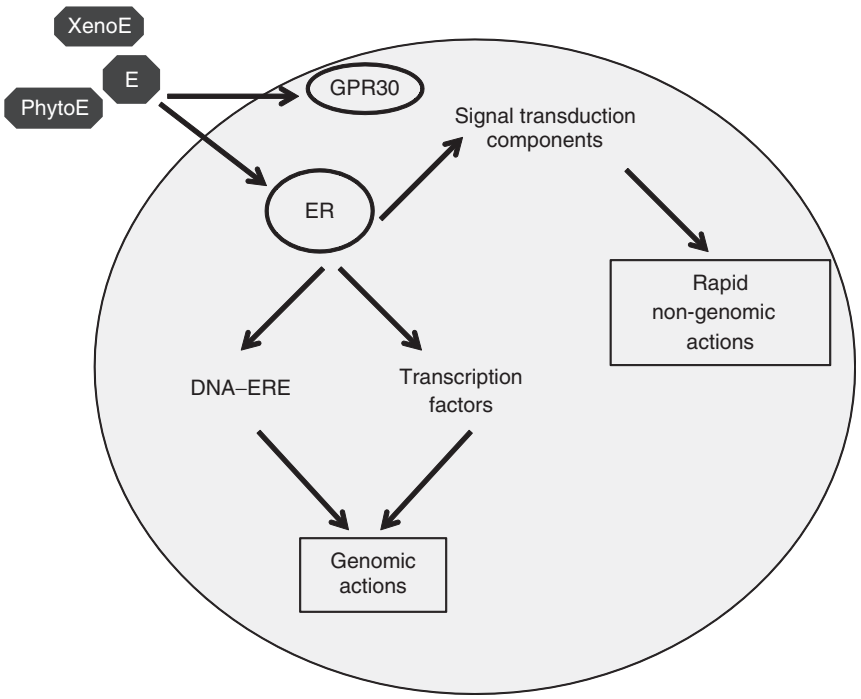

Figure 2 Effect of dietary compounds with estrogenic activity on intracellular mechanisms of estrogen action. Physiological estrogens (E) or dietary phytoestrogens (PhytoE)/xenoestrogens (XenoE) interact with intracellular ER, which can then either bind to estrogen response elements (ERE) in the DNA or to other transcription factors to bring about genomic actions. Interactions through the cell membrane G-protein coupled receptor (GPR30) or ER may also effect rapid nongenomic actions through signal transduction pathways.

of estrogen (ligand) to receptor results in release of associated chaperone proteins, increased receptor phosphorylation, and dimerization of ligand-receptor complexes. These ER dimers then bind directly to specific nucleotide sequences in the DNA termed ERE through regions within the ER protein, which form zinc finger motifs capable of interacting directly with the nucleotide strands of the DNA. Binding of ER to the ERE in the vicinity of estrogen-regulated genes results in an interaction of the ER with other coregulator proteins to modulate the activity of the transactivation complex and hence to alter levels of gene expression. Classical estrogen-regulated genes include genes for the trefoil growth factor pS2, progesterone receptor, and cathepsin D, which are all upregulated by estrogen. However, following the application of microarray technology, it is now known that estrogen can regulate the expression of hundreds of genes across a wide range of functional groupings, and more genes are downregulated (approximately 70%) than are upregulated by estradiol in studies using human breast cancer cells.

Other Mechanisms: Indirect Genomic and Non-Genomic

In addition to direct interactions of the ER protein with ERE in the DNA, ERs can also regulate gene expression through protein-protein interactions with other transcription factors. This so-called indirect genomic mechanism of action (Figure 2) was first shown from studies involving modulatory activity of ERβ on transcription factors of the Fos/Jun/AP-1 complex. Because AP-1 mediates cellular actions of growth factors, this has opened up understanding of how estrogen can influence the response of a cell to growth factors. Estrogen and growth factors have long been known to interact in the regulation of cell growth, but the mechanisms of action are only now beginning to be understood, and in addition to the genomic actions of estrogen, it seems that there is a further mechanism of interaction with growth factor pathways whereby estrogen can mediate fast cellular responses through interaction with cellular signaling phosphorylation cascades. This may be brought about through the estrogen–ER complex interacting at the cell surface with components of signal transduction such as mitogen-activated protein kinases or through binding of estrogen to the cell surface G-protein coupled receptor GPER (GPR30). This mechanism of estrogen action has been termed the nongenomic mechanism (Figure 2).

Molecular Actions of Environmental Estrogens

Environmental estrogens of the diet have been shown to bind to intracellular ERs and so mimic or interfere in the action of physiological estrogens. Their ability to act through such receptor-mediated mechanisms has challenged the concepts of classical toxicology because effects can occur at much lower concentrations and actions can be targeted within the cell through the receptor.

Phytoestrogens

Types and Source

Phytoestrogens are compounds, which occur naturally in plants and are therefore consumed in the diet through eating plant material. There are four main chemical classes: the isoflavones, the coumestans, prenyl flavonoids, and the lignans. Genistein and daidzein are isoflavones found in leguminous plants, especially not only soybeans but also lentils and chickpeas. Equol is a related compound derived from metabolism of daidzein, but ability for metabolic conversion varies between individual human subjects. Other isoflavones in food include glycitein, biochanin A, and formononetin. Coumestrol is a coumestan found in young sprouting legumes such as clover and alfalfa sprouts and is therefore found in many animal feedstuffs. Prenylated flavonoids, including 8-prenylnaringenin and 6-prenylnaringenin, are found in hops and products made from hops such as beer. Resveratrol is a polyphenolic compound found in grapes and therefore red wine. The lignans are found in many cereals especially linseed (flaxseed) and many fruits and vegetables, and include lariciresinol, isolariciresinol, matairesinol, and secoisolariciresinol together with their metabolites enterodiol and enterlactone.

Mechanisms of Action

Many of these compounds share structural similarities (Figure 3) to estradiol (Figure 1) and can therefore bind into the ligand binding domain of the ER enabling estrogenic responses in target cells possessing ER. Crystallographic studies have shown that in contrast to the classical binding characteristics of a substrate to its active site in an enzyme, the ligand binding domain of the ER is larger than the estradiol molecule, which explains why it can accommodate a range of different-sized molecules. There are some common features for binding, which include the presence of a para-hydroxy phenyl grouping, which is present either intrinsically or following metabolic conversion and enabling the hydrogen bonding to amino acids of the ligand binding pocket in an analogous manner to that described for the estradiol molecule.

As for any receptor-binding molecules, there can be a range of outcomes on binding. Compounds, which give responses equivalent to that of estradiol, are described as having full agonist activity; those giving similar responses but of a lesser magnitude to estradiol are said to have partial agonist activity. If a compound is able to reduce the response given in the presence of estradiol, then it is said to have antagonist activity. Studies *in vitro* testing purified compounds have shown that all phytoestrogens bind more weakly to the ER than does estradiol but with considerable variation in their relative binding affinity (RBA). For example, coumestrol binds to the ER with an RBA of only 10-fold lower than 17β-estradiol, but genistein has an RBA of approximately 1000-fold lower. This weaker binding affinity has resulted in the concept that phytoestrogens are 'weak' estrogens. However, when ligand efficacy is considered as well as ligand binding affinity, the efficacy of these compounds is not correspondingly low, and when sufficient concentration is present, both coumestrol and genistein can give the same response as estradiol

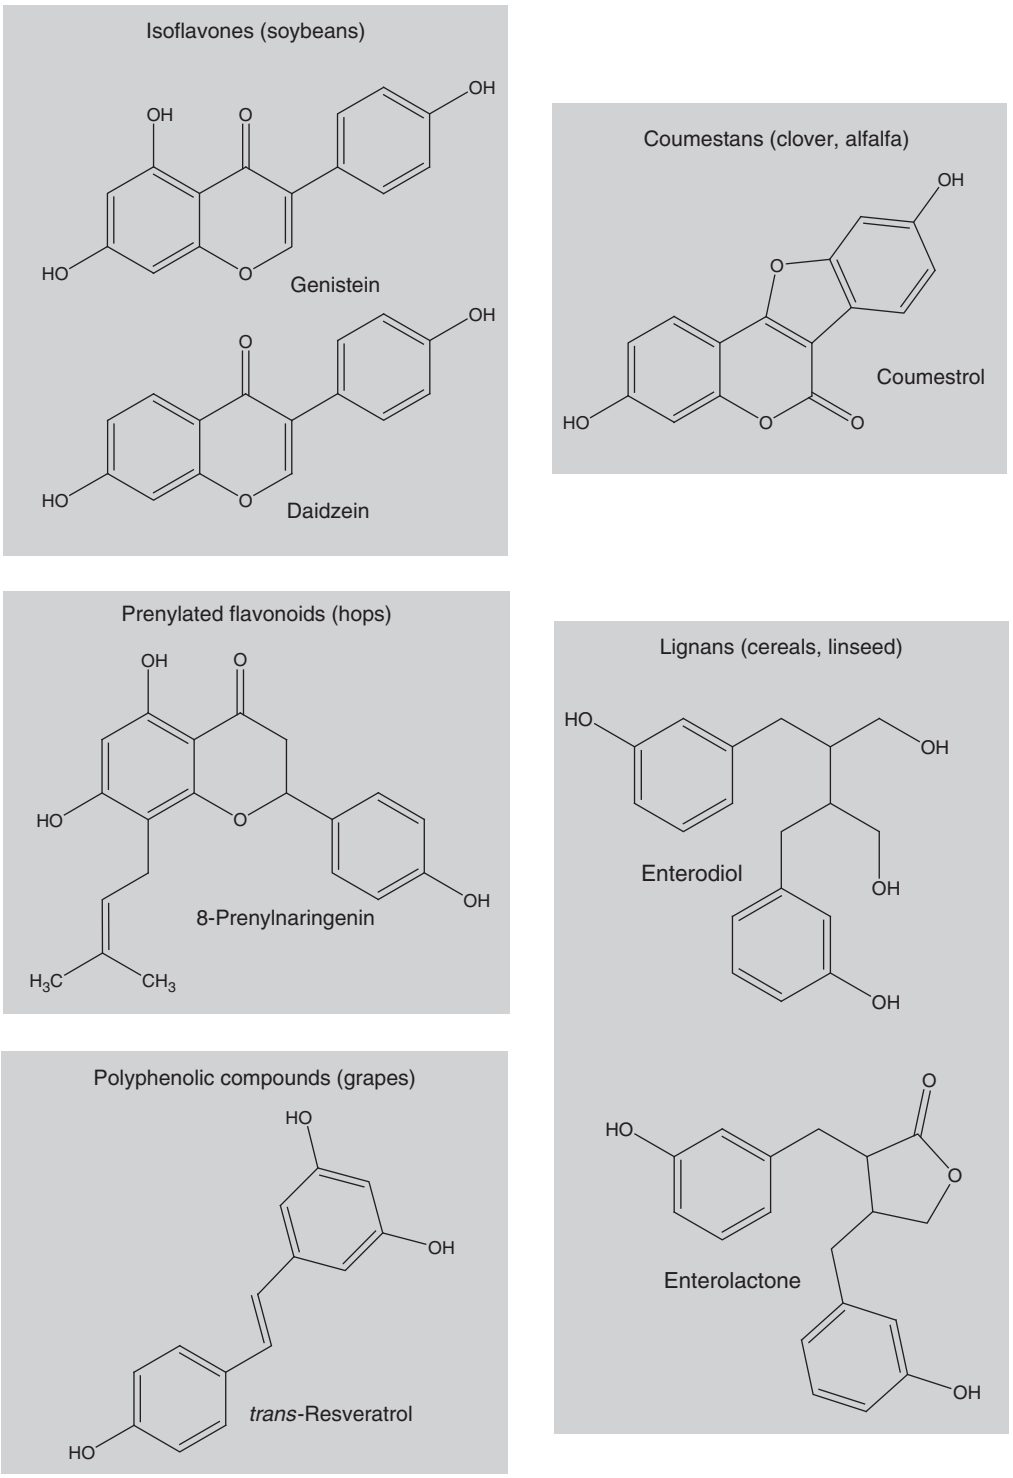

Figure 3 Source and structure of some phytoestrogens present in food.

when tested in cell culture assays on growth of estrogen-responsive cells. Assessment of effects of phytoestrogen needs, therefore, to include a measure of quantity present and not just an RBA value. Tests in cell culture have shown that some phytoestrogens with lower RBA values than genistein, such as resveratrol, are not able to give full agonist responses even at the highest testable concentrations. It is unclear whether this is due to solubility issues in that sufficient concentration cannot be achieved for the full agonist response but operationally, such compounds must be deemed as partial estrogen agonists. Despite theoretical assumptions, there is no evidence from *in vitro* testing for antagonist activity of phytoestrogens:

Inhibitory effects of phytoestrogens observed in cell culture at higher concentrations have been shown as not ER-mediated. However, it remains unexplained as to why this should contrast to the many rodent model experiments, which have shown that phytoestrogens, such as coumestrol, are able to antagonize estradiol-mediated response in the whole animal.

One interesting feature of the phytoestrogens was revealed in the late 1990s when some, such as genistein, were reported to bind with a stronger affinity to ERβ than to ERα. Because ERβ is distributed at low concentrations across many body tissues and ERα levels are not only relatively higher but also more specific in female reproductive tissues, beneficial physiological effects of phytoestrogens are thought to be ERβ-mediated, whereas adverse effects to be ERα-mediated. Because ERβ has also been considered as a tumor suppressor capable of ameliorating the adverse proliferative effects of ERα in cancer, phytoestrogens have become generally considered as beneficial selective ER modulators (SERMs). However, it must be remembered that the difference in RBA is relative not absolute and all phytoestrogens do still bind to both types of ER, so again effects have to be considered with a knowledge of both the relative levels of ERα and ERβ in target cells and the concentration of phytoestrogen in the target tissue.

In the Context of the Complexity of Plant Material

Research publications have now enabled relative specific binding affinities for ER to be tabulated for a range of phytoestrogens, and their relative efficacies have been described in terms of ability to regulate gene expression and/or cell growth in cell lines in culture and to influence reproductive functions in animal models. However, what remains still very poorly understood is how these compounds behave when in the context of the plant material in which they are consumed, and this may provide an explanation for apparently conflicting results between, for example, the known estrogenic activity of genistein and yet the lower incidence of breast cancer in populations consuming large quantities of soy-based products. Although, there may be other components in the soy plant material, which can act to prevent breast cancer development, it is also possible that the activity of genistein is influenced by the context of the plant extract. Diverse actions of genistein have been described in addition to estrogen receptor-mediated mechanisms including its ability to inhibit protein tyrosine kinases, cell cycle progression, DNA topoisomerase, angiogenesis, or to act as antioxidant. Actions of genistein, as indeed for many environmental estrogens, have been shown to be nonmonotonic and with responses, therefore, dependent on concentration, and it is now well established that while low concentrations of genistein can stimulate cell proliferation by an ER-mediated mechanism, higher concentrations can act in an inhibitory mechanism which is not ER-mediated. Furthermore, phytoestrogens can also produce estrogenic effects by modulating concentrations of endogenous estrogens through their ability to influence the activity of enzymes needed for synthesis of estrogens (e.g., aromatase) or of enzymes, that modulate bioavailability of estrogens (sulphatases and sulphotransferases).

Xenoestrogens

Types and Source

Xenoestrogens are synthetic chemicals released into the environment as pollutants from agricultural spraying (pesticides and herbicides), from industrial processes, and waste disposal (PCBs and dioxins). These persistent organochlorine pollutants are generally lipophilic and therefore passed up the food chain partitioned in animal fat. Although they can be found in fatty meat and fish, they are also found in dairy products (milk, butter, and cheese) in the fat content. These compounds are usually consumed in only small quantities but due to their lipophilic properties and long half-lives in the body, they tend to build up in body fat with age, being released only during times of weight loss during fasting or in females into milk during periods of lactation. This, of course, has implications for the diet of the baby who can consume a relatively high load of such compounds from the mother's milk.

Xenoestrogens may also enter food following storage procedures. Alkyl esters of *p*-hydroxybenzoic acid (parabens) are added as preservatives to some foods. Methylparaben, ethylparaben, propylparaben, and butylparaben have been shown to possess estrogenic activity in a range of *in vitro* and *in vivo* assays. On the grounds of endocrine and reproductive toxicity in dietary studies, the acceptable daily intake was withdrawn for propylparaben and butylparaben by the Joint Food and Agriculture Organization and World Health Organization Expert Committee on Food Additives in 2007. Although the other esters remain in use, it is thought that liver esterase activity should result in rapid metabolism and clearance when consumed by the oral route. Plastic containers are used widely for storage of food, and this can provide another source of exposure to estrogenic compounds such as bisphenol A and phthalate esters if they partition into fatty foods. Bisphenol A and some phthalate esters have been shown to possess estrogenic properties in assays *in vitro* and *in vivo*. Because of concern for endocrine disruption following exposure in young children, use of bisphenol A (**Figure 4**) in the manufacture of baby bottles has been ceased in Europe, Canada, and the USA.

Metalloestrogens

Although most compounds that mimic the action of estrogen have organic ring structures, some metal ions have also been shown capable of binding into the ligand binding domain of the ER and enabling estrogenic responses. Such metal ions include aluminum, antimony, arsenic, barium, cadmium, chromium, cobalt, copper, lead, mercury, nickel, selenium, tin, and vanadium, and these have been termed metalloestrogens.

Considerations of Exposure and Bioavailability

Physiological exposure to estrogens is a tightly regulated process such that men are exposed to only low levels, females to low levels before puberty and after menopause, and for females between puberty and menopause the levels cycle in

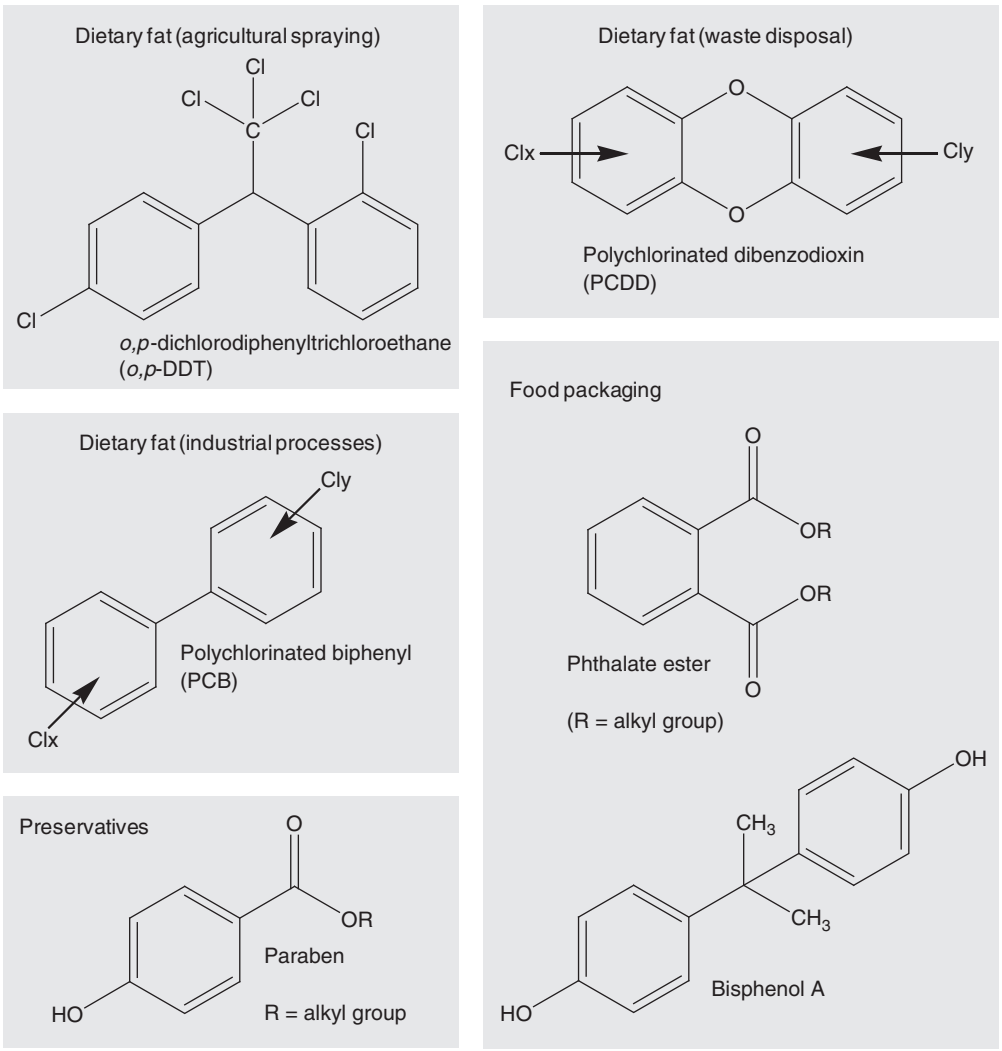

Figure 4 Source and structure of some xenoestrogens present in food.

conjunction with other hormones during the monthly menstrual cycle. By contrast, intake of environmental estrogenic compounds in diet is not linked to physiology, and whereas quantity, metabolism, and clearance may contribute to resulting effects, timing may also be important. Inappropriate exposure to estrogen has been linked to reproductive abnormalities and increased incidence of hormone-dependent cancers. The reproductive and oncological consequences for children born to mothers given the synthetic estrogen, diethylstilboestrol, to prevent miscarriage in early pregnancy in the 1970s has demonstrated the long-term consequences for both genders of exposure before birth to a potent synthetic estrogen.

Although intake of phytoestrogens will vary according to type and amount of plant material consumed, levels taken in the diet can be relatively high compared to intake of xenoestrogens. For example, soybean seeds have been reported to contain in the range 18–1382 mg kg^{-1} genistein and 68–1006 mg kg^{-1} daidzein, whereas total PCB levels have been measured mainly as less than 0.1 mg kg^{-1} in samples of dairy products and meat. However, by contrast, metabolism and clearance of phytoestrogens is also relatively high compared to the xenoestrogens, which due to their lipophilic properties tend to bioaccumulate in adipose tissue over a lifetime.

In addition to these considerations, bioavailability is another factor because many of these compounds are found conjugated to sugars or sulfate groups. Both genistein and daidzein can be detected in the plasma and urine of humans who consume soy foods, but the majority of these isoflavones circulate and are excreted in urine as mono- and di-sulfates, mono- and di-glucuronides, and sulphoglucuronides through conjugation at their 4′- and 7-hydroxyl groups. Glucuronides are the most abundant conjugates, but sulfates of genistein and daidzein have been shown to make up to 24% of the total isoflavone concentration in human plasma. At the target tissues, activity of phytoestrogens will depend not only on the enzymatic hydrolysis of the conjugates back to the aglycones by tissue sulphatases and β-glucuronidases but also on any intrinsic estrogenic activity of the conjugates themselves. Contrary to previous assumptions that conjugation would negate estrogenic activity, genistein glucuronides

have been reported to retain weak ER-binding capability and some monosulphates of genistein, daidzein, and equol to have greater estrogenic activity than the unconjugated phytoestrogen.

Consideration to Effects on Human Health

Much has been written and discussed concerning effects of consumption of compounds with estrogenic activity on human health. Most of the issues remain unresolved, but it is clear that there are likely to be both potential benefits and adverse consequences. On the basis that compounds of 'natural' origin are automatically assumed to be beneficial, whereas man-made compounds are automatically assumed to be adverse, society has responded in opposing ways to the plant-based and synthetic estrogenic compounds. Although both phytoestrogens and xenoestrogens display estrogenic activity in *in vitro* and animal models, society has generally chosen to positively embrace use of the phytoestrogens but to mistrust use of xenoestrogens. With this background, it is likely that the potential benefits of phytoestrogens have been often overstated and adverse effects underappreciated, whereas the opposite may be true for the xenoestrogens.

Female Reproductive Health

From the early studies showing loss of fertility in farm animals grazing on phytoestrogen-rich plants, it has been evident that phytoestrogen intake can influence female reproductive health. Many studies now show that isoflavone intake can increase cycle length and suppress levels of luteinizing hormone and follicle stimulating hormone, which suggests that soy foods should be consumed sparingly in women attempting to become pregnant.

However, intake of phytoestrogens through diet has been linked to a range of beneficial health outcomes, most notably reduction of menopausal symptoms and prevention of osteoporosis. This has stimulated a market for foods and food supplements rich in phytoestrogens on the basis of their potential health benefits. Publication of the million women study in 2002 reporting a link between the use of hormone replacement therapy (HRT) and increased incidence of breast cancer started a trend away from use of synthetic compounds to a search for more 'natural' alternatives. Dietary supplementation with phytoestrogen-rich plant material (such as soy, red clover, black cohosh, or aloe vera) has become, therefore, a favored option by many women as an alternative to HRT, despite the lack of control over quantity of intake or knowledge of long-term effects. Reports that hot flushes and night sweats are greater as perimenopausal side effects in Western than Asian countries where diets are higher in isoflavones has led to the widely held belief that consumption of soy phytoestrogens may offer a more 'natural' relief. However, as yet clinical trials have provided only limited evidence of benefit and there are no authoritative guidelines for women choosing to take such supplements.

Another consequence of reduced estrogen synthesis in the menopause is loss of bone density and consequent increase in risk of bone fracture. In view of their estrogenic properties, dietary supplementation with plant phytoestrogens has, therefore, also become popular in the hope of reducing osteoporosis. Clinical trials and animal experiments have given mixed results and any linkage between soy isoflavone intake and improved bone mineral density remains unresolved.

A clinical case report in 2008 has further linked soy consumption with abnormal endometrial bleeding, but it is not known to what extent this might be more widely associated with increasing incidence of endometriosis.

Male Reproductive Health

Owing to the estrogenic properties of phytoestrogens, questions still exist as to whether there may be adverse reproductive consequences associated with use of soy-based infant formulas for baby boys. Soy-based infant formulae have been used since the 1960s in the UK and have become popular as an alternative to cow's milk for babies with milk allergy. Daily intake of isoflavones by this route has been estimated as up to 4 mg kg^{-1} body weight in the infants, giving plasma isoflavone levels up to 1000 ng ml^{-1}, which is more than 10 000-fold higher than their own endogenous estrogen levels. The long-term effects of exposure to such high levels of estrogen early in life need to remain under investigation especially in the context of male reproductive health.

Cardiovascular Disease

Reduced risk of cardiovascular disease has been a suggested health benefit of soy food consumption, which was initially endorsed by the Food and Drug Administration in 1999 but later questioned by the American Heart Association in 2005. There are numerous risk factors for cardiovascular disease but the only consistent effect in human and animal studies of soy supplementation was a small (3% or less) reduction in levels of low density lipoprotein and interestingly, removal of isoflavones from the soy protein did not eliminate this effect suggesting a more complex link between soy intake and cardiovascular disease.

Obesity, Metabolic Syndrome, Diabetes

Obesogens are defined as compounds which cause weight gain. They may act directly to increase the number of fat cells or the storage of fat within the cells. Alternatively, they may act less directly through altering appetite, metabolic rate, or energy balance. Exposure to some persistent organic pollutants, phthalates, and bisphenol A can give rise to obesity in animal models, and such compounds are increasingly implicated in the rapid rise in obesity, metabolic syndrome, and diabetes in young people. Although mechanisms remain to be identified, it has been shown that some of these compounds can activate the peroxisome proliferator-activated receptor, and activation of this receptor is an important pathway for adipogenesis and obesity.

Hormone-Responsive Cancers

Consumption of soy-based diets in Eastern parts of the world, especially in Japan, where breast cancer incidence is low have led to the assumption that increased soy intake may prevent the development of breast cancer and that phytoestrogens possess antiestrogenic activity. However, epidemiological evidence and clinical trial results are often conflicting and suggest more complex linkage between phytoestrogen intake and breast cancer incidence. Animal models have shown that genistein is capable of reducing development of chemically induced mammary tumors in rats, especially in younger rats, but can stimulate growth of subcutaneous MCF-7-derived tumors in mice. Because studies *in vitro* have found no evidence for antiestrogenic activity of phytoestrogens, the animal studies could be interpreted as suggesting that preventative mechanisms of phytoestrogens act through their antioxidant properties, whereas estrogen agonist properties of phytoestrogens would support growth of estrogen-dependent mammary cancers already present.

There is justified concern surrounding the ability of xenoestrogens from food to bioaccumulate in human body fat, and epidemiological studies are beginning to identify an association with health risks. Understanding of the mechanisms by which such compounds may cause adverse effects has required an appreciation firstly that because they act through receptor-mediated mechanisms, effects occur at much lower concentrations than would be predicted from classical toxicology studies and secondly that single compounds do not act in isolation. The environmental reality is that hundreds of such compounds have now been measured in human body fat and consequences result from long-term exposure to low doses of multiple compounds, the overall composition of which will vary according to dietary and lifestyle choices.

Endocrine Therapy of Cancer

Reduction of estrogen action in the body through either inhibition of estrogen synthesis (aromatase inhibitors) or antagonism of estrogen action (antiestrogen) can be an effective way of reducing growth of endocrine-responsive cancers, and endocrine therapy has become an effective treatment for breast cancer. However, little attention has been given to the potential for environmental estrogens to interfere in the effectiveness of such therapy. Theoretically, it would seem counterproductive to reduce synthesis of estrogen in the body with aromatase inhibitor drugs on the one hand and yet on the other hand not to be aware of consumption of compounds with estrogenic activity in the diet. While it may be difficult to avoid estrogenic chemicals, which are contaminants of the diet, the decision to consume plant material containing high levels of phytoestrogen should be discouraged.

Conclusions

There are many compounds contained in food, both of endogenous and environmental origin, that can mimic or interfere in estrogen action with resulting implications for human health. Greater focus is, therefore, now needed on overall estrogenic load rather than on individual compounds. At the current time, most research has considered one compound at a time, but the environmental reality is that any one individual will consume varied mixtures of phytoestrogens and xenoestrogens, offering the potential for each individual to have high concentrations of different compounds but with a common mechanism of action. Assessment of the estrogenic load from cumulative exposures will need to take account not only of variations in quantity of intake but also absorption, metabolism, and clearance/bioaccumulation, which can be very different for the phytoestrogens and xenoestrogens, especially when considering fatty tissues such as the breast. Furthermore, since different estrogenic compounds have differing RBA for the ER, any functional assessment of concentrations in body tissues needs to be set in the context of the varied potencies of the compounds. In view of increasing reports of susceptibility to endocrine disruption *in utero* or in early life, more attention also needs to be given to exposure at different developmental and life stages. The transgenerational impact of some environmental estrogens suggests that greater attention needs to be given to the diet of women before and during pregnancy. Finally, because estrogenic compounds are no longer confined to diet, overall aggregate contribution from diet cannot be considered in isolation from similar compounds entering through other routes such as water, air, and dermal absorption of personal care products. At the current time, this holistic picture is lacking and measurement needs to be made of wider numbers of estrogenic compounds in any one tissue of an individual person, especially if health benefits are to be fully realized and long-term adverse health outcomes are to be avoided.

ENVIRONMENTAL CONTAMINANTS

Nitrate and Nitrite

A Cockburn, University of Newcastle, Newcastle, UK and Toxico-Logical Consulting Ltd, Ware, UK
CW Heppner and JLCM Dorne, European Food Safety Authority, Parma, Italy

Glossary

Acceptable daily intake (ADI) A level of exposure without appreciable health risk when consumed everyday for a lifetime.
Lowest observed adverse effect level (LOAEL) The lowest concentration of a substance that is found to have no adverse effects on the test subject. These values are usually derived from chronic or subchronic animal studies using the most sensitive species for risk assessment and a dose–response relationship that includes levels producing adverse health effects.
No observed adverse effect level (NOAEL) The maximum concentration of a substance that is found to have no adverse effects on the test subject.
No observed effect level (NOEL) The maximum concentration of a substance that is found to have no effects on the test subject.
Risk assessment A framework to assess the health risk of exposure to a hazard; it comprises four steps: hazard identification, hazard characterization, exposure assessment and risk characterization.

Introduction

Nitrate and nitrite are ubiquitous in the environment and result from nitrogen fixation of dead and decaying plant and animal matter. The nitrite ion is relatively unstable and is readily oxidized to nitrate. Nitrate and nitrite are widely consumed from food and water by animals and humans, and are formed to a limited extent endogenously. Nitrate is used in agriculture as a fertilizer to replace the traditional use of livestock manure and in food processing as an approved food additive. Nitrate's toxicity *per se* is low, but the metabolites, nitrite, nitric oxide, and *N*-nitroso compounds make these substances of regulatory importance because of the potential for adverse health implications in humans and animals.

As food additives, nitrate and nitrite are used as antimicrobial agents, preservatives, and color fixatives in meat and fish. In the EU and when labeled 'for food use,' sodium nitrite may only be sold in a mixture with salt (NaCl) or a salt substitute (OJ L 61, 20.2. 1995, p27). Potassium nitrite is known as E249, sodium nitrite as E250, sodium nitrate as E251, and potassium nitrate as E252 (list of approved food additives see European Parliament and Council Directive No 95/2/EC as amended by Directive.

Recent research has shown that the conversion of nitrate to nitrite plays an important antimicrobial role in the stomach, and other nitrate metabolites also have important physiological/pharmacological roles. The potentially beneficial aspects of nitrate and nitrite are beyond the scope of this article.

This article will first consider the legislation of nitrate and nitrite with an emphasis on European Community legislation, the analytical techniques, and human and animal dietary exposure to both ions in Europe. The toxicology of both nitrate and nitrite will be summarized in laboratory animals, humans, and food-producing animals together with recent risk assessments from an animal health and public health point of view performed recently by the Scientific Panel on Contaminants in the Food Chain (CONTAM) of the European Food Safety Authority.

Legislation

Drinking Water

International efforts have been put in place to reduce and limit the occurrence of nitrate in water. The EU Council Directive 98/83/EC (OJ L 330, 5.12.1998, p. 32–54 corrigendum OJ L 111, 20.4.2001, p. 31) lays down the maximum permitted level of 50 mg nitrate and 0.5 mg nitrite per liter in drinking water. The standard for nitrate is in line with the international standard set by World Health Organization. For nitrite, a guideline value of 3 mg l^{-1} (short-term exposure) and provisional of 0.2 mg l^{-1} (long-term exposure) have been laid down at an international level.

Food

In the EU, maximum permitted levels for nitrate in different leafy vegetables (in particular lettuce and spinach) have been in place since 1997. The current maximum levels are laid down in Commission Regulation (EC) No 1881/2006 setting maximum levels for certain contaminants in foodstuffs (Official Journal L 364, 20.12.2006, p. 5–24). European Parliament and Council Directive No 95/2/EC (Official Journal L61, 18.3.1995, p. 1) as amended by Directive 2006/52/EC

 doi:10.1016/B978-0-12-378612-8.00199-2

(Official Journal L204, 26.7.2006, p. 10–22) lays down maximum limits for nitrate and nitrite when used as food preservative.

Feed

European Parliament and Council Directive 2002/32/EC (Official Journal L 140, 30.5.2002), as amended by Commission directive 2010/6/EU (Official Journal L37, 10.2.2010, p. 29), lays down maximum permitted levels for nitrite as an undesirable substance in feed materials with the exception of silage and incomplete feedingstuffs and feed for dogs and cats. Nitrite is authorized as a preservative with a maximum content of 100 mg kg^{-1} in complete feed for dogs and cats and as an additive in silage (Community Register of Feed Additives pursuant to Regulation (EC) No 1831/2003, entry on sodium nitrite (Dogs, Cats) and sodium nitrite in silage.

Analytical Techniques, Occurrence in Food Sources, and Exposure Assessment

Different analytical methodologies and a variety of detection methods can be applied to determine nitrate and nitrite in various matrices such as water, food, and feedstuffs. Detection limits range from 0.001 to 1 mg l^{-1}. An overview of methods for the analysis of nitrate and nitrite in different matrices can be found in the recent International Agency for Research on Cancer (IARC) monograph No. 94 on nitrate and nitrite.

Human exposure to nitrate is mainly exogenous whereas exposure to nitrite is mainly endogenous via nitrate metabolism. In Europe, the main dietary sources of nitrate are vegetables, preserved meat, and drinking water, with vegetables being the most important source. Nitrate concentrations in vegetables can be influenced by several factors such as light intensity, storage, processing, and cooking. In a recent European survey, mean nitrate concentrations of 1 mg kg^{-1} (e.g., peas) to 4800 mg kg^{-1} (e.g., rucola) have been found. Leafy vegetables (e.g., lettuces and spinach) generally have higher nitrate concentrations compared with seeds or tubers (e.g., potatoes). The critical driver for a high dietary exposure to nitrate is not necessarily the absolute amount of vegetables consumed but the type of vegetable (e.g., leafy vegetables) and the concentration of nitrate related to the conditions of production. The largest source of nitrite is endogenous conversion from nitrate, and the exogenous contribution to nitrite through fruit and vegetables is less important. However, during storage, especially with home-prepared food, transformation of nitrate to nitrite can occur.

In farm animals, exposure to nitrite using the maximum authorized levels in feed (10 mg kg^{-1}) and the EU maximum limit of 0.5 mg l^{-1} in water has been estimated in the recent European Food Safety Authority (EFSA) assessment. Estimates of feed intake are based on typical feeding regimens within Europe that have formed the basis of previous EFSA exposure estimates in livestock. The overall nitrite exposure from feed was found to be 0.37 mg kg^{-1} nitrite body weight (b.w.) per day in pigs and 0.65 mg kg^{-1} nitrite b.w. per day in cattle (Official Journal L 140, 30.5.2002, Official Journal L37, 10.2.2010, p. 29, Community Register of Feed Additives pursuant to Regulation (EC) No 1831/2003, entry on sodium nitrite (Dogs, Cats) and sodium nitrite in silage) which are the most sensitive species to nitrite's toxicity, and these values would rise to 0.42 and 0.70 mg kg^{-1} nitrite b.w. per day, respectively, taking into account water intake as well (assuming the EU maximum level of 0.5 mg l^{-1}). With regard to human exposure, residues in fresh animal products (e.g., milk, meat, and eggs) represent only 3% of total daily dietary exposure to nitrite compared with other sources such as vegetables.

Toxicology and Health-Based Guidance Values

Laboratory Animals

Nitrite and nitrate have been studied extensively over the past half century. A full range of toxicity studies can be found in the literature spanning acute, subacute, and chronic as well as genotoxicity and somewhat limited reproductive toxicology. Toxicokinetic data are also available covering absorption, distribution, metabolism, and excretion. Not all of the work is to modern day standards but the results are sufficiently consistent to give confidence for the establishment of the toxicological profiles and also to understand the species variation in metabolic handling and interconversion of nitrate and nitrite. The rate of absorption of nitrate and nitrite varies between species, being relatively high in humans and rats but lower in ruminants. Both anions are quantitatively well absorbed from the stomach of monogastrics, and rumen in the case of ruminants. For nitrate, approximately 25% of the absorbed material is taken up by the salivary glands, bio-concentrated approximately 10-fold and secreted into the saliva. In the mouth, bacterial reduction of approximately 20% of the secreted nitrate leads to nitrite formation. In the stomach, under acidic conditions, nitrite is transformed to nitric oxide and other metabolites. Once absorbed, nitrite is rapidly distributed in the plasma with rapid binding to the erythrocytes. Nitrite, at normal physiological levels, is metabolized to nitrate. Most of the systemic nitrate is rapidly and extensively excreted in the urine, and thus does not accumulate in tissues. Significant nitrate salvage takes place through selective reabsorption from the kidney together with biliary and salivary recirculation.

For establishing the acceptable daily intake (ADI) values for nitrate and nitrite, the most recent Joint FAO/WHO Expert Committee on Food Additives (JECFA) evaluation used the following studies and endpoints (Table 1).

Acutely, nitrite is approximately 10-fold more toxic than nitrate and three main toxicological endpoints have been identified: equivocal evidence for carcinogenesis in female mice, hypertrophy of the adrenal zona glomerulosa in rats, and methemoglobin (MetHb) formation in a wide range of species including humans. MetHb formation results from a reaction of the nitrite metabolite nitric oxide with oxyhemoglobin. Predisposing factors include increased nitrite concentrations, intestinal infection together with gastric inflammation and low levels of nicotinamide adenine dinucleotide (NADH) cytochrome b5 methemoglobin reductase, which converts MetHb back to hemoglobin (Hb).

Table 1 Summary of NOELs from toxicological studies used to derive ADI values for nitrate and nitrite in the JECFA 2003 evaluation[a]

Type of study	*Toxicological endpoint*	*NOEL sodium salt/anion mg kg^{-1} b.w. day^{-1}*	*ADI sodium salt/anion mg kg^{-1} b.w. day^{-1}*
Nitrate			
Subchronic study in dogs (125 days)	Growth depression	500/370	5.0/3.7
2-year chronic study in rats	Growth depression	500/370	5.0/3.7
Nitrite			
2 years study in rats	Heart and lung toxicity	10/6.7	0.1/0.07

[a]Modified from EFSA, 2008.

Normal physiological MetHb background levels are in the range of 1–3%. Above 10% there is a reduction of oxygen transport, above 20% cyanosis and hypoxia can occur, and 50% becomes life threatening. Infants less than 3 months of age are more susceptible to MetHb. This is a consequence of 40–50% lower MetHb reductase levels compared with adults. Additionally, infants have an increased likelihood of intestinal infections where pathogenic bacteria can rapidly reduce nitrate to nitrite.

The first international evaluation of the risks associated with the ingestion of nitrate and nitrite was conducted by the JECFA in 1961. The former Scientific Committee for Food (SCF) of the EU reviewed the toxicological effects of nitrate and nitrite and established an ADI of 0–3.7 mg kg^{-1} b.w. for nitrate in 1990, retained the ADI in 1995 and derived an ADI of 0–0.06 mg kg^{-1} for nitrite. The JECFA completed its most recent review in 2002 and reconfirmed an ADI of 0–3.7 mg kg^{-1} b.w. for nitrate and set an ADI of 0–0.07 mg kg^{-1} b.w. for nitrite. In 2008, the CONTAM Panel noted that no new data were identified that would require a revision of the ADI values.

Food-Producing Animals

Feed and water constitute the main source of exposure to nitrite and nitrate in animals, which at excessive levels may cause adverse effects; these are principally due to methemoglobinemia especially in the young. The observed adverse effects of nitrite in livestock range from acute to chronic with varying degrees of severity and have been reviewed elsewhere. Clinical signs of acute toxicity predominate, which are generally associated with MetHb and include accelerated pulse, dyspnea, muscle tremors, weakness, vomiting, unstable gait, and cyanosis, and may include death. Symptoms of subchronic and chronic toxicity include reduction in feed intake, milk production in dairy animals, rough hair, and reduced weight gain or actual loss. Low fertility and abortion, the latter correlated with fetal hypoxia due to MetHb, can also occur. Reports of nitrite goitrogenicity have been reported in poultry, whereas nitrate has been shown to have this effect in swine, sheep, and cattle resulting from inhibition of iodine uptake from the thyroid gland by nitric oxide. Contributory factors to the adverse effects of nitrite and nitrate can result from intercurrent treatment with antibiotics which can impact both the salivary and gastro intestinal flora. Intoxication results from the interplay between a range of different exposure scenarios and susceptibility factors which include age, anatomical differences between monogastrics, ruminants, cecal/colonics, and differing physiological sensitivity. As an example, interspecies variability in MetHb reductase activity which converts MetHb to Hb has been estimated as a percentage of the human form for pigs (27%), horses (63%), cattle, cats and goats (90%), dogs (114%), sheep (150%), and rabbit (452%). As noted, the acute toxicity of nitrate is approximately 10-fold less than that of nitrite and this also applies to the potential for MetHb formation. This is because nitrite is active directly whereas nitrate first has to be interconverted to nitrite.

In monogastric animals, with the exception of rats and mice, an important source of nitrite is dietary nitrate that is systemically absorbed, secreted into the saliva, and then reduced to nitrite via nitrate reductase activity due to bacteria in the oral cavity and tongue. Such conversion is pH (alkali) dependent and, therefore, does not normally occur in the stomach of most monogastric animals due to relative acidity (pH <3.5). In contrast, the rumen of ruminants and the enlarged cecum and colon of horses are especially suited for nitrate reduction due to the dense microbial population and a relatively high pH (>5). Because herbivorous species, and in particular ruminants, feed on diets containing high levels of nitrate, they are potentially one of the most sensitive species to nitrite poisoning due to their innate ruminant ability for microbial conversion of nitrate to nitrite. However, under normal circumstances problems do not occur as the resultant nitrite is rapidly removed via bacterial fermentation for anabolism to produce ammonia, amino acids, and proteins. Problems occur only when this process becomes 'overloaded,' for example, by the consumption of contaminated feed or water containing abnormal amounts of nitrate or nitrite.

Evidence for the toxicity of nitrate and nitrite in livestock has been accumulated from a limited range of literature reports. Unlike well-controlled laboratory animal toxicology, the data reported were derived from a wide variety of husbandry practices, dietary regimes, and varied aggregate exposures from soil, water, feed, and forages. In certain instances to help fill data gaps, it was necessary to utilize published data on nitrate allowing a 10-fold ratio in acute toxicity to estimate the corresponding exposure to nitrite. Not all the data for all the species could be derived from vegetable feeding stuffs, some of the findings being taken from the direct dosing of sodium nitrite or nitrate as chemicals *per se*. As much of the data related to different exposures leading to adverse effects, no observed adverse effect levels (NOAELs) were estimated for the different livestock species using an uncertainty factor of 3 to convert lowest observed adverse effect levels (LOAELs) to NOAELs. Where LD50 data were the only figures available, for

Table 2 LOAELs and estimated NOAELs derived from the lowest exposure to nitrite (or nitrate) reported to induce toxicity in livestock and companion species[a]

Species	*Substrate*	*Toxic endpoint*	*LOAEL mg kg^{-1} b.w. day^{-1}*	*NOAEL*[b] mg kg^{-1} b.w. day^{-1}

nitrite or nitrate toxicity, the LOAEL was estimated to be 10% of the LD50 value.

The adverse effects of nitrite as demonstrated by the LOAELs derived in different livestock and companion animals (Table 2) broadly lie in the same range allowing for the different species sensitivities already discussed. Interpretation of the data is restricted as some findings relate to bolus administration of the nitrite or nitrate *per se* whereas other studies related to the nitrite or nitrate resulting from that contained within the feedingstuff. The latter scenario generally results in less toxicity and is more akin to the normal feeding and drinking habits of farmed livestock. However, the consequence of bolus dosing could be considered as the most conservative scenario. Of the food-producing livestock, cattle and pigs are known to be relatively sensitive to nitrite. This is at least partially explained by physiological factors, *vide supra* and confirmed by the figures estimated as NOAELs shown in Table 2.

Risk Assessment of Nitrate in Food and Nitrite in Food and Feed: Implications for Human and Animal Health

The risk-assessment process is conventionally divided into four sequential steps: hazard identification, hazard characterization, exposure assessment, and risk characterization. Risk assessment of chemicals in food differs from its counterpart in feed; the former aims to protect human health and the latter aims to protect both animal and human health. Generically, in feed risk assessment, animal health risks are estimated by comparing either the NOEL, NOAEL, or LOAEL values with the actual or estimated chemical exposure in animals. Human health risks are estimated using the occurrence data of the chemical of interest in animal-based products and consumption data of such animal products in humans. For food risk assessment, human exposure to the chemical is derived from occurrence data and human consumption of each food commodity and then compared with a health-based guidance value such as an ADI to conclude on the level of public health risk. In practice, once a chemical has been identified, its content in food measured through validated analytical techniques, its biological (toxicological) effects characterized in a target species and a safe level derived, one can relate the exposure to its biological effects for risk-assessment purposes.

The recent EFSA risk assessments for nitrate in food and nitrite in feed performed by the EFSA's CONTAM Panel are described below. Epidemiological evidence did not suggest a correlation between food or water nitrate intake and increased cancer risk; such evidence for nitrite intake is, to date, equivocal.

Risk assessment of dietary nitrate in food was addressed specifically with regard to the consumption of 400 g of mixed vegetables, as part of a healthy diet, at typical median nitrate concentration, for Europe, and other sources such as drinking water and cured meat. This conservative scenario gave a dietary exposure of 137 mg person^{-1} day^{-1}, which for a 60-kg human equates to 2.28 mg kg^{-1}day^{-1} which is within the ADI for nitrate of 3.7 mg kg^{-1} b.w. day^{-1}, and does not raise concerns for human health. In addition, because most people eat less than half of the recommended daily intake of 400 g of vegetables as fruit, which has relatively low nitrate levels (approximately 10 mg kg^{-1}), the actual dietary exposure would reduce to 81–106 mg day^{-1} nitrate for the majority of the EU population, i.e., 1.35–1.76 mg kg^{-1} day^{-1}. In addition, processing, for example, washing, peeling, and cooking, would also further decrease such exposure. The CONTAM Panel also took into account high consumers of leafy vegetables with high nitrite content, a small proportion of the population (2.5%) in some European countries, who may intermittently exceed the ADI for nitrate by two-fold. An

example would be the consumption of more than 47 g of rucola at one time assuming the median nitrate concentration level leading to an excursion above the ADI without taking into account any other source of nitrate exposure. However, normal intakes and exposure to nitrate from vegetables are unlikely to result in appreciable health risks. Exceeding the ADI is undesirable and occasional circumstances for which the ADI may be exceeded would need to be assessed on a case-by-case basis, for example, unfavorable local/home production conditions for vegetables high in nitrate or high vegetable consumers (such as rucola).

Risk assessment of nitrite in animal feed was first addressed from the animal health point of view. Total daily nitrite intakes for sensitive species such as pigs and cattle with a NOAEL of 3.3 mg kg^{-1} b.w. day^{-1} in both species were estimated using the maximum exposure level in complete feed according to the current EU legislation (10 mg kg^{-1}) and typical feeding regimens within the EU and maximum nitrite level in forages from member states (cattle). Overall, nitrite intakes in both species were 9-fold and 5-fold below the NOAEL with exposures of 0.37 and 0.65 mg kg^{-1} b.w. day^{-1}, respectively (excluding endogenous formation of nitrite). The CONTAM panel concluded that these levels of exposure do not raise concerns for animal health provided that livestock are husbanded under good agricultural practices. Additionally, the awareness of the livestock producer, in particular regarding conditions that may lead to nitrite poisoning (high nitrate levels in forages and the inter-conversion of nitrate to nitrite) further contributes to the protection of livestock health. With regard to the human health aspect, resulting from the consumption of animal products, typical daily human dietary exposure to nitrite from fresh animal products (e.g., milk, meat, and eggs) represents only 2.9% of total background daily dietary exposure, and such low nitrite levels do not raise concern for human health.

Conclusions and Future Perspectives

Nitrate and nitrite are widely consumed by animals and humans mostly through food from plant sources (i.e., forages and fruit/vegetables) and water, and are also formed to a limited extent endogenously. Nitrate is relatively nontoxic but is readily metabolized to more toxic species such as nitrite. The recent EFSA risk assessment for nitrate in food and nitrite in feed did not raise concerns concerning human or animal health. Additionally, a risk–benefit assessment weighing the risk of nitrate toxicity and the benefit of fruit/vegetable consumption was performed and showed that the beneficial effects of the consumption of 400 g day^{-1} fruit/vegetables, as part of a healthy diet, prevailed. For a future perspective on this, the assessment of the balance between health risks and health benefits requires an extension of the current risk assessment approach to additionally allow a scientific evaluation of health benefits. This should utilize harmonized science-based methodology to allow for a quantitative weighing of risks and benefits with a 'common currency.' The outcomes of both risk and benefit assessment and their weighing should be provided to risk managers together with a detailed description of the assumptions and uncertainties in order to optimize subsequent decision-making. Several EU-funded groups such as BRAFO are currently working in this field.

ENVIRONMENTAL CONTAMINANTS

Perchlorate

CW Murray, FDA Center for Food Safety and Applied Nutrition, College Park, MD, USA
PM Bolger, Senior Managing Scientist, Exponent, Washington, USA

Glossary

Exposure Assessment The qualitative or quantitative evaluation of the likely intake of biological, chemical, and physical agents via food as well as exposures from other sources if relevant.

Goiter A greatly enlarged thyroid gland.

Hazard characterization The qualitative or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents that may be present in food. For chemical agents, a dose–response assessment should be performed. For biological or physical agents, a dose–response assessment should be performed if the data are obtainable.

Hazard identification The identification of biological, chemical, and physical agents capable of causing adverse health effects and which may be present in a particular food or group of foods.

Hypothyroidism Abnormally deficient activity of the thyroid gland.

Provisional maximum tolerable daily intake (PMTDI) The endpoint used for contaminants with no cumulative properties. Its value represents permissible human exposure as a result of the natural occurrence of the substance in food and in drinking water. In the case of trace elements that are both essential nutrients and unavoidable constituents of food, a range is expressed, the lower value representing the level of essentiality and the upper value the PMTDI.

Reference dose (RfD) An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.

Risk characterization The qualitative or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population, based on hazard identification, hazard characterization, and exposure assessment.

Background

Perchlorate (ClO_4^-) is an inorganic anion that has a molecular weight of 99 g mol^{-1}. This inorganic anion is produced naturally and through anthropogenic processes. From both of these processes the anion is found and used in the form of a salt. The most common perchlorate salts are ammonium perchlorate (NH_4ClO_4), lithium perchlorate ($LiClO_4$), potassium perchlorate ($KClO_4$), and magnesium perchlorate ($Mg(ClO_4)_2$). The chemical abstract numbers (CAS No.) for these perchlorate salts are 7790-98-9 for ammonium perchlorate, 7791-03-9 for lithium perchlorate, 7778-74-7 for potassium perchlorate, and 10034-81-8 for magnesium perchlorate. Ammonium perchlorate and potassium perchlorate are used as an oxidizing agent in rocket propellants and with the remaining salts are found in other items (e.g., explosives, road flares, fireworks, and car airbags), occur naturally in some fertilizers, and potash. The use of these perchlorate salts and the disposal of these salts provide a pathway for them to enter into the soil and ground and surface water allowing solvation to occur. The solvation liberates this inorganic anion from its salt and it is able to persist in the environment because it is kinetically stable and degrades slowly over time.

Naturally occurring perchlorate salts have been predominately found in arid regions. The general explanation for the occurrence of perchlorate salts in arid regions results from a photochemical reaction in the atmosphere. The proposed photochemical reaction involves sodium chloride from land or sea that is blown in the atmosphere. The sodium chloride reacts with ozone to form a perchlorate salt. After the perchlorate salt is formed, it dissolves in precipitation and returns to the earth surface. Over a period of time, as the rate of perchlorate salt deposition on the surface becomes greater than the rate of perchlorate salt being dissolved results in perchlorate salt becoming incorporated in the composition of the soil and ground.

The arid regions where the greatest perchlorate deposits are formed are located in South America, specifically in the following countries: Chile, Peru, and Bolivia. Of the three countries, the Atacama Desert in Chile has gained the most attention because the caliche has been mined and exported throughout the world for almost 200 years. The composition of the caliche is gypsum, sodium, and salitre (sodium nitrate ($NaNO_3$) and potassium nitrate (KNO_3)). The perchlorate salt is found as a contaminant in the salitre portion of caliche. It is documented that large quantities of Chilean salitre were

imported to the US during the 1800s to be used as a fertilizer, as a source of iodine, for saltpeter used in gunpowder, and as a feedstock to make nitric acid, explosives, and fireworks.

Besides, perchlorate salts being found in arid regions in South America, it has been found in potash from worldwide evaporate deposits. Potash is potassium carbonate that is derived from wood-ash and various dissolved minerals. Potash is formed in evaporite deposits as parts of the formation of evaporate minerals. The majority of potash, mined and milled, is used for feedstock in making fertilizers. Other uses of potash are for the development of potassium-bearing chemicals and reagents, use in deicing salt solution, detergents, and pharmaceuticals.

The anthropogenically produced perchlorate salts and perchlorate-containing chemicals are produced in large-scale facilities and in laboratory settings. The common reaction used to produce sodium perchlorate involves the electrolysis of sodium chlorate. The reaction used to produce potassium perchlorate or ammonium perchlorate involves an additional step to the electrolysis of sodium chlorate by adding a base, resulting in a precipitate containing either potassium perchlorate or ammonium perchlorate. The large-scale production of perchlorate salts and perchlorate-containing chemicals began in 1890 in Masebo, Sweden, by Stockholm Superfostfat Fabrisk AB. The earliest documented large-scale production of perchlorate salts and perchlorate-containing chemicals in the US was located in Niagara Falls, New York, in 1910 by Oldbury Electro-Chemical. The initial production of perchlorate salts and perchlorate-containing chemicals was limited to ammonium perchlorate, sodium perchlorate, potassium perchlorate, and perchloric acid. These compounds were used primarily in fireworks and railroad signals. Later in the mid-1940s during World War II, perchlorate salts and perchlorate-containing chemicals' production began to increase. Specifically, potassium perchlorate production increased because of its use as an oxidizing agent in solid propellant for missiles and rockets. Later in the 1950s, ammonium perchlorate began to replace potassium perchlorate as the oxidizing agent in solid propellant in larger rocket motors. In the 1960s, ammonium perchlorate was used in NASA's space shuttle booster rockets and in the rocket motors for satellite vehicle. In addition, ammonium, lithium, potassium, and magnesium perchlorate are used in the manufacture of flares, fireworks, explosives, and airbag inflators, and herbicides. Potassium perchlorate has been used as a human medicine and used primarily in the 1950s and 1960s to treat hyperthyroidism.

The occurrence of perchlorate contamination found in the soil and ground and surface water has been the topic of some discussions. It has been suggested that the use of fertilizers contaminated with perchlorate salts and the disposal methods of products using perchlorate salts are pathways for the contamination found in the soil and ground and surface water. It has been argued that the latter pathway is the major route for environmental contamination (NAS 2005). The open-burn/open-detonation or hydromining and hog-out processes were the disposal methods that resulted in contamination of the environment. These disposal methods resulted in the high concentrations found in some soils, groundwater, drinking water, and irrigation water.

Hazard Identification and Characterization

Perchlorate is one of several chemicals that has the ability to disrupt thyroid gland function at pharmacological doses (0.02, 0.1, and 0.5 $mg\,kg^{-1}\,day^{-1}$). From the Greer *et al.* (2002) study, perchlorate at these doses can competitively inhibit iodide uptake from the blood by the sodium–iodide symporter (NIS), a glycoprotein expressed in the outer basolateral membrane of the thyroid follicular cells, into the apical membrane. The inhibition of iodide uptake by perchlorate reduces the amount of iodide that is available for organification, which is the oxidation of iodide by thyroid peroxidase and bound to the thyroglubin. With the reduction of iodide, the availability of thyroglubin needed to synthesize thyroid hormones and the resulting concentration of thyroxine (T_4) and triiodothyronine (T_3) are lowered. Because the concentrations of these hormones are reduced, the brain triggers the release of thyrotropin-releasing hormone (TRH) in the hypothalamus, which, in turn, causes the release of thyrotropin, also known as thyroid-stimulating hormone (TSH) from the anterior pituitary gland. The TSH initiates the production of thyroid hormones by the NIS transporting iodide into the thyroid for the synthesis of T_3 and T_4. If the reduction of iodine is continuous and the uptake of iodine is hindered, it may cause the thyroid to become enlarged (goiter). If the disruption of iodide uptake by the thyroid continues it may result in hypothyroidism which has adverse implications for structural and functional brain development in the fetus, infant and child and metabolism and the functioning of cardiovascular, gastrointestinal, skeletal, neuromuscular and reproductive systems in adults.

In the mid-1990s, the US Environmental Protection Agency (EPA) along with other federal government agencies investigated the potential health effects of perchlorate levels in soil, groundwater, and drinking water around the US. In 2002, EPA asked the National Academy of Sciences (NAS) to review the relevant scientific literature and key finding underlying the EPA's 2002 Toxicological Review. After 3 years of review, the NAS recommended to EPA that a reference dose (RfD) of 0.7 $\mu g\,kg^{-1}\,bw\,day^{-1}$ for perchlorate anions from the Greer *et al.* (2002) study, with the application of an uncertainty factor of 10 would protect the most sensitive population – the fetuses of pregnant women who might have hypothyroidism or iodine deficiency. The RfD calculated by the NAS used a point of departure (POD) based on a no observed effect level (NOEL) of 0.007 $mg\,kg^{-1}\,bw\,day^{-1}$ from the Greer *et al.* (2002) study. The NAS committee discussed the use of the NOEL POD as a different approach from the traditional approach of using the no observed adverse effect level (NOAEL) as the POD for determining an RfD. The NAS committee explained that using a nonadverse effect that precedes the adverse event is a conservative health-protective approach to address the perchlorate risk. Because EPA's adoption of the NAS recommended RfD in 2005, there have been additional studies in the literature by Amitai *et al.* (2007) and Blount *et al.* (2009), which have further investigated the link between perchlorate, iodine status, and thyroid function in newborns, pregnant woman, and adults. In early 2010, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) of the World Health Organization (WHO) evaluated perchlorate.

From their evaluation of perchlorate, the JECFA committee derived a provisional maximum tolerable daily intake (PMDTI) of 0.01 mg kg^{-1} bw day^{-1} from their dose–response analysis. The JECFA committee dose–response modeling used the Greer *et al.* (2002) data and a critical size of 50% inhibition of iodide as the benchmark response. The rationale for using this specific critical size was based on the Greer data showing no associated changes in TSH and thyroid hormones at 50% inhibition of iodide. From the JECFA dose–response model, the committee was able to derive a POD of 0.1 mg kg^{-1} bw day^{-1}, which was four-fold lesser than the 0.4 mg kg^{-1} bw day^{-1} dose from the Greer study that is estimated at sustained exposure to trigger hypothyroidism in normal adults. Finally, the committee applied an uncertainty factor of 10 to their POD for the protection of vulnerable groups – such as pregnant women, fetuses, neonates and young infants, those with iodine-deficient diets, and those with clinical or subclinical hypothyroidism.

Method of Analysis

The most common methodology of analysis and sampling perchlorate levels in foods is ion chromatography – tandem mass spectrometry (IC–MS/MS). This method of analysis is rapid, sensitive, and specific that reduces the amount of sample needed to analyze a food matrix for perchlorate. This methodology consists of a triple-stage quadrupole mass spectrometer, equipped with electrospray ionization (ESI) in the negative ion mode that is used to detect perchlorate anion. An $^{18}O_4$-labeled perchlorate anion internal standard is used to correct for any matrix effects.

Another method of analysis used to analyze perchlorate levels is ion chromatography conductivity detection. This method of analysis uses the EPA method 314 EPA (1999) for determining perchlorate ions in drinking water. Unfortunately, this method of analysis is not as sensitive as the IC–MS/MS in handling complicated food matrices. This system consists of an isocratic pump, an eluent generator, a continuous regenerating trap column, a conductivity detector, guard and separation column pair, and a suppressor.

Exposure

Since the early 2000s, the US government, academia, and international organizations have developed individual food surveys that have collected and sampled foods suspected to have perchlorate levels in them. The analytical results of these collection and sampling efforts are shown in Table 1. This table provides 865 analytical results from the scientific literature that represent foods from the US and Canada. Table 1 also provides for the comparison of perchlorate levels in 8 commodities. Shown in Table 1 are the weighted mean (mean of reported mean levels weighted by number of sample) perchlorate levels. In vegetables, the weighted mean perchlorate level range was 10.3–129.5 μg kg^{-1} and in fruits it demonstrated a range of 5–34.1 μg kg^{-1}. The milk samples demonstrated a weighted mean perchlorate level of 5.8 μg kg^{-1}. Rice had a weighted mean perchlorate level of 0.5 μg kg^{-1}. The individual commodities and their respective perchlorate levels results were compared and 6 of the 8 commodities showed fairly good agreement. The commodities that showed fairly good agreement were milk, iceberg lettuce, oranges, carrots, grapes, and rice. In other commodities (spinach and cantaloupe), perchlorate levels varied.

Several national authorities, academia, and international organizations have derived dietary exposures for perchlorate from their individual collection and sampling of foods. The general methodology for these exposure estimates involved using representative consumption survey data and the individual analytical results for perchlorate level for each food. The exposure estimates derived from their methodology resulted in perchlorate dietary exposure estimates either from a specific targeted food or a perchlorate dietary exposure from a Total Diet Study (TDS).

The US perchlorate dietary exposure estimates, derived from the targeted sampling, provide excellent information about the dietary exposure for the individuals that consume specific food but does not provide a picture of the overall dietary exposure to perchlorate. Shown in Table 2 are perchlorate dietary exposure estimates from targeted foods. Shown in Table 2 are the mean and the 90th percentile perchlorate exposure estimates for three subpopulations, all ages, children, and females. As mentioned earlier in the hazard characterization, children and females represent the most sensitive subpopulations to the adverse health effects of perchlorate. Table 2 displays perchlorate dietary exposure estimates from regions that are suspected to have high contamination of perchlorate in the environment. The perchlorate dietary exposure estimates from the USFDA and Sanchez *et al.* (2009) show good agreement. These perchlorate dietary exposure estimates were derived using US consumption data from the Continuing Survey of Food Intakes by Individuals (CSFII) 1994–1998 and sampled foods known to have high concentration of perchlorate.

Health Canada derived an average perchlorate dietary exposure estimates from consumption data from their Nutrition Canada Food Consumption Survey which is a 24-h dietary recall survey and analytical levels for perchlorate in foods from retail establishments in Ottawa. The foods analyzed by Health Canada were of domestic and imported origin. The averaged exposure for women of child bearing age showed good agreement with the Sanchez *et al.* (2009). In the case of children, the Canadian children exposures were different with the USFDA and Sanchez *et al.* (2009) exposures based on the limited foods analyzed.

The dietary perchlorate exposure estimates derived from the FDA's TDS are shown in Table 3. In general, the TDS provides an overall estimate of the average diet in a specific country. The TDS is often referred to as a market basket study in which 200–300 core foods are collected and analyzed to determine the levels of various contaminants and nutrients in those foods. Often in the TDS, the population is divided into age–gender groups to estimate dietary exposure for the respective groups. In the case of perchlorate, the FDA's mean and the 90th percentile dietary perchlorate exposure estimate for 14 age–gender groups are shown in Table 3 and has a range of 0.09–0.45 μg kg^{-1} bw day^{-1} for the mean and 0.176–0.734 μg kg^{-1} bw day^{-1} for the 90th percentile. For comparison, the results from the USFDA TDS adult age–gender groups were compared with results derived

Risk Characterization

Perchlorate has been evaluated by the NAS and JECFA. The results from these evaluation resulted in an RfD of 0.7 μg kg^{-1} bw day^{-1} by NAS and PMDTI for perchlorate 0.01 mg kg^{-1} bw day^{-1} by JECFA. Both committees acknowledge that perchlorate has a very short life and is rapidly cleared from the body and their evaluations included a 10-fold safety factor of protection for pregnant women, fetuses, neonates and young infants, those with iodine-deficient diets, and those with clinical or subclinical hypothyroidism.

Finally, the reference values derived by NAS and JECFA are compared with dietary perchlorate exposure from the USFDA TDS assessment in **Table 3**. The estimated dietary perchlorate exposure provided in **Table 3** shows that the mean for all age–gender groups from the USFDA TDS is below the RfD and PMDTI. The estimated perchlorate exposure estimates for 13 of the 14 age–gender groups at the 90th percentile were below the NAS RfD, with children of 2 years of age having a perchlorate exposure equal to the RfD. When these age–gender groups were compared with the PMDTI at the 90th percentile, all these groups were well below 0.1 mg kg^{-1} bw day^{-1}.

TOXIC METALS

Contents

Arsenic

SS-H Tao, FDA Center for Food Safety and Applied Nutrition, College Park, MD, USA
PM Bolger, Senior Managing Scientist, Exponent, Washington, USA

Glossary

Benchmark dose – hlower confidence limit (BMDL) The lower boundary of the confidence interval on the benchmark dose (BMD). The BMD is the dose of a substance associated with a specified low incidence of risk, generally in the range of 1-10% of a health effect.
Bioavailability The degree or rate at which a substance is absorbed into a living system or is made available at the site of physiological activity.
Biomarkers Indicators of signaling events in biological systems or samples. They have been used as markers of exposure, effect, and susceptibility.
Carcinogen A chemical capable of inducing cancer.
Minimal risk level (MRL) An estimate of daily human exposure to a hazardous substance that is likely to be without an appreciable risk of adverse noncancer health effects over a specified route and duration of exposure.
Provisional tolerable weekly intake (PTWI) The end-point used by the Joint FAO/WHO Expert Committee on Food Additives that represents the permissible human weekly exposure to those contaminants unavoidably associated with the consumption of otherwise wholesome and nutritious food.

Chemical

Arsenic (CAS no. 7440-38-2), arsenic trioxide (As_2O_3, CAS no. 1327-53-3), arsenic pentoxide (As_2O_5, CAS no. 1303–28-2), sodium arsenite ($NaAsO_2$, CAS no. 7784-46-5), disodium arsenate (Na_2HAsO_4, CAS no. 7778-43-0).

Background

Arsenic is a naturally occurring element that is released from volcanoes and the erosion of arsenic-containing mineral deposits. Human activities such as mining; burning of coal, oil, gasoline, and wood; and the use of arsenic compounds, primarily chromate copper arsenate (CCA), as medicines, pesticides, herbicides, and wood preservatives, also contribute to its environmental contamination. Arsenic exists in many chemical forms and valency states (-3, 0, $+3$, and $+5$). Low concentrations can be found in air, water, soil, and food. The background soil content of arsenic varies widely, typically ranging from 1 to 40 ppm, with an average of 5 ppm. Arsenic concentration in natural surface and groundwater is generally approximately 1 ppb, but may exceed 1 ppm in contaminated areas or areas with high soil arsenic. For example, naturally occurring arsenic-contaminated groundwater has severely affected people in Bangladesh where 35–70 million people have been chronically exposed to elevated arsenic in drinking water. This is the result of tube wells installed more than 30 years ago to tap groundwater as a source of pathogen-free drinking water to prevent infectious diseases.

The primary forms of arsenic found in drinking water are arsenite ($+3$) and arsenate ($+5$), the inorganic forms. Sea water typically contains 1–2 ppb arsenic. Ambient air arsenic background concentrations generally range from less than 1 to 3 ng m^{-3}, but concentrations in an urban area may go up to 100 ng m^{-3}. Food arsenic levels usually range from 20 to 140 μg kg^{-1}. However, higher total arsenic levels are found in seaweed, seafood, mushroom, rice and rice products, and some meat. Most arsenic present in seafood is as the organic form (arsenobetaine and arsenocholine) which is considered to be nontoxic. In general, inorganic arsenic is the most toxic form with trivalent arsenic being more toxic than pentavalent arsenic.

 doi:10.1016/B978-0-12-378612-8.00201-8

Hazard Identification and Characterization

Arsenobetaine, the major form of arsenic in most seafood and fish, is considered to be of no toxicological concern because it is not metabolized and is excreted intact by humans. Arsenosugars and arsenolipids are metabolized to dimethylarsinate in humans, but no specific toxicological information is available. Soluble inorganic arsenic is rapidly and well absorbed (80–90%) after ingestion, distributed throughout the body, metabolized by methylation, and excreted mainly in urine. Organic arsenic is also well absorbed, generally by more than 70%.

Two basic processes are involved in the metabolism of inorganic arsenic: (1) reduction/oxidation reactions that interconvert As^{+3} and As^{+5} and (2) methylation reaction, which converts arsenite to monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA). The latter facilitates the excretion of inorganic arsenic from the body as both MMA and DMA are more readily excreted in urine. Inorganic arsenic can also be excreted directly in the urine. In contrast, with the exception of arsenosugars, ingested organic arsenicals such as MMA, DMA, and arsenobetaine, do not readily enter the cell, undergo limited metabolism, and are excreted unchanged in the urine. High variability of arsenic metabolism and toxicokinetics has been reported among different species, populations, and individuals. Some species (marmoset monkey, guinea-pig, chimpanzee) have minimal or no arsenic methylation capability. In humans, inorganic arsenic is extensively methylated and its metabolites are excreted primarily in the urine. Age, gender, and smoking contribute only minimally to the large individual variations in arsenic methylation in humans. The relative proportions of arsenic metabolites in human urine are usually 40–75% DMA, 20–25% inorganic arsenic, and 15–25% MMA. Similar urinary metabolic profiles were reported among family members. An increase in DMA excretion was observed in individuals with a specific allele on a gene, suggesting its possible association with a genotype that protects against arsenic toxicity. Other than genetic polymorphisms and wide differences in methyltransferase activities, nutritional status (protein, selenium, and folate) can also influence methylation capacity. Urine arsenic is commonly used as a measure of recent exposure. Arsenic levels in hair and nails have been shown to provide reliable biomarkers for long-term chronic exposure to arsenic in humans.

Inorganic arsenic binds to the sulfhydryl groups of cellular proteins, inhibiting the pyruvate and succinate oxidative pathways. It also competes with phosphorus in the oxidative phosphorylation process. Although chronic exposure to inorganic arsenic has been associated with cancers in humans, the exact underlying molecular mechanisms are not clear. Several modes of action (MOA) of inorganic arsenic in carcinogenesis have been proposed, including: induction of oxidative stress; genotoxicity as induction of mutations and chromosomal aberrations; modulation of signal transduction and apoptosis (growth factors, cell proliferation, and promotion); and alterations in gene expressions via hyper- and hypomethylation of DNA. Arsenic does not directly react with DNA, and it is also probable that more than one of these mechanisms are involved. Recent evidence has proved that arsenic activates Hedgehog signaling, a key oncogenic signaling pathway, and also showed that there is a strong positive correlation between arsenic exposure and high levels of Hedgehog activity in a cohort of bladder cancer patients. This is the first report to suggest that activation of Hedgehog signaling may be in part involved in arsenic-induced cancer.

Ingestion of large doses of arsenic can be fatal. The oral lethal dose of arsenic trioxide is reported to be between 70 and 180 mg day^{-1}. The estimated minimum lethal dose in humans ranges from 1 to 3 mg As per kg of bodyweight (bw) per day. Poisoning may appear with daily doses of inorganic arsenic as low as a few mg for a short period of time, for example, weeks. An estimated daily exposure of 1.3–3.6 mg arsenic from the consumption contaminated dried milk for a few weeks resulted in fever, insomnia, and anorexia in more than 12 000 infants (130 deaths) in Japan. Many hospitalized patients also showed liver swelling, anemia, and changes in electrocardiograms. In another episode, more than 200 adults were poisoned by contaminated soy sauce with an estimated daily exposure of 3 mg of arsenic for 2–3 weeks. Depending on dose and duration of exposure, adverse health effects caused by inorganic arsenic can occur in many organs. Symptoms of acute exposure to arsenic in drinking water at doses of 0.2 mg kg^{-1} day^{-1} or above usually occur within the first several hours. Essentially, all cases of short-term high-dose exposure to inorganic arsenic show clinical signs of gastrointestinal effects.

Short-term exposure (weeks/months) to elevated arsenic (0.06 $mg^{-1}day^{-1}$) in drinking water can result in gastrointestinal effects, such as abdominal pain, vomiting, diarrhea, and muscular cramping; hematological effects, such as anemia and leucopenia; and peripheral neuropathy, such as numbness, burning or tingling sensations, or pain in the extremities. A metallic taste, garlic odor in breath and feces, and salvation may also be present. These short-term effects are generally reversible when the exposure is terminated.

For chronic exposure, lower lethal doses of 0.014–0.05 mg As $kg^{-1}day^{-1}$ in drinking water have been reported. Chronic exposure to arsenic in drinking water typically causes specific dermal effects. Diffuse or spotted hyperpigmentation followed by palmer–planter hyperkeratosis occurs after 6 months to 36 months of ingestion of high doses of arsenic (0.04 mg $kg^{-1}day^{-1}$) or 5–15 years of ingestion of low doses of arsenic (0.01 mg $kg^{-1}day^{-1}$ or higher). Chronic exposure to 0.02 mg $kg^{-1}day^{-1}$ or higher has been shown to cause perturbed porphyrin metabolism and irreversible hypertension. In addition to skin lesions, chronic exposure to arsenic is also associated with other health outcomes including peripheral vascular, cardiovascular, diabetes mellitus, peripheral neuropathy, diseases of the respiratory system, negative impacts on fetal and infant development (low birth weight), and cancers (skin and internal organs).

Inorganic arsenic is a listed as a human carcinogen by many national agencies and international organizations. It is a multisite carcinogen; numerous epidemiologic studies provide evidence associating of oral exposure to inorganic arsenic via drinking water with different types of cancers including the skin, urinary bladder, lung, kidney, liver, and prostate. This link between these cancers and arsenic exposure in drinking water was observed in many populations of the world, including Taiwan, Japan, Chile, Argentina, Bangladesh, India, and China. In 2010, The International Agency for Research on Cancer (IARC) concluded that there was sufficient evidence to show

that skin lesions and cancers of the urinary bladder, lung, and skin were caused by arsenic in drinking water, and limited evidence for cancers of the kidney, liver, and prostate.

Assessment of human cancer risk related to the exposure of total inorganic arsenic is limited. Because only drinking water arsenic was measured in most available epidemiological studies the information on total dietary exposure was lacking. In 2010, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) withdrew its provisional tolerable weekly intake (PTWI) for arsenic because evidence from human epidemiology data indicated that it did not protect human health. Therefore, using a range of assumptions to extrapolate drinking water arsenic concentration to total dietary inorganic arsenic exposure, JECFA has determined the 95% confidence limit of the benchmark dose ($BMDL_{005}$) for 0.5% increased incidence of lung cancer over background for inorganic arsenic to be 3.0 $\mu g\ kg^{-1}\ day^{-1}$ (2–7 $\mu g\ kg^{-1}\ day^{-1}$ based on the range of estimated total dietary exposure). Similarly, based on the studies showing statistically significant association of drinking water arsenic concentration below 100 $\mu g\ l^{-1}$ and its adverse effects in humans, the European Food Safety Authority (EFSA) panel on Contaminants in the Food Chain (CONTAM Panel) selected a benchmark response of 1% extra risk and calculated a range of values of the $BMDL_{01}$ instead of a single reference point for inorganic arsenic. The $BMDL_{01}$ values for the various health endpoints, skin lesions, cancers of the skin, urinary bladder, and lung ranged from 0.3 to 8 $\mu g\ kg^{-1}day^{-1}$.

Based on animal studies, Agency for Toxic Substances and Disease Registry (ATSDR) has derived an intermediate oral minimal risk level (MRL) of 0.1 $mg\ kg^{-1}\ day^{-1}$ for MMA for diarrhea in rats exposed to dietary MMA for 13 weeks, a chronic oral MRL of 0.01 $mg\ kg^{-1}\ day^{-1}$ for MMA for increased incidence of progressive nephropathy in male mice exposed to dietary MMA for 2 years, and a chronic oral MRL of 0.02 $mg\ kg^{-1}\ day^{-1}$ for DMA for increased vacuolization of the urothelium in the urinary bladder of female mice exposed to dietary DMA for 2 years. In a 2-year rat bioassay, DMA has been shown to promote carcinogenesis in the urinary bladder but not in other tissues. Cytotoxicity and increased cell proliferation were involved rather than direct DNA damage. However, the relevance of these findings to humans has not been established especially because the rats eliminate DMA much slower than other species, including humans.

Methods of Analysis

Sample preparation is required for the determination of arsenic in food. Acid digestion is usually used for total arsenic determination, whereas milder extraction combined with chemical separation of inorganic and organic arsenic, or chromatographic separation of arsenic species with on-line selective detector of arsenic are needed for the determination of arsenic species from food. A variety of instrumental techniques for the determination of arsenic are available. These include hydride generation atomic absorption spectrometry (HG-AAS), high-performance liquid chromatography (HPLC)–HG-AAS, HPLC combined with hydride generation atomic fluorescence spectrometry (HPLC–HG-AFS), inductively coupled plasma atomic emission spectrometry (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), HPLC–ICP-MS, neutron activation analysis (NAA), and electro-thermal atomization laser-excited atomic fluorescence spectrometry (ETA-LEAFS). For arsenic species determination in food, HPLC–ICP-MS is by far the most common and useful method.

Exposure

For the general population who do not smoke, the most common route of exposure to arsenic is through ingestion, and drinking water and food are the major sources. Depending on arsenic levels in drinking water and food, exposure can vary greatly in different regions. In regions with high natural arsenic levels, drinking water can be the major contributor of inorganic arsenic in the diet. Whereas, in regions where arsenic concentration in the drinking water is low, less than 50 $\mu g\ l^{-1}$, food can be the major contributor. Seafood/fish products contribute the most to dietary total arsenic exposure while cereal and grain products contribute the most of inorganic arsenic. Because rice is generally grown in paddy soil under flooded conditions, it accumulates arsenic from the soil and water more than other cereal grains; its arsenic content is approximately 10 times higher than that of other grains. The predominant arsenic species in rice are inorganic arsenic and DMA. The bioavailability of greenhouse-grown rice in which approximately 86% arsenic is present as DMA was determined to be low: only 33% of total rice arsenic was absorbed in an *in vivo* swine model. Total and inorganic arsenic content in rice varies greatly, ranging from 0.03 to 0.54 and 0.01 to 0.41 $mg\ kg^{-1}$, respectively, and can be influenced by geographic location, cultivar, arsenic levels in irrigation water, soil arsenic, use of arsenic-containing fertilizer and pesticides, etc. The percentage of inorganic arsenic as total arsenic in rice ranged from 11% to 90% or 100%. A recent report indicated that even though Chinese rice has lower inorganic arsenic content than that from other countries, it can contribute significantly to human inorganic arsenic exposure due to high consumption of rice as a staple food.

Dietary exposure to inorganic arsenic has been estimated to be 0.13–0.56 $\mu g\ kg^{-1}day^{-1}$ for average consumers and 0.37–1.22 $\mu g\ kg^{-1}day^{-1}$ for 95th percentile consumers across 19 European countries. This was calculated based on the assumption that the overall average of the proportion of inorganic arsenic to total arsenic for food other than fish and seafood was 70% and a fixed inorganic value of 0.03 $mg\ g^{-1}$ in fish and 0.1 $mg\ kg^{-1}$ in seafood, and using the lower bound and upper bound concentrations. Recently, Xue *et al*. using a probabilistic modeling with the Stochastic Human Exposure and Dose Simulation Dietary model (SHEDS-Dietary) and based on data from the National Health and Nutrition Examination Survey, reported that in the US, the estimated dietary exposures to total and inorganic arsenic were 0.36 and 0.05 $\mu g\ kg^{-1}day^{-1}$, respectively for the mean, and 1.40 and 0.19 $\mu g\ kg^{-1}day^{-1}$, respectively for the 95th percentile.

Risk Characterization

Inorganic arsenic has been identified as a human carcinogen based on numerous epidemiological studies associated with

arsenic levels in drinking water. Food can contribute significantly to total dietary inorganic arsenic exposure in people who are high consumers of rice or algae-based products. Water, depending on arsenic levels, used in food, cooking/preparation and possibly irrigation of crops, particularly rice, can also contribute to arsenic in food. More information on bioavailability and speciation data for different food is needed for improving exposure estimation and for more accurate risk assessment. The estimated mean background dietary exposures to inorganic arsenic in the US and various European and Asian countries were reported to vary from 0.1 to 3.0 μg $kg^{-1}day^{-1}$ that are near or at the range of the $BMDL_{01}$ and $BMDL_{005}$ values identified by EFSA and JECFA, respectively. This suggests that certain populations may have an increase in risk depending on their particular dietary habits.

TOXIC METALS

Cadmium

Y Zang, FDA Center for Food Safety and Applied Nutrition, College Park, MD, USA
PM Bolger, Senior Managing Scientist, Exponent, Washington, USA

Glossary

Beta-2-microglobulin A small protein normally found on the surface of many nucleated cells. It is normally filtered through the glomerulus and gets reabsorbed by renal tubules back into the blood. In case of tubular damage such as in chronic cadmium toxicity, the reabsorption is impaired, resulting in elevated level in urine.

***Itai-Itai* disease** A bone disease caused by industrial cadmium pollution of the food and water supply, found in the polluted Jinzu River basin in Japan. The major symptoms of *Itai-Itai* disease include pain in the joints and the back, resulting from the cadmium-induced bone damage.

Metallothionein A type of low molecular weight, cysteine-rich protein that binds with metals such as copper, cadmium, and zinc.

Provisional tolerable weekly/monthly intake (PTWI/PTMI) An estimate of the amount of a contaminant that can be ingested over a lifetime without appreciable risk.

Tubular proteinuria An increase of urinary excretion of low molecular weight plasma proteins, such as beta-2-microglobulin (β2MG) and retinol-binding protein (RBP). It is an early sign of cadmium-induced renal dysfunction through chronic exposure.

Chemical Names

Cadmium (CAS Number: 7440-43-9); Metallic cadmium, Inorganic cadmium, such as cadmium oxide and cadmium sulfide.

Background

Cadmium is a transition bivalent metal naturally occurring in the earth's crust, and is typically found in ores with other metals such as zinc, lead, and copper. Cadmium has been used widely in the industry as an electroplating agent, a color pigment, and a plastic stabilizer since the 1930s. In many countries including the US, these traditional applications have declined because of its health effects and issues of environmental contamination. Today, cadmium is mainly used in the manufacture of nickel–cadmium batteries and cadmium telluride solar panels.

Cadmium can enter the environment in many ways. Metal mining, smelting, and burning of coal and household waste can release cadmium into the air. Cadmium can enter water from waste water disposal in related industries, and can enter soil from car exhaust, fertilizer usage, and the deposition from the air. High levels of cadmium have been found in the soil close to hazardous waste sites because of spills and leaks. As a chemical element, cadmium does not break down in water and soil, where it can be taken up by plants, fish, and animals.

Hazard Identification and Characterization

Cadmium has no known biological function in animals and humans. Occupational exposure to cadmium, mainly through inhalation, can result in metal fume fever, chemical pneumonitis, pulmonary edema, and lung cancer. In the general population, long-term exposure to cadmium from tobacco smoking and consumption of contaminated food and water can lead to adverse health effects including renal damage and bone demineralization.

In humans, the absorption of cadmium from the gastrointestinal (GI) tract is approximately 5% in adults. Bioavailability of cadmium is lower in zinc and iron-rich foods such as oysters, because these two ions compete with cadmium for absorption from the GI tract. Iron deficiency results in an increased absorption of cadmium, and it has been reported that the divalent metal transporter I (DMTI) acts as the transporter of cadmium. Dietary absorption of cadmium is also favored by deficiencies of zinc, calcium, and protein. Women generally have a higher body burden of cadmium and are more susceptible to cadmium toxicity compared to men. Some studies suggest that the absorption of cadmium from diet in newborns and infants can be seven to eight-folds higher than that in adults.

Cadmium induces and binds with metallothionein (MT) primarily in the liver, and a small amount of the cadmium–MT complex is then transported to the kidneys. The binding of cadmium to MT prevents the free cadmium ions from exerting their toxic effects. However, because of the small molecular weight of MT, the complex can be easily reabsorbed by the renal tubules and then degraded by lysosomes. The degradation releases unbound cadmium, which induces the tubular cells to produce more MT. When the free cadmium ions exceed a certain level at which the newly synthesized MT is insufficient to neutralize them, tubular damages start

 doi:10.1016/B978-0-12-378612-8.00202-X

to occur. This cadmium level is called the 'critical value,' and is commonly quoted as 200 μg g^{-1} renal cortex.

In nonoccupational exposures in humans, cadmium is found mainly in liver (50%) and kidney (15%), with a small amount in bone. Blood cadmium levels are low, usually less than 1 μg l^{-1} and the level in the breast milk is even less. Cadmium does not readily cross the placenta and the blood–brain barrier. Its excretion routes include urinary and fecal, but only approximately 0.001% of the body burden is excreted per day. The biological half-life of cadmium in humans is extremely long, approximately 10–30 years.

In experimental animals, chronic oral exposure to cadmium can result in kidney damage, decrease in bone calcium levels, and adverse effects on developmental, neurobehavioral, and immune systems. Cadmium also causes tumors at multiple tissue sites by various routes of exposure.

In humans, acute toxicity is a rare event. Exposures to high concentrations of cadmium from heavily contaminated food or beverages can result in GI symptoms including nausea, vomiting, and abdominal pain. The 'no observed adverse effect level' (NOAEL) of a single oral dose is estimated to be 3 mg elemental cadmium per person, and the reported lethal doses range from 350 to 8900 mg.

The chronic toxic effects of cadmium are a much greater concern than the acute exposures because they require lower exposure levels and occur more frequently. One of the major toxic effects of low-level oral cadmium exposure is renal injury. Cadmium accumulation in proximal tubules causes histopathological changes in tubular cells and glomeruli, resulting in impairment of renal function as reflected by tubular proteinuria. The most commonly used biomarkers of cadmium-related renal effects include the urinary levels of beta-2-microglobulin (β2MG) and retinol-binding protein (RBP), and the activity of *N*-acetyl-beta-glucosaminidase (NAG) as indicators of tubular toxicity, whereas the urinary albumin, transferrin, and glomerular filtration rate (GFR) are used as indicators of glomerular damages. Cadmium-induced nephrotoxicity has been associated with increased mortality rates in many epidemiological studies, and it may also potentiate diabetes-induced effects on the kidneys.

Long-term consumption of cadmium-contaminated rice caused *Itai-Itai* disease in postmenopausal women in Japan, characterized by severe osteomalacia and osteoporosis, bone deformities, and concomitant renal dysfunction. Cadmium levels lower than what was seen in Japan have been associated with skeletal effects such as bone mineral loss, decreased bone density, and increased bone fragility and fracture.

Some epidemiological evidence suggests that cadmium may be an etiologic agent for cardiovascular disease including hypertension, yet the associations are weak and inconsistent with unclear mechanisms. The relationship between abnormal behavior and decreased intelligence in children and adults exposed to cadmium was also reported, but typically complicated by exposure to other toxic metals. As noted previously, the blood–brain barrier severely limits cadmium access to the central nervous system.

Cadmium and cadmium compounds have been classified as known human carcinogens by the International Agency for Research on Cancer (IARC) and the National Toxicology Program (NTP). Most of the evidence is based on the occupational exposure through inhalation, which has been most clearly associated with lung cancer. Some epidemiologic studies have reported an association between chronic cadmium exposure and cancers of the breast, endometrial, kidney, pancreas, and urinary bladder. The mechanism of cadmium carcinogenesis is not clearly understood.

A Provisional Tolerable Weekly Intake (PTWI) for cadmium of 7 μg kg^{-1} bw was established by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1988 and has been widely accepted. At its 73rd meeting in 2010, JECFA reevaluated cadmium and established a new Provisional Tolerable Monthly Intake (PTMI) of 25 μg kg^{-1} bw, which is equivalent to 0.8 μg kg^{-1} bw day^{-1}. This PTMI, derived based on the renal biomarker β2MG, is intended to protect 95% of the population by age of 50 years without having adverse renal effects. US Agency for Toxic Substances and Disease Registry (ATSDR) established a chronic-duration oral minimal risk level (MRL) of 0.1 μg cadmium kg^{-1} bw day^{-1} in 2008. In the same year, US EPA published a Reference Dose (RfD) of 0.5 μg kg^{-1} bw day^{-1} from water and 1 μg kg^{-1} bw day^{-1} from food based on the critical value of 200 μg g^{-1} renal cortex. This RfD is equivalent to the previous JECFA PTWI.

Methods of Analysis

Quantitative determination of cadmium can be performed using a variety of methods, among which atomic absorption spectroscopy (AAS) is the most commonly used method to quantify cadmium levels in food samples. Other analytical methods include inductively coupled plasma techniques using optical emission spectroscopy (ICP-OES) or mass spectrometry (ICP-MS). In the US Total Diet Study (TDS), the standard method used to measure cadmium level in foodstuffs is graphite furnace AAS (GFAAS). In the European Union (EU), it is required that an acceptable method should have the limit of detection (LOD) less than 1/10 of the maximum level (ML), and the limit of quantification (LOQ) less than 1/5 of the ML.

Exposure

The presence of cadmium in food results from contamination of soil and water. Cadmium can be taken up and accumulated in plants and animals. Concentrations of cadmium in food vary widely among food categories and geographic regions. As consented at the 73rd JECFA meeting, the average occurrences of cadmium range from less than 0.0001 to 0.04 mg kg^{-1} in most food categories. Higher concentrations ranging from 0.1 to 4.8 mg kg^{-1} were reported for certain foods that accumulate relatively high levels of cadmium, such as shellfish/mollusks, animal offal, oilseeds, and vegetables, especially wild mushrooms. Tobacco and cereal grains have the ability to concentrate cadmium to levels of 10–150 μg Cd kg^{-1}. In contrast, eggs and milk usually have lower levels of cadmium. The contribution of each food category in cadmium intake from the total diet varies by countries and regions due to the differences in cadmium occurrences and dietary habits. For instance, the main dietary sources of cadmium in Japan are rice, vegetables/

seaweed, and seafood, whereas cereals/grains, animal offal and vegetables/nuts/pulses are the main sources in Europe.

Food is the major source of cadmium for the general population, especially in nonsmokers. Cigarette smoking can significantly increase the life-time body burden of cadmium. According to the data submitted to JECFA at its 73rd meeting (2010), the estimates for the mean cadmium exposure in adults ranged from 2.2 to 12.0 μg kg^{-1} bw per month in different countries/regions. The cadmium exposures for high consumers, as reported by European Food Safety Authority (EFSA), Lebanon, and the USA, ranged from 6.9 to 12.1 μg kg^{-1} bw per month. For Australia and the USA, mean dietary exposure for children 0.5–12 years of age ranged from 2.7 to 12.9 μg kg^{-1} bw per month. Dietary exposure for vegetarians, according to EFSA's hypothetical model that replaced meat and fish with nuts and oilseed in equal amounts, was estimated to be 21.6 μg kg^{-1} bw per month.

Risk Characterization

Given the results of the dietary exposure assessments described above, the estimated dietary cadmium intake for all age groups, including consumers with high exposures and subgroups with special dietary habits, are below the JECFA PTMI of 25 μg kg^{-1} bw. The risk of adverse renal effects from dietary cadmium exposure is low in the general population, but susceptible populations such as smokers (high background exposure levels), vegetarians, and individuals who frequently eat rice grown in heavily contaminated soil may be at increased risk of adverse renal effects.

TOXIC METALS

Lead

CD Carrington, FDA, Center for Food Safety and Applied Nutrition, College Park, MD, USA
PM Bolger, Senior Managing Scientist, Exponent, Washington, USA

Glossary

Acute toxicity Adverse effects of a substance that result either from a single exposure or from multiple exposures in a short space of time (usually less than 24 hours).
Cardiovascular system Organ system that passes nutrients, gases, hormones, blood cells, etc., to and from cells in the body to help fight diseases and help stabilize body temperature and pH to maintain homeostasis.
Chronic toxicity Property of a substance that has toxic effects on a living organism, when that organism is exposed to the substance continuously or repeatedly.
Electrothermal atomic absorption spectrometry (ETAAS) A type of atomic absorption spectrometry where the sample is atomized using a probe which is rapidly heated by passing a current through it. The probe often is either a graphite tube or a tungsten coil.
Inductively coupled plasma mass spectrometry (ICP-MS) A type of mass spectrometry that is highly sensitive and capable of the determination of a range of metals and several non-metals at concentrations below one part in 10^{12} (part per trillion). It is based on coupling together with inductively coupled plasma as a method of producing ions (ionization) with a mass spectrometer as a method of separating and detecting the ions.
Intelligence quotient (IQ) It is a score derived from one of several different standardized tests designed to assess intelligence. Current IQ tests are constructed so that the median score is set to 100 and a standard deviation to 15.
Osteoporosis Thinning of bone tissue and loss of bone density over time.
Systolic blood pressure (SBP) Maximum blood pressure during each heart beat.
Thiol group A functional group that contains a sulfur atom bonded to a hydrogen atom.

Background

Lead is a ubiquitous element that occurs in the environment due to natural and anthropogenic pathways/sources. Dietary exposures can be elevated because of the use of lead compounds such as those used in paint, gasoline, and solder. Absorption of lead from the gastrointestinal tract is influenced by physiological factors (e.g., age, fasting, calcium and iron status, and pregnancy). In particular, absorption is higher in children than in adults and is lower in the presence of food. Absorbed lead is transferred to soft tissues, including liver and kidney, and to bone where it accumulates with age. The half-life is approximately 30 days in blood and much longer in bone (10–30 years). Conditions, such as pregnancy and osteoporosis, result in bone resorption and elevated blood levels. Lead readily crosses the placenta and is transferred into breast milk. Urine and feces are the major routes of excretion. Lead binds to thiol groups and other ligands in proteins and its toxicity is attributed to inhibition of a number of important enzymes (e.g., heme synthesis) and to interference with calcium, magnesium, and zinc homeostasis. For infants and children, a chronic dietary exposure of 30 $\mu g\,day^{-1}$ is estimated to correspond to a decrease of 1 intelligent quotient (IQ) point. In adults, a dietary lead exposure of 80 $\mu g\,day^{-1}$ is estimated to correspond to an increase in systolic blood pressure of 1 mm Hg. Reductions in population blood levels have primarily occurred because of the elimination of lead fuel additives, lead solder in food cans, and lead additives in paint.

Hazard Identification and Characterization

Blood is the tissue used most frequently to estimate exposure to lead, and blood lead levels generally reflect exposure in recent months. However, if the level of exposure is relatively stable, then blood lead level is a good indicator of exposure over a protracted period of time. Longitudinal surveys in some countries have shown substantial reductions in population blood lead levels in recent decades.

The acute toxicity of lead is low whereas chronic oral exposure has detrimental effects on multiple organs, including the kidneys and liver, and systems, including the cardiovascular, hematological, immune, reproductive, and nervous systems. Lead elicits a wide range of effects, including various neurological and behavioral effects, mortality (mainly due to cardiovascular diseases), impaired renal function, hypertension, impaired fertility and adverse pregnancy outcomes, delayed sexual maturation, and impaired dental health. High doses of inorganic lead compounds are carcinogenic in

experimental animals, causing renal and brain tumors. Results of genotoxicity studies and the inhibition of DNA-repair indicate a non-DNA-reactive mode of action.

For children, the weight of evidence and consistency across studies is greatest for the association of blood lead levels with impaired neurodevelopment, specifically reduction of intelligence as measured by the IQ. This effect has been associated with lower blood lead concentrations than those associated with the effects observed in other organ systems. Although the estimated IQ decrease per microgram per deciliter ($\mu g\ dl^{-1}$) of blood lead is small when viewed as the impact on an individual child (6.9 points over the range of 2.4–30 $\mu g\ dl^{-1}$), the decrement is considered to be important when interpreted as a reduction in population IQ. The most significant impact on population IQ would be at the tails of the IQ distribution such that there would be more children considered to have less than normal IQ and there would be less children deemed to be of superior intelligence. The lead-associated reduction in IQ may also be a marker for other adverse neurodevelopmental effects for which the evidence is not as robust, but which have been observed in children at approximately the same blood lead levels (e.g., executive dysfunction and fine motor deficit).

For adults, the adverse effect for which the weight of evidence is greatest and most consistent is that associated with an increase in blood pressure. As with the IQ detriment, the increase is small when viewed as the effect on an individual's blood pressure, but important when viewed as a shift in the distribution of blood pressure within a population. Increased blood pressure is clearly associated with increased risk of cardiovascular mortality.

Methods of Analysis

Sample preparation used most frequently for the determination of lead in food is acid digestion with strong oxidants in open or closed vessels. Microwave-assisted acid digestion is also used, which allows the use of large sample masses (1–2 g) under controlled temperature and pressure conditions, reducing contamination and avoiding loss of the element during mineralization. The analytical methods of choice for the determination of lead in food and blood are electrothermal atomic absorption spectrometry (ETAAS) and inductively coupled plasma mass spectrometry (ICP-MS). In the past decade, many technical improvements have been made to ETAAS, which allow for the determination in food at the low microgram per kilogram level. ICP-MS is increasingly used in food laboratories owing to its capability to perform multielement measurements in a wide variety of foods. The use of dynamic reaction cell (DRC)-ICP-MS has allowed further refinements resulting in the determination of lead in food at levels lower than 0.1 $\mu g\ kg^{-1}$. In blood, the methods are well established and the level of detection (LOD) of 0.1 $ng\ ml^{-1}$ level is adequate to quantify lead in blood.

Exposure

Lead is taken up from soil into food crops, and the sources of lead in food may also include soil remaining in or on the food, atmospheric deposition, water, contact with lead-containing processing equipment, and packaging. Food categories with the highest frequency of detectable lead include: meat, especially offal, organ meats, and wild game; shellfish (particularly bivalves); cocoa; tea; cereal products; milk; and vegetables. Most foods that contain lead do so in the low parts per billion (ppb) range, however some, like cocoa, organ meats, tea, and coffee, can have somewhat higher averages of more than 100 ppb. In adults, mean exposures tend to range from 0.02 to 3 microgram per kilogram of body weight per day ($\mu g\ kg^{-1}\ bw\ day^{-1}$) whereas higher percentile levels of exposure range from 0.06 to 2.4 $\mu g\ kg^{-1}\ bw\ day^{-1}$. Children's mean exposures range from 0.03 to 9 $\mu g\ kg\ bw\ day^{-1}$. Estimated high end percentile exposures for children range from 0.2 to 8.2 $\mu g\ kg^{-1}\ bw\ day^{-1}$. Overall blood lead levels are useful biomarkers of exposure and reflect dietary exposures as well as exposures from other pathways such as inhalation. The contribution of dietary exposure to the total body burden as measured by blood lead levels will of course vary between countries depending on the individual contributions of nondietary lead sources and pathways.

Risk Characterization

Because there have been many epidemiological studies of the relationship between blood lead levels and children's IQ, characterization of the dose–response relationship requires integration of multiple study results. The Lanphear *et al.* (2005) meta-analysis included 1333 children enrolled in seven longitudinal cohort studies conducted in several countries, who were followed from birth or early infancy to 5 – 10 years of age. The use of a log-linear model produced an estimated IQ decline of 6.9 points in concurrent blood lead level over a range of 2.4–30 $\mu g\ dl^{-1}$. The slope of the inverse association between IQ and concurrent blood lead level was steeper among children with a maximum observed (at any time point) blood lead level below 7.5 $\mu g\ dl^{-1}$ than it was among children with a blood lead level of 7.5 $\mu g/dl^{-1}$ or higher.

The relationship between blood lead levels and dietary exposure to lead has been estimated to be between 0.05 and 0.16 $\mu g\ dl^{-1}$ of lead in blood per 1 $\mu g\ day^{-1}$ of dietary lead exposure. This range is based on toxicokinetic analyses of data on Scottish infants exposed to lead in drinking water.

Dietary lead exposures associated with a range of decreases in IQ (i.e., 0.5 – 3 IQ points) were estimated by using a Monte Carlo simulation, where the resulting confidence interval (CI) reflects the uncertainties in both the dose–response modeling of blood lead levels and the extrapolation to dietary exposure. The chronic dietary exposure corresponding to a decrease of 1 IQ point was estimated to be 30 μg of lead per day, with a 5–95% CI ranging from 4 to 208 $\mu g\ day^{-1}$.

Although the relationship between blood lead levels and children's IQ is roughly linear, there is some evidence that the largest effects occur in the range of 5–15 $\mu g\ dl^{-1}$. To the extent that the dose–response relationship is nonlinear, the incremental effect of dietary exposure is somewhat dependent on the extent to which there are other exposures to lead (e.g., drinking water, air, soil, and paint). Therefore, a linear

estimate (i.e., 1 IQ point per 30 μg day^{-1}) may underestimate the impact in the range of 50 – 150 μg day^{-1}, and overestimate the impact on a level below 50 and above 150 μg day^{-1}.

For adults, increased systolic blood pressure is the most sensitive end-point. A linear slope of 0.28 mm Hg per 1 μg dl^{-1} (5–95% CI 0.03 – 0.53 mm Hg per μg dl^{-1}) relating increases in systolic blood pressure as a function of blood lead level has been derived by averaging the estimates from four different studies. Blood lead levels were converted to dietary exposures using a blood level range of 0.02 – 0.07 μg dl^{-1} per 1 μg day^{-1} of dietary lead exposure. Dietary lead exposure corresponding to an increase in systolic blood pressure of 1 mmHg was estimated to be 80 μg day^{-1}, or approximately 1.2 μg kg^{-1} bw day^{-1}. As the relationship appears to be linear, the increases in blood pressure associated with other dietary exposures are proportional. Published studies used by World Health Organization in estimating the global burden of disease attributable to lead indicate that relative risks of ischemic heart disease and cerebrovascular stroke associated with small increases in blood pressure (0.4 – 3.7 mm Hg systolic blood pressure) have been estimated to be in the range of 1.0–1.4, with higher relative risks at younger ages.

Summary

Neurodevelopmental effects in the fetus, infant, and child are clearly the most sensitive adverse health outcomes of exposure to lead. Estimated mean dietary exposure for children aged approximately 1–4 years ranges from 0.03 to 9 μg kg bw day^{-1}. The health impact at the lower end of this range is calculated to be associated with a population decrease of 0.5 IQ point. The higher end of the exposure range is associated with a population decrease of 3 IQ points, which is demonstrable of some public health concern. For adults, the mean dietary lead exposure estimates range from 0.02 to 3.0 μg kg bw day^{-1}. The lower end of this range is considerably below the exposure level of 1.2 μg kg^{-1} bw day^{-1} which is associated with a population increase in systolic blood pressure of 1 mm Hg. At the higher end of the exposure range, a population increase of approximately 2 mm Hg in systolic blood pressure would be expected to occur. An increase of this magnitude has been associated, in a large meta-analysis, with modest increases in the risks of ischemic heart disease and cerebrovascular stroke. These estimates are of less magnitude and public health concern than that estimated for the neurodevelopmental effects observed in children.

TOXIC METALS

Mercury

K Hailemariam, FDA Center for Food Safety and Applied Nutrition, College Park, MD, USA
PM Bolger, Senior Managing Scientist, Exponent, Washington, USA

Glossary

Exposure Contact with a substance by swallowing, breathing, or touching the skin or eyes. Exposure may be short term (acute exposure), of intermediate duration, or long term (chronic exposure).
Hazard A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.
Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents that may be present in food. For chemical agents, a dose–response assessment should be performed. For biological or physical agents, a dose–response assessment should be performed if the data are obtainable.
Hazard identification Qualitative evaluation of the adverse effects of a substance on humans or other organisms of concern.
In vivo Within a living organism or body, e.g., some toxicity testing is done on whole animals, such as rats or mice.
Minimum risk level (MRL) An estimate of daily human exposure to a hazardous substance at or below which that substance is unlikely to pose a measurable risk of harmful (adverse), noncancerous effects. MRLs are calculated for a route of exposure (inhalation or oral) over a specified time period (acute, intermediate, or chronic). MRLs should not be used as predictors of harmful (adverse) health effects.
Provisional tolerable weekly intake (PTWI) An endpoint used for food contaminants such as heavy metals with cumulative properties. Its value represents permissible human weekly exposure to those contaminants unavoidably associated with the consumption of otherwise wholesome and nutritious foods.
Reference dose (RfD) An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.
Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Chemical Names

Elemental/metallic mercury, Chemical Abstracts Service Registry (CAS) Number: 7439-97-6; inorganic mercury (e.g., mercuric chloride, CAS Number: 7439-97-6, and mercurous chloride, CAS Number: 10112-91-1); organic mercury (e.g., methylmercury, CAS Number: 22967-92-6).

Background

Mercury (Hg) is released into the environment from both natural and anthropogenic sources. Mercury has been used commercially and medically for thousands of years. The ancient Greeks, Romans, and Egyptians used mercury (in the form of mercuric sulfide) for cosmetic and decorative purposes, and in ointments. In the Middle Ages, mercuric salts were used in the treatment of vermin, lice, and most notably syphilis, when Paracelsus noted that a little might be useful but too much could be fatal, leading to his immortal dictum "the dose makes the poison." In the 18th century, the extensive use of mercuric nitrate in the hat-making industry led to the 'mad as a hatter syndrome'.

In the 1940s and 1950s, phenylmercury or inorganic mercury salts were known as causative agents of acrodynia, also known as pink disease. In the 1960s, exposures to methylmercury were noted in Minamata Bay and Niigata, Japan, from consumption of contaminated fish, and in Iraq through consumption of grain treated with a methylmercury-based fungicide. A cosmetic cream from Mexico, called 'Crema de Belleza-Manning,' sold in the US in 1996 was also found to contain mercurous chloride.

In spite of its potential risks, mercury continues to be used in a multitude of products and processes all over the world owing to its unique properties. Mercury is utilized in the electrical industry, dentistry (dental amalgams), numerous industrial processes, including the production of chlorine and caustic soda, in nuclear reactors, as an antifungal agent for wood processing, a solvent for reactive and precious metal,

 doi:10.1016/B978-0-12-378612-8.00204-3

as a preservative of pharmaceutical products, and in energy-saving fluorescent light bulbs.

Hazard Identification and Characterization

Mercury occurs in three basic forms: elemental mercury (metallic), inorganic mercury, and organic mercury (primarily methylmercury). Depending on the dose each form can be toxic to humans, although they behave differently in terms of absorption into the body and the degree to which they migrate to organs. As a result, the toxicity of mercury is dependent on its chemical form.

Elemental mercury is relatively inert and not readily taken up from the gastrointestinal tract in vertebrates, but it is volatile and its vapor is toxic. Effects on the nervous system appear to be the most sensitive toxicological endpoint observed following exposure to elemental mercury.

Inorganic mercury is reported to have hematological, hepatic, renal, reproductive, genotoxic, and general toxicity as well as organ-specific effects in rats and/or mice treated with inorganic mercury in the form of mercuric chloride. Although chronic exposure of mice and rats to mercuric chloride produced some indication of carcinogenicity in male rats, International Agency for Research on Cancer (IARC) reported that there was limited evidence in experimental animals for the carcinogenicity of mercuric chloride.

Exposure to elemental mercury through food is virtually nonexistent. The general population is exposed to methylmercury and inorganic mercury through the diet. However, only a small percentage of inorganic mercury in food is absorbed after ingestion, and it is also considerably less toxic compared to methylmercury. As methylmercury is the most toxic form to which humans are exposed via food, this review focuses only on the potential risk of methylmercury.

Methylmercury is highly toxic to humans. Exposure to methylmercury is known to result in adverse effects in several organ systems (nervous system, kidney, liver, and reproductive organs), with neurotoxicity considered the most sensitive endpoint. Dietary methylmercury is almost completely absorbed into the blood, bound to red blood cells, and distributed to all tissues, including the brain, and is able to cross the blood–brain and the placental barriers. Both neurotoxicity and nephrotoxicity have been associated with acute methylmercury poisoning incidents in humans. Epidemics of poisoning following high-dose exposures to methylmercury in Japan and Iraq demonstrated that neurotoxicity is the health effect of greatest concern when methylmercury exposure of the fetus occurs. Epidemiological studies conducted in New Zealand and the Faroe Islands reported that chronic, low-dose prenatal methylmercury exposure from maternal consumption of fish was associated with more subtle endpoints of neurological outcomes in children. Furthermore, data from animal studies, including studies on nonhuman primates, indicate that the developing nervous system is a sensitive target organ for low-dose methylmercury exposure. Methylmercury has been classified as a possible human carcinogen, based on inadequate data in humans and limited evidence of carcinogenicity in animals.

Unlike elemental or inorganic forms, methylmercury is almost completely absorbed from the gastrointestinal tract and is distributed to all tissues. Methylmercury can be transferred from blood to mother's milk and hair. The concentration of mercury in hair can be used as an indicator of previous exposures, e.g., during pregnancy, although signs of exposure may not be apparent at that time. Methylmercury accumulates in the brain and is demethylated into inorganic mercury with a half-life of approximately 55 days. Animal studies have shown that inorganic mercury deposits formed in the brain play an important role in methylmercury neurotoxicity.

A wide range of adverse health effects has been observed in humans following methylmercury exposure, the severity largely depending upon the magnitude of the dose and the duration of exposure. Methylmercury has been reported to be highly toxic particularly to the nervous system, and the developing brain is thought to be the most sensitive target organ for methylmercury toxicity. As methylmercury is toxic to the developing nervous system, fetuses are especially susceptible. Therefore, the population at highest risk is the fetus and infants of women of child-bearing age who consume fish and seafood. To protect the fetus during the early stages of development, women of child-bearing age are also considered at high risk. Several epidemiological studies have shown that nervous system domains involving fine motor function, attention, verbal learning, and memory can be affected. Furthermore, recent studies suggest that chronic exposure to methylmercury may have toxic effects on the immune and cardiovascular systems.

There are established tolerable intake limits for methylmercury. The United States Environmental Protection Agency (US EPA) established a reference dose (RfD) of 0.1 μg per kg body weight per day methylmercury (0.7 μg per kg body weight per week). The United States Agency for Toxic Substances and Disease Registry (US ATSDR) derived a minimum risk level (MRL) of 0.3 μg per kg bw per day based on the neurodevelopmental effects in a study where children were exposed *in utero* to methylmercury from maternal fish consumption. In 2003, based on assessment of epidemiological studies from the Seychelles and the Faroe Islands that investigated the relationship between maternal exposure to mercury and impaired neurodevelopment in their children, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) recommended a provisional tolerable weekly intake (PTWI) for methylmercury of 1.6 μg per kg bw per week (equivalent to 0.23 μg per kg bw per day of methylmercury) in order to sufficiently protect the developing fetus. Similar tolerable intake limit for methylmercury was also established by other regulatory authorities (e.g., Health Canada, which adopted a provisional tolerable daily intake (PTDI) of 0.20 μg per kg bw per day).

Methods of Analysis

The most commonly used analytical methods for the quantification of total mercury in food are cold vapor atomic absorption spectrometry (CV-AAS) or cold vapor atomic fluorescence spectrometry (CV-AFS), and inductively coupled plasma mass spectrometry (ICP-MS) techniques.

Gas chromatography (GC) has been the most widely used technique for the separation of mercury species in food although high performance liquid chromatograph (HPLC) is increasingly being used. Detection by CV-AAS ($10\ \mu g\ kg^{-1}$), CV-AFS ($1\ \mu g\ kg^{-1}$), microwave-induced plasma atomic emission spectrometry (MIP-AES) or ICP-AES ($5\ \mu g\ kg^{-1}$), MS ($40\ \mu g\ kg^{-1}$), and ICP-MS ($<3\ \mu g\ kg^{-1}$) methods all have sufficient sensitivity for food samples. HPLC/ICP/MS have the additional advantage of permitting separation and quantitation of individual mercury species. The advantages of MS and ICP-MS are their multielement and multi-isotope capabilities, whereas CV-AAS and CV-AFS have the advantage of being comparatively low cost and simple operations.

Exposure

The principal source of human exposure to methylmercury is fish and seafood consumption. Food sources other than fish and seafood products may contain mercury, but mostly in the form of inorganic mercury. The contribution to methylmercury exposure from nonfish and nonseafood is considered to be insignificant. Available data collected on mercury in fish are largely for total mercury rather than methylmercury. The proportion of total mercury contributed by methylmercury generally ranges between 75% and 100% depending on species of fish, size, age, and diet. Dietary exposures to methylmercury and inorganic mercury are fairly similar.

Long-lived predatory fish contain the highest levels of methylmercury, and are significant sources of human exposure to methylmercury. For instance, large fish, such as shark, swordfish, king mackerel, and tilefish have average concentrations of 1.0, 1.0, 0.73, and 1.45 parts per million (ppm) of mercury, respectively; collectively accounting for six-tenths of 1% of US consumption. The average concentration of methylmercury for all commercial fish in the US marketplace is reported to be 0.086 ppm.

All forms of mercury entering the aquatic environment, as a result of anthropogenic or natural sources, are converted into methylmercury by microorganisms and subsequently concentrated in fish and other aquatic species. Methylmercury can have long half-life in fish; thus, large older fish, particularly predatory species, which are high in the food chain, will have accumulated considerably more methylmercury than small younger fish. Therefore, population groups that rely heavily on consumption of these species will have higher dietary intakes than populations with a high intake of fish containing low levels of methylmercury. Factors to be considered in estimating methylmercury exposure and risk from fish consumption include the species of fish consumed, the concentrations of methylmercury in the fish, the quantity of fish consumed, and how frequently fish is consumed.

Risk Characterization

Both the JECFA and the US National Research Council (NRC) evaluations concluded that the developing brain is the most sensitive target organ for methylmercury toxicity. Therefore, pregnant women or women who may become pregnant within the next year are considered to be the most susceptible population because of the risk to the embryo and fetus. The JECFA PTWI of 1.6 μg per kg bw is considered to be sufficiently protective of the developing fetus. Based on current evidence it is clear that infants and children aged up to 17 years are no more sensitive to the adverse effects of methylmercury than the embryo or fetus and may be less so. Nevertheless, available data do not allow the identification of a level of intake higher than the existing PTWI that would not pose a risk of developmental neurotoxicity. Hence, the existing PTWI established for the fetus applies also to children. However, intakes of up to approximately two times higher than this PTWI would not pose any risk of neurotoxicity in the adult population.

For the average consumer, the estimated dietary exposure to methylmercury is reported to be below the PTWI of 1.6 μg per kg bw per week established by the JECFA, but in some cases, high percentile consumers of fish may approach or exceed this value. Populations who frequently consume large predatory fish such as swordfish and shark may have a considerably higher intake of methylmercury and exceed the PTWI.

Methylmercury is the most toxic form of mercury. Although fish and seafood consumption is the main source of exposure to methylmercury, the benefits and risks of their consumption should be balanced, as fish and seafood are important sources of energy, protein, and a variety of essential nutrients, such as vitamins, trace elements, and fatty acids. Therefore, it is highly advisable to optimize the contribution of fish and seafood products to a healthy diet, while at the same time minimizing the exposure to methylmercury.

TOXIC METALS

Trace Metals – Chromium, Nickel, Copper, and Aluminum

A Yalçın Tepe, Giresun University, Giresun, Turkey

Glossary

Carcinogen A chemical capable of inducing cancer.
Homeostasis The property of a system that enables the body's internal environment to be kept stable.
In vitro In an artificial environment, i.e., glass, outside a living organism.
In vivo Occurring or carried out within a living organism.
Metalloprotein A protein that contains a metal ion cofactor.
Mutagenicity An agent that can induce or increase the frequency of mutation in an organism.

Background and Nutritional Aspects

Chromium

Chromium is a ubiquitous element naturally found in rocks, animals, plants, and volcanic soils. Chromium enters the environment mostly in the chromium(III) and chromium(VI) forms as a result of natural processes and human activities, such as chromate production, chrome plating, and leather tanning. Chromium(III) is an essential nutrient that helps the body use sugar, protein, and fat and its shortage in the diet may result in weight loss or decreased growth, improper function of the nervous system, and a diabetic-like condition. There was no sufficient evidence to set an estimated average requirement (EAR) for chromium. Therefore, an adequate intake (AI) was set based on estimated mean intakes. The AI is 35 and 25 μg day^{-1} for young men and women, respectively. Absorption through exposure via the diet and water is consistently low, with values reported in the range of 1–5%. Few serious adverse effects have been associated with excess intake of chromium from food. Therefore, a tolerable upper intake level (UL) was not established.

Nickel

Nickel is a hard, silvery-white lustrous metal and has properties that make it very desirable for combining with other metals, such as iron, copper, chromium, and zinc. Nickel is the 24th most abundant element, found in the Earth's crust, meteorites, and on the ocean floor. It can be found in a variety of oxidation states ranging from 0 to IV. However, Ni(II) is the only oxidation state occurring in ordinary chemistry. Ni(II) forms a wide variety of compounds ranging from simple inorganic complexes (salts) to complexes with various organic ligands. Some plants can take up and accumulate nickel but it does not concentrate much in animals, including fish. There is no established recommended dietary allowance (RDA) for nickel. Common amounts included in dietary supplements range from 35 to 100 μg day^{-1}.

Copper

Copper is a reddish-orange, soft, ductile, and malleable metal that occurs naturally in rock, soil, and water sediment. Most copper compounds occur in $+1$ or $+2$ valence states. Copper is primarily used as a metal or an alloy (e.g., brass, bronze, and gun metal). Copper sulfate is used as a fungicide, algicide, and nutritional supplement. It has been used as a conductor of heat and electricity, building material, and constituent of various metal alloys for thousands of years. Average copper level in human body is 1.4–2.1 mg kg^{-1}. The main criterion used to estimate the EAR for copper is a combination of indicators, including plasma copper and ceruloplasmin concentrations, erythrocyte superoxide dismutase activity, and platelet copper concentration in controlled human depletion/repletion studies. The recommended dietary allowance (RDA) for adults is 900 μg day^{-1}. The median intake of copper from food in the USA is approximately 1.0–1.6 mg day^{-1} for adult men and women and the UL for adults is 10 000 μg day^{-1} (10 mg day^{-1}), which is a value based on protection from liver damage as the critical adverse effect. Copper is an essential element for good health and its deficiency can produce anemia-like symptoms, neutropenia, bone abnormalities, hypopigmentation, impaired growth, increased incidence of infections, osteoporosis, hyperthyroidism, and abnormalities in glucose and cholesterol metabolism. Absorption and excretion feedback mechanisms normally prevent chronic copper toxicity in humans. However, an accumulation of copper in body tissues can occur in rare cases of Wilson's disease.

Aluminum

At approximately 8.8%, aluminum is the third most abundant element in the Earth's crust after oxygen and silicon. It is also

 doi:10.1016/B978-0-12-378612-8.00205-5

present in air, water, and many foods, but not in its metallic form. Rather, aluminum is found in the environment as aluminum compounds, where the aluminum is bound with other chemical species such as silica, oxides, hydroxides, sodium, and fluoride, and as complexes with organic matter. As it is a major constituent of the Earth's crust, aluminum enters environmental media naturally through the weathering of rocks and minerals. Foods naturally high in aluminum include potatoes, spinach, and tea. Processed dairy products, flour, and infant formula may be high in aluminum if they contain aluminum-based food additives. As a lightweight metal with a melting point of 649.8 °C, it is being used increasingly for a number of different and important uses such as: food additives; cooking utensils; food packaging; drugs (antacids); consumer products (antiperspirants, aluminum foil); in the treatment of drinking water as coagulants to reduce organic matter, color, turbidity, and microorganism levels; as a structural material in the construction, automotive, and aircraft industries; and in the production of metal alloys, in the electric industry.

Hazard Identification and Characterization

Hazard identification and characterization are concerned with the inherent properties of a chemical that gives rise to its potential to cause adverse biological effects. These are described for chromium, nickel, copper, and aluminum in the following sections.

Chromium

Not considered a health hazard, chromium(III) in trace levels is an essential nutrient needed by the body for normal energy metabolism that plays a role in glucose, fat, and protein metabolism. The biologically active form of chromium exists as a complex of chromium(III), nicotinic acid, and possibly the amino acids glycine, cysteine, and glutamic acid to form glucose tolerance factor. Absorption of chromium by the oral route ranges from essentially zero for the water-insoluble chromium(III) compound chromic oxide to 10% for potassium chromate. A large amount of absorbed chromium is accumulated in the bone, liver, kidney, and spleen. Although chromium(VI) is a strong oxidizing agent and may damage the kidney, liver, and blood cells through oxidation reactions, the lethal dose 50% for chromium(VI) ranges between 50 and 150 mg per kg bw. The International Agency for Research on Cancer (IARC) has determined that chromium(VI) is carcinogenic to humans and is characterized by significant lethality after acute exposures by the oral, dermal, and inhalation routes. Acute oral toxicity ranges from 1.9 to 3.3 mg per kg bw per day.

Hexavalent chromium is characterized by significant lethality after acute exposures by the oral, dermal, and inhalation routes. Hexavalent chromium also produces significant skin irritation and dermal sensitization. Relative bioavailability of hexavalent chromium through ingestion is also low. The World Health Organization (WHO)-recommended maximum allowable concentration in drinking water for chromium(VI) is 0.05 mg kg^{-1}. Hexavalent chromium is rapidly taken up by cells through the sulfate transport system. Once inside the cell, chromium(VI) is quickly reduced to its trivalent form by cellular reductants, including ascorbic acid, glutathione, flavoenzymes, and riboflavin. Reported effects in humans included oral ulcers, diarrhea, abdominal pain, indigestion, vomiting, leukocytosis, and presence of immature neutrophils by drinking contaminated well water with chromium(VI) concentrations of 20 mg l^{-1}, and an estimated exposure dose of 0.57 mg kg^{-1} day^{-1}. Some chromium(VI) compounds are potent oxidizing agents, such as potassium dichromate and chromium trioxide, and are thus strong irritants of mucosal tissue. Effects included metabolic acidosis, acute tubular necrosis, kidney failure, and death.

In general, hexavalent chromium has given positive results in *in vitro* mutagenicity tests, whereas trivalent chromium compounds have been negative. However, chromium picolinate is more likely to cause deoxyribonucleic acid damage and mutation than other forms of trivalent chromium in mammalian cells. The significance of these observations is unclear and no *in vivo* genotoxicity data are available. For some occupational sources of chromium exposure (e.g., ferrochromium industry and manufacture of chrome pigments) and for some occupations (e.g., leather tannery workers and chromium platters) increased risks have been observed, but almost invariably in the epidemiologic studies the available data do not permit discrimination between the simultaneous exposure to trivalent chromium and hexavalent chromium. Although the chromium compound that increases the risk of lung cancer and sinonasal cancer is yet to be identified, there is a fairly general agreement that hexavalent species are responsible for these diseases, and that the trivalent and metallic species are not. For cancers other than those of the lungs and sinonasal cavity, no consistent pattern of cancer risk has been demonstrated in workers exposed to chromium compounds.

Nickel

Nickel compounds can be grouped according to their solubility in water: Soluble compounds include nickel chloride, nickel sulfate, and nickel nitrate, and less-soluble compounds include nickel oxide and nickel subsulfide. Both the soluble and less-soluble nickel compounds are important with regard to all relevant routes of exposure. Generally, the soluble compounds are considered more toxic than the less-soluble compounds, although the less-soluble compounds are more likely to be carcinogenic at the site of deposition. Nickel sulfate inhalation causes lung and nasal cancer in animals and humans, but the data on carcinogenicity via oral administration of nickel salts is limited. Orally ingested nickel salts can cause adverse effects on kidneys, spleen, lungs, and the myeloid system in experimental animals. Furthermore, perinatal mortality was reported to be increased in the offspring of female rats ingesting nickel salts, even at the lowest administered dose (1.3 mg per kg bw per day of nickel). Contact with nickel sulfate can irritate and burn the skin and eyes. Contact dermatitis, which results from dermal exposure to nickel, is the most prevalent effect of nickel in the general population. Dermatitis resulting from nickel allergy is well reported in the literature.

After ingestion of various nickel compounds in food, beverages, or drinking water, it is absorbed by the gastrointestinal tract at a rate that depends on the chemical form and the solubility. Absorption may also be suppressed by binding or chelating substances, competitive inhibitors, or redox reagents. In contrast, absorption is often enhanced by substances that increase pH, solubility, or oxidation, or by chelating agents that are actively absorbed. Although soluble nickel compounds (nickel sulfate, nickel chloride, and nickel nitrate) are better absorbed than relatively insoluble ones, the contribution of some slightly soluble compounds (nickel metal, nickel carbonate, nickel oxides, and nickel sulfides) to the total nickel absorption may be more considerable, as they are more soluble in the acidic gastric fluids. The absorption of nickel following administration of the drinking water to fasting individuals might be as high as up to approximately 25–27% and approximately 1–6% when administered to nonfasting individuals. Most nickel in food remains unabsorbed in the alimentary tract and passes through into the feces.

In human serum, 34% of the nickel is present with albumin, 26% as a complex associated with a nickel metalloprotein (nickeloplasmin), and 40% as ultrafiltrable material. In human serum, it is present as ultrafiltrable material, associated with albumin, and associated with nickeloplasmin. Limited information exists on tissue distribution in humans. Nickel compounds are considered as human carcinogens based on epidemiological studies, mechanistic information, and evidence from animal studies. The overall findings indicate that nickel ions generated in target cells are determinants for the carcinogenic process.

Copper

Copper is an essential nutrient and incorporated into many metalloenzymes functions, such as hemoglobin formation, drug metabolism, carbohydrate metabolism, catecholamine biosynthesis, the crosslinking of collagen, elastin, hair keratin, and the antioxidant defense mechanism. Copper-dependent enzymes function to reduce activated oxygen species or molecular oxygen, such as cytochrome oxidase, superoxide dismutase, ferroxidases, monoamine oxidase, and dopamine β-monooxygenase. Copper is easily absorbed by the stomach and small intestine. Once nutritional requirements are compensated, there are several mechanisms that prevent copper overload. Excess copper is absorbed into gastrointestinal mucosal cells. Copper that eludes binding to intestinal metallothionein is transported to the liver. It is stored in the liver bound to liver metallothionein, from which it is ultimately released into bile and excreted in the feces. Although copper homeostasis plays an important role in the prevention of copper toxicity, exposure to excessive levels of copper can result in a number of adverse health effects including liver and kidney damage, anemia, immunotoxicity, and developmental toxicity. Many of these effects are consistent with oxidative damage to membranes or macromolecules. Copper can bind to the sulfhydryl groups of several enzymes, such as glucose-6-phosphatase and glutathione reductase, thus interfering with their protection of cells from free radical damage. Gastrointestinal distress is one of the most commonly reported adverse health effect of copper. Nausea, vomiting, and/or abdominal pain have been reported, usually occurring shortly after drinking a copper sulfate solution, beverages that were stored in a copper or untinned brass container, or first-drawn water (water that sat in the pipe overnight). The observed effects are not usually persistent and gastrointestinal effects have not been linked with other health effects. The liver is also a sensitive target of toxicity resulting in necrosis and fibrosis. Liver effects have been observed in individuals diagnosed with Wilson's disease, Indian childhood cirrhosis, or idiopathic copper toxicosis.

Following ingestion of copper, copper levels in the blood rise rapidly. The copper is mainly bound to albumin. There is some indication that albumin plays a passive role in copper transport. It carries a large portion of the exchangeable copper in the circulation and releasing this to other carriers for actual cell-specific uptake. There is also evidence that transcuprein is another plasma protein carrier. Thus, dietary copper is transported to, and enters, the liver and kidney. Copper then reemerges into the plasma bound to the ceruloplasmin, which tightly binds six or seven copper atoms and is the most abundant copper protein in the plasma. Copper is transported from the liver to other tissues via ceruloplasmin.

Numerous factors may affect copper absorption, such as the amount of copper in the diet, competition with other metals, including zinc, iron, and cadmium, and age. The absorption of copper appears to be inversely related to the amount of copper in the gastrointestinal tract. In humans, the amount of stored copper does not appear to influence copper absorption. It has been observed that abnormally high serum copper levels are found in patients with many types of progressive tumors. Depriving malignant tumors of their copper supply may be a potent antiangiogenesis strategy for stabilizing patients with advanced cancer. The liver is the primary organ of copper-induced toxicity in humans and other target organs include bone and the central nervous and immune systems. Based on the WHO values established for human copper intake, the acceptable daily intake (ADI) – or more appropriately designated as 'upper limit for copper intake' – for copper(I) and (II) variants was established by the European Food Safety Authority (EFSA) at 0.15 mg copper per kg bw per day.

Aluminum

Aluminum is used for everything from medications to door frames and car bodies. Aluminum was not considered harmful to human health because of its relatively low bioavailability. However, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) reduced the provisional tolerable weekly intake (PTWI) value for aluminum from 7 to 2 mg per kg bw per week. Oral intake of foodstuffs would appear to be the most important source of aluminum. The hematopoietic system, the nervous system, and bone are three organ systems that are implicated in the toxic effects of aluminum. Increased aluminum exposure can be compensated for by excretion via intestines and normal, healthy kidneys. Body balance is maintained because aluminum is cleared both in feces and in urine. Aluminum is removed from the bloodstream by the

kidneys and other organs. Kidney insufficiency, however, was shown to result in increased aluminum concentrations in the kidneys of dialysis patients. Aluminum produces toxic effects at the cell membrane by altering the physical properties of the membrane, interfering with the function of voltage-activated ionic channels, and altering the secretion of transmitters. Aluminum can affect various key processes in the nucleus, cytoplasm, and mitochondria, such as glucose metabolism, signal transduction, neurotransmitter synthesis, phosphorylation and dephosphorylation of cytoskeletal proteins, slow axonal transport of neurofilament proteins, and inhibition of nucleotide activity. There is no indication from any studies and animal bioassays that aluminum is carcinogenic. Aluminum is neurotoxic to humans under certain specific exposures. To date there is no convincing evidence that aluminum plays a role in Alzheimer's disease. Humans with decreased renal function face a high risk of developing renal osteodystrophic osteomalacia and dialysis encephalopathy from levels of aluminum in food and drinking water, whereas healthy individuals face no risk.

Gastrointestinal absorption of aluminum is low, generally in the range of 0.1–0.4% in humans. Bioavailability of aluminum varies depending mainly on the chemical form of the ingested compound (i.e., type of anion) and the concurrent exposure to dietary chelators, such as citric acid, ascorbic acid, or lactic acid. The total body load of aluminum in healthy human subjects is approximately 30–50 mg. Normal levels of aluminum in serum are approximately 1–3 $\mu g\,l^{-1}$. Of the total body load of aluminum, approximately one-half is in the skeleton and one-fourth is in the lungs.

Methods of Analysis

Chromium

Several methods are available for the analysis of chromium in different biological media. The four most frequently used methods for determining low levels of chromium in biological samples are neutron activation analysis, mass spectrometry, graphite spark atomic emission spectroscopy (AES), and graphite furnace atomic absorption spectroscopy (GFAAS). GFAAS is readily available in conventional laboratories, and this method is capable of determining chromium levels in biological samples when an appropriate background correction method is used. Contamination and chromium loss in environmental samples during sample collection, storage, and pretreatment should be avoided for biological samples.

Nickel

Analytical methods that determine nickel in biological materials are the same as those used for environmental samples. The most common methods determine the total nickel content of the sample instead of the particular nickel compound that may be present. Methodological differences are a function of the nickel level in the sample, digestion procedure required to solubilize the sample, and the level of potentially interfering substances that may be present. Either wet ashing with sulfuric acid or dry ashing through dissolution of the ash with dilute sulfuric or hydrochloric acid is generally a satisfactory method to detect nickel in tissue or food. Another methodological approach utilizes digestion of biological samples with nitric acid that can also be followed by treatment with hydrogen peroxide to remove residual biological material. As the digestion procedures require the use of strong acids and substances with explosion hazards, all safety procedures should be carefully reviewed before the analyses are completed. As nickel is normally present at very low levels in biological samples, sensitive and selective methods are required to determine trace nickel levels in these samples accurately. The AAS and inductively coupled plasma-AES (ICP-AES) are the most common methods.

Copper

Determining specific copper compounds and complexes in samples is difficult. Copper in biological materials such as hair and nails can be determined by using suitable procedures for dissolving the sample matrix and employing the same analytical techniques as with blood and tissue. These methods determine the total amount of copper in the sample. The methodology for analyzing biological material is similar to that used for environmental samples. The most commonly employed methods use atomic absorption spectroscopy (AAS) or ICP-AES. If determination of dissolved and suspended copper is required, samples should be filtered using a 0.45 μm membrane filter. Other analytical methods used for copper analysis include X-ray fluorescence, anodic stripping voltammetry, neutron activation analysis, photon-induced X-ray emission, as well as chemical derivatization, followed by gas chromatographic or liquid chromatographic analysis.

Aluminum

Aluminum is reacted with pyrocatechol violet followed by spectrometric measurement of the resulting colored complex. The method is restricted to the determination of the aquated cations and other forms of aluminum readily converted to the cationic form by acidification. The limit of detection is 2 $\mu g\,l^{-1}$. The limit of detection for the determination of aluminum by ICP-AES ranges from 40 to 100 $\mu g\,l^{-1}$. Flame AAS and GFAAS methods are applicable for the determination of aluminum in water at concentrations of 5–100 and 0.01–0.1 $mg\,l^{-1}$, respectively. The working range of the graphite furnace AAS method can be shifted to higher concentrations by either dilution of the sample or using a smaller sample volume.

In the determination of trace metals, major concerns are contamination and loss. Contamination can be introduced from impurities in reagents and containers as well as from laboratory dust. Losses may also occur due to adsorption onto containers.

Exposure

Chromium

Drinking water and foods are major sources of dietary exposure to chromium. However, the levels of chromium in

air and water are generally low. Fish do not accumulate much chromium in their bodies from water. Drinking water contains generally less than 0.002 mg kg^{-1}. Contaminated well water may contain chromium(VI). Chromium(III) occurs naturally in many fresh vegetables, fruits, meat, yeast, and grain. Different methods of processing, storage, and preparation can alter the chromium content of food. Acidic foods in contact with stainless steel cans or cooking utensils might contain higher levels of chromium because of leaching from stainless steel. Refining processes used to make white bread or sugar can decrease chromium levels. Chromium(III) is an essential nutrient for humans. On average, adults in the US take in an estimated 60 μg of chromium daily from food. People may also be exposed to chromium by using consumer products, such as household utensils, wood preservatives, cement, cleaning products, textiles, and tanned leather.

Chromium(III) is a widely used supplement used to prevent or treat chromium deficiency. Chromium chloride, chromium nicotinate, chromium picolinate, high-chromium yeast, and chromium citrate were not associated with adverse effects at doses of 15 mg per kg bw per day of chromium. Increased levels of tissue chromium indicated that absorption had occurred. Higher doses of chromium (approximately 100 mg per kg bw per day) are associated with reproductive and developmental effects, although these may be secondary to parental toxicity.

Nickel

Nickel usually enters groundwater and surface waters from dissolution of rocks and soils, biological cycles, atmospheric fallout, industrial processes, and waste disposal. Nickel leached from dump sites can contribute to nickel contamination of the aquifer, with potential ecotoxicity. Acid rain has a tendency to mobilize nickel from soil and increase the nickel concentration in groundwater, leading eventually to increased uptake and possible toxicity in microorganisms, plants, and animals. Drinking water usually contains less than 20 μg l^{-1} nickel. Much higher concentrations may occur due to pollution of the water supply or leaching from nickel-containing pipes and nickel-plated faucets.

The concentration of nickel in the water of rivers and lakes is usually very low (less than 0.01 mg kg^{-1}) compared with that in soil (between 4 and 80 mg kg^{-1}).

For the general population, the major source of nickel exposure is food and the water that contains nickel. Contact with trace amounts of nickel on a daily basis is through diet. Foods such as chocolate, soybeans, oatmeal, bananas, barley, beans, cabbage, some nuts, baking powder, and cocoa powder are the major source of exposure to nickel. Nickel is present in tobacco at average contents of 2.2 and 2.3 μg per cigarette and is present in tobacco smoke. Skin absorption can happen from coins, hairpins, jewelry, prosthetic joints, heart valves, and nickel plating. Some cooking utensils can also introduce nickel into the body.

Children may also be exposed to nickel by eating soil, although this is rare. Exposure of an unborn child to nickel is through the transfer of nickel from the mother's blood to fetal blood. Likewise, nursing infants are exposed to nickel through the transfer of nickel from the mother to breast milk. However, the concentration of nickel in breast milk is either similar or less than that in infant formulas and cow's milk. Our daily intake of nickel from drinking water is only approximately 2 μg. Inhalation accounts for 0.1 and 1 μg nickel per day, excluding nickel in tobacco smoke. Exposure to nickel also occurs when touching coins and other metals containing nickel. Reference values for nickel in healthy adults is 0.2 μg l^{-1} in serum and 1–3 μg l^{-1} in urine. The most consistently reported adverse effects resulting from exposure to nickel are contact dermatitis and respiratory effects, including cancer. The IARC has determined that some nickel compounds are carcinogenic to humans and that metallic nickel may possibly be carcinogenic to humans. The Environmental Protection Agency (EPA) has determined that nickel refinery dust and nickel sulfides are human carcinogens.

The EFSA has estimated that the intake of nickel from the average European diet is estimated to be approximately 150 μg day^{-1} (approximately 2.5 μg per kg bw per day), but may reach 900 μg day^{-1} (approximately 15 μg per kg bw per day) or more, when large amounts of food items with high nickel contents are consumed. In addition, first-run drinking water, which may contain up to 1.0 mg l^{-1}, and leaching from kitchen utensils into food may also contribute to nickel intake. Intakes of 150 and 900 μg day^{-1} are approximately 500- and 90-fold lower, respectively, than the lowest dose reported to cause adverse effects in rats. Average intakes from food are about one-third of the lowest intake reported to aggravate hand eczema in nickel-sensitized subjects.

Copper

The mean concentration of copper in soil in the US ranges from 5 to 70 mg kg^{-1}. The estimated daily intake of copper from food is 1.0–1.3 mg kg^{-1} day^{-1} for adults. The primary source of copper intake is the diet; however, the amount of copper in the diet usually does not exceed the average dietary requirements for copper. Drinking water is the primary source of excess copper, especially in water that is first drawn in the morning after sitting in copper piping and brass faucets overnight. Populations living near sources of copper emissions, such as copper smelters and refineries, and workers in these and other industries may also be exposed to high levels of copper in dust by inhalation. Copper concentrations in soils near copper emission sources could be sufficiently high to result in significantly high intakes of copper in young children who ingest soil. Exposure to high levels of copper will result in the same types of effects in children and adults.

The average daily dietary intake of copper from food is approximately 2 mg day^{-1}. The dietary intake of copper may be greater than this average for those individuals who regularly consume organ meats such as liver and kidney, oysters or clams, nuts, seeds, cocoa powder, avocadoes, mushrooms, legumes, and bran and germ portions of grains. These intakes, however, are not expected to exceed the ADI of 0.15 mg per kg bw per day. However, the EFSA has estimated the aggregate exposure from all sources that shows, in particular for children, the overall dietary copper exposure is not negligible and may be significantly higher. Additional potential sources of

dietary copper intakes have not been considered. Moreover, the estimate is not representative for all consumers, and therefore situations may arise where the overall copper intake of some consumer groups exceeds the toxicological reference value.

Aluminum

There is little evidence that aluminum is acutely toxic by oral exposure despite its widespread occurrence in drinking water, fruit juices, wine, and beer, articles of daily use that are made of aluminum, cosmetics and pharmaceuticals such as local therapeutic agents, antidiarrheal drugs or antacids. The use of aluminum cookware, utensils, and wrappings can increase the amount of aluminum in food; however, the magnitude of this increase is generally not of practical importance. Despite aluminum being so ubiquitous in our environment, there is little evidence that any of these sources are contributing to increased levels of aluminum in tissues. At exposure levels of approximately 70–300 mg per kg bw per day in drinking water, the main observed effect is change in body weight gain.

It is impossible to give an average value for the exposure of the general population worldwide to aluminum. Daily intake by humans is estimated to be 1–10 mg. People consume little aluminum from drinking water, which generally does not exceed 0.1 mg l^{-1} even when the water is treated with aluminum salts, for example, alum. The EPA has set a limit of 0.05–0.2 mg l^{-1} for aluminum in drinking water.

The major source of aluminum is food, but levels can vary widely due to dietary habits, aluminum-containing food additives in the food supply and use of aluminum utensils and cooking equipment. Some potential sources of bioavailable aluminum are as follows: alum-treated drinking water, food additives (free-flowing agent in salt, rising agent in some baking powders, and hardening agent for pickles and candied fruits), many antacids, buffered aspirins, abrasives in some toothpastes, beer and soft drinks in aluminum drink cans (aluminum cans are resin-lined but carbonated drinks attack the lining and corrode the aluminum during storage), food cooked in aluminum trays and foils, use of aluminum cookware and kitchen utensils, use of carbonated drink makers and aluminum components in coffee percolators.

Risk Characterization

Chromium

Chromium(III) is an essential mineral and is widely present in a variety of foods. Intake of chromium(III) by the general population is considered adequate. However, the additional intake of chromium(III) supplements for nutritional purposes is not considered to be of concern provided that the amount of total chromium does not exceed 250 μg day^{-1}, the value established by the WHO for supplemental intake of chromium(III). However, exposure to chromium(VI), which is a genotoxic carcinogen, should be maintained as low as reasonably achievable.

Nickel

Although certain compounds of nickel are quite toxic, dietary exposure to these is not a public health concern. The most common adverse health effect in the general population is an allergic reaction to metallic nickel. Nickel is a potent skin sensitizer. The main toxic endpoint for nickel in humans is the aggravation of nickel sensitization, for which a threshold is unclear but which is possible at the levels of nickel found in food. It is therefore not possible to set a safe upper level or guidance for supplemental intake of nickel.

The intake of nickel from the average diet is estimated to be approximately 150 μg day^{-1} (approximately 2.5 μg per kg bw per day), but may reach 0.9 mg day^{-1} (approximately 0.015 mg per kg bw per day) or more, when large amounts of food items with high nickel contents are consumed. In addition, first-run drinking water, which may contain up to 1.0 mg l^{-1}, and leaching from kitchen utensils into food may also contribute to nickel intake. Intakes of 150 and 900 μg day^{-1} are approximately 500- and 90-fold lower, respectively, than the lowest dose reported to cause adverse effects in rats. Average intakes from food are about one-third of the lowest intake reported to aggravate hand eczema in nickel-sensitized subjects.

Copper

Copper is an essential nutrient and the WHO recommends a minimal acceptable copper intake of approximately 1.3 mg day^{-1}. Copper is kept under tight homeostatic control to prevent the accumulation of excess amounts. Acute copper toxicity in humans is rare due to the emetic properties and unpleasant taste of the compounds. There are relatively few data on lower level or chronic oral copper exposure in humans. In the general human population, the key adverse effects usually associated with excess copper intake are gastrointestinal, and can occur as a result of food or beverage contamination. The EFSA has established an ADI of 0.15 mg per kg bw per day. Although dietary intake of copper was below this level, the estimated aggregate exposure assessment from all sources was not negligible. While the estimate is not representative for all European consumers, the overall copper intake of most consumer groups is not expected to exceed the UL reference value of 10 mg day^{-1}.

Aluminum

For adults, the estimates of mean dietary exposure to aluminum-containing food additives from consumption of cereals and cereal-based products are up to the PTWI of 2 mg per kg bw per week, as established by JECFA in 2011. Dietary exposure of children to aluminum-containing food additives, including high dietary exposures (e.g., 90th or 95th percentile), are estimated to be 2-fold higher than the PTWI. For potassium aluminum silicate-based pearlescent pigments at the Codex maximum proposed use levels and using conservative estimates, anticipated dietary exposure at the highest range of estimates could be 200 times higher than the PTWI.

Although aluminum can accumulate in the body, consumption of aluminum-containing food additives would be acceptable if the total dietary exposure to aluminum is below the PTWI. To this end, provisions for food additives containing aluminum should be reviewed so that exposure to aluminum from all sources does not exceed the PTWI for aluminum compounds of 2 mg per kg bw from all sources.

PROCESSING CONTAMINANTS

Contents

Acrylamide

K Skog and G Viklund, Lund University, Lund, Sweden

Glossary

Carcinogen A substance that is directly involved in causing cancer. This may be due to its ability to damage the genome or to disruption of cellular metabolic processes.

Maillard reaction The Maillard reaction is named after the French scientist Louis Camille Maillard (1878–1936), and comprises a complex series of reactions between amino acids and reducing sugars, usually at increased temperatures.

Neurotoxic compound A substance that alters the normal activity of the nervous system in such a way as to cause damage to nervous tissue.

Precursor A compound that participates in the chemical reaction that produces another compound.

Reducing sugar Any sugar that either has an aldehyde group or is capable of forming one through isomerization.

History, Background, and Sources

In 1997, tunnel workers at Hallandsås, in the south of Sweden, were occupationally exposed to acrylamide. They were examined and compared with a nonexposed control group. Surprisingly, it was found that the control group had elevated levels of acrylamide adducts in the blood. Later it was shown that rats fed with a fried diet had elevated levels of acrylamide adducts, indicating that food could be a source of acrylamide. In 2002, the Swedish National Food Administration announced that heat-treated starch-rich foods contained high levels of acrylamide, a compound that has been shown to be neurotoxic to humans and classed as probably carcinogenic to humans (Group 2A). The potential carcinogenicity of acrylamide in humans together with the fact that high amounts, up to a milligram per kilogram, could be formed in certain foods, caused great concern for national authorities and the food industry. This led to the initiation of extensive research activity to find ways of controlling and minimizing acrylamide formation and to obtain data on which to base recommendations for reduction strategies.

The aim of cooking is to increase the palatability and digestibility of foods, to kill possibly harmful microorganisms and to provide variety to our diet. At temperatures above 120 °C, the Maillard reaction takes place, which produces characteristic flavor, aroma, and color. Acrylamide has been shown to be formed via the Maillard reaction as a result of the reaction between the reducing sugars glucose and fructose, and the amino acid asparagine. Potatoes contain relatively high levels of these precursors and, therefore, high levels of acrylamide can be formed in, for example, crisps, but acrylamide is also found in bread, cookies, and coffee. Until more is known about the role of acrylamide in human health it would be prudent to decrease the intake of acrylamide. Considerable research has been devoted to increasing our knowledge concerning the factors that favor acrylamide formation and to find means of reducing its presence in heat-treated foods.

Chemistry, Industrial Use, and Factors Influencing the Formation

Acrylamide Chemistry and Industrial Use

Acrylamide (2-propenamide, CAS number 79–06–1) is a nonflammable, odorless, and white crystalline compound. The molecular structure is shown in Figure 1, and some chemical properties are listed in Table 1.

Acrylamide has been produced industrially since the 1950s. It is mainly used for the production of polyacrylamide which, among other things, is used for drinking water clarification, for waste water treatment, in soil stabilization, and as a grouting agent. Polyacrylamide gels are also used in the paper and textile industries, in ore processing and in cosmetics, and are widely used in research laboratories to separate proteins and other compounds by electrophoresis.

Reaction Pathways for Acrylamide Formation

After the finding of acrylamide in heat-treated foods, several model experiments were performed to elucidate the precursors and reaction routes. It was proposed early that acrylamide is formed via the Maillard reaction, and it was soon demonstrated that formation of acrylamide requires the amino acid asparagine and a carbonyl compound, for example, glucose or fructose. By using labeled asparagine and glucose it was shown that the main reaction pathway is through condensation of the precursors to form a Schiff base that undergoes decarboxylation and a series of rearrangements to eventually form acrylamide. However, the exact pathway from the Schiff base is dependent on the carbonyl source in the reaction and several pathways have been proposed.

Minor amounts of acrylamide can be formed via the Maillard reaction from other amino acids such as glutamine or methionine. Other possible reaction pathways have been suggested, for example, from acrylic acid and ammonia. Acrylic acid may be formed via the Maillard reaction through degradation of aspartic acid or through the oxidation of acrolein, resulting from the oxidation of fatty acids or glycerol. However, this pathway may be limited due to the requirement for ammonia, which reacts readily with carbonyls and other Maillard intermediates. Another minor route is formation from 3-aminopropionamide, which is an intermediate in the Maillard reaction, but can also be formed in foods during storage through enzymatic decarboxylation of asparagine.

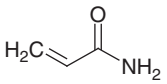

Figure 1 Molecular structure of acrylamide.

Table 1 Some properties of acrylamide

CAS number	*79–06–1*
Molecular formula	C_3H_5NO
Molecular weight	71.08 g mol^{-1}
Boiling point	125 °C at 25 mmHg
Melting point	84.5 °C
Solubility	Soluble in water, alcohols, acetone, and acetonitrile
Reactivity	Reacts with acids, bases, and oxidizing agents
Stability	May polymerize violently at temperature above the melting point

Acrylamide Formation in Model Systems

Several model systems have been used to elucidate factors affecting acrylamide formation, such as temperature and time, water content, the concentration of sugars and amino acids, and pH. These are the same parameters that affect the formation of flavor and color. However, in some studies extreme conditions have been used which are not realistic for food production.

Temperature and Time

Acrylamide starts to form in high amounts at temperatures above 120 °C. Depending on the model system studied, the acrylamide yield reaches a maximum at approximately 160–180 °C. However, the yield of acrylamide in model systems is not very high. Approximately 0.1–0.3% of the asparagine on a molar basis is converted to acrylamide. Acrylamide content increases with time, although a decrease in acrylamide has been observed in a dry glucose/asparagine system after prolonged heating.

Water Content

The formation of acrylamide is dependent on the water content of the system. During roasting and frying water evaporates from the surface. Acrylamide is formed at a higher degree when the surface starts to dry out and the surface temperature rises.

Precursors

The contents of acrylamide precursors: asparagine and reducing sugars (glucose and fructose), are critical factors in acrylamide formation. Using chemical model systems, it has been found that both asparagine and sugars are equally important in determining the reaction rate. Sucrose is not a reducing sugar, but can decompose to glucose and fructose at higher temperatures, and may thus contribute to acrylamide formation to some extent.

pH

The Maillard reaction is pH dependent. In most cases the reaction rate has been found to increase with increasing pH. In a buffered model system with equimolar amounts of asparagine and glucose, more acrylamide was formed at pH 7 and 8 than at lower pH. Lowering the pH favors protonation and may inhibit the formation of the Schiff base necessary for acrylamide formation.

Additives

Divalent cations such as Ca^{2+} and Mg^{2+} have been shown to reduce acrylamide formation. The mechanism responsible is probably covalent binding between the ions and asparagine,

and thus preventing the molecule from participating in acrylamide formation. The addition of Ca^{2+} to a fructose/asparagine model system was found to completely inhibit acrylamide formation.

Other amino acids apart from asparagine can participate in the Maillard reaction and thus competitive reactions can occur. The addition of various amino acids, for example, glycine, cysteine, and lysine to model systems, has been shown to lower the production of acrylamide.

Pretreatment of a potato snack model with the enzyme asparaginase for 30 min at room temperature reduced the asparagine content by 88%; the amount of acrylamide was reduced by 99% when the snack was microwaved on high power for 10 min. When asparaginase was added to fresh homogenized potato and incubated for 30 min at 37 °C, a reduction of up to 97% of acrylamide was obtained after heating at 180 °C for 20 min.

Acrylamide Formation in Heated Potato Products

Potatoes (*Solanum tuberosum L.*) are one of the most widely consumed carbohydrate-rich staple foods in large parts of the world. In Europe, the traditional means of preparation has been to boil fresh potatoes. During recent decades the consumption of fresh potatoes has decreased and there has been an increase in the consumption of processed commercial products, for example, deep-fried and roasted potato products such as crisps and French fries. In some countries, the economic significance of fried and roasted products is higher than that of fresh potatoes.

The acrylamide precursors are naturally occurring in potatoes and the levels differ between varieties and with storage conditions. The genotype of the potato, together with soil, fertilization, and weather conditions during growth, influence the initial sugar content, but the content of free amino acids, for example, asparagine that is the main nitrogen source in potato tubers, is mainly influenced by genotype.

Changes in Potatoes During Storage

Potatoes are often stored for long periods before distribution to retailers or the food industry. Directly after harvest the potatoes should preferably be stored at approximately 15 °C, for 2–3 weeks to heal the wounds arising from harvest and handling. After this period the storage temperature is successively lowered. Storage at 3–4 °C reduces respiration, prevents shrinkage, and sprouting and reduces the risk for storage diseases. However, storage at temperatures below 8 °C causes so-called cold-induced sweetening, i.e., degradation of starch to reducing sugars. A common way to inhibit sprouting at storage temperatures approximately 8 °C is to treat the potatoes with sprout-inhibiting compounds, for example, chlorpropham (isopropyl-N [3-chlorophenyl] carbamate). The conversion of starch to sugars is a reversible process and the sugar levels can be lowered by 'reconditioning' the tubers, i.e., storage for 2–3 weeks at approximately 15 °C. Interestingly, there are potato clones that are more resistant to cold-induced sweetening and therefore can be stored at low temperatures.

Crisp Production

Potato crisps are thin slices, approximately 1.5 mm thick, deep-fried in oil. The industrial production of potato crisps includes several steps: the choice of raw material, washing, slicing, rinsing, and deep-fat frying in a continuous fryer at 150–180 °C. A blanching step, i.e., heating potato slices in water before frying is sometimes used to reduce high levels of sugars, thus avoiding too dark crisp color. However, too high removal of precursors may affect product quality negatively. During frying a crust is formed, and the amino acids and sugars in the outer parts of the potato slices react to form a variety of compounds that are characteristic for the flavor and color of the crisps. French fries are produced in a similar way, but the shape is different.

During deep-frying, heat is efficiently transferred to the potato pieces through convection by the surrounding oil. Deep-fat frying is a more efficient way of cooking than, for example, oven roasting where heat is transferred through radiation and air convection although the oven temperature may be higher ($\sim$200 °C). Deep-frying results in drying of the slices and crust formation. The moisture content decreases from approximately 75% in the potato slices to below 2% in the crisps. As long as water is evaporating from the slices, the surface temperature remains at approximately 100 °C. When the surface starts to dry, and the crust is formed, the temperature increases and high amounts of Maillard products are formed.

Not all potato varieties are suitable for crisp production, because there are high demands on dry matter content and concentrations of reducing sugars. The dry matter content should be high as the yield of potato crisps is directly in proportion to the solids content. The concentration of reducing sugars should be low to avoid excessive browning, and the sugar content of the potatoes should remain low during prolonged storage.

Mitigation Strategies for Heated Potato Products

Much research on acrylamide formation in potato products has been devoted to mitigation strategies including soaking, blanching, addition of various compounds to the blanching water, and coatings. Because acrylamide is formed via the Maillard reaction it is important that the mitigation strategies do not negatively affect the formation of the desired flavor and color compounds. Literature data from some laboratory-scale mitigation studies on potato slices/crisps are compiled in Table 2. The table presents an overview, but it is difficult to exactly compare the results because different time/temperatures have been used and sometimes data on processing conditions are missing.

Good correlations between concentrations of acrylamide and reducing sugars have been obtained in several studies on potato crisps or French fries and in some studies a low content of asparagine gave reduced levels of acrylamide. Thus, the choice of potato variety is crucial to ensure that the acrylamide content is as low as possible, i.e., potatoes should be low in both reducing sugars and asparagines.

Temperature and time are interacting factors, as has been demonstrated in both model systems and potato products. Lowering the temperature may require longer frying times in order to obtain a product that is acceptable to consumers. Lowering the frying temperature or reducing the frying time will reduce the formation of acrylamide in potato products. Deep-frying of potato slices at 150 °C instead of 190 °C was found to give almost 10 times lower levels of acrylamide.

Table 2 Some literature data of mitigation strategies for acrylamide in potato crisps/slices

Mitigation strategy	*Reduction/effect*
Soaking, 50 °C	60%
Blanching, 85 °C for 3.5 min	49–75%
Soaking (60 min at 20 °C) in citric acid (0.05 M)	50%
Soaking (60 min at 20 °C) in acetic acid (0.15 M)	90%
Blanching (3 min at 70 °C) in citric acid (0.05 M)	49%
Blanching (3 min at 70 °C) in acetic acid (0.15 M)	49%
Postdrying (75 min at 105 °C)	69%
Soaking 40, 90 min	20–38%
Immersion in citric acid, 10 or 20 g l^{-1} for 30 min	70%
Blanching in combination with predrying	44%
Organic acids	Significant reduction
Addition of L-lysine, glycine, NaCl, and Ca^{2+}	Lowering effect
Combination citric or acetic acid/L-lysine or glycine	Lowering effect
Addition of $NaHSO_3$, $CaCl_2$, and L-cysteine in blanching water	Reduced acrylamide in the order cysteine > $CaCl_2$ > $NaHSO_3$
Addition of glycine or glutamine during blanching	30%
Coating with chick pea flour	Threefold reduction
Addition of antioxidants	No significant difference
Addition of rosemary herbs to frying oil	25%
Vacuum frying 8 min at 118 °C, vacuum pressure 10 Torr	95%

Note that the products have been heated/fried at different time/temperature combinations.

The precursor content can be significantly reduced by blanching. Blanching has been shown to significantly reduce acrylamide formation in potato crisps/slices or French fries. Soaking is another method used. Soaking is performed at a lower temperature than blanching but based on the same principle, i.e., the leakage of precursors. Blanching is more efficient, because higher temperatures make cell membranes more permeable and enhance the extraction of sugars and asparagine. Blanching has been combined with other methods such as predrying or postdrying to shorten the frying time and thus minimize acrylamide formation.

The Maillard reaction is pH dependent, and considerable research has therefore been directed toward the addition of organic acids, for example, citric acid and acetic acid to blanching or soaking water.

The effect of different additives has been studied on potato products. Dipping potato strips in a $CaCl_2$ solution has been found to inhibit acrylamide formation by up to 95%, whereas the addition of $CaCl_2$ to blanching water at different concentrations before frying, was found to reduce acrylamide in potato crisps to undetectable levels. However, other studies show conflicting results and further research is needed.

The addition of glycine or glutamine to blanching water was found to reduce acrylamide in potato crisps by approximately 30%, compared with a nonblanched control batch. The addition of different concentrations of cysteine to blanching water reduced the acrylamide content in potato crisps to undetectable levels, whereas the content of acrylamide was reduced by the addition of glycine or lysine by between 58% and 89%, compared with blanched controls, depending on the concentration.

In potato slices coated with chick pea flour, the acrylamide content was reduced to one-third, and this was suggested to be due to the protective effect of proteins, for example, complex formation of proteins and starch at the surface of the slice, making the sugars less available for acrylamide formation. Contradictory data have been observed from many studies, for example, soaking in water containing antioxidants before frying had no significant effect on acrylamide content, but the addition of rosemary to frying oil reduced acrylamide content in potato slices by 25%.

Vacuum frying has also been studied as a means of reducing the acrylamide content in crisps. Reducing the boiling point of the oil lowers the frying temperature, and the acrylamide content was reduced by 63% when the crisps were fried at temperatures between 125 and 140 °C. Neither the texture nor the flavor was significantly different from normal frying, whereas the color was mostly darker than the traditionally fried crisps.

Sensory Properties

A trained sensory panel has been used to study the sensory properties of potato crisps after the addition of various salts, organic acids, or amino acids. After blanching in 0.025 M citric acid a sour taste was reported, whereas the taste of crisps treated with acetic or lactic acid were not significantly different from normally blanched crisps. The addition of acetic acid- + lysine gave a pop-corn-like taste, which was not accepted by the panel. $CaCl_2$ gave a more crispy texture, although too high concentrations led to a bitter aftertaste. Crisps blanched in water containing acetic acid or citric acid had a lighter color, whereas the addition of glycine or lysine gave darker crisps. These results show that the additives and their concentrations must be carefully chosen so as not to negatively affect the flavor, color, or texture of the product.

Hazard Identification and Characterization

Until the discovery of acrylamide in foods, only occupational exposure to acrylamide was thought to represent a significant health risk. Today the health effect of dietary exposure to acrylamide is still an open question. Once acrylamide is absorbed from the diet, it is rapidly and extensively absorbed from the gastrointestinal tract and distributed to various tissues. Its double bonds are oxidized to a reactive compound, glycidamide, by the enzyme system cytochrome P450 2E1, see Figure 2. Both acrylamide and glycidamide are conjugated to glutathione and transformed to mercapturic acid derivatives, which are excreted in the urine. Protein binding occurs with both acrylamide and glycidamide. Hemoglobin adducts are often used as a tool in risk evaluation of acrylamide as biomarkers of the internal dose. Glycidamide is more reactive with DNA and forms adducts with the nucleotides guanine and adenine.

The primary concern following exposure to acrylamide via food is a possible cancer risk. Glycidamide is the molecule considered to be responsible for the carcinogenic effects because it can interact with DNA. Acrylamide is carcinogenic in animal experiments; for example, its metabolite glycidamide has shown an increased incidence of small intestinal tumors in mice injected with acrylamide. Long-term studies on rats given oral administration of acrylamide via drinking water showed increased incidences of both thyroid and mammary tumors. Besides being carcinogenic, acrylamide is also neurotoxic to experimental animals and humans, and has been shown to be genotoxic and to give reproductive and developmental effects in experimental animals.

Epidemiological studies have earlier been conducted on occupationally exposed subjects. After the discovery of the presence of acrylamide in different foods, several studies on the cancer risk associated with acrylamide in foods have been carried out on European populations. However, the studies show conflicting results and point to the difficulties of addressing low-level exposure of hazardous compounds from the diet. For appropriate measurements, the studies should be designed especially for investigating the carcinogenic risk of acrylamide, and the exposure assessments should be validated, and all major dietary sources of acrylamide should be taken into account. Furthermore, misclassification may weaken a hypothetical association between acrylamide exposure and cancer. Another problem is that the power of the studies should be high enough to detect small increases in risk expected from the lowest to the highest exposure groups.

There are no human studies on the carcinogenicity of acrylamide as a base for hazard characterization. However, dose descriptors such as BMDL10 (the lower confidence limit on the benchmark dose) for the most sensitive tumor response from rodent bioassays can be used to compare the risk characterization, and this approach has been recommended by the European Food Safety Authority (EFSA) for compounds that are both carcinogenic and genotoxic and has also been used by the Joint Food and Agriculture Organization/World Health Organization (FAO/WHO) Expert Committee on Food Additives (JECFA) in its evaluation of acrylamide.

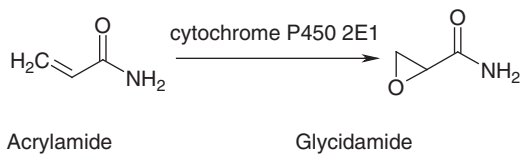

Figure 2 Conversion of acrylamide to glycidamide.

Methods of Analysis of Acrylamide in Foods

The analysis of acrylamide in various foods is difficult as the concentrations can vary from undetectable levels to several milligrams per kilogram, and other substances in the food matrix may cause interference. Several methods have been developed to analyze acrylamide in different foods. High-performance liquid chromatography (HPLC) and gas chromatography (GC) combined with mass spectrometry (MS) are the most commonly used methods for separation and detection. Most of these methods have a detection limit of 10–30 $\mu g\ kg^{-1}$.

A typical extraction procedure includes homogenization of the food sample and extraction with water. Additional steps are sometimes included, for example, defatting of the sample by the addition of isohexane, or precipitation of proteins with Carrez reagents. In an optimization study it was shown that acrylamide was efficiently extracted from various foods, for example, potato crisps, crisp bread, and coffee, using water, and that neither the addition of alcohol nor the removal of fat had any significant effect on the extraction yield. Labeled isotopes, for example, $[^{13}C_3]$-, $[^{13}C_1]$-, and $[^{2}H_3]$-acrylamide, can be added as internal standards to check for losses of acrylamide during the extraction and clean-up procedures. Subsequent clean up of the samples is required, and solid-phase extraction (SPE) is generally used. Acrylamide does not easily bind to any of the conventional sorbents, so the advantage of SPE is mainly the retention of interfering substances.

The choice of analytical column in HPLC analysis is important to achieve sufficiently long retention times because acrylamide is very soluble in water. Graphitic carbon columns and water with a small amount of an organic modifier as mobile phase are most common.

The detection of acrylamide using HPLC–MS is usually carried out using mass spectrometers run in positive electrospray ionization mode. Fragmentation of the ions (MS/MS) is often used to increase sensitivity and selectivity. Protonated acrylamide (m/z 72) gives a fragment at m/z 55, due to the loss of NH_3. This fragment is commonly used for quantification of acrylamide and compared to the corresponding fragment (m/z 58) of an isotope labeled standard such as $[^{2}H_3]$-acrylamide.

HPLC–UV is sometimes used for acrylamide determination, although the selectivity and sensitivity are rather poor. Nevertheless, this method can be used for acrylamide analysis when levels are high and the sensitivity is of less importance.

GC–MS analysis of acrylamide can be performed with or without derivatization. Bromination of acrylamide results in a molecule that is more volatile and less polar, and therefore suitable for GC. Bromination results in a higher molecular weight which improves the MS features. GC–MS can also be performed without bromination, but due to the polarity and low volatility of acrylamide this is not an optimal method and the sample clean up is more demanding.

Computer vision-based image analysis of the color of crisps or French fries has been developed to estimate acrylamide levels. This approach may be useful for online determination of acrylamide during food production. Calibration for each potato variety is important because the variety may influence the color when fried.

Levels in Foods and the Total Diet

Acrylamide has been found at microgram per kilogram levels in a wide range of heat-treated foods, for example, potato products, breakfast cereals, rice, bread, cookies, coffee, prunes, and olives. The highest amounts of acrylamide are generally found in carbohydrate-rich foods. Fried protein-rich foods such as hamburgers, chicken, and fish contain very low levels. Acrylamide has not been found in boiled food. The acrylamide content in some potato products, bread, and breakfast cereals are given in Table 3. There is a great variability not only between different food groups, but also within groups. This is probably due to differences in precursor content, ingredients, and processing conditions. Differences in sampling procedures, for example, if only one brand is analyzed or if the result is a mixture of different brands, may also affect the results. Studies on the stability of acrylamide in foods have revealed that the content in coffee and cacao powder decreased significantly during storage for more than 3 months.

The levels of acrylamide in wheat bread are linearly related to the content of asparagine in the flour, which in turn may vary considerably. In addition, long leavening times reduces the content of acrylamide in the bread. Other factors that affect the amounts of acrylamide in bread and cookies are the amount of reducing sugars and ammonium carbonate in baking powder.

Table 3 Levels of acrylamide in some foods, 2008 (European Food Safety Authority, report)

Food item	*Acrylamide ($\mu g\ kg^{-1}$)*		
	Mean	*Median*	*Maximum*
Potatoes			
Chips (French fries)	278	211	2466
Crisps	614	416	4382
Home-cooked products	180	65	3025
Bread/cereals			
Biscuits	205	120	1940
Bread, soft	38	15	528
Bread, crisp	234	109	1538
Breakfast cereals	160	74	2072
Others			
Coffee, roasted	206	167	1524

Exposure Assessment

Intake estimates vary between populations. Some estimates of the daily intake of acrylamide in different countries and different populations/age groups are presented in Table 4.

The estimated mean intake values in Table 4 range from 0.2 to 1.4 μg kg^{-1} body weight per day. The differences in

Table 4 Examples of estimated intake in different populations

Exposure assessment (year)	*Population/age group*	*Mean*	*90th percentile*
FAO/WHO (2000)		0.3–0.8	
EU/SCF (2002)		0.2–0.4	
Germany (2002)	15–18	1.1	
Switzerland (2002)	16–57	0.28	
France (2002)	>15	0.5	
	2–14	1.4	
Sweden (2002)	18–74	0.45	
Norway (2003)	Males	0.49	1.01
	Females	0.46	0.86
	Boys 9	0.36	0.72
	Girls 9	0.32	0.61
	Boys 13	0.52	1.35
	Girls 13	0.49	1.20
Denmark (2007)	Children 10–13	0.5	
	Adults	0.3	
FDA, USA (2004)	>2	0.43	0.92
	2–5	1.06	2.31
The Netherlands (2003)	1–6	1.04	0.8
	7–18	0.71	0.7
	1–97	0.48	0.2
Belgium (2004)	13–18	0.51	
	Boys 13–18	0.64	
	Girls 13–18	0.46	

The intake is given in micrograms per kilogram body weight per day.
SCF, Scientific Committee on Food.

estimated acrylamide intake are due to several factors, for example, different dietary habits, cooking traditions, and processing techniques. Other factors include dissimilarities in the dietary surveys performed, i.e., how the food intake was recorded, the age group, and how the food items were grouped. In addition, little information on the acrylamide content in home-cooked food is available, which adds to uncertainties in the estimates. Owing to these differences it is difficult to compare intake levels between countries.

There is a variation in consumption patterns between people of different ages: younger people probably tend to eat more snacks like potato crisps than older people, resulting in a higher intake of acrylamide when expressed per kilogram body weight. There is also a tendency for males to have a higher intake than females.

The contributions of different food groups to the intake of acrylamide vary between countries. An example from Sweden shows that a large contribution is from coffee, 23% and the combined contribution from potato crisps, French fries, and other fried potato products is 44%. In Denmark the contribution from coffee is almost the same as in Sweden, 24%, whereas the contribution from fried potato products and crisps is 54%. In a Dutch study the contribution from potato crisps was 31% (age 1–97 years).

Risk Characterization

The risk assessment process consists of four parts: hazard identification, hazard characterization, exposure assessment, and risk characterization. Hazard identification aims to determine the qualitative nature of the adverse effects by a contaminant (genotoxicity, carcinogenicity, neurotoxicity etc.). Hazard characterization determines the relationship between the dose and the incidence of effect. This could be investigated by establishing dose–response relationships. The aim of exposure assessments is to determine the amount of contaminant an individual is likely to receive. Several factors such as dietary habits, lifestyles and cultures could influence this. The final phase of the risk assessment process is risk characterization, which integrates the three processes mentioned above, and determines the probability of an adverse effect by a contaminant to a human population.

For acrylamide the exposure assessment is based on intake estimates, which includes the collection of food consumption data, for example, through food records or household surveys; analysis of the levels of acrylamide, grouping of food items and the choice of modeling of exposure. Biomarkers in urine and blood may also be used to evaluate and confirm the intake. If possible, exposure assessments based on dietary questionnaires should be combined with measurements of biomarkers of exposure. Different methods can be used to model the exposure, for example, point estimates or probabilistic modeling. Owing to the lack of data on the adverse effects of acrylamide on humans, data from animal experiments are required to perform risk characterization. Based on estimates of the intake, and extrapolation of the results from animal experiments, the lifetime cancer risk in humans has been estimated to be between 0.7 and 4.5 per 1000 individuals, depending on the method used.

The risk to human health arising from the intake of low levels of acrylamide during a lifetime of exposure is still unclear. Epidemiological studies have not shown any evidence of increased cancer risk in humans due to acrylamide in food. However, epidemiological studies are often not sufficient to completely disprove an increased risk of cancer. The studies that have been made were not designed to investigate the carcinogenic effect of acrylamide and in some of them not all dietary sources of acrylamide have been taken into account. Furthermore, a comparison of intake estimates based on food frequency questionnaires with hemoglobin adducts showed large overlaps.

Managing the Risk

Scenario analyses performed within an EC project, HEATOX, indicated a possible maximum acrylamide reduction of 40% if all known mitigation efforts were applied. This shows that it is important that the efforts to find more efficient minimizing tools are continued. Advice on consumption can be a complementary way of reducing the intake. This points to the need to consider a management strategy combining regulatory means with consumption advice and risk communication activities. The food industry and catering are the places in the food chain where mitigation efforts would be most efficient and they could benefit from advices in the Acrylamide Toolbox that has been developed by the Confederation of the Food and Drink Industries of the EU.

A large number of foods contributing to acrylamide intake are industrially produced whereas the contribution from home cooking is probably quite small in the general population. Acrylamide exposure from home cooking comes primarily from potato products with some addition of toasted and homemade bread. Home cooking, especially potato products, can generate a very large variation even for the same product, which makes it difficult to predict the real intake from home-cooked foods. Individuals with a high consumption and preference for specific hard fried foods might constitute high exposure risk groups. At the home-cooking level, avoiding overcooking is probably by far the most important action to recommend. Other advice includes clear and accurate cooking instructions on the packaging of prefried products, and clear and accurate instructions for fryers for domestic use. French fries and roast potatoes should be cooked to a golden yellow rather than golden-brown color and bread be toasted to the lightest color acceptable.

Advanced Glycation End Products (AGEs)

R Kent and J Uribarri, The Mount Sinai School of Medicine, New York, NY, USA

Glossary

Adducts A product of addition of two or more distinct molecules, resulting in a single product containing all components of original molecules.

Advanced glycation end product (AGE) Proteins that become glycated after exposure to sugars.

AGE receptor 1 (AGER1) A 48-kDa receptor protein, which when bound by AGE leads to suppression of AGE-induced oxidative stress.

Glycation The nonenyzymatic bonding of a free amino group with a sugar molecule.

Homeostasis model assessment (HOMA) An index using fasting blood glucose and insulin levels used to estimate insulin resistance.

8-Isoprostane A prostaglandin-like compound, which is a biomarker of oxidative stress (OS). It is formed *in vivo* by the free radical-catalyzed peroxidation of essential fatty acids.

Maillard reaction A form of nonenzymatic browning that results from a chemical reaction between an amino acid and the reactive carbonyl group of a reducing sugar.

Oxidative stress An imbalance of prooxidants and antioxidants, resulting from either an increase in oxidizing species or a decrease in antioxidant defenses.

Receptor for AGEs (RAGE) A multiligand receptor of the immunoglobulin superfamily, which when bound leads to activation of inflammatory pathways and increases in OS via intracellular signaling.

Tumor necrosis factor α (TNF-α) An inflammatory cytokine secreted by several cell types, but by macrophages in particular. TNF-α stimulates a cascade of inflammatory cytokines and increases vascular permeability.

Introduction

Modern 'Western' society has brought with itself profound changes in lifestyle, but at the same time a much greater prevalence of chronic diseases, such as cardiovascular disease (CVD), the metabolic syndrome, insulin resistance (IR), obesity, and type-2 diabetes mellitus (T2D). All these diseases seem to have in common, elevated levels of markers of inflammation and oxidative stress (OS). Of the many components of modern lifestyle, which alone or in combination with other factors may play a role in increasing inflammation and OS, diet is a predominant one. Western dietary patterns that emphasize higher consumption of red and processed meats, sweets and desserts, potatoes and French fries, and refined grains have been linked to increased inflammation and OS.

Of the many dietary factors that may be associated with inflammation and OS, particular interest has been focused on a specific group of food-derived proinflammatory and prooxidant compounds, the so-called advanced glycation end products (AGEs). Although AGEs have been widely recognized as important factors in the pathogenesis of diabetic complications, the importance of AGEs of dietary origin as a factor in human disease has been largely unappreciated. In this article, human data that have accumulated in the past two decades on the role of food-derived AGEs in causing chronic human disease are presented.

What are Advanced Glycation End Products or AGEs?

AGEs are a large group of heterogeneous and highly reactive compounds that form through different pathways. They may form by the spontaneous, nonenzymatic reaction of reducing sugars with free amino groups in amino acids. A series of intermediary reactions leads finally to the irreversible formation of AGEs. This is the classic Maillard reaction also called the browning reaction. Alternatively, AGEs can also form through a variety of other reactions, including oxidation of sugars, lipids, and amino acids, which create reactive aldehydes that eventually also form AGEs (Figure 1).

The same AGEs that form endogenously in the above-mentioned reactions can also form in any system in nature wherever the needed reagents are present. For example, AGEs also form spontaneously in food, but cooking the food at high temperatures markedly increases their formation. A portion of the AGEs contained in the foods we eat gets absorbed and becomes incorporated into the body AGE pool with exogenous compounds being indistinguishable from their endogenous counterparts.

Despite the identification of numerous AGE compounds, the elucidation of the structure of pathogenic AGEs remains elusive. Pentosidine, carboxymethyllysine (CML), and methylglyoxal (MG) derivatives are among the better-characterized compounds and they are often used as AGE markers.

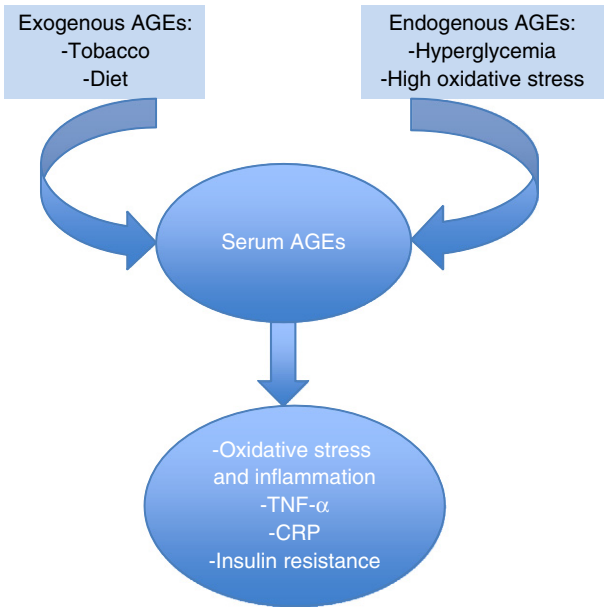

Figure 1 Sources and possible effects of advanced glycation end products (AGEs).

Chemically and immunologically distinct AGEs can coexist on the same carrier proteins. There are many methods to measure AGEs. Detection of their fluorescence capacity is simple but nonspecific. More specific methods include immunoassays and high-performance liquid chromatography/mass spectrometry, each with its own advantages and disadvantages.

AGEs' Interaction Leading to OS and Inflammation

AGEs produce biologic effects through two general mechanisms. First, they induce crosslinking of proteins altering directly their structure and therefore their function. For example, glycation of collagen fibers in the skin and vessel wall changes the characteristics of these proteins and their holding tissues. This produces wrinkling under the skin and stiffness of arterial walls.

AGEs also activate several intracellular pathways acting through receptor and nonreceptor mechanisms. AGEs interact with different cell receptors. The interactions with some of them, such as receptor for AGEs (RAGEs) and EGFR lead to the stimulation of intracellular pathways that eventually increase reactive oxygen species and proinflammatory cytokines, such as TNF-α. The stimulation of other receptors, such as AGE receptor 1 (AGER1), increases AGE breakdown and increase sirtuin 1 (SIRT1) activity and overall decreases cellular proinflammatory activity. AGER1 has been found to be directly associated with the levels of circulating AGEs in healthy subjects. Interestingly, AGER1 levels are much suppressed in subjects who are exposed to a chronic high OS state, such as chronic kidney disease (CKD) and diabetes mellitus patients.

The steady state blood AGE level at any particular point in time reflects the balance of endogenous and exogenous sources and elimination via tissue degradation and renal elimination. AGE elimination is dependent on several mechanisms. MG, for example, is effectively catabolized by the enzymes glyoxalase I and II. Circulating proteins such as lysozyme bind AGEs increasing macrophage endocytosis and degradation of AGEs and increasing their renal excretion. AGE peptides are filtered by the glomerulus and reabsorbed to a variable degree by proximal tubular cells.

Food-Derived AGEs

AGEs form spontaneously in foods, during storage at room temperature, but their rate of formation markedly accelerates as temperature increases during cooking. Besides temperature, other factors known to affect AGE generation in food include nutrient composition, amount of water, pH, presence of trace metals, and the duration of cooking. Food scientists have learned over many decades how to manipulate cooking techniques to get the exact color, aroma, and taste of food they desire, but have been unaware of the potential hazards.

Recently, two large databases with the contents of CML, a commonly measured AGE, in more than 500 food items have become available. These databases allow estimating daily dietary AGE intake as well as designing diets with variable AGE content. These databases show that foods rich in both protein and fat, mostly of animal origin, and cooked at high and dry heat, such as in broiling, grilling, frying, and roasting, tend to be the richest dietary sources of AGEs, whereas low-fat carbohydrate-rich foods tend to be relatively low in AGEs. This may reflect the fact that the AGEs in the diet are generated not only by the Maillard reaction but also by interactions between oxidized lipids and protein; such reactions are known to give rise to AGEs, such as CML. As these fat-rich foods are the ones commonly consumed in the US, most people are constantly ingesting a diet with high-AGE content. Based on the analysis of 3-day food records from a group of 90 healthy subjects eating their usual foods, the average dietary AGE intake was estimated at 16 ± 5 AGE Eq units per day (mean $\pm$ SD).

Knowledge about the effect of cooking temperature, duration of cooking, use of water, and pH of the solution in the generation of food AGEs is of great importance in developing culinary techniques, which allow reduction of food AGE content without necessarily changing the type and quantity of foods consumed. The essential concept here is that it is the way of cooking and not the actual nutrient composition of the food that determines its AGE content; this can be more easily illustrated with an example in which the AGE content of food is expressed in arbitrary AGE kilounits per serving. For example, a 90 oz beefsteak contains 720 AGE kilounits when raw, 2199 kilounits when stewed, and 6731 kilounits when broiled. Moreover, temperature and method of cooking appear to be more critical to AGE formation than the duration of cooking; for example, meat samples broiled or grilled at 230 °C for shorter durations have higher AGE content when compared with samples boiled in liquid media at 100 °C for longer periods. Stewing or steam cooking of meat, which maintains food moisture during cooking, will generate much less AGE than broiling or frying. Marinating will also have an AGE-reducing effect by lowering the local pH of food (pH effect of lemon or vinegar).

Tobacco smoke is another largely ignored exogenous source of AGEs. Tobacco processed in the presence of

reducing sugars leads to the formation of AGEs. Combustion of these adducts during smoking gives rise to reactive AGE formation.

In Vitro Data

Extracts of food containing AGEs tested *in vitro* showed the same biologic properties previously described for endogenous AGEs, namely, protein crosslinks and induction of inflammation and OS. Importantly, these properties persisted when the AGEs were absorbed into the bloodstream after ingestion. For example, LDL obtained from diabetic subjects maintained on a high-AGE diet promoted a marked increase in NF-κB activity in cultured human endothelial cells, compared with LDL obtained from diabetic patients maintained on a low-AGE diet.

Experimental Data

A high dietary AGE intake in mice has been shown to predispose to many chronic diseases, including diabetes types 1 and 2, IR, atherosclerotic disease, and renal disease. More importantly, the institution of a low-AGE diet prevented or significantly ameliorated all the above-mentioned conditions.

Human Data

Observational Data

A number of studies have addressed the clinical relevance of the *in vitro* and animal data discussed in section Experimental Data. A cross-sectional analysis that included a large number of healthy subjects of different age groups demonstrated that dietary AGE intake, adjusted for calories and nutrient intake, significantly correlated with levels of serum CML, MG, 8-isoprostanes (marker of OS), VCAM-1 (marker of endothelial dysfunction), and mononuclear TNF-α, among other inflammatory markers across different age groups. These findings suggest that persons who have diets high in AGEs have relatively high levels of circulating AGEs, which may exceed the capacity of native defenses to remove or neutralize them eventually causing a high OS, a common denominator for most chronic diseases. When some of these subjects were followed for several months without any specific interventions, the spontaneous changes in dietary AGE intake over time also correlated positively with changes in serum AGEs, 8-isoprostane, and TNF-α levels during the same period.

A close association between dietary and blood levels of AGEs, 8-isoprostane, and several markers of inflammation has also been shown in diabetic patients. A recent study of T2D patients of two different ethnic groups (Mexicans and non-Hispanic whites) showed that dietary AGE intake was associated with their risk of CVD. An association between dietary AGE intake and circulating AGE levels was also found in a large population of dialysis patients.

Effects of Acute Oral AGE Loads

A group of diabetic patients and five healthy subjects were challenged with a single meal of egg white, cooked with (AGE-rich) or without fructose. The AGE-rich meal, but not the control meal, produced significant elevations in serum AGE levels in direct proportion to the amount ingested over the next few hours. Only one-third of the absorbed AGEs were detected in the urine over the next 48 h. This study was the first one to clearly demonstrate that food-derived AGEs are absorbed along the gastrointestinal (GI) tract in humans, although the exact mechanism of absorption remains uncertain.

An acute antiendothelial effect of dietary AGEs was demonstrated by administering a single oral dose of a high-AGE beverage to both healthy subjects and diabetic patients. Within 90 min, those drinking the high-AGE beverage showed increased serum AGE levels as well as increased levels of plasminogen activator inhibitor-1 (an inhibitor of fibrinolysis produced by the endothelium) and transient impairment of flow-mediated vasodilatation, both noninvasive indices of endothelial function. These antiendothelial effects were prevented if the subjects were pretreated with an AGE inhibitor (benfotiamine). A single high-AGE solid meal given to diabetic patients also markedly impaired flow-mediated vasodilatation compared with an isocaloric low-AGE meal. As endothelial dysfunction is the earliest abnormality in atherosclerosis, such findings provide a probable mechanistic link between dietary AGE content and CVD.

Clinical Trials with a Low-AGE Diet

Low-AGE Intervention in Healthy Subjects

A group of healthy subjects, equally divided among young and older age groups, were randomly assigned to either their own usual diet or a low-AGE diet. The AGE-restricted diets were otherwise of similar caloric, nutrient, and micronutrient content as at baseline. To reach these goals, participants received detailed instructions on how to prepare their food at home by a study dietitian who was in frequent telephone contact with them. The subjects were required to have a habitually high/normal dietary AGE intake as a condition to participate in the study. After 4 months, significant reductions in serum AGE (both CML and MG) levels were noted, with parallel reductions in plasma levels of 8-isoprostanes, VCAM-1, and peripheral mononuclear cell-derived TNF-α, below baseline values. There was no age difference in the response to the dietary intervention.

Another randomized, crossover study with 62 healthy volunteers compared the effect of two diets, one based on mild steam cooking (low AGE) and the other one on high temperature cooking (high AGE), each one followed for 1 month. The low-AGE diet significantly decreased circulating CML levels and improved insulin sensitivity as assessed by the homeostasis model assessment (HOMA) index.

Low-AGE Intervention in Diabetic Patients

Randomized studies on the effect of an AGE-restricted diet have been performed in two groups of diabetic patients. The first one was a crossover study between low- and regular-AGE diets for a period of 6 weeks. Meals were prepared in the

medical center clinical research unit kitchen, and patients picked them up twice a week during the duration of the study. Patients in the low-AGE diet experienced decreased levels of circulating AGEs (both CML and MG), VCAM-1, C-reactive protein (CRP), and TNF-α (32). Notably, circulating AGE levels decreased by as much as 40% despite same degree of diabetic control. Before this study, high serum AGE levels in diabetic patients were thought to result exclusively from endogenous overproduction owing to hyperglycemia, and therefore this significant fall while maintaining overall same glycemic control was unexpected.

In the second study, patients were randomized to follow either their regular-AGE diet or a low-AGE diet for 4 months (12). A study dietitian followed the patients closely and instructed them how to prepare their own meals at home. At the end of the study, patients in the low-AGE diet showed not only decreased circulating levels of AGEs, 8-isoprostane, RAGE, and TNF-α but also decreased HOMA and increased AGER1 and SIRT1. The reduction of HOMA, which implies improvement of insulin sensitivity, raises a very important consideration. Although it is widely recognized that hyperglycemia in diabetes can increase endogenous production of AGEs, this study suggests that AGEs in turn have an important role in modifying IR and therefore diabetes. This is supported by previous mice experiments showing that high-AGE diet can induce IR and diabetes mellitus, whereas a low-AGE diet has the opposite effect. This newly uncovered information on AGEs and IR needs to be further confirmed in more clinical trials, but clearly opens a big opportunity for a safe, inexpensive, and effective dietary modulation to prevent or ameliorate diabetes.

The effect of an AGE-restricted diet increasing AGER1 and SIRT1 levels in these patients deserves further comments. Other studies have shown that CKD and T2D patients have depressed levels of these two markers of innate immunity. The restoration of their levels following the low-AGE diet demonstrates that the previous suppression was because of an environmental factor, most likely the high AGE-induced high OS. These results may be interpreted as indicating that a high-AGE diet, when sustained, eventually will suppress defensive innate mechanisms, such as AGER1 and SIRT1, which initiates a vicious cycle of further OS increase. The fact that both defense mechanisms can be improved by a simple dietary intervention, both in diabetes and CKD patients (see below), is good news in terms of therapeutic potential.

Low-AGE Intervention Study in CKD Patients

To obtain a measure of the relative impact of the intervention on subjects with different renal abilities to handle oxidants, a subgroup of patients with established CKD not yet on dialysis were challenged with the AGE-restricted diet. The effects of the low-AGE diet in these CKD patients mimicked those in healthy participants (reduction in serum AGEs and in markers of inflammation and OS) and in diabetic patients.

Low AGE Intervention in ESRD Patients on Peritoneal Dialysis

An AGE-restricted diet has also been tested for 4 weeks in a group of patients having nondiabetic end-stage renal disease (ESRD) on maintenance peritoneal dialysis. The results again showed a significant reduction of serum AGEs and CRP.

Diabetic CKD Subjects on a Regular AGE Diet but Exposed to an Agent That Binds AGEs in the GI tract

A group of 20 diabetic CKD patients were studied in a crossover design with one therapy of sevelamer carbonate (1600 mg tid with meals) and another one of calcium carbonate (1200 mg tid with meals) for 8 weeks each. Sevelamer therapy, in contrast to calcium carbonate, reproduced all the previous findings observed on the low dietary AGE intervention, namely, reduced circulating levels of AGEs, 8-isoprostane, TNF-α, all of which were high and increased AGER1 and SIRT1, both of which were low. The study also showed independently that sevelamer, not calcium carbonate, binds AGEs quite effectively *in vitro* and presumably in patients with diabetic CKD. The AGE-binding capacity of sevelamer is most likely responsible for these results, which require confirmation in a larger number of subjects.

Summary

All the above data strongly suggest that dietary AGEs are significant contributors to the body AGE pool and that chronic exposure to these exogenous prooxidant substances gradually erodes native defenses, setting the stage for abnormally high OS and inflammation, precursors of chronic diseases. Real-life dietary patterns are complex and include the simultaneous presence of many factors other than AGEs. Some of these dietary factors are proinflammatory such as fats and AGEs, whereas others are clearly anti-inflammatory such as polyphenols and a variety of antioxidants. The final biologic effect of dietary patterns most likely reflects the combined influence of all these factors, each one of them acting in a different direction and with different intensity. It is the combination of different types of foods and their respective amounts consumed over the day that is important rather than any specific food item with AGE content. Detailed information on how to initiate and maintain a low-AGE diet has been published. Available scientific evidence strongly indicates that restriction of dietary AGEs is a safe and feasible dietary intervention that effectively reverses increased inflammation and OS, both in health and in the disease state.

PROCESSING CONTAMINANTS

Benzene

A Becalski, Health Canada, Ottawa, ON, Canada

Glossary

Aromatic hydrocarbon A hydrocarbon that contains one or more benzene rings.

Gas chromatography/mass spectrometry (GC/MS) A technique, comprising a gas chromatograph (GC) coupled to a mass spectrometer (MS). Using this apparatus complex mixtures of chemicals may be separated, identified and quantified.

Headspace analysis A technique whereby the vapors in the gas above and in equilibrium with a solid or liquid is sampled, as opposed to sampling only the solid or the liquid.

Log octanol–water partitioning coefficient (log K_{ow}) The octanol–water partition coefficient (K_{ow}) is a measure of the equilibrium concentration of a compound between octanol and water and indicates the potential for partitioning into organic matter. K_{ow} is inversely related to the solubility of a compound in water. Log K_{ow} is generally used as a relative indicator of the tendency of an organic compound to adsorb to soil.

Solid-phase microextraction (SPME) A method for collection of volatile compounds in a headspace on a solid fiber for subsequent analysis of the trapped volatiles using a technique like gas chromatography.

Contaminant Definition

Benzene is an organic chemical compound that has the molecular formula C_6H_6 and structure as given in the figure below:

Benzene is the simplest member of monocyclic aromatic hydrocarbons (sometimes abbreviated as MAHs). At room temperature, benzene is a volatile liquid lighter than water and has a boiling point of 80.1 °C. It exhibits slight water solubility at approximately 1 g l^{-1}, but is fully miscible with fats and oils. It has a log K_{ow} value of 2.13.

Toxicity

The International Agency for Research on Cancer has determined that benzene is carcinogenic to humans. The human cancer induced by long-term exposure to high levels of benzene in air is predominantly acute myelogenous leukemia. In animals, benzene is a multiple-site carcinogen by both the inhalation and oral routes. More than 90% of ingested benzene is absorbed in the digestive tract.

Absorbed benzene is distributed throughout the body and tends to partition in fatty tissues. However, at low-exposure levels (as those which are found in the general population), benzene is rapidly metabolized in the liver and excreted mostly as conjugated urinary metabolites.

Use and Occurrence in Environment

Benzene is both an anthropogenically produced and a naturally occurring chemical. It is an important industrial chemical and a precursor in the production of other chemicals, plastics, synthetic rubber, dyes, etc. Benzene is a natural constituent of crude oil (up to 3%), and benzene content in the gasoline is approximately 1%.

Trace amounts of benzene may result when carbon-rich materials undergo incomplete combustion, for example, in forest fires and volcanic emissions. Outdoor air may contain low levels of benzene, typically at a few microgram per cubic meter, from multiple sources: exhaust from motor vehicles; handling of gasoline, tobacco smoke, wood smoke; and from industrial emissions. Urban areas, where the concentration of benzene might exceed 10 μg m^{-3}, are more affected. Indoor air might also be contaminated by vapors from products that might contain benzene, such as gasoline, glues, paints, rubber, waxes, etc. Water and soil are also affected by atmospheric deposition and by spills of benzene-containing materials. Benzene does not bioaccumulate to a significant degree.

Occurrence in Food

Benzene can be introduced to foods by three principal routes:

1. In the absence of good manufacturing, storage, and cooking practices, benzene can be introduced into food as an environmental contaminant.
2. Benzene can be a contaminant present in certain food additives or certain flavors added into foods.

 doi:10.1016/B978-0-12-378612-8.00207-9

3. Benzene can occur in food due to the process-induced changes resulting from high-temperature chemical transformations, ionizing radiation, and from the reaction of added or naturally occurring precursors.

One or more of these sources might be associated with the presence of benzene in food.

Analysis

A number of analytical techniques have been developed for the quantitative determination of benzene. Most of these methods were developed for multiresidue analysis (e.g., benzene, toluene, ethyl benzene and xylenes (BTEX); or other volatile organic chemicals (VOCs)) and they include benzene as a target analyte. Several new methods specifically targeting benzene, some of which use solid-phase microextraction (SPME), were recently developed.

Static headspace sampling followed by gas chromatography/mass spectrometry (GC/MS) is the predominant technique used to determine benzene in foods. Before headspace analysis, solid and viscous foods may need to be homogenized by blending with water. To avoid benzene losses, samples should be chilled to 0 °C before homogenization and processed as quickly as feasible. Benzene in food is usually quantified by isotope dilution method with a d_6-benzene (or $^{13}C_6$-benzene) as an internal standard. The limit of detection is typically in the range of 0.1–1.0 ppb (microgram per kilogram or microgram per liter).

Levels of Benzene in Foods

The occurrence of benzene in foods has been investigated by targeted sampling and market basket sampling as part of total diet studies (TDSs). In general, TDS data and data from targeted sampling show that benzene concentrations in food seldom exceed low ppb (microgram per kilogram or microgram per liter) levels.

TDS and General Surveys

In 1993, UK conducted a TDS investigation of VOCs in 20 food groups collected from 10 UK locations. Benzene concentrations in these food groups ranged from less than 1 ppb in fruit products to 18 ppb in offal.

In a 1995 survey conducted in USA, 22 raw and cooked foods were analyzed. Most of the foods were found to contain less than 1 ppb benzene with the exception of peanuts and canned olives, which were found to contain approximately 2 ppb benzene. In another 1995 survey in USA, benzene was detected in 15 of the 37 foods and beverages analyzed at levels ranging from 0.5 to 9 ppb.

Targeted Surveys

Studies Focused on Environmental Contamination

Once released into the atmosphere, benzene may enter foods via absorption at different points in the food supply chain. Owing to the excellent solubility of benzene in fats and oils, lipid-rich foods are most affected. The sorption of benzene in lipids is rapid as the partition coefficient of lipids/air for benzene is approximately 1000. Infrequently, water contaminated by benzene might also introduce benzene into foods.

In a study conducted in 1996 in UK, 114 retail packs of fatty foods were purchased from shops attached to gasoline stations and stalls on busy roads (such samples were expected to contain higher concentrations of benzene in the air). Shops from the same locations believed to be remote from sources of aromatic hydrocarbons served as a control.

In most of the retail packs analyzed, the center subsamples showed lower concentrations than the surface subsamples. Such distribution indicated that contamination did not occur before or during processing, as the concentrations of benzene would likely be constant throughout the bulk of the food. Instead, it pointed to a passive absorption of benzene from the atmosphere after manufacturing.

However, there were no significant differences of benzene concentration between locations. The maximum concentrations found (calculated after correction for nonhomogeneity) were: bacon 13, cheese 13, butter 16, margarine 17, and lard 10 ppb.

In a study conducted in 1996 in Switzerland, the benzene concentrations in certain virgin olive oils were found to be approximately 50 ppb. A parallel investigation demonstrated that uptake of benzene by olives from ambient outdoor air in the olive groves would result in concentration of only approximately 1 ppb of benzene in the oil.

It was concluded that the production of the oil, and also the collection, transport, and storage of olives were responsible for the increase in the concentration of benzene, predominantly as a result of uptake from the air.

Another study of commercial seed oils showed an average concentration of benzene of 3.9 ppb indicating the ubiquity of traces of this contaminant in oils. It thus appears that approximately 5–10 ppb of benzene in a virgin olive oil might be unavoidable due to the use of motorized equipment during the olive processing.

In a 1996 survey of 24 fruits and vegetables, benzene was found at concentrations ranging from 27 to 56 ppb (dry weight) in the peels of apples, kiwifruit, and oranges. No benzene was found in the pulp of those fruits or the remaining fruits and vegetables.

In addition, benzene can be introduced to foods by a contact with contaminated equipment. For example, contamination of a mineral water (at the level of 10–20 ppb) occurred as a result of an improperly maintained filter. This contamination incident resulted in a worldwide recall of more than 100 million bottles of Perrier mineral water. Other sources of benzene contamination include its migration via contact of food with plastic material harboring traces of benzene.

Studies Focused on Contamination Caused by Substances Added to Foods

Solvent extraction of vegetable oils with hexane or other organic solvents contaminated with benzene can introduce benzene into the oil. In India, relatively high concentrations of benzene were found in refined and unrefined soy oil, i.e., 3.1 and 32 ppm, respectively.

Substances intentionally added to food may contain benzene due to the manner in which they were produced. Liquid smoke flavoring obtained through the incomplete combustion of wood is an example. Benzene was found in two liquid smoke products, at concentration of 21 and 121 ppb.

Studies Focused on Contamination Induced by Processing

Benzene can be introduced into food as a result of grilling over an open flame, especially with wood or charcoal. Benzene concentrations greater than 10 mg m^{-3} were detected in flue gases from glowing charcoal. Benzene can also be introduced into food by smoking as benzene can reach a concentration of approximately 2 mg m^{-3} in an alder wood smoke chamber.

Roasting foods at high temperatures can cause the pyrolysis of organic matter resulting in benzene formation. This occurs either from the recombination of intermediates or by the degradation of compounds containing a benzene moiety, such as phenylalanine.

Most of the data on VOCs released during roasting are reported for roasted coffee beans. Benzene concentrations in roasted coffee beans were estimated to be approximately 0.1–0.15 ppm as compared with 0.1 ppb in brewed coffee.

Trace levels of a few ppb of benzene can occur in some irradiated foods, presumably from radiolytic cleavage of phenylalanine. Some studies also report low-level benzene formation from irradiation of model solutions of benzoate and experimentally prepared foods preserved with benzoate.

In the early 1990s, it was found that benzene could form in certain beverages containing potassium or sodium benzoate and ascorbic acid. Ascorbic acid might be either naturally occurring in fruit juice or added as a preservative or nutrient. Benzoate is used as an antimicrobial agent but it also occurs naturally in many fruits. In cranberries and lingonberries, concentrations of 480 ppm and 600–1300 ppm have been reported. Benzoic acid can also be found in other foods, for example, cinnamon, at concentrations up to few hundred parts per million. When used as a preservative, benzoate may be added to foods at a level of up to 1000 ppm. Benzene forms through a series of reactions mediated by catalytic amounts of iron or copper salts, which produce hydrogen peroxide (H_2O_2). Iron (Fe^{2+}) or copper (Cu^{+}) ions then react with H_2O_2 (Fenton's reaction) to form the hydroxyl radical.

The hydroxyl radical might subsequently react with benzoic acid to form an unstable benzoic acid radical that readily loses CO_2 to form benzene. In the 2000–10 decade, several targeted surveys were conducted to investigate the amount of benzene found in beverages and other foods containing added or naturally occurring benzoate. In some countries, beverages purchased from a retail stores beyond the manufacturer's sell-by-dates contained even higher levels of benzene, up to 263 ppb (Table 1).

Mitigation

Environmental Contamination

Generally, only low-benzene concentrations are found in food. Exposure of foods, especially food rich in lipids, to the air grossly contaminated with benzene could dramatically increase these otherwise low concentrations. Owing to the ubiquity of benzene in the environment, the contamination potential is substantial.

The most likely contamination route is via fugitive emissions of gasoline, especially in confined spaces. These emissions might include accidental spills, losses in refueling, gasoline vapor escaping during engine starts, or from parked hot engines, etc. Even a small amount of gasoline (a few milliliters) could seriously contaminate food stored in a confined space. Such contamination, although significant, might not be detectable by olfactory means.

Good practices must also include preventing contact of food with the exhaust of internal combustion engines, especially gasoline engines without catalytic converters. Shipping and storage of foods should only be done using containers appropriate for that purpose. For example, containers (e.g., freight containers) whose interiors are contaminated by benzene residues (from gasoline, paints, or glues) must be avoided. To prevent uptake of benzene from ambient air, lipid-rich foods should be packaged in container/membrane, which is impervious to benzene and does not release benzene by itself.

Contamination Caused by Substances Added to Foods

The uptake of benzene in grilled foods could be potentially reduced by switching to alternative fuels. One study showed that benzene emissions from flue gases could be reduced by an order of magnitude, depending on the composition of the charcoal used during grilling.

Contamination Induced by Processing

With the exception of beverages, efforts to mitigate process-induced benzene contamination in food have not been deemed necessary. Both the International Council of Beverages Associations and the American Beverage Association have published guidelines that describe mitigation strategies that can be used by the beverage industry to reformulate the affected products. Benzene formation in beverages requires four reactants – benzoate, ascorbic acid, trace metal ions, and oxygen. In principle, the exclusion of any one of these reactants would be an option that could be used to mitigate benzene formation.

Chelating agents, such as ethylenediaminetetraacetic acid (EDTA), may be added to beverages containing benzoate and/or ascorbic acid to reduce the potential for benzene formation; however, EDTA may be less effective in products fortified with calcium. In addition, formulating beverages with sugars, instead of artificial sweeteners, might also help to reduce benzene formation.

Other factors that can reduce *in situ* formation of benzene in beverages are: minimizing exposure of products to high temperatures and/or UV light during the manufacture, storage, distribution, and shelf-life of beverages. In response to these findings, the beverage industry reformulated affected products to eliminate or minimize benzene formation.

Exposure

Dietary exposure to benzene is considered to be of low significance when compared with the total intake of benzene from

Table 1 Levels of benzene found in surveys of beverages

Country	*Year*	*Concentrations found (ppb)*	*Comments*
Australia	2006	1–40	Of 68 beverages, 29 were found to contain benzene concentration higher than 1 ppb, 4 samples contained benzene higher than 5 ppb, and 5 samples contained benzene higher than 10 ppb with a maximum of 40 ppb
Belgium	2008	0.3–11	One hundred thirty-four samples of soft drinks were analyzed, of which 10 samples contained benzene higher than 1 ppb, whereas 1 sample contained 11 ppb of benzene
Canada	2006	1–23	A survey of 124 soft drinks and beverages was conducted. Approximately 60% of the beverages analyzed were found to contain less than 1 ppb benzene. Six products were found to contain benzene higher than the Canadian guideline of 5 ppb for benzene in drinking water; 2 of those products were found to contain benzene higher than the WHO guideline of 10 ppb in drinking water. The highest benzene concentration found was 23 ppb in a low-calorie soft drink specifically marketed to children
Canada	2007	0.06–9.1	Data from the survey of 139 samples of soft drinks indicate that for most of the products, the average benzene concentration has decreased compared with the 2006 survey. The highest concentration found in a ready-to-drink beverage was 9.1 ppb
Ireland	2006	1–17	Of 76 samples of drinks, 7 samples contained benzene at or higher than 1 ppb, only 2 diet products were found to contain benzene higher than 10 ppb; the highest concentration found was 17 ppb
Ireland	2007	1–3.9	Nine of the 63 samples contained benzene higher than 1 ppb
Germany	2008	0.1–42	Seven of the 313 soft drink samples contained benzene higher than 1 ppb, only one sample exceeded 10 ppb guideline. Twenty-nine of the 33 samples of carrot juice for infants contained benzene higher than 1 ppb, with a maximum of 4.6 ppb. The average benzene concentration found in 451 beverages was below the European drinking-water limit of 1 ppb
South Korea	2006	5.7–88	Of 30 beverage samples, 27 products were found to contain benzene
UK	2006	1–28	Of the 150 soft drinks, 107 did not contain benzene higher than 1 ppb. Most of these beverages contained benzoate and ascorbic acid. Thirty-eight samples were found to contain benzene that ranged from 1 to 10 ppb. Four products had benzene concentrations higher than 10 ppb. The highest benzene concentration found was 28 ppb in a diet soft drink
US	2006–7	1–89	In the survey, 199 soft drinks and other beverages were analyzed. More than 90% of the samples analyzed did not contain benzene concentration higher than 5 ppb and most samples contained less than 1 ppb. Eighteen beverages were found to contain benzene above the US EPA MCL of 5 ppb for drinking water.

MCL, Maximum contaminant level; US EPA, US Environmental Protection Agency.

all sources. Several studies concluded that inhalation of contaminated air was the primary route of nonoccupational benzene exposure for nonsmokers, and mainstream cigarette smoke was the primary route for smokers. The average inhalation exposures were estimated to be approximately 3.3 μg per kg of bodyweight per day (0.2 mg day^{-1}, 60 kg adult) for nonsmokers and 33.3 μg per kg of bodyweight per day (2 mg day^{-1}, 60 kg adult) for smokers. These data were based on the benzene concentration in ambient outdoor/indoor air combined with the exposure from gasoline-powered machinery.

Estimates of dietary exposures vary significantly from 3 to 3000 ng per kg of bodyweight per day, with most estimates in the lower range. The variability is caused by using different consumption scenarios. Although these values are not consistent, it is generally considered that dietary intake of benzene is a minor source of total benzene exposure. Many studies point to the likely dietary exposure in the range of 50–200 ng per kg of bodyweight per day (3–12 μg day^{-1}, 60 kg adult). Dietary exposure of benzene would therefore constitute only a few percent of the total exposure to benzene. Mitigation strategies implemented by the beverage industry in 2006 should reduce the dietary exposure to benzene formed in drinks containing benzoate.

Health Risk

The variability of the dietary exposure and the human relevance of an estimated low-dose cancer effect level have resulted in some uncertainty in the assessed health risk from dietary exposure to benzene. However, the risk assessments conducted by several international organizations point to a likely hypothetical risk of cancer, which is defined as a unit risk value over a lifetime, to be in the range of 10^{-5}–10^{-6} (one in one hundred thousands to one in a million).

Risk Management

In general, the low concentrations of benzene found in foods have not generated the level of concern that would warrant the

establishment of formal risk management procedures or regulatory limits. Regulatory limits for benzene in food and beverages have not been established, except for bottled water where the Food and Drug Administration has adopted the US Environmental Protection Agency's maximum contaminant level (MCL) of 5 ppb as a quality standard. The European and Australian standard for benzene in drinking water is 1 ppb, the Canadian guideline is 5 ppb, and the World Health Organization's guideline is 10 ppb.

Recent reports of elevated levels of benzene in soft drinks and beverages initiated a series of actions by food safety organizations and the beverage industry. Actions included verification of the findings, identification of the source of contamination, evaluation of the health risk, and reduction of the concentrations to levels considered to meet acceptable quality standards. These actions were guided by the respective drinking water standards.

In North America and in several other jurisdictions, manufacturers were notified, products with excessive benzene concentration were withdrawn or discontinued, and other products were reformulated to keep the products 'as low as reasonably achievable' in benzene.

Conclusion

Environmental contamination and process-induced contamination are the most important sources of benzene in foods. Nonetheless, levels of benzene in food are generally low. The available data suggest that dietary exposure to benzene, and resultant health risks, are negligible in comparison with the overall exposure from environmental sources.

Biogenic Amines

S Bover-Cid, Institute for Food and Agricultural Research and Technology, Monells, Spain

Glossary

Biogenic amines Also known as biologically active amines, these are nitrogenous low-molecular weight substances of biological origin that can be found in nearly all types of foods in a wide and variable range of concentrations. Dietary biologically active amines can be classified into three different groups according to their origin and chemical structure: aromatic biogenic amines, aliphatic diamines and natural polyamines. Biogenic amines are mainly produced by decarboxylation of the precursor amino acids by specific microbial enzymes.

Cheese reaction A hypertensive response than can occur when subjects treated with monoamino oxidase inhibitor (MAOI) drugs consume foods or beverages rich in tyramine (a biogenic amine resulting from bacterial decarboxylation of tyrosine). Originally, the reaction was attributed to tyramine-rich cheese, though the mechanism of action is common for all types of food containing high amounts of tyramine.

Decarboxylation reaction A chemical reaction in which a carboxyl group (–COOH) is split off from a compound as carbon dioxide (CO_2). Enzymes that catalyze decarboxylation reactions are called decarboxylases, and convert amino acids to amines. A wide variety of decarboxylases occur in living organisms. Decarboxylases responsible for the formation of biogenic amines (i.e., histamine, tyramine, putrescine, cadaverine, phenylethylamine, and tryptamine) are able to convert specific amino acids (i.e., histidine, tyrosine, ornithine, lysine, phenylalanine, and tryptophan, respectively).

Histamine fish poisoning (HFP) A foodborne chemical intoxication caused by the consumption of fish containing high contents of histamine, a biogenic amine derived from bacterial decarboxylation, usually associated with spoilage. HFP formerly called scombrotoxin poisoning because of the frequent association of the illness with the consumption of spoiled scombroid fish such as tuna and mackerel. Histamine intoxication can also occur if other food containing high amounts of histamine is consumed.

Histamine intolerance Health disturbance mainly due to an impaired degradation of histamine ingested through foods. Usually, histamine intolerance is associated with a reduced diamino oxidase (DAO) activity due genetic constitution, physiological status, and intake of DAO-clocking drugs. Under these circumstances, an excess of histamine absorption may cause numerous symptoms mimicking an allergic reaction, including headache, diarrhea, congestion of the nose, asthmatic wheezing, hypotension, arrhythmia, urticaria, pruritus, and flushing.

Biogenic Amines: Classification and Origin

Several nitrogenous low-molecular weight substances with biological functions in animals, plants, and microorganisms are included within the term 'biologically active amines.' Biologically active amines can be classified into several groups according to their biosynthetic pathway and chemical structure, as shown in Figure 1. In food, the biologically active amines, known as (exogenous) biogenic amines, include tyramine, histamine, phenylethylamine, tryptamine, putrescine, and cadaverine, and they are mainly derived from the bacterial decarboxylation of precursor amino acids. Putrescine can also be formed through the deamination of agmatine, an arginine-derived polyamine.

Physiologically natural (endogenous) amines, including the polyamines spermidine and spermine, are not associated with the microbial decarboxylase activity but their intracellular biosynthesis in living organisms involves the incorporation of aminopropyl groups into their precursor putrescine. Some of the above-mentioned biogenic amines can also be synthesized *de novo* in animal and plant tissues and at low concentrations in food can be considered physiologically natural.

Both biogenic amines and polyamines can be found in nearly all types of foods in a wide and variable range of concentrations. Despite biogenic amines of the microbiological origin being the focus of this article, it is worth mentioning that the natural polyamines spermidine and spermine constitute the main amines occurring in fresh products (such as fruit and vegetables, milk, meat, and fish) where they have a physiological role associated with cell growth and proliferation. Polyamine content varies depending on the food type (Table 1). The main polyamine in plant-based products is spermidine, whereas spermine content is higher in foods derived from animals. Apart from the small

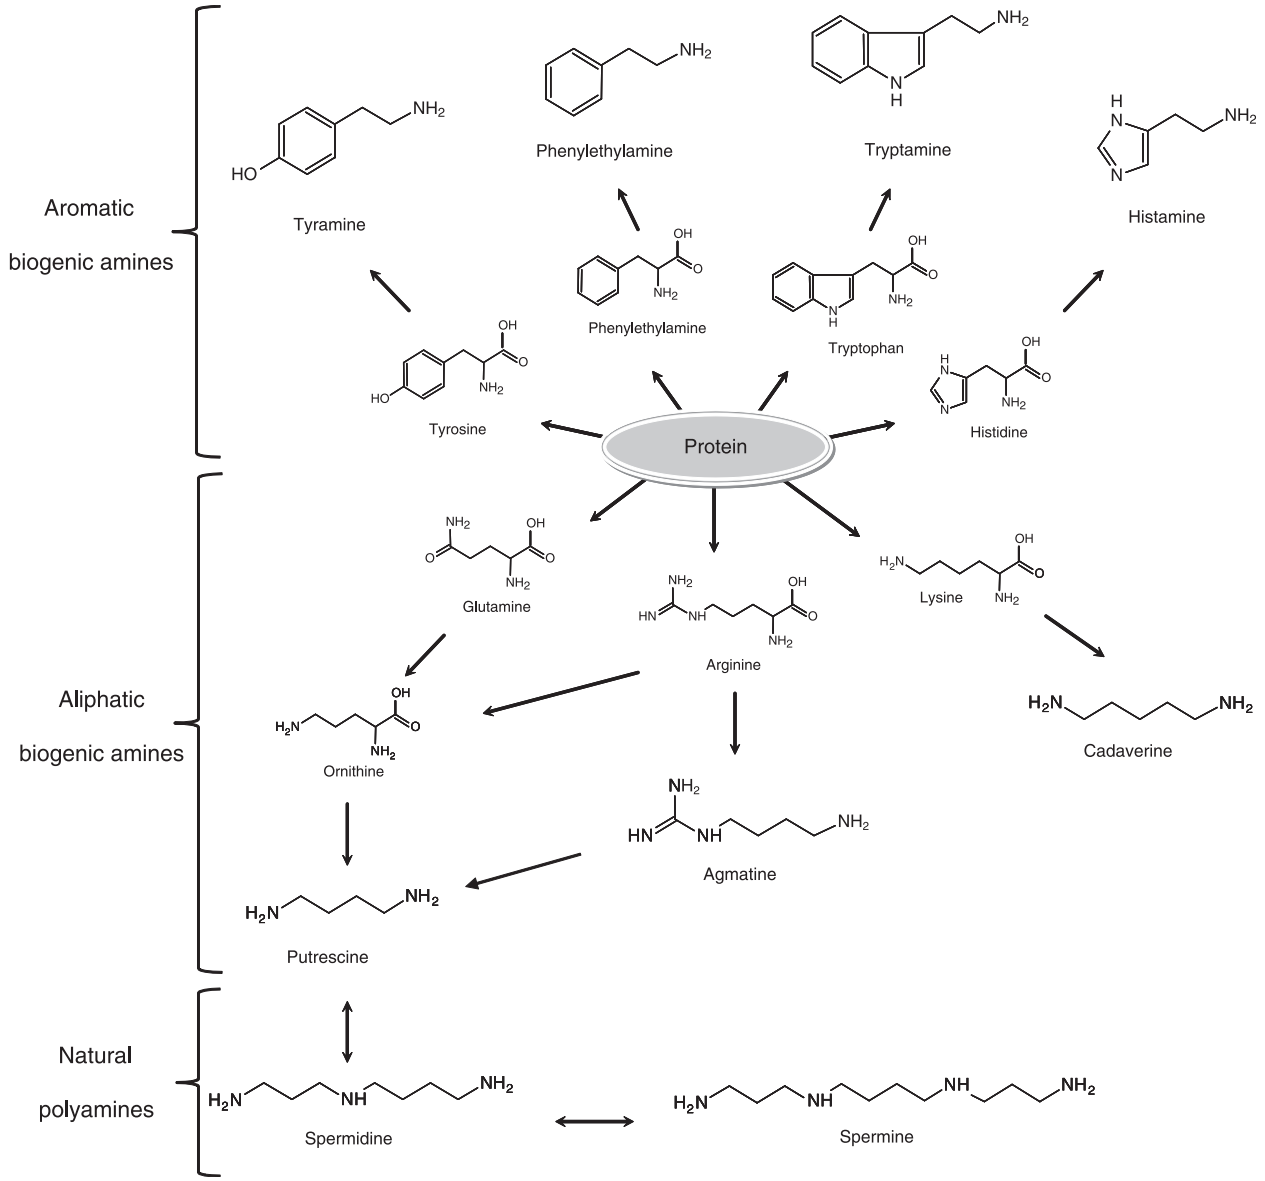

Figure 1 Classification of biologically active amines.

amounts of putrescine, other amines like histamine may occur physiologically in some fresh vegetables (e.g., spinach) as well as products made from blood or liver.

Biogenic amines are found in a wide variety of foods and beverages in which microbial growth and activity has been allowed to occur during storage or production, for example, fish and seafood products, meat and meat products, cheese, fermented vegetables, and beer and wine (Table 1). The accumulation of biogenic amines in food requires the concurrence of several factors, the most important of which are: The occurrence of microorganisms bearing decarboxylase enzymes, the availability of precursor amino acids and favorable environmental conditions for the growth or activity of aminogenic microorganisms.

Several bacterial groups associated with food spoilage and/or with a technological role are known to be able to decarboxylate amino acids and produce one or more biogenic amines to a variable extent. Though the ability to decarboxylate certain amino acids is a strain-dependent property, the ability to produce specific biogenic amines is reported in some bacterial families or genera more often than others. *Enterobacteriaceae*, including mesophilic and psychrotolerant *Morganella*, *Enterobacter*, *Hafnia*, *Proteus*, etc., and *Photobacterium phosphoreum*, are the most prolific histamine-producing bacteria in fish. Many enterobacteria strains isolated from meat and vegetables have been shown to produce diamines, putrescine and cadaverine, and some particular strains have also been described as histamine producers, although less often and to a lesser extent than the enterobacteria isolated from fish products.

Tyramine is usually associated with Gram-positive microorganisms; among these, *Enterococcus* is one of the most frequent and intensive tyramine producers. Other lactic acid bacteria (including lactobacilli, lactococci, pediococci, oenococci, leuconostoc, carnobacteria, etc.) are also meaningful

[b]ND: Not detected.
[c]Not determined.

aminogenic organisms not only as tyramine producers but also as producers of other aromatic (e.g., phenylethylamine) and aliphatic biogenic amines. Although staphylococci are less frequently reported to be powerful aminogenic organisms, the decarboxylase activity has also been reported in some strains.

Other microorganisms belonging to the genera *Clostridium*, *Vibrio*, *Acinetobacter*, *Plesiomonas*, *Pseudomonas*, *Aeromonas*, and *Bacillus*, among others, have also been found to produce biogenic amines.

The function of decarboxylase enzymes in bacterial metabolism is not fully understood, although it has been described as one of the primary emergency systems involved in the acid stress response. Decarboxylases work in cooperation with a membrane antiporter protein, thus enabling amino acids to be transported into the cell and biogenic amines excreted out of the cell. Because decarboxylation consumes a proton, biogenic amine formation contributes to the regulation of intracellular pH and it may also help to increase the pH of the extracellular medium with low buffer capacity. Apart from the alkalization effect, amino acid decarboxylation can also induce metabolic energy generation through a proton motive force.

Decarboxylase synthesis and activity are induced at acidic pH and generally by the presence of precursor amino acids. Therefore, foods containing high levels of precursor may be more susceptible to biogenic amine accumulation, as is the case of histamine accumulation in scombroid fish species that are rich in free histidine. Except for the pyruvoyl-dependent histidine-decarboxylase of Gram-positive bacteria, decarboxylase enzymes require pyridoxal-5′-phosphate (a form of vitamin B_6) as a cofactor. Besides the presence of the cofactor, the proteolysis phenomena and/or yeast autolysis occurring in products undergoing fermentation may also offer a favorable amino acid concentration for biogenic amine production.

In general, biogenic amine accumulation can be expected in almost all food products that contain proteins or certain amounts of amino acids and are subjected to conditions that allow the microbial activity to occur (such as storage and fermentation). Nevertheless, the total content of the different amines strongly depends on the nature of the product, the microorganisms present and the environmental conditions. In perishable products, temperature and storage time probably have a major impact on the accumulation of biogenic amines, mainly not only via the growth of potentially aminogenic organisms but also through the expression of metabolic activity. Other factors such as pH, atmosphere, food ingredients (salt, sugar, etc.), preservatives, and preservation processes, etc., also play a role in the modulation of the aminogenesis process. The influence of these environmental factors is not always well known and it may even be controversial. For instance, despite the fact that an acidic pH may enhance the bacterial-decarboxylase activity, a rapid and sharp acidification in food fermentation inhibits contaminant bacteria and the consequent formation of biogenic amines. Therefore, the type and the amount of biogenic amines in a product depends on multiple and complex variables that may interact among each other, making it difficult to characterize the effects of each technological factor on the aminogenesis during food fermentation, ripening, and storage.

Relevance of Biogenic Amines in Food

Biogenic amines in food are relevant from both the safety and quality point of view. Some biogenic amines have bioactive properties and have been associated with certain adverse health reactions. Nowadays, however, the presence of biogenic amines in food is significant from a hygienic and technological perspective, as their occurrence may be a sign of the unwanted microbial activity and reduced microbiological quality.

Toxicological Risks of Biogenic Amines

Although the health concerns are well documented, information concerning the mechanisms, the toxic doses and the individual factors governing the severity of the reactions is inconsistent. At the moment, it is not possible to perform an accurate and complete risk assessment, mainly because there is no sufficient data available to reasonably estimate the level of illness caused by exposure to dietary biogenic amines. However, the risk profile approach in relation to biogenic amines in food can be applied to describe food safety concerns, as recently done by the European Food Safety Authority (EFSA) BIOHAZ panel (for more details see references in the Further Reading section).

Hazard Identification

Histamine, tyramine, and to a lesser extent phenylethylamine are the main dietary biogenic amines associated with several acute adverse reactions in consumers (Table 2). The bioactivity of biogenic amines mainly involves vasoactive reactions, although they can also be active at a neurological level as neurotransmitters. The health problems that may occur following the ingestion of food containing biologically active amines include histaminic intoxication (also known as histamine fish poisoning (HFP)), food intolerances due to enteral histaminosis, interactions between tyramine and MAOI drugs, and food-induced migraines.

Histamine, as a local hormone and neurotransmitter, has a physiological role in several functions including gastric-acid secretion and local immune response. In animals, histamine causes vasodilatation and subsequent hypotension as well as dermal (flushing and pruritus), gastrointestinal (diarrhea, cramps, and vomiting) and neurological (headache and dizziness) disorders, mediated through the specific histamine receptors of cellular membranes. The most globally widespread form of histamine toxicity is the so-called HFP, which accounts for up to one-third of the seafood-borne outbreaks in humans in countries where statistics are available (e.g., Wales, England, USA, etc.). Many species of marine fish, particularly those containing high concentrations of free histidine (i.e., *Scombridae*, *Scomberesocidae*, mahi-mahi, escolar, sardines, garfish, etc.), have been incriminated in HFP outbreaks. Histamine intoxication and intolerance may also be caused by other histamine-rich food (e.g., cheese, meat products, etc.), although knowledge in this area is even more scarce than for HFP.

Tyramine and phenylethylamine are vasoconstrictive, leading to increased blood pressure if a higher than physiologically normal concentration reaches the blood stream.

Table 2 Hazard identification

	Histamine	*Tyramine (β-phenylethylamine)*	*Putrescine, cadaverine*
Mechanisms of toxicity (acute)	Vasodilatation and psychoactive	Vasoconstriction (release of adrenaline)	Saturation of intestinal barriers (if ratio is 5:1)
Clinical symptoms	Cardiovascular (flushing, urticaria, hypotension, edema, and headache) Gastrointestinal (cramps, diarrhea, and vomiting) Neurological (pain and itching)	Increase in blood pressure, fever, perspiration, and vomiting. Pupil dilatation, lacrimation, etc. Headache and migraine	Enhances the effects of other biogenic amines
Duration	1 min–3 h 'incubation' 3–6 h duration (<12 h)	Few min 'incubation' 10 min–6 h duration	–
Severity	Low to moderate	Low to severe	–
Outbreaks	Mean annual rate (cases/year/million people) of histamine fish poisoning varies among countries, for example, from 31 in Hawaii, USA; 4.9 in Denmark; 3.1 in New Zealand; 2.5 in France; 2.1 in Finland; 1.5 in Taiwan; 1.1 in Japan; <1 in UK, Norway, Switzerland, South Africa, Australia, USA, Sweden, Canada, Netherlands, Philippines	Limited information is available due to a lack of official records	–

Besides hypertension, tyramine and phenylethylamine may also provoke headache, perspiration, vomiting, pupil dilatation, etc. Hypertensive crises and migraines caused by the consumption of tyramine-rich food have occasionally been recorded in scientific publications, but there is limited official epidemiological data available in this respect.

The clinical signs following consumption of biogenic amine (both histamine and tyramine) appear between 30 min and few hours after ingestion and usually disappear within 24 h. The severity of the reactions varies, but it may be considered mild because medical attention is only occasionally required. The mild nature of the symptoms, together with misdiagnosis and the lack of mandatory or adequate systems for reporting these food-borne diseases, account for the poor, or lack of, statistics on the incidence of intoxication due to dietary amines.

The diamines putrescine and cadaverine are not toxic on their own, but they may enhance the absorption of vasoactive amines due to the saturation of intestinal barriers. It has been suggested that the mechanisms involve competition for the mucin attachment sites and detoxification enzymes.

Biologically active amines present in food products have been recognized as precursors of nitroso compounds with the potential carcinogenic activity, which constitutes an indirect additional risk associated with dietary amines. Nitrosamines result from the action of nitrite on secondary amines, which in turn may derive from primary amines (such as aliphatic diamines and polyamines) through a cyclation reaction under certain conditions. However, according to the available information, dietary sources of nitrite and *N*-nitroso compounds, including those derived from biogenic amines, contribute little to the body pool of nitroso compounds; instead the main source comes from the bacterial and mammalian metabolism of ingested nitrates.

Hazard Characterization

Even though there is compelling evidence concerning the involvement of biogenic amines as causative agents of the above-mentioned adverse food reactions, the varying amounts in the products responsible makes these hazards difficult to characterize. There is also a great deal of variability and uncertainty regarding the factors that influence the human clinical response to a given quantity of a biogenic amine. Besides the genetic disposition or the physiological status, several environmental factors such as diet and medication can temporarily modify individual susceptibility. The capacity of detoxifying enzymes (monoamine (MAO) and diamine oxidases (DAO), as well as histamine *N*-methyltransferase (HMT)) at intestinal and hepatic level may be reduced by food components, such as other amines (diamines and polyamines), alcohol and its metabolite acetaldehyde, phenols, etc. However, diet (especially fat and proteins) may reduce biogenic amine bioavailability. The influence of certain medication seems to be far more critical, because it is not only the well-known antidepressant and antiparkinson MAOI drugs that increase susceptibility to biogenic amines but also a considerable number of other commonly used drugs (e.g., acetylcysteine, clavulanic acid, metoclopramide, verapamil, isoniazid, cephalosporins, etc.) also present DAO-inhibition as a side effect.

Bibliographical information regarding the dose of histamine that can trigger toxic reactions is not consistent. From epidemiological studies, most incidents of HFP involve fish with high histamine content (600–3000 mg kg^{-1}). The attack rates are also variable, from 10% to 80% depending on the outbreak. Some reviews and textbooks have suggested guideline levels to define the oral toxicity of histamine (some recorded in Table 3), which reflect 'expert opinion,' but they may be inadequately supported by specific clinical studies. Unfortunately, histamine poisoning has hardly ever been reproduced in clinical studies. The limited results of toxicological studies, usually performed with a reduced number of individuals, have also been compiled in Table 3.

The specific toxicity derived from the vasopressor effect of tyramine can be found from clinical studies focused on the

Table 3 Hazard characterization

	Dose–response relationship (toxic threshold)	*Population affected*
Histamine		
Histamine poisoning (enteral histaminosis)	5–6 mg threshold level	
	8–40 mg light intoxication	
	70–1000 mg moderate intoxication	
	1500–4000 severe intoxication	General – all population; higher sensitivity in DAO deficient individuals
	8–40 mg slight	
	>40 mg moderate	
	>100 mg severe	
	8–40 mg mild poisoning	
	70–1000 mg moderate intensity disorders	
	1500–4000 mg severe incidents	
	100–180 mg in a meal	25–50% of tested volunteers
	75 mg pure histamine (in peppermint tea)	50% of tested volunteers (healthy females without history of food intolerance)
	90 mg in a meal	25% of tested volunteers
	120 mg (intraduodenal administration)	70% of patients suffering from chronic urticaria (susceptible volunteers)
Tyramine (β-phenylethylamine)		
Hypertensive crisis	200–2000 mg TY ($ED_{50} \approx 1400$ mg)	Healthy population (100%) (50%)
PD30[a] dose of TY causing up to 30 mm Hg SBP increase	6 mg mild symptoms	Classical MAOI[c]
	10–25 mg severe	
	50–100 mg tolerated	RIMA (3rd generation of MAOI: reversible/selective)
Migraine[b]	100 mg TY	80% migraine sufferers (0–15% nonmigrainous)
	3 mg PHE	50% migraine sufferers
	5 mg PHE	Intoxication symptoms

[a]Increase of systolic blood pressure up to 30 mm Hg by a given dose of tyramine. Only those clinical studies with human volunteers, in which tyramine is administered orally in a meal have been considered.

[b]Scientific literature (from 1967 to 2001) is barely able to prove the relationship between tyramine and migraine.

[c]The following potentiation factors have been described for MAOI drugs: tranylcypromine 20–56; clorgyline 10; brofaromine 10; phenelzine 13; moclobemide 5–7; befloxatone 5–8; selegiline 2–5.

study of the interaction between dietary tyramine and MAOI drugs. These studies prove that the intestinal barriers to tyramine in nonmedicated healthy volunteers (placebo groups) are quite effective, because 200–2000 mg of tyramine is needed to cause a minimal pressure response (Table 3). For those individuals medicated with MAOI drugs, lesser amounts of dietary tyramine can produce similar effects. The intensity of the MAOI-enhancing action depends on the nature of the drugs (see Table 3 for enhancing factors associated with several MAOI compounds). Third generation MAOI drugs have progressed in safety compared with previous ones, because their action is reversible or selective for the MAO-A or MAO-B isoenzyme.

Tyramine and phenylethylamine have also been identified as causative agents of certain migraines. However, migraine is a multifactorial problem that is not only affected by one dietary component but also by other environmental, physiological, and psychological factors. Limited research has been performed in the past, specifically on the threshold dose of biogenic amines triggering migraine (Table 3), yet the accuracy of their experimental design is doubtful and the results can hardly be considered conclusive.

Exposure Assessment

Table 1 shows some data on the biologically active amine contents of different types of food products. It shows the average value, standard deviation, median, and range, reflecting the wide variability that is characteristic of the presence of biogenic amines in food.

Fresh, unspoiled food usually contains low levels of biogenic amines, if any. Some products, such as fruit and vegetables, have a significant biogenic amine content as a natural constituent. Nevertheless, fermented foods constitute the major dietary source of biogenic amines. The manufacture of these products presents favorable conditions for the bacterial production of biogenic amines, though the type and amounts accumulated vary widely between products, producers, and even between batches of a specific product. In fermented foods, besides the potential aminogenic activity of certain bacteria responsible for the fermentation, the accumulation of biogenic amines can also stem from the unwanted activity of contaminant bacteria present in the raw materials.

Among fermented foods, cheese and dry-fermented sausages are generally associated with the presence of large amounts of biogenic amines, especially tyramine, ranging from

not detected to values higher than 600 mg kg^{-1}. The diamines putrescine and cadaverine are also quite common in fermented products, though the levels may vary more and are often lower than tyramine. The occurrence of histamine varies even more. The amounts of histamine reported in the literature are relatively low in the majority of the sausage and cheese samples, though in some cases histamine levels are notably high. The occurrence of lower amounts of other biogenic amines, such as phenylethylamine and tryptamine, is generally accompanied by a high accumulation of tyramine and/or diamines.

In fermented beverages (e.g., wine and beer), tyramine and histamine contents are much lower than those reported for other fermented foods, because their contents usually do not exceed 5 mg l^{-1}, although in some cases the histamine levels have reached approximately 50 mg l^{-1}. Putrescine has also been described, with a natural (from grapes, malt, and hops) and microbial origin. By contrast, cadaverine has hardly been found in wine but occasionally described in beer.

To assess consumer exposure to biogenic amines in food and the potential risks, it is important to consider that multiple sources of biogenic amines with a variable range of concentrations are possible. Moreover, a reasonable estimate of the quantity (i.e., serving) of the different food products consumed in a meal should be taken into account. Although the overall exposure is difficult to estimate, it is clear that certain food combinations, for example, a meal based on fermented sausages and cheese, accompanied by beer or wine, would be highly probable to reach hazardous biogenic amine thresholds, especially in sensitive individuals.

In a recent assessment published by the EFSA, the biogenic amine contents and the food consumption patterns were combined to provide the exposure values in terms of mg per day as an estimation of a high exposure scenario. For histamine, the food categories which pose a major risk for consumers were fish and fish products (nonfermented) followed by fermented sausages, cheese, and fish sauces. For tyramine, beer (due to the occasional high consumption values recorded), cheese, fermented sausages, and fermented fish were identified as the major exposure sources.

Biogenic Amine Index (BAI) to Assess Food Hygienic Quality

As a result of their microbiological origin, biogenic amines have been used as criteria to assess the hygienic quality of fresh food not only fish and meat but also food products in which the bacterial activity is related to contamination incidents. Significant accumulation of biogenic amines generally occurs before the appearance of sensorial signs of spoilage. Moreover, biogenic amines are resistant to many physical and chemical processes, which is an advantage compared to other hygienic quality indicators (e.g., microbial counts) that can be inactivated by a number of food-processing procedures. The application of a BAI, which includes multiple amines, may increase the specificity and selectivity compared to a single biogenic amine. Most of the BAI consists of a sum of biogenic amines, mainly diamines and histamine, but tyramine has also been considered because it usually increases during fish and meat storage. The natural polyamines spermine, spermidine, and agmatine have also been included in some BAI, dividing the amount of biogenic amines. There is no general agreement on BAI values that denote spoilage because the production of amines depends on the product and many other factors. Thus, the type of microbial populations present in a particular food responsible for alteration can change the profile of amines formed.

In general, the application of a BAI as a criterion for the hygienic quality assessment of fermented products (e.g., fermented sausages, cheese, etc.) is more difficult because the occurrence of biogenic amines cannot be directly and exclusively associated with the quality of the raw materials.

Although there are no legal guidelines that restrict the presence of biogenic amines in wine, it has been reported that different countries have applied specific histamine thresholds to reject wine imports: 2 mg l^{-1} in Germany, 5–6 mg l^{-1} in Belgium, 8 mg l^{-1} in France, and 10 mg l^{-1} in Switzerland.

Legislation

Currently from a legal perspective, maximum legal limits are only set for histamine in certain fish and seafood products, mainly from fish species associated with high levels of histidine (Table 4). The maximum histamine levels permitted and the sampling plans differ depending on the country, with the USA having the most restrictive.

Analytical Methods

Determination of Biogenic Amines in Foods

From an analytical perspective, determining the biologically active amines in food and beverages is not a straightforward issue, mainly due to the variety of chemical structures, the wide range of concentrations and the complexity of most of the food matrices (e.g., high content of free nitrogen compounds and high fat content). Determining the biogenic amines and polyamines in food usually involves two well-differentiated phases: Their extraction from the food sample and their analytical determination.

The aim of extracting amines is to separate them from other potentially interfering compounds and it is an important step to obtain accurate results. The most widely used extraction solvents include acid solutions, such as hydrochloric acid (e.g., 0.1 M), trichloroacetic acid (e.g., 5–10%), and perchloric acid (e.g., 0.4–0.6 M) as well as organic solvents such as methanol, acetone, acetonitrile–perchloric acid, or dichloromethane–perchloric acid.

Amine determination can be carried out using a variety of approaches including biologic, enzymatic, spectrofluorometric, and chromatographic procedures. The last of these are used extensively because several amines can be determined simultaneously with high resolution, sensitivity and versatility, and require a simple treatment of samples. Thin layer chromatography (TLC), gas chromatography, and micellar liquid chromatography methods have been reported in the analysis of biogenic amines. However, high-performance liquid chromatography (HPLC), and more recently, ultrahigh liquid chromatography with reverse-phase columns or ion-exchange columns are the most frequently reported procedures in the

Table 4 Regulations regarding histamine levels in fish and seafood products

Region/Country (regulation reference)	*Criteria*		*Sampling plan*	*Method of analysis*	*Products*
USA (CPG 7108.24)	Defect action level	50 mg kg^{-1}	$n=18$ fish/lot[a]	Fluorimetric AOAC 977.13 (1990)	Many fish species including tuna, escolar, oilfish, marlins, etc. www.cfsan.fda.gov/~comm/haccp4c1.html
	Hazard action level	500 mg kg^{-1}			
EU (Regulation EC 2073/2005)	Safety criterion	$m=100$ mg kg^{-1}	$n=9$ samples; average histamine below m, $c=2$ samples out of 9 are allowed to have histamine concentration between m and M	HPLC Male *et al.* (1996)	Fish species with a high amount of free histidine, i.e., species of the families Scombridae, Clupeidae, Engraulidae, Coryphaenidae, Pomatomidae, and Scomberesocidae
		$M=200$ mg kg^{-1} $m=200$ mg kg^{-1} $M=400$ mg kg^{-1}			Fish products that have undergone enzyme maturation treatment in brine, manufactured from fish species with a high amount of free histidine
South Africa (Government Notice No. R 490)	Decomposition Unsafe	100 mg kg^{-1} 200 mg kg^{-1}		Fluorimetric AOAC 977.13 (1990)	Partly cooked or uncooked seawater and freshwater foods such as prawns, shrimps, crayfish, lobsters, crab meat, oysters, mussels, clams, eels, or fish
Australia (Standard 2.2.3)		200 mg kg^{-1}		Fluorimetric AOAC 977.13 (1990)	Fish and fish products

[a]Fish should be analyzed individually or composited into, for example, 3 composites (6 fish each), then critical limit reduced accordingly, for example, from 50 to 17 mg kg^{-1}.

literature. Biologically active amines are usually detected using fluorometry, UV absorption, multichannel diode array UV, and mass spectrometry. Amine detection usually requires derivatization because most of them have low-absorption coefficients or quantum yields. The most widely used reagents to perform amine derivatization include 5-dimethylamino-1-naphtalene-sulfonyl chloride (dansyl chloride, DnCl), *o*-phthaldialdehyde (OPA), and *N*-acetylcysteine. Derivatization can be applied using pre-, post-, or on-column procedures, depending on the reagent. The reference HPLC procedure indicated by the current EU regulation to determine histamine in fish permits the detection and quantification of histamine and other biogenic amines following their extraction with perchloric acid and dansyl chloride derivatization.

Currently, a biological method based on the histamine-induced contraction of guinea pig ileum, is still recognized by the Association of Official Analytical Chemists (AOAC) as an official method for histamine determination in fish and seafood. However, in addition to the above-mentioned instrumental and biological procedures, other analytical procedures are available and recognized as more economical, less time-consuming and more straightforward techniques, especially for routine screening or controls. For instance, the official method in the USA is the AOAC procedure based on methanol–histamine extraction, purification through an ion-exchange column and fluorescence measurement following derivatization with OPA.

Enzymatic procedures involve the use of amine-specific enzymes such as DAO, MAO, and HMT, that recognize and rapidly transform the substrate into another measurable product quantified amperometrically or by colorimetry. For example, such biosensors have been used to estimate the tyramine content during the bacterial spoilage of meat, or estimate the total concentrations of histamine, cadaverine, and putrescine accumulated in fish during storage.

The immunological approach has also been developed for the analysis of histamine. Commercial kits are available to analyze histamine from aqueous food extracts (e.g., fish, cheese, or sausage) through an enzyme immunoassay. However, the antibodies used in these tests require chemical derivatization of histamine before analysis, using toxic reagents (*p*-benzoquinone) and being also time-consuming. Alternatively, polyclonal antihistamine antibodies that recognize intact histamine have been included in commercial competitive direct enzyme-linked immunosorbent test kits, which seem to provide results comparable with the official fluorometric or HPLC methods.

Determination of Microbial Amino Acid Decarboxylase Capability

Several methods have been described to study the amino acid decarboxylase activity or, at the end, biogenic amine production by microorganisms. Whether or not certain enzymes exist in a particular bacterium depends on its genetic capabilities. Based on polymerase chain reaction (PCR) procedures, specific bacteria showing aminogenic potential can be detected with high speed and sensitivity. The PCR detection

system is based on the use of primers defined according to similarities in the deoxyribose nucleic acid sequence of the genes corresponding to the specific decarboxylase enzyme (e.g., histidine, tyrosine, ornithine, and lysine decarboxylase). However, the presence of the particular amino acid decarboxylase gene does not prove that whether the enzyme will be functional or amines will be formed. Similarly, the PCR test cannot determine whether a food product will contain low or high amine levels. However, the test helps to estimate the potential risk of biogenic amine formation.

As an alternative to molecular methods, assays on growing or resting cells may be performed. The composition of the medium used to grow the microorganism is of great importance because the expression and activity of decarboxylase enzymes depend on environmental factors. One extensively used screening procedure involves the use of a differential medium containing a pH indicator, such as bromocresol purple, and the addition of the precursor amino acids. In a positive result, the medium turns a purple color in response to a pH shift caused by the production of the more alkaline biogenic amines from the precursor amino acids. Occurrence of false-positives is possible due to the formation of alkaline compounds different from biogenic amines, and false-negatives may occur as a consequence of the acid production from the fermentative activity. Therefore, a suitable, more specific and sensitive alternative would perform a quantitative analysis of the biogenic amines potentially formed in the culture broth using one of the chemical, immunological or instrumental procedures described above (e.g., HPLC or TLC).

Control Measures

In the field of food safety, the presence of histamine seems to be the greatest concern associated with biogenic amines. Other amines in food may be of minor concern for the general healthy population, especially compared to the current problems regarding emerging pathogens. However, no positive effect can be attributed to food biogenic amines and furthermore, a proportion of the population may be vulnerable to food intolerances or drug interactions. Therefore, efforts to reduce the occurrence of biogenic amines in food deserve to be prioritized and the challenge for the food industry to offer products with biogenic amine levels as low as possible is justified. This last objective is consistent with the current trends that aim to minimize the risks, optimize the quality of food and even increase the prestige of food products through an added value with respect to consumer health. In this case, the added value is achieved through the reduction or elimination of biogenic amines as undesirable compounds. Moreover, the absence (or very low levels) of biogenic amines in foods could be considered as a quality attribute derived from optimal hygienic and technological practices.

Current knowledge about the actual causes of biogenic amine formation in certain foods has made it possible to design measures to prevent or at least reduce their accumulation during the manufacture and storage of food. Product improvement can be achieved using the following approaches:

(a) Assurance and improvement of the hygienic quality of raw materials and production processes because contaminant microbiota are responsible for biogenic amine formation in many products. Therefore, in addition to good manufacturing practices, food quality and safety management based on hazard analysis and critical control points is essential. The time/temperature binomial is the most critical and determinant risk factor in biogenic amine formation in most fresh and lightly preserved meat and seafood products, as well as in the raw materials (of animal and plant origin) used in the preparation of cooked, ripened, or fermented products. Therefore, storage temperature constitutes the most important control measure to limit biogenic amine accumulation. Other factors, such as packaging atmosphere, salt and other preservatives also inhibit or reduce the potential of aminogenic activity and should be taken into account with regards to lightly preserved fish, meat, and vegetables.

Predictive models of biogenic amines in perishable products, as a function of time and temperature, could be used to avoid storage conditions and time periods resulting in hazardous products. This approach has already been developed for histamine accumulation in seafood, which is particularly associated with growth and histamine formation by *Morganella psychrotolerans* and *Morganella morganii*. The model, included in the Seafood Spoilage and Safety Predictor tool (SSSP v3.1, 2009) provides valuable predictions to determine critical combinations of storage time and temperature enabling to control histaminogenesis in fish.

In the case of fermented foods or beverages, one of the most critical point is also the hygienic status of the raw materials because they are the main source of microbiota that will subsequently be present during fermentation. The hygienic quality of the raw materials may be improved by decreasing microbial charge through sterilization or pasteurization, a common practice in the cheese-making industry. However, in fermented meat products, temperature causes detrimental changes in the raw materials and it is therefore not possible to apply conventional heat treatments. Alternative nonthermal technologies may provide solutions in this case. The application of high-pressure treatments to the raw materials (milk and meat) could be effective in improving the hygienic status and thus reducing the biogenic amine accumulation without changing the sensory properties significantly.

(b) Degradation of biogenic amines once they have been formed, for example, through the use of amine-oxidase positive organisms. Attempts to reduce biogenic amine contents through product irradiation have also been described. Nevertheless, the efficiency of these procedures has not been fully demonstrated and they may even be controversial because in some cases the elimination of biogenic amines could cover up improper hygienic practices.

(c) Implementation of production techniques that inhibit the formation and accumulation of these substances. For foods in which fermenting microbiota may also show the aminogenic activity, the implementation of specific technological procedures can result in effective control measures, along with good hygienic and manufacturing practices.

To minimize biogenic amine accumulation during food fermentation and ripening, the growth and activity of potential aminogenic microorganisms must be reduced. A suitable sausage formulation (by adjusting the type and amount of fermentable sugar, spices, and preservatives) and technological

parameters (temperature and relative humidity) contribute to a proper and quick selection of desired fermentative microbiota. The growth and fermentative activity of these bacteria (mainly lactic acid bacteria) limits the action of contaminant microorganisms and their potential biogenic amine formation. Nevertheless, spontaneous fermentation can also produce notable amounts of biogenic amines. It has been widely demonstrated that the use of accurately selected microorganisms added as starter cultures constitutes one of the most effective control measures for biogenic amines in fermented products. To achieve this, starter cultures must lack aminogenic potential, but they must also be competitive and well adapted to the product fermentation environment. The effectiveness of starter cultures is dependent on the hygienic quality of the raw materials, because the starter culture will compete with the initial microbial load during product fermentation. In addition, technological conditions such as product formulation and processing temperature must be accurately applied to ensure optimal implantation of the starter culture and thus limit the growth and activity of undesired microorganisms.

Within this framework, the so-called 'low-histamine technology' applied to fermented beverages (e.g., wine) has been described, which is based on the assurance of the hygienic quality of the raw materials, the addition of selected starter cultures and the use of specific production techniques that inhibit the formation of histamine. This technology has already been implemented successfully in the manufacturing of traditional wines in certain countries, for instance Switzerland and Spain. The challenge facing the food industry is to extend this technology to other biogenic amines and other products. Indeed, the implementation of 'low biogenic amine technologies' will enable food manufacturers to produce safe and high-quality amine-free food products.

PROCESSING CONTAMINANTS

Chloropropanols and Related Esters

C Crews, The Food and Environment Research Agency, York, UK

Glossary

EFSA The European Food Safety Authority, an EU risk-assessment body for food and feed safety. It provides independent scientific advice to the European Commission, national authorities, the food industry, and other stakeholders.

Gas chromatography (GC) A means of separating volatile compounds by passing a stream of gas through a narrow heated glass tube coated on the inside with an absorptive phase.

Headspace GC A means of sampling volatile compounds from food for analysis by GC.

Mass spectrometry (MS) An instrumental means of detecting, identifying, and measuring compounds by producing and separating ions. Used as a detector for gas chromatography/mass spectrometry (GC–MS).

Chloropropanols

Chloropropanols are contaminants of food safety concern that are produced by chlorination of glycerol or glycerides by reaction with chloride ions. They were initially associated with the flavor-enhancing ingredient hydrolyzed vegetable protein (HVP or acid-HVP) in which they were formed by the action of strong hydrochloric acid during the manufacturing process, thus they have been classified and known as food-processing contaminants. Later, simple chloropropanols were found to be formed under the milder conditions of domestic cooking, and fatty acid esters of chloropropanols were found to be produced during the refining of edible vegetable oils.

A range of chloropropanols were found in HVP by Professor Jan Velisek at the Institute of Chemical Technology in the Czech Republic in 1979. HVP is made by the treatment of vegetable materials such as defatted oil seeds (soy, rapeseed, and peanut), and protein from maize, wheat, and rice with strong (4–6 M) hydrochloric acid at high temperature and pressure, typically 8 h at 100–130 °C. The acid hydrolyzes the proteins to give a range of small molecules including amino acids and peptides with flavor-enhancing properties. The reaction mixture is neutralized with sodium hydroxide or sodium carbonate to give a salty solution that was used to help flavor soups, stocks, and savory foods such as extruded corn snacks.

The chloropropanols were found to have been formed by the reaction of chloride with glycerides in the fat associated with the proteinaceous material. Chlorine atoms replaced some of the fatty acids in the triacylglycerols to form a mixture of compounds including 1- and 2-monochloropropanols, 2- and 3-monochloropropanediols (2-MCPD and 3-MCPD), 1,3- and 2,3-dichloropropanols (1,3-DCP and 2,3-DCP), and fatty acid esters of these compounds. The structures of the major compounds are shown in Figure 1. They can be considered as analogs of glycerol, and are closely associated with the toxic nonchlorinated compound glycidol (3-hydroxy-1,2-epoxypropane). 1,3-DCP is a known carcinogen and 3-MCPD is suspected to be so. Glycidol is a genotoxic

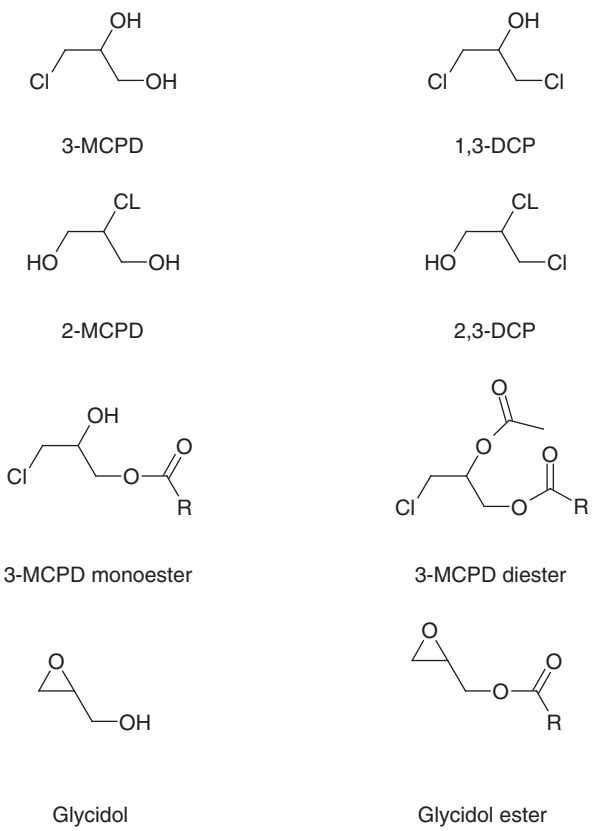

Figure 1 Structures of the major chloropropanols.

 doi:10.1016/B978-0-12-378612-8.00210-9

carcinogen in animals and has been classified as probably carcinogenic to humans by the International Agency for Research on Cancer. It is highly reactive and difficult to measure and has not been the subject of much study. Glycidol esters with fatty acids are, however, associated with MCPD esters and have become of considerable interest.

MCPD esters exist as either mono- or diesters of each of the fatty acids found in oils, as there are about seven common fatty acids, and taking into account the possible positional isomers there are approximately 100 different MCPD esters.

The discovery of chloropropanols in acid-HVP caused concern because many chlorinated compounds are toxic and it was known that 1,3-DCP was a genotoxic carcinogen. Toxicity testing began on the other major chloropropanol, 3-MCPD, and simultaneously the industry took steps to remove the chloropropanols from acid-HVP. The chloropropanol esters were not problematic as they were insoluble in the aqueous acid-HVP solution. The monochloro- and dichloropropanols were volatile and could be removed by evaporating the acid-HVP solution to give a dry product. Monochloropropanediols were more difficult to remove but a major reduction was achieved by careful control of the acid hydrolysis step and incorporating a postproduction alkaline hydrolysis step that cleaved the chlorine from the molecules to form harmless glycerol.

Improvements in analytical methods required to detect the lower levels of 3-MCPD in acid-HVP led to the discovery that it could also be found in certain foods, particularly those that contained salt and fat and were heated or had long storage periods, such as cereal products, canned fish, and salamis. High levels were reported in some soy sauces, although this was probably due to the use of poor quality acid-HVP.

In 2006, it was reported that fatty acid esters of 3-MCPD were present at high levels in refined vegetable oils. These compounds had been somewhat neglected since their discovery in acid-HVP, apart from an early report of their occurrence in some samples of goat's milk. Refined vegetable oils are heavily used within the food industry. Palm oil is particularly popular on account of its low price and adaptability; unfortunately relatively high levels of chloroesters are formed in palm oil on refining. The large number of fatty acids and the possibility of mono- and diesterification of the glycerol skeleton led to the formation of many MCPD esters, including both 3-MCPD and 2-MCPD monoesters and diesters, in which the fatty acid profiles matched those in the oil. They are collectively known as MCPD-esters or bound MCPD, although few bound forms other than fatty acid esters have been reported.

It is known that the esters are formed during the oil refining process and mostly in the deodorization stage. In this the vegetable oils are treated with steam at high temperature and pressure to remove small molecules and free fatty acids that would otherwise taint the oil. It has been demonstrated that the agents responsible for MCPD ester formations are, very probably, naturally occurring inorganic and organic chlorine compounds present naturally in the oilseed that release chlorinating species in the deodorizer. There is concern over the potential for MCPD esters to contribute to the dietary intake of 2- and 3-MCPD from their hydrolysis by lipases in the gastrointestinal tract.

Chloropropanols in Food

MCPD and DCP in HVP

In 1990, the UK Ministry of Agriculture, Fisheries, and Food conducted surveys of the levels of 3-MCPD and 1,3-DCP in acid-HVP and again in 1992, which showed a decline in levels over this period. In the 1990 survey, 23 out of 39 samples tested contained 3-MCPD above 10 mg kg^{-1} but only a single sample contained 1,3-DCP, this at 0.05 mg kg^{-1}. Of the 34 acid-HVP samples surveyed in 1992, 7 contained 3-MCPD in excess of 10 mg kg^{-1} and a further 8 between 1 and 10 mg kg^{-1}. No samples contained 1,3-DCP. In April 1998, a further survey of 3-MCPD in 50 samples of acid-HVP using a more sensitive analytical method found that 21 samples did not contain detectable 3-MCPD. Of the remaining samples, 28 contained between 0.01 mg kg^{-1} and 0.1 mg kg^{-1}, and one that was possibly made with acid-HVP from older stock contained 2 mg kg^{-1}. No further government surveys were carried out, and the food industry has in general replaced acid-HVP by safer flavor enhancers.

MCPD and DCP in Soy Sauces

Surveys in continental Europe indicated that some soy sauces in Denmark, Germany, Sweden, and the Netherlands contained 3-MCPD at levels up to 124 mg kg^{-1}. Government surveys were made of approximately 100 sauces sold in the UK in 2000 and again in 2002. In 2000, 3-MCPD was quantified, after normalization to 40% dry matter, at or above 0.02 mg kg^{-1} in 25 of the samples and over 1 mg kg^{-1} in 16 samples, the highest containing 82.8 mg kg^{-1}. 2-MCPD was found in 26 samples at up to 17.6 mg kg^{-1}. 1,3-DCP was detected in 17 samples between 0.006 and 0.345 mg kg^{-1}, and 2,3-DCP in 11 samples at levels of 0.006–0.043 mg kg^{-1}.

Action was taken to remove the contaminated brands from the market in the UK and in several other countries, and the publicity this entailed produced a short-lived food scare in the UK (Figure 2).

Premium soy sauces are usually labeled as 'traditionally brewed' and are made by a fermentation process in which enzyme action hydrolyzes the proteins. These sauces should not contain materials made by the modern chemical hydrolysis. Government inspections in China revealed that many sauces were made in small factories without adequate controls and these were closed down. The soy sauce industry also found incidences of counterfeiting in which acid hydrolyzed products were labeled as traditionally brewed and sold with forged labels imitating those of premium sauces.

Two years later, a survey targeted at the same brands of soy sauce found 3-MCPD in only 8 of 99 samples, 2-MCPD in 3 samples, and 1,3-DCP in only 1 sample. The highest level of 3-MCPD was 35.9 mg kg^{-1}.

In surveys carried out in China between 2002 and 2004, 37 traditionally brewed soy sauce samples contained 3-MCPD below 0.02 mg kg^{-1}. All of 629 retail soy sauce samples contained 3-MCPD ranging between 0.005 and 189 mg kg^{-1}, and over 12% had levels exceeding the Chinese limit of 1 mg kg^{-1} for acid-HVP.

2-MCPD (maximum 20.3 mg kg^{-1}), 1,3-DCP (maximum 8.3 mg kg^{-1}), and 2,3-DCP (maximum 0.5 mg kg^{-1}) were detected in 48%, 19%, and 4% of the soy sauces, respectively.

Figure 2 Press reaction to finding chloropropanols in soy sauces.

Source: Adapted from data published by the UK Food Standards Agency (http://www.food.gov.uk/) on surveys of process contaminants in UK retail foods.

In all, 80% of acid-HVP samples contained 3-MCPD in excess of 1 mg kg^{-1}. Relatively high levels of 3-MCPD were also found in soy sauce powder, oyster sauce, beef products, instant noodle spices, and health foods.

MCPD in Other Foods

Several surveys have been carried out to determine the levels of 3-MCPD in foods. These have invariably been targeted at foods known or thought to be at risk, such as malts and other cereal products. Only soy sauces and similar products are now monitored for the presence of 1,3-DCP, which is rarely encountered on account of the improvements in acid-HVP manufacture, and where it has been often found to be associated with small-scale fraudulent imitation of reputable brands.

In three surveys that were carried out in the UK during 2007–09 of foods of types thought likely to contain 3-MCPD, including bread, breakfast cereals, biscuits, soy sauces, and roasted coffee. Approximately 80 food samples were analyzed each year. The results are given in Table 1. The types of sample analyzed changed slightly over the years according to previous results, but there was not much variation. In all years, biscuits and crackers had the highest levels of 3-MCPD.

MCPD and Glycidol Esters

Only limited surveys have been carried out in the presence of MCPD esters in foods, and these have so far been largely restricted to vegetable oils. Further surveys can be expected when the analytical methods have been fully validated. Table 2

Table 2 Levels of 3-MCPD esters in selected foods

Food	*Range (mg kg^{-1})*
Biscuits	0.3–0.7
Bread	<0.01–0.04
Bread toasted	0.06–0.16
Cereal	<0.01–1.40
Crackers	0.1–1.14
Crispbread	0.42–0.58
Crisps	0.05–1.19
French fries	0.04–0.40
Chicken grilled	0.26–0.74
Ham	n.d.–2.64
Salami	0.88–6.41
Coffee	<0.1–0.39
Malt and beer	0.01–0.65
Frying oils (fresh and used)	<0.15–16.2
Margarine (fat portion)	<0.15–7.7
Refined coconut oil	1.42–1.69
Refined palm kernel oil	0.85–1.40
Refined palm oil	1.39–4.17
Refined vegetable oils	<0.15–18.8
Unrefined vegetable oils	<0.15–0.31
Coffee creamer	0.13–0.73

shows levels of 3-MCPD esters measured in foods selected as being likely to contain them.

Refined vegetable oils usually contain 3-MCPD esters at about 15 mg kg^{-1} but levels of up to 20 mg kg^{-1} have been encountered. 3-MCPD esters have also been reported in cooked potato products such as crisps and fries (0.021.2 mg kg^{-1}), infant formulae (0.10.6 mg kg^{-1}), and toasted cereals (0.041.4 mg kg^{-1}).

Occurrence of 2-MCPD Esters

2-MCPD esters have been determined only in 60 vegetable oils where they were usually present at 0.5 mg kg^{-1} in refined oils and from 0.2 to 6 mg kg^{-1} in refined palm oils; however, some refined oils contained up to 11 mg kg^{-1}.

Occurrence of Glycidyl Esters

Glycidyl esters have similarly only been found in refined vegetable oils and in products containing them. Table 3 provides a summary of some data for the levels of glycidyl esters in some refined and unrefined oils.

Refined oils usually contained up to 5 mg kg^{-1}, but some had up to 30 mg kg^{-1} and palm oils 0.5–10 mg kg^{-1} glycidyl esters with some identified frying oils containing almost 30 mg kg^{-1}. Infant formulae made with refined oils as ingredients contained up to approximately 3 mg kg^{-1}.

Table 3 Levels of glycidol esters in selected oils and fats

Food	*Number*	*Range (mg kg^{-1})*
Infant formula (fat portion)	56	<0.15–3.0
Animal fats, unrefined	25	<0.1
Frying oils (fresh and used)	51	<0.15–28
Mayonnaise (fat portion)	17	<0.15–0.33
Palm shortening/olein	6	0.4–15.6
Refined palm oil	20	0.30–10
Refined seed oils	15	<0.10–0.60
Refined vegetable oils (not frying)	153	<0.15–4.1
Unrefined vegetable oils	122	<0.10
Vegetable oils	10	<0.2–3.7
Margarine (fat portion)	22	<0.15–5.0

Food Safety Issues

The UK Committee on Carcinogenicity of Chemicals in Food, Consumer Products and the Environment and the Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment declared in 2001 that it was prudent to assume that 1,3-DCP is a genotoxic carcinogen and that exposures to 1,3-DCP should be reduced to as low a level as technologically feasible and also it was prudent to assume that 1,3-DCP may possess genotoxic activity *in vivo*.

The consensus of the expert committees was that the genotoxic activity of 3-MCPD seen *in vitro* was not expressed *in vivo*. Based on these evaluations, a provisional maximum tolerable daily intake (PMTDI) of 2 μg kg^{-1} bodyweight (bw) has been established. The EC has recently set a regulatory limit of 0.02 mg kg^{-1} for 3-MCPD in HVP and soy sauce. The UK Food Advisory Committee (FAC) has advised industry that 'they should continue to take all steps necessary to reduce concentrations of 3-MCPD in foods and food ingredients to the lowest technologically achievable level'. The toxicity of 2-MCPD has not been evaluated in such depth but its occurrence is much lower.

There is considerable concern about MCPD esters if completely hydrolyzed in the intestine they can provide 3-MCPD in excess of the recommended maximum intake. Toxicity testing has shown that excretion rates of 3-MCPD are lower from the esters than free 3-MCPD. The toxic effect of 3-MCPD and its esters (nephrotoxicity, normochromic anemia, and testicular toxicity) were similar but milder for esters (dipalmitate) than for free 3-MCPD.

In 2006, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) evaluated 3-MPCD and 1,3-DCP. The committee decided to maintain the PMTDI 2 μg kg^{-1} bw for 3-MCPD that it originally established in 2001. However, establishment of tolerable intake for 1,3-DCP was considered to be inappropriate because of the nature of the toxicity (tumorigenic in various organs in rats and the contaminant can interact with chromosomes and/or DNA). However, as 3-MCPD is a precursor for 1,3-DCP, the reduction in 3-MCPD levels would also reduce 1,3-DCP levels. Based on this risk assessment, the Codex Alimentarius Commission adopted a Code of Practice for the reduction of 3-MCPD during the

production of acid-HVPs and products that contain acid-HVPs (CAC/RCP 64–2008). Codex also adopted a maximum limit for 3-MCPD of 0.4 mg kg^{-1} in liquid condiments containing acid-HVPs, excluding naturally fermented soy sauce.

Exposure

The adult exposure to 3-MCPD from its esters (assuming complete cleavage in the gut) has been estimated as from 1 to 9.8 μg kg^{-1} bodyweight 3-MCPD per day. This is 0.55 times the PMTDI of 3-MCPD. There is more concern for infants whose diet is limited to infant formula, which usually includes a component of refined oils. The estimated exposure for such infants was 7.325 μg kg^{-1} bodyweight 3-MCPD per day, 3.67.7 times the PMTDI.

Comparison of consumption data and levels of 3-MCPD in food in 2001 showed that for average UK consumers the dietary intake of 3-MCPD was 0.10 μg kg^{-1} bw^{-1} per day for adults, 0.18 μg kg^{-1} bw day for young people aged 4–18 years and 0.28 μg kg^{-1} bw per day for toddlers aged 1.5–4.5 years. These figures were approximately doubled in high level consumers, but all were well below the PMTDI of 2 μg kg^{-1} bw per day recommended by JECFA.

Effects of Domestic Cooking

Domestic cooking modeled in the laboratory for a limited number of selected foods has shown that the level of 3-MCPD increases in most depending on the cooking method. Grilling and toasting increased the 3-MCPD content of bread substantially, forming up to 0.3 mg kg^{-1}. The 3-MCPD content of most cheeses also increased, resulting in levels of up to approximately 0.1 mg kg^{-1}. Microwave cooking elevated 3-MCPD levels in some cheeses to a lesser degree. Frying batters increased 3-MCPD levels to approximately 0.1 mg kg^{-1}. No studies have yet been carried out on the effects of cooking on MCPD esters.

Formation

The formation of chloropropanols is affected not only by the glyceride precursor and chloride concentration but also the temperature and water content. The major precursors are triacylglycerols, with a smaller contribution from other glycerides such as phospholipids and glycerol that are present in foods at lower levels. Glycerol is a better precursor than acylglycerols in products such as baked goods with a low water content. The optimum sodium chloride concentration is between 5% and 10%. Monoacylglycerols are better precursors of 3-MCPD than the di- and triacylglycerols. 3-MCPD production increases with increasing temperature above 160 °C.

MCPD esters have been shown to be intermediates in the formation of free MCPD in food. In refined vegetable oils, where the water content is low, they are present at much higher levels than the free forms. The esters are formed from the reaction of chloride with glycerides at the high temperature of the deodorizer during the refining process. It is believed that the chlorine source is mostly derived from chloride taken up by the plant where it is converted to a number of oil-soluble organochlorine compounds that subsequently break down in the deodorizer.

Glycidol esters do not need the chlorine source and are formed mainly from diacylglycerols during oil deodorization at temperatures above approximately 230 °C.

Analysis

Free Chloropropanols

Several methods exist for the analysis of foods for chloropropanols, all of which have the sensitivity required to give good indications of exposure and to check compliance with regulations. The original methods for measuring 3-MCPD were developed for the analysis of liquid acid-HVP and soy sauce samples. The sample is saturated with salt and the solution held on a column of diatomaceous earth. The chloropropanols are extracted into an organic solvent (ethyl acetate, diethyl ether, or diethyl ether–hexane mixtures) by passing the solvent through the column. The diatomaceous earth prevents the formation of emulsions associated with classical liquid–liquid extraction. The added salt encourages the transfer of organic compounds into the organic solvent and has been shown not to produce additional chloropropanols.

In early procedures, a first elution with diethyl ether–hexane mixture extracted the dichloropropanols and a second elution with diethyl ether alone gave the monochloropropanediols. Portions of these solutions were combined and analyzed by gas chromatography with detection by mass spectrometry (GC–MS). The presence of the polar hydroxyl groups on the chloropropanol molecules meant that derivatization was required to block the activity of these groups. The derivatization reagent that found favor was heptafluorobutyryl imidazole (HFBI). This is a very strong reagent that was able to volatilize coextracted compounds as well as the chloropropanols, and the presence of fluorine in the derivatized molecule meant that electron capture detection could also be used. The mass spectra of the derivatized chloropropanols not only had molecular and fragment ions of quite low intensity but also had ions suitable for confirmation of the identity.

Diol Derivatization

Alternative methods developed and favored in continental Europe involved reaction of the diol group of MCPD with a small range of reagents. Organic derivatives of boronic acid bind across adjacent hydroxyl groups, and the reagent phenylboronic acid (benzeneboronic acid (PBA)) can simultaneously derivatize and extract chloropropanediols when an organic solvent solution of PBA is heated and shaken with the aqueous solution of the sample. The diol groups can also be derivatized with other reagents, including acetone (forming acetonides). The acetonide and phenylboronate derivatives have intense ions in their mass spectra, giving methods with high sensitivity (Figure 3).

Dichloropropanols

As the manufacturing methods for acid-HVP improved, methods for the determination of 1,3-DCP were less in

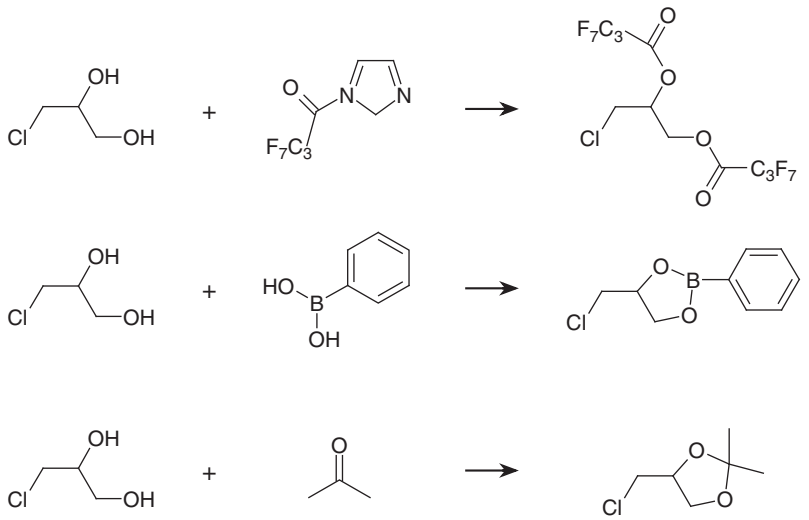

Figure 3 Derivatization of 3-MCPD. Top: with HFBI; center: with PBA; and bottom: with acetone.

demand, and the initial extraction of this compound was dropped except for some applications to the analysis of soy sauces. It also became clear that 1,3-DCP was only present where high levels of 3-MCPD were found, and so for many samples its determination was unnecessary.

As 1,3-DCP is considerably more volatile than the MCPDs it has also often been determined in soy sauces by headspace analysis, in which the sample is heated in a septum-capped sealed vial which caused partitioning of the 1,3-DCP between the sample and the gas phase. The headspace gas is sampled by a heated syringe, or by a sampling loop or the solid phase microextraction technique and the 1,3-DCP determined by GC–MS.

MCPD Esters

Esters of MCPD can be determined by two methods. In the first, the esters are transesterified or hydrolyzed to release free MCPD which is determined by any of the methods described above, and in the second method, the intact esters are determined by high performance liquid chromatography with MS (LCMS).

For direct determination the oil sample is dissolved in a solvent and either injected into an LCMS system, or a preliminary cleanup is carried out using mini columns of silica or columns of silica and C18 material arranged in tandem. Direct determination is made difficult by the fact that oils are not easily soluble in the relatively polar solvents required for LC, and the fact that the esters do not ionize easily. As individual esters are determined a large number of reference standards are required, these are now available commercially. LCMS cannot distinguish between positional isomers of MCPD esters without their prior separation by offline chromatographic techniques.

During indirect determination of MCPD esters all of the individual MCPD fatty acid esters are converted to 2- or 3-MCPD. The free 2- and 3-MCPD can be released from their esters by hydrolysis methods based on enzyme cleavage, or by acid- or alkaline methanolysis. The released 3-MCPD is measured in both the whole food sample and in the hydrolyzed fat, and the total levels of the free compounds calculated. These indirect methods of measuring MCPD esters are more complex than might appear. Acid hydrolysis is relatively slow and has concerns regarding the possible formation of MCPD during the reaction. Alkaline hydrolysis is rapid but requires care in application as the MCPD formed is rapidly dechlorinated in alkaline conditions. Alkaline hydrolysis is also not specific to MCPD esters as glycidol esters are also converted to 2- and 3-MCPD. This can be overcome by first removing the glycidol esters by pretreatment with sulfuric acid.

There is interest in separating monoesters of MCPD from diesters as their intestinal hydrolysis rates are likely to differ, but methods to achieve this separation are not yet readily available.

Glycidol Esters

Glycidol esters can be determined by adapting the indirect alkaline hydrolysis method used for MCPD esters. This entails conversion of the released glycidol to free MCPD and calculating the difference between the MCPD derived from MCPD esters and that derived from the MCPD esters and the glycidol esters together.

For the determination of glycidol esters alone, LCMS following removal of the triacylglycerols by gel permeation chromatography cleanup is also a popular technique.

MCPD and glycidol esters can be measured directly and simultaneously by injection into LC–MS systems.

Furan

C Crews, The Food and Environment Research Agency, York, UK

Furan

Furan (Figure 1) is a five-membered unsaturated cyclic ether (C_4H_4O). It is a very volatile colorless liquid with a boiling point of 31.4 °C. It is only poorly soluble in water, but dissolves in organic solvents. Furan is produced commercially for use as a chemical intermediate and as a solvent. It has long been known a component of cigarette smoke. The name is also applied as an abbreviation of polychlorinated dibenzofurans, which are associated with the environmental contaminants known as polychlorinated dioxins, these should not be confused with the monocyclic compound.

Occurrence

Furan in Food

Furan was reported as present in a wide range of foods during the 1960s. The foods included canned cooked meat, hydrolyzed proteins, bread, and coffee. These findings were not followed up to a significant degree partly because furan was not expected to be a widespread food contaminant and partly because its volatility was so high that many analytical methods aimed at screening foods for volatile components simply missed its presence. Interest in furan as a food contaminant was revitalized in 1996 when it was found during tests of the effects of ionizing irradiation used for preservation of apple juice.

The first major survey of the levels of furan in food was conducted by the US Food and Drug Administration (FDA) in 2004. The FDA published an analytical method that was used to measure furan in a range of particular foods. The survey targeted foods that were sold in cans and jars as furan formed during manufacture would not have escaped through evaporation, and included baby foods, infant formulae, canned vegetables, packaged fruits, and sauce mixtures. The highest levels were found in roasted coffee and in starchy foods such as beans that had been heated in jars or cans.

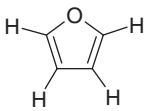

Figure 1 Structure of furan.

Furan levels of over 100 μg kg^{-1} have been found in three major food groups sampled in the US and Europe: coffee, baby food, and sauces and soups. Furan was detected in 262 of the 273 baby food samples reported by FDA (11) and European Food Safety Authority (EFSA) (10) with an average level of 28 μg kg^{-1}, and in 70 of 71 infant foods at similar levels.

Food Safety Issues

Toxicity

Furan is readily absorbed from the lung or intestine. After ingestion it primarily affects the liver where it is metabolized by the P-450 enzyme system with the formation of *cis*-2-butene-1,4-dial. This highly reactive compound is considered to be the genotoxic principle (causing damage to deoxyribonucleic acid, DNA) as it can bind to cellular nucleophiles including proteins and nucleosides. In the liver furan depletes adenosine triphosphate (ATP) irreversibly and causes double-strand breaks in DNA, leading ultimately to cell death.

Some studies of the toxicity and carcinogenicity of furan have been conducted by the US National Toxicology Program (NTP) using rats and mice, but only limited data are available, and there are no human studies. In NTP studies furan administrated by gavage in corn oil induced liver tumors in mice and cholangiocarcinomas, hepatocellular tumors, and mononuclear cell leukemia in rats. The mechanism of this carcinogenicity in rodents has not been fully clarified yet, but both genotoxic and nongenotoxic mechanisms have been proposed.

Carcinogenicity

Furan administered to rats and mice daily at between 2 and 8 mg kg^{-1} body weight per day (rats), and 8–15 mg kg^{-1} body weight per day to mice caused lesions of the liver and increased hepatocellular adenomas and carcinomas.

In a 2-year carcinogenicity study in rats and mice given repeated doses over 16 days or 13 weeks by gavage in corn oil increased mortality was seen with doses at or over 80 mg per kg body weight per day. Dose-related liver lesions were seen at high dose rats (60 mg kg^{-1}) with mice being slightly less affected. Hepatocyte proliferation and apoptosis were seen in a 3-week exposure of female animals at levels of up to 15 mg kg^{-1} body weight per day.

With lower doses of furan (up to 8 mg kg^{-1} body weight per day over 3 weeks) mice exposed to 1 mg kg^{-1} body weight per day or more had increased liver weight and incidence of

hepatic cytotoxicity. Mice exposed to 8 mg kg^{-1} body weight per day had hepatocyte proliferation.

Detailed studies of the mechanisms of tumor induction by furan compared the range of gene mutations with those of controls and concluded that the hepatocarcinogenicity might be partially attributable to genotoxicity, but the evidence is so far inconclusive. Epidemiological comparisons of coffee consumption with human cancers do not show a correlation.

Genotoxicity

Three *in vitro* studies into the genotoxicity of furan had inconclusive results. Furan has been shown not to be mutagenic but its metabolite *cis*-2-butene-1,4-dial is directly mutagenic at nontoxic concentrations in sensitive strains of *Salmonella typhimurium*. The metabolite forms adducts with DNA and proteins.

Accordingly, the International Agency for Research on Cancer has concluded that furan is reasonably anticipated to be a human carcinogen based on sufficient evidence of malignant tumor formation at multiple tissue sites in multiple species of experimental animals.

Furan is carcinogenic to rats and mice, with a dose-dependent increase in liver adenomas and carcinomas. EFSA have concluded that the weight of evidence indicates that furan is a carcinogen and is probably genotoxic.

Exposure

Previous to the discovery of the widespread presence of furan in food the major source of human intake was thought to be commercial use in the workplace. Furan has also been detected in the exhaled breath of smokers, and in the indoor air of homes. Another possible important source is in the air of kitchens and other places where food is heated.

Some typical ranges of furan levels determined in a number of foods are provided in Table 1. The data are taken mainly from surveys reported by the FDA and EFSA. It is of concern that possible human exposure is close to the equivalent doses that produce carcinogenic effects in experimental animals. The two food items that are the cause of most concern regarding exposure to furan are canned and jarred baby foods and coffee.

Table 1 Mean and maximum levels of furan (μg kg^{-1}) typically found in foods

Product	*Mean*	*Maximum*
Coffee, instant	500	2000
Coffee, roast bean	2000	5000
Coffee, roast ground	1000	6000
Baby food	25	200
Infant formula	20	50
Baked beans	25	120
Beer	5	30
Fruit juice	5	420
Meat products	20	120
Milk products	15	80
Sauces	10	120
Soups	25	220
Soy sauce	25	80
Vegetable juice	5	20
Vegetables	10	75

Coffee

Furanic compounds are important contributors to the flavor of coffee. The unroasted (green) beans are virtually free of furan but very high levels ($\sim$4 mg kg^{-1}) are formed when the beans are roasted. Handling processes including grinding lead to a reduction of furan levels but coffee powder still contains approximately 2 mg kg^{-1} furan. Other processes, such as the manufacture of instant coffee, cause a further reduction to 1 mg kg^{-1} or less.

Brewing coffee for consumption decreases the furan level much more significantly depending on the process. Espresso coffees have a high concentration on account of their small volume, and the doses from these and percolator machines are higher than that from cafetiere and instant coffee powder (Table 2).

Baby Food

A very high proportion of baby foods sold in can and jars contain significant levels of furan, typical 5–20 μg kg^{-1}, this being due to the industrial cooking, sterilization, and pasteurization processes and the presence of precursors in many of the food formulations. The highest concentrations (15–35 μg kg^{-1}) are found in canned or jarred baby foods based on pasta, meat, or vegetables, with lower levels (10 μg kg^{-1} or less) in canned or jarred infant beverages, cereals, and fruits.

Other Foods

Of the widely consumed canned and jarred foods surveyed by the FDA and EFSA canned starchy foods such as beans and soups contained the most furan, typically 100 μg kg^{-1}. Some other foods (malted products, gravies, and caramels) contained higher levels. Limited surveys have shown that many foods that are not cooked in closed containers also contain relatively high levels of furan. These are mainly crispbreads and toasted cereal products such as toasted bread.

Effects of Domestic Cooking

Although the topic has received little study it appears that domestic cooking procedures invariably reduce the furan content of foods. Although some furan is almost certainly formed during, for example, the reheating of canned soup, the

Table 2 Furan (μg kg^{-1}) typically found in coffee powders and brewed coffee

	Powder	*Brew*
Regular	1800	24
Decaffeinated	2000	16
Espresso	1700	44
Instant	400	8

procedure leads to an overall loss of furan, presumably to the atmosphere. Actions such as stirring and dispensing food on to plates, and leaving food and beverages to stand causes loss of furan. Mild domestic cooking methods such as reheating prepacked ready meals or soups in a microwave oven do not increase the furan content. There is some evidence that furan driven out of food during domestic cooking can be inhaled from the kitchen air during preparation.

Dietary Exposure

Dietary exposure to furan can be estimated from knowledge of the furan content and intake of foods. These estimates are necessarily based on the food types tested, which have tended to be those likely to contain relatively high furan levels. For adults the most important source is brewed coffee beverages. The intake from this source will obviously vary with the choice of brewing procedure and level of consumption, with cultural differences being significant. The intake for an infrequent consumer of instant coffee, for example, will be much lower than that of the typical Mediterranean heavy consumer of espresso coffees. EFSA has estimated the daily adult intake from coffee to be 2.4–116 μg per person, compared to 1.1–23 μg per person from canned or jarred vegetables and 1.3–50 μg per person from beer.

From the FDA data the adult intake mainly from brewed coffee, was approximately 0.15 μg kg^{-1} body weight per day. Exposure calculations for Germany made by the Federal Institute for Risk Assessment (BfR) were similar to the FDA. From EFSA data collected within the EU the furan intake estimates based on coffee were higher at approximately 0.5–0.7 μg kg^{-1} body weight per day, probably on account of different coffee consumption data.

There is concern regarding the exposure of babies to furan not only because its levels are relatively high in canned and jarred baby foods but also because canned and jarred baby foods may form a high proportion of their diet as well as the larger amounts (relative to body weight) of certain foods.

From the FDA data a mean intake for infants of approximately 0.4 μg furan per kg body weight was calculated for infant foods, and again, similar results were calculated by the BfR for Germany and for the EU by EFSA, which estimated the exposure of babies to furan at <0.2–26 μg furan per day or <0.03–3.5 μg kg^{-1} body weight (bw) per day for a 6-month-old baby weighing 7.5 kg consuming food exclusively from glass jars.

Estimates of exposure indicate a small margin (a factor of approximately 2000) between human exposure doses and those causing liver tumors in experimental animals.

Formation

Several chemical routes of furan formation in foods have been identified. The principal ones being the thermal oxidative degradation of ascorbic acid and unsaturated fatty acids, with degradation of sugars and carotenoids also being important. These reactions are complex but have been studied in some detail through experiments on model food systems comprising only a few reactants. It has become clear; however, that they fall short of representing what happens in whole foods. The furan formation routes shown in Figures 2–4 have been simplified considerably.

When food is heated, sugar and amino acids undergo a series of reactions known as the Maillard reactions, to form products having the distinctive brown color. Large numbers of compounds having a furan ring are formed along with furan itself. Many of these compounds are important flavor constituents and are nontoxic.

In many mechanisms furan is ultimately formed by the decarboxylation of 2-furoic acid or the breakdown of 2-furfural.

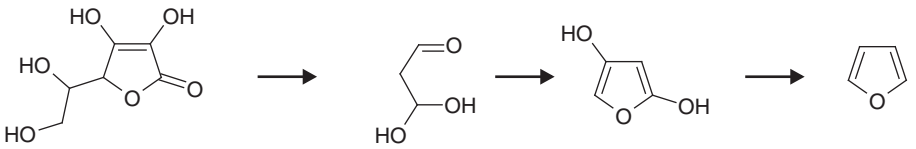

Figure 2 Simplified furan formation route from ascorbic acid.

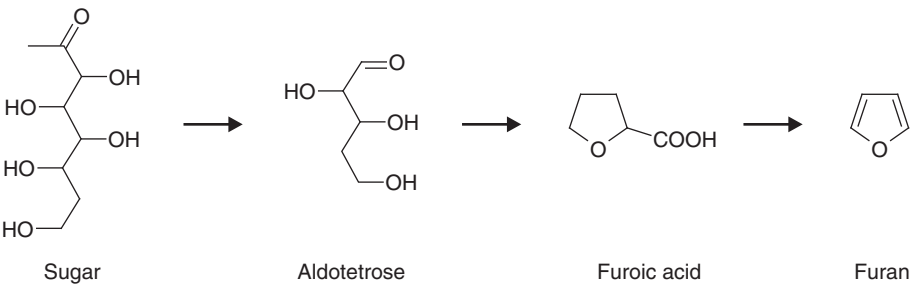

Figure 3 Simplified furan formation route from sugars.

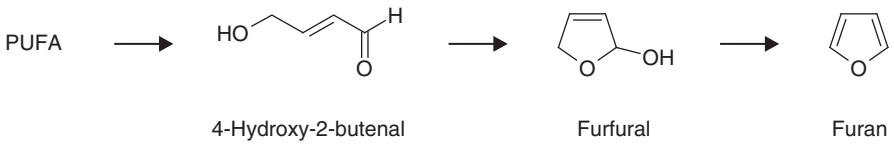

Figure 4 Simplified furan formation route from polyunsaturated fats.

Formation from Ascorbic Acid

Heat treatment of ascorbic acid readily forms furan but the degree of formation is reduced significantly in the presence of other compounds, even some that are also known to be furan precursors. It is strongly affected by the pH and the presence of sugars.

On heating ascorbic acid behaves in similar manner to reducing sugars. In the presence of air it is oxidized to dehydroascorbic acid which is then hydrolyzed to 2,3-diketogulonic acid, decarboxylated, and ultimately dehydrated to 2-furoic acid, 3-deoxypentosulose, and furfural.

In anaerobic conditions ascorbic acid is not oxidized but undergoes hydrolysis, elimination, and decarboxylation to form 2-deoxyaldotetrose and then furan.

Ascorbic acid can act as an oxidizing agent suspected of promoting oxidative degradation of lipids to form furan in some foods that are high in polyunsaturated fatty acids.

Formation from Carbohydrates

Several amino acids and carbohydrates react on heating to form aldotetrose derivatives that undergo cyclization to form furan. Glucose can be dehydrated and subjected to retro-aldol cleavage forming 2-deoxy-3-ketoaldotetrose and ultimately 3-furanone and furan. The final stages of furan formation from sugars is probably the reduction of 3-furanone by formic acid.

In amino acids heating produces acetaldehyde and a glycolaldehyde that undergo aldol condensation to form furan. Not all amino acids form glycolaldehyde and need another source such as reducing sugars for furan formation.

Formation from Fatty Acids

Furan is formed from mono- and diunsaturated fatty acids on heating, whether they are free or esterified in triacylglycerols. The mechanism is one of the free radical autoxidation, which is enhanced by lipid oxidation catalysts such as metal ions, and probably followed by cyclization and dehydration of 4-hydroxy-2-butenal.

Analysis

Early methods for the determination of volatile compounds in food were based on types of distillation with trapping using cold traps or solvent. These methods were not really appropriate for compounds as volatile as furan because evaporation of solvents used to elute analytes from traps also caused loss of furan. Modern methods are virtually all based on headspace gas chromatography with mass spectrometric detection. In this the food sample is placed in a vial sealed with a septum and warmed to partition the furan between the food and the air above it, known as the headspace.

Furan in the air of headspace vial is transferred to a gas chromatograph (GC) with a heated syringe (Figure 5), with a transfer tube or with a solid phase microextraction (SPME) device, which is an absorbent phase on a retractable needle held in the headspace. Detection is invariably by mass spectrometry operated in the selected ion monitoring mode.

The analysis requires considerable care at various stages. The food sample must be homogenized in order to obtain a representative sample. This necessitates stirring, with the concomitant potential for loss of furan, therefore a brief stirring procedure at low temperature is required. The sample is heated for approximately 20 min to equilibrate the furan between the sample and the headspace. At this stage the temperature must be low enough to avoid furan formation, typically 50 °C. A sample of the headspace (approximately 1 ml) is transferred to the GC by means of a heated syringe or a transfer line. Alternatively, SPME may be used in which furan is absorbed on to a coated needle and carried to the GC. All of these methods are easily automated.

GC separation of volatiles including furan can often best be achieved using a porous layer open tube column. This is a bonded porous-polymer phase based on polystyrene and divinylbenzene that is relatively inert and stable to water.

Mass spectrometry is used universally as the furan detector for GC. The mass spectrum of furan has a relatively intense molecular ion at m/z 68 and a fragment ion at m/z 39. Furan can be quantified by using a calibration graph prepared by standards or by adding a range of known levels of furan to samples (standard addition procedure).

Correction for the loss of furan in the later stages of the analysis can be made by adding deuterium labeled furan to the vial. The deuterated furan has all four hydrogen atoms replaced by deuterium. It mimics the behavior of the native furan through the analysis but can be measured independently by the mass spectrometer as it has a molecular ion at m/z 72. The labeled furan is unfortunately too expensive to be added to the food before homogenization unless only a small sample is taken, but this then runs the risk of getting an unrepresentative sample if the food is not homogeneous.

Recoveries from foods are generally better than 90% with limits of detection usually better than 0.3 $\mu g\,kg^{-1}$.

Control

There is so far only a limited and incomplete picture of the levels of furan in foods. There is no evidence so far to suggest

Figure 5 Headspace sampling.

that consumers should alter an infant or child's diet or eating habits to avoid exposure to furan. Also, on account of their complexity, information is lacking with regard to the formation mechanisms.

However, as furan is believed to be carcinogenic some efforts will undoubtedly be made to reduce consumer exposure, and various approaches are available.

Reduction of furan formation in food is challenging due to the large number of precursors in many foods, the requirement to heat process foods to give microbiological safety, and the necessity to heat food in sealed containers to maintain that safety during storage before consumption.

In terms of industrial processing there is limited scope for action. Particular heating regimes are necessary to reduce or prevent the microbiological growth. It must also be considered that changes to the heating regime might make the product unacceptable in terms of taste and appearance and/or promote the formation of other food processing contaminants such as acrylamide and chloropropanols.

As many of the formation mechanisms involve oxidation steps, a promising approach to mitigation is to reduce oxygen by the use of modified atmospheres during heating. Certain additives might also reduce oxidation, for example, by scavenging free radicals. Sulfite added to many foods reduces furan formation significantly.

Furan formation cannot viably be reduced by altering the formulation of some foods because some precursors and catalysts such as ascorbic acid, polyunsaturated fatty acid, and iron are beneficial to health and therefore are desirable food components.

Glossary

Biomarker A biomarker, or biological marker, is in general a substance used as an indicator of a biological state. It is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes.
Caramelization Caramelization is the browning of sugar, a process used extensively in cooking for the resulting nutty flavor and brown color.
Chromatography Chromatography is the collective term for a set of laboratory techniques for the separation of mixtures. The mixture is dissolved in a fluid called the 'mobile phase,' which carries it through a structure holding another material called the 'stationary phase.'
Dietary exposure Dietary exposure assessments combine food consumption data with data on the concentration of chemicals in food. The resulting dietary exposure estimate is then compared with the relevant toxicological or nutritional reference value for the food chemical of concern.
Hydroxymethylfurfural Hydroxymethylfurfural (HMF), also 5-(hydroxymethyl)furfural, is an organic compound derived from the dehydration of certain sugars during caramelization and the Maillard reaction.
Maillard reaction The Maillard reaction is a form of nonenzymatic browning that results from a chemical reaction between an amino acid and a reducing sugar during heating.
Mitigation Mitigation is action to decrease the intensity of undesired substances in foods such as thermal process contaminants in order to reduce their potential effects on consumers' health.
Nucleophile A nucleophile is a species that donates an electron pair to an electrophile to form a chemical bond in a reaction.
Xenobiotic A xenobiotic is a chemical that is found in an organism but that is not normally produced or expected to be present in it.

Description

Hydroxymethylfurfural (HMF) is generated by both the Maillard reaction and sugar dehydration, so it is widespread in processed foods. HMF is highly soluble in water, methanol, ethanol, and ethyl acetate and presents a very low solubility in petroleum ether. For its identification in foods, HMF presents a maximum of absorbance at 284 nm (18 000 M absorptivity) and a secondary band at 230 nm. Also, HMF is a multifunctional molecule containing a furan ring, a carbonyl group, and a hydroxymethyl group (Figure 1).

The hydroxymethyl group can undergo (1) halogen substitution with chloride and bromine to form 5-halomethylfurfurals, (2) oxidation to form 2,5-furandialdehyde, or (3) the Michael addition reaction. The aldehyde group is also reactive and can suffer (1) reduction, (2) condensation reactions, and (3) oxidation to a carboxylic group to form respective furoic acids. Cleavage of the furan ring can occur under acidic conditions to form formic acid and levulinic acid.

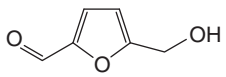

Figure 1 Chemical structure of HMF.

Finally, both hydroxymethyl and aldehyde groups can participate in polymerization reactions with HMF or other molecules. In living tissues, these reactive sites influence the biological activity and fate of HMF.

Health Concerns

Thermal processing and storage of foods cause a complex network of reactions leading to compounds that may impact on human health. Although HMF is a well-known substance in food and chemical industry, the relationship between HMF and its metabolites, and human health has not been studied in detail so far.

Recently, the presence of HMF in foods has raised toxicological concerns because its derivatives (5-chloromethyl- and 5-sulfidemethylfurfural) have been shown to be cytotoxic and genotoxic and to have tumoral effect. But *in vitro* studies have shown that HMF molecule has a weak direct genotoxic and mutagenic potential. Preliminary studies have shown that radiolabeled HMF is rapidly absorbed in the gastrointestinal tract of rodents and also rapidly cleared from all major tissues, with no evidence of significant accumulation, being finally excreted via urine (approximately 90%) and feces

 doi:10.1016/B978-0-12-378612-8.00209-2

(approximately 10%). However, gastrointestinal absorption of HMF can be modulated by other constituents of the diet, such as the fiber content, which seems to reduce HMF transportation and uptake in caco-2 cell lines. Later investigations have demonstrated some covalent binding in the liver, bladder, and kidney and in the gastrointestinal tract after 24 h of exposure. Recently, a reliable method to measure aldehyde adducts to N-terminal valine in hemoglobin from HMF has been reported, which is a step forward for its use as a biomarker of HMF exposure.

There is evidence for the potentially harmful activity of HMF from *in vitro* test systems of different complexities and experiments with laboratory animals. However, the results are still controversial when extrapolated to human level. HMF is bioactivated *in vitro* to 5-sulfooxymethylfurfural (SMF), which has been demonstrated to induce genotoxic and mutagenic effects to bacterial and mammalian cells. The subsequent interaction of this reactive intermediate with critical cellular nucleophiles (DNA, RNA, and proteins) may result in structural damage to these macromolecules. In rodents, HMF has been identified as an initiator and promoter of colon cancer and nephrotoxicity, or chromosomal aberrations. The acute oral toxicity of the pure HMF compound is relatively low and the LD 50 was shown to be 3.1 g/kg of body weight (bw) in rats. The modified theoretical added maximum daily intake (mTAMDI) value was 1600 μg/person/day, which is above the threshold of concern of 540 μg/person/day derived from a large database containing data on subchronic and chronic animal studies.

Living bodies have a chemopreventive machinery to metabolize external substances (xenobiotics) and small endogenous compounds. Apart from the formation of a glycine conjugate or direct oxidation to 2,5-furandialdehyde, HMF is biotransformed by sulfonation. Sulfotransferases (SULTs) are a family of five types of detoxifying enzymes present in the liver, placenta, adrenal gland, endometrium, colon, brain, leukocytes, and other different human tissues. SULTs transfer a sulfomoiety from the cofactor 5′-phosphoadenosine-3′-phosphosulfate (PAPS) to the substrate, which is transformed to a sulfate derivative, and the process is called sulfonation. Sulfoconjuagtes are more water soluble due to better ionization of the sulfate group and decrease the passive absorption over membranes. However, the sulfonation can also result in the bioactivation of some HMF into reactive SMF toward biomolecules. In detail, the family of SULT1A1 is directly involved in the sulfonation of HMF. But extrapolation to humans could be more dramatic because humans express SULT in extrahepatic tissues more extensively than rats and may, therefore, be more sensitive to HMF.

Considering the levels of HMF in certain foods such as coffee, dried fruits, and biscuits, it is important to identify the most important sources of human exposure to HMF. Several investigators started to estimate the dietary exposure to HMF but this is a challenging issue. Coffee was identified as the most important source of HMF intake, representing 63% from the Norwegian population with a daily intake of 5.56 mg day^{-1}. A dietary exposure to HMF from coffee of 8.57 mg day^{-1} for the Spanish population and a total HMF intake of 10 mg $day^{-1}$are estimated. All in all, data from other countries and dietary habits are lacking and are necessary for an appropriate risk evaluation. However, there is a rough estimation showing that humans may ingest from 30 to 150 mg HMF day^{-1} (2.5 mg/bw/day). This value is several orders of magnitude higher than those of other processing contaminants like acrylamide or furan.

Mechanism of Formation

There are two main ways for HMF formation in food, which are (1) sugar degradation and caramelization and (2) the Maillard reaction. HMF is an intermediate in the Maillard reaction, which occurs when reducing hexose moieties are heated in the presence of amino acids or proteins. An alternative source of HMF involves direct thermal dehydration of fructose, sucrose, and, to a lesser extent, glucose. This reaction does not require the presence of amino groups. It is significantly accelerated under acid conditions.

Basically, the Maillard reaction implies condensation between amino groups of amino acids or proteins, typically the epsilon-amino group of lysine residues, and the reactive carbonyl groups of reduced sugars. The complexity of the reaction network is increased when a lipid is present, because lipid peroxidation products with a carbonyl group may take the place of sugar in the reaction. In the first step of this complex cascade of reactions, a stable Amadori product (1-amino-1-deoxy-2-ketone) is formed. The reaction is stopped at this step if reaction conditions are not appropriate or heat input is not severe enough. The Maillard reaction is definitively affected by the temperature/time of the process, reactants, pH, and moisture of the reaction media. The Amadori product is able to yield approximately 10 times more HMF than the respective sugar and amino acid under the same conditions. If thermal conditions and reaction media are appropriate, the colorless Amadori compounds will degrade to the Maillard reaction products, which are involved in aroma generation, color, and formation of melanoidins. At moderate and low pH, the Amadori product form 1,2-eneaminol, in which a hydroxyl group is lost at C-3 followed by deamination at C-1 and hydration to form an intermediary compound called 3-deoxy-2-hexulose, which gets further dehydrated to form HMF. This route is named as 1,2-enolization. The formation of HMF during the Maillard reaction is shown in Figure 2 in a simplified form.

However, HMF is also formed from sugar dehydration under acidic conditions. Caramelization requires higher energy of activation and subsequently higher temperatures than the Maillard reaction, although a similar intermediary is formed, 3-deoxy-2-hexulose, from hexoses degradation. Figure 3 shows the formation of HMF by dehydration of sugars during heating.

During caramelization, reducing sugars directly undergo 1,2-enolization, dehydration, and cyclization reactions to form HMF. Ketohexoses are known to produce HMF more efficiently and selectively than aldohexoses, and this may be due to the fact that aldohexoses enolize to a much lower degree than ketohexoses. In the case of sucrose, a nonreducing sugar, in the Maillard reaction first it is necessary to hydrolyze it into free glucose and fructose to start the reaction. Recently, Perez-Locas and Yaylavan (2008) demonstrated that sucrose degrades into glucose and a very reactive fructofuranosyl cation under reduced moisture conditions and this cation can be effectively converted into HMF. The authors concluded that the amount of HMF formed from sucrose is expected therefore

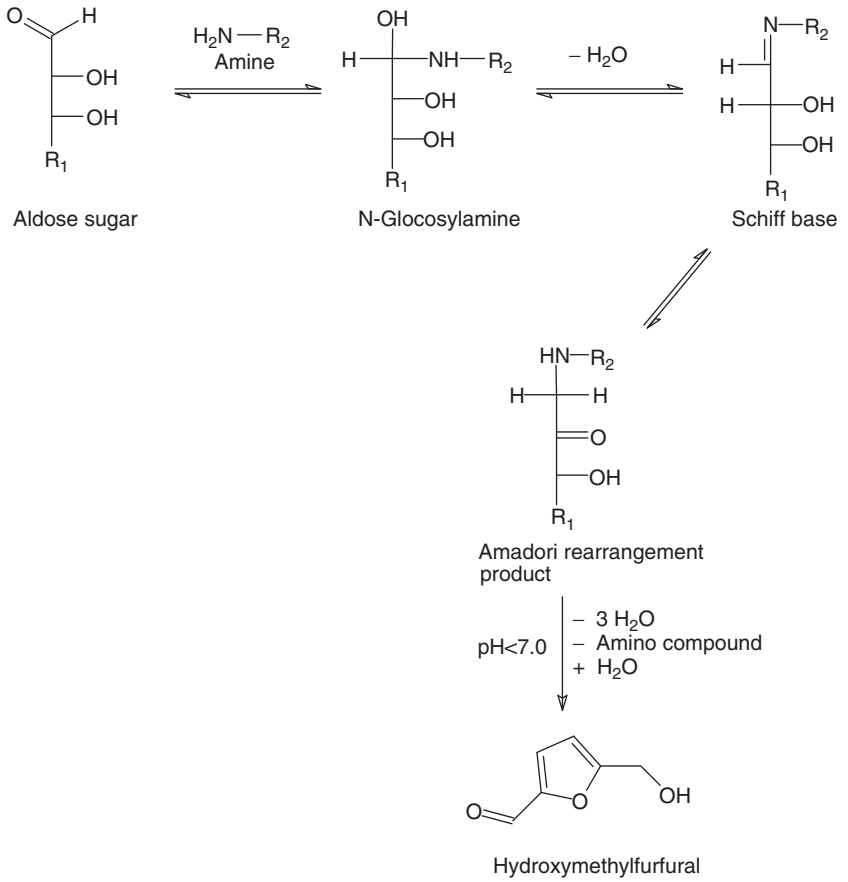

Figure 2 Formation of HMF as a consequence of the Maillard reaction.

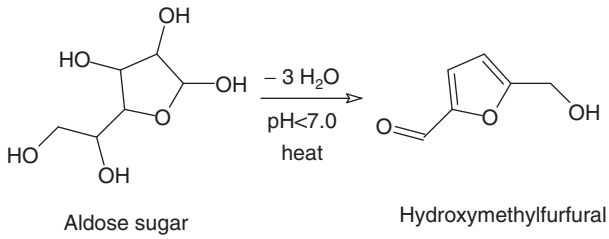

Figure 3 Formation of HMF during heating by dehydration of aldose sugars.

to be higher than that of respective fructose or glucose at higher temperatures due to the more efficient conversion pathway of fructofuranosyl cation into HMF relative to the less efficient classical 3-deoxyglucosone pathway that glucose and fructose follow at lower temperatures under dilute aqueous conditions. Another possible pathway is via cleavage of alpha-dicarbonyl compounds and recombination of methylglyoxal with glyceraldehyde. However, HMF is not a final product of the reaction and it is not necessarily accumulated in the thermally processed food. As a volatile, HMF takes part of the characteristic aroma profile of different heated foods, preferably under roasting. Under more severe heating conditions HMF can react and decompose or polymerize into high molecular-weight food structures, like melanoidins. In summary, the measurement of HMF in foodstuffs is a balance between formation and degradation reactions, transformation or evaporative losses. It is known that HMF can react further by decarboxylation, oxidation, dehydration, and polycondensation reactions and numerous key substances are formed such as furfural, 2.5-furfuraldehyde, 5-hydroxymethylfuroic acid, 5-methylfurfural, levulinic acid, and formic acid.

Food Sources

Although HMF is not present in fresh foods, it rapidly accumulates during thermal processing and storage of carbohydrate-rich products. HMF is widely recognized as a marker of quality deterioration, generated as a result of excessive heating or inadequate storage conditions of foods containing carbohydrates. It is commonly used as a marker of the extent of heat processing in foods where the Maillard reaction and/or caramelization is the main reaction taking place.

The presence of HMF in processed fruits such as fruit juices and concentrates, dried fruits, jams and jellies, alcoholic beverages such as beer and wine, bakery products such as biscuit and bread, breakfast cereals, heated dairy products, roasted nuts, and seeds has been widely reported. The level of HMF largely varies in processed foods depending on the processing and/or storage conditions.

HMF level has been used for measuring honey quality for years. Honey processing frequently requires heating both to

reduce viscosity, and to prevent crystallization or fermentation. Honey heating is usually carried out in two different ways: in air-ventilated chambers at 45–50°C for 4–7 days or by immersion of honey drums in hot water. It is well known that heating of honey results in HMF formation due to acid-catalyzed dehydration of hexoses. The presence of simple sugars (glucose and fructose) and organic acids presents a favorable condition for the production of HMF in honey. The factors affecting the formation of HMF in honey are temperature and time of heating, storage conditions, use of metallic containers, and chemical properties of honey that are related to the floral source from which the honey has been extracted.

HMF may form in low ppm quantities in many processed foods under mild heating conditions. HMF is usually present in low amounts in fruit juices, but concentration and storage conditions may significantly increase its level due to low moisture and high acid conditions. Bakery products contain low and moderate amounts of HMF. Even though the baking conditions are favorable for HMF formation, neutral or slightly basic recipes make bakery products less susceptible to form HMF during baking. HMF may accumulate in large quantities up to a few thousands ppm levels in roasted foods such as coffee, malt, and caramel products due to extremely high temperatures applied during processing. Drying and long-term storage conditions of dried fruits make them susceptible to form large amounts of HMF. High acid conditions are also known to stimulate HMF formation in large quantities in certain foods, including balsamic vinegar.

Mitigation

It has been well described that HMF forms during the Maillard and the caramelization reactions. Considering the possible mechanisms of formation, the factors affecting HMF concentration in foods are shown below:

Factors	*Correlation*
Precursors (sugars, amino acids)	Positive
Temperature	Positive
Time	Positive
pH	Negative
Moisture	Negative

Hexose sugars and amino acids appear as the major precursors for HMF formation in foods. High carbohydrate foods are, therefore, the most susceptible items in terms of HMF formation. Fruit juice concentrate, honey, jams, and jellies are among the foods containing high concentrations of precursors leading to HMF during processing and/or storage. Increasing the temperature during processing and/or storage also increases the rate of HMF formation. So, decreasing the thermal load during processing and storage at lower temperatures are considered as simple ways to mitigate HMF formation in foods. Lower temperature vacuum evaporation and cooking techniques are known to reduce HMF formation in juice concentrates and jams, respectively.

Lowering the pH strongly enhances HMF formation in foods. Processing and storage temperature of acid foods should be kept as low as possible to prevent an excessive formation of HMF. In general, increasing the storage time also increases the amount of HMF formed in foods. Low and moderate moisture conditions are usually associated with increased formation of HMF due to the accelerated Maillard reaction of sugar dehydration.

Analytical Methods

Colorimetric, spectroscopic, and chromatographic methods can be used for the determination of HMF in foods. However, problems have been reported for colorimetric and spectroscopic methods. These include the use of carcinogenic reagents, and the fact that the methods are nonspecific and, therefore, measure components in food that do not lead to HMF leading, to overestimate the HMF content. Several high-performance liquid chromatography methods have been reported for the determination of HMF in various foods. These techniques utilize ultraviolet (UV) detection because of the strong absorption of furfurals at 285 nm. However, many compounds naturally present or formed in foods during processing also absorb at this wavelength. Poor chromatographic resolution of these compounds may adversely affect the quantification of HMF during UV detection.

The usual approach for the extraction of free furfurals from solid food matrices entails extraction with water followed by clarification using the Carrez I and II reagents. This kind of sample treatment can extract almost all HMF present in the sample. Because UV detection is not specific, an accurate detection of HMF will be possible only if a good baseline separation is achieved. However, mass spectrometry detection coupled to liquid chromatographic separation offers more selectivity and accuracy, bringing a significant improvement to the analytical methodology of HMF. The presence of interferences may be problematic, particularly during the UV detection after liquid chromatography separation, when low concentrations of HMF are measured in processed foods. In such a case, (1) a rapid separation of HMF from the matrix coextractives in a narrow-bore column, (2) an efficient cleanup of the extract using solid phase extraction (SPE), and (3) a selective detection of HMF using MS may be combined in an analytical method. If lower concentrations of HMF are required to be detected in foods, not only the sensitivity of instrument's detection capability, but also the success of sample preparation by eliminating the interfering coextractives is important. Even if HMF is soluble in water, it has a hydrophobic moiety that may help in designing a SPE based cleanup strategy. If passed through a cartridge packed with hydrophobic sorbent material, the cartridge retains HMF and other less polar coextractives whereas polar compounds are not. HMF is eluted from the cartridge by passing diethyl ether. By doing so, the extract is not only cleaned up, but also HMF is concentrated to increase the detection sensitivity.

Legislation

For the occurrence of HMF in foods, legislation has been mainly limited to honey worldwide. Codex Alimentarius

(Alinorm 01/25, 2000) established that the HMF content of honey after processing and/or blending must not be higher than 80 mg kg^{-1}. The European Union (EU Directive 110/2001) fixed a HMF limit in honey of 40 mg kg^{-1} with the following exceptions: 80 mg kg^{-1} for honey coming from countries or regions with tropical temperatures and 15 mg kg^{-1} for honey with low enzymatic level. Fruit juices and concentrates that are widely consumed are also common sources of HMF. As one of the quality parameters in many fruit juices, a maximum HMF level of 20 mg l^{-1} has been established for fruit juices according to the European Fruit Juice Association's (AIJN) code of practice (AIJN, 1996).

N-Nitrosamines

C Crews, The Food and Environment Research Agency, York, UK

Introduction

N-nitrosamines are aliphatic or aromatic derivatives of secondary amines, which have a nitroso (–NO) group attached to nitrogen. They are formed by the reaction of nitrite with secondary amines. It should be noted that nitrates may also form *N*-nitrosamines through reduction to nitrites by saliva or enzymes in the intestinal tract. Many *N*-nitrosamines are strongly carcinogenic. They contaminate several foods, beverages, and water, at low levels. The lower molecular weight *N*-*N*-nitrosamines are derived from alkyl or monocyclic secondary amines and have been well characterized. They are known as volatile *N*-nitrosamines on account of their means of analysis. Many larger and more polar *N*-nitrosamines that can be extracted from foods and measured are known as nonvolatile *N*-nitrosamines. A third 'class' is the apparent total *N*-nitrosamine content (ATNC), which is a combined measure of the volatile and nonvolatile *N*-nitrosamines and includes unidentified molecules, such as nitrosated proteins that have not yet been isolated from foods. When the ATNC is measured, its value usually far exceeds the sum of the identified volatile and nonvolatile compounds.

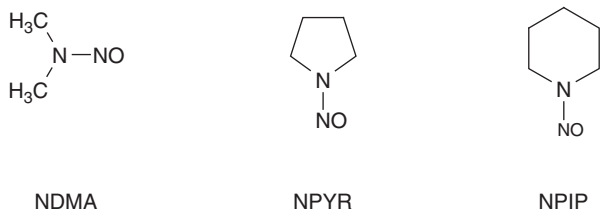
Structures of some important volatile *N*-nitrosamines are shown in Figure 1.

The *N*-nitrosamines of most importance and interest are compounds of relatively low molecular weight, in particular *N*-nitrosodimethylamine (dimethylnitrosamine (NDMA)). The other major *N*-nitrosamines formed from small secondary amines and most commonly encountered in food are *N*-nitrosodiethylamine (NDEA), *N*-nitrosomethylethylamine (NMEA), *N*-nitrosodipropylamine (NDPA), *N*-nitrosodibutylamine (NDBA), *N*-nitrosopyrrolidine (NPYR), and *N*-nitrosopiperidine (NPIP).

The major nonvolatile *N*-nitrosamines are the nitrosated amino acids and related compounds, but there are also important nitrosated products of industrial chemicals such as diethanolamine, that are associated with nonfood products such as cosmetics. The nitrosated amino acids include *N*-nitrosoproline, *N*-nitrososarcosine, *N*-nitrosothiazolidine-4-carboxylic acid, *N*-nitrosooxazolidine-4-carboxylic acid, and *N*-nitroso-2-methyl-thiazolidine-4-carboxylic acid. Structures of some important nonvolatile *N*-nitrosamines are shown in Figure 2.

The toxicity of *N*-nitrosamines came to light in the mid-1950s when it was found that mink fed with herring meal that had been treated with nitrite were dying from liver disease. It was discovered that secondary amines present naturally in the fish had reacted with the nitrite to form NDMA, which had induced cancers in the livers of the mink. This discovery led to the analysis of nitrite-treated foods for *N*-nitrosamines. Analysis progressed slowly until the availability of a very sensitive detector, a nitrosamine-specific nitrogen chemiluminescence detector first marketed as the thermal energy analyzer (TEA), which combined with the fast developing gas chromatographic systems, enabled the detection of very low levels of *N*-nitrosamines even in the 1970s.

Products, such as tobacco, that contain secondary amines not usually found in foods, such as nicotine, invariably contain low levels of their nitrosation products, such as *N*-nitroso-*nor*-nicotine. *N*-nitrosamines are also associated with industrial nonfood products, especially those derived from rubber, and are produced in substantial amounts during the production of hydrazine-based rocket fuels, which has caused environmental pollution.



NDMA NPYR NPIP

Table 1 Range of volatile *N*-nitrosamines measured in selected foods 1973–2001

Food	N-*nitrosamine* ($\mu g\ kg^{-1}$)
Cheese	Not detected–0.5
Milk	Not detected–0.45
Bacon (cooked)	Not detected–6.5
Ham	Not detected–0.1
Salami	Not detected–0.33
Fish (cooked)	Not detected–13.1
Oil	Not detected–0.38
Beer	Not detected–6.8

Occurrence in Food

A summary of typical levels of *N*-nitrosamines are given in Table 1 below:

The foods that are most frequently contaminated with *N*-nitrosamines are cured meats and cheeses, smoked fish and meat, foods dried by combustion gases (malt, milk products, and spices), and some pickled vegetables. Today the NDMA content of products in Western countries has in most cases been reduced to less than 1 $\mu g\ kg^{-1}$. In a large food survey carried out in France in the late 1980s *N*-nitrosamines were found in beer, cured meats, and smoked fish. NDMA was found in 89% of all samples with a maximum level of16 $\mu g\ kg^{-1}$. In beers, NDMA was present in all samples but the maximum level was less than 0.3 $\mu g\ l^{-1}$, very much lower than the 20 $\mu g\ l^{-1}$ encountered in the 1970s and 1980s. NDEA is not frequently encountered but was found in almost all of the distilled stone fruit spirits surveyed in France, at up to 12 $\mu g\ l^{-1}$. NDMA was found in 95% of almost 90 cured meat samples, but in 72% the levels were below 0.5 $\mu g\ kg^{-1}$.

Of the nonvolatile *N*-nitrosamines, *N*-nitrosoproline, and *N*-nitrosothiazolidine-4-carboxylic acid are most frequently found in foods, the other compounds being reported only sporadically. Of note, with the exception of *N*-nitrososarcosine, which is a relatively weak carcinogen, *N*-nitrosated amino acids are not mutagenic and not carcinogenic.

Malt, Beer, and Whiskey

Soon after the discovery of *N*-nitrosamines in fishmeal, they were found to be present in flame-kilned malt, and in beers and whiskies made from the malt. NDMA was found to be present in approximately 70% of all beers tested, with mean concentrations of 2–3 $\mu g\ kg^{-1}$ and maxima of approximately 70 $\mu g\ kg^{-1}$. The levels of NDMA were higher than those of other *N*-nitrosamines. The precursors of NDMA were found to be the secondary amines hordenine and gramine, natural constituents of barley. *N*-nitrosamine levels in malt were reduced by a switch to using indirect heating of the malt during the curing process, but some *N*-nitrosamine persisted in many beers. The source of this was eventually found to be nitrite that had been derived from the bacterial reduction of nitrate in the water used for brewing. This problem has been addressed by ensuring that the yeast used for brewing contains only very low levels of bacteria. NDMA was also present in whiskey made from malt, which continued to cause a problem after changes to the kilning operations as many whiskies are kept to mature for many years before sale.

In a survey of approximately 140 beers purchased in 2003, approximately 80% contained no NDMA subject to a detection limit of 0.1 $\mu g\ l^{-1}$ and only three samples contained over 0.5 $\mu g\ l^{-1}$. The NDMA content was not related to beer strength or type or geographical origin.

Dairy Products

Milk products, mainly dried milk powder and cheese contain comparatively low concentrations of NDMA, again usually less than 1 $\mu g\ kg^{-1}$. NDMA can be formed in milk if direct flame drying procedures are used.

Meats

Many meats, principally the pork products including bacon and hams, are cured by treatment with nitrite in the form of sodium and/or potassium salts. Nitrite is effective in preventing germination and growth of bacteria and in particular, *Clostridium botulinum*, which produces a highly toxic metabolite. Pork contains the secondary amines dimethylamine, proline, piperidine, and pyrrolidine, and it is NDMA, *N*-nitrosoproline, *N*-nitrosopiperidine, and *N*-nitrosopyrrolidine that are most often found in cured meat products. *N*-nitrosopyrrolidine is mainly formed by heat-induced decarboxylation of nitrosoproline or by the direct nitrosation of pyrrolidine, which is a natural component of meat products.

Relatively high amounts of peptide-bound *N*-nitrosoproline can be released by enzymatic degradation or chemical hydrolysis, and this could occur in the digestive system. Nonvolatile *N*-nitroso compounds have been found in nitrite-treated or smoked meat products in much higher concentrations, for example, *N*-nitrosoproline in concentrations up to 360 $\mu g\ kg^{-1}$ in cured meat. Smoked meats contain *N*-nitrosothiazolidine-4-carboxylic acid at levels of up to approximately 1.5 $mg\ kg^{-1}$. The *N*-nitrosothiazolidine-4-carboxylic acid content of bacon has been shown to increase on frying. Smoked meats also contain the noncarcinogenic *N*-nitrosothiazolidine, a nitrosamine that has been found in smoke-treated products in concentrations up to 10 $\mu g\ kg^{-1}$.articleid

Other Foods

N-nitrosamines are not usually detected in surveys of vegetables, fruits, cereals, and cereal products or nonalcoholic beverages. However, the use of artificial fertilizers has increased the levels of nitrates in these foods, particularly leafy greens. Nitrates may be precursors for nitrites *in vivo*.

Water can be a source of NDMA in foods, alcoholic beverages, and other drinks. Here it is formed by the action of certain disinfectant chemicals and from secondary amines present in ion-exchange resins.

Cooking

N-nitrosamines are formed during some forms of cooking, through reaction of amines naturally present with nitric oxide

(NO) in flame gases, or through acceleration of reactions of amines with NO present in the food on account of the elevated temperatures. Formation rates and levels formed depend on the amine and nitrite composition of the food and also the cooking method. Frying produces more *N*-nitrosamines in meat than grilling or baking.

Barbeque cooking produces the highest levels of *N*-nitrosamines on account of the high temperature and the use of naked hot gases. The widespread use of barbeque style grills to cook seafood in the Far East probably contributes to higher levels of *N*-nitrosamine in the food there and high incidence of certain cancers.

Microwave cooking of bacon gives significantly lower levels of *N*-nitrosamines than frying, and cooking of foods by indirect heating procedures, such as microwaving and steaming, produce much less NDMA than direct heating on a barbeque or charcoal grill.

Food Safety Issues

Toxicity

Over 300 *N*-nitroso compounds have been tested for carcinogenicity in animals, and most *N*-nitrosamines have been found positive. Many are also mutagenic and teratogenic. Both NDMA and NDEA are classified as probably carcinogenic to humans (group 2A) by the International Agency for Research on Cancer. Rats and mice exposed continuously to low levels of NDMA for several months had a significantly increased incidence of lung, liver, and kidney tumors including adenomas, carcinomas, and sarcomas in the lung, liver, and kidneys, and hemangiomas in the liver.

N-nitrosamines are readily absorbed from the gastrointestinal tract but do not accumulate in body tissues. They require metabolic activation of their mutagenic and carcinogenic properties. This is catalyzed mainly in the liver by the body's cytochrome CYP2E1 function oxidase system, which hydroxylates and cleaves the *N*-nitrosamine molecule forming a diazonium ion that alkylates nucleophilic sites including deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), which in turn initiates cancer formation. *N*-nitrosamines are carcinogenic in all mammalian species tested and it is assumed that they are similarly human carcinogens. They produce tumors in several but often specific organs depending on the nitrosamine and the animal species. The major organs affected are the liver, lung, kidney, bladder, pancreas, esophagus, and tongue.

Analysis of data collected over several years that compared dietary intake of NDMA with cancer has shown *N*-nitrosamines to be associated with a higher incidence of rectal cancer in both men and women.

Exposure

Humans are rarely exposed to large doses of *N*-nitrosamines but to very low levels in several items of diet that are consumed regularly. This is of concern because *N*-nitrosamines have been shown to have a stronger carcinogenic effect when given repeatedly in low doses than as a single high dose. The total exposure of humans to *N*-nitrosamines has been estimated to be approximately 1 μmol day^{-1}. Diet is the major source, providing over 70% of the total. *N*-nitrosamine intake and excretion studies suggest that *in vivo* formation contributes considerably to the human *N*-nitrosamine exposure.

The US Environmental Protection Agency considers NDMA to be a probable human carcinogen, with an estimated 10^{-6} lifetime exposure cancer risk at 0.7 ng l^{-1} in drinking water. Only a few countries have imposed limits on the *N*-nitrosamine content of foods and these have been restricted to certain commodities. The *N*-nitrosamine level in foods is reasonably well controlled by limits on the quantity of nitrite added to meat and regulations and guidelines regarding the use of direct heating. Maximum admissible concentrations in water have been set at 7 ng l^{-1} (NDMA), 20 ng l^{-1} (NMEA), and 2 ng l^{-1} (NDEA). Although the US regulations limit the *N*-nitrosamine content of beer and bacon to 5 μg kg^{-1}, Italy, Switzerland, and Germany have a limit of 0.5 μg kg^{-1} *N*-nitrosamine in beer.

Although NDMA amounts in beer have been markedly reduced, consumption of beer still is a major factor with respect to the total dietary exposure to *N*-nitrosamines. Approximately 30% of the exposure via food results from the consumption of beer, contributing to approximately 0.1 μg of NDMA per person per day. The daily uptake of NDMA resulting from the consumption of beer in France and Spain has been estimated to be 0.02–0.03 μg per person.

More Asian foods than Western tend to contain *N*-nitrosamines, and these at higher level, possibly due to the higher content of seafood in the diet and the popularity of barbeque cooking. Red meat has been associated with gastric cancer, and higher levels of *N*-nitrosocompounds have been found in the feces of red meat eaters than in people consuming white meat, but there is no direct epidemiological evidence that *N*-nitrosamine are responsible. *N*-nitrosamines can be formed endogenously from secondary amines and nitrite, particularly from fish and vegetables. A meal rich in fish and nitrate-rich vegetables could contribute approximately 3 μg NDMA to the diet. Adult intakes of ingested *N*-nitrosamine have been estimated at approximately 0.1–0.3 μg per person per day, with men consuming slightly more than women, mainly because of beer consumption. The *N*-nitrosamine intake of children from food has been calculated to range from 0.007 to 0.025 μg per person per day.

The contribution to *N*-nitrosamine intake from passive smoking is much higher than intake through food items. In confined spaces tobacco smoke has been estimated to provide up to 3 μg *N*-nitrosamine per adult person per day.

Human exposure to nonvolatile *N*-nitroso compounds has been estimated to be between 10 and 100 μg per person per day; however, research suggests that most nonvolatile *N*-nitroso compounds in food are not carcinogenic.

Formation

Chemically, *N*-nitrosamine formation is thought to proceed via the oxidation of NO to NO_2 in acid conditions and then to N_2O_3 and N_2O_4, wherein each reacts with secondary amines to form *N*-nitrosamines. The nitrosation of secondary amines takes place at acidic pH. It is catalyzed by nucleophilic anions,

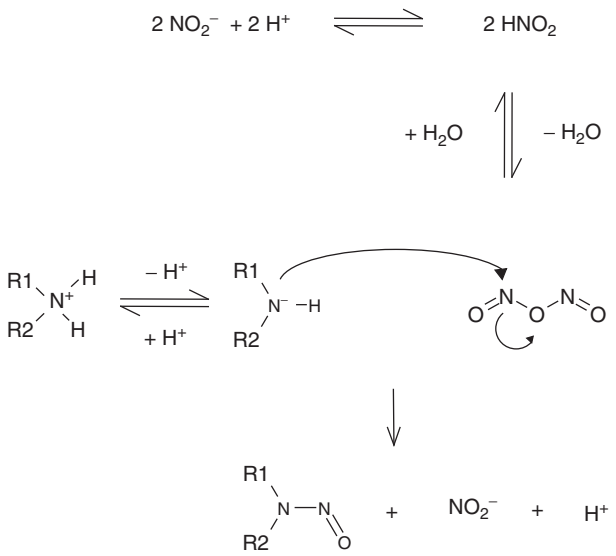

Figure 3 Mechanism of formation of *N*-nitrosamines from secondary amines. Reproduced from Stadler RH and Lineback DR (2009) *Process-Induced Food Toxicants: Occurrence, Formation, Mitigation, and Health Risks*. Hoboken, NJ: John Wiley & Sons, Inc.

such as thiocyanate, bromide, and chloride, and inhibited by ascorbic acid, α-tocopherol, and sulfamic acid and its salts.

The formation mechanism is shown in Figure 3.

Nitrosation of primary amines ultimately leads to alcohols, but tertiary amines can be nitrosated slowly after dealkylation.

Other nitroso compounds can be formed by nitrosation of thio compounds or phenols to give *S*-nitroso and *C*-nitroso compounds, respectively. These do not have carcinogenicity associated with *N*-nitrosamines. *N*-nitrosamides, *N*-nitrosoureas, *N*-nitrosocarbamates, and *N*-nitrosoguanidines are also formed by nitrosation reactions but are thought to be too reactive to exist in foods in stable forms.

In malt, NDMA is formed from nitrosation of dimethylamine released from the naturally occurring tertiary amines hordenine, gramine, or existing freely in the cereal.

N-nitrosamines are formed in some other foods, such as milk powder and some cheeses, during smoking and drying processes as described earlier. They are also formed in water by the action of disinfectant chemicals and from secondary amines present in ion-exchange resins, and water can be contaminated from environmental sources including fires and industrial activities. This contaminated water can be used for direct consumption or for food manufacture.

Several compounds inhibit or prevent *N*-nitrosamine formation, and fortunately most of these (ascorbic and erythorbic acids, butylated hydroxyanisole, butylated hydroxytoluene, and tocopherols) are themselves of low toxicity.

Analysis

Analytical methods for *N*-nitrosamines in food can be divided into those that determine either volatile, nonvolatile, or the apparent total *N*-nitrosamine content (ATNC). These methods involve gas chromatography (GC), liquid chromatography (LC), and no chromatography, respectively. The end determination (detection and measurement) can be made with the nitrosamine-specific TEA in all cases or with mass spectrometry for the chromatographic procedures.

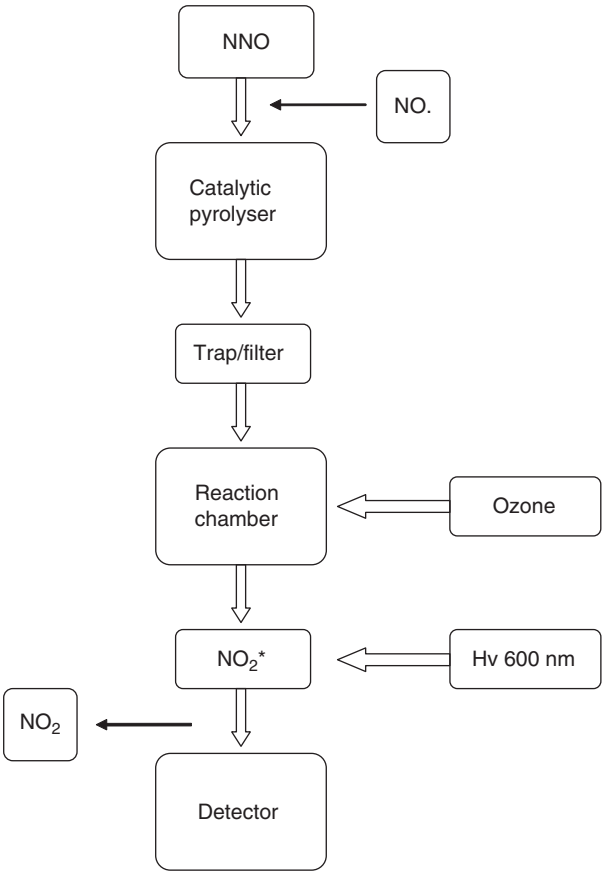

Figure 4 Schematic representation of the operation of nitrogen chemiluminescence detector.

The Thermal Energy Analyzer

The detection of *N*-nitrosamines was revolutionised in the 1970s by the introduction of the TEA, a chemiluminescence detector that was extremely sensitive and specific in detecting *N*-nitrosamines. Today different versions of the detector are available. In certain configurations it can be used to detect non-nitroso nitrogen as well as *N*-nitrosamines, and the generic name 'nitrogen chemiluminescence detector' may be preferred (Figure 4).

In this detector, the sample, in the form of a hot gaseous eluent from a GC, passes through a catalytic pyrolyzer under vacuum at a temperature of 350–500 °C. The temperature is set to be high enough to cleave a nitrosyl radical (NO) from the *N*-nitrosamine, leaving the other organic material to be pyrolyzed to carbon dioxide. The reaction products pass from the pyrolyzer through a filter and the nitrosyl radical is reacted with ozone to produce the electronically excited species (NO_2 radical). This decays to its ground state, emitting light in the near-infrared region, which is converted into an electrical signal by a

sensitive photomultiplier. The lower limit of detection for the instrument is 10 pg at a signal to noise ratio of 3:1.

Limited confirmation that compounds suspected to be *N*-nitrosamines by TEA detection are so, may be made by decomposing them by irradiating their solutions with ultraviolet (UV) light. Then reanalysis with the TEA would show that the response disappears for *N*-nitroso compounds.

Volatile *N*-Nitrosamines

The volatile *N*-nitrosamines including NDMA, NDEA, NMEA, NDPA, NDBA, NPIP, NPYR, and a few minor compounds are isolated from foods by solvent extraction or by distillation. It is somewhat surprising that the more modern headspace sampling methods of volatiles analysis, such as solid phase microextraction (SPME), have had only limited application to *N*-nitrosamine analysis.

Certain procedures are common to most methods. These are the inclusion of a nitrosation suppressant, an artefactual nitrosation indicator, and an internal standard. The nitrosation suppressants most commonly used are sulfamic acid or ammonium sulfamate. Artefactual nitrosation indicators are secondary amines known to be absent from the food matrix but which form *N*-nitrosamines, which are also known to be absent. As dipropylamines and piperidine are not commonly encountered in foods, these have been used the most often. Their use is not pertinent to ATNC determination, where there is no chromatographic separation.

Isotopically labeled internal standards are available and are ideal for gas chromatography–mass spectrometry (GC–MS) and liquid chromatography–mass spectrometry (LC–MS) methods, but cannot be used for TEA detection as the instrument cannot distinguish between the isotopes.

For solid food samples, distillation methods are normally used. The sample is placed in a heated round-bottomed flask in water or in mineral oil containing a nitrosation suppressant, an artefactual nitrosation indicator, and an internal standard. An antifoaming reagent may also be required. The flask is connected to a condenser or more usually in traps sitting a succession of cooling baths of decreasing temperature cooled with ice, dry ice, or liquid nitrogen. Distillation is achieved by passing a slow stream of nitrogen through the heated sample and collecting the distillate in the traps.

For liquid samples, such as beer or water, liquid–liquid extraction methods are used. The sample can be shaken in a separatory funnel with a nonmiscible volatile organic solvent, such as dichloromethane (DCM) or diethyl ether, but it is more convenient and efficient to use solid phase extraction (SPE) methods in which the liquid is adsorbed onto commercially available short-packed columns of an inert support, such as Celite® or a diatomaceous earth. No significant chromatographic separation occurs. The packing material holds the liquid sample and the nitrosamines are extracted from it by passage of DCM. The solid nature of the support prevents emulsion formation.

For both distillation and SPE the solvent is dried and carefully concentrated. A low-boiling solvent is required for successful removal from more volatile *N*-nitrosamines such as NDMA. Despite the concern about the use of chlorinated solvents, DCM meets the requirements most closely and is the solvent mostly often used.

To avoid losses of NDMA and NDEA the DCM must be evaporated very slowly and this is achieved by using a Kuderna–Danish concentrator. This apparatus comprises a round-bottomed flask of 50–250 ml volume with a cone joint at the base to which is attached a tube of 5–10 cm in length with a tapered tip. The top of the flask has a socket joint fitted with a vertically mounted Snyder fractional distillation column. The column is filled with glass materials suitable for fractional distillation. The basal tube is partly immersed in a water bath at approximately 50 °C. The DCM is slowly evaporated until none remains in the main body of the flask, and the collection tube is removed. The DCM is evaporated from the tube under a stream of nitrogen to a volume of approximately 0.5 ml. A low volume of a higher boiling solvent may be added to prevent complete evaporation and potential loss of nitrosamines. The method has been widely used and has been adopted as an official method in several countries.

Solid food samples can be extracted in a similar manner by mixing them with the column material but they are more often analyzed by distillation methods. Clean-up methods involving small chromatographic SPE columns of Florisil®, cyano, silica gel, aminopropyl, and alumina have been applied.

Volatile *N*-nitrosamines can be extracted from beer, water, and certain foods by using SPME. In this technique, a solid needle tipped with a fiber coated with a bonded absorbent organic phase, such as polydimethylsiloxane–divinylbenzene or divinylbenzene–carboxen–polydimethylsiloxane, is immersed into the liquid sample or into the headspace above a solid sample (which may be heated). Over a short period of time the *N*-nitrosamines are absorbed into the fiber, which is placed into a GC–MS or GC–TEA injector port and the *N*-nitrosamines desorbed by rapid heating in the injector of a GC. However, the technique is not reliably repeatable and many common *N*-nitrosamines are insufficiently volatile to produce the sensitivity required.

Supercritical fluid extraction (SFE) in conjunction with a silica SPE cartridge clean-up has been used occasionally to extract volatile *N*-nitrosamines from meat.

Nonvolatile *N*-Nitrosamines

Nonvolatile *N*-nitrosamines can be extracted from foods with polar organic solvents but considerable postextraction clean-up is required. The most popular methods for extracting nonvolatile *N*-nitrosamines from foods, such as meat, are based on dispersal of the sample into an adsorbent diatomaceous earth such as Celite, which is packed into a column and the *N*-nitrosamines eluted with polar solvent.

Alternatively the nonvolatile *N*-nitrosamines are extracted by homogenization of the minced sample with a polar solvent, such as water, acetonitrile, methanol, or mixtures of water with acetonitrile or methanol. The extract is filtered through Celite and concentrated using a rotary evaporator. The concentrate is washed with a nonpolar solvent to remove fats and extracted with a moderately polar solvent, such as ethyl formate or ethyl acetate.

The extract derived from these procedures require considerable clean up, which can take the form of column

chromatography on a cellulose/basic alumina medium with polar organic solvent elution, or use of a strongly basic anion-exchange resin.

The nonvolatile *N*-nitrosamines, typically *N*-nitrosoaminoacids are separated by gas chromatography or by liquid chromatography as described below.

N-nitroso-hydroxypiperidine has been used as an internal standard and artefactual nitrosation prevented by the addition of nitrosating inhibitors, such as sulfamic acid or ascorbic acid.

Chromatography and Detection

Volatile *N*-nitrosamines can be determined by GC on a variety of packed or capillary columns. The relatively high volatility gives short retention times and moderately polar stationary phases are required for high sensitivity. Chemical derivatization is not necessary.

The GC column can be interfaced easily with the TEA, but for mass spectrometry the low molecular weight volatile *N*-nitrosamines, such as NDMA, have poor mass spectra in that the molecular ion is small and of low mass, therefore subject to interference from coeluting compounds. Chemical ionization modes give a strong signal for the protonated molecular ion and are used in the official US methods for water analysis along with large volume injection. The technique has, however, not been applied to foods, where the need for large sample sizes and extensive concentration and clean-up is not compatible with the complex matrices.

Volatile *N*-nitrosamines are quantified by the use of calibration graphs with internal standards being used to correct for losses during the analysis. Selection of an internal standard is limited for the TEA as stable isotopes cannot be distinguished from the native compound. Therefore, an *N*-nitrosamine not present in the food sample must be used. *N*-nitrosodi-isopropylamine is often being used for this purpose.

The limit of detection for solid samples, such as meats and malt, using the distillation method or beers with SPE, both with GC–TEA detection, limits were approximately 0.1 mg kg^{-1}.

Most nonvolatile *N*-nitrosamines can be measured by GC after derivatization to reduce polarity and increase volatility. *N*-nitrosoaminoacids can be methylated at the carboxylic acid function or reacted with trimethylsilyl donors to give trimethylsilyl esters and simultaneously trimethylsilyl ethers of any hydroxyl groups.

High-performance liquid chromatography (HPLC) has equally been applied to nonvolatile *N*-nitrosamine analysis. Linking HPLC systems to the TEA detector is rather difficult in that the solvent evaporates to a high-volume gas in the TEA pyrolyser that has to be removed to maintain a vacuum in the reaction chamber. This can be achieved by a series of cold traps of decreasing temperature, the last containing a slurry of isopentane and liquid nitrogen which condenses all solvent components while allowing the NO to remain gaseous. A special pyrolyser furnace is also required.

Alternatively, nonvolatile *N*-nitrosamines in the eluent from the HPLC column can be collected and denitrosated by hydrobromic acid to produce secondary amines which can be measured by fluorescence detection after conversion to dansyl derivatives. The measurement is made before and after denitrosation and the nonvolatile *N*-nitrosamine content calculated by difference.

In practice the fact that the majority of nonvolatile *N*-nitrosamines have been shown not to be carcinogenic has led to a decline in interest in the determination of these compounds in recent years.

Apparent Total *N*-Nitroso Content

Denitrosation reactions can be used to cleave all of the nitroso bonds in a food sample, releasing nitric oxide that can be detected with the TEA. This technique gives a measure of what has become known as the ATNC.

No chromatographic separation is used. Various reagents have been studied for their ability to cleave NO from *N*-nitrosamines, and the reaction has been much studied to optimize the conditions so that the NO derived from *N*-nitrosamines can be distinguished from the signals from nitrite, *C*- and *S*-nitroso compounds.

Hydrogen bromide is the favored denitrosation reagent. In the procedure most often used, liquid samples, such as beer, are injected into a refluxing mixture of hydrobromic acid and acetic acid in ethyl acetate. The released NO is swept in a stream of argon through a series of cold traps to remove reagent vapor and through alkali traps to remove the acids and passed into the TEA. Before the NO cleavage, inorganic nitrite, *C*- and *S*-nitroso compounds are decomposed by adding acetic acid to the sample. Solid samples can be measured by placing them in the empty apparatus and adding the denitrosation reagent later.

All of the *N*-nitroso compounds in the food sample are converted quantitatively to NO, and a quantitative measure of the ATNC can be made by injection of standards of a nitrosamine. Sequential injections are made of reagent blank, duplicated samples, and standards. The procedure requires great care in operation as the response is rather dependent on the sample water content, gas flow rates, and trap conditions. It is also necessary to use very pure reagents and to clean the apparatus frequently to avoid false positive results.

NDMA is measured in water in the US Environmental Protection Agency method by extraction of a large volume of water using a small charcoal trap, elution of NDMA with a small volume of DCM, and GC–MS in chemical ionization (CI) mode with a large volume injection. The use of GC–MS enables incorporation of isotopically labeled internal standards.

Control

Contamination of food by *N*-nitrosamines has been reduced very substantially since NDMA was found in food products in the 1960s. The food industry reacted quickly to the problem helped by research by government and industry association laboratories. The formation processes were studied and as a result manufacturing processes were revised considerably. Continued efforts have reduced consumer exposure dramatically, particularly in the brewing industry. However, it is believed that further reduction of nitrite and nitrate concentrations in cured meats, or further lowering of processing temperatures would increase the

microbial risks by *C. botulinum* and other bacteria. In many countries, consumers have been advised to reduce the consumption of processed meats.

Polycyclic Aromatic Hydrocarbons (PAHs)

M Huang and TM Penning, University of Pennsylvania, Philadelphia, PA, USA

Glossary

Biomarker A substance that can be used as an indicator of a change in physiology, pathophysiology, or disease state.
Carcinogen A substance that can cause cancer.
Chronic exposure Exposure to a chemical for 365 days or more, as specified in the Agency for Toxic Substances and Disease Registry Toxicological Profiles.
Cocarcinogen A substance that is not carcinogenic by itself but will increase the carcinogenicity of a known carcinogen.
Diels–Alder reaction A cycloaddition reaction between a conjugated diene and alkene. In this chemistry the result is a six-membered carbon (cyclohexene) ring.
Diol epoxide A chemical compound containing two hydroxyl groups and a cyclic ether with three ring atoms.
Mutagen A substance that causes mutations. A mutation is a change in the genetic code or deoxyribonucleic acid sequence that is inherited. Mutations can lead to birth defects, miscarriages, or cancer.
***o*-Quinone** A chemical compound with two carbonyl groups occupying adjacent positions on an aromatic ring.
Radical cation A free radical species that carries a positive charge.
Teratogen A chemical that causes birth defects.

Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a large group of diverse organic compounds that contain two or more fused aromatic rings ranging from the two-ring naphthalene and naphthalene derivates to complex ring structures containing up to 10 rings. PAHs with up to six fused aromatic rings are often known as 'small' PAHs, whereas those containing more than six aromatic rings are called 'large' PAHs. PAHs have also been classified into alternant and nonalternant compounds. Alternant PAHs are those compounds composed solely of fused six-member benzene rings, whereas nonalternant PAHs contain both six-member benzene and five-member carbon rings. Common structural features of PAH compounds are illustrated in Figure 1. Differences in the configuration of rings may lead to differences in properties. In their purest form, PAHs are solids with low volatility at room temperature and range in appearance from colorless to white or pale yellow–green. They are relatively insoluble in water and most can be photooxidized and degraded to simpler substances.

PAHs are formed by condensation of smaller organic compounds by pyrolysis or pyrosynthesis. Smaller organic compounds are pyrolyzed at a high temperature and the free radicals produced join together as aggregate large PAH molecules (pyrosynthesis). Diels–Alder-type rearrangements are commonly involved in the formation of the PAHs. Temperature is an important factor to affect both the structure and diversity of the PAHs formed. Large PAHs are formed at lower levels than small PAHs due to the kinetic limitation in their production through addition of successive rings. In addition, with many more isomers possible for larger PAHs, the occurrence of specific structures is much lower.

PAHs are ubiquitous environmental pollutants. They are not only found naturally in the environment but they can also be man made. PAHs are formed as a result of incomplete combustion of carbon-containing materials, such as wood, coal, oil, gas, or biomass. They are also created in car and diesel exhaust, smoked or charbroiled food, and are present in cigarette smoke condensate, and tobacco products. According to their origins, PAHs are classified into pyrogenic PAHs (Figure 2) arising from fossil fuel combustion and petrogenic PAHs (Figure 3) that are unique to crude oil and contaminate water after an oil spill. Petrogenic PAHs differ in structure to pyrogenic PAHs in that they are either extensively alkylated or oxygenated to yield PAH quinones.

PAHs are complex mixtures of hundreds of chemicals, including derivatives of PAHs, such as nitro- and hydroxy-PAHs, as well as heterocyclic PAHs. In the 1970s, the United States Environmental Protection Agency (US EPA) listed 16 PAHs as priority pollutants. These priority PAHs include naphthalene, acenaphthylene, acenaphthene, fluorene, anthracene, phenanthrene, fluoranthene, pyrene, chrysene, benz[*a*]anthracene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene (B[*a*]P), indeno[1,2,3-*cd*]pyrene, benzo[*g*,*h*,*i*]perylene, and dibenz[*a*,*h*]anthracene (Figure 2). Among these priority PAHs, B[*a*]P, a known human carcinogen, is commonly used as an indicator for PAH exposure.

PAHs are present in air, soil, water, and food, and routes of exposure include inhalation, dermal contact, and ingestion. Some exposures may involve more than one route simultaneously affecting the total absorbed dose (such as dermal and

 doi:10.1016/B978-0-12-378612-8.00212-2

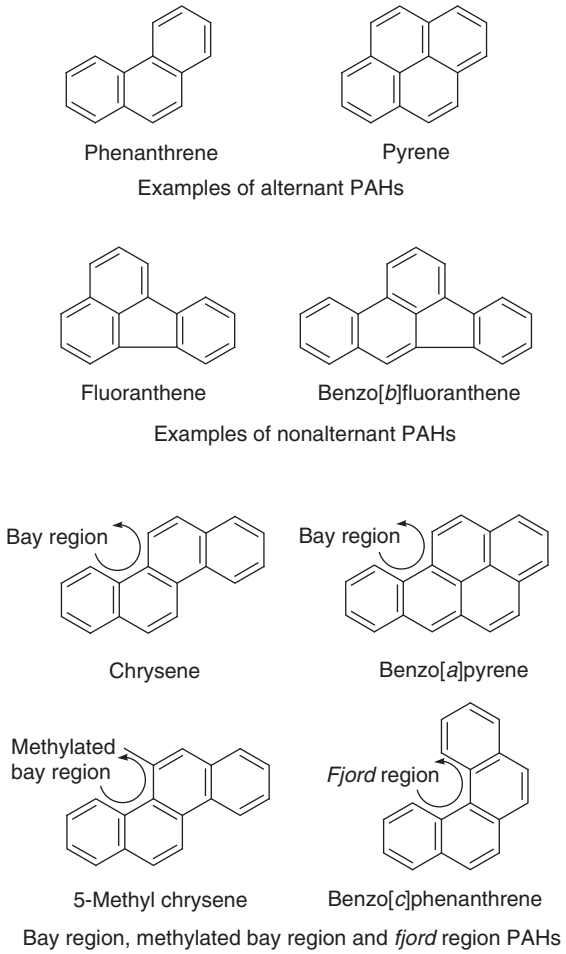

Figure 1 Common structural features of PAH compounds.

inhalation exposures from contaminated air). Occupational sources of exposure mainly involve workers in coal gasification plants, municipal incinerators, smoke houses, and aluminum production facilities. Nonoccupational sources of exposure mainly involve diet, smoking, and burning of coal and wood. In most cases, intake of food is the major involuntary exposure route of PAHs. Therefore, this article will only discuss the occurrence of PAHs in food, health concerns, analysis, mitigation and biomonitoring, and guidelines to reduce PAHs in food.

Occurrence in Food

The food groups with the highest concentration of PAHs include meat and meat products, fish and marine products, dairy products (cheese, butter, cream, and milk), vegetables, cereals, beverages (roasted coffee and tea), and vegetable and animal fats and oils. The occurrence of PAHs in food is mainly due to food preparation and processing techniques such as smoking, roasting, grilling (which includes barbequing), frying, drying, and steaming. The growth of crops and plants in contaminated soils or the presence of marine life or fish in contaminated water provides a portal for PAHs to gain entry into the food chain. In some cases, the presence of PAHs in food products occurs through the use of contaminated packaging material.

Food Preparation and Processing Techniques

Food preparation and processing techniques that increase the amount of PAHs in foods include smoking, roasting, grilling, frying, drying, and steaming, etc. Among them, smoking, roasting, and grilling are the major sources of PAHs in food.

Smoking is often used to preserve and flavor meat, fish, and cheese, etc. The amount of PAHs generated from smoking is influenced by many factors such as temperature of smoke generation, type of wood fuel, oxygen concentration during smoke generation, and type of smoker. The lowest concentration of PAHs was detected in the smoke from the combustion of tree heather wood in the drum, whereas the highest concentration of PAHs was reached when rock rosewood was used in the kiln. Formation of PAHs generated from roasting and grilling (broiling) is due to the pyrolysis of edible oil or fat on the surface of foods, or the pyrolysis of food contacting with flames at high temperature (150–400 °C). Grilling over hot coals (barbequing) is a source of PAHs when meat is cooked in close contact with the hot flame and the meat has not been trimmed of fat or skin. It also occurs when fat drips onto the hot coals. The preparation of coffee beans by roasting is typically performed at high temperatures (180–300 °C) as well. Direct-fired roasting can lead to a higher amount of PAHs in coffee due to the direct contact of the coffee beans with the burner flame. Indirect-fired roasting leads to a lower amount of PAHs in coffee though the combustion gases from the burner do make a contact with the coffee beans.

The process of frying is usually much faster than roasting or grilling (broiling) and thus results in a lower amount of PAHs. If vegetable oil or fat is overheated, the PAHs formed in the cooking fume or oils can be transferred to the kitchen air or fried foods. The process of drying applied to meats, fruits, cereal, grains, oilseeds, and tea can cause the contamination by PAHs from the fine particulate matter smaller than 2.5 μm (PM2.5). In some cases, tea leaves are dried using combustion gas from burning wood, oil, or coal, where combustion products may come into contact with tea leaves and the tea product can absorb the PAHs formed. Steaming has an advantage over other cooking methods because it can minimize or avoid pyrolysis of oil or fat during the cooking process, and thus steaming is considered a healthy cooking technique.

Growth of Crops and Plants in Contaminated Soil

Most PAHs are lipophilic in nature and are absorbed on and concentrated in PM2.5, commonly known as soot. Some atmospheric fine particulate matter containing PAHs contaminate the soil after rain. Consequently, crops such as cereals, grain, fruits, and vegetables grown in contaminated soil will absorb the PAHs. The waxy surface of vegetables and fruits can concentrate PAHs through surface adsorption, and thus the concentration of PAHs is generally greater on plant surfaces (peel and outer leaves) than on internal tissue. In addition, when plants used for fodder are grown in contaminated soil and eaten by grazing herds, PAHs can unintentionally end up in dairy products.

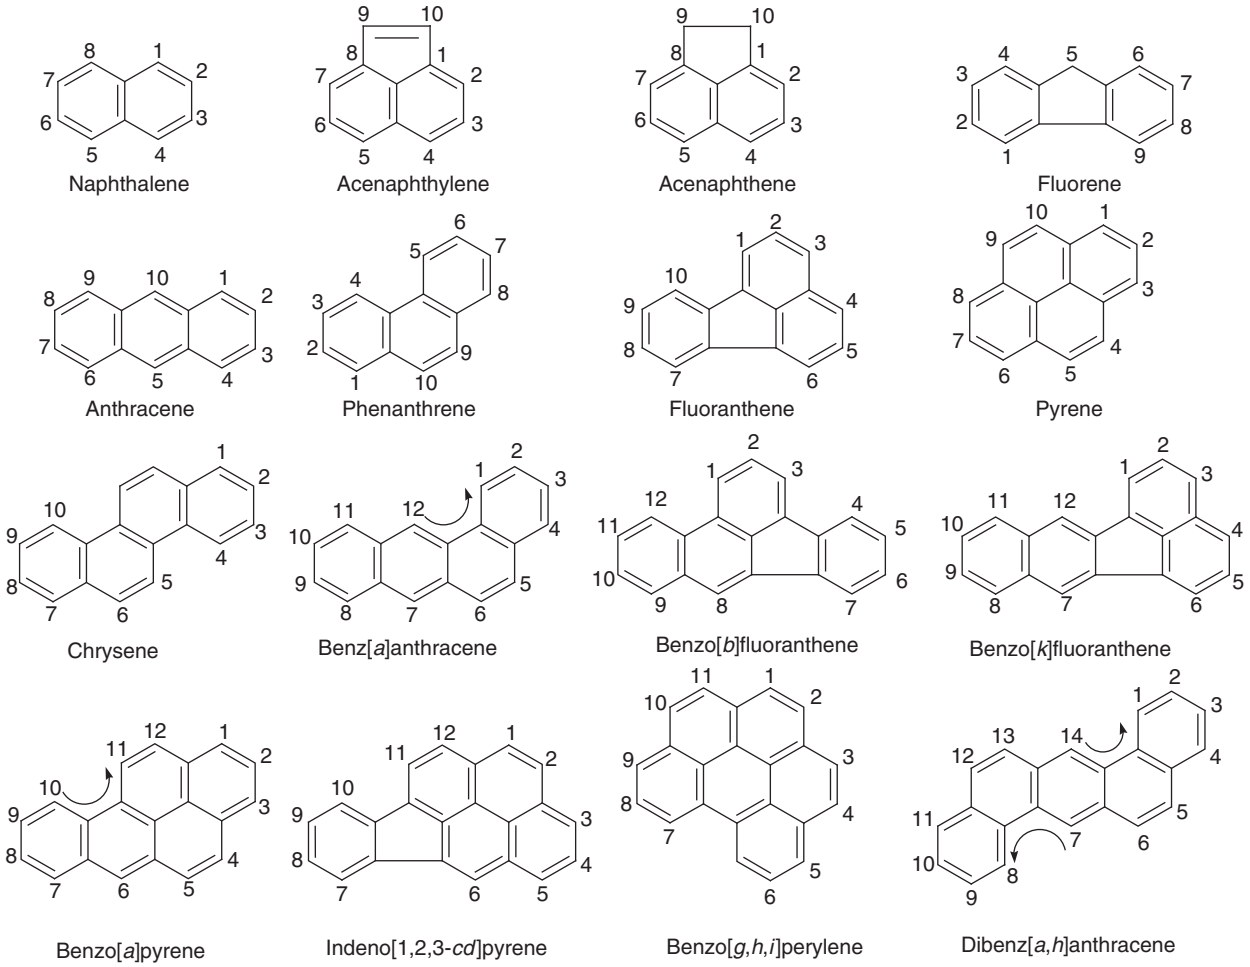

Figure 2 The 16 priority pyrogenic PAHs listed by the United States Environmental Protection Agency (US EPA).

Seafood and Fish Contamination

Oceans and waterways contaminated with crude or engine oil due to either oil tanker disasters and oil spills, for example, Deepwater Horizon, or industrial waste will create sediments more heavily contaminated with both petrogenic and pyrogenic PAHs. Filter-feeding bivalves such as mussels, clams, and oysters near contaminated sediments are the first invertebrate targets for exposure to PAHs as they filter large amounts of water and have a very poor metabolic clearance for PAHs. PAHs can then move through the food chain through predation. The teleosts fish can rapidly metabolize PAHs. In some instances, the metabolites of PAHs can be more harmful than the parent PAHs. Thus both shellfish and finfish are affected.

Use of Contaminated Packaging Materials

Owing to the permeable nature of plastic packaging materials, for example, polyethylene, PAHs can impregnate the material and can be retained on recycling. PAHs present in recycled plastic bags can then diffuse into the food source. Jute bags used for transport and storage of hazel nuts, coffee, cocoa beans, etc., can be contaminated with PAHs, as they are present in the batching oil used to soften the jute fabric.

Health Concerns

Cancer risk has been widely accepted as the most significant health concern associated with PAH-contaminated food. PAHs comprise the largest group of chemical compounds known to cause cancer. However, some PAHs are not carcinogenic but may act as cocarcinogens. PAHs have a low acute toxicity to humans. Based on animal studies the most relevant sites of tumor formation following PAH ingestion are the gastrointestinal tract and digestive system.

Exposure of humans to a single PAH is rare because PAHs always exist in complex mixtures. The mixture is not always of constant composition and thus makes the assessment of health risk difficult. Nevertheless, epidemiological studies support an association between exposure to individual PAH and occurrence of human cancer. Such individual PAHs serve as markers for exposure to the entire PAH mixture. In general, PAHs are carcinogenic when they contain four or more fused

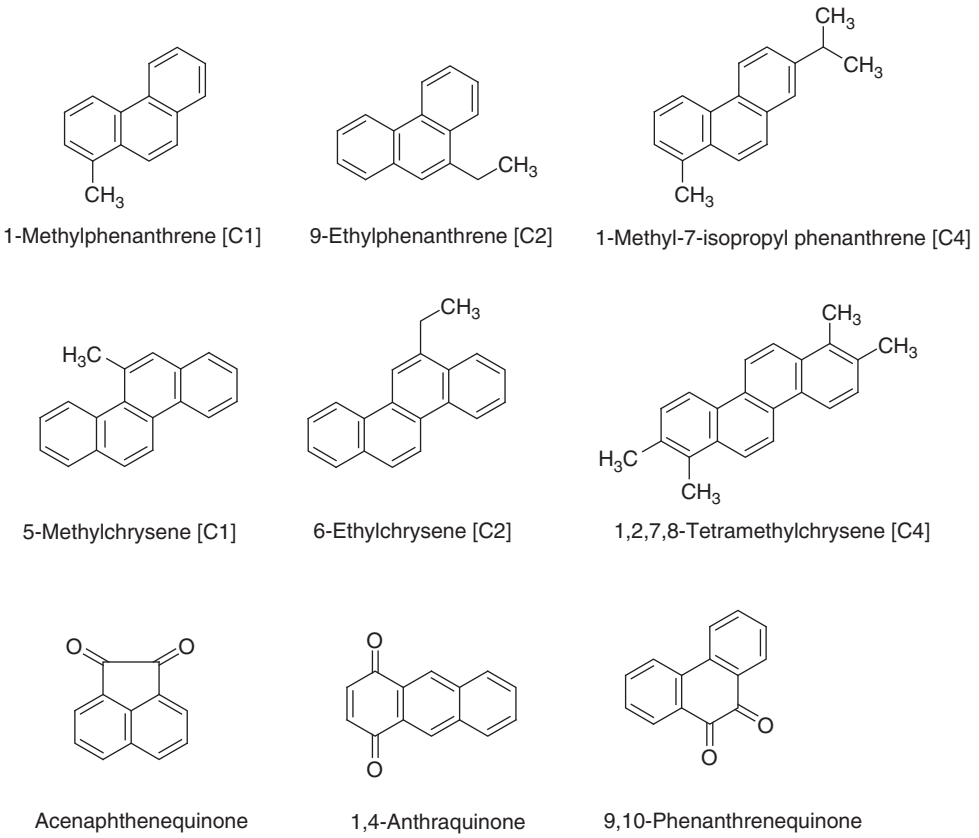

Figure 3 Representative petrogenic PAHs.

rings and a terminal benzene ring, which creates a bay region in the structure (Figure 1). Introduction of a methyl group in the bay region or formation of a *fjord* region generally increases the carcinogenicity of the PAH. Four priority PAHs listed by the US EPA contain a bay region and are strongly carcinogenic in experimental animals. These four carcinogenic priority PAHs are chrysene, benz[*a*]anthracene, B[*a*]P, and dibenz[*a*,*h*]anthracene.

PAHs by themselves are biologically inert and to exert their carcinogenic, mutagenic, and teratogenic effects they must be metabolically activated to biologically reactive intermediates, which covalently modify deoxyribonucleic acid (DNA) to form DNA adducts that may result in mutation. Three pathways of metabolic activation of B[*a*]P, a representative PAH, have been proposed in the literature (Figure 4). These three pathways involve the formation of the following reactive intermediates: radical cations (formed by P-450 peroxidases); the *anti*-diolepoxides (formed by P450 1A1/1B1 monooxygenases and epoxide hydrolase); and the reactive and redox-active PAH *o*-quinones (formed by the combined action of P-450 isozymes, epoxide hydrolase, and aldo-keto reductases (AKRs)).

In addition to the carcinogenicity of PAHs, data from animal studies show that certain PAHs can produce mutagenic/genotoxic, reproductive (both male and female offspring) and developmental, immunotoxic, cardiovascular, and neurologic effects. The mutagenicity/genotoxicity of PAHs shows considerable overlap with carcinogenicity, in agreement with the mechanistic link between PAH–DNA adduct formation, mutations, and cancer outcome following PAH exposure. The reproductive and developmental toxicity of PAHs occurs because their lipophilic character enables them to cross the placenta into the developing embryo and fetus. The immunotoxic effect following exposure to PAHs is most often reported as immunosuppression, which is associated with an increased susceptibility of exposed individuals to the development of cancers or infectious diseases. However, the critical endpoint for the health risk evaluation is the well-documented carcinogenicity of several PAHs.

Analysis

Foods are analyzed for PAHs to ensure their levels are below the legislative limits of concern estimated by government agencies, and to detect fraud and compliance with labeling. Much of the analysis is focused on the detection of pyrogenic PAHs and thus measurements of petrogenic PAHs are not routinely made. Because PAHs are present as mixtures, levels of different pyrogenic PAHs are quantified and summed against the toxicity equivalent quotient (TEQ) for B[*a*]P which has a TEQ equal to 1.0. For example, as chrysene is 1000-fold less carcinogenic than B[*a*]P, its concentration level would be multiplied by 0.001. The analysis of PAHs in food samples presents challenges due to the presence of high amounts of interfering compounds present in complex food matrices.

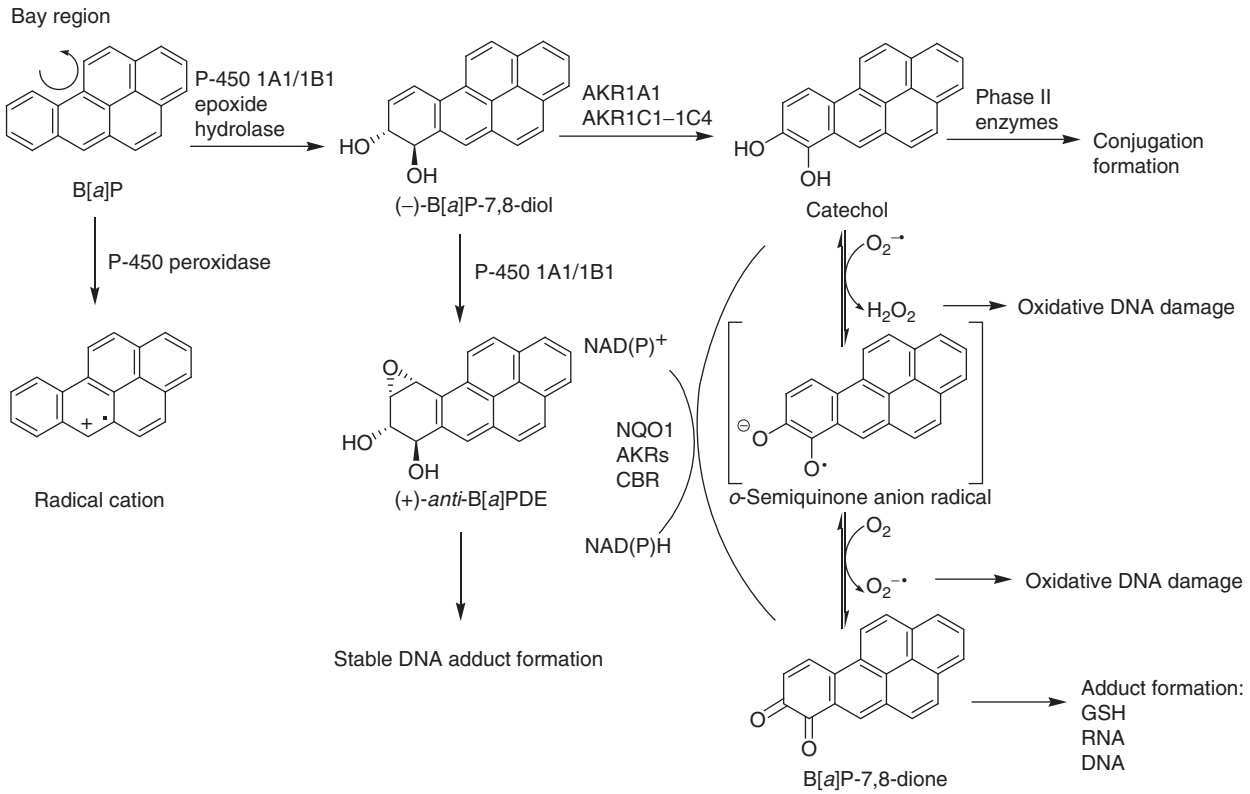

Figure 4 Pathways of PAH metabolic activation using B[*a*]P as an example. Abbreviations: AKR, aldo–keto reductase; (+)-*anti*-B[*a*]PDE, (+)-*anti*-7*beta*,8*alpha*-dihydroxy-7,8,9,10-tetrahydro-9*a*,10*a*-oxo-benzo[*a*]*pyrene*; CBR, carbonyl reductase; GSH, glutathione; NADP, nicotinamide adenine dinucleotide phosphate; NQO1, NADPH: quinone oxidoreductase; P-450, cytochrome P-450; RNA, ribonucleic acid.

Thus proper extraction and clean-up procedures are needed to minimize this effect.

Direct measurement of PAHs in food is conducted using high-performance liquid chromatography (HPLC) coupled with ultraviolet–visible (UV-Vis) or fluorescence detection, and gas chromatography coupled with mass spectrometry (GC–MS). The first official method for the analysis of B[*a*]P in food was based on the ultraviolet absorption of an extract of the food purified by thin layer chromatography in the 1970s. The International Organization for Standardization (ISO) established the analysis for the determination of an enlarged set of PAHs in edible fats and oils by HPLC with fluorescence detection. The sensitivity of a fluorescence detector is generally 20–30 times than that of a UV-Vis detector. In many instances, a fluorescence and UV-Vis detector are placed in tandem for PAH analysis to provide more information on analyte identity. GC–MS typically can achieve a better separation of complex mixtures of PAHs from food extracts. Its combination with isotopically labeled internal standards can accomplish exact quantitation and unambiguous structural identification of the individual PAHs in the mixture.

In addition to direct measurement of PAHs in food sources, it is also possible to measure PAH metabolites as an indicator of past exposure in biological tissues and fluids including blood, urine, and feces, following ingestion of PAH-contaminated foods. Liquid chromatography coupled with mass spectrometry (LC–MS) methods have been developed for PAH metabolites. The softest ionization technique, electrospray ionization, is suitable for the analysis of PAH metabolites, whereas the atmospheric pressure chemical ionization technique can be used to measure parent PAHs due to their better ionization properties under these conditions. The most exact quantitation of PAH metabolites is by LC–MS when this is coupled to the use of isotopically labeled internal standards for each analyte. In most cases, HPLC coupled with UV or fluorescence detection can be used together with LC–MS to simultaneously detect both parent PAHs and their metabolites.

There is considerable evidence that PAHs are enzymatically converted to highly reactive metabolites that bind covalently to macromolecules such as DNA. Thus PAH–DNA adducts may be used as an indicator of exposure in research settings and can be measured in a variety of biological samples of humans and animals. Sensitive methods available to detect PAH–DNA adducts include immunoassays, i.e., enzyme-linked immunosorbent assays (ELISA), radioimmunoassay (RIA), dissociation-enhanced lanthanide fluoroimmunoassay, and ultrasensitive enzyme RIA, [^{32}P]- and [^{35}S]-postlabeling with scintillation counting, surface-enhanced Raman spectroscopy, and synchronous luminescence spectroscopy.

Mitigation and Biomonitoring

It is difficult to completely eliminate PAHs from food to reduce health risks due to their ubiquitous nature. However, the

levels of PAHs in food can be reduced by educating manufacturers and consumers, and by reducing emissions of PAHs to the environment and reducing contamination of the water supply. For instance, the use of PAH-producing commercial smoking and drying processes of food should be avoided. Appropriate advice should be given to consumers who prepare smoked, roasted, grilled, and barbequed food to reduce intake levels of PAHs. Cereals, grain, fruits, and vegetables grown in contaminated soil should be thoroughly washed or peeled before consumption. Seafood and fish from contaminated oceans and waterways should only be consumed if the levels of pyrogenic and petrogenic PAHs are below the limits of concern. Appropriate food packaging such as cellulose-based wrapping can be used to minimize the contamination with PAHs.

Individual risk assessment could be conducted by measuring biomarkers of exposure and effect. Historically, biomarker studies have been conducted in occupationally exposed individuals and smokers. PAHs and their metabolites would be biomarkers of exposure, whereas fingerprints of the exposure long after the metabolites have been cleared would be biomarkers of effect. 1-Hydroxypyrene, a metabolite of pyrene, has been widely used as a urinary biomarker of PAH exposure. In contrast to other PAH metabolites, which are excreted mainly in feces, 1-hydroxypyrene is excreted in urine. The advantage of measuring 1-hydroxypyrene is the relatively high concentrations (2–10%) of pyrene in all PAH mixtures, whereas the disadvantage is that the exposure to the more potent carcinogenic PAHs such as B[*a*]P is not measured. Measurement of 3-hydroxy-B[*a*]P, a metabolite of B[*a*]P, has been historically useful for detecting occupational exposures to PAHs, but lacks sufficient sensitivity to detect nonoccupational exposures to PAHs in food. Another drawback of measuring 3-hydroxy-B[*a*]P is that it is not a metabolite derived from a biological intermediate that might be related to the carcinogenic process. Recently, progress has been made in measuring B[*a*]P-tetraols in the urine of smokers that are derived from the hydrolysis of the diol epoxides and are considered ultimate carcinogens.

As an alternative, PAH–DNA adducts formed from reactive metabolites (mainly diol epoxides) of B[*a*]P and other carcinogenic PAHs have been detected in human bio-specimens following intake of charbroiled meat, exposure to tobacco smoke, or by living in polluted areas. As covalent binding of electrophilic PAH metabolites to DNA is thought to be a key step in the initiation of cancer, measurement of PAH–DNA adducts could be an intermediate biomarker of effect and also of the dose of the ultimate reactive metabolite. In addition, adducts of PAHs with proteins such as albumin and hemoglobin could be promising biomarkers of effect.

Guidelines to Reduce PAHs in Food

World Health Organization (WHO)

The Food and Agriculture Organization of the United Nations and the WHO Joint Expert Committee on Food Additives (JECFA) stated that it is impossible to assume that a safe threshold of PAHs exposure exists, as the adverse health effects of PAHs are due to their toxic metabolites. JECFA evaluated 13 genotoxic and carcinogenic PAHs, namely benz[*a*]anthracene, benzo[*b*]fluoranthene, benzo[*j*]fluoranthene, benzo[*k*]fluoranthene, B[*a*]P, chrysene, dibenz[*a,h*]anthracene, dibenzo[*a,e*]pyrene, dibenzo[*a,h*]pyrene, dibenzo[*a,i*]pyrene, dibenzo[*a,l*]pyrene, indeno[1,2,3-*cd*]pyrene, and 5-methylchrysene. Most of these 13 PAHs are in common with the 16 priority PAHs listed by the US EPA except dibenzopyrenes and 5-methylchrysene. JECFA recommended that B[*a*]P can be used as a surrogate marker of exposure to all these PAHs. In 2009, the Codex Alimentarius Commission (CAC) adopted the first guideline for reducing PAHs intake from smoked or dried food. This guideline emphasized that the combustion of fuel both in smoking and direct drying processes involved in food preparation leads to the formation of PAHs that are possible human carcinogens. In view of the wide use of smoking and direct drying in both food industry and private households, this guideline can also be used as an instructional and education tool for manufacturers and consumers.

Europe

In 2002, the Scientific Committee on Food (SCF) of the European Union (EU) assessed 33 PAHs in food and identified 15 priority PAHs that possess both genotoxic and carcinogenic properties. These 15 EU priority PAHs are benz[*a*]anthracene, benzo[*b*]fluoranthene, benzo[*j*]fluoranthene, benzo[*k*]fluoranthene, benzo[*g,h,i*]perylene, chrysene, cyclopenta[*cd*]pyrene, dibenz[*a,h*]anthracene, dibenzo[*a,e*]pyrene, dibenzo[*a,h*]pyrene, dibenzo[*a,i*]pyrene, dibenzo[*a,l*]pyrene, indeno[1,2,3-*cd*]pyrene, 5-methylchrysene, and B[*a*]P. As recommended by SCF, B[*a*]P was set as a marker for the occurrence and effect of carcinogenic PAHs in food. Because other PAHs are less carcinogenic than B[*a*]P, the total exposure to PAHs would have to exceed that seen from B[*a*]P alone. It is also stated by SCF that the estimated maximum daily intake of B[*a*]P from food is approximately 420 ng B[*a*]P per person, which is approximately 5–6 orders of magnitude lower than the daily doses observed to induce tumors in experimental animals.

In 2005, the European Commission (EC) Regulation 208/2005 was introduced in response to food-contamination problems and 15 EU priority PAHs plus benzo[*c*]fluorene were selected for further investigation by the EC to enable the assessment of the risk of long-term adverse health effects following dietary intake of PAHs. This EU legislation set maximum allowed concentrations for B[*a*]P in various food products in the range 1–10 $\mu g\,kg^{-1}$, and for B[*a*]P and benz[*a*]anthracene in liquid smoke flavoring products of 10 and 2 $\mu g\,kg^{-1}$, respectively. The maximum levels of B[*a*]P in different types of food that are allowed are listed in Table 1. The EC also adopted the 2005/10/EC directive, which describes methods of sampling, sample preparation, and criteria for methods of analysis for B[*a*]P in food.

In 2011, the EC published Regulation 835/2011, an amendment to Regulation 1881/2006 based on the level of B[*a*]P in seafood. The Regulation 835/2011 sets the new maximum permitted levels of four PAHs (B[*a*]P, benz[*a*]anthracene, benzo[*b*]fluoranthene, and chrysene) in seafood. The new levels

Table 1 The limits of maximum level of benzo[*a*]pyrene in different types of food (Commission Regulation of EU, No. 208/2005)

Product	*Maximum level (μg kg^{-1} wet weight)*
Oil and fat	2.0
Foods for infants and young children	1.0
Smoked meats and smoked meat products	5.0
Muscle meat of smoked fish and smoked fishery products, excluding bivalve mollusks	5.0
Muscle meat of fish, other than smoked fish	2.0
Crustaceans and cephalopods, other than smoked	5.0
Bivalve mollusks	10.0

will be introduced on 1 September 2012 and a new set of lower levels will become effective from 1 September 2014. There will be no maximum limit for fish and fishery products that have not been smoked, other than fresh, chilled, or frozen bivalve mollusks. Interestingly, these limits are not based on levels of petrogenic PAH whose TEQ relative to B[*a*]P is unknown.

North America

In the United States, the presence of carcinogens in food is covered by the 'Delaney Clause' of the Federal Food, Drug and Cosmetic Act enforced by the Federal Food and Drug Administration (FDA). Before the 1958 amendment, a substance added to food was presumed safe until it was proven otherwise. The amendment prohibits the FDA approving the use of a food additive found to cause cancer in animals or humans. It has been criticized as being too restrictive by setting a zero level of risk. It applies to only 400 of the 2700 substances that were added to food before the amendment as information on the remaining additives is lacking.

The food preparation and processing techniques described in this article are still permitted to take place. For smoke flavoring agents, the United States have allowed the use of these aromas, provided that B[*a*]P residue does not exceed 0.03 μg kg^{-1} in the final products. The Committee on Diet Nutrition and Cancer appointed by the National Research Council of the United States stated that of the PAHs that commonly occur in the American diet, only three (B[*a*]P, benz[*a*]anthracene, and dibenz[*a*,*h*]anthracene) have been found to be carcinogenic in animals following oral administration.

In Canada, exposure from media other than air has not been taken into account. Only five PAHs (B[*a*]P, benzo[*b*]-fluoranthene, benzo[*j*]fluoranthene, benzo[*k*]fluoranthene, and indeno[1,2,3-*cd*] pyrene) are considered to be entering the environment in a quantity or concentration or under conditions that may constitute a danger to human life or health as defined under the Canadian Environmental Protection Act. The estimated intake (based on B[*a*]P equivalents) of three of the selected PAHs (i.e., B[*a*]P, benzo[*b*]fluoranthene, and benzo[*k*]fluoranthene) for an adult is approximately twofold greater than that inhaled; however, it is likely that there are considerable variations in toxicokinetics and potency by ingestion versus inhalation.

Asia

In China, maximum amounts of B[*a*]P in foods have been set within the regulation GB7104-1994 by the Ministry of Health since 1994. This regulation limits the content of B[*a*]P to 5 μg kg^{-1} in smoked meat, smoked fish products, and cereals. The content of B[*a*]P in edible vegetable oils is set to 10 μg kg^{-1}.

In Singapore, the practice for the reduction of contamination of food with PAHs from smoking and direct drying processes is required by the Agri-Food and Veterinary Authority to comply with the standards recommended by CAC.

Bisphenol A and Endocrine Disruption

LN Vandenberg, Tufts University, Medford, MA, USA

Glossary

Developmental Origins of Health and Disease (DOHaD) hypothesis Postulates that adult diseases, including obesity, diabetes and cancer, can originate due to poor environmental conditions experienced during early development, including gestation.

Endocrine disruptor An exogenous chemical, or mixture of chemicals, that can interfere with any aspect of hormone action.

Low dose Doses in the range of human exposures to endocrine disruptors, which are at doses below those used for traditional toxicological studies.

'Low dose' hypothesis The proposal that endocrine-disrupting chemicals have effects, especially on reproduction and development, at very low doses; the effects observed in exposed animals will occur at similar doses in humans; and humans are being affected by environmental exposures to endocrine disruptors.

Xenoestrogen A synthetic or natural compound, not produced by the body, that mimics the actions of estrogen.

Introduction

There are approximately 80 000 chemicals currently in commerce, and 2000 new chemicals are thought to be added to this list each year. The US Food and Drug Administration (FDA) indicates that at least 1200 of these chemicals have properties that can interfere with the endocrine system by mimicking or blocking the actions of hormones, altering hormone synthesis or secretion, or altering the way that cells respond to hormones. In total, this class of chemicals is referred to as 'endocrine disruptors' or 'endocrine-disrupting chemicals' (EDCs).

A large number of these chemicals come into contact with food. This article will focus on reviewing the science of endocrine disruption and how these chemicals enter the food supply. It will provide an overview of the kinds of chemicals that are known to contaminate food, and then focus on one example: bisphenol A (BPA), an EDC that has been extremely well studied by academic and government scientists and regulatory agencies. This article will cover the controversies associated with BPA and consider whether the lessons learned from this chemical have wider implications for other EDCs found in food.

Overview of EDCs

In the 1950s and 1960s, Rachel Carson's work defined the environmental movement. With the publication of her book, 'Silent Spring,' the public became aware that exposures to chemicals in the environment could affect the health of wild animals and could be a harbinger for devastating effects on human populations as well. Although Carson did not identify environmental contaminants as 'endocrine disruptors' per se, she did note that many of these chemicals were altering the metabolic machinery and nervous systems of exposed animals. She also was one of the first to note that many of these chemicals were bioconcentrating in the food chain, and this bioconcentration was responsible for at least some of the observed toxicities. Chemicals applied to trees to kill insects were accumulating in those insects' bodies and were then consumed by birds. As the birds ate more and more insects, as well as other nontarget organisms (i.e., worms and berries), the chemicals accumulated at higher levels in their bodies and produced adverse effects including egg shell thinning, neuromuscular diseases, wasting, and death. Remarkably, Carson noted that the effects of these chemicals were most profound on the young hatchling birds rather than their parents.

 doi:10.1016/B978-0-12-378612-8.00428-5

Throughout the 1980s and 1990s, Carson's work was expanded on by a number of wildlife biologists including Theo Colborn. Colborn also noticed that many environmental chemicals were affecting the health of wildlife, yet her detailed work was the first to connect the effects of many of these chemicals to alterations in the endocrine system. The connection she drew was that animals were being affected in a variety of ways: diminished reproduction, thyroid problems, altered behavior, and metabolism changes including wasting; each of these factors is controlled by the endocrine system. In 1991, Colborn summoned a small group of scientists from a diversity of backgrounds including ecology, endocrinology, medicine, law, reproductive physiology, toxicology, wildlife management, and cancer biology to discuss their own findings on the effects of environmental chemicals on gene imprinting, sexual differentiation and reproductive function, neurobehavioral development, and autoimmune diseases in mammals and fish. By the end of the meeting, the scientists had agreed on the term 'endocrine disruptor,' writing: "We are certain of the following: A large number of man-made chemicals that have been released into the environment, as well as a few natural ones, have the potential to disrupt the endocrine system of animals, including humans."

Since that time, a number of definitions for 'endocrine disruptor' have been produced. The US Environmental Protection Agency (EPA) defines an endocrine disruptor as "an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development and/or behavior." The World Health Organization (WHO) has produced a similar definition, which states that an EDC is "an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub)populations." Importantly, this definition hinges on the ability to define an 'adverse effect,' which itself is strongly debated in academic and risk assessment communities. Finally, in 2012, representatives from the Endocrine Society, the world's oldest and largest organization devoted to research on hormones, discussed how a simplification of these definitions would provide clarity to the research field. In a rare public health statement, scientists from the Endocrine Society defined an EDC as "an exogenous chemical, or mixture of chemicals, that can interfere with any aspect of hormone action."

Xenoestrogen Hypothesis

In the process of studying EDCs, a group of scientists have also proposed the Xenoestrogen Hypothesis, which theorizes that exposure to hormonally active agents – and in particular those chemicals that mimic the actions of natural hormones – could alter the development of the fetus. These scientists have suggested that *in utero* exposure to EDCs may contribute to endocrine-related diseases including testicular cancer and breast cancer. In fact, numerous epidemiology studies suggest that these and other endocrine-related diseases have increased in incidence in European and the US populations over the past 50 years. Furthermore, studies in developing countries indicate that chronic diseases including diabetes, cardiovascular disease, and even cancers are increasing in incidence, and there has been considerable speculation that chemical exposures, including EDCs, could play a significant role.

'Low Dose' Hypothesis

A related scientific hypothesis that has been proposed is the 'Low Dose' Hypothesis, which suggests that EDCs have effects on exposed animals at doses that are thought to be safe for humans, and humans are also affected by these same environmentally relevant doses. A number of scientists have argued that this concept should not be considered a hypothesis any longer because a significant body of evidence from epidemiology and laboratory animal studies indicates that EDCs affect health endpoints in the range of human exposures. Others, including many risk assessment agencies, maintain that these data are not convincing and point out that epidemiology studies are often not controlled in a way that can conclusively link exposures to particular chemicals to diseases.

The 'Low Dose' Hypothesis, and the data that supports this scientific paradigm, challenges the way the current chemical risk assessments are performed. In traditional toxicology studies, high doses are tested for overt health effects, and then these results are extrapolated using 'uncertainty' factors to calculate a so-called 'tolerable' dose for human exposures, which is assumed to pose no appreciable risk. This dose is rarely tested. Endocrinologists point out that (1) hormones act at extremely low doses in the body, and therefore chemicals that mimic these signaling molecules are also expected to have effects at very low doses; (2) hormones have effects at high doses that are quite different from their effects at low doses. For example, at high doses, estrogen is overtly toxic, but at low doses it has hormonal effects via specific interactions with receptors; (3) the endpoints that are used in traditional toxicology tests may be insufficient to capture the kinds of endpoints that are affected by EDCs.

Developmental Origins of Health and Disease

A final concept that requires attention when considering EDCs is the Developmental Origins of Health and Disease (DOHaD) theory, which proposes that many adult diseases (cancer, obesity, and type 2 diabetes) originate much earlier in life. Some of the earliest evidence for DOHaD came from the exposure of human fetuses to diethylstilbestrol (DES), a potent synthetic estrogen prescribed to pregnant women in the 1940–70s to prevent miscarriage. Not only did this drug have no effect on the ability to maintain pregnancy, but also it was later linked to reproductive tract malformations and cancers in the offspring exposed in the womb. The lesson from DES was two-fold: First, this was an important example of the adverse effect of exogenous hormone exposures during early development, which was not well appreciated at the time, and second, it demonstrated that exposures that occur *in utero* do not necessarily produce congenital birth defects – overt signs of toxicity – but can disrupt organ function in a way that does not manifest until puberty or adulthood.

Endocrine Disruptors in Food

Food and food packaging is an important source of chemical exposures. Some of these compounds are found naturally in foods, whereas others are introduced during the growing, processing, or packaging of food. Importantly, food as consumed should be considered as a source of chemical mixtures that can have the same mechanism of toxicity, or unpredictable interactions can increase toxicity. Thus, although many chemicals are studied as single compounds in *in vitro* and *in vivo* laboratory studies, a number of mixture studies of EDCs have suggested that EDCs with similar modes of action can have additive or even synergistic effects when applied in combination. This means that the toxicity information available from the study of single chemicals must be considered carefully when real-world exposures are concerned.

Phytoestrogens

One source of EDCs is in fact natural, i.e., plant-based (phyto)estrogens. A number of plants contain these plant-based estrogens, and evolutionary biologists have considered the production of these hormone-mimicking agents to be a reactionary response by the plant to protect against herbivory; animals that consume large quantities of plants that contain estrogens are likely to experience infertility. Thus, future generations of the herbivore are less likely to eat future generations of the plant.

Although many plants consumed by humans contain phytoestrogens, one of the best studied examples is soy. Many studies have been dedicated to understand how soy, which contains several individual estrogenic compounds as well as the individual compounds themselves, alters health endpoints in humans. A number of studies have noted that populations with diets high in soy have lower rates of cancer, leading some to conclude that soy – and its phytoestrogens – is protective against cancers. Yet, other studies from laboratory animals indicate that the timing of exposure to these agents is important in considering the health outcomes of consumption. Neonatal exposures to genistein and other phytoestrogens produce alterations in mammary gland development, development of sexually dimorphic regions of the brain, and other estrogen-sensitive endpoints. Thus, even though phytoestrogens are considered 'natural' products, their hormonal activity must be considered in the context of the developmental period of exposure.

Pesticide Residues

A number of EDCs are used as herbicides, insecticides, and fungicides on food crops, and low doses of these chemicals are retained as residues on both fresh and processed plants. Additionally, as mentioned above, many of these chemicals can contaminate the food chain when chemicals sprayed on crops are fed to farm animals. This is not a new problem. In the 1960s, Rachel Carson noted that dichlorodiphenyltrichloroethane (DDT) could be measured in the bodies of the vast majority of Americans, writing, "Among the general population with no known gross exposures to insecticides it may be assumed that much of the DDT stored in fat deposits has entered the body in food. To test this assumption, a scientific team from the US Public Health Service sampled restaurant and institutional meals. *Every meal sampled contained DDT.* From this, the investigators concluded, reasonably enough, that 'few if any foods can be relied upon to be entirely free of DDT.' Analysis of prison meals disclosed such items as stewed dried fruit containing 69.6 ppm and bread containing 100.9 ppm of DDT!" Although DDT has not been used as an insecticide in the US for more than four decades, it (and its metabolites) continues to be measured in human bodies as well as in food.

Industrial Chemicals and Byproducts

A number of industrial chemicals and byproducts are some of the most potent disruptors of the endocrine system. Among these are the polychlorinated biphenyls (PCBs), which had a number of industrial applications. Because of accidents and improper disposal, these chemicals were introduced into the environment, where they persist for long periods of time because of their stability. Another group of EDCs is the dioxins, which consists of a large number of related compounds including dibenzofurans. These are produced as unwanted byproducts in the production of chemical reactions as well as certain natural processes such as forest fires. As environmental pollutants, these so-called 'persistent organic pollutants' (POPs) accumulate in various biota and bioaccumulate in the food chain. POPs include a number of organochlorine pesticides that are no longer used but continue to persist. Monitoring of human milk for POPs undertaken in response to the Stockholm Convention has indicated that women in all countries have been exposure to these exogenous chemicals, although the distribution of POPs differs greatly between industrialized and developing countries. For example, women in developing countries have higher levels of DDT and other pesticides, whereas women in industrialized countries have higher levels of PCBs and dioxins.

Food Packaging

A final source of EDC exposures from food is the packaging itself. A large number of epoxy resins, plastics, and other food-contact materials contain chemicals with endocrine activity, and these chemicals can leach from these food-contact materials into the food itself. Although, like pesticide residues, these chemicals are likely to be found only in small doses, even these small doses are of concern because of their ability to interfere with the endocrine system. As mentioned above, hormones act at extremely low doses, in the part-per-trillion and part-per-billion range. Thus, even small amounts of compounds leaching from food-contact materials are a public health concern. The remainder of this article will focus on one chemical, BPA that is used in a large number of food-contact applications.

Overview of BPA

BPA was first synthesized in 1891 via the combination of two equivalents of phenol with one equivalent of acetone in the

presence of an acid catalyst. It was tested in the 1930s for hormonal activities and was found to have estrogenic properties, although it was never developed for pharmaceutical use. In the 1950s and 1960s, BPA began to be used in the production of plastics and epoxy resins, which eventually would contribute to numerous consumer products. At that time, it was not fully tested for toxicity, and even though it was known to be an estrogen, its hormonal activities were ignored for decades. Today, BPA is one of the highest volume chemicals produced worldwide with approximately 6 billion pounds produced per year and approximately 100 t inadvertently released into the atmosphere during the production process.

Our understanding of BPA's hormonal activities and other toxicities continues to grow as assays examining additional receptor-mediated events are developed. Both *in vitro* and *in vivo* assays demonstrate that this chemical is an estrogen. For years it was considered a 'weak' estrogen because it binds to the nuclear estrogen receptors (ER) with a much lower affinity than 17β-estradiol, a natural estrogen produced in the body. Yet, recent studies indicate that BPA can be equally potent as estradiol in specific biological contexts and binds to membrane ERs and G protein-coupled receptor 30 (GPR30), a type of membrane-bound receptor, with the same affinity as estradiol. Even though BPA is classified as a xenoestrogen, additional studies indicate that it has other endocrine-disrupting properties including the ability to bind estrogen-related receptor γ and the aryl hydrocarbon receptor. BPA also alters thyroid hormone signaling and weakly binds the androgen receptor. Thus, the effects of BPA in a biological context are unlikely to exactly mimic the effects of endogenous estrogens because this chemical can activate multiple pathways.

BPA in Food and Food Packaging

One of the best studied aspects of BPA is its use in food-contact materials. BPA is used as a component of the epoxy resins that line food and beverage cans to prevent interactions between the food materials and the metallic can. When these resins are applied to the surface of the can, some percentage of free BPA remains incompletely polymerized, and this BPA comes in contact with the food; this occurs even when the canning process is optimally conducted. Additionally, the high heat and pressure associated with the sterilization process promotes the migration of BPA out of the resin, and the heat and length of time of storage can also influence this process.

A relatively large number of studies, including several market surveys intended to replicate 'average' daily diets, have demonstrated that the majority of canned foods available in the US and Canada contain measurable levels of BPA. In total, every kind of food (i.e., soups, vegetables, meats, juices, convenience foods, and even pet foods) contains BPA, typically in the range of tens or hundreds of ng g^{-1} food. Additionally, these studies indicate that a single food type (i.e., canned green beans) can have variable concentrations of BPA from can to can, suggesting that human exposure levels cannot be directly calculated by knowing what foods are consumed. Furthermore, even different cans of the exact same food from the same manufacturer can have highly variable concentrations of BPA, indicating that additional unidentified factors can influence the migration of BPA from can linings.

A small number of studies have measured BPA in fresh foods including vegetables, fruits, and meats. The concentrations found in fresh foods, when detected, are very low (typically less than 1 ng g^{-1} food), providing additional evidence that the canning process introduces significant amounts of BPA into the human diet. The source of BPA in fresh foods has not been determined, but because BPA is found in air, dust, and water samples, these are plausible contributing factors.

BPA is also an essential component of polycarbonate plastics, and BPA molecules that are not completely polymerized during the production process can leach from these plastics under normal conditions of use. BPA is also released when these materials are heated, brushed, or exposed to materials with specific pH ranges. For years, polycarbonate plastics were used in the production of the majority of baby bottles, although consumer pressure and recent regulatory actions in several countries, including parts of the EU, Canada, and the US, have shifted toward the use of other types of plastic. Polycarbonate is used in a large number of other consumer products including plastics that come in contact with foods and beverages, and studies using liquid simulants have demonstrated that BPA migration often takes place in the low ng ml^{-1} range.

Finally, a small number of studies have measured the BPA content of food-contact materials including take-out cardboard containers and other paper products (i.e., napkins and paper towels) used in the kitchen. BPA is measured in these products typically in the $\mu g\, g^{-1}$ range, although few studies have determined what concentrations leach into foods. There is some evidence that cardboards and papers made from recycled paper have higher concentrations of BPA; this is likely due to the use of printing dyes containing BPA and the contamination of recycled papers with thermal papers containing BPA, which will be discussed in more detail below.

Nondietary Sources of BPA

The WHO and regulatory agencies around the world have indicated that they believe the majority of human exposures to BPA occur via dietary sources, with leaching into canned foods the highest contributor. However, the WHO acknowledges that their estimates are based on limited data. In contrast to these estimates, a few studies have shown that thermal papers could be a significant source of human exposures. BPA is applied to the surface of these papers, where it changes color when heat is applied, allowing them to be used for receipts, travel tickets, and other applications. BPA readily transfers from these materials to skin and it is absorbed dermally into the bloodstream.

The list of consumer products containing BPA is quite extensive, and the relative contributions from these various sources remain unknown. Cigarette filters and some types of medical equipment, including implantable medical devices, contain BPA. Therefore, some populations (i.e., smokers,

chronically ill patients, infants in the neonatal intensive care unit, etc.) are thought to have higher exposures from these sources. BPA is also found in children's toys, sports equipment, eyeglass lenses, CDs and DVDs, personal care products, dental sealants, paints, plastic dishware and utensils, and household detergents.

Controversies about BPA

Although several important sources of human BPA exposures are known, all sources remain to be elucidated, and the relative contributions of these various sources – as well as their relevant routes of exposure – remain unknown. One major question in the field surrounds actual human exposure levels; a large number of biomonitoring studies clearly indicate that the vast majority of individuals in developed countries have BPA or BPA metabolites in their bodies at all times. The question remains whether the levels that are found in human tissues and fluids are high enough to produce toxicity; the mere presence of a chemical is not considered sufficient evidence that it causes harm. More than two dozen studies have reported free BPA concentrations in the low ng ml^{-1} range in human blood samples from nonoccupationally exposed individuals. Yet, in spite of the consistency reported in numerous studies, the concentration of BPA circulating in the bloodstream remains a major point of controversy. Several scientists have proposed that BPA measured in blood samples does not originate from the blood but is instead a product of contamination. Because BPA is found in many laboratory plastics and reagents as well as air, dust, and water, contamination must be ruled out. However, several studies have made significant and convincing attempts to control and rule out contamination, but this controversy persists.

There is also a large amount of controversy surrounding whether BPA produces effects in laboratory animals, particularly at low doses that are relevant to human exposures. Of course, this question itself has a scientific problem in that 'doses that are relevant to human exposures' are not completely known, considering the large number of consumer products that contain this chemical and the unknown contributions to total exposure concentrations from these various sources. In spite of the difficulties setting a low dose cut-off, several systematic reviews have concluded that BPA does have effects at doses that have been predicted to be safe for humans. In 2007, an expert panel of scientists working on BPA concluded that developmental exposures to BPA (i.e., those that occur during prenatal or perinatal development) alter development of the brain and male reproductive tract, alter enzyme activity, growth and metabolism, and influence behaviors. The panel also concluded that adult exposures alter the male reproductive tract, i.e., adversely affect testicular function. In 2008, the US National Toxicology Program concluded that there was 'some concern' for the effects of BPA on the development of the prostate and brain and on neurobehaviors. In 2010, the US FDA agreed with this assessment, although they maintained that BPA was safe in its current uses in consumer products.

Continuing to feed into this same controversy, there are a small number of studies that have shown no effects of BPA at low doses. Many of these 'no effect' studies are large guideline studies examining validated endpoints and utilizing 'good laboratory practices.' Thus, one major question is why some (often small, academic) studies show effects at low doses and other (often large, industry funded) studies show no effects at low doses. An obvious concern that has been addressed in this field and in other studies of EDCs is whether there is a funder effect, i.e., whether the source of funding has a causative, rather than a correlative relationship with the ability to detect effects of environmental chemicals. There are other issues that need to be considered as well: (1) the large studies examining 'validated' endpoints typically look at insensitive measures of endocrine function, such as the number of pups born to a pregnant female, rather than more sensitive measures like alterations to sex-typical behaviors; (2) the large studies often do not use positive controls to confirm that the endpoints examined respond to low doses of hormones; (3) the large studies often utilize rodent strains that are insensitive to hormones; and (4) the large studies often cannot rule out contamination of the negative control group with hormones or other EDCs. These problems highlight the differences between toxicological approaches and endocrine approaches to studying EDCs.

Finally, there remains controversy regarding whether environmental exposures to BPA are safe for the general human population. A number of epidemiology studies have examined the effects of BPA on endpoints such as obesity, cardiovascular disease, neurobehavioral abnormalities in children, circulating concentrations of endogenous hormones, and others. Unlike epidemiology studies of prescribed pharmaceuticals, where an unexposed population can be compared with individuals administered the compound in question, for BPA comparisons are typically made between individuals with higher exposures and those with lower exposures. However, exposure parameters are determined based on a single, or occasionally a few, urine samples, which may not be the best indicator of typical or previous exposures. Even considering this limitation, a number of epidemiology studies have proposed links between human exposures and diseases/dysfunctions. These studies have not reached the point where they can indicate causation, but they do provide evidence that human exposures to BPA do not have negligible effects.

Can Information Gained from Studying BPA Be Applied to Other EDCs?

BPA is one of the best studied chemicals on earth and is often considered a 'model' for other EDCs. But can the information learned from BPA studies be applied to other chemicals with hormonal activities? This is a fundamental question on several levels: First, it asks whether risk agencies must know every detail about a chemical's actions before taking regulatory action against it. Second, it asks whether there are 'conserved properties' expected for chemicals that interfere with the endocrine system, and whether our knowledge about the actions of natural hormones is sufficient to predict the effects of EDCs. Finally, this question points to the extra-scientific factors involved in the use of chemicals including the benefits derived from those chemicals, the potential risks from using those chemicals, and the role of industry profits in these

discussions. All of these remain open questions, and although BPA may provide lessons that should be applied to other EDCs, this is not the current standard practice in the many fields that contribute to chemical safety assessments.

Conclusions

Food and food packaging serve as significant sources of human exposures to EDCs. Some of these chemicals are natural components found in plant-based foods, but others are hormones added to farm animals to influence body growth and pesticides applied to crops that can bioaccumulate and therefore are also found in meat, eggs, and dairy products. Some are environmental pollutants and some are chemicals used in the resins and plastics used in the food packaging process. Human exposures to single chemicals are likely to be low, but the effects of combinations of these chemicals are largely unstudied and chemical mixtures could have unexpected synergistic effects.

There are more than a thousand studies examining various aspects of BPA use and safety. A few hundred of these studies have examined the effects of BPA on laboratory animals, and more than 100 studies have examined doses below the US EPA 'safe' dose for humans (50 $\mu g\,kg^{-1}\,day^{-1}$). Greater than 90% of these studies have indicated the potential for some type of harm from exposures, with changes to the development of hormone-sensitive organs including the male and female reproductive tracts, the mammary gland, the immune system, metabolic machinery, and the brain. Epidemiology studies hint at similar plausible effects in people exposed via environmental sources (i.e., those that are not occupationally exposed). Yet, BPA continues to be used in a large number of consumer products including numerous food-contact materials, and additional uses continue to be developed.

Ultimately, there are a large number of controversies surrounding BPA and EDCs in general. Countries that use the precautionary principle have limited or banned uses of BPA, indicating that they believe there is sufficient evidence to take action to protect the public from this chemical. Consumer pressures have also influenced the use of BPA in specific products such as baby bottles, but additional studies are needed to determine whether the replacement products also have endocrine-disrupting activities. In sum, the issue of whether the valid uses for BPA – and many other EDCs – can outweigh the costs of their use remains a question that will need to be addressed in the future and continually reevaluated.

HAZARDS OF FOOD CONTACT MATERIAL

Food Packaging Contaminants

J Muncke, Food Packaging Forum, Zurich, Switzerland

Glossary

Flavor scalping Adsorption or absorption of chemical substances from the foodstuff to the food contact material. For example, lipophilic substances that are used as flavoring agents in foods can partition to the packaging material.

Food contact material Packaging, processing, and storage equipment that come into direct contact with food.

Food contact substance Chemical that is used or unintentionally present in food contact materials.

Food simulants Solvents, oil, or polymeric resin that are used to mimic chemical properties of foodstuffs but that lack their chemical complexity and thus simplify chemical analysis of migrants from food contact materials.

Migrant Food contact substance that partitions from food contact material into foodstuff or food simulant.

Migration Process of chemical partitioning from the food contact material to the food.

Release Chemical migration of monomers due to polymer degradation.

Definition

Food packaging contaminants are organic or inorganic chemicals that originate from the food packaging. They are intentionally added substances with a technical function, manufacturing byproducts, impurities of starting materials, or contaminants that are present due to packaging or material recycling (Table 1).

Food packaging contaminants can originate either from the direct food contact material itself or from adhesives, printing inks, and secondary packaging. In the United States of America (USA), food packaging contaminants are also known as indirect food additives and as such not considered to be food contaminants.

Types of Food Packaging Materials and Market Share

Chemical contamination of food from food packaging material largely depends on the type of material in contact with the packaged food. Polymers are the most important food packaging materials (Figure 1), with the most abundant types constituting aproximately 70% of the market share, namely: low-density polyethylene, polypropylene, polyethylene terephthalate (PET), high-density polyethylene, polystyrene (PS) and expanded PS, and polyvinylchloride.

Table 1 Type and example of food packaging contaminants

Type of food packaging contaminants	*Example*
Manufacturing chemicals with technical function	Monomers, additives, catalysts, and printing ink
Nonintentionally added substances (NIAS)	Polymerization byproducts (oligomers), break down products, and impurities of starting materials
Recycling contaminants	Flavor substances, mineral oil, heavy metals, and persistent organic chemicals

Relevance of Food Packaging as Food Contaminant Source

One of the challenges for control of food packaging contaminants is the large amount of different contaminants

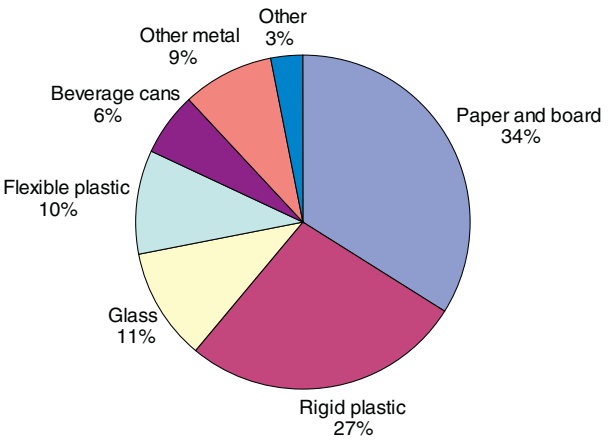

Figure 1 Food packaging materials market share (by value). Reproduced from Rexam (2012) Packaging unwrapped. *Consumer Packaging Report 2011/12.* http://www.rexam.com/files/pdf/packaging_unwrapped_2011.pdf.

 doi:10.1016/B978-0-12-378612-8.00218-3

originating from packaging that can be present in foodstuffs. For food safety control, more than 3000 substances of varying origin (packaging, prefilling, storage, and processing) are considered relevant. This is due to various compounds commonly used for manufacturing plastics, in coatings, and inks or adhesives. Furthermore, synthetic polymers always contain unknown byproducts (nonintentionally added substances (NIAS)) due to the complexity of the chemical manufacturing process. And the environmentally beneficial practice of material recycling can also be a source of inadvertent chemical contamination.

When compared to other types of chemical food contaminants, like pesticides, food packaging is highly relevant (Table 2) with varying levels of contamination for different substances and packaging materials. In fact, food packaging contaminants with their very diverse chemistry are the largest single source of chemical food contaminants. Quantification of food contaminants relies on specific analytical methods for measuring a specific chemical in a given (and usually complex) food matrix. For each contaminant a new analytical method needs to be developed and this can be very time consuming and expensive. However, quantification is only possible for substances with known chemical identity. For unknown chemicals, detection and specific quantification is not possible.

Migration

The process of chemical partitioning from the packaging into food is called migration. Migration is relevant for smaller size molecules and ions (below 1000 Da). The extent to which a substance migrates depends on the physicochemical properties of the migrant, the packaging material, and the food (e.g., fat content) as well as the temperature and duration of storage (Figure 2). Foods that are high in fat content will tend to be more contaminated with lipophilic substances than aqueous foods. The size of packaging in proportion to the amount of food is also relevant, as smaller size packaging has a larger surface to volume ratio, implying a proportionally higher contamination of the food.

Chemical Migrants

The types of chemicals that can migrate from packaging into food are highly diverse and depend on the type of packaging material. Several different types of packaging materials are commonly used (Table 3). For inert materials like stainless steel, ceramic, or glass, only chemicals that are present on the inside surface, directly in contact with the foodstuff, can partition into food. For example, heavy metals that are used in ceramic glazing, or are naturally present in glass raw materials, can transfer from the inner surface to the food by surface

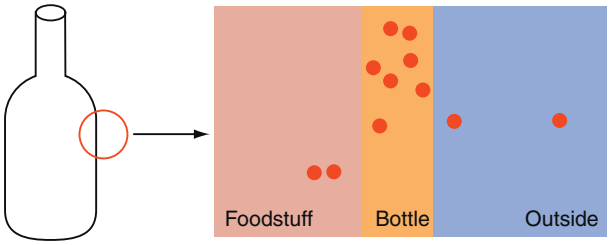

Figure 2 Migration of small size molecules (shown as red dots) from food packaging into food and from environment into food through food packaging.

Table 2 Comparison of potentially hazardous chemicals in food from crop protection to food packaging

Chemical food contaminant	*Crop protection*	*Food packaging*
Legal limits	0.002–50 mg kg^{-1} Maximum residue limits (MRLs) based on compliance with good agricultural practice (GAP)	0.0015–60 mg kg^{-1} Maximum limits based on migration studies and toxicological data
Detected levels	0.001–1 mg kg^{-1} Mean levels with rare examples of levels that cause acute illnesses	Not routinely monitored, but instances of acute illness rarely reported
Frequency of detection	Generally, far less than 1% of fruits and vegetables are analyzed and of these, approximately 1.5% of imported and 1% of domestic samples contain residues above their MRLs or other violation, i.e., pesticide not approved.	Not routinely monitored except for special studies, such as bisphenol A
Control	Minor exceedences of the MRL are not considered to be of public health significance and are handled as technical violations of GAP. As such regulatory warning letters are issued and in the case of repeated violations, future shipments are detained and sampled	Infrequent and perhaps impossible for large number of migrants and unknown substances
Hazard characterization	Premarket assessment of well-defined chemistry and toxicology leading to an acceptable daily intake	Premarket assessment of possible known migrants, but often limited chemistry and toxicology data

Source: Modified from Grob K, Biederman M, Scherbaum E, *et al.* (2006) Food contamination with organic materials in perspective: Packaging materials as the largest and least controlled source? A view focusing on the European situation. *Critical Reviews in Food Science and Nutrition* 46: 529–535.

Table 3 Food packaging materials by type with examples for typical contaminants

Food packaging type	*Materials*	*Typical contaminants*
Plastic	Polyethylene terephthalate	Formaldehyde Acetaldehyde Antimony Ultraviolet (UV) stabilizers
Plastic	Polyethylene	Polyolefin oligomeric saturated hydrocarbons (POSH) Nonylphenol
Plastic	Polyvinylchloride	Vinyl chloride Phthalates Epoxidised soybean oil (ESBO; glass jar closures) Organotins
Plastic	Polystyrene	Styrene Styrene trimers
Plastic	Polypropylene	POSH Erucamide, oleamide Butylated hydroxytoluene
Plastic	Polycarbonate	Bisphenol A
Plastic	Cellulose	Triacetin
Metal	Tin, steel or aluminum with coating	Bisphenol A diglycidyl ether Bisphenol A Ortho-phenylphenol Tin Aluminum
Paper	Nonstick coating	Perfluorinated compounds
Carton (for liquid foods)	Paperboard, aluminum, and polyethylene	POSH Isopropyl thioxanthone Benzophenones
Carton (for dry foods)		Mineral oils Benzophenones Phthalates
Carton (secondary packaging)	Card board	Mineral oils
Glass	Glass container, closure with gasket	Phthalates ESBO Lead
Glass	Glass container, plastic closure	UV stabilizers
Ceramic	Glazed ceramic	Heavy metals

exchange. For these materials neither chemical diffusion from within the packaging material is possible, nor can compounds from the outside (printing inks and adhesives) migrate through the packaging into the food. This inertness is due to the chemical structure of glass, an amorphous noncrystal solid with pore sizes that are too small to allow molecules or single atoms to pass through.

However, chemical contamination of glass-packaged oily foods is observed when plasticizers, like epoxidized soybean oil or phthalates, migrate from the closure's gasket. Careful manufacturing, as well as specially developed low migration closures address this issue.

For noninert materials, like plastics, elastomers, and paper and board, migration can occur either from the packaging material itself or from the outside of the packaging. For example, mineral oils used in printing inks have been found to migrate through carton board packaging into dry foods. Paper-based materials have a large pore size and this permits migration of smaller molecules from the outside to the food inside. To reduce or prevent food contamination, barrier materials can be used. For example, this can be a carton with an inner bag made of aluminum foil. Another form of chemical contamination may be caused by offset migration, when the outside layer of a food contact material comes into contact with its inside layer and thereby transfers chemicals like printing ink components to the direct food contact side. This can be the case for beverage cartons or paper cups that are stacked on top of each other.

Release

Another source of chemical contaminants is from the degrading polymer, when small-sized monomers are released and can migrate into the food. Chemical contamination by release is relevant mainly for reusable food contact materials, like plastic baby bottles or plastic kitchenware (Table 8). Under normal conditions of use, the polymer should not degrade; however, under highly alkaline or acidic conditions some types of polymer will degrade and subsequently release monomers. For example, a polycarbonate container that is made with bisphenol A (BPA) can degrade under alkaline conditions and, as a consequence, continuously release BPA into the contents. Release also becomes relevant over time, when a plastic ages and starts to become brittle. Additives, like ultraviolet stabilizers, are added to plastics to prevent photodegradation.

Scalping

Partitioning of small molecules from foodstuff into packaging material is also possible. This process is called scalping. It can be an indirect source of food packaging contaminants when plastic packaging materials are reused or recycled. Limonene, a flavor substance typically present in fruit juices and sugary soft drinks, partitions into plastic packaging. For refillable plastic bottles this is an issue because limonene is not sufficiently removed by washing. For this reason the refilling of plastic bottles has been deemed unsuitable in certain countries (Switzerland and Japan). Scalping is also of concern when plastic packaging was misused to store nonfood items, such as hazardous chemicals, before recycling. Before it is turned into new food packaging, postconsumer plastic is, therefore, subject to a recycling process that is designed to eliminate chemical contamination. The effectiveness of this process is assessed by challenge tests. In Europe, each food-grade plastic recycling facility must undergo independent review by the European Food Safety Agency (EFSA). In addition, both Europe and the USA restrict the amount of nonfood packaging plastic that is permitted for recycling into food packaging.

Detection of Chemical Contaminants from Food Packaging

Study Design

Identifying the presence of a chemical in food does not render information about the chemical's source. Chemical contamination of food can occur at various stages during food production, processing, filling, and storage. To identify packaging as the source of food contamination a study requires a specific protocol (Table 4). In some cases, a dynamic study design is chosen, where several samples are taken at different times under controlled storage conditions (i.e., temperature and light). Alternatively, for solid foods, samples can be taken from different layers within the packaged food. If there is a difference in contaminant concentrations between the

Table 4 Study designs for identification of food packaging migrants

Time frame	*Sample source*	*Sample type*	*Specifics*
Dynamic: several subsequent time points for measurement in the same sample	Retail: marketed food in final packaging (with or without secondary packaging)	Food	Evidence for migration from food packaging, but no evidence for actual origin of contaminant (i.e., technical agent, NIAS, environmental contaminant, secondary packaging, etc.); no control over time and temperature, i.e., how long has food been in contact with the packaging since filling and what were storage conditions
		Food simulant	If food simulant is used, the originally packaged foodstuff is discarded and the initial migration is not assessed
	Supplier: prefilling packaging before actual food contact	Food	Control over time and temperature from the time food was put in contact with the packaging; may lack final packaging context (printing ink, adhesive, and secondary packaging)
		Food simulant	Common design for premarket food contact material testing; usually lacks final packaging context (inks, adhesives, and secondary packaging)
Static: single time point measurement	Retail: marketed food in final packaging (with or without secondary packaging)	Food	Suitable for dry foods only, where there is no mixing within the packaging Evidence for migration from the packaging is derived by comparing migrant levels in the outer food layer in direct contact with the packaging to the inner food layer.
	Supplier: prefilling packaging before actual food contact	Food simulant	Only makes sense in the context of a larger sampling campaign, where samples are taken throughout food processing, filling, and storage

inner layer compared to the outer layer, with the outer layer showing higher contaminant levels, then migration from the packaging can be suspected as the main source of the chemical contamination.

For certain contaminants, like phthalates that are ubiquitous in the environment, identifying the contamination source can be challenging. Contaminants may migrate from food packaging even though they were not added to the packaging (in contrast to the NIAS that are byproducts of packaging material manufacture). In this case the packaging may have absorbed chemicals from secondary packaging or the environment that can then pass through the packaging into the food.

The third option is to analyze the packaging material before it comes into contact with food. The food contact material can either be extracted or the residual level of a chemical of interest can be assessed, which would allow modeling the maximum possible migration into food. Alternatively, the virgin food contact material can be subjected to an actual migration experiment using food simulants and subsequent chemical quantification.

Food Simulants

Migration of chemicals from packaging into food is usually assessed using food simulants. Food simulants are substitutes for foods that are used to enable chemical analysis. This is useful because quantification requires a distinct and sensitive analytical method for each specific chemical and type of foodstuff. Food simulants represent different groups of food in terms of their chemical properties (**Tables 5** and **6**): hydrophilic, lipophilic, or amphiphilic. Several different types of food simulants are commonly used. For example, migration into oily foods is measured using vegetable oils as the food simulant. For water-based foods, solutions of 10% ethanol or 3% acetic acid are used. Foods that have properties of emulsions (water-in-oil) are simulated by 50% ethanol solutions. Migration of volatile substances into dry foods is approximated using a solid food simulant based on a synthetic polymer with defined pore size (known under the trade name 'Tenax' and in the European Union (EU) as food simulant E).

In general, migration into food simulants is expected to exceed migration into actual foods. Therefore, food simulants generally are thought to overestimate the actual migration into foods. There are, however, exceptions; for example, the migration of perfluorinated compounds into butter. This group of chemicals partitions to a smaller extent into vegetable oil than into an emulsion like butter. A more realistic food simulant for butter, therefore, is a 50% ethanol solution.

For overall migration testing (i.e., an assessment of the mixture of chemicals that can migrate from the entire packaging into food), all food simulants can be used. However, as this analysis is unspecific, the most commonly used food simulant for this purpose is distilled water.

Test Conditions

The extent of chemical migration from food packaging into food and food simulant is highly correlated with temperature and time. This means that appropriate test conditions must be chosen to best reflect the reality of food processing, filling into the packaging, transport, distribution, storage and, if applicable, preparation (i.e., for foods that are cooked or heated in their packaging) (**Table 7**). For food contact materials that are intended for repeated use (like bowls, cooking tools, etc.) migration needs to be assessed in three consecutive experiments under relevant testing conditions, whereby the third experiment needs to comply with the specific migration limits

Table 5 Food type and corresponding food simulant (US Food and Drug Administration guidance)

Food type	*Food simulant*
Aqueous and acidic foods, beverages	10% Ethanol; water (distilled); and 3% acetic acid
Low- and high-alcoholic foods, beverages	50% Ethanol
Fatty foods	Food oil (e.g., corn oil), HB307, and Miglyol 812 (HB307 is a mixture of synthetic triglycerides, primarily C_{10}, C_{12}, and C_{14}. Miglyol 812 is derived from coconut oil)

Table 6 EU list of food simulants. Details on which specific foods are to be tested with which food simulants are given in the relevant regulation (European Commission, EC 10/2011)

Food Simulant	*Abbreviation*	*Use*
10% Ethanol	Food simulant A	Aqueous foods
3% Acetic acid	Food simulant B	Aqueous and/or acidic (pH $<$ 4.5),
20% Ethanol	Food simulant C	Aqueous, alcoholic ($\leq$20% ethanol), and/or fatty food
50% Ethanol	Food simulant D1	Fatty, alcoholic ($>$20% ethanol), and/or emulsions (oil-in-water)
Vegetable oil	Food simulant D2	Fatty, with free fats contacting the food contact material surface
Tenax (poly(2,6-diphenyl-p-phenylene oxide), particle size 60–80 mesh, and pore size 200 nm	Food simulant E	Dry foods (for specific migration testing)
Distilled water	–	Overall migration testing

Table 7 Test conditions reflecting specific filling, transport/storage, and use conditions

Test conditions		*Reality of use*	*Example*
Time	*Temperature*		
240 h (10 days)	40 °C	Filling, storage, and/or use at room temperature	PET bottle; midterm storage (>1 month)
48 h (2 days)	121 °C	After filling sterilization by autoclave	Glass jar with twist-off cap; PP pouch
24 h	40 °C	One day storage at room temperature	Sandwich pack
2 h	70 °C	Consumption of hot contents (single use)	PS cup, paper cup
1 h	175 °C	Home preparation of food in original packaging by oven cooking	PET tray; fatty food simulant
4 h	Boiling point of food simulant (reflux)		PET tray; aqueous food simulant
0.5 h (30 min)	40 or 20 °C	Short exposure at room temperature	PP reusable juice cup
0.5 h (30 min)	175 °C	Mixing and serving hot food	PA cooking spatula

Abbreviations: PA, Polyamide; PET, polyethylene terephthalate; PP, polypropylene; PS, polystyrene.
Source: Adapted from Cooper I (2007) Plastics and chemical migration into food. In: Barnes KA, Sinclair CR, and Watson DH (eds.) *Chemical Migration and Food Contact Materials*, pp. 228–250. Cambridge: CRC Press/Woodhead Publishing Limited.

(EU). This approach assesses migration of additives, residual monomer, and byproducts. Single-use food packaging articles, like PET soft drink bottles or PS ice cream containers, must comply with their intended-use conditions. If consumers reuse these items, legal compliance is not required.

Assessment of Overall Migration

In Europe, overall migration to any of the food simulants should not exceed 10 mg dm^{-2} for plastics and multilayered multimaterials such as beverage cartons consisting of several layers of different materials. The measurement of overall migration for nonvolatile substances from packaging is an assessment of packaging quality and measured in food simulants. A defined piece of packaging material is weighed and then incubated with the food simulant under the appropriate testing conditions (depending on the intended use). Unspecific migration is then assessed by evaporating nonoily food simulants and determining the residue's mass. For oily food simulants the mass loss of the plastic food contact material is assessed. Because plastics can absorb oil this assessment requires an initial extraction or cleaning phase, followed by subsequent weighing.

Chemical Quantification

Quantification of specific migrants from food packaging requires a dedicated analytical method for each migrant of interest. The different steps that are necessary for compound quantification depend on the physicochemical properties of the compound (vapor pressure, lipophilicity, molecular weight, etc.), on the properties of the food contact material (lipophilicity, pore size, etc.) and on the nature of the foodstuff into which migration should be assessed (fatty/aqueous/emulsion; liquid/dry).

Migration is usually assessed experimentally using a migration cell, where a defined surface of the packaging material is brought into contact with a food simulant under controlled conditions (temperature, pressure, and time). Subsequently the migrant of interest is analyzed in the food simulant. Analyses are usually carried out using liquid or gas chromatography for quantification with subsequent mass spectrometry for identification/confirmation. Analytical methods may vary and essentially depend on the migrant of interest (molecular weight, state of matter, chemical stability, etc). Migrants can be analyzed directly in the food or in an appropriate food simulant, whereby the concentration in food is legally specified (i.e., must not exceed the legal limit).

Biological Assessment of Overall Migration

Food packaging can transfer many different compounds into foods, including unknown substances that are present due to manufacturing side reactions. The current risk assessment approach manages single substances and assumes that relevant effects are only caused at higher concentrations. This approach has been criticized lately, because recent toxicological research has highlighted that additional aspects of toxicity can be relevant. In particular, mixtures of chemicals can act additively and cause an effect, even though individual compounds are present at low doses. Furthermore, there is an ongoing debate about effects of chemicals at low doses that are missed by conventional testing at higher concentrations. Exposure to chemicals during sensitive windows of development (pre- and neonatal) can impact health throughout life. Endocrine disrupting chemicals are of specific concern. Therefore it has been suggested to additionally use effect-directed analysis of overall migration, rather than only relying on substance-by-substance chemical safety testing. So far only academic studies have used this approach and it is not commonly required for safety testing of food packaging materials by regulators.

Migration Modeling

It is possible using appropriate mathematical models to assess the migration of a chemical into food. The concentration of the substance of interest in the packaging needs to be known.

Table 8 Nonpackaging food contact materials and typical migrants

Food contact material	*Article type*	*Migrant*
Polyamide (nylon)	Cooking and serving spoon	Primary aromatic amines
Melamine–formaldehyde resin	Children's tableware	Formaldehyde
Polycarbonate	Refillable water bottle	Bisphenol A

The extent that a compound can migrate will depend on the material properties (pore size, thickness, shape, and surface area); concentration of the compound in the material; thermodynamic properties of the migrant; chemistry of the foodstuff and on other aspects, like temperature at filling and during storage, and storage time. The most commonly used models are based on Fickian diffusion and have been validated for different food contact plastics under various experimental conditions. Migration models have been found to give fairly accurate predictions of actual migration for several migrants, but under certain conditions and for certain migrants, exceptions have been noted.

Food Contact Materials Other than Packaging

During the processing, filling, and preparation of foods several materials come into contact with foodstuffs (storage containers, conveyor belts, gloves, chopping boards, surfaces, cookware, etc.). These items can also be sources of chemical migration into food. Therefore, such types of food contact materials are included in the US and EU regulation of food contact materials. Examples for reusable articles and typical migrants are given in Table 8.

Migrants Reacting with Foods

Migrants that react with food ingredients and thereby form new chemical species, present a special challenge. For example, BPA diglycidyl ether (BADGE) can form chlorinated or hydroxylated species with food compounds. Therefore, when only BADGE contamination is assessed in food, these species are missed. The result is an underestimation of BADGE migration. Another example is benzoic acid (migrating from packaging material), which may react with ascorbic acid present in the food to form benzene. In such cases, it can be a challenge to identify the source of food contamination. Furthermore, the use of food simulants will miss such unwanted crossreactions in many cases.

Risk Assessment and Management in the EU, Japan, and USA

The underlying principle of regulation is that there are levels of chemical food contamination which are considered not dangerous to human health for the entire population. This threshold-based risk assessment principle is universal for all legislatures; however, the risk management varies in different countries.

In Europe, risk management is based on migration from food packaging into food. In this approach, single substances are permitted to contaminate foods at levels below the tolerable daily intake (TDI), derived from toxicological data. In this approach, a worst-case human exposure is assumed. However, such a practise may also lack an incentive for packaging producers to reduce migration to technically feasible levels. Industry maintains that the use of chemicals beyond what is technically necessary is not economic and therefore would not be common practice.

In the USA, risk management includes an estimate of human exposure to food packaging contaminants through the diet. In particular, the Food and Drug Administration (FDA) provides Consumption Factors and food-type distribution factors that allow an estimation of actual consumer exposure. This approach is more realistic in terms of actual human exposure to food packaging contaminants; however, it is also not simple to validate the correctness of the estimation factors that are used, leaving room for potential systematic error. It can be assumed that permitted levels of food contact substances in food packaging would tend to be higher with this estimated exposure approach compared to a regulation based on migration.

EU

In Europe, food packaging contaminants are regulated by the European Commission, Directorate General Health and Consumers under the Food Packaging Framework Regulation (Food Packaging Framework Regulation (EC 1935/2004), Article 3: "Materials and articles, including active and intelligent materials and articles, shall be manufactured in compliance with good manufacturing practice so that, under normal or foreseeable conditions of use, they do not transfer their constituents to food in quantities which could: (a) endanger human health;[…]"). EFSA provides scientific advice to the Commission on food packaging contaminants. Food packaging contaminants are managed based on toxicological testing of single substances. For plastic packaging and plastics layers in multimaterial packaging these levels are specified as specific migration limits (SML) and based on a substance's TDI. For a substance that lacks an SML, the overall migration limit of 10 mg dm^{-2} of food contact surface or 60 mg kg^{-1} food (for baby foods) applies. The overall migration limit applies to nonvolatile substances.

The European food contact materials regulation has two notable provisions:

1. The Fat Reduction Factor (FRF) can be applied when assessing the SML for lipophilic migrants from plastics into fatty foods. The underlying rationale for the FRF is that lipophilic foods will contain higher levels of lipohilic contaminants; however, consumers only consume a limited amount of highly fatty foods per day (i.e., less than the risk assessment assumption of 1 kg of food per person per day). The FRF does not apply to packaging for infant foods.
2. The Functional Barrier concept permits the use of not explicitly authorized substances in food packaging plastic

layers behind barrier materials that reduce their migration into food. These substances may not exceed the migration threshold of 10 μg kg^{-1} food. Exempted from this rule are nanoparticles and compounds that are carcinogenic, mutagenic, or toxic to reproduction.

Japan

In Japan, acceptable levels of food packaging contaminants are self-regulated by the food packaging industry and similar to regulations in Europe and the US. An overall migration limit is set at 30 mg/kg food, and for select substances, specific migration limits exist.

USA

In the USA, regulation of food contact materials (Code of Federal Regulations Part 21) is the responsibility of the FDA. Food contact substances are chemicals that are present in food packaging and must be shown to be safe before they can be marketed. They are authorized either by the Food Additive Petition or by the Food Contact Notification Program. The latter requires less toxicological testing; however, exposure levels must not exceed 1 mg per person per day. If exposures are above this level, a Food Additive Petition is required. A third option for authorization is the Threshold of Regulation: If the estimated daily exposure to a food contact substance lies below 1.5 μg per person per day, toxicological data is not required at all, if the substance's chemical structure is without toxicity alerts. Furthermore, chemicals may also be used in food packaging if they are generally recognized as safe (GRAS). Not all substances that are used under GRAS status are listed by FDA. For the other food contact substances, inventories are available online. Substances that were authorized under the Food Contact Notification Program can only be used by the notifying company.

HAZARDS OF FOOD CONTACT MATERIAL

Phthalates

RW Benson, US Environmental Protection Agency, Denver, CO, USA

Glossary

Hazard index The sum of the hazard quotients for a series of chemicals of interest.

Hazard quotient The human exposure to a chemical of interest (mg kg^{-1}-day^{-1}) divided by its reference dose (RfD) (mg kg^{-1}-day^{-1}).

RfD An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a no adverse effect level, lowest observed adverse effect level, or benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used.

Uncertainty factor One of several, generally 10-fold, default factors used in operationally deriving the reference dose from experimental data

Chemical Name and Structure

The phthalate esters that are the subject of this article are derivatives of phthalic acid, in which the acid groups are in the ortho position. The two alcohol groups can be the same or different and straight or branched chain. Phthalates are manufactured by reacting phthalic anhydride with alcohols (Figure 1).

Uses

Phthalate esters are used to impart flexibility to plastic products. Many consumer and food packaging products contain phthalate esters. The major uses of the selected phthalate esters are summarized in (Table 1). The phthalate esters are not covalently bound in the products in which they are used and can leach into the surrounding environment.

Hazard Characterization

Extensive data have been published since 2000, showing that phthalate esters with side chains of 3–10 carbon units are developmental toxicants. The phthalate diester is rapidly converted to the phthalate monoester in rats and humans.

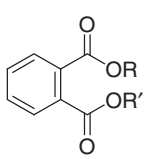

Figure 1 General structure of phthalate esters.

This metabolism occurs by nonspecific esterases in the digestive tract before absorption and in tissues after absorption. For those phthalate esters that cause developmental effects, the phthalate monoester metabolite is believed to be the toxic chemical.

Matsumoto *et al.* summarized the studies available in human populations. A number of studies show an association between effects (sperm and semen parameters in adults; anogenital distance in newborn males; and serum hormone levels in newborn infants) and environmental exposure to phthalates. After a thorough review of these studies, Matsumoto *et al.* concluded: "some of the findings in human populations are consistent with animal data suggesting that PAEs (phthalic acid esters) and their metabolites produce toxic effects in the reproductive system. However, it is not yet possible to conclude whether phthalate exposure is harmful for human populations."

Based on the extensive data available from laboratory animals, there is concern that environmental exposure to phthalate esters could cause adverse effects on the developing human male reproductive system. Additional concern is raised by the demonstration that phthalate monoesters known to cause developmental toxicity in rats are detected in a large percentage of human amniotic fluid samples.

Benson conducted a literature review for the phthalate esters that have the potential to be developmental toxicants based on structure–activity relationships. The focus was on the phthalate esters with a side chain containing 4–10 carbon units in the ortho position. The shorter chain phthalate esters (dimethyl phthalate and diethyl phthalate) were not included because these chemicals were not found to be developmental toxicants in laboratory animal studies. Relevant toxicological data following *in utero* exposure was located for dibutyl phthalate (DBP), diisobutyl phthalate (DiBP), butyl benzyl

 doi:10.1016/B978-0-12-378612-8.00219-5

Table 1 Phthalate diester, its corresponding monoester metabolite, and uses

Phthalate diester	*Monoester metabolite*	*Major uses*
Dibutyl phthalate CAS # 84-74-2 Molecular weight: 278	Monobutyl phthalate (MBP)	Plastic products containing nitrocellulose, polyvinyl acetate, or polyvinyl chloride; pharmaceutical coatings; lubricant for aerosol valves; antifoaming agent; skin emollient; nail polishes; fingernail elongators; and hair spray
Diisobutyl phthalate CAS # 84-69-5 Molecular weight: 278	Monoisobutyl phthalate	Same as dibutyl phthalate but less commonly used
Butylbenzyl phthalate CAS # 85-68-7 Molecular weight: 312	MBP and monobenzyl phthalate	Polyvinyl chloride products including vinyl tile, food conveyer belts, carpet tile, artificial leather, tarps, automotive trim, weather strippers, traffic cones, and vinyl gloves
Diethylhexyl phthalate CAS # 117-81-7 Molecular weight: 390	Monoethylhexyl phthalate	Polyvinyl chloride products including building products, car products, clothing, food packaging, children's products, and in medical devices (storage containers, bags, and flexible tubing)
Dipentyl phthalate CAS # 131-18-0 Molecular weight: 306	Monopentyl phthalate	Not found
Diisononyl phthalate CAS # 68515-48-0 and 28553-12-0 Molecular weight: 419	Monoisononyl phthalate	Flexible polyvinyl chloride products including children's toys, flooring, gloves, food packaging material, drinking straws, and garden hoses

phthalate (BBP), diethylhexyl phthalate (DEHP), dipentyl phthalate (DPP), and diisononyl phthalate (DiNP). Benson focused on the most sensitive effect in the most sensitive life stage, the reproductive tract of the developing male fetus, to develop the reference dose (RfD) for each of the phthalate esters.

The development of the male reproductive tract is dependent on the presence of testosterone and the androgen receptor. Any chemical that reduces the concentration of the androgen receptor–testosterone complex during the critical developmental window has the potential of causing irreversible malformations of the male reproductive tract. The mechanism of action in laboratory rats for each of the phthalate esters that are the subject of this article is the decrease in the concentration of fetal testosterone in Leydig cells during the critical developmental window in the rat. The decrease in testosterone concentration is triggered by a decrease in gene expression for the proteins involved in the rate-limiting steps of testosterone synthesis. These steps include transport of cholesterol into the mitochondria facilitated by steroidogenic acute regulatory protein (STAR) and the conversion of cholesterol to pregnenolone by the enzyme CYP11A1 (also known as P450 side-chain cleavage enzyme).

There is experimental evidence that the decrease in fetal testosterone caused by cumulative exposure to these six phthalate esters in rats follows a dose additional model (Howdeshell *et al.*). Therefore, it is appropriate to conduct a cumulative risk assessment for simultaneous exposure to these phthalate esters using a dose addition model. This article provides examples of a cumulative risk assessment using exposure information from a US and German population.

Calculation of the Reference Dose

The standard US Environmental Protection Agency (EPA) approach was used to derive the RfD for the selected phthalate esters. The uncertainty factors included a factor of 10 for intraspecies variability, a factor of 10 for interspecies variability, and, if needed, a factor for extrapolation from a lowest observed adverse effect level (LOAEL) to a no adverse effect level (NOAEL).

For these phthalate esters the most vulnerable target for adverse health effects is the reproductive tract of the developing male fetus. Therefore, the RfD is based on exposure–response data from studies following *in utero* exposure. This RfD will protect humans from other adverse effects that may occur at a higher exposure during neonatal or adult life.

Benson derived RfDs for DBP, DiBP, BBP, DEHP, DPP, and DiNP using the NOAEL or LOAEL values for each phthalate ester from the published literature. If appropriate, benchmark dose analysis was conducted using EPA software. These values are summarized in **Table 2**.

These RfDs are based on the assumption that the adverse health effect observed at the lowest exposure in laboratory rats (decrease in testosterone concentration in fetal Leydig cells) is relevant to humans. Some recent toxicological studies provide fairly convincing evidence that the decrease in fetal testosterone concentration is a species-specific response. Gaido *et al.* first demonstrated that adverse developmental effects occurred in mice in the absence of a decrease in testosterone concentration and an absence in a decrease in gene expression for the proteins involved in the rate-limiting steps in cholesterol transport into the mitochondria and formation of pregnenolone. A 250- or 500-mg DBP per kg-day exposure to the mouse from gestational day 16–18 significantly increased the seminiferous cord diameter, number of multinucleated gonocytes per cord, and number of nuclei per multinucleated gonocytes. The exposure of 250 mg kg^{-1}-day^{-1} was the lowest exposure tested in this study.

Two research groups have investigated the possibility of a species-dependent response using xenografts of testicular tissue from different species implanted into rodent hosts.

Table 2 Reference dose for selected phthalate esters

Chemical	*Critical effect and reference*	*POD/UF*	*RfD*
DBP	Decreased fetal testosterone NOAEL = 30 mg kg^{-1}-day^{-1} Lehmann *et al.* (2004)	NOAEL/100	0.3 mg kg^{-1}-day^{-1} or 0.00108 mmol kg^{-1}-day^{-1}
DiBP	Decreased fetal testosterone production $BMDL_{1SD}$ = 80 mg kg^{-1}-day^{-1} Howdeshell *et al.* (2008)	$BMDL_{1SD}$/100	0.8 mg kg^{-1}-day^{-1} or 0.00288 mmol kg^{-1}-day^{-1}
BBP	Decreased fetal testosterone production $BMDL_{1SD}$ = 102 mg kg^{-1}-day^{-1} Howdeshell *et al.* (2008)	$BMDL_{1SD}$/100	1 mg kg^{-1}-day^{-1} or 0.00327 mmol kg^{-1}-day^{-1}
DEHP	Small or absent male reproductive organs $BMDL_{10}$ = 27 mg kg^{-1}-day^{-1} NTP 2005	$BMDL_{10}$/100	0.3 mg kg^{-1}-day^{-1} or 0.000692 mmol kg^{-1}-day^{-1}
DPP	Decreased fetal testosterone production $BMDL_{1SD}$ = 17 mg kg^{-1}-day^{-1} Howdeshell *et al.* 2008	$BMDL_{1SD}$/100	0.2 mg kg^{-1}-day^{-1} or 0.000548 mmol kg^{-1}-day^{-1}
DiNP	Decreased fetal testosterone LOAEL = 750 mg kg^{-1}-day^{-1} Borch *et al.* (2004)	LOAEL/1000	0.8 mg kg^{-1}-day^{-1} or 0.00179 mmol kg^{-1}-day^{-1}

Abbreviations: BBP, butyl benzyl phthalate; DBP, dibutyl phthalate; DEHP, diethylhexyl phthalate; DiBP, diisobutyl phthalate; DiNP, diisononyl phthalate; DPP, dipentyl phthalate; LOAEL, lowest observed adverse effect level; RfD, reference dose.

POD is the point of departure and UF is the total uncertainty factor.

$BMDL_{1SD}$ = lower 95% confidence limit of the exposure necessary to give a 1 standard deviation decrease in testosterone versus control.

$BMDL_{10}$ = lower 95% confidence limit of the exposure necessary to give a 10% increase in adverse effect versus control.

RfD (mmol kg^{-1}-day^{-1}) = Rfd (mg kg^{-1}-day^{-1})/molecular weight (mg $mmol^{-1}$).

Mitchell *et al*. compared the effect in human fetal tissue versus rat fetal tissue xenografts in host mice. Human fetal tissue xenografts in mice showed no significant decrease in testosterone concentration following exposure to DBP or monobutyl phthalate. In contrast, rat fetal tissue xenografts showed decreases in testosterone concentration and decreased expression of rat testis CYP11A1 and STAR mRNA as found in intact rats.

Heger *et al*. found comparable results. These researchers implanted fetal rat, fetal mouse, or fetal human testis tissue into immunodeficient rat and mouse hosts. Host animals were treated by gavage with a range of doses of DBP. Consistent with the *in utero* response, phthalate exposure induced mononuclear gonocytes formation in rat and mouse xenografts, but only the rat xenograft exhibited suppressed expression of steroidogenesis genes. Across the range of doses tested, human fetal testis xenografts exhibited mononuclear gonocyte induction at all exposures (100, 250, and 500 mg kg^{-1}-day^{-1}) but were resistant to suppression of steroidogenic genes at all exposures.

It is not known whether transport of the toxic metabolite to the testicular xenografts is the same as that in intact animals. In the studies of Heger *et al*., an exposure of 100 mg kg^{-1}-day^{-1} of DBP in the host animal is an adverse effect level in the human testicular xenograft. In intact rats, Lehmann *et al*. found a no effect level for a decrease in testosterone concentration at 30 mg kg^{-1}-day^{-1} and an effect level at 50 mg kg^{-1}-day^{-1}. This comparison would suggest that a hazard quotient for DBP using a decrease in testosterone concentration or using induction of mononuclear gonocytes as the end point would be in the same range. However, there are no comparable data available for the other phthalate esters.

Exposure Assessment

Because the phthalate esters are used in such a wide variety of consumer products and are not covalently bound in the products in which they are used, human exposure to the phthalate esters is widespread. Some common examples are listed below.

- Inhalation of emissions from manufacturing facilities
- Dermal uptake from use in vinyl gloves and cosmetics
- Ingestion of dust from emissions from floor and carpet tile and products used in automotive interiors
- Ingestion from plastic coatings on pharmaceuticals
- Ingestion from uses in children's chew toys
- Ingestion from uses in food packaging
- Intravenous exposure from uses in medical storage bags and tubing.

Phthalate esters have no direct uses in food. Atmospheric deposition on agricultural products from nearby manufacturing facilities is possible. However, the occurrence of a phthalate ester in food is more likely to be the result of contamination by transfer of the phthalate ester from materials in contact with the food during processing, handling, or transportation. Examples of materials that can contain a phthalate ester capable of transfer to the food include plastic bottles and containers, flexible plastic tubing, food conveyer belts, and various food-packaging materials.

Limited data on the estimated exposure of humans to DBP, BBP, DEHP, and DiNP from food are available from a dietary study conducted in Denmark and from measurement of these chemicals in selected fatty foods in the United Kingdom.

Mean exposure to DBP is 0.2–1.8 μg per kg of body weight-day; BBP is 0.1–0.4 μg per kg of body weight-day; and DEHP is 2–3 μg per kg of body weight-day. DiNP was below the detection limit in the foods surveyed. Migration is more extensive to fatty foods because the octanol–water partition coefficient (log Kow) exceeds 1.

Data on human exposure to phthalate esters are available for the US population from the National Health and Nutrition Examination Survey (NHANES) surveys in 1999–2000, 2001–2002, 2003–2004, 2005–2006, and 2007–2008. These studies measured the concentration of the monoester metabolites in the urine of a cross section of the US population aged 6 years and above. As the monoester metabolites and additional oxidation products are rapidly excreted in urine (that is, they do not bioaccumulate), measurements of metabolites in urine can be used to estimate total exposure to phthalate esters in the individual.

Kohn *et al*. used an earlier data set from 289 individuals and a linear two-compartment model to estimate the exposures (mg kg^{-1}-day^{-1}) in the general population. No study has used the same method as Kohn *et al*. to update these exposure estimates, taking into account the additional data sets available from the NHANES surveys. However, these subsequent NHANES data sets show values that are comparable to or somewhat lower than those used in the original analysis of Kohn *et al*. Therefore, large differences in the exposure estimates are not anticipated.

Data on human exposure to phthalate esters are also available from a German population (Wittassek and Angerer). The authors calculated the oral exposure from the urinary levels of the metabolites and urinary excretion factors determined from human metabolism studies. These data for both populations are summarized in Table 3 and Table 4. Data on exposure from food only are not available for the US or German populations. However, comparison of the results presented above implies that food is a significant contributor to the total exposure to phthalate esters.

Because of the widespread nature of human exposure to phthalate esters, it is more informative to consider total exposure, rather than focus on specific sources of exposure.

Table 3 Exposure to selected phthalate esters for a US population in mg kg^{-1}-day^{-1}

Chemical	*Median*	*95th Percentile*	*Maximum*
DBP	0.0013	0.0061	0.094
DiBP	0.0002	0.0011	0.016
BBP	0.00088	0.0040	0.029
DEHP	0.00071	0.0036	0.046
DPP	Not available	Not available	Not available
DiNP	<LOD	0.0017	0.022

Abbreviations: BBP, butyl benzyl phthalate; DBP, dibutyl phthalate; DEHP, diethylhexyl phthalate; DiBP, diisobutyl phthalate; DiNP, diisononyl phthalate; DPP, dipentyl phthalate; LOD, limit of detection.

Exposure to BBP, DEHP, and DiNP is directly reproduced from Kohn M, Parham F, Masten S, *et al.* (2000) Human exposure estimates for phthalates. *Environmental Health Perspectives* 108: A440–A442, Table 2. The original data used reported the urinary excretion of DBP and DiBP as a single summed value. Subsequent data collected by NHANES show that urinary excretion of DiBP (creatinine corrected) is approximately 15% of the excretion of DBP (creatinine corrected). Accordingly, the DBP values have been reduced by 15% and the remainder is attributed to DiBP.

Table 4 Exposure to selected phthalate esters for a German population in mg kg^{-1}-day^{-1}

Chemical	*Median*	*95th Percentile*	*Maximum*
DBP	0.0021	Not provided	0.230
DiBP	0.0015	Not provided	0.0273
BBP	0.0003	Not provided	0.0022
DEHP	0.0027	Not provided	0.0422
DPP	Not available	Not available	Not available
DiNP	0.0006	Not provided	0.0368

Abbreviations: BBP, butyl benzyl phthalate; DBP, dibutyl phthalate; DEHP, diethylhexyl phthalate; DiBP, diisobutyl phthalate; DiNP, diisononyl phthalate; DPP, dipentyl phthalate.

Data are reproduced from Wittassek M and Angerer J (2008) Phthalates: Metabolism and exposure. *International Journal of Andrology* 31: 131–138, for 102 individuals.

Risk Assessment

DBP, DiBP, BBP, DEHP, DPP, and DiNP cause a similar spectrum of adverse health effects in laboratory rats and operate by the same mechanism of action: reduction of the testosterone concentration in the fetal Leydig cells. The reduced concentration of the testosterone–androgen receptor concentration causes a failure in subsequent signaling pathways that are required for the development of the male reproductive organs. Therefore, it is appropriate to use a dose addition model in cumulative risk assessment for these phthalate esters. A response addition model is not appropriate.

The simplest way of doing a dose addition approach is to calculate the hazard quotient for each chemical and then calculate the hazard index as the sum of the individual hazard quotients. The step-by-step procedure is described below.

1. The hazard quotient is calculated for the median exposure to each phthalate ester by dividing the median exposure in mg kg^{-1}-day^{-1} (Table 3 or 4) by the RfD in mg kg^{-1}-day^{-1} for the respective phthalate ester (Table 2).
2. The hazard quotients are added for the median exposure to get the hazard index for the median exposure.
3. Step 1 and 2 are repeated for the 95th percentile exposure and maximum exposure.
4. All values are rounded to one significant digit.
5. The calculated Hazard Quotients and Hazard Indices for the US and German populations are summarized in Table 5 and 6, respectively.

Risk Characterization

A hazard index of less than 1 means that there is little probability that an adverse effect might be observed from the combined exposure to the chemicals. A hazard index of 1–100 means that there is a potential that an adverse effect might be observed from the combined exposure to the chemicals. A hazard index of 100 or more indicates that the estimated exposure is comparable to the NOAEL observed in laboratory animals and indicates a high potential that an adverse effect might be observed in humans

Table 5 Hazard quotient and hazard index calculation for a US population

Chemical	*Median exposure*	*95th Percentile exposure*	*Maximum exposure*
	Hazard quotient	*Hazard quotient*	*Hazard quotient*
DBP	0.004	0.02	0.3
DiBP	0.0003	0.001	0.02
BBP	0.0009	0.004	0.03
DEHP	0.002	0.01	0.2
DPP	Not calculated	Not calculated	Not calculated
DiNP	Not calculated	0.002	0.03
	Median exposure	95th Percentile exposure	Maximum exposure
	Hazard index	Hazard index	Hazard index
	0.007	0.04	0.6

Abbreviations: BBP, butyl benzyl phthalate; DBP, dibutyl phthalate; DEHP, diethylhexyl phthalate; DiBP, diisobutyl phthalate; DiNP, diisononyl phthalate; DPP, dipentyl phthalate.

Table 6 Hazard quotient and hazard index calculation for a German population

Chemical	*Median exposure*	*95th Percentile exposure*	*Maximum exposure*
	Hazard quotient	*Hazard quotient*	*Hazard quotient*
DBP	0.007	Not calculated	0.8
DiBP	0.002	Not calculated	0.003
BBP	0.0003	Not calculated	0.002
DEHP	0.002	Not calculated	0.01
DPP	Not calculated	Not calculated	Not calculated
DiNP	0.0008	Not calculated	0.05
	Median exposure	95th Percentile exposure	Maximum exposure
	Hazard index	Hazard index	Hazard index
	0.01	Not calculated	0.9

Abbreviations: BBP, butyl benzyl phthalate; DBP, dibutyl phthalate; DEHP, diethylhexyl phthalate; DiBP, diisobutyl phthalate; DiNP, diisononyl phthalate; DPP, dipentyl phthalate.

from the combined exposure to these chemicals. As can be seen from the results summarized in Tables 5 and 6, the hazard index for the median, 95th percentile, and maximum exposed individuals are less than 1. Thus, it is unlikely that humans are experiencing an adverse developmental effect from current environmental exposure to these phthalate esters.

Management Interventions

The United States and the European Union have limited the quantity of BBP, DBP, and DEHP in children's toys that can be taken into the mouth to 0.1% by mass of the product. The European Union has also restricted the use of BBP, DBP, and DEHP to food contact surfaces only for nonfatty foods up to 0.1%, 0.05%, and 0.1%, respectively, in the final product. These restrictions also established Specific migration limits of 30, 0.3, and 1.5 mg kg^{-1} food for BBP, DBP, and DEHP, respectively. There are no comparable restrictions in the US on the use of BBP, DBP, and DEHP in products with contact to food.

Current Status

The European Union is continuing to investigate the safety of the uses of BBP, DBP, and DEHP under the Registration, Evaluation, Authorization and Restriction of Chemicals program.

HAZARDS OF FOOD CONTACT MATERIAL

Nanotechnologies and Nanomaterials

BG Priestly, Monash University, Melbourne, VIC, Australia
A Bartholomaeus, University of Canberra, Canberra, ACT, Australia, and University of Queensland, Brisbane, QLD, Australia
R Drew, ToxConsult Pty Ltd., Melbourne, VIC, Australia, and Monash University, Melbourne, VIC, Australia

Glossary

Agglomeration The tendency of nanoparticles to aggregate or clump together.
Biopersistent Resistant to solubilization or normal processes of tissue clearance or elimination.
Engineered nanoparticles Particulate material, generally of low solubility, engineered or manufactured to exploit functionality or properties different from those of particles of the same chemical composition with a larger particle size. The use of the term 'engineered' attempts to differentiate manufactured nanoparticles from those likely to be found in the environment from anthropomorphic or natural sources (e.g., ultrafine air pollutants).
Nanomaterials Materials engineered at the nanoscale to have novel functionality or properties. Such properties will typically, but not exclusively, be demonstrated in the size range 1–100 nm, but this size range should be considered approximate.
Nanoscale The size range from approximately 1–100 nm.

Description and Definitions

In recent years, a range of technologies derived from almost all scientific disciplines, across chemistry, physics, and biology, have advanced substantially in their ability to manipulate materials at the nanometer scale. Although frequently referred to as nanotechnology in the singular, in reality there is no one unifying technology that covers the wide range of nanomaterials being developed. The most common definitions for nanomaterials use as their basis size or structure in at least one dimension of between 1 and 100 nm. Thus a nanoparticle has three dimensions between 1 and 100 nm, a nanorod or nanotube has two dimensions in this range, and a nanosheet or nanomembrane has one dimension in this range.

These size boundaries are arbitrary and do not reflect in any way a point or range necessarily related to novelty or hazard. Properties of interest and relevance to safety assessment extend above the 100 nm cutoff without inflexion or discontinuity related to the arbitrary 100 nm cutoff. Also, particulate matter may have a size distribution where a certain proportion is in the nanoparticle range. There is no consensus on what proportion of the nanoscale component of a powder would result in a departure from its normal functional and toxicological properties. Current definitions of nanotechnology are beginning to reflect the significance of functional novelty as a characteristic more important than size.

This article relates to general background information on engineered nanoparticles (ENPs) as they pertain to food manufacture. The article neither covers potential ENP use in medical, veterinary or agricultural preparations nor nanotechnology applications in food packaging or other industrial uses. Although there may be potential for industrial or cosmetic ENPs being released into the environment, at this time it is hypothetical that they may enter the human food chain. A significant issue is whether nanomaterials released into the environment will retain the unique characteristics that determine their novel functionality, and whether analytical techniques are sufficiently sensitive and specific to characterize these properties.

Historical Context

Although there is a general perception that nano-structured materials in food is a very recent, or even future, issue, much of what is currently presented as nanotechnology utilizes long-standing principles and technologies previously known by other names. Certainly, the sophistication of current nanotechnologies has grown dramatically, but in many cases the advance relates to achieving high levels of precision and uniformity in the size and other characteristics of previously available nano-dimensioned materials.

Colloidal metals, earths, and other particulates, in the nanometer range have been known and studied for the better part of a century. Colloidal silver, with a long history of medical use, is today called nano-silver. Gold leaf with a thickness less than 100 nm has been used as an edible food decoration for hundreds of years. Engineered nanostructures in food, such as ice cream and other food emulsions, have been a routine aspect of food processing for centuries.

Surfactant micelles are dynamic self-assembling nanostructures with dimensions inclusive of the low nanometer scale. Nanoparticles, or more accurately aggregates and agglomerates of nanoparticles such as the fumed silicon dioxides, also have a long history of use in food, cosmetics, and

 doi:10.1016/B978-0-12-378612-8.00224-9

pharmaceuticals. Indeed food, whether fresh or manufactured, is naturally structured at the nanometer scale. Ribosomes, the protein synthetic structure of cells, for example, have a size of approximately 30 nm, and other cellular structures are of similar size. The first food a newborn child consumes at its mothers breast is a nano-food, as is all milk. The milk protein casein is a micelle of approximately 20 nm diameter. The organoleptic properties of ice cream depend on its nanostructure of fat globules, stabilized by the nano-membranes of 10–20 nm casein micelles. Thus nanostructures and nanomaterials in food are neither new nor novel. Nonetheless, the sophistication of the nanotechnologies is increasing and new, unfamiliar materials will eventually be developed for food applications, including those associated with food packaging and processing materials. As is true for any other new material for food use, careful consideration of their safety is essential before their introduction.

Safety Concerns

Safety concerns about nanomaterials are driven mainly by the accumulated knowledge of the health effects of inhaled nanoparticles; for example, the increase in cardiovascular, airways, and pulmonary diseases, and mortality associated with ultrafine air pollutants. Human exposure to ultrafine air pollutants has been occurring for millennia, with significant increases since the industrial revolution. With the development of nanofibers and nanorods, such as single- and multiwalled carbon nanotubes, concerns have also been raised about the potential for inhaled nanoparticles to mimic the adverse health effects of pathogenic fibers, such as asbestos and silicates. Although these concerns may be valid in some applications, there is no indication that materials of this type are under development for food-related applications. Nor are health effects observed with inhaled nanomaterials necessarily relevant for food.

The international research effort on the safety of nanomaterials is primarily directed at occupational exposure because this is where the highest exposure potential exists. The nanotoxicology literature is virtually exploding, with hundreds of papers being published each year, with many reviews periodically summarizing and consolidating the information.

Current knowledge indicates the potential for nanoparticles to produce adverse health effects essentially relies on their ability to:

- mobilize tissue macrophages to elicit sustained local inflammatory reactions, generally mediated by macrophage-generated reactive oxygen species (ROS) and inflammatory cytokines,
- cross membrane barriers preventing entry of larger particles to the systemic circulation, or
- in some cases, penetrate cell membranes and initiate ROS formation, impair cellular functional pathways, or to initiate apoptosis.

Many of these factors are influenced by nanoparticle size, surface characteristics, manufacturing impurities and chemicals entrained within/on the nanoparticle, or the ability of the nanoparticle to dissolve, releasing its chemical constituents. Nanoparticle surfaces modified by chemical functionalization or adherent coatings can significantly alter intrinsic toxicity.

Mechanistic aspects and comparative toxicity of different types of nanoparticles have been studied in a range of *in vitro* experimental systems, such as cell cultures. However, caution must be exercised in extrapolating from such studies to assess human health risks. Cell cultures often lack critical metabolic and transport functions that can modify toxic responses. There is substantial uncertainty regarding the relevance of concentrations eliciting effects *in vitro* to those that may be in tissues after whole animal or human exposure. At this time the latter are not well defined. At this time, concentrations that nanomaterials may achieve in tissues *in vivo* are not well defined, although pharmacokinetic modelling may address some of these uncertainties. Furthermore, many such studies fail to adequately characterize the nanoparticles or the effects of the dispersing media on their aggregation and agglomeration. It has been suggested the term 'nanoparticles' is used indiscriminately in many articles. Because of the above, a misleading impression may be gained of potential *in vivo* toxicity by relying only on *in vitro* information. Furthermore proteins and other macromolecules adhere to the surface of nanoparticles to create a 'corona' that largely determines how cells 'see' and react with nanoparticles. The corona may well be different *in vitro* from that *in vivo*, and could change as the nanoparticle moves from extracellular fluid into the cell.

Perhaps the most important potential property of a nanoparticle influencing its longer term toxicity is its biopersistence – that is, the ability to penetrate into body tissues and resist normal clearance mechanisms (macrophage engulfment or renal/fecal excretion). If, and to what degree, a nanoparticle is biopersistent is dependent on both the composition of the particle and the surface area to volume ratio. Although bulk silica is essentially insoluble in aqueous media, silica nanospheres used as intravenous drug delivery vehicles slowly dissolve in biological fluids and are eliminated as the dissolved silica. An example of the importance of biopersistence, however, is seen with pathogenic fibers such as asbestos, and probably carbon nanotubes. With these materials, aspect ratio (diameter to length) is a critical factor determining potential for adverse health effects after inhalation.

Current data do not suggest that long term accumulation of nanoparticles, where it occurs, is in itself sufficient to cause toxicity. Titanium dioxide, for example, administered over a lifetime to rats and mice at very high doses (50,000 ppm in the diet) produces no ill effects. Nonetheless, the long term fate of nonsoluble bio-stable nanoparticles is not generally well understood.

Novel Characteristics of Nanomaterials

Nanomaterials are developed on the premise that their characteristics, when compared to those of the bulk-phase materials from which they are constituted, confer novel functional properties. In the case of nanomaterials for food use, these can include:

- Packaging material biosensors that detect food spoilage.
- Materials that alter oxygen permeability and thereby limit food spoilage.

- Encapsulation of food components to regulate their systemic absorption.
- Modification of food texture to enhance taste or other characteristics.
- Materials that sense the environment within a food package and release preservatives or other food additives only as required to protect the food within the package.

Pharmacokinetics as a Source of Novelty

Pharmacokinetics is the study of the absorption, distribution, metabolism, and excretion of materials in living organisms. A difference in pharmacokinetics between soluble small organic molecules and insoluble bio-stable nanoparticles is at least partially predictable on the basis of existing data and on anatomical and physiological considerations. Of greatest potential concern is the finding that certain bio-stable nanomaterials exhibit long tissue retention times, in particular in the liver, spleen, and lymph nodes. In this regard however, very small nano-nanoparticles (less than 10 nm) with very high surface areas and very low mass, composed of even very slightly soluble materials such as silica, have the potential to be slowly biodegraded through slow dissolution or other processes. For example, zinc oxide would not normally be considered as a soluble material, but it is slowly solubilized in biological fluids.

Altered pharmacokinetic behavior is one of the major potential sources of novelty for nanomaterials, and nanoparticles especially. Although the use of nanoparticles is expected to be limited in food compared to other industry sectors, their pharmacokinetic characteristics, particularly tissue retention and poor excretion, should be considered early in product development of poorly soluble nanoscale and microscale particulates. This work should include classical pharmacokinetic studies following oral ingestion, using techniques that differentiate between dissolved and particulate material in biological matrices, as well as investigations of the fate of insoluble materials in long-term studies. It is appreciated, however, that measurement of nanoparticles in tissue can be a significant challenge.

Absorption

To be absorbed from the gastrointestinal tract (GIT), a particulate in a food (whether nanoscale or microscale) must first resist dissolution and degradation in the stomach and intestine and be able to diffuse across the gastric mucosa to the surface of the epithelia where it can be absorbed. Because both particle dissolution kinetics and solubility are size dependent, nanoscale particulate materials can dissolve more quickly, and theoretically, to a greater extent than macroscopic particles of the same material. Nanomaterials which dissolve in the water or lipid phases in the food, or GIT, cease to be nanoparticles. Similarly nanomaterials that are susceptible to digestion or other forms of degradation in the gut resulting in soluble materials, also cease to be nanomaterials and their subsequent pharmacokinetics will be that of conventional materials.

Intestinal absorption and tissue disposition of particulates is, compared with small soluble molecules, significantly restricted by the large number of physiological barriers that exist to defend the body from particulate invasion. Nevertheless, evidence has accumulated demonstrating some absorption of certain nanoscale and microscale particulates across the intestinal mucosa, via M cells (which favor particles around one micrometer in size) to underlying lymphoid follicles, and also through normal columnar epithelia. The absorption is, however, very limited, to just a few percent of the administered dose.

A number of interrelated factors influence particle uptake from the gut. Size is but one, and not necessarily the most important aspect to be considered; composition, hydrophobicity, charge, and surface modifications also influence absorption. Thus, although reducing particle size from microscale to nanoscale may increase absorption, this is not universally true, and it appears to be material dependent. For example, 2.5 nm diameter dendrimers of polystyrene are not absorbed to a significantly greater extent than 50 nm polystyrene spheres.

Distribution

Unlike soluble chemicals, nanoparticles appear to be predominately absorbed from the intestine via the lymphoid system and distributed to local lymph nodes. There is little data to support significant uptake of nanoparticles through intestinal capillaries directly into portal blood and thence to the liver. Tissue disposition studies have typically reported low levels (up to a few percent of dose), mainly distributed to the mesenteric lymph nodes, the liver, and the spleen, due to uptake by the phagocytic cells embedded within these tissues.

Bio-stable particulates including polystyrene spheres and carbon black nanoparticles have been reported to be retained for significant periods in Peyer's patches and mesenteric lymph nodes, but importantly, with no associated short-term pathology. Long-term studies have not yet been conducted.

Studies of intravenously administered particulates have shown that under normal circumstances, they rapidly adsorb protein to form a protein corona. This promotes recognition and rapid clearance from the blood by the mononuclear phagocytic system (MPS) (previously known as the reticuloendothelial system) with particles predominately recovered in the Kupffer cells of the liver and in splenic macrophages, in lymph nodes, and in some cases in the bone marrow. The protein coronas are complex and variable, and of the approximately 3700 proteins in the plasma proteome, approximately 50 have been identified in contact with various nanoparticles. Opsonins, which may form part of the protein corona, may enhance uptake of the coated material by cells of the mononuclear MPS. Their presence creates a molecular signature that is recognized by immune and other cells, and which determines the biodistribution.

Whether nanoparticles bind proteins at all depends mainly on their surface characteristics, primarily hydrophobicity and charge. Other factors including core constituents, size, shape, and curvature influence the amount of protein bound, but not protein identity. In pharmaceutical applications, nanomaterials have been engineered to reduce this clearance, for example, through binding of polyethylene glycol (PEG) molecules to the surface to achieve usable blood circulation times. The PEG molecules prevent protein binding and reduce

recognition and uptake by the MPS leading to longer half lives of the nanoparticle.

Retention of bio-stable particulates can be very prolonged. For example, after intravenous (IV) administration of 13 nm quantum dots, 100% of the dose was recovered in the bodies of mice at 28 days, mainly in the muscle, skin, bone, and liver.

Elimination

The renal elimination of particulates from the blood is relatively well understood. For particulates, glomerular filtration is strictly dependent on the hydrodynamic diameter (HD) of the particle. For example, inulin which has a HD of approximately 3 nm is completely filtered whereas for IgG protein, which has a HD of approximately 11.0 nm, glomerular filtration is negligible. For bio-stable or slowly biodegraded materials, a HD below 5.5 nm is likely to be needed to permit complete elimination in urine. Similar findings have been reported for hydrophilic macromolecules such as dendrimer-based MRI contrast agents.

The hepatobiliary system is the primary route of excretion for particles not excreted in urine. The weight of evidence to date suggests elimination of particles in the bile and feces may occur at low to moderate levels, but this is a relatively slow and inefficient process with only modest percentages of the administered dose eliminated.

Regulation

Current size-based definitions of nanotechnologies and materials do not provide a sound foundation for a consideration of a safety assessment approach, as they do not capture any concept of functional or biological novelty. Although many countries have developed programs to promote nanotechnology development, none has developed separate safety assessment programs for nanomaterials. The current regulatory systems rely on safety evaluation protocols that are well established for the regulation of chemicals.

An underlying concern for the food industry and other proponents of nanotechnology is that the development of nanotechnology for food processing and packaging may be on a similar trajectory to technologies based on genetically modified (GM) organisms. Often community resistance to technological development is based on uncertainties and concerns about safety evaluation.

In the broader sense, all materials have structure at the nanometer scale. All polymers, gels, emulsions, clays, colloids, and larger organic molecules are nanomaterials, many of them engineered. Living cells contain functional nanostructures and our environment contains a wide range of natural and anthropogenic nanoparticles. From a regulatory perspective, it is novelty, not size, which raises concern. Thus, if sugar were fabricated into nanotubes (nano fairy floss/cotton candy) this material may well have very interesting novel properties in some applications but its addition to food would result only in dissolved sugar and not therefore present any novelty from a risk perspective.

Similarly, as most food additives are present in foods in a dissolved form, either in lipids or water, their preparation as nanoscaled powders to facilitate dispersion and dissolution presents neither novelty nor additional regulatory concern. Conversely, where a substance remains particulate in the final food as consumed, nano size has potential to alter characteristics relevant to safety assessment and therefore requires greater scrutiny.

In responding to the increased sophistication of the nanotechnologies, the primary focus for both regulators and the food industry is thus on materials likely to exhibit physicochemical and biological novelty.

The FAO/WHO reviewed the safety assessment and regulation of nanomaterials in food and agriculture in 2009. This report concludes that current risk assessment methodologies employed by the FAO/WHO and Codex are suitable for engineered nanoparticles. However, the report emphasized that the impacts of any novel features of nanomaterials need to be addressed. Furthermore, interaction of nanomaterials with other components of food (e.g., proteins, lipids, carbohydrates, and nucleic acids) must be taken into consideration. A similar position has emerged from ongoing reviews of the applications of nanotechnology in food by national regulatory agencies, such as Food Standards Australia New Zealand (FSANZ), the US Food & Drug Authority (FDA) and the European Food Safety Authority (EFSA).

FOOD ADDITIVES

Contents

Food Additives – General

LD Tomaska, Tharwa, ACT, Australia
S Brooke-Taylor, Bright, VIC, Australia

Glossary

Acceptable daily intake (ADI) The amount of a substance that may be consumed every day throughout an entire lifetime without appreciable risk. Expressed as mg per kg bodyweight per day, the ADI is normally calculated by dividing the no observed (adverse) effect level, by a safety/uncertainty factor of 100 in order to address the uncertainties associated with the available scientific data.

ADI 'not specified' A term used by the Joint FAO/WHO Expert Committee on Food Additives to signify that no adverse effects have been identified from exposure to the food additive, even at levels many times higher than those necessary for its technological function. Consequently, there is no appreciable risk from exposure arising from its use as a food additive under 'good manufacturing practices.'

Food additive Natural or synthetic chemically defined substances added to food to preserve flavor or enhance its taste and appearance or for other technological functions.

International Numbering System (INS) The INS for food additives developed and maintained by the Codex Alimentarius.

No observed adverse effect level (NOAEL) A level of chemical that produces no adverse effect. Expressed usually in mg per kg bodyweight per day.

Food Additives and History of Use

The use of food additives is not a modern invention. The earliest food additives, used as long ago as 5000 years, included vinegar to pickle vegetables; salting and smoking to help preserve meat and fish; herbs to improve flavor; and vegetable coloring to improve appearance of food. Today, food additives are added to food for these and a very wide variety of other purposes including uses to regulate acidity, prevent food from adhering to surfaces, reduce foaming, enhance texture, improve food's baking quality or color, and so on. Food additives can increase both the shelf life and the safety of food by preventing growth of spoilage and disease-causing organisms. They also offer the benefit of readily available and lower-priced food to consumers. This may also serve to reduce wastage. The use of food additives make possible the amazing choices of processed foods that millions of people enjoy on a daily basis, and reduce the time that they need to spend on food preparation.

Food additives can be naturally derived, for example, ascorbic acid (vitamin C) in citrus fruit and lecithin in eggs and soybeans, or can be synthetic. Some food additives have more than one functional use, for example, chitinase, used as a thickener, is also thought to have some antibacterial properties. Whether natural or synthetic, they are used in food in small quantities.

The first half of the twentieth century saw a significant increase in the use of food additives. Initially, their use was not controlled, and a number of these were subsequently shown to pose safety concerns. For example, in the early 1900s, borax (or boric acid) was widely used as a food preservative. Following administration to human volunteers, borax was shown to be too toxic for use in food. More recently, borax has been shown to be a potential reproductive toxin that posed an

Table 1 Food additive functional classes

The food additive functional classes are based on the Codex Class Names and the International Numbering System for Food Additives (CAC/GL 36-1989).

Acidity regulator
A food additive that controls the acidity or alkalinity of a food:

Acid
Acidifier
Acidity regulator
Alkali
Base
Buffer
Buffering agent
pH Adjusting agent

Anticaking agent
Reduces the tendency of particles of food to adhere to one another:

Anticaking agent
Antistick agent
Drying agent
Dusting agent

Antifoaming agent
A food additive that prevents or reduces foaming:

Antifoaming agent
Defoaming agent

Antioxidant
A food additive that prolongs the shelf life of foods by protecting against deterioration caused by oxidation:

Antibrowning agent
Antioxidant
Antioxidant synergist

Bleaching agent
A food additive (nonflour use) used to decolorize food. Bleaching agents do not include pigments:

Bleaching agent

Bulking agent
A food additive that contributes to the bulk of a food without contributing significantly to its available energy value:

Bulking agent
Filler

Carbonating agent
A food additive used to provide carbonation in a food:

Carbonating agent

Carrier
A food additive used to dissolve, dilute, disperse, or otherwise physically modify a food additive or nutrient without altering its function (and without exerting any technological effect itself) in order to facilitate its handling, application or use of the food additive or nutrient:

Carrier
Carrier solvent
Diluent for other food additives
Encapsulating agent
Nutrient carrier

(*Continued*)

Table 1 Continued

Color
A food additive that adds or restores color in a food:

Color
Decorative pigment
Surface colorant

Color retention agent
A food additive that stabilizes, retains or intensifies the color of a food:

Color adjunct
Color fixative
Color retention agent
Color stabilizer

Emulsifier
A food additive that forms or maintains a uniform emulsion of two or more phases in a food:

Clouding agent
Crystallization inhibitor
Density adjustment agent (flavoring oils in beverages)
Dispersing agent
Emulsifier
Plasticizer
Surface active agent
Suspension agent

Emulsifying salt
A food additive that, in the manufacture of processed food, rearranges proteins in order to prevent fat separation:

Emulsifying salt
Melding salt

Firming agent
A food additive that makes or keeps tissues of fruit or vegetables firm and crisp, or interacts with gelling agents to produce or strengthen a gel:

Firming agent

Flavor enhancer
A food additive that enhances the existing taste and/or odor of a food:

Flavor enhancer
Flavor synergist

Flour treatment agent
A food additive that is added to flour or dough to improve its baking quality or color:

Dough conditioner
Dough strengthening agent
Flour bleaching agent
Flour improver
Flour treatment agent

Foaming agent
A food additive that makes it possible to form or maintain a uniform dispersion of a gaseous phase in a liquid or solid food:

Aerating agent
Foaming agent
Whipping agent

Gelling agent
A food additive that gives a food texture through formation of a gel:

Gelling agent

(*Continued*)

Table 1 Continued

Glazing agent
A food additive that when applied to the external surface of a food, imparts a shiny appearance or provides a protective coating:
Coating agent
Film forming agent
Glazing agent
Polishing agent
Sealing agent
Surface-finishing agent
Humectant
A food additive that prevents food from drying out by counteracting the effect of a dry atmosphere:
Humectant
Moisture/water retention agent
Wetting agent
Packaging gas
A food additive gas that is introduced into a container before, during or after filling with food with the intention to protect the food, for example, from oxidation or spoilage:
Packaging gas
Preservative
A food additive that prolongs the shelf life of a food by protecting against deterioration caused by microorganisms:
Antimicrobial preservative
Antimicrobial synergist
Antimold and antirope agent
Antimycotic agent
Bacteriophage control agent
Fungistatic agent
Preservative
Propellant
A food additive gas that expels a food from a container:
Propellant
Raising agent
A food additive or a combination of food additives that liberate(s) gas and thereby increase(s) the volume of a dough or batter:
Raising agent
Sequestrant
A food additive that controls the availability of a cation:
Sequestrant
Stabilizer
A food additive that makes it possible to maintain a uniform dispersion of two or more components:
Colloidal stabilizer
Emulsion stabilizer
Foam stabilizer
Stabilizer
Sweetener
A food additive (other than a mono- or disaccharide sugar) that imparts a sweet taste to a food:
Bulk sweetener
Intense sweetener
Sweetener

(*Continued*)

Table 1 Continued

Thickener
A food additive that increases the viscosity of a food:
Binder
Bodying agent
Texturizing agent
Thickener

unacceptable risk to human health. As a result, borax is neither permitted for use in food manufacturing in a majority of countries nor is it traded internationally for food purposes. However, it is still used illegally in some countries to lengthen the shelf life of certain foods, such as rice noodles and dumplings, and therefore continues to pose a health risk to consumers.

Chemical Characterization

The Codex Alimentarius defines food additives as: "any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result, (directly or indirectly) in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include contaminants, or substances added to food for maintaining or improving nutritional qualities, or sodium chloride."

Food additives as a group consist of a plethora of different chemicals numbering in several thousands; they cannot be described here individually; a number of food additives are discussed in more detail in other articles of this encyclopedia. The Codex Alimentarius Commission, an international body made up of some 190 countries, currently groups food additives into 27 classes, based on their functional use (**Table 1**).

Every food additive is assigned a unique number in the International Numbering System (INS), adopted and extended by the Codex Alimentarius. Most countries use these numbers in one form or another, to uniquely identify a food additive in legislation and for labeling purposes. The INS assigns a unique three- or four-digit reference number to each additive (e.g., ascorbic acid is 300), providing a shorthand way of labeling the ingredients of prepackaged foods and preventing confusion potentially caused by different nomenclature, spelling, and language differences. Number ranges have been preassigned to food additive classifications, so also gives information on the primary purpose of the additive, even without knowing the name (e.g., 600–699 series are flavor enhancers).

Control of Food Additives

Although it is true that all chemicals pose a potential risk to human health at some level of exposure (the Paracelsus

Principle), food additives as a class of chemicals are generally low in toxicity to human. The specific regulation of food additives to protect human health began in the mid-twentieth century when legislation, such as the 1958 Food Additives Amendment and 1960 Color Additives Amendment of the US Food and Drug Administration, required manufacturers to prove the safety of new additives before use. The testing requirements for food additives have increased steadily over the years and additives with suspected structures are required to undergo additional testing. For example, potential carcinogens need to be tested in two lifetime feeding studies in animals, usually the rat and mouse.

Today, the use of food additives is regulated by national legislation in most countries, and in international trade, as based on the recommendations of the Codex Alimentarius Commission. The overriding principle in controlling the use of these chemicals in food is that only additives which are shown to be safe can be used. This requirement is based on the fact that a choice can be made about the use of food additives; in other words, it is a discretionary activity. This is in contrast to naturally occurring contaminants and the presence of many microbial organisms in food, which are not deliberately added and, consequently, their presence in food must be controlled through other means.

Today, all new food additives undergo a safety assessment to minimize any potential adverse effects of food additive to human health. An extensive range of animal and other tests have been devised to assess health risk to humans. These tests assess the potential for acute and chronic toxicity, genetic damage, or cancer and any possible effect on development and reproduction. It is argued that these tests do not address the entire spectrum of toxicities that can be caused by chemicals, especially issues such as behavioral changes and that these issues need to be addressed through new tests.

A formal process exists for analyzing the test data on food additives. This safety evaluation is carried out at a number of different levels. At a global level it is performed by a scientific advisory body to the Food and Agriculture Organization (FAO) and World Health Organization (WHO), namely the Joint FAO/WHO Expert Committee on Food Additives (JECFA). In addition to countries, JECFA advises the Codex Alimentarius Commission, which has international responsibility for managing food safety and developing food standards. JECFA has been meeting annually to conduct safety evaluations of additives since 1956. The members of JECFA are selected on the basis of their scientific credentials. If supported by the safety data, JECFA will establish an acceptable daily intake (ADI) for a food additive as part of its evaluation. JECFA will also conduct an exposure assessment to determine if the proposed uses and maximum levels (MLs) in food are within the ADI. Their findings are published and are otherwise made public on the Internet.

Therefore, food additives are regulated as a positive list, which means that only food additives specifically listed in the regulations of a country can legally be added to food products, and the MLs in food must not be exceeded. This is in contrast to chemical and microbiological contaminants which are regulated as a negative list: Only those contaminants that are of concern to human health are subject to regulatory control with specified maximum limits in food.

A significant number of food additives currently in use have been assigned 'ADI not specified,' based on a documented history of safe use or extensive testing indicating a low order of toxicity compared with any possible exposure. These additives are permitted for use under conditions of good manufacturing practice. Substances approved this way in the USA and other countries are classified as 'generally recognized as safe'. More recently, Codex Alimentarius has assigned numerical use limits for many of these additives as part of their inclusion in the General Standard for Food Additives.

Legislative discrepancies exist between different countries in the definition of 'food additive.' For example, in the USA the term 'food additive' is not only limited to substances added for a technological purpose but also includes ingredients indirectly added for other purposes, such as boiler water additives and monomers from plastic food contact materials, and consequently some 3000 substances are approved for use as 'food additives.' In contrast, Canadian regulations recognize only approximately 400 'technical' food additives. Under international agreement, the Codex Alimentarius standards, which underpin international trade through their reference in the World Trade Organization (WTO) Sanitary and Phytosanitary (SPS) Agreement, are binding on national governments unless the country can demonstrate, through the use of a sound scientific risk assessment that the standard is insufficient to protect the health of their population. Where Codex is silent, countries are free to adopt their own standards subject to certain disciplines, for example, nondiscriminatory. National differences may often be ascribed to political and societal expectations of each country and may be challenged under WTO SPS Agreement.

Possibly the principal concern currently expressed by consumers in relation to food additives, both natural and synthetic, is the belief that their consumption may be associated with unwanted behavioral effects such as hyperactivity, especially in children. Another concern is that they may be linked to food allergies and insensitivities. The implicated food additives include food dyes and colorings (such as tartrazine, quinoline yellow, sunset yellow, and ponceau 4R), antioxidants (such as butylated hydroxy anisole (BHA) and butylated hydroxy toluene (BHT)), emulsifiers and stabilizers (such as gums and lecithin), flavorings and taste enhancers (such as monosodium glutamate (MSG), spices, and artificial sweeteners), and preservatives (such as benzoates, nitrates, and sulfites). The majority of these and other food additives have undergone reevaluation based on their human health risk assessments.

The majority of these as well as other food have undergone reevaluations of their human health risk assessments as a part of a periodic review. Current credible scientific evidence does not support a link between exposure to many of these food additives and adverse behavioral effects such as hypersensitivity. It is argued that the conventional testing of food additives is insufficiently sensitive to detect effects that are specific to humans and occur at a relatively low incidence in a population. A UK 'Southampton' study attempted to test the link between food additive coloring and changes in behavior. In this study, children received two mixtures of four synthetic colors plus sodium benzoate preservative in the diet and their behavior was observed. The study did not find a link.

Consequently, human health risks, such as behavioral changes or sensitivities, that may be caused by food additives be managed by labeling of prepacked food, to enable sensitive individuals to identify and avoid the specific chemical of concern. Policies covering unpackaged food and meals eaten out are highly variable. Education of consumers to avoid such additives is currently one of the approaches taken to manage these risks. There is also a shift by manufacturers to substitute the food additives with 'natural/from nature' foods that have the desired properties such as juice concentrates in place of colorings.

Human health continues to be at risk from the illegal use of chemicals that are not approved for use as food additives in the manufacture of food. For example, in developing countries, street-food vendors have been reported to continue to misuse of boric acid and Sudan Red.

Hazard Identification and Characterization

Most countries now require that all new food additives undergo a safety assessment before they are permitted for use in food manufacture. Also, new data on the toxicity of, or exposure to, an already approved food additive will trigger the need to reevaluate its risk to human health. Some countries regularly schedule periodic reviews of approved food additives in the recognition that testing requirements have increased, based on new knowledge about how chemicals can cause adverse effects in humans. Reviews can also be triggered by new information in the scientific or medical literature, ensuring that approved food additives continue to be safe to humans.

The purpose of performing a human health risk assessment for any given food additive is to determine a safe level of intake. Such an assessment determines whether the food additive can be allowed for use in food and in what amounts. The safe level of intake is defined as ADI, and is the level of intake by a human of a food additive, per day, for which no appreciable adverse effects are expected to occur when consumed over a lifetime. The ADI is usually expressed as milligrams of the chemical ingested per kilogram of bodyweight. The concept of ADI is based on the premise that, for compounds other than carcinogens and certain other toxins, there exists a discrete threshold of exposure below which adverse effects do not occur. Any chemical that is assessed to be both genotoxic and a potential carcinogen is not permitted for use as a food additive.

The safety assessment includes an evaluation of toxicological studies that identify the toxicity profile of a chemical, such as adverse effects and target organs of toxicity, and identification of the threshold level of chemicals that are associated to no toxic effects. Such a safety assessment identifies levels of chemicals that produce no observed adverse effect level (NOAEL), which is used to derive the ADI. It is customary to apply a 100-fold safety/uncertainty factor to the NOAEL to derive the ADI.

Many of the food additives in use today have been assessed by JECFA as well as by various regional bodies, such as the European Food Safety Authority and countries such as the USA, Canada, Japan, and Australia and are regarded as safe, when used as specified.

Exposure Assessment

An additional consideration of a safety assessment is the premise that the permitted use of food additives must not exceed the ADI. For example, although a specific color may be used in many foods up to a specified ML, the combined daily exposure to that coloring agent from all of these foods must not exceed the ADI established for that chemical. This is determined by an exposure assessment, which considers daily consumption of foods or food groups and concentration of the food additives in those foods or food groups. Often, the maximum permitted levels in each food group are used in these calculations, which tend to overestimate exposure for most people, and add a significant margin of safety to the assessment.

The methodology used for exposure assessment varies between countries due to different dietary patterns and the availability and quality food consumption data. JECFA undertakes exposure assessment for food additives using data drawn from the WHO Global Environment Monitoring System (GEMS)/Food Contamination Monitoring and Assessment Program (WHO GEMS food) as well as considering assessments made available to it by individual member countries. When feasible, JECFA will use the GEMS/Food Consumption Cluster Diets as the food consumption component of the exposure assessment.

Risk Characterization

Risk characterization considers the assessment of exposure to a chemical in context of its ADI. It determines whether the ADI may be exceeded and what the potential health consequences, i.e., severity and target population, may be, taking into consideration uncertainties and assumptions in the information.

For a new food additive, the risk characterization is relatively straightforward. If the ADI is not exceeded by the possible exposure, the additive is recommended for approval. However, if the ADI is exceeded, the additive is not recommended for approval. In such cases, the sponsor may either submit additional data to support an increase in the ADI, reduce the use levels in food, or eliminate some uses entirely. As the variety of processed foods increases, and the use of food additives widens, the possibility of exceeding the ADI increasingly comes under closer scrutiny for many established food additives.

One of the main issues debated is whether exceeding an ADI is a human health risk. Clearly, the ADI is the health standard for a food additive, so legislatively it should not be exceeded. For a scientist, the considerations include the fact that the ADI usually incorporates a 100-fold 'safety/uncertainty factor' that sets the ADI for a chemical 100 times below the level that caused no effect in the most sensitive animal species in experimental studies. In addition, exposure estimates often overestimate the level of a food additive in the diet, thereby adding an additional margin of safety. So, while exceeding the ADI for a food additive needs to be redressed, it should rarely be a cause for immediate public health action and concern.

Specifications and Methods of Analysis

The past misuse of food additives to adulterate food has, to some extent, driven the development of analytical methods. These are used today for regulatory purposes to ensure that food additives do not exceed their MLs or are not being used for unapproved uses or in unapproved foods. For some chemicals, rapid field tests have been developed to allow inspectors to quickly identify foods that have been adulterated. Analytical methods need to have large throughput capacity to handle large number of samples.

During the meetings of JECFA, the WHO experts conduct the safety assessment and the FAO experts focus on developing specifications and methods of analysis for those specifications. The specifications for the food additive is based on the specific chemical that is used in the toxicity testing of the food additive as that is the material being evaluated and approved. Slight variations in the manufacturing process or in the case of natural products, the extraction and purification process can alter the specifications of a food additive and possibly introduce a potential harmful contaminant. Consequently, all of the food additives have a defined method of analysis, identified under their unique identifier within the INS. These can be found in a number of internationally published sources of monographs:

- Combined Compendium of Food Additive Specifications, FAO JECFA.
- Food Chemicals Codex.
- European Union (EU) directives on food additives specification.
- The Specifications and Standards for Food Additives, Ministry of Health and Welfare (Japan).

Conclusion

Food additives are among the safest chemicals present in food because of the rigorous testing that is required before they may legally be used in food. Although certain safety issues associated with some food additives continue to be debated, the periodic review of food additives ensures that such concerns are addressed, using the most advanced testing protocols.

FOOD ADDITIVES

Antioxidants

C Schyvens, Food Standards Australia New Zealand, Canberra, ACT, Australia

Glossary

Clastogen An agent (certain chemicals, X-rays, ultraviolet light) capable of causing breaks in chromosomes.

Forestomach A nonglandular stomach that exists in certain animal species and is located between the esophagus and the primary glandular stomach, but is not present in humans.

Hyperplasia An increase in the number of normal cells in an organ or tissue. The presence of hyperplasia may be a sign of abnormal or precancerous changes.

Reactive oxygen species (ROS) Chemically reactive molecules containing oxygen, which can result in cellular damage if overproduced.

Two-generation study A study that investigates the effect of a test substance on the integrity and performance of the male and female reproductive systems, e.g., gonadal function, estrous cycle, mating behavior, conception, gestation, parturition, lactation, and weaning in the parents and progeny (F1 offspring), and the growth and development of the two generations of offspring (F1 and F2).

Introduction

Antioxidants are a group of food preservatives that delay or prevent the deterioration of foods by oxidative mechanisms. They include butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tertiary butylhydroquinone (TBHQ), tocopherols, ascorbic acid, citric acid, and sulfites, the latter of which also has antimicrobial properties. These molecules act by scavenging free radicals or oxygen, or by inhibiting enzymes that facilitate oxidation.

Oxidation of food is a common problem of both fresh and processed food. In many cases, reducing exposure to air by effective food packaging or by using modified atmosphere can help reduce oxidation. However, total exclusion of oxygen is often not feasible. In many foods, specific enzymes may also be involved in the oxidation of food molecules, leading to quality changes in the food. One type of oxidation reaction involves enzymes (phenolases) that oxidize amino acids, such as tyrosine in fruits including bananas and apples, causing browning. Antioxidants that inhibit enzyme-catalyzed oxidation include molecules that bind free oxygen, i.e., reducing agents such as ascorbic acid (vitamin C) and molecules that inactivate the enzymes, such as citric acid and sulfites.

Food can also undergo autooxidation; for example, the autooxidation of unsaturated fatty acids involves the reaction between carbon–carbon bonds and oxygen in the same or adjacent molecule. The products of autooxidation, called free radicals, are very reactive, producing compounds that cause off-odors and off-flavors characteristic of rancidity. Antioxidants, such as BHA, BHT, and TBHQ, react with free radicals to slow down the rate of autooxidation. Some of these antioxidants continue to attract public controversy regarding their safety to human health. This article outlines the risk assessment findings for BHA and BHT.

History of BHA and BHT

BHA and BHT are two antioxidants that are used to prolong the shelf-life of foods by protecting them against deterioration caused by oxidation, such as fat rancidity and color changes. BHA is an effective antioxidant in animal fats used in baked products. It is stable at high temperatures. BHT has characteristics similar to BHA and is also an effective antioxidant in animal fats, although it has limited use in oils.

Both antioxidants are also used in industries other than food. Since 1947, BHA has been used as an antioxidant and preservative in food packaging, animal feed, and cosmetics. BHT was patented in the US in 1947 and received approval for use as a food additive and preservative by the US Food and Drug Administration in 1954. Since 1959, BHT has been generally recognized as safe for use in foods.

Chemical Characterization

BHA

BHA (3-tertiary-butyl-4-hydroxyanisole) is a mixture of the two chemical isomers, 2(3)-tertiary-butyl-4-hydroxyanisole (3-BHA) and 2-tertiary-butyl-4-hydroxyanisol (2-BHA). Food grade BHA contains more than 85% 3-BHA and less than 15% 2-BHA.

BHA is a white or slightly yellow waxy solid that has an aromatic odor and a slightly bitter burning taste. It degrades following prolonged exposure to light. It is often produced in tablet form to prevent caking. BHA is insoluble in water, but is

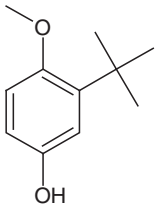

Figure 1 Structural formula of BHA (2-BHA isomer).

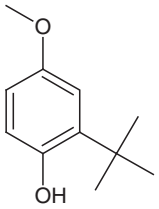

Figure 2 Structural formula of BHA (3-BHA isomer).

freely soluble in fats and oils. It has a melting point of 48–55 °C and boiling point of 264–270 °C (Figures 1 and 2).

BHT

BHT (2,6-ditertiary-butyl-*p*-cresol; 4-methyl-2,6-ditertiary-butyl-phenol) is a white crystalline solid. It is insoluble in water but readily soluble in fats and oils, exhibiting greater solubility in fats and oils than BHA or TBHQ. It has a melting point of 70 °C and a boiling point of 265 °C (Figure 3).

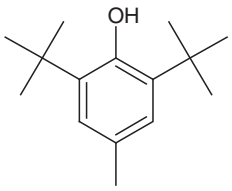

Figure 3 Structural formula of BHT.

Hazard Identification and Characterization

BHA

BHA is rapidly absorbed from the gastrointestinal tract (GIT), metabolized and excreted in the urine and feces, mainly in the form of metabolites. The acute toxicity of BHA in rats and mice has been reported as low, with oral LD_{50} values >2000 mg kg^{-1} bodyweight.

A large number of long-term toxicity and carcinogenicity studies have been performed with BHA, demonstrating proliferative changes in the forestomach. The studies have been undertaken using species with a forestomach (mice, rats, and hamsters) and without (guinea-pigs, dogs, pigs, and monkeys). Gastric epithelial hyperplasias, papillomas, and carcinomas linked to BHA exposure were only seen in species with forestomachs.

BHA is not genotoxic. Some clastogenic activity exerted *in vitro* by BHA and its metabolite, TBHQ, is concluded to be secondary to the formation of reactive oxygen species via a nongenotoxic threshold mechanism involving prooxidant species.

The National Toxicological Program (NTP) has listed BHA as 'reasonably anticipated to be a human carcinogen.' This has been based on studies in experimental animals demonstrating that dietary exposure to BHA caused benign and malignant tumors of the forestomach (papilloma and squamous-cell carcinoma) in rats of both sexes and in male mice and hamsters. There are no data available on the carcinogenicity of BHA in humans. NTP classification notwithstanding, the current consensus opinion is that these findings are not relevant to humans.

The Joint Food and Agriculture Organization (FAO)/World Health Organization (WHO) Expert Committee on Food Additives (JECFA) and the European Union Scientific Committee on Food (SCF) have considered the toxicity data on BHA on several occasions. A no observed adverse effect level (NOAEL) was established in 1989 by JECFA and SCF of 0.1% BHA in the diet, equivalent to 50.0 mg kg^{-1} bodyweight per day from chronic toxicity studies in rats. This was based on data indicating that 0.125% BHA but not 0.1% BHA in the diet induced mild hyperplasia in the rat forestomach. Subsequent consideration by the WHO and others have highlighted the limitations of rodent forestomach tumors for predicting human carcinogenicity due to mode-of-action and exposure conditions, concluding that these findings were not relevant to humans.

In 2011 the European Food Safety Authority (EFSA, SCF's contemporary) established a NOAEL at 100 mg kg^{-1} bodyweight per day, noting that, as humans do not have a forestomach, forestomach hyperplasia in rodents may no longer be considered relevant for human risk assessment. This value was based on a NOAEL for reproductive and developmental toxicity of 0.125% BHA in the diet (equivalent to at least 100 mg kg^{-1} bodyweight per day) that demonstrated rat pups showing growth retardation, increased mortality, and behavioral effects at higher dose levels.

In 1989, the JECFA and the SCF established an acceptable daily intake (ADI) for BHA of 0–0.5 mg kg^{-1} bodyweight per day based on the rat NOAEL of 50.0 mg kg^{-1} bodyweight per day using an uncertainty factor of 100. In 2011, the EFSA established an ADI for BHA of 1.0 mg kg^{-1} bodyweight per day based on the rat NOAEL of 100 mg kg^{-1} bodyweight per day due to adverse developmental effects in rat pups, and using an uncertainty factor of 100.

BHT

BHT is rapidly absorbed from the GIT. On absorption, BHT is distributed to the liver and body fat. Excretion is primarily via urine and to a smaller extent in the feces. There are significant species differences in the metabolism of BHT. In particular, biliary excretion of BHT seems not to be as significant in humans as it is in rats, rabbits, and dogs.

The acute toxicity of BHT in rats, mice, cats, and rabbits is low with oral LD_{50} values of >2000 mg kg^{-1} bodyweight and $>10\,000$ mg kg^{-1} bodyweight in guinea-pigs.

Short-term or subchronic exposure to BHT induces histopathological changes in the liver, lungs, and/or kidneys of mice, rats, and chickens. Increases in relative thyroid and

adrenal weights in rats were also identified. In mice and rats, exposure to high levels of BHT may also cause hemorrhage as a consequence of vitamin K antagonism.

In long-term toxicity studies, BHT at high doses can exert liver and lung tumor-promoting effects in some animal models. JECFA noted that in view of the probable involvement of hepatic enzyme induction in the development of hepatocellular damage associated with exposure to repeated doses of BHT, a well-defined threshold was demonstrated at 100 mg kg^{-1} bodyweight per day in rats. A NOAEL of 25 mg kg^{-1} bodyweight per day for BHT was based on effects in the reproductive studies (litter, size, sex ratio, and pup body weight gain during lactation) and hepatic enzyme induction seen in two separate two-generation studies in rats. BHT is not genotoxic.

In 1989, the SCF established an ADI of 0–0.05 mg kg^{-1} bodyweight per day for BHT based on the rat NOAEL of 5 mg kg^{-1} bodyweight per day and using an uncertainty factor of 100. An ADI for BHT was later established by JECFA in 1996 at 0–0.3 mg kg^{-1} bodyweight per day based on the rat NOAEL of 25 mg kg^{-1} bodyweight per day and using an equivalent uncertainty factor of 100. In 2012, EFSA reviewed the data for BHT and noted the outcomes from the two-generation rat studies. Consequently, the ADI was revised using the rat NOAEL of 25 mg kg^{-1} bodyweight per day and using an uncertainty factor of 100, to derive a value of 0.25 mg kg^{-1} bodyweight per day.

Exposure

BHA

Routes of exposure to BHA are ingestion, inhalation, and dermal contact. However, exposure to the latter two routes is minimal and only ingestion will be considered here.

The 1999 JECFA review of BHA dietary intake noted that estimates of national mean intake by consumers of BHA were lower than the ADI of 0–0.5 mg kg^{-1} bodyweight, ranging from 1% of the ADI for Japan to 80% of the ADI for Australia/New Zealand, and the US. The JECFA estimate assumes that all foods contain the maximum permitted levels of the food additives, often resulting in significant overestimation of exposure, given that foods in general contain much lower amounts of food additive than the maximum permitted levels and that many foods do not contain the additive at all.

Estimates of the intake of high consumers of BHA, based on food additive levels in national standards, exceeded the ADI in some cases, but ranged from 30% of the ADI for France to 260% of the ADI for Australia/New Zealand. However, the available data were insufficient to estimate the number of high consumers or the magnitude or duration of intake at levels above the ADI over a lifetime

The EFSA review of BHA dietary intake concluded that when considering the maximum permitted limits (MPLs), estimates reported for the UK adult population give a mean dietary exposure of 0.1 mg kg^{-1} bodyweight per day and 0.14 mg kg^{-1} bodyweight per day for high-level consumers, which are within the ADI. The main contributors to the total anticipated mean exposure to BHA (greater than 10%) were soups (14%), sauces and seasonings (13%), fine bakery wares (33%), and breakfast cereals (20%).

The mean dietary exposure of European children (aged 1–14 years) ranged from 0.1 to 0.3 mg kg^{-1} bodyweight per day and from 0.2 mg kg^{-1} bodyweight per day at the 95th percentile, which are within the ADI. The main contributors to the total anticipated mean exposure to BHA (>10% in all countries, contributions differed by country) were fine bakery wares (18–69%), snacks (10–19%), processed potato products (14–71%), and breakfast cereals (15–23%). These 2011 EFSA estimates are based on combining national data on food consumption with the maximum permitted usage levels for the additive, which can result in an overestimation of exposure.

BHT

The JECFA review of BHT intake noted that estimates of mean intake based on model diets or individual consumption data combined with the General Standard for Food Additives levels of use, consistently exceeded the ADI. Using this method, the mean intake was estimated to be between 0.70 and 0.99 mg kg^{-1} bodyweight (230% and 240% of the ADI for China and the US, respectively), and the intakes of high consumers were estimated to be from 2.0 to 6.0 mg kg^{-1} bodyweight. This method assumes that all foods contain the MPLs of the food additives, often resulting in significant overestimation of exposure, given that foods in general contain much lower amounts of food additives than the MPLs.

In contrast, intake estimates based on national levels of use were relatively consistent, ranging from 0 to 0.11 mg kg^{-1} bodyweight per day (0–30% of ADI) on the basis of poundage, 0.502 to 0.1 mg kg^{-1} bodyweight per day (20–40% of the ADI) on the basis of household surveys or sales data, 0.02 to 0.09 mg kg^{-1} per day (10–30% of the ADI) on the basis of model diets and nation levels of use (except the USA), and 0.02 to 0.1 mg kg^{-1} bodyweight per day (0.1–30% of the ADI) on the basis of individual consumption data.

JECFA also recognized that BHT is likely to be used in conjunction with other antioxidants, such as BHA and TBHQ, which act synergistically with BHT. Consequently, the amount of BHT used in practice will be lower and it will be used in fewer foods than assumed in the estimates. This also indicates that JECFA figures are an overestimate .

The 2012 EFSA review of BHT dietary intake concluded that when using a worst-case scenario of combined exposure to BHT from the food categories where its use is authorized, the EFSA Panel on Food Additives and Nutrient Sources Added to Food (ANS) estimated the potential exposure for adults to be on average 0.01–0.03 mg kg^{-1} bodyweight per day and 0.03–0.17 mg kg^{-1} bodyweight per day at the 95th percentile. For children, the ANS estimated the potential exposure in the range of 0.01–0.09 mg kg^{-1} per day at the mean and in the range of 0.05–0.30 mg kg^{-1} bodyweight per day at the 95th percentile. Given the assumptions, this is likely to be an overestimate of the actual exposure.

The ANS Panel noted that at the average exposure of adults to BHT is unlikely to exceed the 2012 ADI of 0.25 mg kg^{-1} bodyweight per day and at the 95th percentile. However, for children, while the ADI would unlikely be exceeded at the mean, it did exceed it for high consumers (assume 95th percentile) in some European countries, for example, Finland and the Netherlands.

Risk Characterization

Long-term toxicity and carcinogenicity studies involving the oral consumption of BHA or BHT in laboratory animals have indicated some species-specific toxicological effects. Given the extensive and long history of use of these synthetic antioxidants in food, together with animal studies, the weight of scientific evidence indicates that these chemicals are safe for use as food additives, with a clearly defined ADI. Although some dietary exposure estimates indicate limited exceedance of ADI for BHA and for BHT by average and higher consumers, these are based on the assumption that all foods contain the maximum permitted levels of BHA/BHT and as such tend to significantly overestimate actual exposure. On the basis of this information, it is concluded that there are presently no public health and safety concerns from the consumption of BHA or BHT in food at the MPLs. Increasing use of chemicals such as BHA and BHA in foods and other goods, however, needs to be monitored to ensure that the exposure remains within the allowed limits.

Methods of Analysis

A number of methods of analysis are available for the detection of BHA and BHT and are described in the scientific literature. For BHA, high-performance liquid chromatography (HPLC) and spectrofluorometric methods have been described. For BHT, HPLC, gas chromatography (GC) coupled with mass spectrometry (MS), gas chromatography with a flame ionization detector (FID) and direct Fourier transform infrared (FITR) spectroscopic methods are available.

Specifications have been prepared for BHA at the 33rd JECFA (1988), published in *FNP* 38 (1988) and *FNP* 52 (1992). Specifications for BHT have been prepared at the 37th JECFA (1990), published in *FNP* 52 (1992) superseding specifications prepared at the 30th JECFA (1986), published in *FNP* 37 (1986). Metals and arsenic specifications have been revised at the 61st JECFA (2003).

Glossary

Acceptable daily intake (ADI) The amount of a substance that may be consumed every day throughout an entire lifetime without appreciable risk. Expressed as mg per kg bodyweight per day, the ADI is normally calculated by dividing the no observed (adverse) effect level, by a safety/uncertainty factor of 100 in order to address the uncertainties associated with the available scientific data.

Acceptable daily intake 'not specified' A term used by the Joint FAO/WHO Expert Committee on Food Additives to signify that no adverse effects have been identified from exposure to the food additive, even at levels many times higher than those necessary for its technological function. Consequently, there is no appreciable risk from exposure arising from its use as a food additive under 'good manufacturing practices.'

Food additive Natural or synthetic chemically defined substances added to food to preserve flavor or enhance its taste and appearance or for other technological functions.

International Numbering System (INS) The INS for food additives developed and maintained by the Codex Alimentarius.

No observed adverse effect level (NOAEL) A level of chemical that produces no adverse effect. Expressed usually in mg per kg bodyweight per day.

Overview

Food manufacturing processes can cause degradation or loss of the natural pigments in the raw food and production of many processed foods, such as ice cream and snack foods, require the addition of color. Given raw materials often vary in color intensity, colorants may be added to ensure the processed food is uniform in color.

Colorants are used as food additives at relatively low levels to achieve the technological function; they may be natural or synthetic in origin. Most natural colors are derived from plant tissues and include:

- anthocyanins giving red and blue color, which are obtained from strawberries and grapes;
- carotenoids giving yellow, orange, and red color, which are obtained from annatto, saffron, paprika, carrot, and mushrooms; and
- phenolics with orange/yellow color, which are obtained from turmeric.

Many carotenoids used as food colorants are also synthesized chemically. Synthetic colorants are used, as there are often problems in terms of food processing with the intensity variation and water solubility associated with the natural colorants.

In general, colorants are water soluble, and their stability may be affected by light, heat, pH, and reducing and oxidizing agents. A number of food dyes have been chemically synthesized and approved for use in various countries, although different countries still vary in the spectrum of food colorants permitted. The Codex Alimentarius Commission (Codex) recommends standards that aim to harmonize the use of food additives, including colorants, and better facilitate trade in food, while ensuring human health is protected. All synthetic colorants have undergone extensive toxicological analysis before they can be used. Such tests are carried out in animals and require interpretation as to their relevance to humans, i.e., safety assessment.

The use of synthetic colors in foods has been an area of debate in recent years due to a proposed linked between behavioral disturbances, especially hyperactivity, in children and dietary exposure to colors in food. A study published in 2007 by McCann *et al.* contributed to this debate, with the authors concluding that their research demonstrated the effect of food color mixtures (which included Ponceau 4R, Sunset Yellow, and Quinoline Yellow) and preservatives (sodium benzoate) on increased hyperactivity in sensitive children. Subsequent assessments of this study by many independent scientific bodies concluded that the study provided limited evidence of small effects on children's behavior, but that these effects were not consistent and the study did not give cause to amend current safety limits for these food additives.

Therefore, although a causative link between exposure to colorants in food and hypersensitivity in children has not been demonstrated to date in animal studies, it is argued that animal studies may not be able to pick up these effects; however, food safety experts maintain that long-term studies, as well as multigeneration studies in animals do have the

capacity to identify neurotoxic effects. Epidemiological studies may be helpful, but they present challenges that include the design and size of the study and adequate exclusion of confounding factors.

Allergy and sensitivity reactions affect a small proportion of the population, with estimates ranging between 1% and 5% of the population with greater numbers reported for children than adults. In many countries, concerned individuals manage potential risks from food additives through avoidance of processed foods that contain the suspected agent, including those that are suspected to be caused by colors. The regulatory approach is to provide consumers with the relevant information on the label of foods to allow consumers to make an informed choice. However, this information is not consistently applied among unpackaged foods, for example, bulk food and foods eaten outside of home.

Some colorants are no longer approved for use in food, but are still used in some countries illegally, and may pose health risks. One of these is Sudan Red, which is a suspected carcinogen. The illegal use of this color in chili peppers has caused international concern, because many products were contaminated; however, in this instance, the levels of Sudan Red found in these foods were too low to pose a significant risk to human health.

The remainder of this article examines in detail the risk assessment information relevant to some colors of recent public interest: Ponceau 4R, Quinoline Yellow, and Sunset Yellow.

Ponceau 4R

History

Ponceau 4R (which is known by more than 100 synonyms including C.I. Food Red 7, Cochineal Red A, and New Coccine) is a synthetic red azo dye used in a range of alcoholic and nonalcoholic beverages, and a variety of foodstuffs including confectionary, desserts, cheeses, meats, preserved fruits, and sauces. The Codex General Standard for Food Additives specifies maximum limits for Ponceau 4R of 50–500 mg kg^{-1} in a range of foods and beverages. In Europe, the maximum permitted levels (MPLs) in food and beverages range up to 500 and 200 mg kg^{-1}, respectively. In Australia and New Zealand, the MPLs are up to 70 mg kg^{-1} in beverages and 290 mg kg^{-1} in foods. Ponceau 4R is not an approved food additive in the US or Canada due to a rationalization of the number of food additives.

The main health issue that attracts public interest in relation to the dietary consumption of Ponceau 4R (and a number of other synthetic food colors) is the possible effects on children's behavior, especially hyperactivity. The United Kingdom's Food Safety Authority (UKFSA) commissioned the 'Southampton study,' which investigated the effect of mixtures of six synthetic food colors (one of which was Ponceau 4R) and a preservative (sodium benzoate) on the behavior of children. The authors of this study suggested there was a link between consumption of these additive mixtures and hyperactivity in children. The UK Committee on Toxicity, Consumer Products and the Environment and European Food Safety Authority (EFSA) expert panels reviewed the results of this study and concluded that, although it provided limited evidence of small effects on children's behavior, these effects were not consistent and that the study did not give cause to amend current safety limits for these food additives.

Subsequently, the UKFSA Board decided there should be voluntary action by manufacturers in the UK to remove these colors by 2009. On 9 July 2008, the European Parliament ruled that food products containing specific food colors (tartrazine, Quinoline Yellow, Sunset Yellow, carmoisine, Ponceau 4R, and Allura Red) would need to be labeled 'May have an adverse effect on activity and attention in children.' This came into effect in July 2010. The risk management decisions by the UKFSA and the EU Parliament in relation to those food colors are not supported by the scientific opinion of EFSA.

In March 2011, the United States Food and Drug Administration (US FDA) held a public hearing, and sought the advice of its Food Advisory Committee on a possible linkage between dietary exposure to food colors and hyperactivity in children. In preparation for the hearing, the US FDA reviewed the available evidence, including the Southampton study and concluded that it did not warrant further action.

It is recognized that some people prefer to avoid certain food additives and therefore Ponceau 4R, like other food additives, is required to be identified by its class name (e.g., color) and by an individual name or code number (i.e., E124).

Chemical Characterization

Ponceau 4R exists principally as trisodium-2-hydroxy-1-(4-sulfonato-1-naphthylazo)-6,8-naphthalenedisulfonate (chemical abstracts service (CAS) No. 2611-82-7; International Numbering System No. 124) (Figure 1), with subsidiary coloring matters and sodium chloride or sodium sulfate.

From a food technology perspective, Ponceau 4R is a strawberry red color shade and is stable to light, heat, and acid but fades in the presence of ascorbic acid and SO_2.

Hazard Identification and Characterization

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has evaluated the toxicity of Ponceau 4R on several occasions, most recently in 2011. The acceptable daily intake (ADI) of 0–4 mg per kg bodyweight per day was established in 1983 and confirmed in 2011 based on the no observed adverse

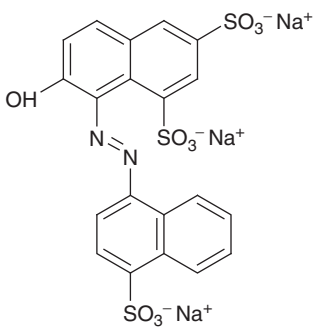

Figure 1 Structure of Ponceau 4R (trisodium-2-hydroxy-1-(4-sulfonato-1-naphthylazo)-6,8-naphthalenedisulfonate).

effect level (NOAEL) of 375 mg per kg bodyweight per day for renal effects in a long-term mouse study and using a 100-fold safety factor. In laboratory animal studies, Ponceau 4R was poorly absorbed from the digestive tract, where it is anaerobically reduced by microflora, with small levels of the resulting metabolites systemically absorbed. Ponceau 4R does not accumulate in any tissue. JECFA concluded that Ponceau 4R was not carcinogenic, genotoxic, neurotoxic, or caused reproductive or developmental toxicity. JECFA reviewed human data in relation to alleged allergic reactions to Ponceau 4R (urticarial and vasculitic reactions) but was unable to draw any conclusions due to limitations in the study design. Although Ponceau 4R was one of the six colors tested in the study by McCann *et al.* in 2007, dosing as a mixture did not enable the possible effect of Ponceau 4R to be elucidated.

The EU Scientific Committee on Food (SCF) evaluated Ponceau 4R in 1984, establishing the same ADI as JECFA. EFSA reconsidered Ponceau 4R, noting the absence of genotoxic and carcinogenic potential, and reaffirming its previous view that the study by McCann *et al.* provided no basis to amend the ADI. However, EFSA did revise the European ADI for Ponceau 4R from 4 to 0.7 mg per kg bodyweight per day without reevaluating the original laboratory animal studies that underpinned the ADI established by JECFA. Based on the JECFA summary report, EFSA concluded that the NOAEL for glomerulonephrosis in the pivotal, long-term mouse study was 70 mg per kg bodyweight per day. EFSA noted that sensitivity (i.e., mainly skin-related) reactions to Ponceau 4R (within mixtures of other colors) had been reported in some individuals within clinic populations. However, these reactions would be rare in the general population. On this basis, EFSA concluded that such sensitive individuals may react at doses of Ponceau lower than the ADI.

Exposure

The dietary exposure of Ponceau 4R for different population groups was examined by EFSA, Food Standards Australia New Zealand (FSANZ), and JECFA, and are summarized in Table 1. The relatively large difference in dietary exposure estimates between Europe and Australia are attributable to the use of maximum permitted, or reported use levels, and mean analyzed levels, respectively. JECFA considered that the use of the latter gives a more realistic exposure estimate.

Table 1 Dietary intakes of Ponceau 4R in different regions

Country (years)	*Mean intake (mg per kg bodyweight)*	*High-level intake*[a] *(mg per kg bodyweight)*
Europe		
Children, 1–10	0.3–2.5	0.7–6.7

>25	<0.01	0.01
>2	<0.01	0.01

[a]95th or 97.5th percentile.

Risk Characterization

Conservative intake calculations performed by EFSA and using MPLs of Ponceau 4R in foods found an exceedance of the ADI of 0.7 mg per kg bodyweight per day for high percentile (97.5th) adults and 1–10-year-old children (95th/97.5th). In contrast, the use of analytical levels measured in foods to generate a more realistic Australian exposure estimate determined that all groups of consumers were well below the ADI (maximum of approximately 0.5% of the ADI in high-level consumers). The Australian exposure estimates are also below the EFSA ADI (approximately 35% of the ADI in high-level consumers). Given that the exposure estimates such as those of EFSA are recognized to significantly overestimate exposures, it is concluded that the current intakes of Ponceau 4R are not likely to pose a risk to human health.

Methods of Analysis

Methods of analysis for Ponceau 4R are described in the detailed product specifications prepared by the 74th JECFA in 2012 and EFSA in 2009.

Summary

Ponceau 4R is a red food color permitted to be added to a variety of beverages and solid foodstuffs in Europe and Australia. Health issues that are, at times, attributed to artificial colors per se include possible intolerance reactions in sensitive individuals and adverse effects on children's behavior. However, available data provide no compelling scientific case that Ponceau 4R can do either. The toxicity of Ponceau 4R has been evaluated by JECFA and EFSA. The compound is poorly absorbed from the digestive tract and is of relatively low toxicity, with no evidence of carcinogenicity, genotoxicity, neurotoxicity, or reproductive and developmental toxicity. Conservative dietary exposure calculations using maximum permitted European levels determined that exposures from diets were well within the European ADI of 0.7 mg per kg bodyweight per day and the JECFA ADI of 4 mg per kg bodyweight per day. In contrast, the use of analytical concentration data from Australia that reflect actual exposures rather than maximum levels permitted in foods indicated that the dietary exposure for the whole population was less than 2% of the JECFA ADI of 4 mg per kg bodyweight per day. In recognition that some people prefer to avoid this colorant, many countries mandate the labeling of prepackaged food to facilitate consumer choice.

Quinoline Yellow

History

Quinoline Yellow (also known as Acid Yellow, Food Yellow 13, C.I. 47005, and C.I.) is a synthetic colorant, classified into the

quinophthalone class of dyes. Quinoline Yellow is commonly used in confectionery, soft drinks, as well as other food and beverages. It is also used in the medical and cosmetic industries. Some sensitivity to Quinoline Yellow has been reported following exposure; however, a direct causative relationship has not been directly demonstrated.

Quinoline Yellow is a permitted food additive in certain countries. For example, in the EU, Quinoline Yellow is permitted in beverages, with a maximum level of 200 mg l^{-1} for alcoholic and 100 mg l^{-1} in nonalcoholic beverages. It is also used in a variety of foods, with MPLs ranging from 50 mg kg^{-1} in complete weight control formulas to 500 mg kg^{-1} in sauces, decorations, and coatings. In Australia, the MPLs for Quinoline Yellow in beverages is 70 mg l^{-1} and in other foods at 290 mg kg^{-1}.

In contrast, Quinoline Yellow is not listed as a permitted food color in Canada or the US, but is permitted in medicines and cosmetics. At present, there are no provisions for Quinoline Yellow by Codex.

Following the release of the McCann *et al.* study and suggested link between food colors and behavior alterations in children, there was considerable focus on the use of colors in food by food regulatory agencies across the world. Independent scientific review of this study (see Ponceau 4R above) concluded that, although it provided limited evidence of small effects on children's behavior, these effects were not consistent and that the study did not give cause to amend current safety limits for these food additives.

In 2011, US FDA Food advisory committee meeting also considered the outcomes of the McCann *et al.* study and concluded that the link between the dietary exposure to color additives in food and behavioral problems (e.g., hyperactivity) in children could not be established.

In 2009, the EFSA Panel on Food Additives and Nutrient Sources Added to Food (ANS) reevaluated Quinoline Yellow as part of their on-going review of food additives. The ANS findings concurred with those of the Panel on Food Additives, Flavourings, Processing Aids and Materials in Contact with Food (AFC), in relation to the McCann *et al.* study. As part of the broader review on Quinoline Yellow, a study investigating the long-term effects of chronic exposure to Quinoline Yellow and the reproductive and developmental toxicity of exposure was considered. In 2009, EFSA evaluated the toxicological database of Quinoline Yellow and established an ADI of 0–0.5 mg kg^{-1} bodyweight.

Chemical Characterization

Quinoline Yellow (CAS No. 8004-92-0; Molecular weight 477.38 g $mole^{-1}$) is a water soluble dye used to color food yellow/yellow–green and is stable under standard conditions. It can exist in three forms, usually as a mixture of monosulfonate ($C_{18}H_9NNaO_5S$), disulfonate ($C_{18}H_9NNa_2O_8S_2$), or trisulfonate ($C_{18}H_9NNa_3O_{11}S_3$). The principal component, however, is the disulfonate form, otherwise known as disodium 2-(1,3-dioxoindan-2-yl) quinoline-6,8-disulfonate (Figure 2). For purity purposes, the disulfonate form must be greater than or equal to 70%. Uncolored compounds such a sodium chloride and sodium sulfate may also be present in this mixture. Quinoline Yellow can be in a methylated or unmethylated state, and toxicological data of either form is used in safety assessments.

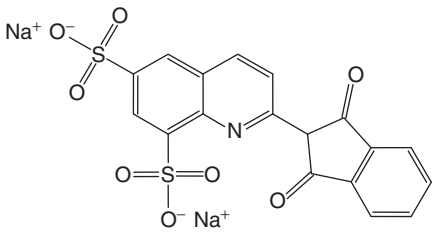

Figure 2 The chemical structure of the principal form of Quinoline Yellow (disodium 2-(1,3-dioxoindan-2-yl) quinoline-6,8-disulfonate).

Hazard Identification and Characterization

The toxicological evaluation of Quinoline Yellow as a food additive has been reviewed a number of times by the JECFA, with its first consideration by the committee in 1964 at its 8th meeting. A summary of JECFA evaluations of Quinoline Yellow from 1964 to 2011 are shown in Table 2. The most recent evaluation was conducted by JECFA at the request of Codex.

At this meeting, no new data was available to the committee for consideration; however, unpublished long-term generational reproductive toxicity studies not previously

Reports referenced can be found in the section Relevant Websites.

considered were included. The EFSA's redefinition of the ADI for Quinoline Yellow in 2009 was also taken into account.

Experimental feeding studies in rats and dogs has shown that the absorption rate of Quinoline Yellow is low (approximately 3–4%), with a large proportion of the absorbed color excreted in the urine. Unabsorbed Quinoline Yellow is excreted via the feces. Toxicological assessments over several evaluations has indicated that Quinoline Yellow is not carcinogenic or genotoxic. Generational studies in animals have indicated no adverse effect on reproduction.

Following deliberations of the JECFA in 2011, a temporary ADI of 0–5 mg kg^{-1} bodyweight was established, pending receipt of an unpublished toxicological study by 2013.

Exposure

The dietary exposure to Quinoline Yellow in a variety of population groups has been estimated in Australia, Europe, and the UK (Table 3). Major food contributors to this exposure were found to be soft drink, bakery products, and desserts.

Dietary exposure estimates to Quinoline Yellow in Australia were lower than those in the UK or Europe. JECFA considered this large difference to be a result of the approach taken in estimating the dietary exposures for the different region. For example, the dietary exposures for Australia were based on actual analytical concentrations determined in food, whereas the Europe and UK dietary exposure estimates used the assumption that all foods to which this color is added contained it at the maximum permitted use level, resulting in a significant overestimate. Dietary exposure estimates derived from the actual concentration data in foods was considered to provide a more accurate estimate of the dietary exposure to Quinoline Yellow.

Table 3 Estimated dietary exposures to Quinoline Yellow in three regions at the mean- and high-level intake

[d]Maximum concentrations based on permitted use levels was used; high-level intake refers to the 97.5th percentile consumers.

Risk Characterization

Quinoline Yellow has not been associated with any significant long-term toxicity, is not genotoxic or carcinogenic and there is no evidence of adverse effects on reproduction or development based on studies in animals. A recent study suggested, but could not establish a link between the dietary exposure to multiple color additives including Quinoline Yellow in food and behavioral problems such as hyperactivity in children. A temporary ADI of 0–5 mg kg^{-1} bodyweight was set by JECFA in 2011. The exposure estimates indicate that dietary exposure to this colorant is below the temporary ADI of 0–5 mg per kg bodyweight per day. Given the low toxicity of Quinoline Yellow, the conservative method of establishing the ADI and the fact that the exposure is well within the ADI, dietary exposure to Quinoline Yellow is considered to be safe to human health.

Methods of Analysis

The tentative specifications and methods of analysis for Quinoline Yellow are described by EFSA and JECFA.

Summary

Quinoline Yellow is a synthetic dye that is used in the food as a coloring agent in confectionery, soft drinks, and other food and beverages. It is permitted for use in food in Australia and Europe, however, it is not permitted in the US or Canada. The use of Quinoline Yellow in foods has been an area of debate recently due to the McCann study that purported a link between hyperactivity in children and dietary exposure to a mixture of colors including Quinoline Yellow. However, reviews of this study by various independent scientific authorities concluded that the study did not give cause to amend current safety limits for these food additives. Recent reviews conducted by EFSA and JECFA have not found any new evidence to indicate a concern over the safety of Quinoline Yellow. A temporary ADI of Quinoline Yellow was set recently by JECFA at 0–5 mg per kg bodyweight per day, pending receipt of an unpublished toxicological study. The estimates for Quinoline Yellow intake from food, estimated in several countries and regions indicate that dietary exposure is within the limits of the JECFA temporary ADI and therefore is safe to human health.

Sunset Yellow FCF

History

Sunset Yellow FCF is a synthetic azo dye with a long history of use as a coloring for beverages and variety of foods, including confectionary, desserts, soups, cheeses, savory snacks, sauces, and preserved fruits. The Codex GFSA includes provisions for Sunset Yellow FCF in a wide range of foods and beverages with maximum levels ranging from 50 to 400 mg kg^{-1}. In Europe, the MPLs in food and beverages range from 50 to 500 mg kg^{-1} with a similar range in Australia and New Zealand. In Canada and the US, Sunset Yellow FCF is permitted to be added to foods with no maximum levels specified.

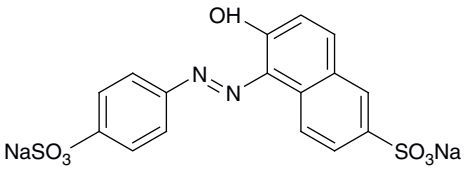

Figure 3 Structural formula for the principal component of Sunset Yellow FCF.

As for several other synthetic food colors, Sunset Yellow FCF has attracted attention because of a claimed effect on children's behavior. The UKFSA commissioned the 'Southampton study,' which investigated the effect of mixtures of six synthetic food colors (one of which was Sunset Yellow FCF) and also contained a preservative (sodium benzoate) on the behavior of children. This study, and the resulting risk management actions in the UK, EU, and the US, are described in the section above, Ponceau 4R and Quinoline Yellow.

Chemical Characterization

The major chemical component of Sunset Yellow FCF is disodium 6-hydroxy-5-(4-sulfonatophenylazo)-2-naphthalenesulfonate (CAS No. 2783-94-0; Figure 3). Sunset Yellow FCF is an orange color shade and possesses good light, heat, and acid stability, but fades in the presence of ascorbic acid and SO_2.

Hazard Identification and Characterization

The JECFA has evaluated the toxicity of Sunset Yellow FCF on several occasions, most recently in 2011. JECFA initially established on ADI of 0–2.5 mg kg^{-1} bodyweight. The current JECFA ADI of 0–4 mg kg^{-1} bodyweight was established based on the NOAEL of 375 mg per kg bodyweight per day for reduced bodyweight in the offspring of rats in a long-term study and using a 100-fold safety/uncertainty factor. In laboratory animal studies, Sunset Yellow FCF is poorly absorbed from the digestive tract where it is metabolized by bacteria to yield sulfanilic acid and 1-amino-2-naphthol-6-sulfonic acid, which are absorbed and metabolized to various *N*-acetylated forms. Sunset Yellow FCF has not shown potential for carcinogenicity, genotoxicity, or developmental toxicity. JECFA considered reports suggesting that asthma or chronic idiopathic urticaria/angioedema in humans may be induced by oral exposure to Sunset Yellow FCF and noted that most of these reports are characterized by poorly controlled challenge procedures and that no conclusions could be made from the available evidence.

The EU SCF evaluated Sunset Yellow FCF in 1984, establishing an ADI of 0–2.5 mg kg^{-1} bodyweight. EFSA reevaluated Sunset Yellow FCF based on the existing database in addition to the supplementary studies published in the scientific literature. EFSA noted the absence of genotoxic and carcinogenic potential. It also reaffirmed a previous view that the 2007 McCann study on a link between hyperactivity in children and exposure to some food additives including colors, provided no basis to amend the ADI. However, EFSA concluded that findings for the testes in a supplementary 90-day rat study gave reason to reduce the ADI, by an extra safety/uncertainty factor of 2.5, to 0–1 mg kg^{-1} bodyweight and made the ADI temporary. Both JECFA and EFSA noted that the test material for this study was obtained from a local market in India and its purity was not specified. Despite a lack of treatment-related effects on the testes in other rodent studies, including 2-year studies in mice and rats at higher dose levels, EFSA recommended that clarification of the effects of Sunset Yellow FCF on the testis, sperm morphology, and sperm mobility should be provided, based on a 28-day study performed according to Organisation for Economic Co-operation and Development test guideline 407.

With regard to intolerance reactions in humans, EFSA concluded that there was only limited scientific evidence to suggest such a response. However, EFSA concluded that sensitive individuals may react at doses that are within the ADI. This final statement, however, did not appear to be supported by any scientific evidence.

Table 4 Dietary intakes of Sunset Yellow FCF in different regions

Region (years)	*Mean intake (mg per kg bodyweight per day)*	*High-level intake[a] (mg per kg bodyweight per day)*
Europe

>25	0.01	0.04
>2	0.02	0.06

[a]90th, 95th, or 97.5th percentile.

Exposure

The dietary intake of Sunset Yellow FCF for different population groups were examined by EFSA, Food Standards Australia New Zealand (FSANZ), and JECFA, and are summarized in Table 4. The relatively large difference in dietary exposure estimates between Europe and Australia are attributable to the use of maximum permitted or reported use levels, and mean analyzed levels, respectively. JECFA considered that the use of the latter gives a more realistic exposure estimate.

Risk Characterization

The toxicity of Sunset Yellow FCF has been evaluated recently, indicating no concern over its carcinogenic, genotoxic, or developmental potential. Some questions remain over effects on testes, but this is currently not supported by other studies on testicular effects. Intake calculations performed by EFSA using MPLs of Sunset Yellow FCF in food found exceedances of the ADI of 0–1 mg kg^{-1} bodyweight for high percentile (97.5th) adults and 1–10-year-old children (95th/97.5th), but such methodology generally produces significant overestimates. In

contrast, the use of levels from the analytical survey in Australia to generate a data-based exposure estimate determined that all groups of consumers were well below the ADI of 0–4 mg kg^{-1} bodyweight (maximum of approximately 3% of the ADI in high-level consumers). The Australian exposure estimates are also below the EFSA ADI (approximately12% of the ADI in high-level consumers). Current dietary intakes of Sunset Yellow FCF are therefore not considered to present any human health concerns.

Methods of Analysis

Methods for the analysis of Sunset Yellow FCF in food are described by EFSA.

Summary

Sunset Yellow FCF (also known as Orange Yellow S, C.I. Food Yellow 3, FD&C Yellow #6) is a synthetic azo dye permitted to be added to a variety of beverages and foods. The toxicology of Sunset Yellow FCF has been recently evaluated by the JECFA and EFSA. Systemic absorption of the compound is minimal following oral ingestion. The toxicological properties of Sunset Yellow FCF are well characterized and there is no evidence of carcinogenicity, genotoxicity, or developmental toxicity. ADIs of 0–1 and 0–4 mg kg^{-1} bodyweight have been established by EFSA and JECFA, respectively. EFSA established a lower ADI because of concerns regarding potential effects on the testes observed in a 90-day rat study. However, both EFSA and JECFA noted that the test article in this study was of unspecified purity. Treatment-related effects on the testes have not been observed in other rodent studies of longer duration using higher dose levels of Sunset Yellow FCF. Dietary exposure assessments using modeling assumptions that produce a very conservative estimate in Europe determined that there were exceedances of the EFSA ADI of 0–1 mg kg^{-1} bodyweight. In contrast, the use of analytical concentration data from Australia to generate a more realistic exposure estimate indicated that intakes were well below the JECFA ADI of 0–4 mg kg^{-1} bodyweight and also below the lower ADI established by EFSA. Exposure estimates based on analytical data are more reliable and therefore, the conclusion is reached that the current use of Sunset Yellow FCF is safe.

As for several other synthetic colors, it has been claimed that Sunset Yellow FCF causes intolerance reactions in sensitive individuals and adverse effects on children's behavior. However, there is little robust scientific evidence that Sunset Yellow FCF can cause such effects. Labeling of processed prepackaged foods provides a tool for consumers wishing to avoid this colorant.

FOOD ADDITIVES

Flavors and Flavor Enhancers

TE Kaitano, Food Standards Australia New Zealand, Wellington, New Zealand

Glossary

Acceptable daily intake (ADI) An estimate of the amount of a substance that can be ingested daily over a lifetime without appreciable risk to health.

Adverse reaction With respect to food, an unintended and undesirable response by the body to food. Examples include food allergies that involve an immune response to specific components of food, and food intolerances that include metabolic food disorders such as phenylketonuria, and idiosyncratic reactions that occur through unknown mechanisms.

Blood–brain barrier A barrier that separates the brain and spinal cord from the blood. The barrier protects the central nervous system from unwanted and/or potentially harmful substances.

ED_{50} The dose causing 50% of subjects in an experiment to show a specified treatment-related effect following administration of a test substance.

Median lethal dose (LD_{50}) The dose of a test substance causing 50% mortality in experimental animals.

Parenteral Administration of a substance into the body via a route other than oral, e.g., by intravenous means.

Umami It is the savory taste, which is one of the five basic tastes (others are salty, sour, sweet, and bitter).

Flavorings are substances used to impart taste and/or smell to food, and/or to intensify the existing flavors of products. Flavor enhancers activate receptors for the umami or savory taste (the four other tastes are sweet, salt, sour, and bitter) and, thus, introduce a new taste to products. Thus, flavor enhancers are actually themselves a type of flavor. Flavorings have a long history of safe use in a wide variety of foods, from confectionery and soft drinks to cereals, cakes, and yogurts. Compared with flavors, the number of flavor enhancers in use is far fewer, but consumer concern for their safety has made them the subject of much public debate.

Flavoring agents are composed of large and divergent groups of materials, including:

- artificial substances unlikely to occur naturally in food;
- natural materials not normally consumed as food, their derived products, and the equivalent nature-identical flavorings
- herbs and spices, their derived products, and the equivalent nature-identical flavorings; and
- natural flavoring substances obtained from vegetable and animal products normally consumed as food, whether processed or not, and their synthetic equivalents.

The safety evaluation of flavoring agents presents a special challenge. Flavoring substances are generally consumed in low amounts, but there are several thousand individual flavoring substances in commercial use worldwide.

All of the existing individual flavoring substances can be arranged into approximately 40 groups comprising substances with related chemical structures and similar known or predicted metabolic fates. A general method for the safety evaluation of flavoring agents takes the approach that in most cases, dietary exposure to these substances is low and self-limiting, and the majority of flavors are metabolized rapidly to innocuous end products. This fact limits the need for toxicological testing of many flavoring agents, and therefore the safety evaluation of flavors is done by combining data on intake, metabolic fate, and basic toxicity to perform assessments of flavorings in related structural groups.

The current Joint Food and Agriculture Organization/World Health Organization (FAO/WHO) Expert Committee on Food Additives (JECFA) Procedure for the Safety Evaluation of Flavoring Agents is outlined in Environmental Health Criteria (EHC) 240 of the International Programme on Chemical Safety (IPCS). The approach incorporates a series of criteria designed to provide a method to evaluate the large number of flavorings. The criteria take account of available information on dietary exposure from current uses, structure–activity relationships, and known or predicted metabolism, plus any available toxicity data on the compound or structurally related compounds. The use of these criteria provides a means of sorting flavoring substances in terms of presence or absence of potential safety concerns and provides guidance on the nature and extent of data required to perform a safety evaluation.

The criteria take advantage of the fact that some flavoring agents occur as normal constituents of mammalian tissues or are metabolized to form such constituents and are then completely metabolized to innocuous end products, such as

 doi:10.1016/B978-0-12-378612-8.00230-4

carbon dioxide and water. Flavoring agents with these characteristics are considered to be safe for consumption if dietary exposure is below the threshold of concern for the structural class, but are evaluated on the basis of toxicity data if dietary exposure is above the threshold of concern for the structural class. This safety evaluation may involve the use of toxicity data on the individual substance concerned or may rely, at least in part, on toxicity data on substances of closely related structure.

For flavoring agents that are not known or predicted to be metabolized to innocuous end products, the safety evaluation must be based on toxicity data, even if estimated dietary exposure is low. In such cases, there must be an adequate margin of safety between dietary exposure to flavoring agent and the no observed effect level or no observed adverse effect level (NOEL/NOAEL) for the substance or the NOEL/NOAEL for a substance of closely related structure on which the safety evaluation relies.

Flavoring agents currently in use for which no toxicity or metabolic data exist, and for which estimated dietary exposure is extremely low, less than 1.5 μg day^{-1}, are considered not to present a safety concern provided they do not contain structural alerts for genotoxicity.

The safety evaluation procedure is not intended to be applied to flavoring agents with existing unresolved problems of toxicity. Alternative approaches are used when data on specific flavoring agents are considered to warrant such action. Where acceptable daily intakes (ADIs) had previously been established for some flavoring agents or groups of flavoring agents, they are retained, as the information on which they are based is considered to be relevant for an evaluation of their safety and, in addition, they may have other uses as food additive.

Arguably, the most contentious flavor enhancer added to food from the perspective of a safety to human health is monosodium L-glutamate (MSG). Public perception continues to raise this as an issue of interest to the health authorities of many countries. An overview on its safety is presented in this article.

Monosodium L-glutamate

Overview

L-Glutamate occurs naturally in many foods and has a characteristic savory taste, sometimes called umami. Its salts including monosodium L-glutamate (MSG) have been used as flavor enhancers for over a century.

Since the 1960s, MSG has been reported to trigger minor adverse reactions now called the 'MSG symptom complex.' However, studies, such as blind challenge studies, to date have failed to prove an unequivocal link between MSG and the reported symptoms.

MSG has been associated with brain lesions in animals at plasma levels that can only be attained by parenteral injection or a large oral bolus. Such high plasma levels cannot be reached in humans when MSG is used as a flavor enhancer because the maximum palatable level of glutamate in food is limited to approximately 60 mg kg^{-1} bodyweight; ingestion with food delays and significantly dampens the elevation of plasma glutamate levels; and glutamate is extensively metabolized by enterocytes. Humans are therefore not at risk of adverse neurological effects from exposure to dietary MSG.

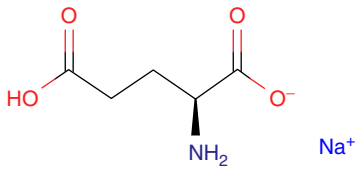

Figure 1 Chemical structure of monosodium L-glutamate, CAS No. 142-47-2. Reproduced from United States National Library of Medicine (2012) Sodium glutamate. Available at http://chem.sis.nlm.nih.gov/chemidplus/.

The conclusion from the assessment of a plethora of studies is that glutamate is safe for use by the general population as a flavor enhancer. Many countries regulate the labeling of food with information about additives such as MSG to inform consumer choice and provide a tool for individuals who prefer to avoid food additives, including MSG.

History

In 1908, Kikunae Ikeda, a Japanese scientist, discovered that MSG was responsible for the characteristic meaty or savory taste of the broth of dried bonito and Japanese seaweed (*Laminaria japonica*), and called this taste 'umami'. He patented an MSG production method involving hydrolysis of plant and animal proteins using strong acids. MSG is now produced via fermentation processes using starch hydrolysates and molasses from sugarcane and sugar beets and is used in a wide variety of processed and restaurant food as a flavor enhancer. Potassium, ammonium, and magnesium salts of glutamic acid are also used for the same purpose.

MSG has been the subject of much public controversy owing to its claimed association with what was initially termed 'Chinese restaurant syndrome,' but is now generally referred to as 'MSG symptom complex.'

Chemical Characterization

Pure MSG is a water-soluble white powder. Glutamates dissociate in aqueous solution to give the glutamate anion and the corresponding cation, for example, Na^+, K^+, and Mg^{2+}. Therefore, there is no difference between glutamate added as MSG, and that occurring naturally in food. The chemical structure of MSG is shown in Figure 1.

Some cations such as Na^+, K^+, and Mg^{2+} enhance the umami taste. L-Glutamate bound in protein molecules and D-glutamate do not possess this taste. All references to MSG and glutamate in this article refer to the L-isomer.

Hazard Identification and Characterization

Self-reported reactions in humans include headaches, general weakness, palpitations, and pain at the back of the neck starting about an hour after eating food containing MSG, and lasting for 2 h with no apparent long-term effect. It was hypothesized in the late 1960s that MSG, along with salt and

alcohol, could be responsible for the MSG syndrome complex. Since then, numerous 'case reports' and studies have appeared in the literature attempting to either prove or disprove this link.

MSG is now considered to be one of the most intensively scrutinized food additives. It has been reviewed twice by the JECFA, last in 1987. The European Commission published an opinion of its Scientific Committee for Food (SCF) in 1991, whereas the United States Food and Drug Administration commissioned the Federation of American Societies for Experimental Biology (FASEB) to compile a report on MSG, which was published in 1995. In Australasia, Food Standards Australia New Zealand (FSANZ) published a safety assessment of MSG in 2003. Academics have also reviewed MSG, one of the most notable being a consensus conference at the University of Hohenheim in 1997. A recent review focused on whether MSG triggers asthma in asthmatic individuals.

The list of adverse reactions claimed to be associated with MSG has grown significantly since 1968. It now includes burning sensations in the back of the neck, forearms and chest; facial pressure/tightness; chest pain; headache; nausea; palpitation; numbness in the back of the neck, radiating to arms and back; tingling, warmth, weakness in the face, temples, upper back, neck and arms; bronchospasm (observed in asthmatics only); drowsiness; and weakness.

The JECFA Review

JECFA reviewed hundreds of studies covering acute, subchronic, and chronic toxicity tests in animals and studies in human volunteers. The oral median lethal dose (LD_{50}) for MSG in the mouse and rat is very high, between 10 and 20 g kg^{-1} bodyweight. In this context, the largest palatable dose of MSG for humans is approximately 60 mg kg^{-1} bodyweight, so acute toxicity in humans is highly unlikely. Subchronic and chronic toxicity studies in rats and mice at dietary levels of up to 4% the diet did not reveal any adverse effects in either species. In dogs, no treatment-related effects were seen in 2-year feeding studies at dietary levels of up to 10%.

JECFA specifically reviewed the potential neurotoxicity of MSG because brain lesions (focal necrosis of the hypothalamus) had been reported in rodents and rabbits after intravenous or subcutaneous administration of glutamate or after very high bolus doses by gavage. In all, JECFA reviewed 59 different studies in mice, rats, hamsters, dogs, rabbits, guinea pigs, duck, and primates.

Mice were the most sensitive species for the brain lesions findings. Blood levels associated with neuronal damage were 100–300 μmol dl^{-1} in neonates, 380 μmol dl^{-1} in weanlings, and >630 μmol dl^{-1} in adults. In humans, plasma levels of this magnitude have not been attained even after bolus doses of 150 mg kg^{-1} bodyweight (approximately 10 g for a 70 kg adult). The oral effective dose $(ED)_{50}$ for production of brain lesions in the neonatal mouse is approximately 500 mg kg^{-1} bodyweight by gavage, whereas the largest palatable level for humans is approximately 60 mg kg^{-1} bodyweight with higher doses causing nausea. It was thus concluded that voluntary ingestion would not exceed this level and therefore could not reach threshold levels associated with this toxicity finding.

In humans, extensive studies in volunteers have failed to link MSG to the range of symptoms seen in the MSG symptom complex. In studies with lactating mothers, oral administration of 6 g MSG in water or liquid diet did not affect normal glutamate levels in milk. Studies in humans have also shown that oral administration of palatable doses of MSG does not result in an appreciable increase in blood glutamate levels.

On the basis of the available evidence, JECFA concluded that the total dietary intake of glutamates from all sources, i.e., glutamates naturally present in food and those added at levels necessary to achieve the desired flavor-enhancing effect, do not represent a health hazard. Consequently, JECFA concluded it was not necessary to set an ADI for L-glutamic acid and its monosodium, potassium, calcium, and ammonium salts.

European Commission Review

The European Commission's SCF reviewed acute, subchronic, and chronic toxicity studies in mice, rats, and dogs and found no MSG-related adverse effects. MSG neither affected any reproductive nor developmental parameters in mice, rats, rabbits, and monkeys. The SCF noted that no brain lesions have occurred in mice, rats, or hamsters exposed to very high doses of MSG in the diet.

In terms of idiosyncratic reactions to MSG in humans, the SCF noted that some of the reactions have also been observed with glutamate-free foods. Considering the large normal dietary intake of glutamates and data from animal and human studies, the SCF concluded it was not necessary to establish an ADI for glutamates.

FASEB Review

FASEB concluded that there was no evidence suggesting that orally administered MSG can affect the central nervous system in humans. Based on testimonial reports and a review of the literature at the time, FASEB concluded there was a subpopulation of presumably healthy individuals who react with the MSG symptom complex within 1 h of ingesting a bolus of ≥ 3 g MSG given without food. They also concluded that there appeared to be a subpopulation of individuals with severe unstable asthma who may experience bronchospasms after ingesting large doses of MSG (1.5–2.5 g) without food.

However, a more recent review concluded that there was no evidence to suggest MSG is associated with asthma attack in chronic asthmatics. Another study using mouse models of asthma concluded MSG was not involved in the development of asthma or in acute asthmatic responses.

The FSANZ Review

FSANZ's review of eight studies conducted between 1987 and 1999 investigating the putative link between MSG and asthma attacks concluded that the evidence for MSG-induced asthma attacks is inconclusive. The weight of evidence from more recent studies suggests MSG is not a significant trigger factor for asthma.

Regarding the link between dietary exposure to MSG and the MSG symptom complex, FSANZ concurred with FASEB that a small subpopulation may experience adverse reactions on consuming large amounts (>3 g) of MSG in the absence of food. These reactions are neither serious nor long lasting and, more significantly, are expected to be attenuated when MSG is consumed with food, particularly carbohydrate-rich food.

The Hohenheim Consensus Meeting on MSG

Hohenheim consensus conferences are meetings convened by the University of Hohenheim bringing together global experts. One of these was convened to discuss MSG in 1997, with a subsequent update in 2007.

The conference concluded that glutamate has not been shown to trigger bronchospasms or to exert adverse effects on the lung. Studies involving known asthmatics with self-reported MSG sensitivity have failed to establish such a link. The conference also concluded that there are no clear criteria that could be used to define MSG-sensitive individuals.

It was also concluded there is no evidence that dietary glutamate (natural and when added as a flavor enhancer) causes neurological effects in humans. Plasma levels of glutamate do not rise even when a meal containing added glutamate is consumed because up to 95% of glutamate in food is used as an energy source by enterocytes. The blood–brain barrier prevents influx of plasma glutamate into the central nervous system. Even a defective blood–brain barrier is unlikely to increase the risk of glutamate-mediated neurotoxicity since dietary intake of glutamate does not cause an increase in plasma levels.

In considering the potential effects of dietary glutamate on the fetus, it was concluded that the placenta metabolizes glutamate to the extent that it is an effective barrier. Studies have shown that fetal levels of glutamate remained the same even when maternally high plasma levels were attained. Therefore, orally administered glutamate is not expected to affect fetal development.

Exposure

Humans are exposed to dietary glutamate from birth, even when exclusively breastfed, because human milk also contains glutamate. It is estimated that a 4 kg infant consuming 600 ml milk per day would ingest approximately 76 mg free glutamate and 1.3–1.5 g bound glutamate per day.

Global consumption of MSG used as a food additive increased by 2.5 times between 1995 and 2007. The amount of bound and free glutamate naturally occurring in food is shown in Table 1.

Table 1 Natural glutamate content in foods

Food type	*Bound glutamate (mg 100 g^{-1})*	*Free glutamate (mg 100 g^{-1})*
Cow's milk	819	2
Human milk	229	22
Parmesan cheese	9 847	1200
Eggs	1 583	23
Chicken	3 309	44
Duck	3 636	69
Beef	2 846	33
Pork	2 325	23
Cod	2 101	9
Mackerel	22 382	36
Salmon	2 216	20
Peas	5 583	200
Corn	1 765	130
Carrots	218	33
Spinach	289	39
Tomatoes	238	140
Potatoes	280	180
Concentrated extracts (e.g., marmite and oyster sauce)	–	900–1960

Source: Reproduced from Yoshida Y (1998) Umami taste and traditional seasonings. *Food Reviews International* 14: 213–246 and Nicholas and Jones (1991).

Risk Characterization

The only toxic effects observed in studies with MSG were brain lesions induced in laboratory animals at very high plasma glutamate levels following very high bolus doses without food. Such high plasma levels cannot be reached in humans when MSG is used as a flavor enhancer because food delays and significantly dampens the elevation of plasma glutamate levels; glutamate is extensively metabolized by enterocytes and the maximum palatable level of glutamate in food is limited to approximately 60 mg kg^{-1} bodyweight. Humans are therefore not at risk of adverse neurological effects from exposure to dietary MSG.

Assessment of many studies involving individuals with self-reported sensitivity to glutamate have failed to prove an unequivocal link between glutamate ingestion and the 'MSG symptom complex,' particularly those symptoms that can be objectively measured, for example, bronchospasms. There are no traits or phenotypes that are uniquely associated with these individuals.

In conclusion, available evidence confirms the use of MSG at levels sufficient to attain a flavor-enhancing effect does not present a risk to the general population. The dose levels associated with adverse effects in experimental animals far exceed the levels necessary to achieve the desired technological effect in food. Moreover, the quantity of MSG that can be added to food is limited because large amounts of MSG make food unpalatable.

Reviews by several regulatory and expert bodies have all reached the same conclusion, and MSG continues to be used globally. Individuals who prefer to avoid this food additive can do so, as many countries provide labeling information for processed food. However, it is more difficult to do this with unpackaged food or meals eaten outside the home. It is worth noting that avoiding MSG altogether is difficult because glutamate is naturally present in a wide variety of foods as shown in Table 1.

FOOD ADDITIVES

Preservatives

N Fletcher, Food Standards Australia New Zealand, Canberra, ACT, Australia

Introduction

The safety of certain preservatives, as with other food additives, has been the subject of debate among the consumer groups, academics, and food regulators. As a case study, this article looks at the safety issues associated with the preservatives sodium nitrate and nitrite. Nitrate and nitrite ions are ubiquitous in the environment and occur naturally in fruits and vegetables as a part of the nitrogen cycle. Nitrate and nitrite, as their sodium or potassium salts, have been used as food additives in cured meats for many years primarily to prevent growth and toxin production by *Clostridium botulinum*. The toxicology of nitrate and nitrite has been comprehensively reviewed by the Joint FAO/WHO Expert Committee on Food Additives (JECFA), which established acceptable daily intakes (ADIs) of 0–3.7 mg kg^{-1} bodyweight for nitrate and 0–0.07 mg kg^{-1} bodyweight for nitrite.

These reviews also considered concerns that the presence of nitrite and *N*-nitrosatable compounds may give rise to the endogenous formation of potentially carcinogenic *N*-nitroso compounds. Exposure to nitrate in the diet occurs mainly through ingestion of fruits and vegetables, particularly leafy green vegetables. Conversely, exposure to nitrite occurs mainly through the endogenous conversion of ingested nitrate to nitrite in human saliva, and this exposure pathway is generally considered to significantly exceed the exposure to nitrite through direct addition to food. The European Food Safety Authority (EFSA) concluded that exposure to nitrate and nitrite in fruits and vegetables is not likely to be associated with appreciable health risks, and as such, the recognized health benefits from consuming these foods should prevail. When used as food additives, EFSA has advised that levels of nitrate and nitrite added to meat should be kept to the minimum level to achieve their technological function, in order to ensure the microbiological safety of meat, and potential exposure to preformed *N*-nitroso compounds is kept to minimum achievable levels.

History of Nitrate and Nitrite

Nitrate and nitrite, as their sodium or potassium salts, have been used as food additives for many years to prevent growth of and toxin production by pathogenic bacteria, in particular *C. botulinum*, and as a color retention agent. Addition of nitrite or nitrate improves the microbiological safety of these foods and extends their safe shelf life. This offers benefits to consumers in terms of the availability of a variety of different foods that are safe, convenient, and cost effective. Nitrite exerts a concentration-dependent antimicrobial effect in cured meat products, including against *C. botulinum*. Nitrate, by contrast, has no direct activity against *C. botulinum* but functions as a source of nitrite, generated by microbial activity in particular traditional products.

Although the use of nitrate and nitrite may improve the microbiological safety of meat, the use of nitrite to cure meat was also seriously questioned in the 1970s due to the potential for the presence of preformed *N*-nitrosamines, which may have a carcinogenic potential. These issues were considered in reports published by the National Academy of Sciences in the early 1980s, which to some extent alleviated public concern in relation to potential human health risks associated with cured meats.

Significant concentrations of nitrate are also found naturally in various fruits and vegetables. It has long been established that these levels are dependent on a number of factors including the use of fertilizer, location and soil type, carbon dioxide concentrations (in greenhouse vegetables), seasonal light intensity and duration of light exposure, and water availability. Nitrate concentrations in vegetables may also vary up to orders of magnitude dependent on the vegetable species and the part of the plant sampled. High concentrations of nitrate tend to accumulate in the leaves, roots, petioles, or stems of certain plants meaning that leafy vegetables including lettuce or spinach, and root crops such as beetroot, may accumulate high concentrations of nitrate. In contrast, levels of nitrate in vegetables such as carrots or onions are likely to be lower. Nitrite concentrations generally tend to be low in fresh undamaged vegetables; however, levels can increase rapidly in certain nitrate-rich vegetables, particularly if pureed and stored at room temperature. In addition to temperature, this increase is dependent on nitrate reductase activity in the plant and the level of bacterial contamination.

Chemical Characterization

Sodium nitrate ($NaNo_3$; 7631-99-4) consists of clear, colorless, odorless transparent crystals or white granules that are deliquescent in moist air. It is freely soluble in water and slightly soluble in ethanol. Sodium nitrite ($NaNo_2$; 7632-00-0) is a white or slightly yellow solid that is freely soluble in water and sparingly soluble in ethanol.

Hazard Identification and Characterization

JECFA has evaluated the toxicity of nitrate and nitrite on several occasions and most recently in 2002. An ADI of 0–3.7 mg kg^{-1} bodyweight was established for nitrate based on a no observed adverse effect level (NOAEL) of 370 mg per kg bodyweight per day in a 2-year rat study and applying a 100-fold safety factor. At higher doses, rats showed slightly depressed growth and inanition.

For nitrite, JECFA established an ADI of 0–0.07 mg kg^{-1} bodyweight based on a NOAEL of 6.7 mg per kg bodyweight per day in a 2-year rat study in which effects were seen in the heart and lungs at higher doses. Nitrite reacts with hemoglobin to form methemoglobin in the blood, which is the critical acute toxicological endpoint following nitrate and nitrite exposure. JECFA considered that as increased levels of methemoglobin can occur after a single dose, the acute toxicity of nitrite should be reviewed at a future meeting. The EU Scientific Committee for Food (SCF) also reviewed the toxicological effects of nitrate and nitrite and established an ADI of 0–3.7 mg kg^{-1} bodyweight for nitrate in 1990 and retained the ADI in 1995. The SCF derived an ADI of 0–0.06 mg kg^{-1} bodyweight for nitrite. In 2008, the EFSA confirmed the ADI for nitrate.

There have been a number of studies that have investigated the carcinogenic potential of nitrate and nitrite, and concerns have also been raised that the additives may give rise to the formation of potentially carcinogenic *N*-nitroso compounds. The results of carcinogenicity studies with nitrate in mice and rats were negative. In a 2-year National Toxicology Program study, there was equivocal evidence of an increased incidence of squamous cell papilloma and carcinoma in the forestomach in female mice given sodium nitrite at 165 mg per kg bodyweight per day. Nitrite was not carcinogenic in male mice or male and female rats.

At its 44th meeting, JECFA concluded that the epidemiological data provided no evidence for an association between exposure of humans to nitrate and nitrite and the risk for cancer. Additional epidemiological studies evaluated at the 50th meeting did not provide evidence that nitrate or nitrite was carcinogenic to humans. The Committee did note that several *N*-nitroso compounds were formed endogenously when nitrite and *N*-nitrosatable compounds were present together at high concentrations. However, it was concluded that as there was no quantitative evidence of endogenous formation of carcinogenic *N*-nitroso compounds at levels likely to be achieved in the diet, a quantitative risk assessment on the basis of endogenously formed *N*-nitroso compounds was not appropriate.

A recent epidemiological study in 2012 by An Pan *et al.*, which looked at a possible link between nitrates/nitrites and premature deaths, attracted some attention when it's authors stated, "this study provides clear evidence that regular consumption of red meat, especially processed meat, contributes substantially to premature death." The study claimed that when deaths were broken down into specific causes, eating any kind of red meat increased the chances of dying from heart disease by 16% and from cancer by 10%. Processed red meat raised the risk of heart disease death by 21% and cancer death by 16%. However, although this and several other studies associate processed-meat consumption with an increased risk of mortality, a causal link remains to be established.

Exposure

The EFSA Panel on Contaminants in the Food Chain investigated the amounts of nitrate found in vegetables consumed and any relevant considerations on the possible balance between risks and benefits. Using a conservative approach, the panel compared nitrate exposure estimates with the ADI for nitrate (equivalent to 222 mg day^{-1} for a 60 kg person). On that basis, it was estimated that a person eating 400 g of mixed vegetables would ingest approximately 157 mg of nitrate per day, which is below the ADI and the panel noted that for most people, actual nitrate intakes were likely to be substantially lower. For a small part of the population in some countries that eat mainly leafy vegetables, the ADI could be exceeded. However, it was concluded that the estimated exposures to nitrate from vegetables are unlikely to result in appreciable health risks, and as such, the recognized beneficial effects of consumption of vegetables should prevail.

Importantly, the report also recognized that exposure to nitrite occurs mainly through the endogenous metabolism of ingested nitrate to nitrite, and although fruits and vegetables contribute 11–41% of exogenous nitrite dietary intake, this amount is significantly exceeded by the endogenous reduction of secreted salivary nitrate. As such, the exposure assessment focused mainly on nitrate concentrations in vegetables and considered nitrite only in the context of dealing with the total body burden of nitrate and its metabolites. More recently, the EFSA Panel on Food Additives and Nutrient Sources Added to Food issued a statement on nitrites in meat products. The panel noted that in several European countries the mean exposure estimates for nitrite added to foods were above the ADI. The panel concluded that, consistent with recommendations made by the SCF in 1995, exposures to preformed nitrosamines in food should be minimized by technological practices including reducing the levels of nitrate and nitrite added to foods to ensure microbiological safety.

In a study conducted by the Australian regulatory body, Food Standards Australia New Zealand, the major sources of estimated nitrate dietary exposures across different population groups were vegetables (42–78%) and fruits (including juices) (11–30%). Highest concentrations of nitrate were generally found in leafy green vegetables such as spinach, consistent with other international findings. Vegetables (44–57%) and fruits (including juices) (20–38%) were also the major contributors to estimated dietary nitrite exposure across the population groups. Nitrite exposure from processed meats accounted for only a relatively small amount of total dietary nitrite exposure (5–7%). Estimated Australian dietary exposures to nitrate and nitrite were not considered to represent an appreciable health and safety risk. Rather, the health benefits of fruits and vegetables are widely accepted, including evidence of a protective effect of certain vegetables, legumes, and fruits against the development of a number of noncommunicable chronic diseases, among them cancer and cardiovascular disease.

Methods of Analysis

Methods of analysis for nitrates and nitrites are described in the detailed product specifications prepared by the 44th JECFA (1995), published in Food and Nutrition Paper Add 3 19 (1995).

Risk Characterization

The main concern associated with the addition of sodium nitrate/nitrite to food was its carcinogenic potential. Assessment of studies in laboratory animals found no evidence to support these concerns and epidemiological data provided no evidence for an association between exposure of humans to nitrate and nitrite and the risk for cancer. Significantly, exposure to nitrite occurs mainly through the endogenous metabolic conversion of ingested nitrate to nitrite, and although fruits and vegetables contribute between 11% and 41% of exogenous nitrite dietary intake, this amount is significantly exceeded by the body's reduction of secreted salivary nitrate.

Another concern associated with nitrates/nitrites centers around the concern that these food additives may give rise to the formation of potentially carcinogenic *N*-nitroso compounds. Assessments of this issue concluded that several *N*-nitroso compounds are formed endogenously when nitrite and *N*-nitrosatable compounds are present together at high concentrations, but there was no quantitative evidence of endogenous formation of carcinogenic *N*-nitroso compounds at levels likely to be achieved in the diet.

Estimates of the dietary exposure from added nitrates/nitrites suggest that it is likely to be within the ADI, albeit the mean exposure estimates for nitrite added to foods are above the ADI in some European countries. Given that nitrites are formed from natural as well as added nitrates by the body's metabolic processes, any risk to human health must be considered as a balance between the benefit that the food preservation confers on the safety of food and the health risk of exceeding the ADI. Preformed nitrosamines in food can and should be minimized by technological practices including reducing the levels of nitrate and nitrite added to foods to ensure microbiological safety.

FOOD ADDITIVES

Natural Preservatives

L Angiolillo, A Conte, and MA Del Nobile, University of Foggia, Foggia, Italy

Glossary

Antimicrobial A substance that fights microbial infection by killing microorganisms or inhibiting their replication or growth.

Antioxidant A substance that reduces damage due to oxygen, such as that caused by free radicals.

Functional group An atom or group of atoms, such as a carboxyl group, that replaces hydrogen in an organic compound and that defines the structure of a family of compounds and determines the properties of the family.

Shelf life The time length that foods, beverages, pharmaceutical drugs, chemicals, and many other perishable items are given before they are considered unsuitable for sale, use, or consumption. In some regions, a best before, use by or freshness date is required on packaged perishable foods.

Background to Food Preservatives

The efficiency of chemical preservatives depends primarily on the concentration of the preservative, the composition of food, and the type of microorganism or process to be inhibited. They are among the most effective means for maintaining food quality and are generally used for many preservation purposes. Examples of food preservatives that inhibit microbes include benzoates, nitrites, ascorbates, and sorbates. Preservatives that act as an antioxidants include butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT). Some chemicals such as sulfites and sulfur dioxide can be used for both. For labeling purposes, preservatives currently authorized in the European Union are given numbers in the range from E200 to E297.

Sorbic acid and its more soluble potassium salt are among the most efficient and versatile food preservatives used today. Sorbate preservatives are effective inhibitors of most common microorganisms that can attack foods, without affecting the taste, color, or flavor. Sorbates are used at their optimum effectiveness below pH 6.0 and are relatively ineffective at pH 7.0.

Benzoic acid received its name from the gum benzoin, the plant from whose resin it was first derived. In the nineteenth century it was synthesized from coal tar. Today it is manufactured from toluene, a petroleum by-product. It is classified as a carboxylic acid, weakly acidic, with a pH of 2.8. In normal conditions it has a white, flaky appearance that actually consists of small, needlelike crystals. Both benzoic acid and sodium benzoate have inhibitory effects on the yeast growth. Like most food additives, the amount of benzoates that can be added to foods is carefully controlled. For example, the Codex Alimentarius Commission (Codex), an intergovernmental organization that makes recommendations on food safety standards, and limits the amount of benzoic acid and its salts to 0.05–0.1% by volume. Most foods are allowed no more than 1 mg kg^{-1}. Liquid egg products, diet foods, chewing gum, and processed vegetables are the foods with the highest amount of benzoate legally allowed.

Sulfites are used as an antioxidants to prevent the discoloration of light-colored fruits and vegetables, such as dried apples and dehydrated potatoes. They are also used in the winemaking process because they inhibit bacterial growth without interfering with the development of yeasts. The use of sulfites in foods that are important sources of thiamine (vitamin B_1) is prohibited because of their ability to destroy thiamine. In the USA, the Food and Drug Administration (FDA) estimated that more than 1 million asthmatics are sensitive or allergic to sulfites. In 1986 FDA ruled that the sulfites used specifically as preservatives must be listed on the label, regardless of the amount in the finished product. FDA also banned the use of sulfites on fresh fruits and vegetables intended to be sold as such. In other countries, sulfites used in food processing, but not serving as preservatives in the final food, must be listed on the label if they are present at levels of 10 ppm or higher, which is consistent with Codex labeling recommendations.

BHA and BHT are phenolic compounds added to foods to preserve fats. They also may have antiviral and antimicrobial activities. BHA is a mixture of the isomers 3-tert-butyl-4-hydroxyanisole and 2-tert-butyl-4-hydroxyanisole. Oxygen reacts preferentially with BHA or BHT rather than oxidizing the fats or oils, thereby protecting them from spoilage. BHA is generally used to keep fats from becoming rancid. It is also used as a yeast defoaming agent. BHA can be found in butter, meat, cereals, chewing gum, baked goods, snack foods, dehydrated potatoes, and beer. It is used to preserve food odor, color, and flavor. Many packaging materials incorporate BHT.

 doi:10.1016/B978-0-12-378612-8.00438-8

Both antioxidants have undergone the safety evaluations by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and a number of national authorities. A transient elevation of plasmatic lipids and cholesterol can be observed with BHA. An acceptable daily intake (ADI) of 0–0.5 mg kg^{-1} bodyweight was established by JECFA for BHA in 1989. A lower ADI (0–0.05 mg kg^{-1} bodyweight) for BHT was established in 1989 on the basis of reproduction and thyroid and hematological effects observed in a 90 day feeding study in the rat by the Scientific Committee for Food of the European Commission. Further details on the toxicology of these compounds can be found in other article.

All food preservatives are submitted to a scientific risk assessment consisting of establishing a health-based reference value, such as the ADI and comparison of that value with the predicted or measured dietary exposure. The concentration limits for food additives are therefore established on the basis of their safety assessment consistent with their technical function. For over the past 10 years, systems to monitor the intake of these substances were established by many countries. Recommendations for similar procedures were also made by the Codex Committee on Food Additives. The possible adverse health effects of the additives include possible reactions to benzoates or sulfites in susceptible subjects suffering from asthma or urticarial and local gastric irritations and toxicity in subjects with reduced sulfite oxidase activity. The ADIs for benzoates and sulfites were established by JECFA at 0–5 and 0–0.7 mg kg^{-1} bodyweight, respectively. Further details on the benzoates are provided in other article.

Natural Preservatives

Owing to greater consumer concern for synthetic chemical additives, food preserved with natural preservatives has become more popular. Plant essential oils, as well as similar compounds, have been considered as promising natural antimicrobials. Their selection should be based on the sensory and chemical compatibility with the target food, on the efficiency against undesirable microorganisms, on the safety concern, and cost. Originally added to change or improve taste, spices and herbs can also be used to enhance the shelf life. Usually, compounds with phenolic groups are most effective. Among these, the oils of clove, oregano, rosemary, thyme, sage, and vanillin have been found to be the most consistently effective compounds. They are generally more inhibitory against Gram-positive than Gram-negative bacteria. Plant essential oils are usually a mixture of several components. The oils with high levels of eugenol (allspice, clove bud and leaf, bay, and cinnamon leaf), cinnamamic aldehyde (cinnamon bark, cassia oil), and citral are usually strong antimicrobials. Activity of sage and rosemary is due to borneol and other phenolics in the terpene fraction. The volatile terpenes carvacrol, p-cymene, and thymol are responsible for the antimicrobial activity of oregano, thyme, and savory. Spices (woody stemmed plants), which have strong antimicrobial activity include all spice, cinnamon, clove, mustard, and vanillin. As a general observation, spice extracts are less effective than the whole spice. The greater resistance of Gram-negative bacteria to essential oils is likely due in part to the greater complexity of the double membrane containing cell envelope of these organisms, in contrast with the single membrane structure of Gram-positive bacteria. The modulating influence of food composition on the antimicrobial effectiveness of essential oils is an important area of study. The presence of fat, carbohydrate, protein, salt, and pH generally influence the effectiveness of these agents in foods. Their antimicrobial strength is also reduced in foods with low water activity. By encapsulating antimicrobial essential oils, not only they can be protected from heat, but also be released at a controlled rate to deliver effective inhibitory concentrations over extended periods.

Biological preservation implies a novel scientifically based approach to improve the microbiological safety of foods. By definition, this concept refers to the use of antagonistic microorganisms or their metabolic products to inhibit or destroy undesired microorganisms in foods. Owing to their typical association with food fermentation and long tradition as food-grade bacteria, lactic acid bacteria (LAB) are generally recognized as safe. LAB can exert a biopreservative or inhibitory effect against other microorganisms as a result of competition for nutrients and/or of the production of bacteriocins and other antagonistic compounds, such as organic acids and hydrogen peroxide. Bacteriocins are extracellularly released peptides or protein molecules that are bactericidal for bacteria that are closely related to the producing microorganism. However, some bacteriocins do not kill susceptible bacteria but instead exhibit a bacteriostatic mode of action. The majority of LAB bacteriocins studied have been shown to be small peptides with a molecular weight below 10 000 Da. Their bactericidal activity appears to be limited to other Gram-positive bacteria; each producer bacterial strain has a mechanism of self-protection against its own bacteriocin. One group of these low molecular weight bacteriocins contains unusual amino acids, such as lanthionine and β-methyl-lanthionine. These bacteriocins are known as 'lantibiotics.' The most prominent member of this group is nisin, a bacteriocin produced by strains of *Lactococcus lactis* and it is the only one that has found practical applications in food technology. Unfortunately, Gram-negative bacteria are generally not sensitive to LAB bacteriocins unless the barrier function of their outer membrane is destroyed by the treatment with chelating agents. There are several possible strategies for the application of bacteriocins in the preservation of food, such as inoculation of the food with LAB that produce bacteriocins, addition of purified or semipurified bacteriocin to food, and the use of a product previously fermented with bacteriocin-producing strain. One hurdle that needs to be overcome before the commercial use of a new bacteriocin as a biopreservative is its legal acceptance as a food additive. To date, only nisin has been accepted as a food additive. Novel approaches are needed to increase the effectiveness of protective cultures in foods, such as the use of recombinant DNA technology for the amplification of bacteriocin genes, or the microencapsulation technology to protect the compounds.

FOOD ADDITIVES

Sweeteners

M O'Mullane, B Fields, and G Stanley, Food Standards Australia New Zealand, Canberra, ACT, Australia

Glossary

Chromosomal aberrations These are the disruptions in the number or structure of chromosomes in a cell.

Clastogenicity It refers to breaks in chromosomes, leading to sections of the chromosome being deleted, added, or rearranged.

Hyperplasia It is an increase in the number of cells/proliferation of cells.

Transitional cell carcinoma A type of cancer that typically occurs in the urinary system: the kidney, urinary bladder, and accessory organs. The term arises from the transitional epithelium, a tissue lining the inner surface of these organs.

Introduction

Sweeteners are food additives used as substitutes for sugar, mainly sucrose and fructose (honey and high-fructose corn syrup). Those that are not natural are, in general, called intense sweeteners. They have a relative sweetness many times that of sugar, which means they can be used in much smaller amounts. Most of the sugar substitutes approved for use in food are artificially synthesized compounds. However, some bulk natural sugar substitutes are also used, including sorbitol and xylitol, which are produced by catalytic hydrogenation of the appropriate reducing sugar. Steviol glycosides are natural plant extracts and are approximately 300 times sweeter than sugar. Some nonsugar sweeteners are polyols, also known as 'sugar alcohols.' These are, in general, less sweet than sucrose but have similar bulk properties and can be used in a wide range of food products.

Many intense sweeteners were discovered by accident. In 1879, a lab worker spilled a chemical he was synthesizing onto his hands, he accidentally licked his fingers and saccharin was discovered. Almost 60 years later, a graduate student detected the sweet taste of a chemical that had accidentally contaminated the cigarette he was smoking, thus discovering cyclamate. In 1965, a chemist licked his fingers while concocting an antiulcer drug and brought aspartame into the world. Now more than 6000 different types of foods and drinks worldwide are sweetened by the use of these and other intense sweeteners. The most widely approved intensely sweet sugar substitutes are stevia, aspartame and its derivative neotame, sucralose, acesulfame, and saccharin.

Intense sweeteners may be used either individually or blended with other sweeteners. Blends are commonly used by the food industry because the sweetener flavors can be synergistic. This can reduce the total amount of individual sweeteners needed in food. A common blend is acesulfame potassium with aspartame, which is often used in diet soft drinks.

More than 100 years ago, the introduction of the artificial sweetener saccharin in the USA began as an ongoing controversy over its safety toward human health that was finally resolved in 2001. Intense sweeteners are regulated as food additives and undergo a comprehensive safety assessment before being permitted in the food supply. To date, the available scientific information does not support a change in conclusions about the safety of the currently approved intense sweeteners. However, community concerns continue to be raised about aspartame and saccharin. This article outlines the risk assessment data for these two intense sweeteners, as well as steviol glycosides.

Nonetheless, discrepancies in the way food additives are regulated and contribute to consumer perceptions about their safety. For example, the use of cyclamates has attracted public interest, possibly resulting from the fact that it is in use in many parts of the world, but not in use or restricted in some countries, such as the USA. The USA banned the use of cyclamates in 1970s based on studies in which high doses of cyclamates caused bladder cancer in rats, a tumor that is also very commonly found in untreated rats. In Canada, cyclamate is restricted for use as a tabletop sweetener; it is unrestricted in the UK, and Joint FAO/WHO Expert Committee on Food Additives (JECFA) has established an acceptable daily intake (ADI) of 11 mg kg^{-1} bodyweight (bw) day^{-1}. Codex Alimentarius Commission continues to work toward harmonization of standards, including those for intense sweeteners, as there are both safety and trade issues in question. As new information arises, reviews will continue to ensure that the ingestion of such sweeteners in food remains safe.

Aspartame

History

Aspartame or L-α-aspartyl-L-phenylalanine methyl ester (CAS No. 22839-47-0; INS No. 951) was inadvertently discovered in 1965. As a consequence of its relatively high sweetness (it is approximately 200 times sweeter than sugar), only small

amounts are needed to sweeten foods and beverages. Aspartame is one of the most widely used nonnutritive, intense sweeteners in the world, with food regulatory agencies independently approving it for use in a range of foods including desserts, carbonated soft drinks, yoghurt, weight-control products, and confectionary, as well as its use as tabletop sweeteners.

Aspartame was first approved by the US Food and Drug Administration (USFDA) in 1974 and marketed in 1981. In Europe, aspartame was authorized for use in foods and as a tabletop sweetener during the 1980s. During the postmarket surveillance period, a number of health effects were claimed to be associated with dietary exposure to aspartame including neurological and behavioral effects (such as seizures and hyperactivity), allergic-type reactions, and cancer (brain and breast). A range of other adverse effects (multiple sclerosis, lupus, Alzheimer's, etc.) were also claimed to be linked to exposure to aspartame, through nonscientific Internet communications, and these claims were fuelled by alleged biases in the original US approval process and concerns over the integrity of the studies used to support approval. Comprehensive toxicological reviews and specific studies investigating these claims found no evidence to support any link with aspartame exposure.

The only identified food safety issue in relation to the consumption of aspartame is for a very small proportion of the population that has the rare genetic disorder, phenylketonuria (PKU). This disorder is characterized by a deficiency in the enzyme, phenylalanine hydroxylase, which metabolizes the amino acid phenylalanine. The buildup of phenylalanine in blood can result in toxicity to the brain. PKU is managed by controlling phenylalanine intake in the diet or a combination of diet and medication. As many artificially sweetened foods and soft drinks contain aspartame (which breaks down to phenylalanine in the digestive tract), mandatory labeling was introduced to alert people with PKU that the product contained phenylalanine.

It is recognized that some people prefer to avoid certain food additives and therefore aspartame, like other food additives, is required to be identified by its class name (e.g., sweetener) and by an individual name or code number (e.g., E951 in the UK and Europe).

Chemical Characterization

Aspartame is a methyl ester of a dipeptide consisting of two amino acids, aspartic acid, and phenylalanine (Figure 1). In the digestive tract, aspartame is completely hydrolyzed to its constituent amino acids in addition to methanol. On this basis, there is no systemic exposure to the parent compound. Aspartic acid, phenylalanine, and methanol are all found naturally in food at levels of intake greatly overshadowing of that arising from the gastrointestinal tract hydrolysis of aspartame. For example, aspartic acid and phenylalanine derived from aspartame intake have been calculated to be approximately 2% and 3%, respectively, of the total dietary intake of these amino acids in adults and approximately 1% of the total dietary intake in children. In addition to these metabolites, aspartame may be converted to aspartylphenylalanine diketopiperazine (DKP) when food products containing aspartame are stored under conditions of high temperatures and high pH.

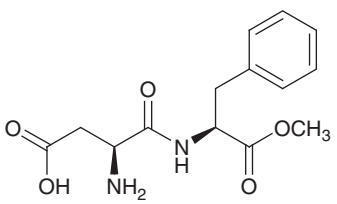

Figure 1 Structure of aspartame.

Hazard Identification and Characterization

The toxicological database for aspartame is extensive, consisting of studies conducted in both laboratory animals and humans. Aspartame, its metabolites, and breakdown product have been the subject of comprehensive reviews by the JECFA, the European Food Safety Authority (EFSA), and the USFDA in addition to a number of nongovernment expert panels. The consensus of these reviews is that the consumption of aspartame below the ADI is safe for all groups of consumers, with the exception of individuals with PKU.

JECFA established an ADI of 40 mg kg^{-1} bw day^{-1} for aspartame based on the no-observed adverse effect level (NOAEL) of 4000 mg kg^{-1} bw day^{-1}, the highest dose tested in a rat multigeneration study. This ADI is consistent with that set by the European Commission's (EC), Scientific Committee on Food (SCF) (1985), and the Food Directorate of Health Canada (1979) (formerly the Health Protection Branch of Health and Welfare Canada). The USFDA originally set an ADI of 20 mg kg^{-1} bw day^{-1} based on the NOAEL of 2000 mg kg^{-1} bw day^{-1} for reduced bodyweights in offspring in the same study at the next highest dose of 4000 mg kg^{-1} bw day^{-1}. Note that JECFA and others considered the reduced bodyweight to be an indirect effect resulting from decreased food consumption. Following the evaluation of additional human data, the USFDA set an ADI of 50 mg kg^{-1} bw day^{-1} for aspartame. The ADI for DKP set by JECFA and the SCF (1985) is 7.5 mg kg^{-1} bw day^{-1} based on the NOAEL of 7500 mg kg^{-1} bw day^{-1} for decreased bodyweight gain at greater than 1500 mg kg^{-1} bw day^{-1} in a chronic rat study. However, the USFDA considered the decreased bodyweight gain to be incidental in nature and therefore used the highest dose (3000 mg kg^{-1} bw day^{-1}) as the basis for its ADI of 30 mg kg^{-1} bw day^{-1}.

European legislation for harmonizing the use of aspartame was introduced in 1994 following evaluations by the SCF in 1984 and 1988, with supplementary reviews performed in 1997 and 2002. In its most recent evaluation, the SCF in 2002 concluded on the basis of its review of all data available that there was no need to revise its earlier risk assessment, which concluded that aspartame is safe. The SCF also confirmed the previously established ADI of 40 mg kg^{-1} bw day^{-1}.

An extensive review carried out by a panel of internationally recognized scientists, who evaluated more than 500 studies, articles, and reports conducted over the last 25 years on aspartame, including unpublished works submitted to the USFDA for the approval of aspartame. The panel concluded that aspartame is safe, in the amounts people currently consume in food. No credible evidence was found that aspartame could cause cancer, affect nervous system function, learning or behavior, or have any adverse effect on health, even when consumed in much greater amounts than the ADI.

During 2008 and 2009, the Advisory Forum of EFSA, made up of risk assessment experts from EU Member States, reviewed the available information and data on the safety of aspartame in view of ongoing public concern. An organizing team considered and reported on the amount of aspartame people were consuming and the information available on the effect of aspartame on brain function, appetite, allergies, immune system, metabolism, diabetes, and cancer (including cancer epidemiology and genotoxicity). The national experts did not identify any new evidence that suggested that EFSA should reconsider its previous opinion that aspartame is a safe food additive.

In 2007, a study by the European Ramazzini Foundation (ERF) suggested that aspartame can cause cancer in rats at levels close to ADI. EFSA reviewed this study and released an updated scientific opinion in March 2009. EFSA (2009) concluded that on the basis of all the evidence currently available, including the published ERF study, that aspartame did not produce cancer.

More recently, two new studies have been released; the first by Soffritti *et al*. in 2010 from the ERF, which shows that life expectancy in mice remains unchanged following a lifetime of daily exposure to aspartame. The report also claims that the incidence of some cancer types at death is slightly increased among mice consuming aspartame. The second is an epidemiological study by Halldorsson *et al*. in 2010, which examined an association between the consumption of sugar-sweetened and artificially sweetened soft drinks and the risk of preterm delivery in Danish pregnant women. EFSA have evaluated these new studies and in a statement dated 28 Feb 2011, EFSA concluded that these two recent publications did not give reason to reconsider previous safety assessments of aspartame or of other sweeteners currently authorized in the European Union.

At the request of the European Commission, EFSA is currently undertaking a full reevaluation of aspartame, including all unpublished data that were used to support the original European authorization.

Exposure

The dietary intake of aspartame for different populations groups in the USA, seven European countries, Brazil, and Canada was reviewed by Butchko *et al*. in 2002 and are summarized in Table 1. More recent data from the US indicated that mean and 95th percentile intakes were 4.9 and 13.3 mg kg^{-1} bw day^{-1}, respectively. In Australia and New Zealand, the highest consumption of aspartame was in adults 25–39 years of age (mean = 3.4 mg kg^{-1} bw day^{-1}, 95th percentile = 9.98 mg kg^{-1} bw day^{-1}).

Table 1 Dietary intakes of aspartame in different countries

Country	*Mean intake (mg kg^{-1} bw)*	*90th percentile intake (mg kg^{-1} bw)*
USA	–	2–3 (adults) 2.5–5 (children)
Finland	1.15 (diabetic children)	–
France	–	7.8 (97.5th percentile, diabetic children)

Abbreviation: bw, bodyweight.

Risk Characterization

Aspartame has been extensively studied, and evaluation of these studies has concluded that there are no remaining concerns over its toxicology, with a clear ADI established. As illustrated in the above section (Table 1), surveys conducted to date have determined that the consumption of aspartame is well below the ADI for all age groups and on this basis poses no safety issues for the health of consumers.

Methods of Analysis

Methods of analysis for aspartame are described in the detailed product specifications prepared by the 25th JECFA (1981), published in FNP 19 (1981) and in FNP 52 (1992).

Summary

Aspartame is a nonnutritive, intense sweetener used to replace sugar in food and beverages. It has been approved for use in more than one hundred countries and is an ingredient in several thousand different types of foods and drinks. Controversy about aspartame started during the premarket approval review and continued in the postmarket surveillance period in the early 1980s, it arose and focused mainly on fears of possible adverse neurological and gastrointestinal effects and a suspected link with cancer. Public concern over aspartame was further raised as these and other adverse effects were claimed on the Internet. Comprehensive scientific evaluations conducted independently by national food regulatory agencies and nongovernment panels of internationally recognized experts have consistently concluded that aspartame is a safe food

additive. Despite the weight of scientific evidence (aspartame is often described as one of the most studied food additives in history), public perception about possible negative health effects persist, posing periodic challenges for risk communicators.

Saccharin (Including Sodium and Calcium Saccharin)

History

Saccharin is approximately 300–500 times sweeter than sugar and is heat stable, allowing it to be used in cooking and baking, as well as a sweetener for foods and beverages. It is approved for use in more than 100 countries. It is generally used in combination with other sweeteners as it can have a slight bitter aftertaste when used on its own.

Although saccharin has been in use for more than a century, its safety has repeatedly been questioned. On the basis that sodium saccharin was carcinogenic in laboratory rats, in the 1970s saccharin was delisted as a food additive in Canada, although restricted, access as a tabletop sweetener was maintained. In 1977, a moratorium was placed on the use of saccharin in the USA until additional research on its safety could be conducted. The moratorium was withdrawn in 1991. In addition, some countries (e.g., the UK and USA) introduced the requirement that all foods containing saccharin had to be labeled with a warning statement alerting consumers that saccharin may be hazardous to health, by virtue of its carcinogenicity in laboratory animals. In Australia, the carcinogenic potential of saccharin for humans was not accepted, particularly at the low dose levels to which humans are exposed.

Currently in countries and regions, such as Australia, the USA and the EU, saccharin is approved for use as a sweetener in food in accordance with specific conditions.

Chemical Characterization

Saccharin(3-oxo-2,3-dihydrobenzo[d]isothiazol-1,1-dioxide) is a condensed heterocyclic *o*-sulfobenzimide, discovered in the late 1870s by chemists in the USA. It is commercially available in four forms: acid saccharin, sodium saccharin, potassium saccharin and calcium saccharin. Sodium saccharin is the most commonly used form because of its high solubility, stability, and low production costs. In the literature, the term 'saccharin' is sometimes used in a generic sense to encompass both saccharin and its salts. However, all four forms are manufactured to meet Food Chemicals Codex specifications (Figure 2).

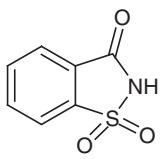

Figure 2 Structure of saccharin.

Hazard Identification and Characterization

Saccharin is excreted unchanged predominantly in the urine, and there is no evidence to suggest that it is metabolized in animals or humans.

Sodium saccharin has been administered to rats and mice in chronic feeding and multigenerational reproduction studies. Most studies, which were considered to be adequate for regulatory purposes, showed no adverse effects, but a statistically significant increase in bladder tumors (transitional cell carcinomas) was found in male rats at high dose levels ($\geq$4% in diet) in some reproduction studies. Similar effects were not observed in mice or female rats. The most plausible explanation of these effects in male rats at high dietary exposure of sodium saccharin is that the sodium ion causes the formation of a calcium–phosphate precipitate in urine which is cytotoxic to the urothelium, resulting in mild regenerative hyperplasia that leads to tumor formation in a small number of rats. A similar response in male rats is also observed following dietary exposure at high concentration to other sodium salts such as glutamate, aspartate, citrate, or chloride. At lower dose levels of sodium saccharin ($<$4%), there was neither tumor formation nor evidence of pathological changes in the bladder.

Although, saccharin did not induce gene mutations in the standard bacterial *in vitro* studies (Ames tests), there is a range of positive and negative findings, with many of the positive *in vitro* findings being attributed to increased osmolality (i.e., nonspecific ionic effects). It was also suggested that impurities or contaminants in the manufacture of saccharin might explain the positive results of the *in vivo* studies. However, the parent compound does not resemble an electrophilic chemical carcinogen that would bind to DNA, and the available evidence indicates no binding of sodium saccharin to DNA in rat bladder or liver. Overall, the results of tests for genotoxicity do not support a mechanism for the induction of bladder tumors in rats involving direct interaction of sodium saccharin with DNA.

In 1997, the International Agency for Research on Cancer (IARC) concluded that sodium saccharin produces bladder tumors in male rats by a non-DNA reactive mechanism that is not relevant to humans because of critical interspecies differences in urine composition (i.e., elevated pH and sodium levels).

The epidemiological studies on saccharin did not show any evidence that saccharin ingestion increases the incidence of bladder cancer in human population. The most recent reviews concluded that there is no detectable association between saccharin consumption and bladder cancer in humans.

The JECFA has considered the data on saccharin on several occasions. In 1982, at the 21st JECFA meeting the previous ADI of 5 mg kg^{-1} bw day^{-1} was changed to 2.5 mg kg^{-1} bw day^{-1} due to concerns over the carcinogenic potential (bladder tumors) in animals following high dietary doses of saccharin. JECFA's evaluation in 1993 considered that the 1% dietary level in a two-generation feeding study in rats (equivalent to 500 mg kg^{-1} bw day^{-1}) was the NOEL and dismissed the bladder cancer in male rates as unrelated to humans. Consequently, JECFA allocated a group an ADI of 5 mg kg^{-1} bw day^{-1} to saccharin and its calcium, potassium, and sodium salts based on a safety factor of 100.

Exposure

Most global surveys have indicated that there are no exceedences of the ADI for saccharin, including the most recent survey undertaken in Australia.

Risk Characterization

Studies in animals and humans indicate that, after absorption, saccharin is excreted unchanged in the urine. Excretion occurs relatively rapidly with no evidence of accumulation. Based primarily on mechanistic studies, there is convincing evidence that the saccharin-induced bladder cancer observed in male rats is a species-specific high-dose phenomenon. The evidence also suggests that it occurs through a nongenotoxic mode of action. As a consequence, it is unlikely to be relevant for humans because of critical interspecies differences in urine composition. Epidemiological studies have been unable to demonstrate an association between dietary exposure to saccharin and bladder cancer.

Based on an adequate range of studies measuring relevant toxicological endpoints for saccharin, a NOEL of 500 mg kg^{-1} bw day^{-1} was established in two-generation long-term rat study. After incorporating a 100-fold safety factor for intra- and interspecies extrapolation of the NOEL, an ADI of 5 mg kg^{-1} bw day^{-1} was allocated by JECFA to saccharin and its calcium, potassium, and sodium salts. Dietary intake of saccharin is well below the JECFA ADI for all age and gender groups.

Methods of Analysis

Several international pharmacopoeias specify colorimetry and infrared absorption spectrophotometry as the methods for identification, and titration with sodium hydroxide or perchloric acid as methods for assaying the purity of saccharin, sodium saccharin, and calcium saccharin.

Specifications have been prepared at the 24th JECFA (1980), published in FNP 17 (1980) and in FNP 52 (1992). Metals and arsenic specifications for saccharin were revised at the 57th JECFA (2001) (http://www.fao.org/ag/agn/jecfaadditives/results.htmladditiveName=saccharin&ins=&cas1=&cas2=&cas3=&techFunction=-1&searchBy=aname).

Summary

Saccharin has been the subject of extensive scientific research and is one of the oldest researched intense sweeteners. The term 'saccharin' is sometimes used in a generic sense to encompass both saccharin and its salts. Despite bladder tumors observed in male rats that were fed high dietary doses of saccharin, it is considered safe for human consumption based on an extensive body of scientific evidence. It was established that the tumors observed in male rats treated at high doses with saccharin were species specific and not relevant to humans consuming saccharin, because the bladder tumors observed in rats are due to a mechanism not relevant to humans. An internationally established ADI of 0–5 mg kg^{-1} bw day^{-1} has been set by the JECFA. Current surveys suggest that dietary exposure for average and high consumers is within this ADI. Therefore, despite the early literature linking saccharin consumption to an adverse health outcome in humans, the overall weight of scientific evidence does not support this conclusion, and it is considered to be a safe food additive for human consumption.

Steviol Glycosides

History

The term steviol glycosides refers to mixtures of compounds extracted from the leaves of the plant *Stevia rebaudiana*. Several of these glycosides have the property of intense sweetness. Two of the major steviol glycosides contributing to the sweet taste of stevia extracts, namely, stevioside and rebaudioside A are reported to be 100–400 times as sweet as sucrose.

Purified stevia extracts have a long history of use as sweeteners in some countries (e.g., Japan), whereas regulatory approval of steviol glycosides in Europe, the USA, Australia, and New Zealand has been relatively recent. Steviol glycosides were approved as food additives in the USA, Australia, and New Zealand in 2008 and in Europe in 2011. Steviol glycosides are permitted in a large variety of foods and beverages over a wide range of maximum permitted levels. For example, in Australia and New Zealand, maximum permitted levels range from 50 (in fruit and vegetable juices) to 1100 mg kg^{-1} (in sugar confectionary).

Chemical Characterization

The major sweet components of steviol glycoside preparations are stevioside (CAS No. 57817-89-7; Figure 1) and rebaudioside A (CAS No. 58543-16-1). Other steviol glycosides include rebaudioside B, rebaudioside C, rebaudioside D, rebaudioside F, dulcoside A, rubusoside, and steviolbioside, which are generally present at levels lower than stevioside or rebaudioside A. The structural formula of stevioside, one of the principal components of steviol glycoside preparations, is given in Figure 3.

Hazard Identification and Characterization

The JECFA has evaluated steviol glycosides on several occasions. In 2004, at the 63rd JECFA meeting noted that steviol glycosides are poorly absorbed and are metabolized by the intestinal microflora by successive hydrolytic removal of glucose units to steviol which is well absorbed. Steviol glycosides have not shown potential for genotoxicity, carcinogenicity, or reproductive/developmental toxicity. A temporary ADI of 2 mg kg^{-1} bw for steviol glycosides, expressed as steviol, was established on the basis of a NOAEL of 383 mg kg^{-1} bw day^{-1} in a 2-year feeding study in rats and applying a safety factor of 200. The safety factor of 200 incorporated an additional twofold factor because of uncertainty surrounding potential pharmacological effects of steviol glycosides in humans.

In 2008, at the 69th JECFA meeting new clinical studies were considered on the effects of steviol glycosides on blood pressure in healthy volunteers with normal or low-normal blood pressure and on glucose homeostasis in men and women with type 2 diabetes mellitus. JECFA concluded that

[d]The lower end of the ranges for Australia and New Zealand were obtained assuming a 30% market uptake scenario (i.e., assumes steviol glycosides would account for 30% of total intense sweetener use). The upper end of the ranges corresponds to the highest values obtained from two 'brand loyal' exposure scenarios.
Source: Reproduced from FSANZ (2011) Application A1037-Food Standards Australia New Zealand. Available at: http://www.foodstandards.gov.au/foodstandards/applications/applicationa1037stev4605.cfm

the new studies showed no adverse effects at doses up to 4 mg kg^{-1} bw day^{-1}, expressed as steviol. The new data were considered sufficient evidence to justify removal of the temporary ADI designation and the additional twofold safety factor. A full ADI for steviol glycosides of 4 mg kg^{-1} bw, expressed as steviol, was therefore established.

EFSA and Food Standards Australia New Zealand (FSANZ) have also evaluated steviol glycosides, and both established an ADI of 4 mg kg^{-1} bw, expressed as steviol.

Exposure

Dietary exposure estimates to steviol glycosides have been made by JECFA, EFSA, and FSANZ and are summarized in Table 2. A major factor contributing to the differences in these exposure estimates is the differing assumptions regarding the degree of replacement of dietary sugars and other sweeteners in the diet by steviol glycosides. To better estimate actual exposure to steviol glycosides, the EU decided in late 2011 that it will request actual use levels of steviol glycosides in foods to enable EFSA to perform a refined dietary exposure assessment.

In the assessment conducted by JECFA, estimates were made for 13 grouped geographical regions worldwide, assuming that steviol glycosides would replace all dietary sugars at the lowest reported relative sweetness ratio for steviol glycosides and sucrose, i.e., 200:1. The resulting dietary exposure estimates ranged from 0.9–5.0 mg kg^{-1} bw day^{-1}, expressed as steviol, depending on the region. JECFA also evaluated an estimate of dietary exposure to steviol glycosides based on the replacement of all dietary sugars in the USA. Using data indicating a per capita intake in the USA of 176 g of caloric sweetener per day, dietary exposure to steviol

glycosides was estimated to be 4.8 mg kg^{-1} bw day^{-1} using the relative molecular mass of rebaudioside A or 5.8 mg kg^{-1} bw day^{-1} using the relative molecular mass of stevioside, to convert to steviol equivalents. JECFA noted that these estimates are conservative, in that it is very unlikely that all sweeteners in the diets would be replaced by steviol glycosides. It was estimated by JECFA that actual intakes would likely be 20–30% of these values.

The most recent dietary exposure assessment conducted by FSANZ considered a 30% market share scenario and two separate scenarios for 'brand loyal' consumers. These scenarios are also based on conservative assumptions that are likely to lead to considerable overestimates of dietary exposure.

Risk Characterization

Steviol glycosides have a low-toxicity profile, with no evidence of mutagenic or carcinogenic potential, or effects on fetal development. A clear ADI has been established at 4 mg kg^{-1} bw. Although some dietary exposure estimates suggest a potential to exceed the ADI, these are considered to be overconservative in their assumptions about the extent of the use of these sweeteners in the food supply. Assuming a more realistic 30% market uptake scenario, the highest predicted dietary exposure is expected to be approximately 60% of the ADI. No human health concerns are therefore expected from approved uses of steviol glycosides in food.

Methods of Analysis in Food

Analytical methods have been developed for the quantification of steviol glycosides in food and beverage matrices.

Summary

Steviol glycosides are intensely sweet plant-derived compounds permitted to be added to a wide variety of foods and beverages. An extensive toxicological database on steviol glycosides has been evaluated by several government authorities who concluded that there is no evidence of genotoxicity, carcinogenicity, or reproductive/developmental toxicity. An ADI of 0–4 mg kg^{-1} bw has been established from laboratory animal studies by the JECFA. Clinical trials in human volunteers have demonstrated the safety of steviol glycosides at levels corresponding to the upper end of the ADI range. Some dietary exposure assessment scenarios have resulted in predicted exposures that exceed the ADI; however, assuming a 30% market uptake scenario of steviol glycosides, the highest predicted exposure is within the ADI.

PREFACE

Why an Encyclopedia on Food Safety?

With the world's growing population, the provision of a safe, nutritious, and wholesome food supply has become a major challenge. To achieve this, effective risk management based on sound science and unbiased information is required by all stakeholders, including the food industry, governments, and consumers themselves. In addition, the globalization of the food supply requires the harmonization of policies and standards based on a common understanding of food safety among authorities in countries around the world.

Furthermore, reports of food safety incidents and foodborne disease outbreaks in one country are disseminated almost instantaneously through the 24/7 news cycle to consumers in other countries all over the world. Consequently, food safety managers in government and industry are sometimes called on to respond to queries from politicians, the media, and the general public even before they may be aware of the problem. Taking effective intervention measures and communicating the basis of their decisions and actions are essential for maintaining confidence in the safety of the food supply.

In all the above circumstances, sound scientific information is the key to effectively and efficiently assess, manage, and communicate on food safety risks. Yet, professionals and other specialists working in this multidisciplinary field are finding it increasingly difficult to keep up with developments outside their immediate areas of expertise. The time and staff needed to provide this information are beyond the resources of most individuals and organizations. Therefore, a single source of concise, reliable, and authoritative information on food safety has, more than ever, become a necessity.

This is the role that the Encyclopedia on Food Safety sought to fulfill by gathering all of the world's knowledge and expertise covering the entire spectrum of food safety topics into one comprehensive reference work. This was done with the objective of facilitating the work of those working in the field of food safety and related fields, such as nutrition, food science and technology, and environment. The Encyclopedia also provides a platform for experts to share their state-of-the art expertise and experience with the rest of the food safety community. Furthermore, the Encyclopedia's online feature is designed for rapid search and retrieval of relevant information.

Who Will Benefit from the Food Safety Encyclopedia?

The Encyclopedia will be useful for professionals and other specialists working in, but not limited to, the following institutions:

- Regulatory and enforcement agencies.
- Food industry.
- Trade and industry organizations.
- Audit and certification bodies.
- Academic institutions.
- Private and governmental scientific and research institutions.
- International and nongovernmental organizations with an interest in food.

What Does the Encyclopedia of Food Safety Contain?

With some 280 articles, the Encyclopedia provides comprehensive coverage a broad range of food safety topics, which may be grouped under the following general categories:

- History and basic sciences that support food safety.
- Foodborne diseases, including surveillance and investigation.
- Foodborne hazards, including microbiological and chemical agents.
- Substances added to food, both directly and indirectly.
- Food technologies, including the latest developments.
- Food commodities, including their potential hazards and controls.
- Food safety management systems, including their elements and the roles of stakeholders.

In developing the Encyclopedia, the editors and members of the Editorial Advisory Board have aimed to ensure that the Encyclopedia provides:

- Contributions by the foremost authorities in their fields.
- Unbiased and concise overviews on a multitude of food safety subjects.
- References for further information
- Specialized and general definitions for food safety terminology.

While the editors have made every effort to ensure that the Encyclopedia reflects the most complete and up-to-date information available, new scientific findings, and advances in food safety occur continuously. In undertaking a project of this scale and with the inevitably delays that occur during production, the editors acknowledge that some topics may have been omitted or insufficiently addressed. Therefore, the feedback of readers to point out any such errors or oversights will be greatly appreciated and will facilitate the development of future editions.

Acknowledgments

The lead editors would like to thank the Editorial Advisory Board members, section editors, and particularly, the authors who have generously contributed their time and talent to the development of this Encyclopedia. We are indebted to the Elsevier secretariat, which has assisted in the production of this work since its inception. Finally, a special note of thanks goes to our families whose patience and support are greatly appreciated.

Ewen Todd Consulting LLC, Okemos, MI, USA

DEDICATION

This Encyclopedia is dedicated to our children, our grandchildren, and all the world's future generations who we hope will enjoy the benefits of a safe and nutritious food supply, produced with fair management of people working in industry and ethical treatment of animals.

FOREWORD I

Today's food system is one of the humanity's great achievements. It includes millions of commercial actors all over the world who produce, process, transport, store, market, and serve food that feeds billions of people daily. The complexity, diversity, and scope of the food system are almost beyond comprehension – ranging from small producers and processors serving local communities to vast global enterprises producing food for millions and managing extended international supply chains – all aimed at meeting high consumer expectations for safe, nutritious, and affordable food.

For all of its successes, the food system is full of challenges. Food insecurity and hunger remain major problems worldwide, and, for those with ready access to the foods of their choice, it is too easy to choose products high in salt, fat, and added sugar. Food safety – the task of avoiding chemical and microbiological contamination of food that can make people sick – is another persistent and dynamic challenge. In fact, new products in the marketplace, new patterns of production and supply, new consumer behaviors and new bacterial and chemical hazards – coupled with high consumer expectations – conspire to make food safety one of the central challenges of today's food system.

People working in the food system know this. Prominent illness outbreaks and contamination incidents take a toll on the public's health and cause a loss of confidence that can steer consumers away from healthy foods, like fresh fruits and vegetables, and impose big economic losses on food producers and processors. And the food system is responding with a heightened awareness of food safety at all levels of the food system and tremendous effort across the system to improve food safety. Much progress is being made.

One of the most important food safety developments of the last quarter century has been the emergence of a widely shared, science-based understanding of foodborne illness, its causes, and how it can be prevented. This begins with the understanding that the current burden of foodborne illness is unacceptable because it is largely preventable. It is preventable if we see food safety as a food system issue and recognize that microbiological and chemical hazards can enter the food supply at any point in the system along the pathway from the farm through processing, transport, storage, and retail sale. Likewise, opportunities to minimize hazards and help prevent food safety problems exist throughout the system, which means that everyone in the system shares responsibility for the safety of the food we eat.

Fulfilling this responsibility requires that we understand as much as we can about food safety hazards and their causes, devise the appropriate, science-based preventive controls for particular hazards and food production settings, monitor their effectiveness, and adjust the controls as needed based on experience. In short, progress on food safety depends fundamentally on a strong base of knowledge and continuous learning to systematically prevent food safety problems. And participants across the global food safety community are actively seeking and applying the knowledge needed to produce safe food and meet high consumer expectations.

This food safety encyclopedia provides a comprehensive overview of what we know about food safety hazards and control measures. We have more to learn, but the knowledge compiled in this encyclopedia demonstrates that we know a lot and that what we know can help empower participants in today's food system to fulfill their food safety responsibility. Although the food safety challenge is global and continuing, and may seem daunting, it can be met if all who share responsibility for food safety take advantage of the knowledge we have, participate in continuous learning, and place first priority every day on protecting the safety of food. That will be good for the food system – and for the consumers it serves.

Michael R Taylor
Deputy Commissioner for Foods and Veterinary Medicine, US Food and Drug Administration (FDA), Silver Spring, MD, USA

FOREWORD II

Food is one of the most basic requirements to sustain life. However, the safety of food and water cannot be taken for granted. Owing to both manmade and natural processes, an array of chemical and microbiological disease-causing agents find their way into food through multiple routes. When contaminated, such food can endanger or even destroy life. Therefore, from time immemorial, humankind has waged a constant battle against foodborne disease. Over many centuries of human development, people invented technologies that helped them fighting this battle, such as cooking, smoking, sun drying, canning, and freezing, to mention but a few. But like any scientific advance, some of these technologies presented their own food safety issues.

In a number of holy books, religious proscriptions for handling food contributed to food safety. In addition, many centuries ago, some governments already recognized that they had responsibilities in this domain and many laws were enacted to ensure the purity of certain foods. But it was only at the end of the nineteenth century, following scientific developments in the field microbiology and other areas of food science, that 'modern' food regulatory activities started.

In 1948, the availability, accessibility, and affordability of food were recognized as a basic human right by the United Nations in its Universal Declaration of Human Rights (Article 25, 1948). Implicit in this concept is the assumption that the food is first and foremost safe to consume, i.e., absence of health damaging properties. It is therefore not surprising that in the same year, the World Health Organization (WHO) was established as a specialized agency of the United Nations with a broad health mandate that included the specific responsibility to "develop, establish and promote international standards with respect to food…". Subsequently in 1963, WHO together with the Food and Agriculture Organization of the United Nations established an intergovernmental body to develop international standards for food – the Codex Alimentarius Commission. Today Codex stands as a major achievement in the promotion of food safety worldwide with an extensive collection of health and safety recommendations for food that are international recognized and referenced by the World Trade Organization and its member countries.

Thirty years ago, in 1983, WHO, again jointly with FAO, convened an Expert Committee on Food Safety to review the global food safety situation and provide guidance for governments, the food industry and consumers on how to cope with the inherent hazards and risks of our food supply. Based on available data and evidence at the time, the committee concluded that "illness due to contaminated food is perhaps the most widespread health problem in the contemporary world and an important cause of reduced economic productivity."

Unfortunately, this rather alarming statement appears to be still true today. Recent studies examining the morbidity and mortality of foodborne diseases have confirmed the significant public health burden posed by these diseases. In developed countries, one-quarter to one-third of the population are made ill each year because of foodborne diseases. In the developing world, the burden is much more severe. For example, diarrheal diseases are now estimated to cause 2.43 million deaths a year. According to WHO statistics, this is the second leading cause of mortality in low-income countries and kills more people than human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), malaria, or tuberculosis.

In addition, the large number of food safety crises, which occur with increasing frequency, is contributing to the growing public demand for better health protection from contaminated food. This has prompted governments to strengthen their food safety legislation, improve capacities and infrastructure, and tighten control measures. Examples of governmental measures include the creation of European Food Safety Agency by the European Union in 2002, the Food Safety Modernization Act in the USA of 2011 and, most recently, 2013, the commitment of the Premier of the People's Republic of China, Mr. Li Keqiang, to act with an 'iron fist' to improve food safety.

These positive developments are, unfortunately, contrasted by the fact that in many other countries, mostly developing countries, food safety does not receive the attention it deserves. In this regard, the medical profession and public health community appear to be slow in accepting the role that contaminated food plays in the epidemiology of diarrhea, particularly in infants and young children. The treatment of hospitalized cases and outpatients is rarely seen as an opportunity for educating patients and their families on why foodborne diseases occur and how they can be prevented. Two publications published in WHO's Bulletin in 1993 and 2003 urged the health sector to take steps to correct this oversight. Yet even today progress has been disappointing. For example, in the 2009, United Nations Children's Fund (UNICEF) and WHO published a document entitled 'Diarrhea: Why children are still dying and what can be done,' that again overlooked food safety as one of the most important interventions for these diseases. Consequently, in a recent publication in a prestigious *Medical Journal of Gastroenterology*, the issue had to be raised again and omission corrected. It can only be hoped that the public health and donor communities will eventually adopt a more holistic approach for the prevention of diarrheal diseases, which includes essential food safety interventions.

It is for this and many other reasons that I enthusiastically welcome the initiative of Elsevier to publish this Encyclopedia of Food Safety under the editorial leadership of Drs. Yasmine Motarjemi and Gerald Moy (my former WHO colleagues) as well as Dr Ewen Todd, a world renowned expert in food safety. The laudable collaboration and support of the Editorial Advisory Board, Section Coordinators, and the many authors who have freely devoted their time to advance the cause of food safety through the development of this Encyclopedia is also acknowledged.

With such a collection of information, whoever needs first-hand, reliable, and authoritative information on food safety does not need to consult various books, periodicals, or

websites. All of what is presently known in this domain can be found in this comprehensive work. In particular, the Encyclopedia will be useful for decision-makers, managers, officials, and scientists working in government, the food industry, academia, and nongovernmental organizations.

This Encyclopedia may be particularly important for colleagues in developing countries to not only improve food safety for their people but also convince politicians and other policy makers of the pivotal role of food safety in health and development. Without this awareness, the ultimate goal of safe food for all cannot be achieved.

F Käferstein
Former Director, Food Safety and Food Aid Programme (1980–98), World Health Organization, Wiesbaden, Germany

EDITOR-IN-CHIEF

Yasmine Motarjemi holds a Masters degree in Food Science and Technology from the University of Languedoc, Montpellier, France (1978) and a Doctoral degree in Food Engineering from the University of Lund, Sweden (1988).

After her research and academic career at the University of Lund, in 1990, she joined the World Health Organization in Geneva as Senior Scientist. In WHO, she was responsible for the surveillance and prevention of foodborne illnesses (including education of professional food handlers and consumers), the development of the food safety assurance systems (e.g., Hazard Analysis and Critical Control Point system), and for assistance to the WHO Member States in strengthening their national food safety programme. She also contributed to the development of the risk analysis process. She has served in the Secretariat of various sessions of the Codex Alimentarius Commission and its Committees.

From 2000 to 2011, she held the position of Assistant Vice President in Nestlé where she worked as the Corporate Food Safety Manager. In this capacity, she has, among others, developed the Nestlé Food Safety Management system and managed various emerging food safety issues and crises.

She is the author, co-author, or editor of numerous peer-reviewed articles, books, training manuals, and other publications. Her latest books are Food Safety Management: A Practical Guide for the Food Industry (Elsevier 2014) and Invisible Things (original in French under the title: Les Invisibles), a book on food safety for children.

CO-EDITORS BIOGRAPHY

Dr Gerald G Moy, since his retirement from the World Health Organization in 2008, is a scientific adviser with Food Safety Consultants International working with numerous governments and international organizations. His expertise includes assessment of national food safety programs, risk assessment of chemical hazards in food, total diet studies, food safety during mass gatherings, and food defense. Dr Moy is the editor-in-chief for recently published book Total Diet Studies (Springer) and is currently preparing a chapter on food and water protection for a book on key public health considerations during mass gatherings. He serves on the International Scientific Advisory Committee of the China National Center for Food Safety Risk Assessment, the Technical Advisory Group of the World Food Program Technical Advisory Group, and the WHO International Virtual Advisory Group on Mass Gatherings. He is the author of numerous book chapters, articles, and publications and serves on the editorial boards for several food safety journals.

He received his BS in chemistry from the University of Wisconsin and his PhD in physical organic chemistry from Oregon State University, followed by a post-doctoral fellowship in biophysics at the University of New Mexico. He is a Fellow in International Academy of Food Science and Technology and a recipient of the 2009 Great Wall Friendship Award for his contributions to food safety during the Beijing Olympics.

Ewen CD Todd is the President of Ewen Todd Consulting and the former Professor in the Department of Advertising, Public Relations and Retailing, and he is also the Adjunct Professor in the Departments of Food Science and Human Nutrition and Large Animal Clinical Sciences at Michigan State University (MSU). He was former directors of the Food Safety Policy Center and the National Food Safety and Toxicology Center at MSU. At both these centers, Dr. Todd coordinated research in microbiology, toxicology, epidemiology, risk assessment, social science, and policy in the area of food safety, distance education programs, and outreach in the community. Previously, he was in the Bureau of Microbial Hazards, Health Products and Food Branch, Health Canada, Ottawa where he was a research scientist for 33 years working on methods development for pathogens in foods, foodborne disease investigation and reporting, costs and surveillance of disease, illnesses caused by seafood toxins, and risk assessment of foodborne pathogens. He also helped develop risk management strategies for the Department including producing videos and pamphlets on food safety education. Some of his recent research has been working on *Listeria* and *E. coli* O157 transfer coefficient and modeling projects, hygiene in child care centers, schools, and elder care facilities. He has also collaborated with government agencies and academia in Spain, Kuwait, Saudi Arabia, Lebanon, Cambodia, Korea, Japan, and China on food safety issues, and is an expert witness in legal suits involving food safety. He has published extensively on many different aspects of food safety, including 11 recent papers on food workers and hand hygiene. He is active in the International Association for Food Protection (IAFP) and other organizations, and speaks and organizes symposia at national and international meetings. He is the associate editor for the Journal of Food Science and is a frequent reviewer of manuscripts submitted to several different scientific journals.

He has received the Government of Canada Distinctive Service Award for extraordinary teamwork and support to the Science and Technology Community; Recipient of the Excellence in Science Award for 1998 by Health Canada; Deputy Minister's Award of Team Excellence for the work done in promoting the Fight BAC! Campaign in Canada; the Professional Institute of the Public Service of Canada Gold Medal for Pure and Applied Science; and he is Fellow of the American Association for the Advancement of Science, the IAFP, and the MSU University Outreach and Engagement. He is also an honorary life member of the IAFP. He is a graduate of Glasgow University with a BSc in Bacteriology and a PhD in bacterial systematics.

Environmental Contaminants

Toxic Metals

Foods, Materials and Risks

Safety of Food and Beverages

VOLUME 4 Food Safety Management

Food Safety Management

Public Health Measures

Food Safety Assurance Systems

Institutions Involved in Food Safety

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into five broad sections, presented in four volumes. The sections consist of:

1. **History, science, and methods**: this section includes papers which help in the understanding of basic sciences underpinning food safety and foodborne diseases and their historical development.
2. **Hazards and diseases**: this section addresses the features of major foodborne hazards be they chemical, microbial, parasitical or physical and their health consequence.
3. **Food technologies**: this section explains the various food technologies and aspects related to their safety, or risks in their application.
4. **Foods, materials, and risks**: similarly, in this section, various groups of food products are described in terms of their risks and measures needed to ensure their safety.
5. **Food safety management**: finally, in this part, the building blocks of food safety management in the private and public sector are explained. The role of major international organizations is also reported.

To help realize the full potential of the material in the Encyclopedia the authors have provided five features to help you find the topic of your choice: a preface giving an overview of the encyclopedia and its objectives, a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1 Contents List by Subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2 Alphabetical Contents List

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the alphabetical order. This list provides both the volume number and the page number of each entry. On the opening page of an entry a contents list is provided so that the full details of any articles within the entry are immediately available.

3 Cross-references

All of the entries in the Encyclopedia have been extensively cross-references. The cross-references, which appear at the end of the entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other entries.
iii. To indicate the material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry Characteristics of Foodborne Hazard and Diseases | Drug Resistant Pathogens.

> *See also*: Bacteria: *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli* and Other Pathogenic *Escherichia coli*; *Shigella*; *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. Characteristics of Foodborne Hazard and Diseases: Cost of Foodborne Diseases. Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings; Surveillance of Foodborne Diseases

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi, and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli*), parallel discussion in other entries (e.g., Other Pathogenic *Escherichia coli*), and reference to entries that broaden the discussion (e.g., Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings).

4 Index

The index provides you with the page number where the material is located. The index entries differentiate between materials that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5 Contributors

A full list of contributors is listed at the beginning of each volume.

GLOSSARY OF SELECTED TERMS

This Glossary of Selected Terms is a partial list of definitions for terms commonly used in the area of food safety. The terms selected are those that are important for communication among the various disciplines or are often subject to misunderstanding. Most of the definitions are taken from those recommended by international organizations or given by the authors contributing to this Encyclopedia. In cases where there are different definitions for a term, the Glossary presents the definition that is most consistent with usage by the majority of authors. Note that in some instances, slight differences between general definitions in this Glossary and those appearing in the individual articles may occur as the result of the specific context of the articles.

Acceptable daily intake The estimate of the amount of a substance in food or drinking water, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk to the consumer.

Acute reference dose The estimate of the amount of a substance in food or drinking water, expressed on a body mass basis, that can be ingested in a period of 24 h or less without appreciable health risk to the consumer.

Adulteration (economic) A fraudulent action which is intended to omit a valuable constituent or substitute another substance, in whole or in part, for a valuable constituent; conceal damage or inferiority in any manner; or add any substance to increase its bulk or weight, reduce its quality or strength, or make it appear bigger or of greater value than it is (Note that in the US, adulterated food is generally defined as impure, unsafe, or unwholesome food.).

Antiseptic A substance that inhibits the growth and development of microorganisms. For practical purposes, antiseptics are routinely thought of as topical agents, for application to skin, mucous membranes, and inanimate objects, although a formal definition includes agents which are used internally, such as the urinary tract antiseptics.

As low as reasonably achievable A risk management approach that aims to keep exposure to a substance at the lowest level that is realistically achievable.

Asymptomatic shedder A person who does not exhibit the symptoms of an illness but excrete the pathogen (*see also* carrier).

Benchmark Reference point or standard against which performance or achievements can be assessed. A benchmark refers to the performance that has been achieved in the recent past by other comparable organizations, or what can be reasonably inferred to have been achieved in the circumstances.

Biomarkers Indicators of changes or events in human biological systems. Biomarkers of exposure refer to cellular, biochemical, or molecular measures that are obtained from biological media such as human tissues, cells or fluids, and are indicative of exposure to a substance. Biomarkers of effect refer to biological changes that represent an alteration in endogenous body constituents (e.g., depression of cholinesterase levels as an indicator of exposure to pesticides).

Carrier A person or animal that harbors a specific infectious agent without discernible clinical disease and serves as a potential source of infection. The carrier state may exist in an individual with an infection that is unapparent throughout its course (commonly known as healthy or asymptomatic carrier), or during the incubation period, convalescence and postconvalescence of an individual with a clinically recognizable disease (commonly known as an incubatory or convalescent carrier). Under either circumstance the carrier state may be of short or long duration (temporary or transient carrier, or chronic carrier) (*see also* asymptomatic shedder).

Case-fatality rate Usually expressed as the percentage of persons diagnosed as having a specified disease who die as a result of that illness within a given period. This term is most frequently applied to a specific outbreak of acute disease in which all patients have been followed for an adequate period of time to include all attributable deaths. The case-fatality rate must be clearly differentiated from the mortality rate (Compare with mortality rate).

Colony-forming unit A measure of viable bacterial or fungal cells in which a colony represents an aggregate of cells derived from a single progenitor cell.

Contaminant Any biological, chemical, or physical agent not intentionally added to food, which is present in food as a result of the production, manufacture, processing, preparation, transport, or holding of such food (Compare with hazard).

Control (noun) The state wherein correct procedures are being followed and critical criteria are being met.

Control (verb) To take all necessary actions to ensure and maintain compliance with criteria established in the Hazard analysis and critical control point system (HACCP) plan.

Control measure Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Corrective action Any action to be taken when the results of monitoring at the Critical Control Point (CCP) indicate a loss of control.

Crisis A predicted or unpredicted event which represents an immediate or future significant threat to an organization, its employees, consumers, and the public at large.

Critical control point A step at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Critical limit (CL) A criterion which separates acceptability from unacceptability.

Detergent A chemical used to remove grease, dirt and food, such as washing-up liquid.

Disability adjusted life year (DALY) A metric used to express a health gap that extends the concept of potential years of life lost due to premature death to include equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. The DALY combines in one measure the time lived with disability and the time lost due to premature mortality. One DALY can be thought of as one lost year of 'healthy' life and the burden of disease as a measurement of

the gap between current health status and an ideal situation where everyone lives into old age free of disease and disability.

Disinfectant A chemical agent or a process that destroys, neutralizes, or inhibits the growth of pathogenic microorganisms (*see also* sanitizer).

Dose–response assessment The determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response) in the exposed organism, system, or (sub) population in reaction to the agent.

Endotoxin A toxin present in intact bacterial cells and released when bacteria die or the cells are disrupted. A notable endotoxin is lipopolysaccharide, which is a major constituent of the outer cell membrane of Gram-negative bacteria and can cause toxic effect on lysis of bacteria. The term 'endotoxin' is to be differentiated from 'exotoxin', which is a toxin secreted in the surrounding medium and environment of the bacterial cell.

Enterotoxin A cytotoxin produced by bacteria that is specific for the mucous membrane of the intestine and causes diarrhea and/or vomiting associated with foodborne disease. Many infectious microorganisms produce enterotoxins in the gut, but some are produced external to the host (*see also* exotoxin and endotoxin).

Exotoxin A toxin that is secreted by bacteria. There are many different types of exotoxins. They can be released into the susceptible host (after infection and growth) or into the environment, including food (after contamination and growth). Those released into the intestines are typically heat labile (but some *E. coli* strains can produce both heat labile (HL) and heat stable (HS) toxins). *Clostridium perfringens* produces a HL enterotoxin after completion of sporulation in the host's intestines. *Staphyloccocus aureus* and *Bacillus cereus* enterotoxins produced in food are HS and cause vomiting and diarrhea, whereas toxins of *Clostridium botulinum* toxin, also produced in food, are HL and cause systemic neurological symptoms (*see also* exotoxin and endotoxin).

Epidemic The occurrence in a community or region of a group of illnesses which are similar in nature and clearly in excess of normal expectancy, and derived from a common or from a propagated source (Compare with pandemic).

Equivalence The situation where the application of two different food safety management measures lead to the same, or equivalent, public health outcomes.

Equivalence of sanitary measures (import–export of food) Equivalence is the state wherein sanitary measures applied in an exporting country, though different from the measures applied in an importing country, achieve, as demonstrated by the exporting country, the importing country's appropriate level of sanitary protection.

Exposure assessment The qualitative and/or quantitative evaluation of the likely ingestion of a biological, chemical, or physical agent in food as well as exposures from other sources if relevant.

Fecal–oral route A means of spreading pathogenic microorganisms from feces produced by an infected host to another host, usually via the mouth; for example, contact between contaminated hands or objects and the mouth.

Flow diagram A systematic representation of the sequence of steps or operations used in the production or manufacture of a particular food item.

Food Any substance, whether processed, semiprocessed, or raw, which is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation or treatment of 'food' but does not include cosmetics or tobacco or substances used only as drugs.

Food additive Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport, or holding of such food results, or may be reasonably expected to result, (directly or indirectly) in it or its byproducts becoming a component of or otherwise affecting the characteristics of such foods.

Food allergy A form of food intolerance in which there is evidence of an abnormal immunological reaction to the food (Compare with food intolerance).

Food establishment Any building or area in which food is handled and the surroundings under the control of the same management.

Food handler Any person who handles, prepares, or serves food, be they domestic food handlers, such as preparing family food, or professional food handlers, such as those working in food service establishments (cooks and waiters), retail stores, supermarkets, etc. (*see also* food worker).

Food hygiene All conditions and measures necessary to ensure the safety and suitability of food at all stages of the food chain.

Food industry The term includes primary manufacturing and processing industry as well as some other establishments involved in the food chain.

Food intolerance A reproducible, unpleasant reaction to a food or food ingredient, including reactions due to immunological effects, biochemical factors, such as enzyme deficiencies and anaphylactic reactions that often include histamine release (Compare with food allergy).

Food poisoning (or acute foodborne intoxication) A disease caused by a toxin or a chemical in food with symptoms usually appearing within 24 h after ingesting the agent. This term is commonly misused as a synonym for foodborne disease, which covers both infections and intoxications.

Food safety Assurance that food will not cause harm to the consumer, when it is prepared and/or eaten according to its intended use (Compare with food suitability and food hygiene).

Food safety hazard A biological, chemical, or physical agent in, or condition* of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to property of a food.

Food safety objective (FSO) The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP) (Compare with Performance objective).

Food suitability Assurance that food is acceptable for human consumption according to its intended use (Compare with food safety and food hygiene).
Food worker Individuals who harvest, process, prepare and serve food, i.e., across the whole food chain to retail/foodservice; it is broader than that of a food handler, who typically works in foodservice establishments typically foodservice; however, the two terms are used interchangeably in the literature (*see also* food handler).
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of contaminated food, including drink.
Foodborne pathogens Disease-causing microorganisms that are transmitted to humans via foods.
Generally recognized as safe Status of a substance that is generally recognized, among qualified experts, as having been adequately shown to be safe under the conditions of its intended use (used mainly in the USA).
Genomics The study of an organism via decoding the entire genetic sequence of the organism.
Genetic modification A process of altering the genetic makeup of an organism by techniques of modern biotechnology.
Genetically modified organism (GMO) AGMO or genetically engineered organism is an organism whose genetic material has been altered using genetic engineering techniques.
Good animal husbandry practice A system of management controls that need to be adopted at the level of primary producers to ensure production of food of animal origin that is safe for human consumption and acceptable for trade in the world market.
Good hygienic practice A system of management controls that need to be adopted at production, processing, storage, distribution, and preparation to ensure safety and suitability of products of consumption.
Good laboratory practice A system of management controls for laboratories and research organizations to ensure the quality, integrity, consistency, and reliability of results.
HACCP plan A document prepared in accordance with the principles of HACCP to ensure control of hazards which are significant for food safety in the segment of the food chain under consideration (see also HACCP).
Hazard A biological, chemical, or physical agent in, or condition*; of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to a property of a food.
Hazard analysis The process of collecting and evaluating information on hazards and conditions leading to their presence to decide which are significant for food safety and therefore should be addressed in the HACCP plan.
Hazard analysis and critical control point system A preventive system which identifies, evaluates, and controls hazards which are significant for food safety.
Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with a biological, chemical, or physical agent which may be present in food. For a chemical agent, a dose–response assessment should be performed. For a biological or physical agent, a dose–response assessment should be performed if the data are obtainable.
Hazard identification The identification of the type and nature of adverse effects that a biological, chemical, or physical agent in food is capable of causing in an exposed population.
Incidence rate The number of new cases of a condition arising in a defined group within a given period or the number of new infections per unit of person–time at risk (Compare with prevalence).
In vitro In an artificial environment outside the living organism.
In vivo Within a living organism.
Lethal dose 50% The dose of a substance that would be expected to kill half of a population of exposed organisms.
Margin of exposure Ratio of the no-observed-adverse-effect level or benchmark dose lower confidence limit for the critical effect to the theoretical, predicted, or estimated exposure dose or concentration.
Maximum residue limit The maximum concentration of residues resulting from the use of a pesticide or veterinary drug that is acceptable in or on a food.
Minimum infective dose The lowest number of microorganisms required to cause an infection in the host.
Monitoring (CCP) The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a CCP is under control.
Monitoring (general) Continuous or repeated observation, measurement and evaluation of health, and/or environmental or technical data for defined purposes, according to prearranged schedules in space and time, using comparable methods for sensing and data collection.
Morbidity rate An expression of the number of illnesses in a population at risk over a given period of time (usually one year).
Mortality rate An expression of the number of deaths in a population at risk over a given period of time (usually one year).
Nanomaterials Materials engineered at the nanoscale to have novel functionality or properties. Such properties will typically, but not exclusively, be demonstrated in the size range 1–100 nm, but this size range should be considered approximate.
Nanoparticles Particles with one or more external dimensions in the range 1–100 nm, but this size range should be considered approximate.
Nanotechnology The manipulation or materials at the nano level.
Notifiable disease A disease that must, by law or by ministerial decree, be reported to a government authority.
Outbreak A group of at least two cases of a single illness that are demonstrated by epidemiological investigation to have a single common exposure or source.
Pandemic Epidemic occurring over a very wide area, crossing international boundaries (often more than one continent) and usually affecting a large number of people.
Pasteurization A process involving heat treatment at a prescribed time–temperature combination to kill vegetative forms of pathogens that may be present, while causing minimal changes in the composition, flavor, and nutritive value of food. However, with advances and the development

of new food technologies, the term is sometimes used for nonthermal technologies leading to the same effect.

Pathogen An organism capable of causing disease.

Pathogenesis The course of a disease from its origin to its manifestation; more specifically it refers to the cellular events and reactions, and other pathologic mechanisms occurring in the development of the disease.

Pathogenicity Ability of a microorganism to cause disease in a host (Compare with virulence).

Performance criterion The effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a performance objective (PO) or an FSO.

Performance objective The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable (Compare with Food Safety Objective).

Pesticide Any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production; storage; transport; and distribution and processing of food, agricultural commodities, or animal feeds or which may be administered to animals for the control of ectoparasites. The term includes insecticides, herbicides, fungicides, rodenticides and algicides as well as plant growth regulators, defoliants, desiccants, and agents for thinning fruit or preventing the premature fall of fruit.

Prerequisite program Practices and conditions needed prior to and during the implementation of HACCP and which are essential to food safety.

Prevalence The number of persons in a population who have a disease at a specified point in time or over a specified period of time (Compare with incidence rate).

Primary production Those initial steps in the food chain up to and including, for example, harvesting, slaughter, milking, and fishing.

Processing aid Any substance or material, not including apparatus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods, or its ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the nonintentional but unavoidable presence of residues or derivatives in the final product.

Processing contaminant Undesirable contaminants that are formed during the treatment of food as a result of the interaction of their natural components or their ingredients.

Provisional maximum tolerable daily intake (PMTDI) The health-based reference value used for contaminants with no cumulative properties. Its value represents permissible human exposure as a result of the natural occurrence of the substance in food and in drinking water. In the case of trace elements that are both essential nutrients and unavoidable constituents of food, a range is expressed, the lower value representing the level of essentiality and the upper value the PMTDI.

Provisional tolerable monthly intake The health-based reference value used for a food contaminant with cumulative properties that has a very long half-life in the human body. Its value represents permissible human monthly exposure to a contaminant unavoidably associated with otherwise wholesome and nutritious foods.

Provisional tolerable weekly intake The health-based reference value used for food contaminants such as heavy metals with cumulative properties. Its value represents permissible human weekly exposure to those contaminants unavoidably associated with the consumption of otherwise wholesome and nutritious foods.

Quality management Quality management includes all the activities that organization use to direct, control, and coordinate quality. These activities include formulating a quality policy and setting quality objectives. They also include quality planning, quality control, quality assurance, and quality improvements.

Recommended dietary allowance The average daily dietary nutrient intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy subjects in a particular life stage and gender group.

Reservoir An animal species that specifically harbors an infectious agent over long periods, often without harm to the host.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Risk analysis A process of decision making (usually government) for managing food safety, consisting of three components: risk assessment, risk management, and risk communication.

Risk assessment A scientifically based process for evaluating risks associated with foodborne hazards, consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization.

Risk assessment policy Documented guidelines on the choice of options and associated judgments for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties, including the explanation of risk assessment findings and the basis of risk management decisions.

Risk estimate The quantitative estimation of risk resulting from risk characterization.

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and, if needed, selecting appropriate prevention and control options.

Risk manager A person or an organization (usually government) with the authority to decide on the acceptability of risk and, if necessary, measures needed for their management.

Risk profile The description of the food safety problem and its context.

Safe (food) A level of risk that is deemed to be acceptable by some standard. The question of safety always involves the question of to whom the risk is acceptable, and by what criteria that party judges it so.

Sanitizer Type of antimicrobial (disinfectant) that kills or irreversibly inactivates microorganisms present on a surface, especially designed for use on food-processing equipment. The US Environmental Protection Agency further defines a sanitizer as providing at least 99.9% reductions of all microorganisms on a surface (*see also* disinfectant).

Shelf-life The predicted time at which a product will change from acceptable to unacceptable quality. It is influenced by factors such as raw ingredient quality, processing conditions, packaging practices, and storage conditions. Typically, shelf-life is determined by a combination of microbial, sensory, and chemical methods. 'Shelf-life' can be expressed on food labels by a variety of dates, including 'expiry', 'use by', 'sell by', 'best before', and 'consume by', depending on the applicable legislation.

Step (HACCP) A point, procedure, operation, or stage in the food chain including raw materials, from primary production to final consumption.

Strain An isolate of the same type of microorganism possessing different properties.

Surveillance The systematic, ongoing collection, collation, and analysis of data on specific diseases in a defined population, to guide public health decisions.

Surveillance (active) Public health surveillance that regularly reaches out to diagnostic laboratories or to clinicians to actively collect reports of specific diagnoses of infections.

Surveillance (passive) Public health surveillance that collects reports of specific diagnoses from clinicians or diagnostic laboratories, which they are required or requested to submit because of notifiable diseases regulations.

Time–temperature abuse A situation where food has not been cooked for long enough or at a sufficient high temperature to reduce contaminants to safe levels, or food has been stored for a time or at a temperature that permits bacteria to proliferate.

Traceability/product tracing The ability to follow, forward as well as backward, the movement of a food through specified stage(s) of production, processing, and distribution.

Uncertainty In risk assessment, imperfect knowledge concerning the present or future state of an organism, system, or (sub) population under consideration.

Validation (analytical methods) Practice undertaken to substantiate or confirm methods or procedures perform as expected and in a reliable manner and consistently meet expectations.

Validation (control measures) Obtaining evidence that a control measure or combination of control measures, if properly implemented, is capable of controlling the hazard to a specified outcome.

Validation (HACCP) Obtaining evidence that the elements of the HACCP plan are effective.

Variability Heterogeneity of values over time, space, or different members of a population. Variability implies real differences among members of that population.

Verification (general) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine whether a control measure is or has been operating as intended.

Verification (HACCP) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine compliance with the HACCP plan.

Veterinary drug Any substance applied or administered to any food-producing animal, such as meat or milk producing animals, poultry, fish, or bees, whether used for therapeutic, prophylactic, or diagnostic purposes, or for modification of physiological functions or behavior.

Virulence The degree of pathogenicity of a microorganism as indicated by case-fatality rates and/or its ability to invade the tissues of the host; the competence of any infectious agent to produce pathologic effects. The virulence of a microorganism is a measure of the severity of the disease it causes (Compare with pathogenicity).

Waterborne disease A disease resulting from the contamination of water either by pathogenic viruses, bacteria or protozoa, or by chemical substances. These agents are directly transmitted to people when the water is used for drinking, preparing food, recreation, or other domestic purposes.

Withdrawal period (veterinary drugs) The interval between the time of the last administration of a veterinary drug and the time of the collection of edible tissue or products from a treated animal that ensures the concentration of residues in food comply with the maximum residue limit for the drug.

Zoonosis A disease that can be passed directly or indirectly from animals, whether wild or domesticated, to humans. Also called zoonotic disease.

ABBREVIATIONS OF TECHNICAL TERMS

This is a nonexhaustive list of commonly used abbreviations in the area of food safety.

ADI	Acceptable daily intake.
ADME	Absorption, distribution, metabolism, and excretion.
AI	Adequate intake.
ALARA	As low as reasonably achievable.
ALOP	Appropriate level of protection.
ARfD	Acute reference dose.
BMD	Benchmark dose.
BMDL	Benchmark dose at lower confidence limit.
CCP	Critical control point.
CFR	Case fatality rate.
CFU	Colony forming unit.
CIP	Cleaning in place.
DALY	Disability adjusted life year.
DGGE	Denaturing gradient gel electrophoresis.
DNA	Deoxyribonucleic acid.
EAR	Estimated average requirement.
ED_{50}	Effective dose 50%.
ELISA	Enzyme linked immunosorbent assay.
EMRL	Extraneous maximum residue limit.
FSO	Food safety objective.
GAHP	Good animal husbandry practice.
GAP	Good agricultural practice.
GHP	Good hygienic practice.
GAqP	Good aquacultural practice.
GC	Gas chromatography.
GC–MS	Gas chromatography–mass spectrometry.
GHP	Good hygienic practice.
GLP	Good laboratory practice.
GM	Genetically modified.
GMO	Genetically modified organism.
GMP	Good manufacturing practice.
GPVD	Good practice in the use of veterinary drugs.
GRAS	Generally recognized as safe.
HAB	Harmful algal bloom.
HACCP	Hazard analysis and critical control point.
HPLC	High performance liquid chromatography.
HPLC–MS	High performance liquid chromatography–mass spectrometry.
HPP	High pressure processing.
HTST	High temperature short time.
HUS	Hemolytic uremic syndrome.
IEDI	International estimated daily intake.
IESTI	International estimated short term Intake.
LD_{50}	Lethal dose 50%.
LOAEL	Lowest observed adverse effect level.
LOD	Limit of detection.
LOQ	Limit of quantitation.
MFFB	Moisture on a fat free bases.
ML	Maximum level.
MLST	Multilocus sequence typing.
MLVA	Multiple locus variable number tandem repeat analysis.
MOE	Margin of exposure.
MRL	Maximum residue limit.
mRNA	Messenger ribonucleic acid.
MS	Mass spectrometry.
NEDI	National estimated daily intake.
NOAEL	No observed adverse effect level.
NOEL	No observed effect level.
OPRP	Operational prerequisite programme.
PC	Performance criterion.
PCR	Polymerase chain reaction.
PDCA	Plan do check act.
PEF	Pulsed electric fields.
PFGE	Pulsed field gel electrophoresis.
PMTDI	Provisional maximum tolerable daily intake.
PO	Performance objective.
PRP	Prerequisite program.
PrP	Protease resistant protein.
PTMI	Provisional tolerable monthly intake.
PTWI	Provisional tolerable weekly intake.
QPS	Qualified presumption of safety.
RDA	Recommended dietary allowance.
RNA	Ribonucleic acid.
SMEs	Small- and medium-sized enterprises.
SOP	Standard operating procedure.
SPS Agreement	Agreement on the Application of Sanitary and Phytosanitary Measures.
TBT Agreement	Agreement on Technical Barriers to Trade.
TDI	Tolerable daily intake.
TDS	Total diet study.
TEF	Toxic equivalency factor.
TEQ	Toxic equivalence.
TMDI	Theoretical maximum daily intake.
TSE	Transmissible spongiform encephalopathy.
UHT	Ultra high temperature.
UL	Upper limit.
UV	Ultra violet.

PESTICIDE RESIDUES

Contents

Conazoles

M Tasheva, Sofia, Bulgaria

Glossary

ADME An acronym in pharmacokinetics for absorption, distribution, metabolism, and excretion of xenobiotics within an organism.
Constitutive androstane receptor (CAR) A member of the nuclear receptor superfamily and is a key regulator of xenobiotic and endobiotic metabolism.
Cytochrome P450 aromatase The enzyme essential for the conversion of androgens to estrogens.
Cytochrome P450 superfamily (officially abbreviated as CYP) A large and diverse group of enzymes. The function of most CYP enzymes is to catalyze the oxidation of organic compounds.
Dystocia Impeded or difficult birth. Dystocia and delays in parturition are toxicities common to many conazole fungicides, they may be related to aromatase inhibition.
Lanosterol 14 α-demethylase (or CYP51A1, P45014DM) A cytochrome P450 (family 51, subfamily A, polypeptide 1) enzyme that converts lanosterol to cholesterol.

Chemical Group(s) and Mode of Pesticidal Action

The conazole fungicides represent a large group of compounds widely used in agriculture for protection and treatment of fungal diseases in crop plants and as pharmaceuticals in human and veterinary medicine. The information below refers to conazoles used as plant protection products.

According to their chemical structure, conazole fungicides are classified into triazoles and imidazoles, but their antifungal activity is due to the same molecular mechanism:

- Imidazoles: imazalil (enilconazole as pharmaceutical), oxpoconazole, pefurazoate, prochloraz, and triflumizole.
- Triazoles: azaconazole, bitertanol, bromuconazole, cyproconazole, difenoconazole, diniconazole, epoxiconazole, etaconazole, fenbuconazole, fluquinconazole, flusilazole, flutriafol, hexaconazole, imibenconazole, ipconazole, metconazole, myclobutanil, penconazole, propiconazole, prothioconazole, simeconazole, tebuconazole, tetraconazole, triadimefon, triadimenol, and triticonazole.

The common feature in the chemical structure of imidazole fungicides is the imidazole ring (Figure 1) and in the structure of triazole fungicides it is the 1,2,4-triazole ring (Figure 2).

The target site of conazole fungicides it is the inhibition of C14-demethylase in sterol biosynthesis (*erg11/cyp51*). The antifungal effect of conazoles is due to inhibition of sterol

Figure 1 Imidazole.

Figure 2 1,2,4-triazole.

 doi:10.1016/B978-0-12-378612-8.00241-9

14-demethylase in fungi, thereby blocking the biosynthesis of ergosterol. The lack of ergosterol is detrimental because it is an essential sterol component in the membranes of fungi.

The CYP51 gene is functionally conserved and is the only member of the cytochrome P450 superfamily (CYP) having catalytically identical orthologues in plants, fungi, prokaryotes, and higher species. It encodes for lanosterol demethylase activity, critical for sterol biosynthesis in mammals. In humans, the sterol 14-demethylase, i.e. CYP51, is expressed in many different tissues. It is, therefore, plausible that the mechanism by which the triazoles perform their fungicidal activity is the same as that responsible for some of the toxic effects in mammals.

Uses

The major uses of conazoles are for protective and curative treatment of fungal diseases in cereals, oil seeds, fruit trees, grapes, vegetables, sugar beets, etc. They are used for seed dressings and by pre- and postharvest application to crops. The conazole fungicides are highly effective against many different fungal diseases, especially powdery mildews, rusts, and many leaf-spotting fungi.

The first representatives of the conazole fungicides were introduced in the 1970s. The most used imidazoles are imazalil and prochloraz, introduced in 1973 and 1977, respectively. Triazoles are the largest class of fungicides. The first launched triazole in 1973 was triadimefon followed soon by triadimenol and bitertanol. Numerous other triazoles have been discovered and placed on the market since then. The current ranking of global sales is: tebuconazole, epoxiconazole, propiconazole, difenoconazole, flusilazole, tetraconazole, fluquinconazole, and flutriafol.

There are no available data on the volume of conazole fungicides used in the agriculture world-wide. In the USA, there is also no precise information on the proportion of conazoles from all used fungicides.

For the period 1992–03 the conazole fungicides were in third place in the ranking of all used chemical classes of fungicides in the European Union. They are also reported to be in the top five chemical classes used in cereals.

Relevant Absorption, Distribution, Metabolism and Excretion Characteristics

Imidazoles such as prochloraz and imazalil show rapid and nearly complete oral absorption, extensive distribution, rapid and complete excretion.

Most triazoles are also rapidly absorbed and widely distributed, with the highest concentration usually in kidney and in liver.

Triazoles are extensively metabolized. Three common metabolites of triazoles have been identified: 1,2,4-triazole (free triazole), triazole alanine, and triazole acetic acid. Triazole alanine and triazole acetic acid are formed in plants, and 1,2,4-triazole in both plants and mammals (rat).

Formation of 1,2,4-triazole in the rat is less than 20% for the majority (approximately 80%) of the triazole fungicides for which data are available. Two compounds (tetraconazole and flusilazole) demonstrate relatively high conversion (68–77%) in rat metabolism studies. As a plant metabolite, and given the wide use of triazole fungicides, free triazole is found in a variety of food commodities, including animal byproducts. 1,2,4-triazole appears to be relatively stable in the environment, and may be found in rotational crops as well as in water. Based on the currently available toxicology data, the toxicological effects of 1,2,4-triazole are sufficiently different from those of the conjugates triazole alanine and triazole acetic acid. Triazole alanine and triazole acetic acid have generally not been found to be significant metabolites in rats, lactating goats, or laying hens.

Relevant Toxic Effects From Acute Exposure and Repeated Exposure

The acute oral toxicity of conazoles to mammals varies from moderate to low (LD50 values between 300 and more than 2000 mg kg^{-1} body weight). The toxicity after acute dermal exposure is low (LD50 higher than mg kg^{-1} body weight).

A number of adverse effects have been observed in laboratory animals after repeated administration of triazoles, such as developmental effects, effects on reproduction, hepatotoxicity, hepatocarcinogenicity in mice, and production of other types of tumors (thyroid, testis), via nongenotoxic mechanisms.

Developmental effects: To some extent, triazoles show a typical pattern of developmental toxicity in laboratory animals. They are usually embryotoxic, cause delayed development (decreased fetal weight and delayed ossification), and also induce the following malformations and variations in rats:

- Craniofacial or brain malformations (cleft palate, hypognathia, macroglossia, exophtalmus, and hydrocephalus) observed with bitertanol, cyproconazole, diniconazole, epoxiconazole, flusilazole, propiconazole, and triadimefon.
- Variations of the urinary tract (dilated ureter and renal pelvis, absent renal papillae, hydronephrosis, and distension of urinary bladder) observed with cyproconazole, flusilazole, hexaconazole, propiconazole, tetraconazole, triadimefon, and metconazole.
- Additional cervical ribs observed with bromuconazole, diniconazole, epoxiconazole, flusilazole, myclobutanil, hexaconazole, penconazole, prothioconazole, tetraconazole, triadimenol, and triticonazole.

Most of the developmental effects in rats occur at high dose levels which are maternally toxic. In the rat, it was noted that malformations such as cleft palate and variations such as absent renal papillae were seen at high doses. The finding of increased incidence of skeletal variations was considered to indicate some embryotoxicity. The other skeletal variations seen were of less toxicological concern.

Reproductive effects: Reproductive toxicity, generally observed at parentally toxic doses includes impaired fertility, prolonged gestation, dystocia, reduced survival and reduced pup/litter weight, and perinatal mortality. There is evidence for aromatase inhibition from *in vitro* and *in vivo* studies.

Effects on reproduction are reported with bitertanol, cyproconazole, epoxiconazole, fenbuconazole, flusilazole, flutriafol, metconazole, myclobutanil, penconazole, prothioconazole, tetraconazole, triadimenfon, triadimenol, and triticonazole.

Hepatotoxicity, hepatocarcinogenicity in mice and other types of tumors (thyroid, testis): Triazoles have been shown to have effects on the liver to various degrees (changes in the activities of a number of P450 enzymes, hypertrophy resulting in increased liver weight, chronic inflammation, and necrosis) and several of them induce mouse hepatocellular tumors and rat thyroid follicular cell tumors. There is evidence that tumor formation is via nongenotoxic mechanisms and that the tumors may be a consequence of effects on the liver.

Hepatocellular adenomas and adenomas/carcinomas have been observed in mice exposed to bromuconazole, cyproconazole, difenoconazole, diniconazole, epoxiconazole, fenbuconazole, fluquiconazole, flusilazole, metconazole, propiconazole, tebuconazole, tetraconazole, triadimefon, and triadimenol.

The mechanism of hepatic toxicity of conazoles in mammals is still not very well characterized because multiple effects have been identified. The conazoles had effects on nuclear receptors as evidenced by increased expression and enzymatic activities of a series of related cytochrome P450s.

As discussed above, the fungicidal activity of triazoles is a consequence of their direct inhibition of CYP51 (lanosterol-14-alpha-demethylase). In mammals, CYP51 is part of the pathway leading to the biosynthesis of cholesterol which is the primary sterol in the cell membrane of mammals and is required for the sex steroid hormone and vitamin D synthesis. Triazoles can also inhibit several other P450 enzymes, including members of the CYP1A, CYP2C, and CYP3A subfamilies, as well as CYPC19 and CYP26, though specificity varies with structure. Hence, the effects of triazoles on mixed function oxidase activity are a balance between induction and inhibition of a variety of CYP enzymes.

The imidazole fungicide prochloraz is also a potent inducer of hepatic microsomal monooxydase system in rats and mice. The spectrum of induction is similar to phenobarbital induction.

In rodents, one consequence of activation of nuclear receptors such as constitutive androstane receptor (CAR) is hepatic hyperplasia, and this might underlie some of the effects of the triazoles reported in the liver.

Conazoles are generally not genotoxic in standard *in vitro* and *in vivo* tests.

Effect in humans: There are no reported effects in humans similar to those described in experimental animals. A few adverse effects in persons involved in manufacturing and use of prochloraz and its formulations included ocular and dermal irritation after heavy exposure to plant protection products containing prochloraz.

Imazalil (enilconazole) was used at oral therapeutic doses of up to 1200 mg over 6 months for the treatment of chronic fungal infection due to *Alternaria alternata* in a single patient (female). The drug was tolerated without evident toxicity based on hematology and clinical observations with the exception of the induction of nausea at high-dose levels. Very limited studies of pharmacokinetics were carried out: at a dose of 400 mg day^{-1}, the maximum serum concentration was approximately 2 μg ml^{-1}, whereas at a dose of 1200 mg, the maximum serum concentration was approximately 4 μg ml^{-1}. The half-life was approximately 2 h, and administration of 1200 mg daily for 1 month did not result in accumulation. No changes in clinical chemical parameters were seen.

Occurrence in Food

Risks from long-term and short-term dietary intakes of residues of conazole fungicides have been assessed by the Joint FAO/WHO Meeting on Pesticide Residues.

For the assessment of the long-term intake of residues, the international estimated daily intake (IEDI) was calculated for different diets representative for relevant global regions. For the assessment of the short-term intake of residues, the international estimated short-term intake (IESTI) was calculated for relevant food commodities for which residue data and consumption data were available.

Table 1 Dietary risk assessment for selected conazoles (2000–10)

Compound	*Long-term risk assessment*		*Short-term risk assessment*	
	ADI (mg per kg bw)	*IEDI (% of the maximum ADI)*	*ARfD (mg per kg bw)*	*IESTI (% of the ARfD)*
Bitertanol	0–0.01	2–10	Not necessary	Not calculated
Cyproconazole	0–0.02	1–2	0.06	Ch: 0–4% GP: 0–5%
Difenoconazole	0–0.01	0–10	0.3	Ch: 0–10% GP: 0–7%
Fenbuconazole	0–0.03	0–20	Not necessary	Not calculated
Flusilazole	0–0.007	2–10	0.02	Ch: 0–100% GP: 0–40%
Prochloraz	0–0.01	7–10	0.1	Ch: 0–3% GP: 0–1%
Propiconazole	0–0.07	0–2	0.3	Ch: 0–70% GP: 0–30%
Tebuconazole	0–0.03	1–8	Not necessary	Not calculated

Abbreviations: ADI, acceptable daily intake; IEDI, international estimated daily intake; ARfD, acute reference dose; IESTI, international estimated short-term intake.

The long-term and short-term intakes of residues of selected conazoles are unlikely to present a public health concern (Table 1).

Glossary

Food Any substance, whether processed, semi-processed, or raw, that is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation or treatment of 'food' but does not include cosmetics, tobacco, or substances used only as drugs. (In the context of this topic level contribution, drinking water is food).

Hazard A biological, chemical or physical agent in, or condition of, food with the potential to cause an adverse health effect.

Monitoring (general) The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a control measure is under control.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to hazard(s) in food.

Introduction

Dithiocarbamates are a class of organ sulfur compounds of which 21 known compounds are employed as pesticides. They are analogs of carbamates in which both oxygen atoms are replaced by sulfur atoms and are generated by reacting primary and secondary amines with carbon disulfide under alkaline conditions. Dithiocarbamates readily form octahedral complexes with metal ions such as Cu(II), Fe(II) and Fe(III), Co(II), Mn(II), and Ni(II). Some of the most used dithiocarbamates are summarized in Table 1. Based on the carbon skeleton structure, dithiocarbamates are categorized into three groups namely dimethyldithiocarbamates (DMDs), ethylene-bis-dithiocarbamates (EBDCs), and propylene-bis-dithiocarbamates.

Most of these compounds are rapidly degraded in the environment to yield thioureas such as ethylenethiourea (ETU), ethyleneurea (EU), and propylenethiourea. ETU is of toxicological concern due to its carcinogenicity, teratogenicity, and antithyroid properties. Maneb, mancozeb, and metiram can induce thyroid cancer in laboratory animals possibly via the formation of ETU. Thus, for risk assessment purposes these pesticides are grouped together.

The powerful fungicidal effect of EBDs is due to their metabolites or decomposition products, such as ethylene-bis-isothiocyanate, ethylenethiuram, and carbonyl sulfide. The mechanism of the pesticidal activity of dithiocarbamates is inhibition of catalytic and regulatory thiol groups of cytoplasm constituents by organic electrophiles (isocyanates, carbonyl disulfide, and isothiocyanates) generated by metabolism of the parent molecules or by the coordinated metal ions (Zn(II) and Mn(II)), which occurs at nearly neutral pH (higher than 5.5–6.0). The wide range of action and the poor biocidal specificity of these compounds toward fungi, bacteria, plants, and insects, as well as the undesired toxicity against mammals, are all due to this mechanism.

Sources and Uses of Dithiocarbamates

Dithiocarbamates are synthetic compounds most of them having been developed during and after World War II. There is no known natural source of these compounds. Dithiocarbamates are mainly used in agriculture as pesticides, although a close chemical analog (disulfiram, Antabuse) is used as a human pharmaceutical agent in the treatment of alcohol abuse. As pesticides, they are effective against a broad spectrum of plant diseases caused by fungi and are mostly used to protect fruits and vegetables. They are nonsystemic fungicides which stay on the surface of the crop after application and prevent fungal growth on them, without penetrating into the vegetable tissue. The residual products from their application include ETU, EU, imidazole derivatives, diisothiocyanates, diamines, disulfides, and the coordinating metals, so that washing or fruit peeling to remove these products is generally sufficient to reduce or avoid consumer exposure. Some dithiocarbamates are also used for vector insect control in public health and in the household.

Dithiocarbamates are the most often used pesticides in EU and other parts of the world (Table 2) and are most frequently detected in monitoring programs. Given their wide range of applications, they are produced in great quantities. The worldwide consumption is between 25 000 and 35 000 metric tons per year.

In the industry some products are also used as slimicides in watercooling systems, in sugar, pulp and paper manufacturing, and as vulcanization accelerators and antioxidants in rubber product manufacturing. Because of their chelating characteristics, they are used as scavengers of thiol-binding metals in wastewater treatment.

Absorption, Metabolism, and Excretion of Dithiocarbamates

As a general rule, dithiocarbamates can be absorbed via the skin, the mucous membranes and the respiratory and gastrointestinal tracts, whereas metal-complex alkylenebisdithiocarbamates are poorly absorbed both from the gastrointestinal tract and through the skin. Dithiocarbamates such as EBDCs are metabolized via hepatic microsomal enzymes to produce ETU. The elimination of ETU is largely through the kidney, and its elimination half-life is variable, ranging between 32 and 100 h, according to the species involved. Toxicokinetic data of these compounds in humans are not univocal: In some studies ETU can be detected in urine several days after exposure, whereas other studies suggest a short half-life of elimination.

Metabolism of dialkyldithiocarbamates results in the formation of dialkylthiocarbamic acid, free or as the *S*-glucuronide conjugate, of carbon disulfide and dialkyl amine as the decomposition products of the former, of formaldehyde, of sulfate as the final catabolic product of excess thiolic sulfur. The metabolic decomposition of EBDCs mammals results in formation, in addition to ETU, of carbon disulfide, ethylenediamine (EDA), ethylene bisthiuram disulfides, of hydrogen sulfide and ethylenebisthiocyanate. ETU is further broken down to carbon and nitrogen precursors which are incorporated into compounds such as oxalic acid, glycine, and urea. Dithiocarbamates and their metabolic products are found in the liver, kidneys, and the thyroid gland, but accumulation of these compounds does not take place because of their rapid metabolism.

Toxic Effects of Dithiocarbamates in Laboratory Animals

In rats, some dithiocarbamates tested at high dose-induced effects on reproduction (reduction of reproductive capacity) and on endocrine function. In teratogenicity studies dithiocarbamates induced an increase in resorption sites, and somatic and skeletal malformations in mice and rats. The doses needed to produce these effects were usually higher than 200 mg kg_{bw}^{-1} in rats and above 100 mg kg_{bw}^{-1} in mice, so being of questionable relevance for human toxicity in realistic exposure conditions. High levels of dithiocarbamates have also produced increased thyroid weight, reduction in colloid in thyroid follicles, thyroid hyperplasia, and nodular goiter. Prolonged administration of ETU to rats caused thyroid neoplasm. These neoplasms are observed as a consequence of inhibition of the production of thyroid hormones, with a consequent hyperincretion of the thyroid stimulating hormone (TSH), bringing about a goitrogenic effect and thyroid tumor. This carcinogenic activity of ETU was considered by International Agency for Research on Cancer (IARC) to be specifically linked with the different physiology of thyroid hormones in rodents, with no apparent risk to humans at doses below those able to cause a goitrogenic effect. For this reason, ETU has been allocated in IARC group 3. At dose above 50 mg kg_{bw}^{-1} (a level still unrealistic for even occupational human exposure) dithiocarbamates produce neurotoxic effects characterized by ataxia and paralysis of the hind legs, demyelination and degeneration of peripheral nerves in rats and rabbits.

The amine constituents of some dithiocarbamates may be converted *in vivo* to *N*-nitroso derivatives, which are considered to be both mutagenic and carcinogenic.

Health Effects of Dithiocarbamates in Human

In human beings the acute toxicity of dithiocarbamates is low, so that acute risk for consumers is consequently negligible. Toxic consequences of long-term exposure have been mainly studied in exposed agricultural workers, who may face skin sensitization, diffuse erythema, and eczematoid epidermatitis of the eyelids and inguinal regions when coming into contact with these compounds. Because of their metal-chelating properties, dithiocarbamates may cause a redistribution of toxic thiol-binding heavy metals such as lead and cadmium, in organs such as the brain. In very heavily exposed workers, similarly to animals, an inhibition in the production of thyroid hormones has been observed, with a compensative incretion of TSH. Regular contact with dithiocarbamates can cause functional changes in the nervous and hepatobiliary systems, and skin contact may induce contact dermatitis. An increase in T-cell proliferative responses to mitogens has been pointed out in mancozeb applicators in vineyards, thus suggesting a slight immunomodulatory effect of EBDCs.

Monitoring of Dithiocarbamates in Food

The hazard associated with the use of dithiocarbamates for the general population is the residue left on the foodstuff, which can be conveniently reduced or eliminated by washing or peeling fruit and vegetables before eating or cooking. As ETU is teratogenic, carcinogenic, mutagenic, and immunotoxic in test animals and accumulates in the thyroid of animals fed contaminated fodder, this exposure pathway may be a potential health hazard to humans.

Residues of dithiocarbamates in foodstuffs are determined by generation of carbon disulfide (CS_2) on hot acid digestion of the whole sample, followed by reaction of CS_2 with Cu(II) to yield a cupric complex which is quantified by spectrophotometry. Not only this method does not identify the specific dithiocarbamate (DTC) compound, but, worse, may also suffer from interference from CS_2 generated on hot acid digestion from natural compounds, such as phenyl isothiocyanate and other glucosinolates, originally present as micronutrients in the plant material, thus leading to false positives and overestimation of exposure. Also determination of the DTC-bound metal is used; however, the method suffers from most of the same inconveniences (no specificity for individual products and interference from other, even natural, sources of the metal in the foodstuff). As ETU cannot generate CS_2, this approach cannot be used to measure this major target compound, in monitoring the specific group of EBDs, the only able to generate ETU as metabolite. For this reason in some countries monitoring is performed through the

determination of ETU concentration in selected food commodities. Following suitable cleanup and gas chromatography (GC) conditions, individual EBDCs can be measured in various foodstuffs with a minimum detection limit of 10 ppb or 10 μg kg^{-1}. As derivatization is necessary for the GC analysis, additional ETU may be formed during reactions at elevated temperatures as a result of decomposition of EBDC residue present in the sample. As an alternative, liquid chromatography has also been applied using for detection either a nonselective UV absorbance (which necessitates a complicated sample cleanup) or a selective electrochemical detection, for which sample cleanup is much simpler.

Dietary Intake of Dithiocarbamates

Exposure of the general population to dithiocarbamates and to their breakdown products results from occasional residues in the diet. To evaluate the potential risk of dietary exposure to dithiocarbamates, the estimated intakes need to be compared with a toxicological reference value of one compound within the dithiocarbamate class or to a group of compounds with the same mechanism of toxicity, assumed to have been present in the food analyzed. Dithiocarbamates degrade rapidly after application to crops, yielding degradation products such as ETU, ethylene thiuram disulfide and [2, 1-C]-1, 2, 4-dithiazole-3-thione. Cooking of some foods treated before with EBDCs, have shown to result to a high level of ETU after cooking. Thus, boiling of foods containing the parent compounds can result in a high level of ETU. A group ADI for EBDCs is normally assigned as no distinction of specific parent material can be made during analysis.

Maximum allowable residue level, acceptable daily intake, and acute reference dose of dithiocarbamates have been set by Joint FAO/WHO Meeting on Pesticide Residues and other regulatory authorities to safeguard health of consumers of various foodstuffs (**Tables 3–5**).

PESTICIDE RESIDUES

Herbicides

I Dewhurst, Chemicals Regulation Directorate, York, UK

Glossary

Acceptable daily intake Estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a (sub)population may be exposed daily over their lifetimes without appreciable health risk.

Acute reference dose Estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a (sub)population may be exposed on a single day or at a single meal without appreciable health risk.

Epidemiology The study of factors associated with the frequency and distribution of disease or other health-related effects, and their causes, in a defined human population.

Herbicide active substance A chemical used to control or kill weeds.

Herbicide formulation A product consisting of one or more herbicide active substances and other chemicals (such as solvents or surfactants) that enhance the application or effectiveness of the active substance.

Mechanism of action A detailed description of how a chemical produces a biological effect, for example, by acting at a specific receptor or biomolecule.

Mode of action The general description of how a chemical produces a biological effect, for example, by acting on the thyroid.

Chemical Groups and Modes of Pesticidal Actions

Herbicides represent a diverse group of chemicals, which are used to control weeds. The Herbicide Resistance Action Committee (HRAC) lists over 250 active substances as having herbicidal activity, divided into 24 groups/subgroups based on the mode of herbicidal action (examples are in Table 1. The European Union (EU) pesticides database lists 324 herbicides. Some herbicidal modes of action are plant specific (e.g., synthetic plant hormones) but others have close correlates in mammals (e.g., Group D, electron cycling, and free radical generation) which are related to the observed toxicity.

In addition to having a range of chemistry, herbicides can be classified based on the method of application and mode of action, such as:

- Selective – affects certain plants only (e.g., broad-leaved weeds) without damaging others.
- Broad spectrum – act on all types of weeds.
- Systemic – transported through the weed.
- Contact – act only on the part of plant exposed to them, generally faster acting than systemic herbicides.
- Preemergence – acts to stop seed germination.
- Postemergence – acts on the seedlings or mature weed.
- Residual – persists in the soil to act on germination.

Many herbicide active substances are acids, which are formulated as either esters (e.g., aryloxyphenoxypropionate derivatives (FOPs)) or salts (e.g., glyphosate). Esterification can aid penetration of the plant cuticle followed by hydrolysis to liberate the acid.

It is not possible within the confines of this article to cover the modes of action of all herbicides, and the reader is referred to the HRAC website as an initial source of additional detail.

Table 1 Examples of HRAC herbicide groupings

HRAC group	*Mode of herbicidal action*	*Chemical classes*	*Herbicide (ISO name)*
A	Acetyl CoA carboxylase inhibition	Aryloxyphenoxypropionate (FOPs)	Haloxyfop
		Cyclohexanedione	Tralkoxydim
B	Acetolactate synthetase inhibition	Sulphonyl urea	Amidosulfuron
		Imidazolinone	Imiazethapyr
C	Inhibition of photosynthesis at photosystem II	Triazine	Atrazine
		Urea	Linuron
D	Photosystem-I- electron diversion	Bipyridylium	Paraquat
F	Bleaching	Triketone	Mesotrione
G	Inhibition of 5-enolpyruvyl shikimate-3-phosphate (EPSP) synthetase	Glycine	Glyphosate
O	Action-like indole acetic acid (synthetic auxin)	Phenoxycarboxylic acid	2,4-D

Uses

The range of uses of herbicides is broad as are application rates, varying by active substance and weed type. Herbicide formulations also vary greatly in composition from simple aqueous solutions, granules containing only active substance and binding agent, to those containing many coformulants to aid solubility, adherence to the weed and/or penetration through the plant cuticle. Application can be before planting or during crop growth (with selective herbicides), and in the case of some products a short-time before harvest for desiccation (e.g., glyphosate applied at before the harvesting of oil seed rape).

The total mass of herbicide applied in the UK has fallen by approximately 30% over the past two decades (Figure 1) despite a 30% increase in area treated This is presumably due to new products being effective at lower application rates.

In the USA, 178 000 t of herbicide was applied in 2002 a reduction from approximately 203 000 t in 1992. However, the use of glyphosate rose sixfold during the same period, as it replaced a number of older herbicides, to represent over 25% of the total mass of herbicides applied. Overall herbicide usage in the EU does not appear to have decreased significantly between 1992 and 2003. However, owing to different methods used to acquire the data, drawing any conclusions by comparing across the usage surveys should be performed with caution.

In addition to agricultural use, herbicides have uses in controlling weeds on lawns, around trees in urban areas, and for controlling weeds/algae on hard surfaces such as paths, roadways, and railways.

Relevant absorption, distribution, metabolism, and excretion (ADME) Characteristics

The ADME characteristics of herbicides vary between classes as well as individual chemicals. Details on the ADME of individual compounds can be found in publications such as World Health Organization (WHO)/International Programme on Chemical Safety (IPCS) Environmental Health Criteria documents, European Food Safety Authority (EFSA) conclusions, or United States Environmental Protection Agency (USEPA) documents. A few examples are given below.

Paraquat is poorly absorbed orally with approximately 10–20% of the dose systemically available in rats; similar results have been estimated from some human poisoning cases. In dogs there is evidence of saturation of absorption at moderate dose levels, with absorption of approximately 50% reported at 0.1 mg kg^{-1} body weight (bw) and approximately 30% at 2–5 mg kg^{-1} bw. Dermal absorption is $<1\%$. Paraquat concentrations in the lung and kidney were significantly higher than those in plasma following oral, intraperitoneal, or intravenous dosing. Paraquat is actively transported into the lung via a polyamine transporter. Paraquat metabolism is limited with the majority of the absorbed dose excreted in urine as paraquat. Kidney damage produced by paraquat contributes to enhanced retention in tissues. Patients excreting more than 1 mg paraquat per hour for 8 h or more, or have paraquat plasma concentrations of >0.3 mg l^{-1} 15 h post ingestion are likely to die.

Phenoxycarboxylic acids, such as 2,4-D, are generally well absorbed in (approximately 90%) following oral dosing, though dermal penetration is approximately 5%; however, the kinetics vary between different esters and salts. In humans, oral absorption of 2,4-D is moderately rapid with peak plasma levels seen at approximately 12 h. 2,4-D is widely distributed, can pass the placenta readily, and has been shown to bind reversibly to plasma proteins. In human poisoning cases, highest levels were found in the liver and kidneys. 2,4-D is excreted unmetabolized primarily in urine. With esters of phenoxy-acids the initial metabolism is hydrolysis to release the free acid and alcohol.

The oral absorption of glyphosate is incomplete, with approximately 30% absorbed from a bolus dose and approximately 10% when incorporated into rat diet. Dermal absorption of glyphosate is low (typically $<5\%$). Absorbed glyphosate is widely distributed, with some evidence of low-level accumulation of ^{14}C in the bone. Excretion of absorbed glyphosate is almost entirely in the urine without being metabolized.

Atrazine is well absorbed orally in rats, widely distributed, and initial excretion is rapid – predominantly in urine (approximately 80%). There is accumulation in erythrocytes

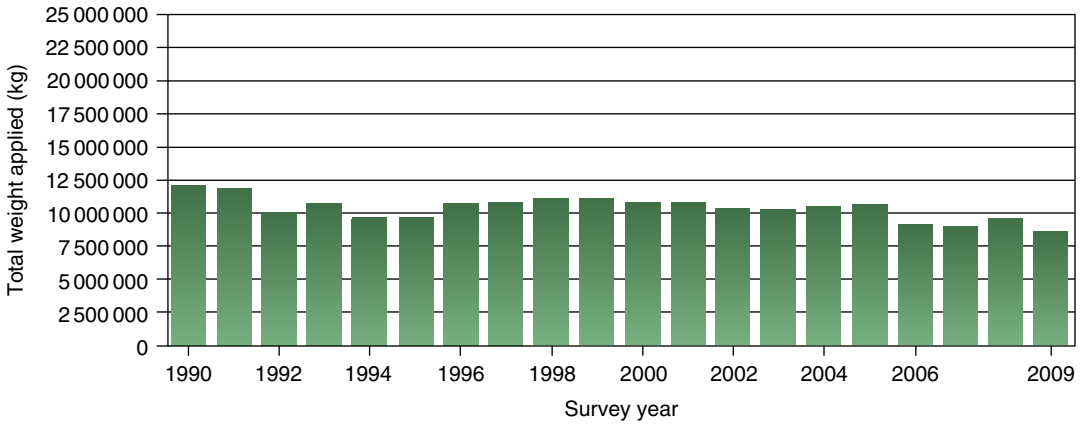

Figure 1 Mass of herbicides applied in the UK.

due to binding to the β-chain of rodent hemoglobin, which is considered to be of limited relevance to other species. Dermal absorption is $<5\%$ through human skin *in vitro* or *in vivo*. The metabolism of atrazine is extensive, with the main reactions being dealkylations.

Relevant Toxic Effects: From Acute Exposure and Repeated Exposure

The toxicity of herbicides varies between classes as well as individual chemicals. Details on the toxicity of individual compounds can be found in publications such as WHO/IPCS Environmental Health Criteria documents, EFSA conclusions, or USEPA documents. Very few herbicides have been evaluated by Joint FAO/WHO Meeting on Pesticide Residues.

Paraquat is acutely toxic by the oral (LD50s 20–500 mg kg^{-1} bw), dermal (LD50s $<100->2000$ mg kg^{-1} bw), and inhalation routes (LC50s 1–10 mg m^{-3}). Following repeated oral exposures the most sensitive organ is the lung where inflammation and progressive pulmonary fibrosis are seen at doses of approximately 1 mg per kg bw per day; higher doses produce kidney lesions. Initial lung changes are on type I pneumocytes. Paraquat is not genotoxic, carcinogenic, teratogenic, or toxic to reproduction. Investigative work using perilethal, parenteral doses has shown lesions of the *substantia nigra* consistent with those in patients with Parkinsonism.

2,4-D is of moderate oral toxicity (LD50s 300–1000 mg kg^{-1} bw) but of low dermal toxicity. In repeat dose studies the target organ is the kidney. 2,4-D is not genotoxic, carcinogenic, teratogenic, or toxic to reproduction.

Glyphosate is of low acute toxicity, but some formulations are moderately toxic. In repeat dose studies effects are seen only at high dose levels (e.g., 5000 ppm in the diet), predominantly reductions in bw gain, with salivary gland changes in some studies, and following chronic exposure liver hypertrophy and necrosis. Glyphosate is not genotoxic, carcinogenic, teratogenic, or toxic to reproduction.

Atrazine is of low acute toxicity. Positive results for skin sensitization have been reported in guinea-pigs and humans. Repeat dose studies did not present a consistent picture, reduced bw gain was seen together with slight effect on erythrocyte parameters, equivocal effects on the ovary and in dogs cardiotoxicity at a high dose level. The weight of evidence is that atrazine is not genotoxic, it is not teratogenic and does not affect reproduction without other toxicity. Atrazine is not carcinogenic in mice but produced mammary gland tumors in female Sprague Dawley (SD) rats. Investigative studies have shown the mechanism of tumor production, involves decrease in prolactin and leuteinizing hormone leading to suppressed estrus cycling and ovulation, which is unlikely to be relevant to humans due to the differences in the hypothalamic–pituitary–ovarian pathway between SD rats and humans.

Human Data

Paraquat has been involved in a significant number human poisoning cases, over 1000 of which have resulted in death. Some of these cases resulted from occupational exposures associated with poor hygiene practices and/or faulty equipment. Many cases were deliberate or accidental oral exposures. In cases of very high exposure death is due to kidney/multiorgan failure and/or pulmonary edema. With low to moderate ingestion, death due to pulmonary fibrosis can occur several days to weeks after exposure. The lethal oral dose of paraquat is approximately 2 g for an adult (approximately 30 mg kg^{-1} bw), equivalent to approximately 40 ml of a concentrated paraquat product. In survivors of paraquat poisoning there is evidence of complete recover of pulmonary function. There have been no reports of death attributed to inhalation of paraquat.

2,4-D has been involved in a number of human poisoning cases. In most instances the actual exposure is unknown but exposures to 100 ml of formulated product can cause death. The primary target organs are the kidney and heart. Birth defects and other adverse health effects ascribed to a 2,4-D containing formulation known as 'Agent Orange' have been shown to be the due to the presence of dioxins, which can be present, primarily as a byproduct of the synthesis of 2,4,5-T, the other herbicidal component of 'Agent Orange.'

Glyphosate containing products have been involved in a number of deaths predominantly from deliberate ingestion of several hundred milliliters of product. In many cases the initial signs (gastrointestinal erosion and oral ulceration) have been linked a surfactant rather than glyphosate *per se*. Death has been attributed to cardiac or respiratory arrest; at sublethal doses there is evidence of renal damage.

Epidemiological investigations have presented inconsistent results for reported associations between diseases and both generic herbicide use or use of specific compounds. Some positive associations have included phenoxy acids and non-Hodgkin's lymphoma; paraquat and Parkinsonism; and atrazine production and prostate cancer. However, other investigators have found no such correlations.

Occurrence in Food

Herbicide residues in crops are generally low, with many maximum residue levels set at the limit of quantification. This is because any significant residues present in a crop will normally damage the crop and reduce yield before they would engender any health risk. Genetically modified, herbicide-resistant crops permit the use of certain herbicides (e.g., glyphosate) while crops are growing. This can result in significant residues of the herbicide and/or metabolites.

Herbicides are not sought routinely in surveillance and monitoring schemes, but glyphosate was detected, although at low levels, in approximately 10% of the cereal samples analyzed for it in 2007 in the EU. Dietary exposures to herbicides are generally well below reference doses; however, if the herbicides are not degraded in the environment they might be transported to water sources resulting in human exposures via drinking water. In many countries, limits/guideline levels are applied to pesticide levels in drinking water (e.g., a total of 0.5 $\mu g\ l^{-1}$ in the EU; WHO).

Inorganic and Other Metal-Containing Compounds

A Moretto, University of Milano, Milan, Italy, and Luigi Sacco Hospital, Milan, Italy

Glossary

Absorption, distribution, metabolism, and excretion The absorption, distribution, metabolism, and excretion of a compound provides information on the extent and rate of absorption of a herbicide; tissues or organs receiving the highest exposures; the extent of metabolism and the types of metabolites formed; and the rate and extent of excretion (clearance) from the body.

Acceptable daily intake The estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a (sub)population may be exposed daily over their lifetimes without an appreciable health risk.

Acute reference dose The estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a (sub)population may be exposed during a meal or a day without appreciable health risk.

International estimated daily intake The long-term (lifetime) intake that is obtained from the World Health Organization (WHO) Global Environment Monitoring System (GEMS)/Food Regional Diets, which is based on per capita consumption.

International estimated short-term intake The short-term intake based on a large portion of a commodity that is consumed on a single day both by the general population and by children aged 6 years and under. The large portion values are obtained from actual food consumption survey data for individuals identified as 97.5 percentile consumers of the commodity among eaters only.

LD50 The LD50 (median lethal dose or 'lethal dose, 50%') is the dose of a chemical that would be expected to kill half of a population of exposed organisms.

National estimated daily intake The national estimated daily intake (NEDI) is a prediction of the daily intake of a pesticide residue, which is based on the most realistic estimate of residue levels in food and the best available data on food consumption for a specific population. The proportion of the commodity treated or imported may be used to correct residue estimates. When adequate information is available, monitoring and surveillance data or total diet studies may also be used.

Supervised trial median residues, Supervised trial median residues-processing Supervised trial median residues (STMR) is a median value of the residues of a pesticide measured after a supervised trial performed according to good agricultural practices. A supervised trial median residues-processing (STMR-P) is for a processed commodity calculated by applying a modification factor for the process (e.g., peeling or cooking) to the STMR calculated for the raw agricultural commodity.

Theoretical maximum daily intake The theoretical maximum daily intake (TMDI) is a prediction of the maximum daily intake of a pesticide residue, assuming that residues are present at the maximum residue levels (MRLs) and that average daily consumption of foods per person is represented by regional diets.

Introduction

Inorganic and organometallic compounds have been used as pesticides. At present, in most developed countries, only copper compounds are used in significant amount as fungicides. The others have been banned for either toxicological or environmental reasons. It is believed that some organotins are still used in some developing countries. Copper compounds, if used as directed, do not pose health risks. However, the estimated long-term intake in the European Union is not much below the acceptable daily intake, when other non-pesticidal sources of copper are considered. Organotins have a nonnegligible acute toxicity. Also, triphenyltin has immunotoxic and, possible, carcinogenic effects, and cyhexatin/azocyclotin have embryotoxic properties. However, estimated intakes are below reference values.

Chemical Groups and Modes of Pesticidal Actions

Copper

Copper and copper compounds share the similar pesticidal activities and toxicity, the latter is associated with copper content. They are used as fungicides in several crops, mainly grapes and tomatoes, and seed treatment.

Tin

Organic tin compounds, such as triphenyltin (fentin) acetate and triphenyltin (fentin) hydroxide, are used as fungicides, whereas others such as cyhexatin and the closely related azocyclotin are also used as acaricides in several crops. Their efficacy depends mostly on the organic part rather than on the metal itself.

Bismuth

Compounds of bismuth (in particular bismuth subcarbonate) have been used in agriculture combined with other pesticides, because they tend to increase the insects feeding on poisoned foliage.

Mercury

Mercuric chloride and organic mercury can be used as fungicides in agriculture and other settings, including seed treatment. Mercuric chloride has also insecticidal activity.

Uses

Copper

Copper compounds are also allowed to be used in the so called 'organic' farming. Scarce data are available on the amount of copper compounds used. In the UK there was an increase from an average yearly use of 27 t in the 1990s to a little more than 40 t in the last 10 years.

Tin

Cyhexatin, azocyclotin, triphenyltin (fentin) acetate, and triphenyltin (fentin) hydroxide are no longer registered in the EU and USA. However, their use still persist in other parts of the world. For this reason, a brief description isprovided below. Only data for fentin (hydroxide and acetate) are available from the UK showing that approximately 45 t $year^{-1}$ were used in early 1990s down to approximately 30 t in 2003 when it was banned.

Bismuth

Bismuth compounds have been used in the past in certain crops against foliar diseases, but its use is now discontinued.

Mercury

Mercuric chloride and organomercury compounds are no longer used as pesticides, at least in all developed countries. In view of this fact, and because mercury is discussed in other chapters of the encyclopedia, it will not be discussed in this article.

Relevant Absorption, Distribution, Metabolism, and Excretion Characteristics

Copper

As a micronutrient essential for life, copper follows a specific homeostatic regulation mechanism, which allows excess copper to be excreted mainly through the bile; once absorbed, copper is bound to proteins (up to 93% being ceruloplasmin), so that the free copper is normally not found neither in the blood nor in the cells. It also forms metalloproteins that function as enzymes. Copper levels in blood and tissues are generally stable; the body is able to maintain a balance of dietary copper intake and excretion that allows normal physiological processes to take place. The liver is the principal organ for regulation of copper, and main excretion is via the bile. Liver copper levels increase significantly following dosing with T_{max} at 12 h; elimination is rapid, with levels returning to control by 48 h after dosage. Oral absorption of copper varies according to the diet; for humans, a copper-adequate diet results in 36% absorption,whereas a low-copper diet and a high-copper diet results in 56% and 12% absorption. Metabolism does not occur. Copper does not accumulate, except in cases of genetic disease or chronic administration of high doses, where copper accumulates in the liver.

Tin

- Azocyclotin (tri(cyclohexyl)-1H-1,2,4-triazole-1-yltin) and cyhexatin (tricyclohexyltin hydroxide) are chemically related organotin compounds; azocyclotin breaks down to cyhexatin and 1,2,4-triazole. Azocyclotin has similar systemic toxicological properties to cyhexatin and may also have additional properties attributable to the 1,2,4-triazole that is formed. Oral doses of azocyclotin and cyhexatin were absorbed to a limited extent in rats: 12% and 2–10%, respectively. Azocyclotin completely breaks down to cyhexatin, and then the cyclohexyl rings are split to produce dicyclohexyltin and monocyclohexylstannoic acid. These are further hydroxylated and/or destannylated.
- Absorption of fentin is not complete and excretion is rapid with no indication of accumulation. Fentin acetate is rapidly hydrolized to fentin hydroxide, and then it is dephenylated and mainly excreted via feces. Some free tin may also be formed but it could not be quantified.

Relevant Toxic Effects: From Acute Exposure and Repeated Exposure

Copper

Acute oral LD50 in the rat is between 490 and 1280 mg kg^{-1} body weight (bw) for copper hydroxide, between 950 and 1860 mg kg^{-1} bw for copper oxychloride, between 300 and 500 mg kg^{-1} bw for tribasic copper sulphate and copper (I) oxide, and higher than 2000 mg kg^{-1} bw for the Bordeaux mixture. Copper hydroxide and the Bordeaux mixture may cause toxic effects by inhalation and present a risk of serious damage to eyes. Target organs of excess copper after oral administration are the liver and kidneys. Genotoxicity and carcinogenicity are not of concern on oral administration. Copper did not produce adverse effect on fertility, reproductive parameters or development, or neurotoxicity in animals. In humans, with genetic condition where the gene for copper transporter protein is inactive (as in Wilson's disease), copper progressively accumulates in the liver and brain, and in later stages of the disease (which is fatal due to liver failure if not treated) it shows signs of neurotoxicity. In genetically normal humans and laboratory animals, the homeostatic mechanisms that regulate copper prevent any accumulation in the brain and neural tissues so that copper does not show a neurotoxic potential. There was no evidence for adverse effects from oral exposure due to customary diets worldwide, or for any adverse effects of copper on pregnancy, parturition, lactation, or growth

and development in humans. There was evidence of toxicity particularly to neonates who were repeatedly exposed to milk heated in copper vessels or exposed to acid fruit stewed in copper vessels. A single case of long-term administration of excess copper as a dietary supplement resulting in liver failure is described in the literature. The upper limit of copper intake without adverse effect is not well defined, but is well recognised to be between 10 and 12 mg Cu per person per day, although some reports described the upper limit dose exposure for long period of time as being not adverse in a few individuals. Based on the WHO values established for human copper intake, the acceptable daily intake (ADI) – or more appropriately designated as 'upper limit for copper intake' for copper is 0.15 mg Cu kg^{-1} bw day^{-1}, and no acute reference dose (ARfD) was allocated based on the toxicological profile.

Tin

- Azocyclotin and cyhexatin have moderate acute toxicity by the oral route, the LD50 in rats are 209–265 mg kg^{-1} bw, respectively. The most sensitive effect seen in long-term studies of toxicity/carcinogenicity with azocyclotin and cyhexatin in mice and rats was decreased body weight, whereas at higher doses in short-term studies, the main toxicological effects seen in rats were local effects on the gastric mucosa, hematological changes, and hepatotoxicity. In long-term studies, cyhexatin also caused increased retinal atrophy. No neurotoxic, genotoxic, or carcinogenic effects were observed with either compound. They were not teratogenic, but cyhexatin caused embryotoxicity in rabbits. A group ADI of 0–0.003 mg kg^{-1} bw and a group ARfD of 0.02 mg kg^{-1} bw for both compounds was established by the 2005 JMPR.
- Fentin in rats after acute oral administration has an LD50 of approximately 160 mg kg^{-1} bw. In developmental toxicity studies, fentin cause resorptions in pregnant rabbits at dose levels only slightly higher than it caused maternal effects on body weight. Multigeneration reproductive toxicity study in the rats showed increased susceptibility in the offspring (based on offspring toxicity [decreased litter size, liver and spleen weight] was seen at a dose lower than parental toxicity [decreased body weight gain]). No malformations were observed in any study. EPA has classified fentin as a probable human carcinogen (B2) based on evidence of carcinogenicity in mice (liver tumors) and rats (pituitary and testicular tumors). However, fentin is unlikely to be genotoxic *in vivo*. In short-term and long-term toxicity studies show fentin immunosuppressive properties (lymphopenia and lymphocyte depletion of spleen and thymus, resulting in altered humoral and cellular immunity). The US EPA established an ADI of 0–0.00003 mg kg^{-1} bw and an ARfD of 0.001 mg kg^{-1}.

Occurrence in Food

Copper

Copper is present in almost all foods, and most human diets naturally include between 1 and 2 mg per person per day of copper, with some containing up to 4 mg per person per day. In plants, copper is absorbed from soil through the roots. On foliar application, the transportation and distribution of copper in plants are limited. For instance, residue levels in treated crops such as tomatoes ranged from 1.9 to 3.9 mg kg^{-1}, table grapes from 2.2 to 12 mg kg^{-1}, and wine grapes from 2.2 to 56 mg kg^{-1}. The levels of copper in untreated crops (background) ranged from 0.15 to 1.2 mg kg^{-1} in tomatoes and 0.54 to 4.8 mg kg^{-1} in grapes. In the EU, the following MRL have been set: 5 mg kg^{-1} for tomatoes, 20 mg kg^{-1} for table grapes, and 50 mg kg^{-1} for wine grapes. The Theoretical Maximum daily intake (TMDI) was 245%, 38% and 22% of the ADI of 0.15 mg kg^{-1} bw day^{-1} for French adults, toddlers, and infants, respectively. Wine was by far the highest contributor to the copper intake estimated for adults. The TMDI for the general population based on the WHO consumption data was estimated as 62% of the ADI. The refined national (Germany and UK) estimated intakes (NEDI) for adults, children, toddlers, and infants were highest for the UK toddler at 26% of the ADI.

As exposure to copper is not due to residues from the use as a plant protection product, an aggregate exposure assessment was performed in EU, including background levels of copper in food and drinking water, based on a French dietary survey. This aggregate estimate shows that, in particular for children, the overall dietary copper exposure is not negligible and approximates the established toxicological reference value.

Daily copper intakes of adult European consumers due to untreated food correspond to 13–40% of the proposed ADI, whereas for children between 3–14 years correspond to 51% of the ADI. When in addition, the median residue levels (STMR) in treated grapes and tomatoes are considered, and the average content in water is replaced by the highest copper content of 0.5 mg l^{-1} in drinking water in France, the calculated NEDI represent 40%, 103% and 92% of the ADI for the French adults, infants, and toddlers, respectively.

Tin

- Azocyclotin and cyhexatin residues are generally low. Both the long-term (IEDI) and short-term (IESTI) risk assessments were reassuring. In fact, the IEDIs were calculated for the five GEMS/Food regional diets from the STMR and supervised trial median residues-processing (STMR-P) values for fruits and processed products, and they ranged from 0 to 5% of the ADI, whereas the IESTIs ranged from 3 to 20% of the ARfD.
- Fentin acute dietary risk from food in the USA is up to 34% of the ARfD, whereas it is $<5\%$ for the ADI (chronic noncancer dietary risk). The chronic cancer dietary risk from food was estimated to be 1.1×10^{-6}–8.7×10^{-8} for the general US population, depending on the exposure scenario chosen.

Organophosphates and Carbamates

A Moretto, University of Milano, Milan, Italy, and Luigi Sacco Hospital, Milan, Italy

Glossary

Absorption, distribution, metabolism, and excretion Absorption, distribution, metabolism, and excretion of a herbicide provides information on the extent and rate of absorption of a herbicide; tissues or organs receiving the highest exposures; the extent of metabolism and the types of metabolites formed; the rate and extent of excretion (clearance) from the body.

Acceptable daily intake Estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a subpopulation may be exposed daily over their lifetimes without appreciable health risk.

Acute reference dose Estimated maximum amount of an agent, expressed on a body mass basis, to which individuals in a subpopulation may be exposed during a meal or in one day without appreciable health risk.

International estimated daily intake Long-term (lifetime) intakes are obtained from the World Health Organization (WHO) Global Environment Monitoring System (GEMS)/Food Regional Diets that are based on per capita consumption.

International estimated short-term intake) Short-term intakes are based on a large portion of a commodity that is consumed on a single day both by the general population and by children aged 6 and under. The large-portion values are obtained from actual food consumption survey data for individuals identified as 97.5 percentile consumers of the commodity among eaters only.

LD50 Lethal dose 50%: the dose of a chemical that would be expected to kill half of a population of exposed organisms.

Pesticide formulation A product consisting of one or more active substances and other chemicals (such as solvents or surfactants) that enhance the application or effectiveness of the active substance.

Chemical Groups and Modes of Pesticidal Action

Organophosphates (OP) share a common chemical structure, but they differ significantly in the details of their structure, and hence in their properties and uses. Similar considerations can be applied to carbamates (CA). OP and CA insecticides represent two groups of chemicals that are usually dealt with together because they act on the same molecular target, neural acetylcolinesterase (AChE), in both mammals and insects. Their structural difference is reflected in some differences in the interaction with AChE, which in any case results in the inhibition of its enzymatic activity. There are only a few OPs (e.g., merphos) and a number of carbamates that are not significant AChE inhibitors and are not used as insecticides. For instance, the OP merphos was used as a cotton defoliant, the dithiocarbamates (e.g., mancozeb, maneb) are used as fungicides, the carbamates with a bulky substitution on the nitrogen (e.g., phenmedipham) or the thiocarbamates (e.g., molinate) are used as herbicides. These compounds will not be dealt within this article.

Uses

The range of uses of OP and CA insecticides is very broad, as are the application rates, varying by active substance, the crop to be used on, and the pest. It should also be noted that OPs and CAs are used in public health against vectors of diseases such as the malaria mosquitoes. In this case, some of these compounds are also allowed to be used indoors, based on certain toxicological and chemicophysical characteristics. In addition, other OPs, or even OPs used as insecticides, – were used for the treatment of human diseases such as parasitosis, myasthenia, or glaucoma.

OPs and CAs are the most used insecticides after the banning of most organochlorines such as DDT. Their use is now declining, especially for OPs, except in developing countries. In fact, in Europe (UK and Germany) the estimated sales of OPs declined from approximately 525 t to 258 t from 1995 to 2009, a reduction of a little more than 50%. Similarly in Japan, the decline was >40% from 2000 to 2009 (3350 t), in the USA >50% from 1995 to 2006 (17 000 t) and >70% from 1980 to 2006. On the contrary, in developing countries such as Bangladesh, there was a steady increase from 1995 to 2000 (+160%), to 2005 (+510%), to 2009 (+1000%) to approximately 8300 t. The trends for CAs were similar, except in Europe (UK and Germany) where there were minimal changes from 1995 to 2009, with sales being approximately 190 t. In 2009, sales were 494 t in Japan, and 23 000 t in Bangladesh.

Relevant ADME Characteristics

The absorption, distribution, metabolism, and excretion (ADME) characteristics of OPs and CAs vary. Most OPs and CAs are rapidly absorbed, metabolized, and excreted, but some OPs have a relatively long time of excretion (a few days as compared to a few hours). Hence, their effects after acute poisoning may last longer (e.g., fenitrothion). In urine, OPs are rarely excreted and only metabolites are generally found. The most known and usually determined ones are the alkylphosphates that are derived from most OPs; therefore finding them in urine gives little information on the individual compound to which the subject has been exposed. Some specific metabolites can be measured, including 3,5,6-trichloro-2-pirydinol from chlorpyrifos and p-nitrophenol from parathion. Details on the ADME of individual compounds can be found in publications such as WHO/International Programme on Chemical Safety (IPCS) Environmental Health Criteria, Food and Agriculture Organization (FAO)/WHO Joint Meeting on Pesticide Residues (JMPR) publications, European Food Safety Authority (EFSA) conclusions, or US Environmental Protection Agency documents.

Relevant Toxic Effects: From Acute Exposure and Repeated Exposure

The toxicity of OPs and CAs is due to the accumulation of acetylcholine at nerve terminals because of acetylcholinesterase inhibition. The compounds only differ in potency and duration of the effects. In particular, inhibition of AChE caused by CAs is rapidly (minutes–hours) reversible whereas that caused by OPs is essentially irreversible and takes many hours or even days to recover. For these reasons, repeated exposures to OPs over consecutive days may cause a cumulation of effects, whereas in the case of CAs, only acute, reversible effects can be observed that recover before the exposure during the following day. However, acute toxicities, as defined by the LD50, vary significantly and those of CAs overlap with those of OPs. For instance, the OP LD50 may vary from approximately 3 mg kg^{-1} bw (mevinphos) to $>10\,000$ mg kg^{-1} bw (malathion) similar to those of CA that range from approximately 1 mg kg^{-1} bw (aldicarb) to hundreds of mg kg^{-1} bw.

The signs of the cholinergic syndrome are typical and should be easily recognized by the physician. These include excessive salivation, lacrimation, sweating, urinary urgency, miosis, blurred vision, abdominal cramps, muscle fasciculation, and heart arrhythmias. More severe poisoning include bronchoconstriction, blurred vision, dizziness, confusion, convulsions, and coma. Besides unspecific supportive treatment, there are antidotes available against OP poisoning (atropine and oximes) that are not suggested for the self-limiting, rapidly reversible poisoning by CAs. Supportive treatment includes anticonvulsants such as benzodiazepines, and mechanical ventilation. If appropriate therapy is provided on time, and especially convulsions and hypoxia are prevented, full recovery occurs and no long-term sequelae are expected.

Children have been reported to be more sensitive to toxic effects than adults. However, this higher sensitivity applies only to acute high exposures and is due to the lower capacity of the detoxifying machinery that is overcome in children at somewhat lower doses that in adults. On the contrary, at low doses, such as those derived from residues in food, there appears to be no significant difference in sensitivity between the young and adults. Several OPs and CAs have been banned in industrialized countries because of high, acute toxicity (e.g., mevinphos, aldicarb) that caused both occupational and, rarely, foodborne poisoning. However, it should be noted that those episodes were subsequent to gross misuse of the compounds.

Certain OPs have been reported to cause a peripheral polyneuropathy, known as organophosphate-induced delayed polyneuropathy (OPIDP). However, only few of OPIDP-causing OPs are still on the market (e.g., methamidophos, dichlorvos) and they cause it only at doses causing severe, life-threatening acute poisoning, which can never occur as a consequence of their presence as residues in food.

The possibility of long-term effects following prolonged exposure to OPs (much less so to CAs) has been raised by several studies. However, except for individuals suffering from a previous acute poisoning, there is no compelling epidemiological or experimental evidence that this might be the case. In any case, such a possibility has only been raised as a consequence of nonfood exposure (e.g., occupational or environmental).

Details on the toxicity of individual compounds can be found in publications such as WHO/IPCS Environmental Health Criteria, FAO/WHO JMPR, EFSA conclusions, or US Environmental Protection Agency documents.

Occurrence in Food

OP and CA residues in food crops can be found in concentrations that depend on the compound, use rate, and crop.

The evaluation of active substances by the Joint FAO/WHO Meeting on Pesticide Residues includes a dietary risk assessment, based on the evaluation of the toxicological properties and the residue aspects of the compounds. For the assessment of the long-term intake of residues, the international estimated daily intake (IEDI) was calculated for different diets representative for relevant global regions. For the assessment of the short-term intake of residues, the international estimated short-term intake (IESTI) was calculated for relevant food commodities for which residue data and consumption data were available.

In summary, the long-term intake of residues of selected OPs and CAs (Table 1) is unlikely to present a public health concern, except that in a few cases, when based on a conservative approach as that used by the FAO/WHO. However, the short-term intake of residues of most of the OPs and CAs requires a closer scrutiny to identify which crops pose the higher risk (i.e., % acute reference dose (ARfD) >100) and may present a public health concern. For instance, a refinement of the assessment can be carried out by actually measuring (monitoring) the residue levels in marketed crops. This can also be applied to the few instances where the acceptable daily intake is exceeded. For instance, OPs and CAs are sought routinely in surveillance and monitoring schemes, and are found in less than 10% of the samples in the EU and at levels that are generally below (even well below) the maximum residue limits . Therefore, dietary exposures to OPs and

Table 1 Dietary risk assessment for selected OPs and CAs

Compound	*Long-term risk assessment*		*Short-term risk assessment*

Glossary

Acceptable daily intake The dose of a specific contaminant that may be absorbed daily by an individual for the whole life without an appreciable increase of the health risk.
Acute reference dose An estimate of a chemical substance in food or drinking water expressed in a body weight basis that can be ingested over a short period of time usually during one meal or in one day without appreciable health risk to the consumer.
Bioaccumulation The gradual build up over time of a chemical within a living organism, which occurs either because the chemical is taken up faster than it can be metabolized and excreted.
Biomagnification The increasing concentration of a substance in the tissues of organisms at successively higher levels in a food chain. As a result, organisms at the top of the food chain have higher levels (body burden) of a persistent toxin or pollutant than those at lower levels.
Contaminant Any biological or chemical agent, foreign matter, or other substances not intentionally added to food which may compromise food safety or suitability.
Food safety The assurance that food will not cause harm to the consumer when it is prepared and/or eaten according to its intended use.
Lipophilic It means having a strong attraction for fats/able to dissolve, be dissolved in, or absorb lipids (fats).
Monitoring The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a control measure is under control.
Provisional tolerable daily intakes Maximum doses that are set for substances that are anticipated to be without health risk to humans when taken daily over the course of time. They are expressed in one day time unit.
Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and, if needed, selecting appropriate prevention and control options.

Introduction

Organochlorinated pesticides (OCPs) are a structurally heterogeneous class of organic compounds composed primarily of carbon, hydrogen, and chlorine atoms. The chlorine atoms on the organic moieties contribute to the high stability, slow biodegradation, and high lipid solubility of most OCPs, properties that, in turn, lead to their accumulation in animal tissues, including humans. OCPs of a prominent environmental and public health concern include dichlorodiphenytrichlorolethanes (DDT complex), hexachlorocyclohexanes (HCH), cyclodienes, hexachlorobenzene (HCB), and other insecticides such as chlordecone and mirex. Some typical compounds are illustrated in Table 1.

OCPs have broad spectrum insecticidal activity and primarily act as excitatory neurotoxins, by altering the movement of ions across the nerve cell membranes, thus changing the ability of the nerve to fire. For example, DDT act through neurotoxicity by causing repetitive firing of nerve cells and makes them unable to fire in response to a signal. Lindane kills insects by stimulating the central nervous system (CNS) causing trembling, hyperexcitation, loss of coordination, paralysis, and eventually death. Cyclodienes act by blocking the chloride channel of gamma aminobutyric acid (GABA) receptors and inhibiting GABA-ergic neurotransmission. Dicofol inhibits electron transport during energy-producing mitochondrial electron transport and oxidative phosphorylation. By interrupting this process the insects fail to store energy for the later use. Pentachlorophenol acts mainly through an inhibition of phosphorilative oxidation, with a consequent block in energy storage and the fungicide HCB acts through an inhibition of porphyrins metabolism.

Table 1 Structures of some organochlorine pesticides of major environmental and toxicological concern

Description of substance	*Chemical structure*
1. Dichlorodiphenyl-ethanes *p,p′*- DDT IUPAC: 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane CAS No.: 50-29-3 Molecular formula: $C_{14}H_9Cl_5$; Formula weight: 354.49	p,p′-DDD IUPAC: 1,1-dichloro-2, 2-bis (4-chlorophenyl)ethane CAS. 5. Others Mirex IUPAC: 1,1a,2,2,3,3a,4,5,5a,5b,6-dodecachloroacta-hydro-1,3,4-metheno-1H-cyclobuta[cd]pentalene CAS No.: 2385-85-5 Molecular formula: $C_{10}Cl_{12}$; Formula weight: 545.5	Chlordecone (Kepone) IUPAC: 1,1a,3,3a,4,5,5,5a,5b,6-Decachlorooctahydro-2*H*-1,3,4-(methanetriyl)cyclobuta[*cd*]pentalen-2-one CAS No.: 143-50-0 Molecular formula: $C_{10}Cl_{10}O$; Formula weight: 490.64	
Uses of OCPs

OCPs have been used for several applications and were widely dispersed into the environment over the past 50 years. Now, many of these compounds are ubiquitously found as trace contaminants in soil, sediment, air, biota, and food, even in places where they were never used, including Antarctica. DDT has been employed as an insecticide in agriculture and public health. Banned for use in agriculture, its only permitted use is for indoor spraying of walls to control the malaria vector mosquito. It is estimated that 600 000 t of DDT was used domestically in the USA 30 years before its ban. Over 80% of the pesticide used during 1970–72 was applied to cotton crops and the remainder was used on peanut and soybean crops. Chlordane, heptachlor, and pentachlorophenol are used to treat wood to prevent pest damage. Under the Stockholm Convention on Persistent Organic Pollutants (POPs), the production and use of most of the older OCPs are restricted or banned. However, several OCPs are still being used.

For example, the annual production of endosulfan is estimated to range between 18 000 and 20 000 t worldwide. In the USA, 400 t is estimated to be used annually for domestic purpose. The main uses include control of pests in vegetables, fruits, cereal grains and cotton, ornamental shrubs, trees, vines, and ornamental plants. In Africa it is commonly used in cotton production at a dose rate between 0.1 and 0.2 t km^2, whereas in India it is used to control pests on cashew plantations at a dose rate of 0.12 t km^2. The estimated annual production in India is 9500 t, where 4500–5000 t is consumed domestically. Codex Alimentarius recommends maximum residue limits for endosulfan on several food commodities.

Another OCP in use is dicofol with an estimated global production of 5500 t per annum. In 2000, the use of dicofol in Europe was estimated to be 290 t, the same estimated annual use in North America. The average application rate is 0.044 t km^2. Dicofol is used for foliar spray on agricultural crops, such as beans, grapes, citrus, cucurbits, tomatoes, apple and cotton, and ornamentals. It is also used for mite control. DDT can be found as an impurity of dicofol because it is produced as an intermediate during its manufacture.

Lindane has been used to protect crop seeds from insects, for pest control in forests, on livestock and household pets for control of ticks and other pests, and in homes to control ants and other household pests. It is also used to control head lice and scabies in humans. The estimation of global production between 1950 and 2000 was 600 000 t, of which the majority was used in agriculture (Table 2).

OCPs entering the environment persist for long periods, in particular where ambient temperatures and UV irradiation are low. Owing to their appreciable volatility and chemical resistance to degradation, they are transported in the atmosphere, contaminating places very far from the sites of application or use, in general from tropical countries to the coldest areas of the world. Owing to health and environmental concerns associated with their biomagnification and accumulation, most OCPs were banned from use in most countries since 1970s. More recently, the production and use of 10 OCPs along with polychlorinated biphenyls and dioxins were banned under Stockholm Convention on POPs, but some exceptions were allowed (Table 3).

Relevant Absorption, Distribution, Metabolism and Excretion Characteristics

When OCP-contaminated food is consumed, the OCPs are rapidly absorbed from the small intestine and distributed throughout the body. Because OCPs are poorly biodegradable and strongly soluble in body lipids, they accumulate in body tissues with high lipid content, such as the adipose tissue, the brain, the liver, the kidney, and the myocardium. Thereafter a continuous exchange between blood and tissues takes place. In pregnant women these chemicals cross the placenta. In lactating women OCPs are secreted into breast milk, thus transferring the mother's burden to the young through breastfeeding.

Most of the limited OCPs biodegradation and elimination from the body takes place slowly through the kidney.

Source: Adapted from Moon H, Kim H, Choi M, Yu J, and Choi H (2009) Human health risk of polychlorinated biphenyls and organochlorine pesticides resulting from seafood consumption in South Korea, 2005–2007. *Food and Chemical Toxicology* 47: 1819–1825.

Although they are excreted to some extent in the bile, most are reabsorbed. Most OCPs have long elimination half-lives and can be detected in fat years after the last exposure. DDT has a half-life of approximately 3.4 years in adipose tissue. Dichlorodiphenyldichloroethylene (DDE), the principal DDT metabolite, is more stable than DDT and is rarely excreted from the body, but both are excreted in breast milk. Dieldrin has a half-life of approximately 267 days in blood, which is suspected to be shorter than those of heptachlor epoxide and α-, β-, and γ- isomers of HCH. Note that α- and β-HCH have no insecticidal activity and are contaminants of technical grade lindane. Comparing the three HCH isomers, β-HCH is eliminated very slowly from the body and thus has a significant contribution to the total HCH body burden. Its half-life in human blood is estimated to be approximately 7.2 years.

Prolonged half-lives in the body have some exceptions: for example, estimated half-life of endrin is 24 h, whereas that of lindane and chlordane is between 10 and 20 days. Aldrin is readily metabolized to dieldrin so that residues are rarely found in food and animals. 1,3-dichloropropene is excreted in urine as a mercapturic acid derivative and thioethers within few hours after absorption. Thus the degree of accumulation depends on metabolic rate, where slowly metabolized OCPs exhibit the highest accumulation rate and persist in the tissues for long periods of time.

Occurrence in Food

As a consequence of widespread environmental contamination and biomagnification along the food chain, OCPs are

present in foods at levels which show significant variability among countries and different areas within individual countries, in particular, in areas previously or currently used for intense agricultural activities with high levels of OCP application. The dietary intake thus varies among countries and population groups within countries, as exemplified by the data reported in **Tables 3–5**. World Health Organization has reported that the highest dietary intake of DDT and the older OCPs was in developing countries where some OCPs are still used or where their use was only recently banned.

Human exposure mainly occurs through trace environmental contamination of food, which accounts for more than 90% of total OCPs burden. Most food contamination occurs in meat and meat products, fish, milk, and other dairy products. Deposition of airborne OCPs on pasture is considered the primary pathway from which these pollutants enter the food chain,

although in regions with highly contaminated soil, green vegetables may significantly contribute to human exposure. Food-producing animals bioaccumulate OCPs in their adipose tissue through ingestion of contaminated pasture or the feed derived from contaminated fatty materials. OCPs are transferred to animal milk and enter into human diet through milk and dairy products. Although fish and seafood is a small fraction of human diet, it is a major route of exposure for Arctic populations who live on marine mammals, which are at the top of the marine trophic network, which serves to biomagnify the OCPs.

In the past, phenoxyacetates, widely used herbicides were found to be contaminated by dioxin. In particular formulations containing 2,4,5-trichlorophenoxy acid (2,4,5-T) were found to be contaminated by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin as well as other dioxin isomers. This caused episodes of significant environmental contamination where the highest levels were observed in 1970s, when phenoxy herbicides found high levels of use in rice crops.

Monitoring of OCPs in Food

Multiresidue analysis is usually employed to determine the levels of OCPs in foods for health risk assessment. Validated methods, including sampling, sample storage and transport, and sample processing and analysis, have been issued by several international agencies and national regulatory bodies. Following appropriate sample extraction and purification, analyses are usually performed by gas chromatography with electron-capture detection. For some OCPs, the use of high-resolution gas chromatography–mass spectrometry with stable-isotope labeled analogs as internal standards is preferred. Key analytical issues to obtain reliable data are not only sensitivity in the parts-per-trillion (nanogram per kilogram) range but also resolution of specific isomers, because of their toxicities, may be orders of magnitude different.

Health Effects of OCPs

The toxicity of OCPs in humans differs significantly and the CNS is the main target organ, where they cause either

depression or stimulation. Organochlorines disturb the neuronal membrane causing hyperexcitability of the nervous system. Cyclodienes, HCH, and toxaphene inhibit GABA-mediated chloride influx in the CNS, whereas DDT affects potassium and voltage-dependent sodium channels. Owing to its uncoupling effect on phosphorylative oxidation, pentachlorophenol acute toxicity is characterized by sudden liberation of energy by the body, with hyperpyrexia, tremors, profuse sweating, and convulsions.

DDT is capable of inducing alterations on reproduction and development in animals. This property is attributed to a hormone-altering action of DDT isomers and metabolites. *o,p′*-DDT isomer has the strongest estrogen-like properties, whereas *p,p′*-DDE has antiandrogenic properties and has been shown to alter the development of reproductive organs when administered perinatally to rats. Scarce and inconsistent evidence is available in humans, and the significance for human health of the estrogenic properties identified in laboratory animals remains unclear. However, certain studies suggest the need for further investigation. For example, one study reported a significant reduction of anal position index among babies born from mothers who suffered a significant increase of maternal *p,p′*-DDE serum levels during the first trimester of pregnancy. Other studies found that DDT exposure and altered menstrual cycles and human perinatal exposure to DDT at levels $>0.20\,\mu g\,l^{1}$ was associated with adverse effects on neurodevelopment up to the age of 4 years. Prepubertal exposure to DDT was associated with breast cancer in some studies, but not confirmed by others.

HCB has been shown to cause hepatic, neurological, developmental, endocrine, and immunological toxicity in human. In 1970s, consumption of bread produced with HCB contaminated seeds in Turkey caused an epidemic of chemical porphyria. The latter is caused by the ability of HCB to inhibit hepatic delta-aminolevulinate synthetase, delta-aminolevulinate dehydratase, and uroporphyrinogen decarboxylase enzymes, which are responsible for porphyrins metabolism. All isomers of HCH have been shown to produce liver and kidney effects with α- and β-isomers being much more toxic. Endosulfan has significant teratogenic effects in highly exposed laboratory animals, but there is no evidence of a similar effect in humans. *In vitro* studies have shown that this OCP can promote proliferation of human breast cancer cells, but there are no epidemiological studies linking exposure to endosulfan and increase of cancer risk in humans.

Epigenetic effects, attributable to an altered expression of specific genes due to impairment of DNA methylation balance, have been hypothesized for some persistent organic pesticides. Low doses of DDT have been shown to affect DNA methylation in experimental animals, whereas in studies carried out on Greenlandic Inuit populations suggest a significant inverse linear relationship between DNA methylation and plasma concentrations of DDT, DDE, β-benzenehexachloride, oxychlordane, α-chlordane, and mirex.

Health-based guidance values have been established by WHO and other international organizations (**Tables 4** and **5**). These are used as guidance during evaluation of safety through comparison with exposure estimated from measured levels of the chemical in specific foods and estimated dietary intake of those foods.

Risk Management of OCPs

Compounds with a potential for accumulation, such as DDT/DDE, dieldrin/aldrin, endrin, HCB, and β-HCH, can be found in animal products for weeks or months after exposure of the animal. Therefore, the risk for residues in animal products is considered to be high. Lindane (γ-HCH) and chlordane pose intermediate risks for residues in animal products. However, endosulfan, deltamethrin, and methoxychlor are rapidly metabolized and they are seldom found in animal products. The restricted use or banning of most OCP compounds in Western countries have limited possible threats they might pose to health.

Cessation of direct application as pesticides on animals and reducing their presence in their feed, housing, or pasture is the best way of controlling residues in animal products. In particular, control of OCP levels in feedstuffs is an important risk management intervention. If acceptable limits for residues are exceeded, removal of the contaminated items from the human food chain is necessary. For animals that are contaminated, extending the time before these animals or their products can be used for food can allow levels in their tissues to deplete. For growing animals, reduction in contamination levels due to dilution may also help to achieve a product in compliance with legal residue limits.

Conclusion

OCPs are a class of pesticides that were widely used in agriculture and public health because of their effectiveness over prolonged periods of time. However, health and environmental concerns have resulted in a ban on the production and use of most OCPs. Despite the ban, the persistence of residues of OCPs in the environment still results in the contamination of food, particularly foods of animal origin. Residues can also be found in the human body and in human milk around the world. Thus continued research is needed on these contaminants, their body burden and potential health effects, and ways to reduce their bioavailability in food. Moreover, effective policies are needed to control their manufacture and release into the global environment.

Pyrethroids

R Pfeil, Federal Institute for Risk Assessment, Berlin, Germany

Glossary

CS-syndrome An acute poisoning syndrome characterized by choreoathetosis and salivation, typically produced by high doses of type II pyrethroids.

Paresthesia An abnormal sensation, such as prickling, itching, or, when more severe, burning of the skin.

Pyrethrins Several esters extracted from the flowers of three species of *Chrysanthemum*, used chiefly as an insecticide.

Pyrethroids Any of a class of synthetic, pyrethrin-like insecticides with a mechanism of action similar to that of naturally occurring pyrethrins.

T-syndrome An acute poisoning syndrome characterized by whole-body tremors, typically produced by high doses of type I pyrethroids.

Type I pyrethroids Pyrethroids lacking an α-cyano group in the molecule.

Type II pyrethroids Pyrethroids containing an α-cyano group in the molecule.

Chemical Groups and Modes of Pesticidal Action

Pyrethroids are synthetic insecticides derived from the naturally occurring pyrethrins, the six insecticidal compounds of pyrethrum isolated from the *Chrysanthemum* genus of plants.

Like pyrethrins, pyrethroids are composed of two basic structural moieties, an acid and an alcohol. In most pyrethroids, the acid portion consists of chrysanthemic acid, a cyclopropane ring bonded to a carboxylic acid moiety, and a variety of halogenated and nonhalogenated substituents, which were introduced to increase their photostability. The alcohol portion is either a primary or a secondary alcohol, which is bound to a variety of heterocyclic structures. In addition, several pyrethroids have a cyano group bound to the α-methylene of the alcohol, which results in enhanced insecticidal potency of the compound. Compounds lacking the α-cyano substituent are termed type I pyrethroids (e.g., allethrin, bifenthrin, etofenprox, permethrin, phenothrin, resmethrin, and tefluthrin), whereas compounds with an α-cyano group are termed type II pyrethroids (e.g., cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, esfenvalerate, fenpropathrin, and τ-fluvalinate).

With a few exceptions, pyrethroids have 1-3 asymmetric carbon atoms. Compounds containing an asymmetric center may exist in two forms that are mirror images (enantiomers) and which are described as *R*- or *S*-configuration. For cyclopropanecarboxylic acid derivatives, only isomers with the *R*-configuration at C-1 position of the cyclopropane ring have substantial insecticidal activity, whereas the 1*S* isomers are not insecticidal. Furthermore, compounds containing two asymmetric centers at C-1 and C-3 position of the cyclopropane ring consist of two pairs of isomers, which are designated as *cis* and *trans*, based on the orientation of substituents of C-1 and C-3 in relation to the cyclopropane ring or the similarly restricting structure that may have been introduced to replace this ring.

The insecticidal properties of pyrethroids are due to their ability to disrupt the electrical signaling in the nervous system, an effect that is also relevant to mammals. Pyrethroids modify the gating characteristics of voltage-sensitive sodium channels in neuronal membranes to delay their closure. In general, type I pyrethroids prolong sodium channel opening only long enough to cause repetitive firing of action potentials (repetitive discharge) following a single stimulus. In contrast, type II pyrethroids prolong sodium channel opening for such long periods that the membrane potential becomes depolarized to the point that the generation of an action potential is impossible (depolarization-dependent block). Type I pyrethroids have a greater insecticidal activity when the ambient temperature decreases, whereas type II pyrethroids become more effective with increase in temperature.

Pyrethroids also decrease chloride channel currents, thereby increasing excitability, and it is likely that this action contributes to most characteristics of poisoning with type II pyrethroids. At relatively high concentrations, pyrethroids can also act on γ-aminobutyric acid (GABA)-gated chloride channels, which may be responsible for the seizures seen with severe type II pyrethroid poisoning.

Uses

Natural pyrethrins and the early pyrethroids (e.g., allethrin, resmethrin, and tetramethrin) are sensitive to photodegradation and have thus rarely been used in agriculture, with the exception of uses in glasshouses or in organic farming.

In commercial formulations, pyrethrins are often mixed with piperonyl butoxide, a synergist that increases insecticidal efficacy (but also toxicity) by the inhibition of pyrethrin metabolism. Additionally, the early pyrethroids are used as effective domestic insecticides that possess very low mammalian toxicity.

The introduction of light-stable pyrethroids in the early 1970s permitted to control numerous pests of agricultural significance. Pyrethroids are nonsystemic insecticides (i.e., no uptake through leaves and roots) with contact and stomach action and a rapid knockdown effect. They are effective against a wide range of chewing, sucking, and boring insects, particularly Coleoptera, Diptera, Heteroptera, Homoptera, Lepidoptera, Orthoptera, and Thysanoptera species in many crops (e.g., cereals, citrus, corn, cotton, fruits, hops, grapes, oilseed rape, potatoes, soya beans, sugar beet, vegetables, forestry, and ornamentals).

Owing to their high insecticidal activity, pyrethroids can be applied at dose rates as low as 2.5 g ha^{-1}, whereas the usual application rates vary widely between 5 and 200 g ha^{-1}, depending on the different intrinsic activities and/or different content of active isomers of the compounds.

In USA, approximately 900 tons active ingredient (a.i.) of permethrin and approximately 450 tons a.i. of cypermethrin have been applied annually to agricultural, residential, and public health usages. The great majority of use (>70% for permethrin and >85% for cypermethrin) occurred in nonagricultural settings. The annual usage of nonphotostable pyrethroids was <14 tons a.i. for allethrin, <23 tons a.i. for resmethrin, and 7–14 tons a.i. for tetramethrin, with the majority used for nonagricultural purposes.

In Germany, approximately 100 tons a.i. of pyrethroids have been marketed in plant protection products in 2009, with highest domestic sales reported for β-cyfluthrin, λ-cyhalothrin, etofenprox, α- and ζ-cypermethrin, bifenthrin, deltamethrin, esfenvalerate, and tefluthrin.

Apart from their use in agriculture, pyrethroids are of great importance for control of insect pests in public health and animal health. For example, in vector control programs, more than 520 tons a.i. of pyrethroids have annually been used worldwide.

Relevant Absorption, Distribution, Metabolism, and Excretion Characteristics

Because pyrethroids exhibit a wide structural diversity, there are some inherent differences in their absorption, distribution, metabolism, and excretion characteristics. Also, oral absorption data from toxicokinetic studies may be influenced significantly by the dosing vehicle and the dosing volume.

Absorption of pyrethroids from the gastrointestinal tract is rapid and usually incomplete, with estimates of approximately 30–70% of an orally administered dose for most compounds. First-pass metabolism may contribute significantly to a decrease in bioavailability. Once absorbed, pyrethroids distribute rapidly throughout the body and particularly into tissues with high-lipid content, including the central nervous system (CNS). For permethrin, deltamethrin, and λ-cyhalothrin, maximum plasma concentrations were achieved within 2–4 h. Plasma and brain half-life estimates were between 10 and 39 h and 14 and 35 h, respectively, whereas the half-life time in fat was up to 30 days. Owing to the slow elimination, pyrethroids may accumulate in fatty tissues when administered repeatedly.

The clearance rate is notably dependent on the structure, with *trans*-isomers hydrolysis being catalyzed by hepatic carboxylesterases, whereas hydrolysis of *cis*-isomers by oxidases is a relatively slow mechanism. Thus, the half-lives of *trans*-isomers are generally shorter by 2- to 10-fold than of their *cis*-counterparts. The slower breakdown of *cis*-isomers may contribute, in addition to their higher affinity to the sodium channel complex, to their greater mammalian toxicity. The rate of metabolism is also influenced by the presence of an α-cyano group, which slows both hydrolysis and oxidation.

Pyrethroids are metabolized rapidly by ester hydrolysis to their acid and alcohol components. This reaction is followed by hydroxylation and conjugation to glucuronides and sulfates, which are excreted in the urine. Generally, the metabolic reactions involved are exclusively detoxification processes, and data available suggest that the major esterase metabolites of pyrethroids lack neurotoxic activity.

Relevant Toxic Effects: From Acute Exposure and Repeated Exposure

The acute toxicity of pyrethroids to mammals varies widely, depending on the structure of the compound and the route of administration. Following acute oral exposure, the toxicity is strongly influenced by the dosing vehicle. Administration in aqueous suspensions gives normally lower acute oral toxicities than administration in vegetable oils, presumably because the low aqueous solubility of pyrethroids limits their bioavailability when administered in aqueous suspensions. With a few exceptions, most pyrethroids that are currently used in agriculture have oral lethal dose, 50% (LD50) values between 50 and 500 mg per kg body weight when administered in vegetable oils to rats and are therefore classified as 'moderately hazardous.' Pyrethroids with oral LD50 values of more than 500 mg per kg body weight, which are, therefore, classified as 'slightly hazardous' or 'unlikely to present acute hazard in normal use,' are mostly type I pyrethroids.

In general, pyrethroids have low acute toxicities following dermal exposure due to their limited absorption through the skin, whereas administration by routes that favor delivery to the CNS (e.g., intravenous injection) enhances the expression of acute toxicity.

Pyrethroids have been classified according to the acute intoxication syndromes they produce in rodents after administration of near-lethal to lethal doses. Signs of intoxication generally fell into one of two categories, which were designated the T-syndrome (tremor) and the CS-syndrome (choreoathetosis and salivation). In general, type II pyrethroids containing an α-cyano group produce the CS-syndrome, whereas type I pyrethroids lacking the α-cyano group tend to produce the T-syndrome. However, exceptions to this classification scheme have been noted because a few compounds produce elements of both syndromes (tremor and salivation).

The clinical effects produced by type I pyrethroids are characterized by aggressive sparring, increased sensitivity to external stimuli, fine tremors progressing to the whole body, spontaneous muscular contractions, hyperthermia, and death. The effects are generated largely by action on the CNS, but there is also evidence for repetitive firing in sensory nerves, which may be the mechanism causing paresthesia and the hyperexcitable state.

Because type II pyrethroids prolong the mean open time of sodium channels compared with type I compounds, they produce a more complex poisoning syndrome that involves salivation, increased extensor tone in the hind limbs, incoordination, tremors progressing to generalized choreoathetosis (writhing spasms), loss of consciousness, tonic seizures, and death. Unlike the type I pyrethroids, type II compounds generally decrease rather than increase the startle response to sound. Also, type II pyrethroids do not typically produce the repetitive activity in sensory nerves seen with type I compounds.

In repeated-exposure toxicity studies, the main target organ of pyrethroids was the nervous system, with clinical signs and neurobehavioral effects similar to those observed in acute toxicity studies. Microscopic lesions in peripheral nerves occurred only at lethal doses. Other findings at the highest dose levels were reduced body weight gain and liver enlargement, but this did not occur with all pyrethroids.

There is no evidence from epidemiological studies that pyrethroids induce cancer in humans. Also, long-term studies in experimental animals have not revealed a distinct carcinogenic hazard relevant to humans, although increased incidences of certain tumors in rodents have been observed occasionally.

Pyrethroids were generally not genotoxic in standard tests in bacteria, yeasts, mammalian cells *in vitro*, and rodents *in vivo*.

Pyrethroids did not impair the mating capacity and fertility in experimental animals. No evidence of teratogenicity was observed in experimental animals, even at doses producing clinical signs of maternal toxicity.

Neonatal rats are approximately 6–17 times more sensitive than adults to acute high-dose toxicity of type I and II pyrethroids, probably due to their incompletely developed detoxification enzyme system of the liver rather than greater sensitivity of the neonatal CNS.

Developmental neurotoxicity studies in mice exposed to pyrethroids during postnatal days 10–16 identified changes in motor activity and muscarinic acetylcholine receptor density in the brain of adult mice. However, a review of 22 developmental neurotoxicity studies in rodents did not reveal a consistent pattern of pyrethroid-induced effects on the CNS of a developing rodent, and further well-designed studies are needed to identify the potential neurotoxicity of pyrethroids after exposure during early development periods.

Human cases of systemic poisoning are rare and usually result from accidental exposure or intentional ingestion of pyrethroids, particularly the more potent type II compounds. Massive ingestion gives rise to sore throat, nausea, vomiting, and abdominal pain within minutes. Further systemic effects occurring 4–48 h after exposure include dizziness; headache; fatigue; increased secretions; and in rare, severe cases convulsions and coma.

Dermal exposure can result in transient paresthesia with many pyrethroids, presumably due to hyperactivity of cutaneous sensory nerve fibers, whereas inhalation exposure can result in upper airway irritation.

Occurrence in Food

The evaluation of active substances by the Joint Food and Agriculture Organization/World Health Organization Meeting on Pesticide Residues includes a dietary risk assessment, based on the evaluation of the toxicological properties and the residue aspects of the compounds. For the assessment of the long-term intake of residues, the International Estimated Daily Intake was calculated for different diets representative for relevant global regions. For the assessment of the short-term

Table 1 Dietary risk assessment for selected pyrethroids

Compound	*Long-term risk assessment*		*Short-term risk assessment*	
	ADI (mg per kg body weight)	*IEDI (% of the maximum ADI)*	*ARfD (mg per kg body weight)*	*IESTI (% of the ARfD)*
Bifenthrin	0–0.01	8–20	0.01	Ch: 0–430 GP: 0–230
Cyfluthrin, β-cyfluthrin	0–0.04	0–2	0.04	Ch: 0–240 GP: 0–120
Cyhalothrin, λ-cyhalothrin	0–0.02	3–10	0.02	Ch: 0–60 GP: 0–40
Cypermethrins (including α- and ζ-cypermthrin)	0–0.02	7–30	0.04	Ch: 0–40 GP: 0–20
Deltamethrin	0–0.01	20–30	0.05	Ch: 0–130 GP: 0–58
Esfenvalerate	0–0.02	50–70	0.02	Ch: 0–10 GP: 0–3
Fenpropathrin	0–0.03	3–80	Not established	Not calculated

Abbreviations: ADI, acceptable daily intake; IEDI, international estimated daily intake; ARfD, acute reference dose; Ch, children 6 years and below; GP, general population.

intake of residues, the International Estimated Short-Term Intake (IESTI) was calculated for relevant food commodities, for which residue and consumption data were available.

In summary, the long-term intake of residues of selected pyrethroids (Table 1) is unlikely to present a public health concern. Also, the short-term intake of residues of most of the selected pyrethroids is unlikely to present a public health concern, with the exception of ifenthrin (IESTI $>100\%$ for strawberries), cyfluthrin (IESTI $>100\%$ for head cabbage and/or broccoli), and deltamethrin (IESTI $>100\%$ for spinach and Chinese cabbage for children). However, higher than 100% should not necessarily be interpreted as giving rise to a health concern because the assessments are based on conservative assumptions and, therefore, refinements of those estimates are possible.

VETERINARY DRUGS RESIDUES

Contents

Veterinary Drugs – General

SF Sundlof, Senior Vice President for Regulatory Affairs, Kindred Biosciences, Inc., San Francisco, CA, USA

Glossary

Acceptable daily intake The amount of total residue that can safely be consumed per day over a human's lifetime. The ADI is calculated by dividing the no observed adverse effect level (from the most appropriate toxicological study) by a safety factor.

Marker residue The residue selected for assay by the regulatory method. In general, the marker residue is a subset of the total residue; for example, the marker residue could be the parent drug, a metabolite, or a combination of residues.

Maximum residue limit The maximum concentration of a marker residue or other residue indicated for monitoring that can legally remain in a specific edible tissue of a treated animal.

No observed adverse effect level The highest dose level of a drug tested that produces no observable effects. It is expressed usually in mg kg^{-1} bw day^{-1}.

Regulatory method The aggregate of all analytical procedures for quantifying and confirming the presence of the marker residue in the target tissue of the target animal.

Target animal The species and animal production class for which the veterinary drug has been authorized.

Target tissue The edible tissue selected to monitor for residues in the target animals.

Total residues The aggregate of all compounds that result from the use of an animal drug, including the drug, its metabolites, and any other substances formed in or on food because of such drug use.

Veterinary drug residue Any compound present in edible tissues of animals that results from the use of a drug and includes the drug, its metabolites, and any other substance formed in or on food because of the drug's use.

Withdrawal period The duration of time following administration of a veterinary drug required to assure that drug residues in animal-derived foods are below a determined maximum residue limit.

Veterinary Drugs and History of Use

Throughout recorded history, humans have endeavored to treat diseases with medicinal substances. The development of drugs for treating animals occurred simultaneously with the development of human drugs, and little distinction was made between human and animal medicine until recent times. As early as 2000 BC, the Egyptians recorded in the Kahun papyrus prescriptions for treating animal diseases and uterine diseases of women. However, it was not until the Twentieth Century that governments began to regulate the manufacturing, labeling, conditions of use, and sale of human and veterinary drugs. The Food and Drug Administration in the United States was the first government agency in the world to attempt broad scientific review of foods and drugs, and in the present day, most developed countries have adopted similar regulatory schemes.

In 1996, the International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) was established under the auspices of the World Organisation for Animal Health to harmonize the studies and data requirements for veterinary drug marketing authorization across countries and regions. With regard to food safety, the role of VICH is to harmonize technical requirements but not to assess data or establish any safety standards. That

responsibility rests with Codex Alimentarius Commission, which establishes maximum residue limits (MRLs) for residues from veterinary drugs in foods of animal origin on international level primarily based on risk assessments performed by the Joint FAO/WHO Expert Committee on Food Additives (JECFA).

The basic tenets of veterinary drug regulation dictate that the drug must be safe for the animal, effective for its intended use, and manufactured to a high standard of quality. The demonstration of drug safety, efficacy, and quality is a rigorous and demanding process that relies on data generated through high quality, well-controlled, scientific studies. For veterinary drugs intended for use in food-producing animals, the safety assessment also requires that food from animals treated with the drug will not harm consumers. This article will focus on the food safety evaluation of veterinary drugs used in food-producing animals (risk assessment) and the procedures used to mitigate any potential harm to consumers caused by residues of veterinary drugs in animal-derived foods (risk management).

Drug Use in Food-Producing Animals

The Codex Alimentarius Commission defines a veterinary drug as any substance applied or administered to any food-producing animal such as meat or milk of animals, poultry, fish, or bees, whether used for therapeutic, prophylactic or diagnostic purposes, or for modification of physiological functions or behavior. This broad definition includes drugs for:

- treatment of diseases or other pathological conditions.
- prevention of diseases or other pathological conditions.
- diagnosis of diseases.
- zootechnical purposes such as estrus synchronization, induced ovulation, chemical castration, etc.
- improved production such as increase in growth rate, feed efficiency, milk production, etc.
- behavior modification, such as tranquilizers.

In the European Union, some substances such as anticoccidial compounds administered in animal feed are regulated as feed additives; however, these substances are considered to be veterinary drugs within the Codex Alimentarius Commission.

Veterinary Drug Residues and Food Safety

To protect consumers from adverse health effects caused by foodborne residues of veterinary drugs, developed and many developing countries maintain strict controls on authorization, labeling, and use of veterinary drugs in food-producing animals. National authorities further conduct surveillance programs to detect drug residues in animal tissue at levels greater than the maximum legal limit, i.e., MRLs, and take enforcement actions against those responsible for the violation. The Codex Alimentarius Commission has examined the most commonly used veterinary drugs and established appropriate MRLs for meat, poultry, fish, milk, eggs, and honey. These international standards not only assist government authorities in protecting their domestic food supply but also greatly facilitate international trade in animal-derived foods.

Dietary exposure to veterinary drug residues can cause acute or chronic adverse health consequences depending on the drug and dose. Acute responses can result from anaphylactic or pharmacologic reactions; however, these appear to be rare events. Anaphylactic reactions have been reported in previously sensitized individuals following consumption of milk or meat containing residues of penicillin. Outbreaks of food poisoning in several countries have been caused by consumption of liver from cattle and pigs treated illegally with the beta agonist drug clenbuterol to increase growth rate. Symptoms included palpitations, nausea, vomiting, dizziness, chest tightness, uneasiness, trembling, and instability.

Of greater concern are the adverse health consequences caused by chronic dietary exposure to drug residues at subacute doses. In authorizing the marketing and use of veterinary drugs, regulatory bodies establish the conditions of use, often called good veterinary practice, to ensure that any residues in animal-derived foods will not cause harmful effects when consumed over a lifetime. Hazard identification and characterization for veterinary drug residues are essentially the same as for food additives, and pesticides use the same methods and evaluation criteria. However, the safety assessment is made more complicated by the pharmacokinetics of the drug in the target animal to which the drug was administered. Drugs administered orally may be completely, partially, or not absorbed at all. Following absorption, drugs are distributed to the various tissues and organs. Lipophilic drugs will concentrate in tissues and fluids with high fat content, such as muscle and milk. Hydrophilic drugs tend to accumulate in highly perfused tissues such as the kidneys. Many drugs bind to plasma proteins thus restricting their distribution to the intravascular space. Drugs are metabolized to various degrees depending on their chemical structure and the capacity of the target animal species to transform the drug. Finally, drugs and their metabolites are eliminated by the animal through various routes. The most important routes are renal and hepatic, but lipophilic drugs tend to be excreted in milk as fat deposits are mobilized during lactation. All these factors affect the concentration of residues in animal-derived foods and must be taken into account in calculating the MRL and withdrawal period.

Toxicological Testing

Toxicological testing for veterinary drugs is based on the same battery of tests used in evaluating food additives and pesticides. Testing should include an assessment of systemic toxicity, reproduction toxicity, developmental toxicity, genotoxicity, carcinogenicity, and effects on the human intestinal flora. In general, oral administration is the route of choice for *in vivo* tests.

Systemic Toxicity Testing

Repeat-dose toxicity testing should be performed to define:

1. Toxic effects based on repeated and/or cumulative exposures to the compound and/or its metabolites,

2. Incidence and severity of the effect in relation to dose and/or duration of exposure,
3. Doses associated with toxic and biological responses, and
4. A dose with no observed toxic or biological response.

Reproduction Toxicity Testing

Multigeneration reproduction studies are designed to detect any effect on mammalian reproduction. These include effects on male and female fertility, mating, conception, implantation, ability to maintain pregnancy to term, parturition, lactation, survival, growth and development of the offspring from birth through to weaning, sexual maturity, and the subsequent reproductive function of the offspring as adults.

Developmental Toxicity Testing

Developmental toxicity testing is used to detect any adverse effects on the pregnant female and development of the embryo and fetus consequent to exposure of the female from implantation through the entire period of gestation to the day before cesarean section. Such adverse effects include enhanced toxicity relative to that observed in nonpregnant females, embryo-fetal death, altered fetal growth, and structural changes to the fetus.

Genotoxicity Testing

A battery of genotoxicity tests are used to identify substances that have the capacity to damage the genetic information within cells. Substances that are considered to be genotoxic should be regarded as potential carcinogens. Those that cause genetic damage in germ cells also have the potential to cause reproductive/developmental effects.

Carcinogenicity Testing

Compounds that are suspected to have carcinogenic potential are tested by the oral route for carcinogenicity. The decision to conduct carcinogenicity testing is based on all available data including results of genotoxicity testing, structure activity relationship information, and results of repeat-dose and mechanistic studies. Carcinogenicity testing is performed using a carcinogenicity bioassay. However, information derived from a combined assay for carcinogenicity and chronic toxicity may also be acceptable.

Testing for Effects on the Human Intestinal Flora

For compounds with antibacterial properties, testing is conducted to determine the effects of residues of the drug on the human intestinal flora.

ADI Determination

The toxicological tests are designed to determine the dose at which the compound produces an adverse effect and a dose which produces no observed adverse effect. If the drug is not a carcinogen, the no observed adverse effect level of the most sensitive effect in the most sensitive species is divided by a safety factor (usually 100) to calculate the acceptable daily intake (ADI) for drug residues.

MRL Determination

To assess exposure to veterinary drug residues from the diet, it is necessary to determine the daily consumption of animal-derived foods by the general population. Table 1 lists the consumption values for a 60 kg adult that the JECFA has established to calculate MRLs. This model diet is intended to provide a conservative estimate of dietary exposure.

The safe concentration is the maximum concentration of total residues (parent drug and metabolites) in each edible tissue that when consumed in the amounts, listed in Table 1, will not exceed the ADI.

$$\text{Safe concentration} = \frac{\text{ADI } \mu\text{g kg}^{-1} \text{ daily} \times 60 \text{ kg}^{-1}}{\text{grams consumed day}^{-1}} \quad [1]$$

Because it is not practical for regulatory purposes to monitor total residues in edible tissues, a single analyte, designated as the marker residue, is selected whose concentration is in a known relationship to the concentration of the total residue in the last tissue (target tissue) to deplete to its safe concentration. The target tissue and marker residue are selected so that the absence of marker residue above a designated concentration (MRL) will confirm that each edible tissue has a concentration of total residue at or below its safe concentration.

$$\text{MRL} = \text{Safe concentration } \mu\text{g g}^{-1} \frac{\text{Marker residue } \mu\text{g g}^{-1}}{\text{Total residue } \mu\text{g g}^{-1}} \quad [2]$$

In the United States, MRLs are considered to be food safety standards because they are derived from the ADI; however, the Codex Alimentarius Commission, EU, and other countries perform a second calculation based on good veterinary practice. If the levels of residues estimated from supervised trials, when the drug is administered according to good veterinary practice, are below the MRL as calculated in eqn [2], then the levels determined by good veterinary practice will dictate the

Table 1 Daily consumption values

Edible product	*Grams consumed*
Muscle	300
Liver	100
Kidney	50
Fat	50
Eggs	100
Milk	1500
Honey	50

MRL, provided that practical analytical methods are available for routine residue analysis. Finding residues above MRLs based on good veterinary practice indicates that the veterinary drug has been misused but does not necessarily imply a food safety risk.

Establishing Withdrawal Periods

The withdrawal period is a risk management tool designed to ensure that veterinary drug residues will deplete to levels at or below the MRL when the drug is used in accordance with good veterinary practice.

Establishing a withdrawal period requires data collected from residue depletion studies in the target animal population. The studies are designed to simulate the conditions of use paying particular attention to the proposed dosing regimen, normal husbandry conditions, animal gender, and animal maturity. Animal treatment should be consistent with the intended product label including, for injectable products, the location and injection method. The highest intended treatment dose is administered for the maximum intended duration. Tissues for residue analysis are collected from animals as a function of time after the final treatment.

For residue studies in tissues, marker residue data are obtained from the target tissue of at least 16 animals with four animals being slaughtered at each of four evenly distributed time points. For residue studies in milk, sufficient data are provided by at least 20 animals with milk collected from all animals at evenly spaced time points.

Residue concentrations are transformed logarithmically, and their depletion is plotted over time followed by linear regression analysis. The withdrawal period is the point on the regression line in which the marker residue is at or below the MRL in 99% of the target animal population with a confidence level of 95%. This practically assures that food from an animal treated with a drug in accordance with good veterinary practice will not contain residues above the MRL. The combination of MRLs, withdrawal periods, and good veterinary practice is essential to maintaining a safe food supply.

Risk Management at the International Level

Codex established the Codex Committee on Residues of Veterinary Drugs in Food in 1986. Since that time, Codex has adopted 590 MRLs for some 59 veterinary drugs. Most countries use Codex MRLs as a basis for establishing their national regulations for veterinary drug use. Although, harmonization has been achieved for a wide variety of veterinary drugs, differences in food safety policies among countries have resulted in difference in MRLs, permitted uses, and marketing authorizations, some of which have disrupted trade, such as the dispute between the USA and EU on the use of hormones in beef cattle. Another contentious trade issues is the use of ractopamine in finishing swine.

VETERINARY DRUGS RESIDUES

Antibacterials

S Fanning, J Wang, and N Leonard, University College Dublin, Dublin, Ireland

Glossary

Actinomycete A group of Gram-positive bacteria with high guanine and cytosine content in their DNA.
Efflux pumps Proteinaceous transporters localized in the cytoplasmic membrane of all bacterial cell types that can contribute to antimicrobial resistance. Transmembrane spanning proteins that vary in structural complexity.
Metaphylaxis The administration of drugs to herds of animals as therapy for sick animals combined with prophylaxis in healthy animals.
Mobile genetic element (MGE) MGEs include plasmids and conjugative transposons and these DNA structures can contain one or more antimicrobial resistance-encoding gene(s).
Prophylaxis The administration of drugs to herds of animals to prevent the emergence of disease.
Transposons DNA sequences that move from one location on the genome to another and are frequently called 'jumping genes.'
Zoonosis Any infectious disease that can be transmitted between species from animals to humans or from humans to animals (the latter is sometimes called reverse zoonosis or anthroponosis).

Use of Antibacterial Compounds in Food-Producing Animals

Food-Producing Animals

Traditionally, the important food-producing animal species include cattle, pigs, and poultry. Other minor species are sheep, ducks, goats, llamas/alpacas/camels, deer, rabbits, and some wild game. To assure the long-term care, health, and welfare of food-producing animal species, antibacterial compounds are used for treatment. These same drugs can also be given prophylactically to prevent infectious diseases in both domestic and food-producing animals, including fish. On occasion, certain antibacterial classes can be used as growth promoters to improve feed conversion efficiency when poultry, pigs, and feedlot cattle are being intensively reared. In such cases, antibacterial drugs are administered to all animals in the group, flock, or herd, via the animals' feed or drinking water.

Antibacterial Drugs Licensed for Use in Food-Producing Animals

In general, antibacterial compounds are used for three purposes in animals: therapeutic use to treat sick animals; prophylactic use to prevent infection in flocks/herds of food-producing animals; and as growth promoters to improve feed utilization and reduce production time. In 2011, Bush and coworkers indicated that more than 50% of the antibiotics produced are included as components in animal feeds to promote growth. This practice has been ongoing since the 1950s, despite efforts to prevent such use by several agencies including the World Health Organization (WHO) and the European Union (EU).

Europe has adopted a proactive stance on the use of antimicrobials. On 1 July 1999, the EU banned the use of most antimicrobial agents for growth promotion in an effort to preserve the efficacy of important human drug classes. The EU also established the European Antimicrobial Resistance Surveillance System to monitor levels of resistance in important human pathogens. On 1 January 2006, the EU banned the feeding of all antimicrobials and related drugs to food-producing animals for growth-promoting purposes. Currently, in Europe, no antimicrobial agents can be used in farm animals for growth promotion purposes. In 2004, the US Food and Drug Administration (USFDA) banned enrofloxacin (a fluoroquinolone (FQ) prescribed for therapeutic purposes and not growth promotion) in chickens and turkeys on the grounds that its use contributed to the increase in FQ resistance, being detected in bacterial pathogens isolated from humans. Subsequently, this move was followed in April 2012 by an order that prohibits certain uses of the cephalosporin class of antimicrobial drugs in cattle, pigs, chickens, and turkeys, in an effort to preserve the efficacy of cephalosporins for the treatment of infections in humans. Table 1 provides a list of the 16 antimicrobial classes along with specific drugs in each class that are available as commercial preparations for use in food-producing animals. The agents listed in Table 1 are approved by the USFDA. Agents approved for use in other countries vary greatly depending on national regulations.

Discovery of Antibacterial Drug Classes, Their Mode of Action, and Use in Food-Animal Production

Discovery of Antibacterial Drugs

The origin of antimicrobial agent discovery can be traced to 1929 when Alexander Fleming recognized the antibacterial activity of a substance secreted by *Penicillium notatum* on a contaminated culture plate. Subsequently, the first synthetic chemotherapeutic agents, the sulfonamides, were developed by Gerhard Domagk in 1935. Following these events, Selman Waksman announced the discovery of a new antibiotic, streptomycin, which was produced by the actinomycete, *Streptomyces griseus*. Over the following decade, microorganisms producing chloramphenicol, neomycin, and tetracyclines were isolated and studied. By the 1970s, it was widely accepted that antibacterial therapy signaled the end of bacterial infections as a significant cause of mortality in human and animal populations. However, this misguided optimism was dispelled by the emergence of antimicrobial resistance, resulting from the widespread use of these therapeutic agents. Veterinary public health professionals are now confronted by resistant bacterial pathogens and the transfer of these resistant microbes, or resistance elements contained therein, from animals to humans. The latter could be considered as a modern zoonosis.

Modes of Action of Antibacterial Compounds

Antibacterial compounds used in the treatment of bacterial infections fall into relatively few groups or families according to their principal mechanism of action. There are five recognized modes of action that can be outlined briefly, as follows:

Inhibition of Cell Wall Synthesis

Because peptidoglycan is a unique component of bacterial cell walls, antibacterial agents that prevent the cross-linking of peptidoglycan chains inhibit cell wall synthesis and are considered to be selectively toxic for bacteria. β-Lactams are a class of antibacterial agents that can target bacterial cell wall synthesis, and these compounds specifically act on the transpeptidation step during the synthesis of peptidoglycan. These β-lactam antibiotics bind cell receptors known as penicillin binding proteins, thereby inhibiting their activity. In addition to interfering with transpeptidation, many of these drugs promote autolysin activity causing cell lysis. The penicillins and cephalosporins comprise the largest and most important class of antibacterial drugs which inhibit the cell wall synthesis. Bacitracin and glycopeptides also interfere with cell wall synthesis by preventing the cross-linking steps required during this process.

Disruption of Cell Membrane Structure

Comparatively few antibacterial drugs act on the bacterial cell membrane. As antibacterial agents of this type are more toxic for animal cells when compared to other classes, their use is generally limited to topical application(s). Polypeptides represent one group that interfere with the normal functioning of the bacterial cell membrane.

Inhibition of Nucleic Acid Synthesis

Quinolone and FQ antimicrobial agents act by binding to bacterial topoisomerases and interfering with DNA replication and supercoiling of the chromosomal structure. Rifamycins target a subunit of the RNA polymerase enzyme and inhibit bacterial DNA-dependent RNA synthesis.

Inhibition of Protein Synthesis

Protein synthesis is a process targeted by a number of different classes of antibacterial agents. The selective toxicity of some relates to the key differences in structure between prokaryotic and eukaryotic ribosomes. This mode of action is characteristic of aminoglycosides, aminocyclitols, amphenicols, macrolides, lincosamides, streptogramins, and tetracyclines.

Inhibition of a Unique Bacterial Metabolic Pathway

Sulfonamides and trimethoprim target the folic acid biochemical pathway of bacteria. These antibacterial compounds are termed folic acid pathway inhibitors. Sulfonamides interfere with the formation of folic acid, an essential precursor for nucleic acid synthesis. The synthetic pyrimidine derivative, trimethoprim, inhibits the activity of dihydrofolate reductase, a later step in this anabolic pathway. When used in combination, the action of each agent is potentiated resulting in enhanced activity against bacteria. Potentiated sulfonamides are selectively toxic for bacteria because animals can absorb preformed folic acid from their feed. Figure 1 provides a brief schematic summary of the different classes of antibacterial drugs and their corresponding target sites within the typical bacterial cell.

Use of Antibacterial Drugs in Food-Animal Production

Antibacterial drugs are used in food-producing animals primarily to control infectious diseases caused by various pathogenic bacteria. Therapeutic use generally involves the treatment of sick animals on an individual basis, but on occasion it can require the use of medicated feed or water to treat a group, herd, or flock of animals.

It is not uncommon for veterinarians to administer antibacterial drugs to animals which are not showing any clinical signs of infection, but which are at high risk of becoming infected. Herds or flocks of food-producing animals may be given antibacterial drugs if there is a risk of an outbreak of infectious disease due to exposure to a particular disease agent and/or when unfavorable host or environmental conditions arise. Application of antibacterials to prevent infection is referred to as prophylaxis, and in food-animal production, this is a common practice during stressful periods of an animal's life such as following transport of (beef) animals to feedlots or at the weaning stage of production for pigs. Prophylactic or metaphylactic use of antibacterials can aid in the control and prevention of animal diseases in both food and companion animals. However, use of antibacterials should never be intended to replace the requirement for good management practices, given that their use may eventually lead to resistance.

Importantly, veterinary public health professional bodies are now developing and adopting guidelines and codes of practice for the prudent use of antibacterial compounds. These guidelines highlight the need for proper laboratory confirmed diagnosis, specific therapy, and judicious use of these chemotherapeutic agents for a defined period.

Antibacterial Resistance and Public Health

Linking the Use of Antibacterials in Food-Animal Production and Public Health

Several different classes of antibacterials are now recognized (Table 1) and many of these are used in both animal and human medicine. Bacteria of food-animal origin elaborating a resistance phenotype to a particular drug class, could compromise chemotherapeutic treatment in a human when either the same drug or a different member of this drug class is used. Table 2 identifies the major classes of antimicrobial agents used in both animal and human medicine.

Furthermore, bacteria of animal origin can act as a reservoir of resistance genes, which are frequently carried on mobile genetic elements (MGEs) and these MGEs can be transmitted to other animal and human pathogens alike. In a recent study on bovine *E. coli* isolates recovered from Irish farms, resistance to ampicillin, neomycin, streptomycin, sulfonamide, and tetracycline was associated with integrons and MGEs, such as transposons and conjugative plasmids, which highlight the importance of the commensal microflora of food-producing animals as a reservoir of transferable multidrug resistance. It has been suggested that those antibacterials that are important in human medicine should not be used therapeutically in food-producing animals, particularly for mass medication.

Antibacterial Resistance Mechanisms

Four mechanisms account for bacterial resistance to antibacterials. These include the following:

1. Enzymatic degradation of the drug (often referred to as drug inactivation).
2. Structural modification of the drug target (drug-target modification).
3. Reduced permeability of the drug.
4. Active export of the drug (reduced intracellular accumulation associated with reduced membrane permeability or increased drug efflux).

Bacterial resistance can be defined in broad terms, as either innate (intrinsic) or acquired (extrinsic). Innate resistance relates to the general physiology of a bacterium arising from its phenotype and can include the complexity of the bacterial cell wall structure, activity of a bacterium's efflux pumps, or enzymatic inactivation of an antibacterial agent. In *Salmonella* one of the main mechanisms of antimicrobial resistance is the overexpression of efflux pumps. Chemically modulating the activity of efflux pumps may present a new therapeutic approach to target resistant bacteria, through the use of efflux pump inhibitors in combination with the antibacterials to which the microorganism is already resistant. In contrast, acquired resistance can arise from a mutation in a resident gene or the acquisition of exogenous genetic material encoding resistance genes via conjugation; transformation, and/or transduction. These mechanisms involve different MGEs including conjugative plasmids and transposons; the uptake of naked DNA and bacteriophages carrying resistance genes. The same class of antimicrobial-resistant genes or closely related genes can often be identified in different bacterial species, pointing to the fact that horizontal gene transfer occurs between bacteria of the same genus and between unrelated genera. Thus, resistance genes have the potential to spread widely among both pathogenic and commensal bacteria, alike. Figure 2 provides a schematic summary of the general mechanisms involved in the development of antimicrobial resistance. Each of these resistance mechanisms has one or more genetic components and these genes may be chromosomally located or carried on an MGE.

Cross-Resistance

This occurs when a single resistance mechanism confers resistance to more than one member of an antimicrobial class. In some cases where compounds have overlapping targets in the organism, resistance to chemically unrelated agents can occur. For example, if resistance to any of the three antimicrobial classes, macrolides, the lincosamides, or streptogramin B is present in an organism, the use of one of these antimicrobials will result in the selection and maintenance of resistance to all three antimicrobial classes (cross-selection). This is because all three of these classes have target sites on the bacterial ribosome and a change in the structure of ribosomal RNA results in cross-resistance to all three classes of the drug.

Table 2 Major classes of antimicrobials shared by food-producing animals and humans

Class of antimicrobial	*Selected examples of agents within each class*
β–lactams	Penicillin, amoxicillin, and ceftiofur
Macrolides and lincosamides	Tylosin[a] and tilmicosin[a], tulathromycin[a], and lincomycin
Aminoglycosides	Gentamicin and neomycin
Colistin	Colistin sulfate and colistimethate sodium
Fluoroquinolones	Enrofloxacin[a], danofloxacin[a], ciprofloxacin
Tetracyclines	Tetracycline; oxytetracycline, and chlortetracycline
Sulfonamides	Sulfamethoxazole and sulfadiazine
Streptogramins	Quinupristin/dalfopristin[b] and virginiamycin[a]
Polypeptides	Bacitracin
Phenicols	Florfenicol[a]
Pleuromutilin	Tiamulin[a] and retapamulin[b]

[a]Used in animals only.
[b]Used in humans only.

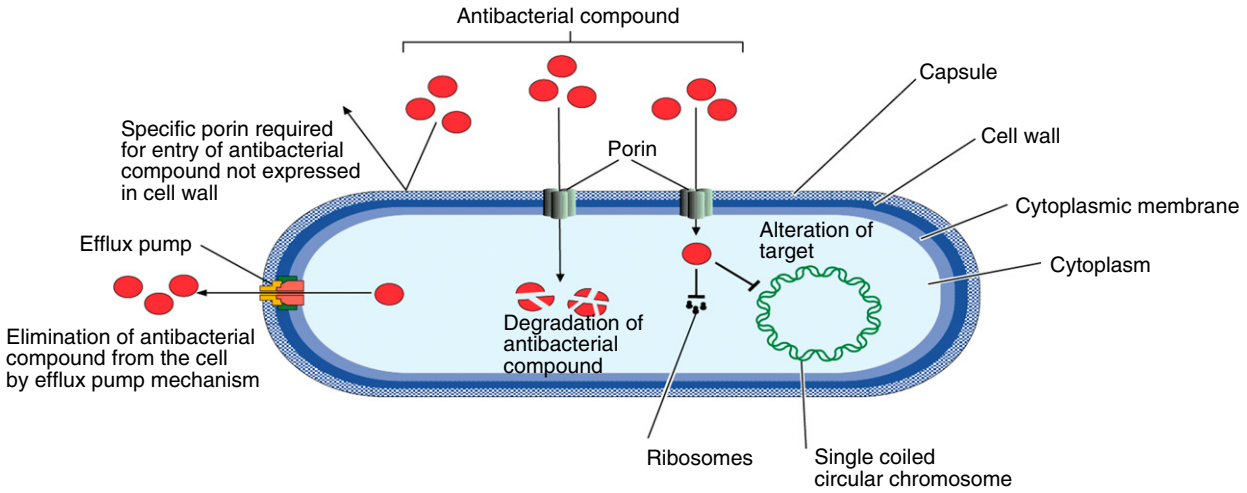

Figure 2 The general mechanisms involved in the development of antimicrobial resistance. Reproduced with permission from Quinn PJ, Markey BK, Leonard FC, *et al.* (2011) *Veterinary Microbiology and Microbial Diseases*. Oxford: Wiley-Blackwell Publishers.

Coresistance

This occurs when two or more resistance genes are physically linked in the same bacterium and each confers resistance to members of separate antimicrobial classes. An example is the resistance elements in *Salmonella* Typhimurium DT104 that confer resistance to ampicillin, chloramphenicol, streptomycin, sulfonamide, and tetracycline (ACSSuT phenotype). Use of any of these drugs will select for the retention of resistance to the other antimicrobials also. The above concepts help to explain some of the resistance problems which arise in human medicine through the use of antimicrobial agents in animals, even when these agents are not used in clinical therapy.

Resistance Linked to the Use of Antibacterials in Agriculture and Overlaps with Public Health

Resistance to antimicrobials associated with their use in animals is an issue of concern to all health care professionals. Much of this relates to the potential for transfer of antimicrobial-resistant pathogens via the food chain along with the risk of transfer of antimicrobial resistance-encoding genes from animal enteric flora to human pathogens. Consequently, it is not surprising that reports are now describing a reduction in the efficacy of antibacterial therapy in animals colonized with resistant bacteria. For several decades, many scientific studies have commented on the fact that use of antibacterials in food-producing animals can be linked to the emergence of resistant bacterial infections in humans. In 2000, a WHO report on infectious disease stated 'Since the discovery of the growth-promoting and disease-fighting capabilities of antibiotics, farmers, fish-farmers, and livestock producers have used antibiotics in everything from apples to aquaculture. This ongoing and often low-level dosing for growth and prophylaxis inevitably results in the development of resistance in bacteria in or near livestock, and also heightens fear of new resistant strains jumping between species.'

There is heightened public health concern about the increase in antimicrobial resistance, not least because studies have begun to report new multidrug-resistant strains of bacteria that have not in the past been associated with food or food-producing animals. An example of this is the emergence of livestock-associated methicillin-resistant *Staphylococcus aureus* (LA-MRSA). This bacterium represents a new health threat for persons in the pig/livestock industries. Although the risk of foodborne infection with LA-MRSA appears to be extremely low, this superbug can be transmitted to humans in direct contact with animals and consequently, MRSA can no longer be considered just a hospital problem. Similarly, public health concerns have also arisen due to an increase in the reporting of foodborne zoonotic bacteria associated with resistance to extended spectrum β-lactam antibiotics including organisms expressing AmpC enzymes. In particular these resistance markers have been associated with plasmids that can be transferred between strains of *E. coli* and *Salmonella* species.

Residues of Antibacterial Drugs in Food Matrices

When administered to food-producing animals and others, veterinary drugs can be metabolized. Breakdown products or residues of these drugs can include the unaltered parent compound itself and/or its metabolites and these can be detected in edible portions of an animal food product. Residues may also include associated excipients contained in a veterinary drug preparation. Concerns about antibacterial residues in foods of animal origin center around human health and economic effects. Food-containing drug residues, when consumed, may elicit a severe allergic reaction in sensitive individuals. In addition, the presence of residues may lead to changes in the human intestinal microflora and act to select for resistance.

Residues of antimicrobial compounds in foods of animal origin could also negatively affect some food-processing procedures. As an example, these chemical contaminants could inhibit the activity of starter cultures used in the production of

certain fermented meats, yogurt, and cheeses, leading to economic losses for food producers. Furthermore, if consumers lose confidence in the safety of the food supply, arising from the threat of resistant bacteria or drug residues, it can be expected that they will reduce their consumption, a feature which would result in economic losses to the broader food industry.

Control of Residues

As a means of controlling residues in food of animal origin, an essential step would be to educate veterinary professionals and others through suitable programs. Steps should be taken to encourage the veterinarian and livestock producer to eliminate the nontherapeutic use of antimicrobial compounds in food production as has been undertaken in Denmark.

It would be beneficial to establish surveillance systems to monitor antimicrobial resistance in human and food-animal populations, antimicrobial drug consumption in food animals in addition to suitable simple and robust field tests for the identification of drug residues in edible animal products. Maximum residue limit (MRL) is defined as the highest concentration of a contaminating metabolite resulting from the use of a veterinary medicinal product which may be legally permitted or recognized as acceptable in or on a food. In Europe, tests are regularly performed to detect the presence of antibacterial residues in food. Before the animal or animal products can be sold for slaughter/consumption, a withholding period must be observed which is of sufficient duration to allow for any residues to be eliminated, such that antibacterial residues are no longer detected at concentrations above the MRL. These time periods are mandated in order to reduce the exposure for humans to residues of veterinary medicinal compounds in foods of animal origin. In addition, many professional veterinary bodies worldwide are examining ways to reduce the overuse and misuse of antibacterials in food-producing animals and develop novel nonpharmacological-based preventive strategies, including good hygiene measures.

Conclusion

Antimicrobial-resistant pathogens are a major challenge for animal and human health alike. Transmission of antimicrobial-resistant bacteria or their corresponding genes from food-producing animals to humans must be controlled. Efforts to promote the judicious use of these important chemotherapeutic agents in animals should be encouraged. A collaborative engagement, involving all stakeholders along the farm-to-fork continuum would serve as a first step toward reducing the use of antimicrobial compounds in agriculture along with seeking to educate the public and health care professionals on the prudent use of antibacterial drugs. The latter step will become even more important in the future, if we are to attempt to preserve the efficacy of existing compounds, and ensure the welfare of animals and the safety of animal food products for the benefit of public health.

VETERINARY DRUGS RESIDUES

Anthelmintics

R Romero-González, A Garrido Frenich, and JL Martínez Vidal, University of Almeria, Almeria, Spain

Glossary

Anthelmintic Any drug that destroys or causes the expulsion of parasitic intestinal worms.
Chromatography Physical method of separation in which the components to be separated are distributed between two phases, one of which is stationary (stationary phase) whereas the other (the mobile phase) moves in a definite direction.
Helminth Parasitic worm found in the intestines of vertebrates, especially roundworms, tapeworms, and flukes.
Liquid chromatography A separation technique in which the mobile phase is liquid.
Mass spectrometry The art of measuring atoms and molecules to determine their molecular weight.
Maximum residue limit Maximum concentration of residue established by a standard-setting body in a food product obtained from an animal that has received a veterinary medicine or has been exposed to a biocidal product for use in animal husbandry.
Metabolite Any intermediate or product resulting by metabolism or by a metabolic process.
Nematode Unsegmented worms of the phylum Nematoda with elongated rounded body, pointed at both ends.
Pharmacokinetics A branch of pharmacology dedicated to the study of the time course of drug absorption, distribution, metabolism, and excretion.
Transformation products Chemical species resulting from environmental or metabolic processes.

Introduction

There are several types of veterinary drugs that can be applied to livestock, such as aminoglycosides, macrolides, tetracyclines, β-agonists, and anthelmintics. Among these, anthelmintics (also called parasiticides, endectocides, and nematocides), are usually used to treat parasitic worms infections, including flatworms (tapeworms and flukes) and roundworms (nematodes), which usually infect human, livestock, and crops, affecting food production. For instance, gastrointestinal nematodes are parasites that cause important economic losses to livestock worldwide due to reduced appetite, lower body weights, reduced egg production (poultry), and death.

To combat helminthiasis, several approaches have been proposed including regulation of parasitic vectors in populations, zootechnical strategies, and breeding of resistant animals. However, treatment with anthelmintics is the option most widely used as vaccines have proven ineffective till date. Before 1940s, only natural compounds including arecoline, lead arsenate, nicotine, and carbon tetrachloride were applied, but they are also toxic to the host. In 1960s and 1970s, organophosphate anthelmintics were introduced, although some of them have been removed from the market due to their toxicity.

In general, broad-spectrum anthelmintics are effective, although most of them are usually used for specific infections. In fact, the term anthelmintic refers to the spectrum of pharmaceutical activity and not to a common chemical substructure of these drugs. Furthermore, the efficacy of these products depends on the pharmacokinetics in the host, including the complex interaction between formulation and route of administration, physicochemical properties of the compound and the metabolites generated.

New compounds have been developed to overcome drug resistance to conventional anthelmintics caused by direct exposure of helminths to the drug at therapeutic doses.

Moreover, the presence of anthelmintic residues in livestock may have serious consequences on consumers, and international organizations and governments have established maximum residue limits (MRLs) of these compounds in several matrices, in order to assure food safety. The unauthorized or incorrect use of anthelmintics can result in the introduction of harmful residues into the food chain. As a consequence, the development of sensitive analytical methods that fulfill the requirements established by governments and international standard-setting bodies is needed. For that purpose, advanced analytical methods mainly based on liquid chromatography (LC) coupled to mass spectrometry (MS) have been widely used for the determination of anthelmintic residues in edible tissues, in order to assure food safety as well as to increase the knowledge of the pharmacokinetics of these compounds.

Types of Anthelmintics

Anthelmintics are usually classified into several types on the basis of similar chemical structure and mode of action. Basically, three main families can be distinguished: benzimidazoles, nicotinic receptor agonists, and macrocyclic lactones.

Most members within each group have similar effects, although they are small chemical differences.

Benzimidazoles

They are considered as the first chemical class of modern anthelmintics. This group includes benzimidazole carbamates, thiabendazole analogs, triclabendazole and prodrug netobimin, and a phenylguanidine derivative which is rapidly converted into albendazole *in vivo*. Thiabendazole was first discovered in 1961, and subsequently other benzimidazoles were introduced as broad-spectrum anthelmintics such as albendazole, fenbendazole, flubendazole, mebendazole, oxfendazole, and triclabendazole.

It can be observed in Figure 1, that they have a bicyclic ring system in their structures in which benzene is fused to the 4 and 5 positions of the heterocycle (imidazole).

They are the largest chemical family to treat endoparasitic diseases in domestic animals and they are widely used for prevention and treatment of parasitic infections (i.e., nematodes) in aquaculture and livestock with an excellent nematocidal activity. Furthermore, some of them have been used as pre- or postharvest fungicides. In general they interfere with the worm's energy metabolism at the cellular level. Thus, they bind to a specific building block, β-tubulin, preventing its incorporation into certain cellular structures.

Nicotinic Receptor Agonists

This class of anthelmintics is formed by several classes of compounds with different chemical structures as shown in Figure 1. Thus, they include imidazothiazoles, such as levamisole, and tetrahydropyrimidines, such as pyrantel and morantel. They cause spastic muscle paralysis of the worm due to prolonged activation of the excitatory nicotinic acetylcholine receptors on body wall muscle. This type of compound only affects adult and larval population worms, whereas benzimidazoles are also able to kill worm eggs.

Macrocyclic Lactones (Avermectins and Milbemycins)

Macrocyclic lactones are considered as the last 'traditional' class of anthelmintics introduced consisting of two closely related chemical groups: avermectins, which include abamectin, doramectin, ivermectin, emamectin, eprinomectin, and selamectin; and milbemycins (also called nemodectins), with moxidectin being the most representative compound. The structure of these type of compounds are shown in Figure 2, and it can be observed that avermectins are complex macrocyclics containing a 16-membered ring, linked to a disaccharide, showing different polarity, whereas, milbemycins do not have saccharide substituents.

Ivermectin was the first macrocyclic lactone introduced as a anthelmintic by Merck in the 1980s. It is a semisynthetic derivative of avermectin, which is a large macrocyclic lactone fermentation product of *Streptomyces avermitilis*. It was the first drug to kill migrating larval stages of worms as well as adults, and therefore, other companies developed analogs such as doramectin, selamectin, etc.

In general, each drug has two homologs, with the major component comprising more than 80%, which is usually used

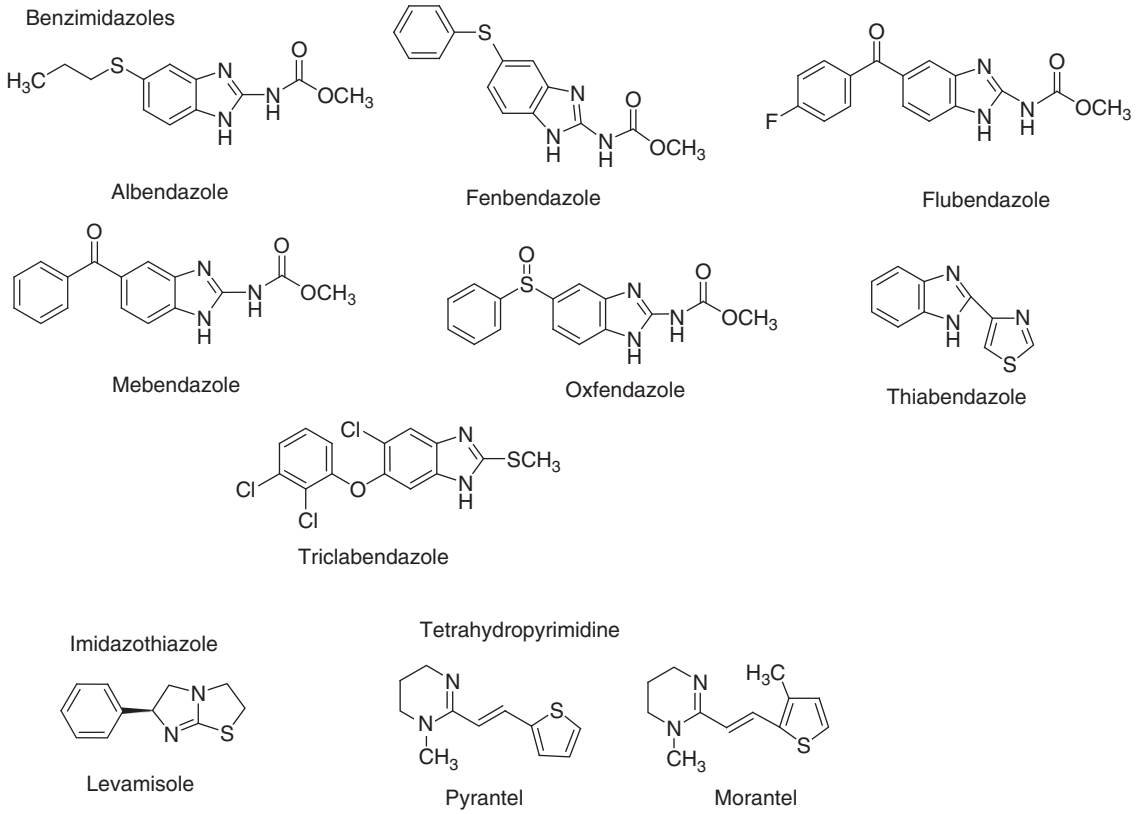

Figure 1 Chemical structure of benzimidazoles and nicotinic receptor agonists.

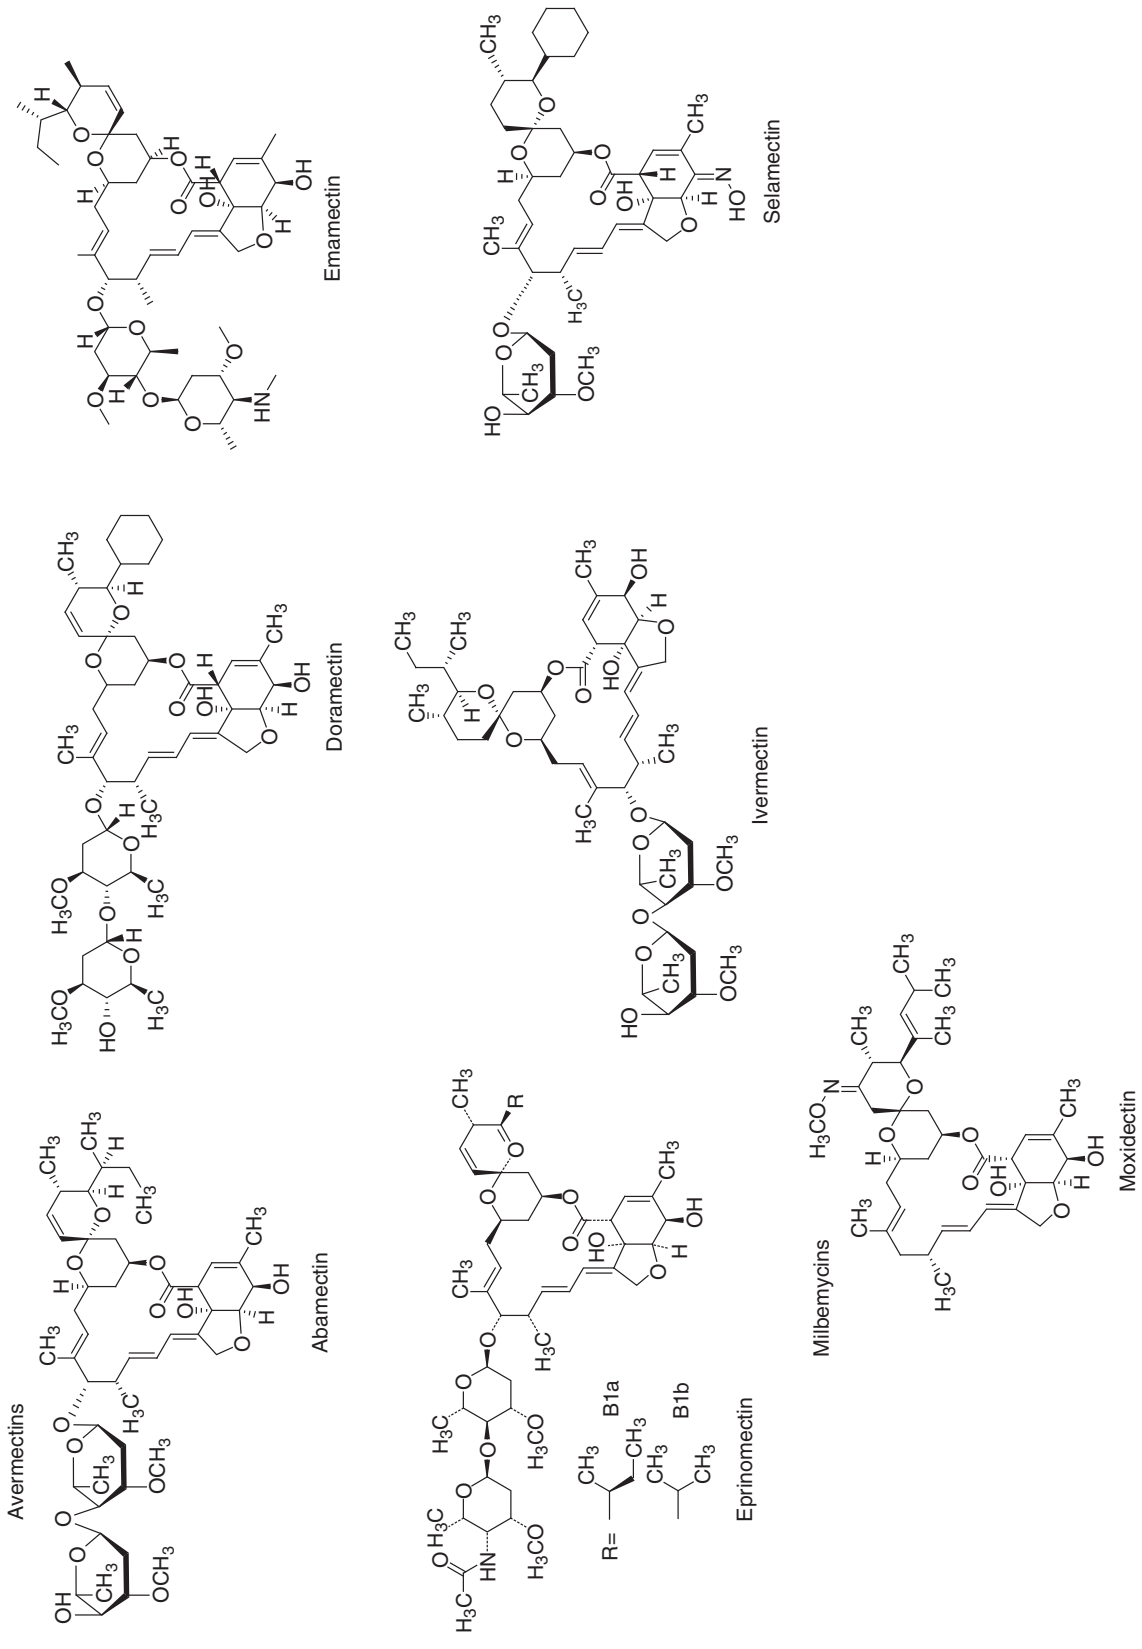

Figure 2 Chemical structure of macrocyclic lactones.

as the marker compound to calculate total residues in edible tissues. Thus, abamectin is a mixture of avermectins containing more than 80% of avermectin B1a and less than 20% of avermectin B1b, being the a and b series sec-butyl and isopropyl homologs, respectively. By contrast, ivermectin can be obtained by the reduction of abamectin (*cis*-hydrogenated product at the 22,23 position) and has higher activity and broader spectrum. Abamectin, ivermectin, and doramectin only contain C, H, and O, and further modifications of the avermectin structure have been obtained by introducing other atoms, such as N, to achieve different insecticidal properties with reduced withdrawal times.

Meanwhile, moxidectin was introduced in 1997. Isolated from *Streptomyces cyanogrise* and *Streptomyces hygroscopicus*, it is able to kill certain worms resistant to ivermectin.

Finally it must be highlighted that macrocyclic lactones have been used against a wide range of nematode and arthropod parasites in livestock. Basically they interfere with gamma-aminobutyric acid-mediated neurotransmission, causing paralysis and death of the parasite. In fact, they are the most potent killer of worms and are more persistent in their effect. Although they have a wide margin of safety for livestock, and are effective against all stages of worms, they are ineffective against cestodes (tapeworms) and trematodes (liver flukes).

Other Anthelmintic Agents

In addition to these major anthelmintic classes, there are some specific compounds that are more effective for treating certain infections. Thus, emodepside, nitazoxanide, piperazine, paraherquamide, and praziquantel can also be used as anthelmintics. For instance, emodepside is effective against parasites that are resistant to benzimidazoles, levamisole, and ivermectin.

Furthermore, some parasitic worms are resistant to conventional classes of anthelmintics, and therefore, new classes of anthelmintics, with new modes of action, are being proposed. Thus, a new class of anthelmintic, named aminoacetonitrile derivative (AAD) has been developed. For instance, in 2009 Novartis introduced (Zolvix®), which is the AAD monepantel. It is effective against some nematodes resistant to other drugs, because its mode of action, which is based on a nematode-specific clade of acetylcholine receptor subunits, is different. This new class is well tolerated and has low toxicity to mammals. Another example is tribendimidine, with high activity against *Ascaris lumbricoides* and *Necator americanus*. No mutagenic and clastogenic effects were observed compared with other anthelmintic agents, and therefore it is considered safe with a broad range of activities.

Anthelmintic Toxicity and Legislation

Although anthelmintics are effective against worms, they may also affect the host itself based on the same biochemical mechanism that operates against the parasite or by specific mechanism to the host. The widespread use of anthelmintics implies the possibility of the presence of residues in edible tissues, and toxic effects could be associated with chronic exposure to these compounds, such as teratogenicity, congenital malformations, diarrhea, anemia, pulmonary edema, or necrotic lymphadenopathy.

Among the different classes of anthelmintics discussed in the Introduction, it has been observed that avermectins and milbemycins are usually safe, considering they usually modify certain types of communication between two nerve cells. This type of communication is characteristic in nematodes and arthropods but in vertebrates it only exists in the central nervous system and these compounds do not penetrate the brain and spinal cord. Thus, ivermectin has been well tolerated in humans and no indication of associated central nervous system toxicity has been observed at doses up to 10 times the highest US Food and Drug Administration-approved dose of 200 $\mu g\ kg^{-1}$.

In relation to benzimidazoles, several studies have been carried out to evaluate the toxicity of these compounds, considering that they have a wide range of toxicity including teratogenic effects, congenital malformations, and anemia effects. Furthermore, some of the transformation products of this class of compounds show higher toxicity than the parent compound. For instance, hydroxymebendazole has been found to be more embryotoxic than mebendazole. Furthermore, albendazole sulfoxide has teratogenic effects in several species including humans, but at different concentrations. However, several toxicological effects between the two isomers of this compound were noted. Thus, the (+) enantiomer was the predominant enantiomer in the bovine, ovine, and caprine and in which teratogenicity and clinical development abnormalities have not been reported after conventional usage.

Meanwhile, European Medicines Agency (EMA) has indicated that albendazole should be regarded as a potential mutagen and no level had been identified at which there would be 'no mutagenic risk' to consumers of meat containing albendazole residues. However, it has been observed that there is a threshold value below which aneuploidy genesis will not occur, ensuring that conventional therapeutic use of albendazole as well as other similar compounds will not pose a risk in humans. In fact, it is recognized that there is no indication of harmful effects of this compound in humans and animals despite its worldwide use. For instance, there are no reports of a teratogenic action in humans, not even in women dosed during pregnancy.

In relation to other benzimidazoles it has been noted that mebendazole has low systemic toxic potential, but at high doses it can cause anemia and liver damage. Considering the toxic effect that this type of compound can provoke, considerable effort has been focused on the development of a new generation of benzimidazoles, which are more soluble and produce minimal acute damage to the animal – even at very high doses.

By contrast, praziquantel is unlikely to be of toxicological concern to humans and the European Union (EU) has granted marketing authorization of this compound for use on several animals without the need to set an MRL.

Finally, it must be emphasized that levamisole, pyrantel, and morantel are more toxic, considering that they affect transmission of neural impulses of the host, but at higher doses. In fact, levamisole has the narrowest margin of safety, although toxicity is usually due to excess dosage. Thus, EMA

suggest an MRL of 10 μg kg^{-1} of this compound in muscle, fat, and kidney from bovine, ovine, porcine, and poultry.

Although these compounds have toxic effects at high doses in laboratory animals, levels detected in food are generally below toxicity thresholds and pose no risk to consumers, though special attention should be paid to the presence of this type of residues in milk.

Legislation

Although anthelmintics are more toxic to parasites than mammals, food produced from treated animals should not contain residues of such drugs which would pose a food safety risk. Therefore, national and international organizations establish MRLs of these drugs in foodstuffs. In this sense, only a limited number of products are licensed for treatment of animals during the lactating period and have a MRL set under European Commission Regulation 37/2010, in order to protect consumers from risks related to these compounds. An overview of the established MRLs are listed in Table 1. It can be observed that different MRLs have been established for the anthelmintic, depending on the matrix and different marker residue. Thus, the marker residue of most benzimidazoles in foodstuffs is defined as the sum of the parent and its persistent metabolites. For instance, the marker residue definition of albendazole includes the sum of albendazole sulfoxide, albendazole sulfone, and albendazole 2-amino-sulfone, whereas for oxfendazole, the marker residue is defined as the sum of extractable residues, which maybe oxidized to oxfendazole sulfone.

Furthermore, it must be emphasized that flubendazole is the only benzimidazole registered for poultry in different countries, although other benzimidazoles such as albendazole are used to treat helminth infections in poultry because of cost reasons. In fact, MRLs have been established for this molecule in several target tissues of poultry, including eggs (400 μg kg^{-1}).

Like the EU, other countries have established legislation and regulations regarding human health, food safety, and environmental protection. In the USA, MRLs or tolerances for veterinary drugs in foodstuffs can be found in the Code of Federal Regulations, namely Title 21 (Food and Drugs, 500–600). For instance, ivermectin has been approved in the USA for use in several animal species, including nonlactating cattle. Doramectin and moxidectin are approved for use in beef cattle and nonlactating dairy cows, whereas eprinomectin was recently approved for use in beef and dairy cattle. Furthermore, in 2006 the USA approved febendazole for the control of nematodes in turkeys, establishing a MRL of 6000 μg kg^{-1} in liver and 2000 μg kg^{-1} in muscle, fenbendazole sulfone being the marker residue.

In Canada, the Department of Health is in charge of administering a variety of laws, and develops and enforces regulations. It has also established MRLs for monitoring of residues of veterinary drugs in food. For instance, in this country, abamectin, doramectin, eprinomectin, ivermectin, and moxidectin are used to treat food animals such as bison, cattle, deer, sheep, swine, and reindeer against nematodes and arthropods; emamectin is used to control sea lice in fish farms and selamectin is used for the treatment of pets against heart- and roundworms. Only eprinomectin and moxidectin are permitted for use in dairy cattle, with no milk withholding time, considering that eprinomectin was designed to exhibit a low milk/plasma ratio, and moxidectin is less toxic with a larger acceptable daily intake.

China has also established legislation regarding the presence of anthelmintics in edible tissues. For instance, the MRLs for triclabendazole in edible ruminant tissues were set at 200, 300, and 300 μg kg^{-1} in muscle, liver, and kidney tissues of bovines respectively, whereas in goats, the MRL was set at 100 μg kg^{-1} in the same tissues.

It must be highlighted that, depending on the country or government organization, the MRLs set for the same combination compound/matrix maybe different. For instance, eprinomectin has an MRL in milk of 20 μg kg^{-1} in Canada and EU, whereas the MRL is lower (12 μg kg^{-1}) in the USA. Meanwhile, in China, MRLs are set at 100 μg kg^{-1} for avermectin, ivermectin, and doramectin in bovine liver and 20 and 100 μg kg^{-1} for avermectin and doramectin, respectively in bovine muscle, whereas in the EU, MRLs in bovine liver are 20, 100, 100, and 600 μg kg^{-1} for avermectin, ivermectin, doramectin, and eprinomectin, respectively.

In relation to benzimidazoles, for instance, China and EU have established MRLs for these compounds, which range from 50 to 400 μg kg^{-1} and 10 to 5000 μg kg^{-1} respectively, depending on the matrix and compound. Thus, albendazole and related products (albendazole sulfoxide, sulfone, and amino sulfone) have an MRL of 100 μg kg^{-1} in milk, muscle, and fat, whereas it is set at 5000 μg kg^{-1} for kidney and liver. However, for flubendazole, an MRL of 400 μg kg^{-1} was set in eggs.

Finally, it must be emphasized that although most residue surveillance programs test for the presence of anthelmintic residues in edible tissues, few positive results were found. Thus, the presence of anthelmintics in muscle in several countries of Europe were tested and of 1061 beef samples, only 2.45% contained detectable amounts of anthelmintic residues at concentrations ranging from 0.2 to 171 μg kg^{-1}. However, none of the positive results were above EU MRL or action level, indicating that the risk of exposure of the European consumer to this type of drugs is negligible.

Furthermore, albendazole and metabolites have been analyzed in porcine muscle and livers, but only two metabolites, albendazole sulfone and albendazole 2-amino-sulfone were detected in some porcine livers but at concentrations lower than the MRLs established by the EU.

Pharmacokinetics of Anthelmintics

After administration, anthelmintics are usually absorbed into the bloodstream and transported to different parts of the body, including the liver, where they maybe metabolized through oxidation and cleavage reactions, and excreted in the feces and urine. The characterization of the kinetic behavior, metabolic fate, excretion, and residue profile of anthelmintics in the target animal will contribute to its optimized use as well as the determination of the length of the withdrawal time.

However, the administration of anthelmintics does not always result in the expected therapeutic success, because

Table 1 MRLs for some anthelmintic drug residues in several matrices under European Commission Regulation 37/2010

Compound	*Marker residue*	*Animal species*	*MRL* ($\mu g\ kg^{-1}$)	*Target tissues*
Albendazole	Sum of albendazole sulfoxide, albendazole sulfone, and albendazole 2-amino sulfone, expressed as albendazole	All ruminants	100	Muscle
			100	Fat
			1000	Liver
			500	Kidney
			100	Milk
Fenbendazole	Sum of extractable residues which maybe oxidized to oxfendazole sulfone	All ruminants, porcine, and Equidae	50	Muscle
			50	Fat
			500	Liver
			50	Kidney
		All ruminants	10	Milk
Flubendazole	Sum of flubendazole and (2-amino 1H-benzimidazol-5-yl)(4fluorophenyl)methanone	Poultry and porcine	50	Muscle
			50	Skin and fat
			400	Liver
			300	Kidney
	Flubendazole	Poultry	400	Eggs
Mebendazole[a]	Sum of mebendazole methyl (5-(1-hydroxy, 1-phenyl)methyl-1H-benzimidazol-2-yl)carbamate and (2-amino-1H-benzimidazol-5-yl)phenylmethanone, expressed as mebendazole equivalents	Ovine, caprine, and Equidae	60	Muscle
			60	Fat
			400	Liver
			60	Kidney
Oxfendazole	Sum of extractable residues which maybe oxidized to oxfendazole sulfone	All ruminants, porcine, and Equidae	50	Muscle
			50	Fat
			500	Liver
			50	Kidney
		All ruminants	10	Milk
Thiabendazole	Sum of thiabendazole and 5-hydroxy thiabendazole	Bovine and caprine	100	Muscle
			100	Fat
			100	Liver
			100	Kidney
			100	Milk
Triclabendazole[a]	Sum of extractable residues which maybe oxidized to keto-triclabendazole	All ruminants	225	Muscle
			100	Fat
			250	Liver
			150	Kidney
Abamectin[a]	Avermectin B1a	Bovine	10	Fat
			20	Liver
		Ovine	20	Muscle
			50	Fat
			25	Liver
			20	Kidney
Doramectin	Doramectin	All mammalian food producing species	40	Muscle
			150	Fat
			100	Liver
			60	Kidney
Emamectin	Emamectin B1a	Fin fish	100	Muscle and skin
Eprinomectin	Eprinomectin B1a	Bovine	50	Muscle
			250	Fat
			1500	Liver
			300	Kidney
			20	Milk
Ivermectin[a]	22,23-dihydro-avermectin B1a	All mammalian food producing species	100	Fat
			100	Liver
			30	Kidney

(*Continued*)

Table 1 Continued

Compound	*Marker residue*	*Animal species*	*MRL* ($\mu g\ kg^{-1}$)	*Target tissues*
Moxidectin	Moxidectin	Bovine, ovine, and Equidae	50	Muscle
			500	Fat
			100	Liver
			50	Kidney
		Bovine and ovine	40	Milk
Levamisole[b]	Levamisole	Bovine, ovine, porcine, and poultry	10	Muscle
			10	Fat
			100	Liver
			10	Kidney
Morantel	Sum of residues which may be hydrolyzed to N-methyl-1,3-propanediamine and expressed as morantel equivalents	All ruminants	100	Muscle
			100	Fat
			800	Liver
			200	Kidney
			50	Milk

[a]Not for use in animals from which milk is produced for human consumption.
[b]Not for use in animals from which milk or eggs is produced for human consumption.
Abbreviation: MRLs, maximum residue limits.

host-related factors can modify pharmacokinetic behavior and efficacy of the selected compound. Thus, the factors affecting drug pharmacokinetics can be distinguished between two groups: interindividual (species, sex, and genetics) and intraindividual (age, gestation, stress, medication, food, and environment) factors. Interindividual factors remain constant during the life of an organism, whereas intraindividual ones change during the life. Basically they are related to physiological and pathological state of an organism. For instance, it has been observed that the metabolic interconversion between fenbendazole sulfide and sulfoxide differs in horses compared to ruminants, and the bioavailability and residence time were lower and shorter in horses than in ruminants.

Extensive work has been carried out to study the pharmacokinetic and metabolism of certain benzimidazoles. In general, benzimidazoles are limited in absorption from the gastrointestinal tract due to the poor solubility of these drugs and the absorption is generally fast (from 2–7 h with flubendazole to 6–30 h for other compounds). Mebendazole is absorbed from the gastrointestinal tract and is intensively metabolized in sheep through ketoreduction and decarbamylation followed by conjugation.

Furthermore, it is known that the absorption and the efficacy are influenced by their administration with food. Thus, the bioavailability of benzimidazole sulfides is markedly reduced in ruminants which have had unrestricted access to food compared with those given restricted access prior to treatment. Sometimes in order to minimize the metabolic oxidation of benzimidazole sulfides and sulfoxides to sulfones, metabolic inhibitors are added. For instance, piperonyl butoxide has been added to modify the pharmacokinetic profile of febendazole.

The pharmacokinetics of albendazole has been studied in several animal species, although few studies have been carried out in poultry. In general, it is rapidly metabolized in all species, and the plasma levels of oxidized metabolites (sulfoxide and sulfone) are much higher than the parent drug. In fact, the sulfoxide transformation product is considered the active metabolite responsible for the therapeutic activity of albendazole, whereas albendazole sulfone is considered an inactive compound. Furthermore, it can be noted that the coadministration of other drugs such as cimetidine and praziquantel affects the kinetics of albendazole probably by the induction of the second sulfonation step. In poultry it has been observed that the maximum concentration was obtained at 1 h and it was only detected for 6 h after treatment. However, albendazole sulfoxide was detected for 25 h after treatment. Furthermore, these results were compared with those obtained in other species such as calf, dogs, goats, pigs, and sheep, and the maximum concentration (C_{max}) and time to reach it (T_{max}) are lower in chickens. Therefore, it was concluded that albendazole was absorbed to a greater extent and more quickly in poultry than in mammalian species. Finally, only albendazole metabolites can be measured in eggs if single oral dose was given. However, if the treatment is applied during 7 days, albendazole and its metabolites can be simultaneously detected in yolk, whereas albendazole cannot be detected in egg albumin. The absence of albendazole in albumin can be explained considering the relatively higher lipid solubility of albendazole compared with its metabolites. In the same way, it has been observed that the concentration of flubendazole in egg yolk was about five times higher than in the albumin.

Other compounds that have been studied are mebendazole and triclabendazole. Thus, some metabolites such as hydroxymebendazole (reduced metabolite) and aminomebendazole (hydrolyzed metabolite) can be found in food from animals treated with mebendazole, with the highest concentrations in liver of the reduced metabolite. In fact, this metabolite can be detected in liver for 14 days after administration. In relation to triclabendazole, it is rapidly removed from blood by the liver, and it is oxidized to the sulfoxide and sulfone, which are the main metabolites detected in plasma.

For nicotinic receptor agonists, it has been shown that the absorption and excretion of levamisole is fast and it is not affected by the route of administration because of its high solubility. It has been observed that the levels of this drug in blood cattle are maximum in less than 1 h, and 90% of the total dose is excreted in urine in 24 h. However, pyrantel is poorly soluble in water and its metabolism is fast, with the metabolites excreted rapidly in the urine. Morantel is absorbed rapidly from the upper small intestine of sheep and metabolized rapidly in liver (17% of the initial dose is excreted in the urine as metabolites within 96 h after dosing).

In general, macrocyclic lactones are hydrophobic and they are distributed throughout the body and some of them can be concentrated in adipose tissue. Depending on the species, they have an elimination half-life of 32–178 h. In this sense, a pharmacokinetic study of emamectin benzoate has been carried out in Atlantic salmon and it was shown that emamectin B1a was the major residue component (>80% in edible tissues). Therefore, this compound has been used as marker residue in edible tissues of Atlantic salmon for monitoring emamectin benzoate.

Further metabolic studies have been carried out with other anthelmintic drugs. Thus, the metabolism of praziquantel has been studied in several tissues of rainbow trout maintained at different temperatures (12 and 18 °C), observing that absorption was faster at higher temperatures, whereas the elimination of the drug was less dependent on the temperature. Thus, after 32 h, 67–96% of the drug has been eliminated from the tissues.

In relation to the elimination of anthelmintics, biliary secretion is an important pathway for elimination of macrocyclic lactones. Thus, they are primarily excreted in the feces and the remainder (<10%) in the urine. However, more lipophilic compounds are also excreted in milk. Biliary route is the most important pathway for secretion and recycling of benzimidazoles to the gastrointestinal tract, as well as praziquantel, which is partly excreted by bile fluid and partly as water soluble metabolites through the kidneys. Furthermore, the intestinal clearance of albendazole sulfoxide exhibits a stereoselective elimination of the (−) form.

The excretion of anthelmintics in the feces of livestock has given rise to concern as avermectins have adverse effects in dipteran flies and coleopteran beetles. However, benzimidazoles are unlikely to affect dung-dwelling arthropods and the environmental impact is not limited to specific effect on scavenger insects. For instance, the fecal concentration of febendazole and its metabolites was determined in horses, noting that no drug could be detected at 12 h post dosing. The maximal concentration was monitored at 24 h, and no target compounds were detected after 72 h. In feces the highest concentration was observed for the parent compound.

Analytical Methodology

Anthelmintic residues are mainly determined applying LC techniques coupled to several detectors, although some benzimidazoles have been determined by gas chromatography (GC). However, GC is not suitable for quantification because of thermal decomposition in the chromatograph or nonreproducible ionization in the source of the MS.

Benzimidazoles could be detected using ultraviolet (UV) or fluorescence detection, considering that most of them (albendazole, flubendazole, and thiabendazole) have natural fluorescence. Furthermore in relation to UV, the use of diode array is very useful, considering that individual analytes have characteristic spectra. Levamisole can also be detected by UV.

Meanwhile, avermectins can be detected using fluorescence detection including a derivatization reaction using trifluoroacetic acid, and this methodology has been used for the determination of emamectin in Atlantic salmon. Although the limits of detection provided by fluorescence detectors are below the MRLs established by governments, there are some problems related to the derivatization step such as instability of fluorescent derivatives, slow and/or incomplete formation of derivatives, and the low reproducibility of the results.

Furthermore, and according to current legislation in Europe, MS should be used for confirmation purposes in the determination of residues in foodstuffs. Therefore, conventional detection has been replaced by MS applying several detectors, such as single quadrupole, triple quadrupole, time of flight (TOF), and Orbitrap. In this sense, several ionization techniques, such as electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization, have been used. Moreover, the application of MS analyzers allows the identification and quantification of metabolites of anthelmintics in the samples.

However, in the case of avermectins, the use of MS is not a straightforward strategy. These compounds are heavy (molecular weight ranging from 600 to 900 Da), but most of them only contain one nitrogen atom in their structure. In fact, ivermectin, doramectin, and abamectin only contain C, H, and O, which have negative effects on the ionization. This implies that several assays have been carried out to study the best ionization of these compounds. For instance, it has been indicated that for abamectin, the determination of ammonium adduct by ESI is the best option, although other studies have indicated that the use of APCI with negative ionization provided $[M-H]^-$ as the predominant ion for ivermectins. In general, it has been reported that avermectins, which are devoid of nitrogen atoms, produce significantly higher abundances for $[M+Na]^+$ than $[M+H]^+$. Furthermore, another difficulty is that sodium adducts are difficult to break and therefore several authors have evaluated alternative ionization processes, observing that negative ESI or APCI could overcome many of these problems.

In relation to the LC separation, C18 or C8 columns are mainly used. Moreover, the selection of the mobile phase is critical for the correct ionization of the target compounds. Acetonitrile and methanol are usually used for the determination of anthelmintics, although for avermectins, the use of methanol increases the sensitivity of the compounds in relation to acetonitrile. The pH of the mobile phase maybe critical in order to get suitable chromatographic separation, and ammonium formate or acetate could provide suitable results. Furthermore, in the past decade, ultra high-performance LC has been widely used in order to reduce analysis time, obtaining narrower peaks, and increasing sample

throughput. Furthermore, the combination of LC with tandem MS (MS/MS) allows the selective determination of these compounds.

Finally, it must be emphasized that sample preparation is the critical step for the simultaneous determination of several analytes in complex matrices. In relation to the extraction of these compounds from several matrices, different methodologies have been applied. Thus, liquid–liquid partition using acetonitrile has been used, allowing the deproteination of proteins. Solid phase extraction (SPE) has also been evaluated, utilizing C18, polymer sorbents or strong cation cartridges. However, they are laborious and time-consuming, and new approaches could be applied. Thus, immunoaffinity chromatography (IAC) could be used as a valuable tool for clean-up, allowing a fast and selective extraction of avermectins from extracts of bovine and swine liver. Furthermore, the combination of IAC with LC–MS provides sensitive and selective methods. However, matrix solid phase dispersion has been applied for the determination of 37 anthelmintic drugs and metabolites in muscle. In addition, pressurized liquid extraction has been applied for the determination of benzimidazoles in tissues of animals such as swine, cattle, sheep, and chickens. Finally, it must be noted that low temperature clean-up has been used for the determination of ivermectins and moxidectin in bovine muscle.

Furthermore, benzimidazoles are usually extracted by relatively polar aqueous extraction solutions. However, some metabolites are covalently bound to matrix components (liver or kidney) and chemical or enzymatic hydrolysis should be included in the extraction procedure, although simplified methods using anhydrous acetonitrile could be used.

Nowadays, generic extraction conditions can be applied for the simultaneous extraction of several types of compounds in a single analytical method. However, the inclusion of some anthelmintics such as avermectins is not easy considering the low sensitivity obtained by the use of LC–MS/MS, and special attention should be paid to these compounds, when they are included in multiresidue methods. In this sense, QuEChERS approach (acronym for Quick, Easy, Cheap, Effective, Rugged and Safe), which is based on acetonitrile extraction followed by a phase separation induced by the addition of salts and a clean-up step based on dispersive SPE, has been successfully applied for the extraction of this type of compounds from edible tissues.

Conclusions and Future Trends

As described in this article, the use of anthelmintics to treat helminth parasites and the resulting residues in edible tissues is a problem of major concern. Furthermore, the development of resistance to the currently used anthelmintics is an issue of increasing importance. In this sense, the development of new compounds, such as AAD, are needed in order to improve the characteristics of conventional classes of anthelmintics such as lower toxicity, favorable pharmacokinetic properties, and broad-spectrum capacities.

Furthermore, additional studies should be carried out to more thoroughly examine the pharmacokinetics and metabolism of these compounds, especially during pregnancy. The possibility of elimination of some nonpolar compounds by milk should be also evaluated in order to minimize the risk of the presence of anthelmintic residues in this matrix. To assure a sustainable inventory of effective anthelmintics, monitoring of drug resistance and research with combinations of current or future drugs will be necessary.

Moreover and despite the evaluation of the metabolism of anthelmintics in vertebrates, much attention should be paid to the evaluation of metabolism of these products in parasitic helminths.

In relation to analytical methodologies, current methods should include known metabolites in routine analyses in order to fulfill current legislation. However, anthelmintic metabolism is complex, and it is necessary to develop and validate new analytical methods that allow the accurate determination of new metabolites in foodstuffs. For that purpose, high resolution MS analyzers such as TOF or Orbitrap are very helpful, considering that they acquire full-scan spectra, and target, nontarget and unknown analysis that could be carried out in one single analysis.

Finally and considering the different MRLs established by several countries or organizations for the same combination anthelmintic/matrix, international legislation should be harmonized, in order to avoid some problems during export.

VETERINARY DRUGS RESIDUES

Anabolics

M Smith, US Food and Drug Administration (FDA), Rockville, MD, USA

Glossary

Anabolic steroids A class of steroid substances that increase protein synthesis within cells, resulting in the buildup of cellular tissue (anabolism), particularly in muscle.

Beta-agonist A class of substances that act on adrenergic receptors, thereby causing smooth muscle relaxation, dilation of bronchial passages, vasodilation in muscle and liver, and release of insulin, and that have anabolic effects in animals.

Codex Alimentarius Commission The governing body of the joint UN World Health Organization (WHO)/Food and Agriculture Organization (FAO) food standards program that develops standards, codes of practice, guidelines, and other recommendations to ensure the health of consumers and fair practices in the international food trade.

Joint FAO/WHO Expert Committee on Food Additives (JECFA) The independent expert scientific review body that provides risk assessments and scientific support for Codex food additive, contaminant, and veterinary drug residue standards.

Somatotropins Protein hormones consisting of large complex peptides. Natural somatotropins are produced in the pituitary gland and function in regulating metabolic processes and increasing anabolism.

World Trade Organization (WTO) The international organization that seeks to supervise and liberalize international trade.

Introduction

Very few issues involving veterinary medicines have resulted in more controversies over the years than those surrounding the use in animals of drugs that promote anabolism and the safety of food produced from those treated animals. Although the USA/Canada–European Union (EU) beef hormones trade dispute has faded from the headlines, there are still significant differences of opinion concerning the outcome of that World Trade Organization (WTO) action. Disagreements within the Codex international standard-setting deliberations have also continued over the use of hormones and other anabolics such as somatotropins and the beta-agonists, ractopamine and zilpaterol, in food-producing animals, including the development of maximum residue limits (MRLs) in foods.

Somatotropins

There was little interest in using somatotropins commercially in animal production until in the 1980s, when they could be produced in large quantities through recombinant deoxyribonucleic acid (DNA) technology. After a comprehensive review of its safety and efficacy, including with regard to human food safety, recombinant bovine somatotropin (bST) received approval by the US Food and Drug Administration (FDA) in November 1993 as an animal drug intended to increase milk production in dairy cows. Worldwide at this time, Mexico, Brazil, and approximately 20 other countries have also approved bST for commercial sale, whereas a number of other countries do not permit its use (e.g., Canada, Australia, Japan, and all EU countries). As part of the conditions for approval in the USA, the drug's sponsor initiated a post-approval monitoring program to determine if the incidence of mastitis and antibiotic use was manageable under actual use conditions and if label directions were adequate. This program was significant because it represented the most extensive postapproval study ever conducted for any animal product that FDA has approved. When FDA evaluated the data collected in this program, it concluded that 'the effects of the use of bST were in close agreement with the effects observed in the sponsor's preclearance studies' and that bST was safe and exhibited no adverse effects on the milk supply.

But questions have continued to be raised over the years by others including the European Commission and Health Canada. One issue for which Canada expressed concern in April 1998 related to a 90-day oral toxicity study in rats. Canada maintained that this study was 'misreported' by the FDA and alleged that there was significant absorption of oral bST based on serum antibody levels in and toxicity to the rats. This assertion, as well as the circumstances under which it was made public, became highly controversial, and, following publication of the Canadian report, several groups and individuals in the USA raised questions about the safety of milk from bST-treated cows. In response to these concerns, FDA prepared the 'Report on the FDA's Review of the Safety of Recombinant bST.' The report affirmed the original review of the 90-day rat oral toxicity study, concluding again that there

were 'no biologically significant observed effects in either the thyroid or the prostate.' In addition, FDA conducted a review of the report cited by Health Canada of the antibody response to oral bST. Although it concurred that oral exposure to high doses of bST results in antibody production, FDA concluded that 'there is no evidence for biologically significant absorption of intact bST from the gastrointestinal tract.'

FDA also reviewed the March 1999 European Commission Directorate General XXIV 'Report on Public Health Aspects of the Use of bST' and took issue with the conclusions of the report with respect to the safety of insulin-like growth factor 1 (IGF-1). IGF-1 is a hormone similar in structure to insulin. It plays an important role in bST stimulating milk production in cows. Concern centers on the fact that some studies of IGF-1 have shown a correlation between abnormally high levels of circulating IGF-1 and the development and growth of human cancers. The FDA asserted that the conclusions 'do not appear to be consistent with the current state of scientific knowledge.' Specifically, the report stated that establishing an *in vivo* quantitative dose–effect relationship for IGF-1 is virtually impossible because of the diverse biological effects attributable to the intrinsic activity of IGF-1. But the FDA found that there are standard procedures for assessing the hazard associated with all types of compounds that exert a broad variety of metabolic effects. FDA concluded the data provide ample evidence that 'the amount of IGF-1 and truncated forms excreted in milk following the administration of bST to dairy cows is safe for all consumers, including infants and that additional exposure data are not necessary.' The EU also cited the increased risk of mastitis from use of bST and therefore the possibility of increased use of antibiotics and possible concomitant increased antimicrobial resistance, and continued a moratorium on the drug's sale that had been in place since 1990. A permanent EU ban started in January 2000. Referring to the animal protection goals of EU Council Directive 98/58/EC, the bST ban was based solely on a regard for the welfare requirements of animals, and no concerns about the safety of milk produced from treated animals were expressed when the prohibition was put into effect.

FDA's determination that food products from cows treated with bST are safe for consumers has been supported by numerous scientific and regulatory bodies including the Joint FAO/WHO Expert Committee on Food Additives (JECFA). In 1992, the JECFA concluded that 'the lack of oral activity of bST and IGF-1 and the low level and nontoxic nature of the residues of these compounds, even at exaggerated doses, results in an extremely large margin of safety for humans consuming dairy products from bST-treated cows.' In 1998, the JECFA reaffirmed the safety of milk and meat from bST-treated cows. The Codex Committee on Residues of Veterinary Drugs in Foods (CCRVDF), acting on the advice of the JECFA, recommended that the Codex Alimentarius Commission should adopt an MRL for bST in food. But the European Commission opposed the advancement of an MRL for bST within Codex, and proposed to retain the draft MRL at Step 7 until another review by the JECFA. Nevertheless, the CCRVDF decided in June 1999 to take the proposal forward for discussion in the Codex Commission, but the matter ended up being withdrawn from the agenda. Final approval of bST through Codex has been delayed ever since that time. During its session in July 2012, the Codex Commission continued to hold bST at Step 8 but asked for an updated review of the scientific data to be undertaken by the JECFA, thereby establishing a process for possible progression of MRLs for bST at a future time.

Porcine somatotropin (pST) is a growth hormone naturally produced in pigs and is also produced through recombinant DNA technology. pST injections or implants containing this hormone cause pigs to gain more muscle and less fat in comparison with untreated animals. This hormone has been approved for use in a number of countries including Australia, Mexico, Peru, and Vietnam but has not yet been approved in the USA. In 1999 after reviewing pST, the JECFA noted the following: the lack of increased concentrations of pST residues in the edible tissues of treated animals, the lack of a biologically significant increase in the intake of IGF-1 by humans who consume the edible tissues of treated animals, and the lack of toxicological concern with regard to the levels of residues of pST and exogenous IGF-1 likely to occur in treated pigs. The JECFA stated that pST can be used in pigs without appreciable risk to the health of consumers and recommended that it was not necessary to set any MRLs for edible tissues in pigs. The CCRVDF and the Codex Commission finalized these conclusions in 2003. pST is not approvable in the EU because of the blanket prohibition contained in Council Directive 96/22/EC for substances used in stock farming having a hormonal or thyrostatic action and for beta-agonists.

Steroid Hormones Used in Food-Producing Animals

The use of hormonally active steroids as growth promoters in farm animals can increase the production of veal and beef significantly (up to 15%). The USA and a number of other countries worldwide have approved some of these substances for use at low concentrations to increase the rate of weight gain and/or improve feed efficiency in beef cattle. In the USA, these drugs are available for over-the-counter purchase and are usually administered by livestock producers. The naturally occurring (endogenous) steroid hormones approved by the FDA (i.e., estradiol, progesterone, and testosterone) are formulated as implantable pellets and are designed to deliver the hormones at a slow, constant rate when injected subcutaneously under the skin of the animal's ear. Numerous scientific studies have demonstrated that, when these drugs are utilized in accordance with their approved conditions of use, concentrations of the hormones in edible food tissues remain within the normal physiological range that has been established for untreated animals of the same age and sex. Because of the slow release of very small amounts of the hormone and a short average half-life (approximately 10 min), it has been determined by FDA and other agencies that no preslaughter withdrawal time is necessary to protect the public health and that consumers are not at risk from eating food from animals treated with these compounds. For the synthetic steroid hormones that have been approved by the FDA and other agencies (i.e., trenbolone acetate, zeranol, and melengestrol acetate (MGA)), extensive toxicological testing in animals was required to determine safe levels in edible tissues because these substances are not metabolized as quickly as the naturally occurring steroid hormones. For all of the synthetic hormones,

the FDA required the manufacturers to provide evidence demonstrating that the amount of residue left in each edible tissue after treatment is below the level determined to be safe.

Hormones in Beef Trade Controversy

Starting in 1981, the EU began restricting the use in livestock production of natural hormones to therapeutic purposes only. In 1985, it also prohibited the use of synthetic hormones and imports of meat from animals that had been administered these hormones. The EU justified the ban as needed to protect the health and safety of consumers from the illegal and unregulated use of hormones in livestock production in several EU Member States. On 1 January 1989, the EU banned the import of US beef produced with the six FDA-approved hormones. This action dramatically reduced beef exports to EU Member States. For the USA the value of the lost exports was approximately $100 million, and it retaliated by imposing 100% duties on $100 million in EU products exported to the USA. This retaliation continued with some adjustments during the period 1989–96. Then in 1999 the USA imposed another 100% *ad valorem* duty on selected food products from EU countries.

In April 1996, the USA requested that the WTO establish a dispute panel to consider the US claim that the EU's prohibitions against the six US-approved hormones "adversely affect imports [into the EU] of meat and meat products and appeared to be inconsistent with the obligations of the European Communities under the WTO Agreement on the Application of Sanitary and Phytosanitary (SPS) Measures (SPS Agreement)." The WTO's dispute resolution procedures permit a WTO member government to request that a dispute resolution panel be established to determine whether measures maintained by another WTO member government violate its obligations under the WTO agreements. Such a panel, normally consisting of three individuals selected in consultation with the parties to the dispute, considers written submissions and oral arguments by the parties. According to the applicable WTO procedures, a panel may seek advice from experts selected in consultation with the parties to the dispute, particularly in a dispute involving scientific or technical issues. In May 1996, a panel was formed "to examine … the matter … and to make such findings as will assist … in making the recommendations or in giving the rulings provided for in the SPS (and other WTO) agreements." After consulting with scientific and technical experts, the panel issued its final report in June 1997, finding that the EU measures were not in accord with the SPS Agreement. Following an EU appeal of the initial findings of the panel, in February 1998 the WTO upheld the panel's findings and found specifically that the EU was inconsistent with Article 5.1 of the SPS Agreement. (Article 5.1 states: "Members shall ensure that their sanitary or phytosanitary measures are based on an assessment, as appropriate to the circumstances, of the risks to humans, animal or plant life or health, taking into account risk assessment techniques developed by the relevant international organizations.") The panel said the EU 'maintained measures which were not based on a risk assessment' as required by Article 5.1. The panel also stated that the EU actions were not in accord with Article 3.3 of the SPS Agreement. (Article 3.3 states: "Members may introduce or maintain sanitary or phytosanitary measures which result in a higher level of sanitary or phytosanitary protection than would be achieved by measures based on the relevant international standards, guidelines, or recommendations, if there is a scientific justification, or as a consequence of the level of sanitary or phytosanitary protection a Member determines to be appropriate in accordance with the relevant provisions of paragraphs 1 through 8 of Article 5.") The panel found that "by maintaining sanitary measures which are not based on existing international standards without justification under Article 3.3 of the SPS Agreement, it had acted inconsistently with the requirements … of that agreement." Finally, after arbitration proceedings and other delays, in July 1999 the WTO authorized the USA to begin collecting tariffs, by suspending its concessions on $116.8 million worth of imports from the EU, the amount that it lost each year due to the EU hormone ban.

Following these WTO findings, the EU announced it would conduct additional studies and risk assessments on hormones that would satisfy its Article 5.1 obligations. In November 2004, the EU filed a request for consultations with the USA asserting that the USA should have removed its retaliatory measures because the EU believed it had now removed the measures found to be SPS inconsistent by the WTO dispute panel. Specifically, the EU believed that it was now in conformity with the dispute panel because on 14 October 2003, it had amended Council Directive 96/22/EC (the prohibition on the use in stock farming of certain substances having a hormonal, thyrostatic, or beta-agonist action) to include all uses of these drugs. The EU further asserted that the amendment of this EU directive was based on comprehensive risk assessments, in particular on the opinions of its Scientific Committee on Veterinary Measures relating to Public Health. Underpinning these risk assessments were a number of EU-funded and -initiated studies and projects. The EU concluded that 'the avoidance of intake of oestradiol 17β is of absolute importance to human health and that, consequently, the placing on the market of meat containing this substance should be prohibited.' And with regard to the other hormones in dispute, the EU provisionally prohibited the placing on the market of meat containing these substances because it asserted that relevant scientific evidence was insufficient. The EU stated that assessments of the safety of hormone residues in meat are based on 'uncertain assumptions and inadequate scientific data'; i.e., data on residue levels in meat were based on studies using methods that were inadequate to measure precisely the low levels found in animal tissues and there was only limited information on the levels of the various metabolites of the steroids. The EU also questioned the reliability of data on daily production rates of human steroid hormones in healthy prepubertal children. The USA disagreed and denied both that the new Council Directive 96/22/EC was based on science and that it implemented the WTO panel's recommendations and rulings. The USA believed that, contrary to the EU's claim, there were no studies that demonstrated there was increased health risk from the consumption of meat from animals treated with growth-promoting hormones.

In January 2005, the EU requested the WTO to convene another dispute panel, and the first meeting of the new

panel and the disputing parties took place in September 2005. To highlight the broad interest that this trade case continued to have, it is interesting to note that it was the first time a WTO dispute panel meeting had been conducted and broadcast in full transparency. The EU reaffirmed its position that there were possible risks to human health associated with hormone-treated meat, given the available scientific data. The EU claimed it had complied with its WTO obligations and challenged the USA for maintaining its prohibitive import tariffs on EU products. The USA disputed whether the EU had conducted an adequate risk assessment to support its position and maintained that there was a clear worldwide scientific consensus supporting the safety to consumers of eating hormone-treated meat. In October 2008, the WTO issued a mixed ruling allowing the USA to continue its trade sanctions, but allowing the EU to maintain its ban.

Then in January 2009, the USA announced its intent to make changes to the list of EU products subject to increased tariffs under the dispute, including changes to the EU countries and products affected, and higher tariffs on some products. The EU claimed that these actions constituted an 'escalation' of the dispute. On 25 September 2009, following a series of negotiations, the USA and the EU signed a memorandum of understanding, which phased in certain changes over several years, including raising the amount of US beef certified as having no added hormones that would be permitted to be imported into the EU. In May 2011, the USA announced it was terminating higher duties for imported products listed under the dispute. In April 2012, agreement was reached to end this prolonged trade dispute when the EU Member States agreed to increase the quota of 'no hormone added' beef permitted to be imported into the EU and the USA agreed to drop its *ad valorem* punitive duties on EU products exported to the USA. Although this agreement is seen as a 'pragmatic' step forward, no decision was made, nor is likely to be made, by the WTO on the substantive public health issues surrounding this long-standing dispute.

International Risk Assessment and Management

In pressing its case in the hormone trade dispute with the EU, the USA relied significantly on the safety decisions made by the Codex Commission, the CCRVDF, and the JECFA.

For the six hormones at issue in this dispute, the JECFA had assessed five of the substances (all except MGA) and made MRL recommendations on four of them (excluding trenbolone) during its meeting in 1987. For trenbolone, further data were sought and a JECFA MRL recommendation was made in 1989. After failing to reach a consensus for several years, in June 1995 the Codex Commission adopted on the basis of a vote the standards for the five hormones. These standards apply exclusively with respect to cattle and meat and meat products of bovine origin, when these hormones are used for growth promotion purposes. The standard for MGA was not adopted at that time.

For the three natural hormones, the Codex considered it 'unnecessary' to establish MRLs because these hormones are produced endogenously at variable levels in human beings. The Codex found that residues resulting from the use of these substances as growth promoters in accordance with good animal husbandry practice are by comparison minimal and unlikely to pose a hazard to human health.

The JECFA had concluded in 1988 that 'residues arising from the use of testosterone and estradiol-17 as growth promoters in accordance with good animal husbandry practice are unlikely to pose a hazard to human health and that the amount of exogenous progesterone ingested in meat from treated animals would not be capable of exerting a hormonal effect, and therefore, any toxic effect, in human beings.' The term 'good animal husbandry practices' is recognized by the JECFA to mean 'the official recommended or authorized usage including withdrawal periods, approved by national authorities, of veterinary drugs under practical conditions.' This is an important condition given that some of the EU concerns raised as part of the WTO trade dispute made reference to the improper use of hormones.

With respect to two of the synthetic hormones (zeranol and trenbolone), the JECFA recommendations concluded that any toxic effects of these hormones are associated with their hormonal properties and that an acceptable daily intake (ADI) could thus be established on the basis of a no-hormonal-effect level. The JECFA adopted what it considered to be a conservative approach by studying animals highly sensitive to these hormonal substances and using a safety factor of 100. The JECFA recommendations included the following: an ADI of 0–0.5 $\mu g\,kg^{-1}$ body weight for zeranol and 0–0.0225 $\mu g\,kg^{-1}$ body weight for trenbolone, and for both hormones an MRL of 2.25 $\mu g\,kg^{-1}$ in bovine muscle and 10.25 $\mu g\,kg^{-1}$ in bovine liver. According to the JECFA, the MRLs thus obtained would not exceed the ADI or safe level at any time after implantation of the drug, regardless of the withdrawal period used.

The Codex Commission by a majority vote of 33 to 29 (seven countries abstaining) adopted the JECFA recommendations for these hormones. The Commission usually adopts its standards by consensus, but in this case after several years it became clear that consensus was not possible. The approval of these five hormones by the Codex provided important support for the USA in its subsequent case in the WTO against the EU. At its 2007 meeting, the CCRVDF could not reach consensus on the advancement of the proposed MRLs for MGA. But at that meeting the draft MRLs for MGA in cattle tissue were retained at Step 7 of the 8 step adoption process with the understanding that the EU would provide new data for a re-evaluation of MGA by the JECFA. Furthermore, if no new information was forthcoming, or if the JECFA reaffirmed its decision, the CCRVDF agreed that it would advance the MRLs for MGA to Step 8 at its next session. The JECFA reviewed additional data submitted by the EU and concluded that the new data did not provide any basis to reconsider the ADI. But the EU still maintained its concern regarding the advancement of the draft MRLs for MGA to Step 8 and stated that it continued to have safety concerns especially for particular susceptible population groups. This view was also supported by other delegations. But still other countries supported the findings of the JECFA's re-evaluation and the CCRVDF agreed to advance the draft MRLs for MGA in cattle tissues to the Codex Commission for adoption at Step 8.

The EU, China, Norway, and Switzerland expressed their opposition to this decision. After reviewing all positions again, the Commission at its July 2009 meeting adopted the draft MRLs. The delegations of the EU, Bosnia and Herzegovina, China, Croatia, Norway, and Switzerland expressed their strong opposition to the adoption of these MRLs.

Use of Ractopamine in Swine and Beef

Ractopamine hydrochloride is a drug that stimulates beta-adrenergic receptors. This class of substances has effects similar to epinephrine and also has anabolic effects tending to the conservation of lean muscle and reduction of fat. Ractopamine was approved by the FDA for use in swine in 1999 with the claims of increased rate of weight gain, improved feed efficiency, and increased carcass leanness in finishing swine fed a complete ration containing at least 16% crude protein from 150 to 240 lb body weight. An ADI of 1.25 μg kg^{-1} body weight in the human diet was established, with a tolerance for parent ractopamine in swine liver of 0.15 ppm (150 ppb, or 150 μg kg^{-1} of liver) and a tolerance of 0.05 ppm for parent ractopamine in swine muscle (50 ppb, or 50 μg kg^{-1} of muscle). No withdrawal time is required on this FDA approval. Ractopamine was subsequently approved by the FDA for use in cattle in 2003 and turkeys in 2008. Ractopamine has been approved for use as a veterinary drug in swine in 21 countries (e.g., Australia, Brazil, Canada, Hong Kong, Indonesia, Mexico, New Zealand, South Africa, South Korea, and the USA). In addition, Canada, Mexico, Indonesia, and the USA have also approved its use in beef. Japan has established an ADI and MRLs for pork and beef, but has not yet approved the product for use; however, Japan recognizes its use in other countries for import purposes. In August 2007, Taiwan determined that ractopamine could be safely used in cattle and swine and notified the WTO that it planned to adopt the recommended Codex MRL of 10 ppb. Taiwan then reconsidered this approach and in 2010 began enforcing a zero tolerance for ractopamine residues and testing levels in beef imports from the USA and other countries. In 2011 Taiwan approved beef imports if they contained no more than the Codex MRL (10 ppb). Taiwan is yet to adopt MRLs for ractopamine in pork.

The EU and China have not approved ractopamine for domestic use and do not allow residues of ractopamine in imported food. As described above in the Section Somatotropins, the EU prohibits the use of all beta-agonists intended solely for growth promotion without any therapeutic purposes. The EU also has stated that it is of the opinion that there are still unanswered safety questions and scientific concerns linked to the use of ractopamine. China developed residue data in swine, particularly in lung, which it believed raised concerns for the safety of food derived from animals treated with ractopamine.

Ractopamine was first evaluated by the JECFA in 1992, when it was determined that there were insufficient data on which to establish an ADI or recommend MRLs. Ractopamine was again evaluated by the JECFA in 2004 and an ADI of 0–1 μg per kg of body weight per day was established and it was determined that MRLs could be recommended to CCRVDF. Specifically, the JECFA established MRLs in muscle, fat, liver, and kidney of 10, 10, 40, and 90 ppb, respectively. At the JECFA meeting held in 2006, ractopamine was reevaluated and the previously recommended MRLs were reaffirmed. And as a result of a request in 2009 by the Codex Commission, a special electronic session of the JECFA was held in 2010 during which residue data in swine provided by China were evaluated.

In 2010, over the objection of several countries, the CCRVDF forwarded draft MRLs for residues of ractopamine to the Codex Commission to be considered at Step 8. At its 2010 meeting, the Commission failed for the third time to adopt recommended MRLs for ractopamine in pork and beef. The opposition to adoption was led by the EU, which objected because the EU prohibits the use of beta-agonists intended solely for growth promotion without any therapeutic purposes. The EU also stated that it was of the opinion that there were still unanswered safety questions and scientific concerns linked to the use of ractopamine. Although many delegations at the Commission meeting supported adoption of the recommended MRLs, consensus was not achieved and no vote was taken. The EU was joined by Russia, Switzerland, and Norway to oppose the MRLs. China also opposed adoption because of its continuing concerns about concentrations of the residue in lung, which is heavily consumed in some regions in China.

At the 2011 Commission meeting, some delegations maintained that there were still unanswered safety questions which required further studies, particularly with respect to the residues in lung tissue and scientific concerns linked to the use of ractopamine. They also opposed finalizing the MRLs because the decision did not have a broad consensus of agreement and therefore would undermine the credibility of Codex. China referred to their experimental findings on residues in pig lungs and voiced their concern with the safety of ractopamine, especially their concern with the risks related to residues in lung tissue and other offal tissues. China expressed the view that, before ractopamine MRLs are adopted, a risk assessment should be completed, one that fully considers the safety questions raised by Chinese consumption data. The WHO JECFA secretary reminded the Commission that the JECFA had evaluated extensive residue data, including the additional residue studies in pigs submitted by China, and that the JECFA again reaffirmed the MRLs for muscle, fat, liver, and kidney. With regard to the Chinese data, the JECFA was of the opinion that, when consumed, lung and other nonstandard tissues generally replaced the standard tissues (e.g., muscle meat) and were not added to the daily consumption of products of animal origin. The JECFA concluded that even if residue levels in lung were higher than in the other tissues, based on the estimated dietary exposure, they did not indicate a health concern. At the end of this and other discussions, the Commission attendees voted not to proceed on a vote to adopt the ractopamine MRLs and they were retained at Step 8.

The delay by holding the ractopamine MRLs at Step 8 raised some fundamental questions within Codex regarding the balance between science-based decision making and the role of other factors in setting Codex standards. The USA and a number of other countries believed that the scientific issues concerning the safety of ractopamine had been resolved

through multiple JECFA evaluations. They did agree that the JECFA should proceed to recommend an MRL for lung tissue but that work would not affect the pending MRLs in muscle, fat, liver, and kidney. Some countries expressed their belief that the opposition to adoption of MRLs for ractopamine by the EU and some other countries is primarily based on nonscientific issues.

At the Codex Commission meeting in July 2012, there remained no substantive changes in positions and no consensus on adoption of the MRLs. After the Delegation of Ghana requested a vote on adoption of the proposed MRLs, the Commission voted 69 to 67 to adopt the MRLs for ractopamine. The EU and eight other countries expressed their reservations for the adoption. The Commission also agreed to place the veterinary drug zilpaterol, another beta-agonist that is similar to ractopamine, on the priority list for future evaluation by the JECFA.

Illegal Use of Anabolics in Food-Producing Animals

During the 1980s, there were widespread press reports in Europe of black market sales of 'hormone cocktails' by a 'hormone mafia' as well as several reports of serious health effects from consuming meat from treated animals. More recent studies have concluded that in some EU Member States, an extended black market in veterinary anabolic hormones still exists. Illegal use of hormones has also been a problem in the USA. In 2004 the FDA responded to several cases of unapproved uses of growth-promoting hormone implants in nonruminating veal calves that went to slaughter. There are no FDA-approved growth-promoting hormone implants for veal calves, and the extra-label use for nontherapeutic purposes in veal of these growth-promoting hormonal implants is illegal. As a result of these investigations, the FDA took very aggressive monitoring and enforcement actions to ensure that this activity did not continue.

Clenbuterol is a beta-agonist that has the ability to increase muscle mass, but residues in tissues of treated animals can cause symptoms of acute poisoning in people who consume them. Although this drug was reviewed by the JECFA and Codex has adopted MRLs for some food-producing animals (cattle and horses), Codex recommends that it be used only after approval by national authorities and only in association with therapeutic uses and under well-controlled withdrawal times. Beta-agonists represent a class of drugs having similar modes of action, but not all have the same safety or toxicity profile. Clenbuterol is metabolized by oxidative and conjugative pathways and has a long plasma half-life. Ractopamine is a beta-agonist that is metabolized solely by conjugation, has a relatively short plasma half-life, and has low oral potencies in humans. Clenbuterol and some other beta-agonists having relatively slow rates of elimination demonstrate high oral potencies in humans. As a result of illegal use, clenbuterol in edible tissues of livestock represents a serious risk to consumers. At the concentrations of clenbuterol measured in some contaminated liver and meat samples, pharmacological effects may be expected in humans after consuming 100–200 g of product. As mentioned above in the Section Somatotropins, EU legislation forbids the use of beta-agonists as growth-promoting substances in cattle raised for human consumption. However, it is recognized that this EU ban has not eliminated illegal uses of beta-agonists in Europe. There are permitted uses of beta-agonists, including clenbuterol, in the EU and some other countries as a therapeutic treatment for inhibition of uterine contractions (tocolysis) for female cattle during calving and of respiratory diseases and tocolysis for horses not raised for human consumption. In 1990 symptoms, but no deaths, from clenbuterol residue-induced food poisoning were reported from investigations of separate events in Spain and France. After a number of food poisoning incidents involving pork and some pig organs in Shanghai (2006), in Guangdong Province (2009), and in Henan Province (2011), serious penalties were imposed in China against individuals promoting the use of clenbuterol in animal feed.

In 1991, following some serious violations, the FDA advised the public of the possibility of illegal clenbuterol use in domestic animals and of its concern about adverse effects on public health if residue was present in food. The FDA also alerted consumers and others about illegal importation of this drug or of meat containing residues. Over the years the FDA has found several individuals guilty of distributing clenbuterol for use in food-producing animals. Results of monitoring programs in EU Member States during 1992 and 1993 for the occurrence of residues of beta-agonists in food-producing animals vary substantially with respect to the percentages of positive samples, ranging from 0% to 7%. Investigators have reported that as late as 2010, 'dozens of illegal veterinary drugs are used in the EU and the number of active compounds is still expanding.' These substances include estrogenic, androgenic, and progestagenic compounds, as well as thyreostatic, corticosteroidal, and beta-adrenergic compounds. In the EU one estimate of the number of different illegal 'hormones' that have been identified ranged from 35 to 55. Because of the illegal black markets that exist for these substances, there are likely many counterfeit products that are being offered as well. In addition, Internet sales and more open borders, especially in Europe, have made these problems more acute in recent years. The illegal use of clenbuterol and other growth promotants in food-producing animals remains a serious problem worldwide.

Conclusion

Since 1995, with the enactment of the SPS Agreement, Codex MRLs have essentially become the de facto world standards for drug residues in food. This is because if other countries establish more stringent MRLs, those countries can be required to independently demonstrate that their MRLs are based on competent and valid risk analyses or take the chance of becoming subject to trade sanctions. Because of this increased importance of Codex standards in determining the outcome of trade disputes, the establishment of MRLs for animal drugs has become extremely contentious and difficult both in the JECFA deliberations and within the Codex Step 8 process. This has been especially true for drugs that affect muscle mass or otherwise increase food production. Although Codex standards are voluntary and countries are free to conduct their own

scientific reviews and risk assessments, many countries do rely on Codex standards to ensure the protection of consumers and promote fair trading practices. Adoption of Codex standards is especially important for countries that do not have the resources to carry out their own risk assessments. In addition, other countries that have not established veterinary drug MRLs, but want to import animal-derived food from countries that use and enforce Codex MRLs, can permit the entry of those products and have confidence in their safety.

Many controversies and serious differences of opinion continue regarding the safe use of anabolic substances in veterinary medicine, particularly when they are used for growth promotion and increased food production purposes. It is clear that differing decisions by national authorities and disagreements that continue to arise out of Codex and JECFA conclusions can lend support or nonsupport to opposing views about the safety of these drugs. The WTO trade dispute between the USA/Canada and EU over the safety of hormones has persisted without substantive resolution for almost 20 years. Some critics may have differences of opinion about how to interpret the scientific evidence supporting Codex or JECFA decisions. Some critics believe that Codex committees like CCRVDF should consider 'other relevant factors' such as animal welfare or environmental concerns. Still other critics may find fault in the selection procedures for the scientific experts who participate in the JECFA, including the overall composition of the JECFA, the scientific competence of the experts, and the potential conflicts of interest of the experts. Also, some critics see JECFA's reliance on unpublished industry data and lack of procedural transparency to be problems. Although Codex, JECFA and many of the countries that participate in Codex have dealt effectively with many of these criticisms, some of these issues are not easily resolved. But it is important that they continue to be addressed. Those individuals and countries participating in Codex and JECFA must work as effectively as possible to deal directly with these criticisms and other subjects that may undermine the credibility of Codex and JECFA.

Some countries are concerned that any lack of confidence or even misinformation about the scientific and public health protection basis for Codex standards will create more confusion and further undermine the work of Codex in the future. Many also believe that the widely publicized disagreements concerning the safety of anabolic drug residues in food have made worse, and even encouraged, certain illegal activities that seriously threaten public and animal health. If the scientific bases for health and safety standards are perceived by a vocal few to be invalid, whether they are viewed as overly protective or not protective enough, there may emerge a distrust by the public of the regulatory actions that result from those standards. Failing credibility may also result in increased problems related to a growing lack of compliance by product manufacturers and users. For example, increasing reports of illegal products being available on black markets in some countries and through Internet sales may indicate, in addition to inadequate enforcement capabilities, that some government regulatory requirements are viewed as arbitrary or scientifically unjustifiable. The availability and use of such illegal products clearly can greatly undermine public health efforts, exacerbate regulatory control problems, and significantly compromise the important goals that Codex and other food safety organizations and national regulatory agencies are pursuing.

Countries participating in and/or relying on Codex and JECFA programs must work in the most effective ways to assure the integrity and transparency of these programs and work hard to build more consensus regarding the decisions that are made by these organizations. This will help ensure that Codex decisions truly further the stated goals of Codex: protecting the public health and assuring fair food trade practices. A lesser result is not acceptable.

Disclaimer

Some antimicrobials are commonly used in livestock feed at low doses for growth promotion or feed conversion efficiency (e.g., bambermycins, zinc bacitracin, salinomycin, virginiamycin, monensin sodium, carbadox, and lasalocid sodium). Some of these drugs affect the movement of ions across biologic membranes in the gut or modify the rumen and the physiology of the colon microflora by, for example, increasing nitrogen utilization. Others may act to selectively modify the microbial populations within the animal alimentary tract to improve production efficiency and to maintain health by, for example, combating low-level infections. These substances are not generally classed as anabolic agents and are not included in the subject matter of this article.

The opinions and information in this review article are those of the author and do not represent the views and/or policies of the FDA.

VETERINARY DRUGS RESIDUES

Coccidiostats

A Anadón and MR Martínez-Larrañaga, Universidad Complutense de Madrid, Madrid, Spain

Glossary

Acceptable daily intake (ADI) The estimate of the residue, expressed in terms of μg or mg per kg of bodyweight, that can be ingested daily over a lifetime without any appreciable health risk.

Acute reference dose (ARfD) The estimate of the amount of a substance in food or drinking water, expressed on a bodyweight basis, that can be ingested in a period of 24 h or less without appreciable health risk to the consumer. It is derived on the basis of all the known facts at the time of evaluation. The ARfD is expressed in mg of the chemical per kg of bodyweight.

Adverse effect Change in morphology, physiology, growth, development, or lifespan of an organism which results in the impairment of functional capacity or impairment of the capacity to compensate for additional stress or increase in susceptibility to the harmful effects of other environmental influences.

Food-producing animals Defined as animals bred, raised, kept, slaughtered, or harvested for the purposes of producing food.

Marker residue A marker residue is that residue, the concentration of which decreases in a known relationship to the concentration of total residues in tissues, eggs, milk, or other animal tissues.

Maximum residue limits (MRLs) The maximum concentration of residue resulting from the use of a veterinary medicinal product (expressed in mg per kg or μg per kg on a fresh weight basis) which may be accepted by the community to be legally permitted or recognized as acceptable in or on food.

No observed adverse effect level (NOAEL) The greatest concentration or amount of an agent, found by study or observation, that causes no detectable adverse alteration of morphology, functional capacity, growth, development, or lifespan of the target.

Residues All pharmacologically active substances, expressed in mg per kg or μg per kg on a fresh weight basis, whether active substances, excipients, or degradation products, and their metabolites which remain in food obtained from animals.

Target tissue The edible tissue selected to monitor for the marker residue in the target animal.

Withdrawal period The interval between the time of the last administration of a veterinary drug and the time when the animal can be safely slaughtered for food or when milk or eggs can be safely consumed.

Coccidiosis

Coccidiosis is a parasitic disease, which can occur wherever animals are housed in small areas that are contaminated with coccidial oocysts. Coccidiosis has affected historically all species of wild and domestic birds. The nature of the parasitic infestation is present in all poultry farms, even in the presence of high sanitary standards and good management, with a high potential impact on animal welfare. Coccidia are without question the most important parasites of poultry in terms of distribution, frequency, and economic losses. Coccidiosis is an important enteric disease often caused by highly host-specific intestinal protozoan intracellular parasites which belong to the genus *Eimeria* (phylum Apicomplexa), and is characterized by high mortality. Some species tend to be more pathogenic in terms of the inoculation dose required to produce measurable effects, but all species of avian *Eimeria* produce weight loss, increased feed conversion ratios, loss of skin pigment, and decreased egg production. Avian coccidia of the genus *Eimeria* are extremely host specific. Chickens, turkeys, pheasants, and Japanese and bobwhite quails all have their own species. Each poultry species may be infected with several different *Eimeria* species (*Eimeria necatrix, Eimeria tenella, Eimeria acervulina, Eimeria brunetti, Eimeria maxima, and Eimeria mivati* in broiler chickens or chickens for fattening; *Eimeria meleagrimitis, Eimeria gallopavonis, Eimeria adenoides, and Eimeria dispersa* in turkeys; *Eimeria duodenalis, Eimeria colchici, and Eimeria phasiani* in pheasants). Although there are no exact prevalence and incidence data on clinical and subclinical coccidiosis in commercial poultry, it is widely acknowledged that the parasites are present in all commercial flocks.

The life cycle of the coccidium is complex (Figure 1). It begins when a susceptible bird ingests sporulated oocysts from the environment in contaminated litter, feed, and water. After ingestion, the sporozoites are released from the oocysts, and actively penetrate the host cells (intestinal mucosa or epithelial cells lining the gut wall), and develop intracellularly into multinucleate schizonts (also called meronts). The

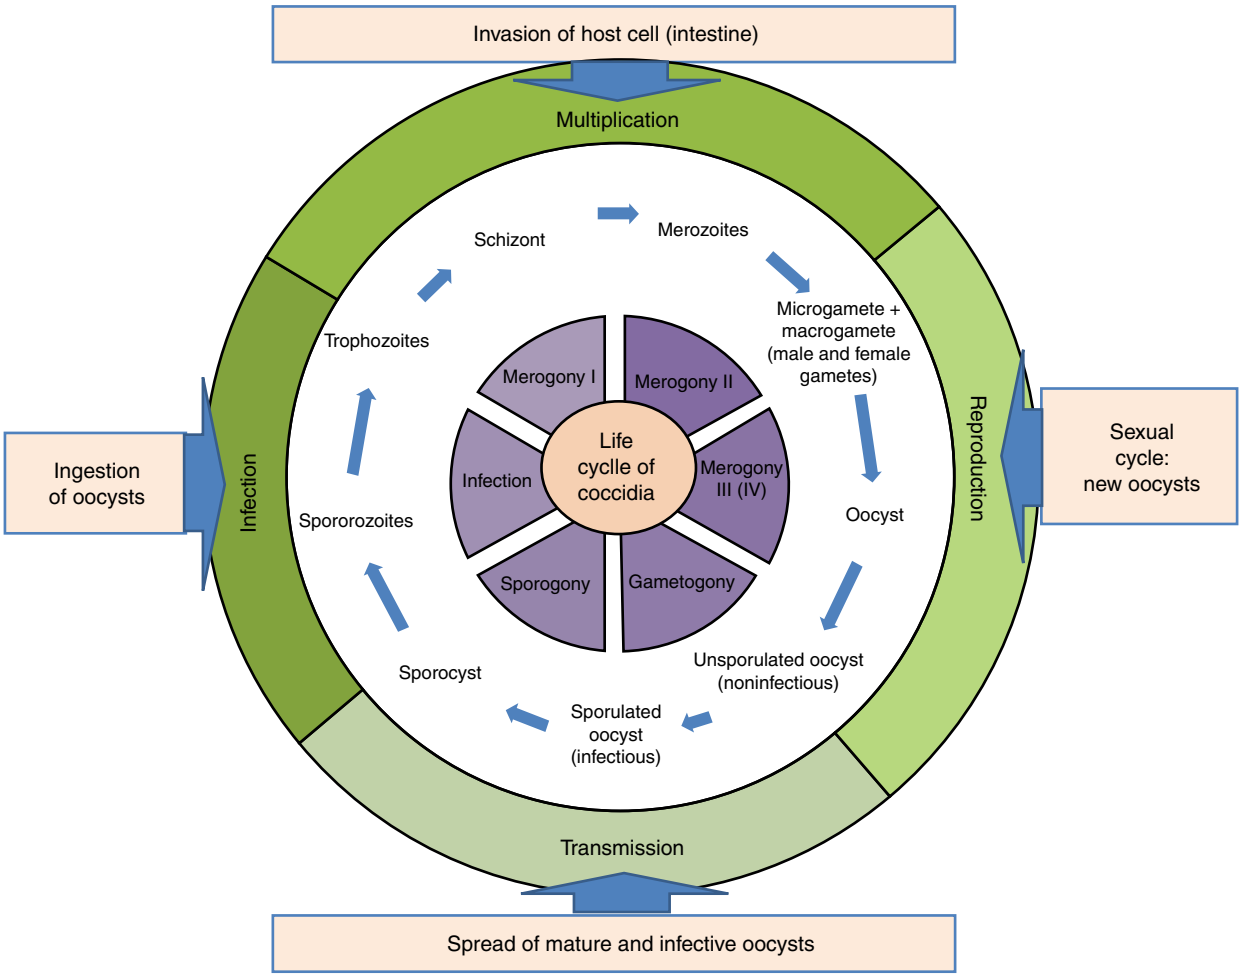

Figure 1 Life cycle and reproduction of Coccidia.

sporozoite transforms into trophozoite, which undergoes multiple karyokinesis and eventually produces numerous merozoites. This sequence of developmental events occurs a predetermined number of times (reinfective cycle), and each cycle is called a generation. Eventually the merozoites produced by the terminal generation of merozoites transform into sexual gametes. Some merozoites become differentiated into male and female gametes and the sexual part of the cycle is initiated. Immature sexual forms are known as gametocytes. The male gametocytes divide into a large number of mobile microgametocytes, whereas the development of macrogametocytes (female) leads to the production of a single microgametocyte. The male and female gametocytes unite resulting in the production of a zygote, which secretes a cyst wall and becomes an oocyst. The oocyst is excreted in the feces, usually in the nonsporulated condition. Sporulation occurs in the environment. Each oocyst ingested by the host may give rise to hundreds of thousands of infective oocysts in the feces within 7–12 days. Transmission from one farm to another is facilitated by the movement of personnel and equipment, and even new farms will have the parasite present within a few weeks after poultry are introduced.

Coccidiostats or Anticoccidials Drugs Used in Poultry

In intensive poultry production, the main method of controlling coccidiosis is through the addition of drugs used as anticoccidial drugs or coccidiostats in the feed at the authorized levels and observing the prescribed hygiene requirements. All coccidiostats inhibit reproduction and do not fully eliminate the parasite from the intestine of the animal avoiding losses due to acute and often lethal coccidiosis. Eggs are however, a special issue. Maximum age levels and restrictions on usage in layer feed may not always be enough to ensure that eggs are free of coccidiostats. The strategy of medications for layers is different because most anticoccidial therapy must cease at the time when the bird comes to lay eggs, to avoid the potential deposition of drug residues in eggs. The objective is to prevent clinical coccidiosis while still encouraging the development of active immunity during the first 14–20 weeks of life. Prophylactic medication with coccidiostats in the feed remains the major way of preventing coccidiosis. The biggest problem associated with this control is the development of resistance by the coccidium to all medications available for use.

Coccidiosis is generally well controlled using currently available polyether ionophore antibiotics, but the susceptibility of *Eimeria* species varies considerably with *E. maxima*, *E. acervulina*, and *E. tenella* considered the most difficult species to control. The introduction of the first polyether ionophore coccidiostat (monensin) in the 1970s represented a major achievement in the control of coccidiosis. Before this, coccidiosis outbreaks were common and more difficult to treat or prevent, as only nonpolyether ionophore coccidiostats were available and these were much less effective because of the rapid development of immunity by the parasite. The intensive use of most coccidiostats is accompanied by the development of tolerance or reduction in the susceptibility of the target population. Repeated exposure to the same coccidiostats can result in the selection of drug-resistant strains of *Eimeria* which might be expected to result in the reduced efficacy of coccidiostats. The efficacy of modern coccidiostats is affected by the severity of exposure to coccidia. Some drugs, such as the polyether ionophores, will still work if exposure to the coccidian is mild. If conditions change, the exposure level rises, these drugs are often not able to control resistant populations of the coccidian.

Outbreaks of clinical coccidiosis commonly occur when the coccidiostats are excluded from the feed during antibacterial therapy, typically at approximately 3–4 weeks of age. Combinations of antibacterials with coccidiostats help to prevent this type of outbreak. In addition, potentiated sulfonamides (e.g., sulfadimethoxine and ormetoprim in a 5:3 ratio), which have both coccidiostatic and antibacterial efficacy, can be useful. The main method of controlling coccidiosis is through the addition of coccidiostats to the feed. They need to be administered throughout the life of the bird as is in the case of chickens for fattening or broilers in order to protect against reinfection from the ever-present oocyst stage of the malady.

Coccidiostats or anticoccidial drugs can act at specific times during the life cycle or exert their effects at several phases. Coccidiostats can act on extracellular stages (sporozoites and merozoites) to prevent penetration of cells or on the intracellular stages to stop or inhibit development, and a few anticoccidials affect the sporulation of oocysts after they are excreted. There are two classes of coccidiostats: (1) Coccidiostatics, which arrest or inhibit growth of intracellular coccidian and give rise to latent infection after drug withdrawal and (2) Coccidiocides, which kill most of the coccidial stages. Some coccidiostatic drugs may be initially coccidiostatic but eventually coccidiocidal depending on factors as length of time on medication, dosage, and species of coccidia. Most coccidiostats currently used in the poultry production are coccidiocides.

Legislative Framework for Coccidiostats

The legislative background for coccidiostats or anticoccidial drugs in the European Union (EU) are regarded as feed additives or veterinary medicines products.

The requirements and procedures for the marketing authorization for veterinary medicinal products in the EU are primarily laid down in Directive 2001/82/EC and in Regulation (European Commission (EC)) No. 726/2004. These texts additionally lay down harmonized provisions in related areas such as manufacturing, wholesaling, or advertising of veterinary medicinal products. Currently, the EU is assessing the safety of all pharmacologically active substances that are administered to food-producing animals, and is attempting to set a single legally binding maximum residue limit (MRL) for each substance. These are laid down in Regulation (EC) No. 470/2009, on MRLs, Regulation (EC) No. 470/2009, repealing Council Regulation (European Economic Community (EEC)) No. 2377/90 and amending Directive 2001/82/EC, and of the Council and Regulation (EC) No. 726/2004. Under the Regulation (EEC) No. 2377/90 only those compounds listed in Annexes I, II, and III can be used in food-producing animals. Annex IV is the designation of drugs considered unsafe on consumer health grounds. Drugs in this last Annex are effectively prohibited for use in food-producing animals within the EU.

The Commission Regulation (EU) No. 37/2010 on pharmacologically active substances and their classification regarding MRL in foodstuffs of animal origin, in its annex included two tables. **Table 1** (allowed substances) lists the pharmacologically active substance, marker residue, animal species, MRL value, target tissues, other provisions (according to Article 14(7) of Regulation (EC) No. 470/2009), and therapeutic classification, and **Table 2** lists prohibited substances where an MRL cannot be established. This classification substitutes the 4 annexes of the Council Regulation (EEC) No. 2377/90.

In the EU, feed additives are regulated by different legislation than veterinary medicinal products. The legal basis for additives for use in animal nutrition is laid down in Regulation (EC) No. 1831/2003 that repeals Directive 70/524/EEC and for which authorization and prerequisites of coccidiostats for their use are defined for individual products (brand names) following review by the European Food Safety Authority (EFSA) of data provided by the applicant (**Tables 1** and **2**). Only additives that have been through an authorization procedure may be placed on the market. Authorizations are granted for specific animal species, specific conditions of use, and for 10 year periods. According to Article 6 of this regulation a feed additive shall be allocated to one or more of the following categories, depending on its functions and properties: (1) technological additives; (2) sensory additives; (3) nutritional additives; (4) zootechnical additives; and (5) coccidiostats and histomonostats. More recently, there have been included several coccidiostats of antibiotic origin to be used in chicken and turkey species under certain conditions. The EFSA is responsible for conducting the evaluation of the data submitted requesting authorizations. MRLs and postmarket monitoring plans may be established for a feed additive if deemed necessary.

Management of Resistance

A number of strategies have been developed to extend the useful life of coccidiostats, while still controlling coccidiosis. The programs used for coccidiostats are the following: (1) continuous, (2) shuttle, and (3) rotation. In some cases, birds

Table 1 Coccidiostat polyether ionophores authorized in the EU

Name of additive	*Trademark*	*Target species*	*Minimum/ Maximum (mg per kg per feed)*	*Withdrawal period (WP)*	*MRL (μg kg^{-1})*
Polyether ionophores					
Monensin sodium	125 mg kg^{-1} (Coxidin and Elancoban)	Chickens for fattening	100–125	1 day	25 (skin/fat) 8 (liver, kidney, and muscle)
	120 mg kg^{-1} (Elancoban)	Chickens reared for laying (maximum 16 weeks)	100–120		
	100 mg kg^{-1} (Coxidin and Elancoban)	Turkeys for fattening (maximum 16 weeks)	90–100		
Lasalocid sodium	125 mg kg^{-1} (Avatec)	Chickens for fattening	75–125	5 days	60 (muscle) 300 (skin/fat and liver)
		Chickens reared for laying (maximum 16 weeks)	75–125		
		Turkeys (maximum 12 weeks)	90–125		150 (kidney) 150 (eggs)
Maduramicin ammonium	5 mg kg^{-1} (Cygro)	Chickens for fattening	5	5 days	No MRL has been established
		Turkeys (maximum 16 weeks)	5		
Narasin	70 mg kg^{-1} (Monteban)	Chickens for fattening	60–70	1 day	50 (liver, kidney, muscle, and skin/fat)
Narasin + nicarbazin	40–50 mg narasin per kg + 40–50 mg nicarbazin per kg (Maxiban G160)	Chickens for fattening	80–100	0 days	50 μg narasin per kg liver, kidney, muscle, and skin/fat
Salinomycin sodium	70 mg kg^{-1} (Salinomax and Sacox)	Chickens for fattening	50–70	1 day	5 (liver, kidney, and muscle)
	(Kokcisan)		60–70		15 (skin/fat)
	50 mg kg^{-1} (Sacox)	Chickens reared for laying (maximum 12 weeks)	50	Not required	
Semduramicin sodium	25 mg kg^{-1} (Aviax)	Chickens for fattening	20–25	5 days	No MRL has been established

Abbreviation: MRL, maximum residue limit.

are given one coccidiostat continuously through succeeding flocks, but two or more coccidiostats (e.g., shuttle programs) may be given during the life of a flock being convenient to provide a particular coccidiostat for a period during which one type of feed is given. Shuttle and rotational programs can be used to block the development of drug resistance. A 'shuttle program' usually involves a change coccidiostats within a single grow-out period (between the starter and grower rations) (i.e., a chemical in the starter feed, a polyether ionophore in the grower feed, and no medications in the finisher feed) whereas a 'rotational program' has an objective to rotate the agents (i.e., rotation between medications at different times of the year) between grow-out periods (i.e., one class might be used in starter feed, another in growers, returning to the first for the finished diet followed by a withdrawal diet or nicarbazin during the fall and winter and a different medication in the spring and summers), all help to delay, or in some cases even avoid, the emergence of resistance. It is known that any resistant forms from a previous flock may survive in the litter for a short period, so drugs are usually included in the starter feed. These programs take advantage of the different coccidiostat properties with a different mode of action (e.g., between polyether ionophores that share a similar mode of action and nonpolyether ionophores), matching spectrum of activity, potency, and drug cost against risk of infection, while slowing the rate of development of resistance. It is generally accepted the rotational programs provide increased drug efficacy at the time of change by letting coccidia regain sensitivity during the off-time of each drug.

Classes of Coccidiostats or Anticoccidial Drugs

The coccidiostats or anticoccidial drugs can be grouped into two major classes. In the first class includes polyether ionophore antibiotics which are produced by fermentation with several strains of *Streptomyces* spp. and *Actinomadura* spp. comprising the following substances: monensin sodium, lasalocid sodium, maduramicin ammonium, narasin, salinomycin sodium, and semduramicin sodium. This class of polyether ionophores has limited antibacterial activity, especially against *Clostridium* and can interact with other antibiotics when they are concurrently administered. The second

Table 2 Coccidiostats nonpolyether ionophores authorized in the EU

Name of additive	*Trademark*	*Target species*	*Minimum/ Maximum (mg per kg per feed)*	*Withdrawal period (WP)*	*MRL ($\mu g\ kg^{-1}$)*
Nonpolyether ionophores					
Decoquinate	40 mg kg^{-1} (Deccox)	Chickens for fattening	20–40	3 days	No MRL has been established
Robenidine hydrochloride	36 mg kg^{-1} (Cycostat)	Chickens for fattening and Turkeys	30–36	5 days	No MRL has been established
Halofuginone hydrobromide	3 mg kg^{-1} (Stenorol)	Chickens for fattening Chickens reared for laying (maximum 12 weeks) Turkeys (maximum 16 weeks)	2–3	5 days	10 (muscle) 25 (fat) 30 (liver and kidney)
Diclazuril hydrochloride	1 mg kg^{-1} (Clinacox)	Chickens for fattening (maximum 12 weeks) Chickens reared for laying (maximum 16 weeks) Turkeys for fattening (maximum 12 weeks)	1	5 days Not required 5 days	No MRL has been established
Nicarbazin	50 mg kg^{-1} (Maxiban)	Chickens for fattening	40–50	5 days	200 (muscle, liver, kidney, and skin/fat)

Abbreviation: MRL, maximum residue limit.

class includes the nonpolyether ionophores (often referred as synthetic compounds or chemicals).

Polyether Ionophore Antibiotics

Polyether ionophores are produced by saprophytic fungi, predominantly *Streptomyces* spp. or *Actinomadura* spp. (i.e., maduramicin and semduramicin) containing mycelial biomass (maduramicin can be extracted into granular carrier); continuing commercial success is due to their broad-spectrum activity against pathogenic *Eimeria* spp. in poultry and also to a prolonged absence of serious problems with drug resistance.

In vitro studies with monensin, salinomycin, or lasalocid reveal that sporozoites of *E. tenella* are damaged after 24 h incubation, but are not if incubation is shortened (20 min); under laboratory conditions, polyethers allow a relatively high oocyst output due obviously to their lack of activity against sporozoites *in vivo*. It has been shown that these polyether ionophores do not only cause irreversible damage to free merozoites and mature schizonts of first- and second-generation coccidia but also to erythrocytic stages of various chloroquine-resistant malaria parasites.

Polyether ionophores can have both anticoccidial and antibacterial activity, and the group is used extensively in poultry. Other uses are as growth-promoting agents (nowadays forbidden in the EU) and as an active compound against clostridiosis.

Polyether ionophores (ion carriers) facilitate movement of some monovalent cations, such as sodium and potassium, and divalent cations such as calcium and magnesium across cell membranes. Polyether ionophores as a class are divided into two general groups based on the mode of ion transfer across membranes. These include channel formers and ion carriers. Channel-forming ionophores arrange themselves inside the membrane structure creating a hydrophilic channel for the ions. By this means, ions from outside the cell pass through the provided hydrophilic channel into the cell. There are two subclasses of ion carrier ionophores: (1) neutral ionophores and (2) carboxylic ionophores. Both neutral and carboxylic ionophores are compounds that form lipid-soluble dynamically reversible complexes with cations and by this means facilitate specific ionic transport across biological membranes. Neutral ionophores are highly toxic because they form charged complexes that are capable of perturbing biologic membranes and action potentials. The carboxylic polyether ionophores are open-chained oxygenated heterocyclic rings with a single terminal carboxyl group of moderate molecular weight (200–2000) which form zwitterionic complexes with cations and promote electrically neutral cation exchange diffusion that is tolerated better in intact organisms. They form lipid-soluble complexes with polar cations (K^+, Na^+, Ca^{2+}, and Mg^{2+}) enhancing their transport across biomolecular lipid membranes. The transport of specific ions (Na^+, K^+, and Ca^{2+}) across membranes is responsible for multiple pharmacologic effects at the cellular level. The carboxylic polyether ionophores mediate concentration-dependent, pH-sensitive transport of ions independent of membrane potentials. They act as 'exchange diffusion' carriers, transporting a cation during both stages of the exchange cycle.

Members of the polyether ionophores group are classified as either monovalent or divalent on the basis of their affinity for particular cations. The monovalent ionophores (salinomycin, monensin, narasin, maduramicin, and semduramicin) tend to combine more readily with Na^+ and K^+, whereas

lasalocid, a divalent ionophore combines with Na^+ and K^+, as well as with Ca^{2+} and Mg^{2+}. It is known that monensin, classified as an Na^+-selective ionophore, binds to Na^+ outside the cell, and carries it into the cell, then produces high intracellular Na^+ concentrations. Na^+ influx is compensated by the much slower K^+ efflux where an initial H^+ (proton) efflux may result in intracellular alkalosis. With salinomycin and narasin and others that show K^+ selectivity, the K^+ egress is countered by an initial H^+ ingress, which could result in intracellular acidosis. Overall, monensin forms monovalent complexes with Na^+, whereas salinomycin and narasin preferentially complex K^+ and lasalocid Ca^{2+}.

The carboxylic polyether ionophores direct their effects at both the asexual and sexual cycles of coccidian causing the normal transport of Na^+ and K^+ ions across surface membranes to fail. The polyether ionophores are coccidiocidal because of their ability to preferentially move ions, usually Na^+, into various stages of the parasite, altering ionic balance in the coccidian. Because coccidia intracellular parasites cannot make adenosine triphosphate (ATP) to drive their Na–K ATPase pumps, the coccidial organism loses the ability to osmoregulate and increasing intracellular sodium is transferred to other organelles. Polyether ionophores are not used in human beings for prophylaxis or therapy.

In general, polyether ionophores, when administered orally to chickens, are rapidly absorbed from the gut and widely distributed to the tissues. Its residues in food products are of special concern because of the high degree of toxicity of these drugs to many species.

Monovalent cationic

Monensin Monensin was the first carboxylic polyether ionophore introduced in the USA for the control of coccidiosis in 1971. Monensin belongs to the polyether monocarboxylic acid chemical family, and it is produced by the fermentation of a *Streptomyces cinnamonensis* strain. Monensin is used in the prevention of coccidiosis in poultry caused by *E. necatrix*, *E. tenella*, *E. acervulina*, *E. brunette*, *E. maxima*, and *E. mivati*. Monensin sodium is a coccidiostat agent that is authorized in the EU as a feed additive in poultry. Monensin sodium is active mainly against Gram-positive bacteria, is absorbed and metabolized extensively by chickens and turkeys, and its metabolic fate is similar in both species. Unchanged monensin represents a limited fraction of the excreted monensin-related compounds. The monensin residues were readily detected in liver (giving the highest residue concentrations), fat, and muscle between 0 and 2 days postdrug withdrawal. Monensin residues are sometimes not detectable at all in the eggs of treated hens. For practical reasons, the skin/fat has been retained as the target tissue in poultry. A great number of metabolites have been isolated from the excreta and tissues. The main excretion route for monensin is fecal and metabolites are produced by either single or combined demethylation, decarboxylation, and hydroxylation reactions.

Salinomycin Salinomycin was approved for chickens in 1983. It is a sodium salt of a polyether monocarboxylic acid produced by *Streptomyces albus*. Salinomycin sodium is authorized in the EU as a coccidiostat feed additive. It is used in the prevention of coccidiosis in poultry caused by *E. necatrix*, *E. tenella*, *E. acervulina*, *E. brunette*, *E. maxima*, and *E. mivati*. Salinomycin is active against certain Gram-positive bacteria, whereas Enterobacteriaceae are resistant. In addition, it is known that salinomycin has an inhibitory effect on *Clostridium perfringens*, therefore the use of salinomycin leads to a decrease in the incidence of necrotic enteritis in broiler chickens. Salinomycin is absorbed to a certain extent in the chicken and extensively metabolized although the concentration present in the edible tissues of the animals are very low and scarcely detectable. Salinomycin is considered as the marker residue and skin/fat as the target tissue. Salinomycin produces relatively low residue levels in the eggs compared with other polyether ionophores.

Narasin Narasin was approved for chickens in 1986. Narasin is a polyether antibiotic produced by the fermentation of a strain of *Streptomyces aureofaciens*. Narasin is authorized as a coccidiostat feed additive for the control of *Eimeria* infection in chickens for fattening. Narasin, at the levels used for the treatment of coccidiosis, is also effective in the prevention of necrotic enteritis in chickens. The antimicrobial spectrum of narasin is mainly limited to Gram-positive bacteria, including enterococci, staphylococci, and *C. perfringens*. Narasin is absorbed to an unknown extent and excreted rapidly via feces by the chicken. The main metabolic pathway in the chicken and rat involves oxidative processes leading to the formation of very similar metabolites in both species in terms of chemical structure and biological activity. For food control purposes narasin can be selected as a marker residue and skin/fat as the target tissue. Narasin is used also in combination with nicarbazin for chickens for fattening. The passage of narasin into egg yolk has been reported.

Maduramicin Maduramicin was approved for chickens in 1989. Maduramicin ammonium is a polyether carboxylic ionophore agent that is authorized as a coccidiostat feed additive in the chicken and turkey for the control of *E. adenoides, E. meleagrimitis, E. gallopavonis, and E. dispersa*. Maduramicin can inhibit the growth of Gram-positive microorganisms. Maduramicin and/or its metabolites are rapidly eliminated in chickens. Steady state is observed after 3 days in the excreta, but after 6 days in plasma. Maduramicin is the main compound excreted (26%). *O*-Demethylation represents the main metabolic pathway of maduramicin in chickens. Maduramicin is the marker residue in all tissues tested. Tissue residue kinetics of total residues and marker residue indicate a rapid decline of residues in all tissues.

Semduramicin Semduramicin was approved for chickens in 1994. It is a monocarboxylic acid polyether ionophore produced by the fermentation *of Actinomadura roseorufa* and is authorized in the EU as a coccidiostat feed additive against poultry *Eimeria*. Gram-negative aerobic and anaerobic bacteria were not affected by semduramicin. *Clostridium perfringens, Clostridium difficile, Eubacterium limosum*, and Groups C and E *Streptococci* were more susceptible. Following a 7-day oral administration of the ^{14}C-uniformally labeled compound at the dose corresponding to the intended use, i.e., 25 mg kg^{-1} in feedstuffs, the total radioactivity measured in

plasma at slaughter following a 6-h withdrawal period was very low (0.025 μg ml^{-1} equivalent semduramicin). No MRL has been established for semduramicin in animal tissues and eggs.

Divalent cationic

Lasalocid sodium Lasalocid has been marketed since 1977 for chickens. Lasalocid sodium belongs to the divalent polyether ionophore family and is produced by the fermentation of *Streptomyces lasaliensis* subsp. *lasaliensis*. It is a polyether carboxylic ionophore agent that is authorized as a coccidiostat in the EU. Lasalocid can selectively destroy intracellular sporozoites while remaining relatively non-injurious to the host cell. Lasalocid sodium is effective in controlling the coccidiosis in chickens and turkeys and has a selective antimicrobial activity against Gram-positive bacteria whereas many Gram-negative strains are naturally resistant. Lasalocid sodium is absorbed and metabolized into a number of metabolites; none of which have been identified in the excreta or in tissues. The liver is the target tissue. Lasalocid residues may persist in edible tissues for longer periods than either salinomycin or monensin and may require a substantially longer withdrawal period than any of the other polyether ionophore compounds. The marker residue has not been identified. Lasalocid produced the highest residue concentrations in eggs compared with other ionophores.

Nonpolyether Ionophores (Synthetic Compounds or Chemicals)

Decoquinate

Decoquinate was first described in 1968. It belongs to the quinolone derivative group, and has been used as a coccidiostat in various animal species. Other substances belonging to the quinolone derivative group are buquinolate and methylbenzoquate. Decoquinate is a 4-hydroxyquinolone (ethyl-6-decyloxy-7-ethoxy-4-hydroxyquinoline-3-carboxylate) used for the prevention of coccidiosis in broiler chickens caused by *E. tenella, E. necatrix, E. acervulina, E. mivati, E. maxima,* or *E. brunetti*. It acts on the sporozoite stage of the life cycle by disrupting electron transport in the mitochondrial cytochrome system of coccidia. Its main use is in shuttle programs and withdrawal feeds. Rapid emergence of resistance to this compound and others as buquinolate and nequinate has been their major weakness. For that reason, clinical use remained limited, as there was evidence of the emergence of resistance of coccidia against decoquinate when used for a longer period on the same farm. Decoquinate can have an anticoccidial effect on first-generation schizonts of *E. tenella*, adversely affect sporulation, and permit the development of immunity if fed at levels lower than its coccidiostatic levels. Decoquinate is only absorbed to a small extent from the gastrointestinal tract of chicken, and once absorbed, is rapidly cleared from blood and tissues via bile and to a much lesser extent in urine. Decoquinate is distributed widely in tissues. Skin/fat is the target tissue.

Robenidine

Robenidine hydrochloride (*N*1,*N*3-bis(*p*-chlorobenzylidene) amino]guanidine hydrochloride) belongs to a chemical group of guanidines and is used in poultry and rabbits. Initially it acts as a coccidiostat and arrests the development of the first-generation schizonts of *E. tenella* by preventing the formation of merozoites. An additional effect on gametogeny has been identified. Robenidine hydrochloride is authorized as a coccidiostat feed additive in the EU and it is primarily active against Gram-positive bacteria. It is absorbed to a limited extent and excreted rapidly. Its metabolic fate has been established involving the splitting of the molecule at the semicarbazide bonds, oxidation of the *p*-chlorobenzaldehyde formed to *p*-chlorobenzoic acid, and conjugation of the latter with amino acids. Unchanged robenidine is the major compound excreted by chicken and turkey. Robenidine is the marker residue in chicken and turkey. In chickens, it is not completely absorbed from the GI tract; the absorbed portion is well distributed to tissues and extensively metabolized. Excretion occurs over several days following oral administration. Residues are detected in the eggs, primarily the yolk, of treated hens for weeks after medication is withdrawn.

Amprolium

Amprolium is structurally similar to vitamin B_1. When it is administered orally to chickens, it has a low bioavailability, but the absorbed fraction is widely distributed into the tissues and rapidly eliminated in the urine and feces. Amprolium administered to laying hens is deposited primarily in the egg yolk, and residues can be detected in eggs for 10 days or more after cessation of treatment, depending on the dose and assay sensitivity.

No MRL has been established for this compound.

Halofuginone

Halofuginone (DL-*trans*-7-bromo-6-chloro-3-[3-(3-hydroxy-2-piperidyl)-acetonyl]-4(3H)-quinazolinone hydrobromide) is a potent anticoccidial that belongs to the chemical group of quinazolinones. It is effective against most asexual stages of *Eimeria* spp. in chickens and turkeys. It has both coccidiostatic and coccidiocidal effects. When halofuginone is given to laying hens at low doses in the feed, residues of this substance are not detectable in eggs, but at high doses, residues can be detected from days to weeks, depending on the concentration level added to the feed. Residues appeared at similar levels in eggs (yolk and albumen), but residues are more persistent in yolk.

Diclazuril

Diclazuril is a synthetic compound of the triazines group that is used as a feed additive and veterinary drug for the control of coccidiosis. Other substances of this group are clazuril (authorized as anticoccidial drug for use orally in pigeons) and toltrazuril. Chemically, the structure of diclazuril is 2,6-dichloro-α-(4-chlorophenyl)-4-(4,5-dihydro-3,5-dioxo-1,2,4-triazin-2(3H)-yl)benzeneacetonitrile. In chickens and turkeys infected by a single *Eimeria* strain or mixed *Eimeria* strains, diclazuril showed anticoccidial activity at all the doses tested (diclazuril acts on the asexual or sexual stages of coccidia blocking the excretion of oocysts). In birds, the highest plasma concentration of ingested radioactivity was observed 6 h after a single administration. Plasma radioactivity was due almost exclusively to unchanged diclazuril until 72 h

after dose. Diclazuril cannot be used in animals from which eggs are produced for human consumption.

Toltrazuril

Toltrazuril is a triazinetrione derivative used as an anticoccidial agent. It is widely used in chickens, turkeys, pigs, and cattle for the prevention and treatment of coccidiosis, by administration in drinking water. Following repeated oral administration to chickens of ^{14}C-toltrazuril during 2 days, 50% and 90% of the total radioactivity administrated was eliminated by 4.5 and 15.5 days after dosing, respectively. In turkeys, following repeated administration of unlabeled toltrazuril for 2 days, toltrazuril concentrations in plasma were low and the unchanged compound was not detected 24 h after the last dose. Toltrazuril sulfone was the major metabolite, and 8 days after the last administration in chickens, represented 100% of the total radioactivity in muscle and fat and 80% in the liver. Toltrazuril sulfone is the most appropriate marker residue for chicken and turkey. MRL has been established for this compound in poultry: 200 $\mu g\,kg^{-1}$ (skin/fat), 600 $\mu g\,kg^{-1}$ (liver) and 400 $\mu g\,kg^{-1}$ (kidney). Toltrazuril cannot be used in animals from which eggs are produced for human consumption.

Nicarbazin

Nicarbazin is an anticoccidial belonging to carbanilide group. Nicarbazin is marketed as a coccidiostat for chickens for fattening up to an age of 28 days. Nicarbazin is a synthetic complex composed of an equimolar amount of 4,4′-dinitrocarbanilide (DNC) and 2-hydroxy-4,6-dimethylpyrimidine (HDP). DNC is also known as *N*,*N*′-bis(4-nitrophenyl) urea. The mode of action seems to be via inhibition of succinate and the energy-dependent transhydrogenases, and the accumulation of calcium in the presence of ATP. Nicarbazin causes the destruction of second-generation schizonts suggesting a coccidiocidal mode of action. However, there were also findings indicating a coccidiostatic action or both. Nicarbazin is active on several *Eimeria* strains. Nicarbazin once ingested is rapidly separated into its two components, HDP and DNC. DNC from nicarbazin was considerably more available to the animal than DNC given alone or administered simultaneously with HDP in similar proportions as in nicarbazin. DNC appeared as the marker residue, and the liver was the target tissue. DNC residues declined rapidly from tissues following nicarbazin withdrawal. HDP-related residues are much lower than those derived from DNC. Nicarbazin should not be used in layers because of decreases in egg production.

Sulfonamides

Sulfonamides are simple synthetic compounds related to *para*-aminobenzoic acid (PABA). Trimethoprim and pyrimethamine do not contain sulfur. Many bacteria absorb *p*-aminobenzoate, convert it into dihydrofolate and tetrahydrofolate, and then ultimately use it to synthesize purines for nucleic acid synthesis. By virtue of their chemical resemblance to *p*-aminobenzoate, sulfonamides inhibit the synthesis of folates by blocking the conversion of PABA to dihydrofolic acid. Trimethoprim and pyrimethamine are diaminopyrimidine derivatives that inhibit the conversion of dihydrofolate to tetrahydrofolate by bacterial forms of dihydrofolate reductase.

Sulfonamides (bacteriostatic) and trimethoprim (bactericidal) are commonly used in combination where they are bactericidal, because (1) they inhibit two different reactions on the same metabolic pathway and thus exhibit synergistic activity and (2) the combination reduces the likelihood that resistance will develop. Sulfonamides have been used in poultry in the prevention and treatment of coccidiosis. The potentiated sulfonamides have a fairly broad spectrum of activity.

Many organisms once susceptible are now resistant to sulfonamides, often due to single-step mutations in the target enzyme. However, useful activity still includes many Gram-positive and Gram-negative organisms as well as *Chlamydia*. Most sulfonamides in this class are absorbed from the gastrointestinal tract and distribute into most tissues including the central nervous system. Mainly they are eliminated unchanged in urine, although some undergo modification in the liver before elimination in urine. The rate at which sulfonamides are eliminated in the urine varies according to the extent to which they are protein bound. Sulfamerazine and sulfadimethoxine are frequently combined with trimethoprim for oral administration in sporadic coccidiosis outbreaks.

Resistance to sulfonamides and trimethoprim is widespread and operates by various mechanisms (chromosomal mutation in the target enzyme, plasmid-mediated acquisition of alternative forms of the target enzymes, reduced permeability of the cell membrane, and altered means of PABA utilization).

Drug Residues from Coccidiostat Use

Residues are low levels of the drug and its metabolites which remain in the animal carcass or other food products of animal origin following drug administration.

For food-producing animals, studies are required to observe how rapidly residues of veterinary drugs are eliminated from the animal. The data obtained in these studies are available to predict a preslaughter withdrawal time appropriate to allow depletion of the residue to acceptable levels (i.e., MRLs) in the target tissues. To define the depletion profile for the major edible tissues and products (e.g., muscle, liver, skin/fat, and kidney of slaughtered animals as well as eggs) a minimum number of animals per slaughter time and eggs per time point are needed.

The MRL is the highest concentration of a residue for a particular chemical that is legally permitted in food. An appropriate withdrawal period (for products for food-producing animals) is then established by regulatory authorities to ensure that the residues are depleted to below the MRL.

Residues are a problem if they still persist at unacceptable levels at slaughter, as they then expose the consumer to potentially unsafe residues.

MRL

The MRLs (termed tolerances in the USA) are established to set a maximum level of the coccidiostatic substances that may remain in the animal without posing a risk to consumers of

food derived from the animal. MRLs are the points of reference for the establishment of withdrawal periods required for marketing authorizations of veterinary medicinal products used in food-producing animals. Withdrawal periods are essential for the control of residues in the food of animal origin.

To establish MRLs for a given drug requires provision of the following data: knowledge of dosage schedule (dose, frequency, and duration of treatment) and administration route; metabolic and pharmacokinetic data in laboratory animals and each of the target food-producing animals; distribution and residue depletion data for the major edible tissue (i.e., muscle, fat, liver, and kidney) in each target species using radiolabeled drug; validated analytical methods for the detection and quantitation of residues, including the marker residue; and data defining the effect of residues on food processing.

The toxicological data are used not only to characterize the biological properties of the molecule but also to identify a no observed adverse effect level (NOAEL), which in turn is used to calculate an acceptable daily intake (ADI), which represents the quantity of drug residue that can be safely consumed daily for a lifetime without an adverse effect on consumer health. For substances with an ADI derived from toxicological endpoints, all metabolites are considered to have the same toxicological significance as the parent drug unless that metabolite has greater toxicity than the parent drug. The MRL is then elaborated from this ADI along with knowledge of the depletion kinetics of the drug in the animal or its milk or eggs, and with reference to standard consumption values for particular types of food. The Joint FAO/WHO Expert Committee on Food Additives (JECFA) uses a model diet (daily food basket) approach which overestimates daily consumption, which for poultry is: 300 g muscle, 100 g liver, 10 g kidney, 90 g fat, and 100 g eggs. The toxicity study (or studies) used to identify the NOAEL for the critical effect may be referred to as the pivotal study (or studies). To reduce the uncertainty associated with the imprecision of the NOAEL and to make full use of the dose–response curve, proposals have been made for a more precise calculation of a dose that produces a small increase in the level of adverse responses. This dose is referred to as a 'benchmark dose' (BMD) and could be used as an alternative to the NOAEL in order to derive an ADI. By agreement, a default safety (uncertainty) factor of 100 (a10-fold factor for interspecies differences (extrapolation from laboratory animals to humans) and a 10-fold factor for human interindividual variation) is normally used. When an NOAEL has not been identified for the most appropriate endpoint, the lowest observed adverse effect level (LOAEL) can be used. Drugs may also produce adverse effects after short-term high-level exposure and in such cases, JECFA will establish an acute reference dose (ARfD) in addition to the ADI. The identification of NOAELs, the calculation of ADI values, and the establishment of MRLs is a complex scientific process involving toxicology, pharmacology, microbiology, residue depletion kinetics, and analytical method, but the MRL values ensure that the ADI will not be exceeded by the consumer when eating foods of animal origin.

The MRL has been calculated to ensure that the dietary exposure is lower than the relevant ADI. The MRL is the point on the residue depletion curve at which the concentration of the marker residue in the target tissue depletes to describing the upper one-sided 95% confidence limit over the 95th percentile. Actually JECFA uses the median of the residue distribution to substitute for the MRL in the dietary exposure estimate (called the estimate daily intake) and changes the model for exposure assessment.

The EU MRL values for drugs used as anticoccidials in food-producing animals are listed in Table 3.

Drug Withdrawal/Withholding Periods

A critical factor in the medication of all food-producing animals is the mandatory withdrawal period, defined as the time during which the coccidiostat must not be administered prior the slaughter of the animal for consumption or the taking of food products produced, for example, eggs. Withdrawal periods are set to ensure that any remaining residues are below the MRL. This is an integral part of the regulatory authorities' approval process and is designed to ensure that no significant drug residue is present in the bird at slaughter based on the MRL established. Adherence to the withdrawal period provides assurance that food derived from treated animals will not exceed the MRL for the drug substance. The withdrawal period is intended to ensure that no harmful residues remain in edible tissues and products after slaughter. Failure to observe the preslaughter withdrawal period while using an animal drug is the major cause of violative drug residues in poultry and egg production in the EU. Even if the withdrawal period is only a few days or few hours, the resulting residues can violate the national regulations against sale of adulterated foodstuffs which can cause distortions in competition between Member States of the EU.

Carryover or Cross Contamination of the Feed of Coccidiostats

Different studies have shown that an entire contamination-free production of premixes and compound feeds in existing multiproduct plants is not possible in practice. Practical experience indicates that in feed mills, residual quantities of medicated feedingstuffs may be retained at various points along the production line and end up in the beginning of the production of another feed product, contaminating subsequent batches of feed as they are processed. This unavoidable carryover may occur at all stages of production and processing of feed but also during storage and transport. EFSA defined cross contamination as contamination of feeds that are produced after the production of a mixed feed, containing additives with residual amounts of the previous feed batch. For example, some feed additives and premixes with properties, such as strong adhesion to walls, particle size and density, and electrostatic properties, may influence cross-contamination behavior and affect how cross-contamination occurs. The electrostatic properties of some drugs, particularly those in powder form, aggravate the problem, making it more difficult to clean the equipment between batches. The technological equipment in the feed mill, such as the design of dosage and grinding and mixing equipment, can influence the

Table 3 EU MRLs for drugs used as anticoccidials (Regulation (EU) No. 37/2010 of 22 December 2009)

Pharmacologically active substance(s)	*Marker residue*	*Animal species*	*MRLs*	*Target tissues*	*Other provisions*	*Therapeutic classification*
Amprolium	Not applicable	Poultry	No MRL required	Not applicable	For oral use only	No entry
Clazuril	Not applicable	Pigeon	No MRL required	Not applicable	No entry	No entry
Decoquinate	Not applicable	Bovine and ovine	No MRL required	Not applicable	For oral use only Not for use in animals from which milk is produced for human consumption	No entry
Diclazuril	Not applicable	All ruminants and porcine	No MRL required	Not applicable	For oral use only	No entry
		Poultry	500 $\mu g\ kg^{-1}$ 500 $\mu g\ kg^{-1}$ 1500 $\mu g\ kg^{-1}$ 1000 $\mu g\ kg^{-1}$	Muscle Skin/fat Liver Kidney	Not for use in animals from which eggs are produced for human consumption	Antiparasitic agents/agents acting against protozoa
Halofuginone	Halofuginone	Bovine	10 $\mu g\ kg^{-1}$ 25 $\mu g\ kg^{-1}$ 30 $\mu g\ kg^{-1}$ 30 $\mu g\ kg^{-1}$	Muscle Fat Liver Kidney	Not for use in animals from which milk is produced for human consumption	Antiparasitic agents/agents acting against protozoa
Lasalocid	Lasalocid A	Poultry	60 $\mu g\ kg^{-1}$ 300 $\mu g\ kg^{-1}$ 150 $\mu g\ kg^{-1}$ 150 $\mu g\ kg^{-1}$	Muscle Skin + fat and liver Kidney Eggs	No entry	Anti-infectious agents/antibiotics
Monensin	Monensin A	Bovine	2 $\mu g\ kg^{-1}$ 10 $\mu g\ kg^{-1}$ 30 $\mu g\ kg^{-1}$ 2 $\mu g\ kg^{-1}$ 2 $\mu g\ kg^{-1}$	Muscle Fat Liver Kidney Milk	No entry	Anti-infectious agents/antibiotics

Toltrazuril	Toltrazuril sulfone	All mammalian food-producing species	100 μg kg^{-1} 150 μg kg^{-1} 500 μg kg^{-1} 250 μg kg^{-1}	Muscle Fat Liver Kidney	Not for use in animals from which milk is produced for human consumption	Antiparasitic agents/agents acting against protozoa
		Poultry	100 μg kg^{-1} 200 μg kg^{-1} 600 μg kg^{-1} 400 μg kg^{-1}	Muscle Skin + fat Liver Kidney	Not for use in animals from which eggs are produced for human consumption	
Sulfonamides (all substances belonging to the sulfonamide group)	Parent drug	All food-producing species	100 μg kg^{-1} 100 μg kg^{-1} 100 μg kg^{-1} 100 μg kg^{-1}	Muscle Fat Liver Kidney	The combined total residues of all substances within the sulfonamide group should not exceed 100 μg kg^{-1} For fin fish the muscle MRL relates to 'muscle and skin in natural proportions' MRLs for fat, liver, and kidney do not apply to fin fish Not for use in animals from which eggs are produced for human consumption	Anti-infectious agents/ chemotherapeutics
		Bovine, ovine, and caprine	100 μg kg^{-1}	Milk		
Trimethoprim	Trimethoprim	All food-producing species	50 μg kg^{-1} 50 μg kg^{-1} 50 μg kg^{-1} 50 μg kg^{-1} 50 μg kg^{-1}	Muscle Fat Liver Kidney Milk	For porcine and poultry species the fat MRL relates to 'skin and fat in natural proportions' Not for use in animals from which eggs are produced for human consumption	Anti-infectious agents/ chemotherapeutics

Abbreviation: MRLs, maximum residue limits.

Table 4 Maximum levels in foodstuffs (Regulation (EC) No. 124/2009, and Regulation (EU) No. 610/2012)

Substance	*Foodstuffs*	*Maximum content in $\mu g\ kg^{-1}$ (ppb) wet weight*
Lasalocid sodium	Food of animal origin from animal species other than poultry and bovine	
	– Milk	1
	– Liver	50
	– Kidney	20
	– Other food	5
Narasin	Food of animal origin from animal species other than chickens for fattening	
	– Eggs	2
	– Milk	1
	– Liver	50
	– Other food	5
Salinomycin sodium	Food of animal origin from animal species other than chickens for fattening and rabbits for fattening	
	– Eggs	3
	– Liver	5
	– Other food	2
Monensin sodium	Food of animal origin from animal species other than chickens for fattening, turkeys, and bovine (including dairy cattle)	
	– Liver	8
	– Other food	2
Semduramicin	Food of animal origin from animal species other than chickens for fattening	2
Maduramicin	Food of animal origin from animal species other than chickens for fattening and turkeys	
	– Eggs	12
	– Other food	2
Robenidine	Food of animal origin from animal species other than chickens for fattening, turkey and rabbits for fattening and breeding	
	– Eggs	25
	– Liver, kidney, skin and fat	50
	– Other food	5
Decoquinate	Food of animal origin from animal species other than chickens for fattening, bovine, and ovine except dairy animals	20
Halofuginone	Food of animal origin from animal species other than chickens for fattening, turkeys, and bovine except dairy cattle	
	– Eggs	6
	– Liver and kidney	30
	– Milk	1
	– Other food	3
Nicarbazin (residue: 4,4′-dinitrocarbanilide)	Food of animal origin from animal species other than chickens for fattening	
	– Eggs	300
	– Milk	5
	– Liver	300
	– Kidney	100
	– Other food	50
Diclazuril	Food of animal origin from animal species other than chickens for fattening, guinea fowl, rabbits for fattening and breeding, ruminants, and porcine	
	– Eggs	2
	– Liver and kidney	40
	– Other food	5

level of cross contamination. Cross contamination of feed batches can result in the exposure of nontarget animals and induce adverse health effects in these animals due to a specific sensitivity of mammalian species as compared to poultry. Residue formation in edible tissues of nontarget species may result in unexpected human exposure through the consumption of animal products.

The legal basis of this technological process in the EU is Regulation (EC) No. 183/2005 which provides that feed business operators shall ensure that establishments under

their control are approved by the competent authority in case these establishments are manufacturing and/or placing on the market coccidiostats and histomonostats or premixes containing coccidiostats and histomonostats.

The maximum tolerances for the presence of active substances contained in coccidiostats have been established in the food of animal origin and in feedingstuffs (Table 4).

Carryover or cross contamination has been evaluated. Regular investigations have been performed with some coccidiostats, including lasalocid and nicarbazin and showed the persistence of these compounds in various feed batches produced after the intentional incorporation of a polyether ionophore coccidiostat into feed. The health risk to nontarget species resulting from the consumption of cross-contaminated feed with coccidiostats at levels of 2%, 5%, or 10% was evaluated by the EFSA and a revision of the risk assessments has been done.

The MRLs for the coccidiostats lasalocid sodium, narasin, salinomycin sodium, monensin sodium, semduramicin, maduramicin, robenidine, decoquinate, halofuginone, nicarbazin, and diclazuril are updated in Table 3.

VETERINARY DRUGS RESIDUES

Ectoparasiticides

T de Waal, University College Dublin, Dublin, Ireland
M Danaher, Teagasc Food Research Centre, Dublin, Ireland

Glossary

Acaricide Chemical used for the control of ticks.
Ectoparasiticide Chemical used for the control of ectoparasites.
Endectocide A drug effective against both endo- and ectoparasites.
Insecticides Chemicals used for insect control.
Metaphylaxis The administration of drugs to herds of animals as therapy for sick animals combined with prophylaxis in healthy animals.
Prophylaxis The administration of drugs to herds of animals to prevent disease.
Synergist Chemical used to enhance the parasiticidal activity of certain active ingredients or help to overcome resistance.

Introduction

Food-producing animals are infected by a number of ectoparasites, including lice, ticks, mange mites, myiasis larvae, and nuisance flies. Infection with these parasites causes irritation leading to fleece and hide damage, due to the direct damage caused by the parasites and/or self-inflicted trauma. When infestation reaches critical levels it can also result in reduced feed intake, weight loss, poor body condition, reduced milk yield and wool production. In addition, many ectoparasites also act as vectors for several important diseases, such as babesiosis, theileriosis, and trypanosomosis. Control of the parasites is largely based on the use of chemicals that are usually applied topically to the skin and have a direct effect on the parasite. Some ectoparasiticides can also be given parenterally which will then act systemically when the parasite takes up the compound while feeding on the host.

Summary of Each of the Individual Drug Classes

Most ectoparasiticides are neurotoxins, exerting their effect on the nervous system of the target parasite. Those used in large animals can be grouped according to structure and modes of action into the organochlorines, organophosphates and carbamates, pyrethrins and pyrethroids, formamidines, macrocyclic lactones (MLs) (avermectins and milbemycins), insect growth regulators, and a number of miscellaneous compounds, including synergists such as piperonyl butoxide (Table 1).

Owing to widespread resistance and concerns regarding the environmental persistence of organochlorines, some products have been withdrawn from the market in many parts of the world. Organophosphates are extremely toxic in animals and humans leading to chronic toxicity, and several compounds possess teratogenic potential and are seldom used today. Carbamate insecticides are closely related to organophosphates but they cause a spontaneously reversible block on acetylcholinesterase. The main carbamate compounds used today are carbaryl and propoxur. Carbaryl has low mammalian toxicity but may be carcinogenic.

Natural pyrethrins are derived from the chrysanthemum plant and synthetic pyrethorids (SPs) are synthesized chemicals modeled on the natural pyrethrin molecule. The SPs are more stable with longer residual activity and higher potency, providing a rapid knock-down effect on insects. Some preparations contain piperonyl butoxide, which acts as a synergist by helping to prevent the pyrethrin or pyrethroid metabolism by microsomal mixed-function oxidase systems in insects. The mode of action appears to be an interference with Na^+ channels of both peripheral and central neurons, resulting in delayed repolarization and eventual paralysis.

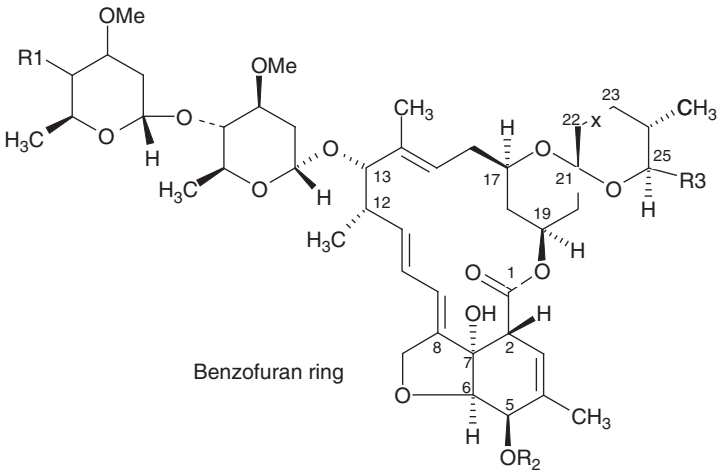
The amidines (formamidines) are acaricides inhibiting monoamine oxidase, which is responsible for the metabolism of neurotransmitter amines in ticks and mites. Amitraz causes rapid detachment of blood feeding acarids. They are also octopamine receptor agonists in insects.

The avermectins and milbemycins belong to a family of compounds called the macrocyclic lactones and are natural fermentation products of soil dwelling streptomycete microorganisms. MLs are large complex ringed structures; avermectins have a 16-membered macrocyclic ring, containing a spiroketal group, a benzofuran ring, and disaccharide or monosaccharide functionalities as can be seen in Figures 1 and 2. Milbemycins are structurally similar to avermectins but lack the disaccharide group. Ivermectin was the first antiparasitic agent that showed broad-spectrum activity against both nematodes and arthropods. This unique broad-spectrum activity against both endo- and ectoparasites has resulted in the MLs being classified as endectocides. The activity against

 doi:10.1016/B978-0-12-378612-8.00247-X

Table 1 Summary of major chemical classes of ectoparasiticides used in food-producing animals

Drug class	*First introduction*	*Examples*	*Application*	*Used*	*Safety*
Organochlorines	1940	Dichlorodiphenyltrichloroethane, dieldrin, and benzene hexachloride	Control of most ectoparasites. Long persistence in coat/fleece	Widely used to control flystrike (fly larvae) and sheep scab in sheep	Toxicity = central nervous system stimulation. No longer in use in many parts of the world due to human and environmental safety issues
Organophosphates	1950	Chlorfenvinphos, diazinon, malathion, and phosmet	Control of most ectoparasites. Long persistence in coat/fleece	Used against fly larvae, flies, lice ticks, and mites	Extremely toxic in animals and humans, some compounds also teratogenic
Pyrethrins and synthetic pyrethroids	1970	Cypermethrin, deltamethrin, flumethrin, and permethrin	Spray, dip, pour-on, or spot-on formulations	Biting and nuisance flies, lice, and ticks. Some compounds also effective against mange mites	Among the safest ectoparasiticides in mammals and birds but are highly toxic to fish and aquatic invertebrates
Formamidines	1960	Amitraz	Spray, dip, pour-on, or spot-on formulations	Control of ticks, lice, and mites in cattle, sheep, and pigs	Relatively wide safety margin in mammals; the most frequently associated adverse effect is sedation, which may be associated with an agonist activity of amitraz on α2-receptors in mammalian species
Macrocyclic lactones	1980	Avermectin – abamectin, doramectin, and eprinomectin. Milbemycin – moxidectin, and milbemycin oxime	Orally, parenterally, or topically as pour-on or spot-on formulations	Parenteral administration more effective against sucking lice and certain mites, whereas topically applied products more suitable for controlling biting lice and flies. Usually little effects against ticks. Used in cattle, sheep, and pigs	Generally wide safety margin. Persistent in body for extended periods
Insect growth regulators	1970	Methoprene, lufenuron, dicyclanil and cyromazine	Oral or topical spray formulations	Mainly used for blowfly control in sheep and fly control in poultry	They constitute a group of chemical compounds that do not kill the target parasite directly, but interfere with growth and development



Avermectin	R1	R2	R3	C_{22}-x-C_{23}
A_{1a}	OH	CH_3	$CHCH_3CH_2CH_3$	-CH=CH-
A_{1b}	OH	CH_3	$CHCH_3CH_3$	-CH=CH-
Avermectin B_{1a}	OH	H	$CHCH_3CH_2CH_3$	-CH=CH-
Avermectin B_{1b}	OH	H	$CHCH_3CH_3$	-CH=CH-
A_{2a}	OH	CH_3	$CHCH_3CH_2CH_3$	-CH_2-CHOH-
A_{2b}	OH	CH_3	$CHCH_3CH_3$	-CH_2-CHOH-
B_{2a}	OH	H	$CHCH_3CH_2CH_3$	-CH_2-CHOH-
B_{2b}	OH	H	$CHCH_3CH_3$	-CH_2-CHOH-
	Benzofuran ring			
Doramectin	OH	H	C_6H_{11}	-CH=CH-
Emamectin Benzoate B_{1a}	$C_6H_5COOHCH_3NH$	H	$CHCH_3CH_2CH_3$	-CH=CH-
Eprinomectin B_{1a}	$NHCOCH_3$	H	$CHCH_3CH_2CH_3$	-CH=CH-
Ivermectin B_{1a}	OH	H	$CHCH_3CH_2CH_3$	-CH_2-CH-

Figure 1 Chemical structures of avermectins.

ectoparasites is dependent on the product formulation of the active molecule and the method of application. The mode of action of avermectins and milbemycins is not completely understood.

Ectoparasiticide Resistance to Drugs and Impact on Public Health

Resistance of arthropods to the lethal effects of parasiticides has been known for more than a century. To date more than 500 species of resistant insects, mites, and ticks have been documented of which 40% are parasites of humans or animals.

The mechanism of resistance can be classified as either physiological or behavioral. Physiological mechanisms include increased metabolism of the insecticide (detoxification), decreased sensitivity of the target site, or decreased penetration into the target organism. The resistance mechanism generally involves one gene, although a combination of genes have also been implicated in certain cases.

Tolerance or resistance to all of the organophosphates currently in the market has been reported in specific ectoparasites (e.g., *Rhipicephalus (Boophilus) microplus* and adult blowflies) although largely restricted to certain parts of the world. The development of resistance to the organochlorines as well as environmental concerns has led to their withdrawal from the market.

Pyrethroid resistant strains of the cattle tick (*R. (B.) microplus)*, horn flies (*Haematobia irritans*), houseflies, and lice have been reported. Resistance against amitraz has also been documented in several strains of *R. (B.) microplus* in Australia,

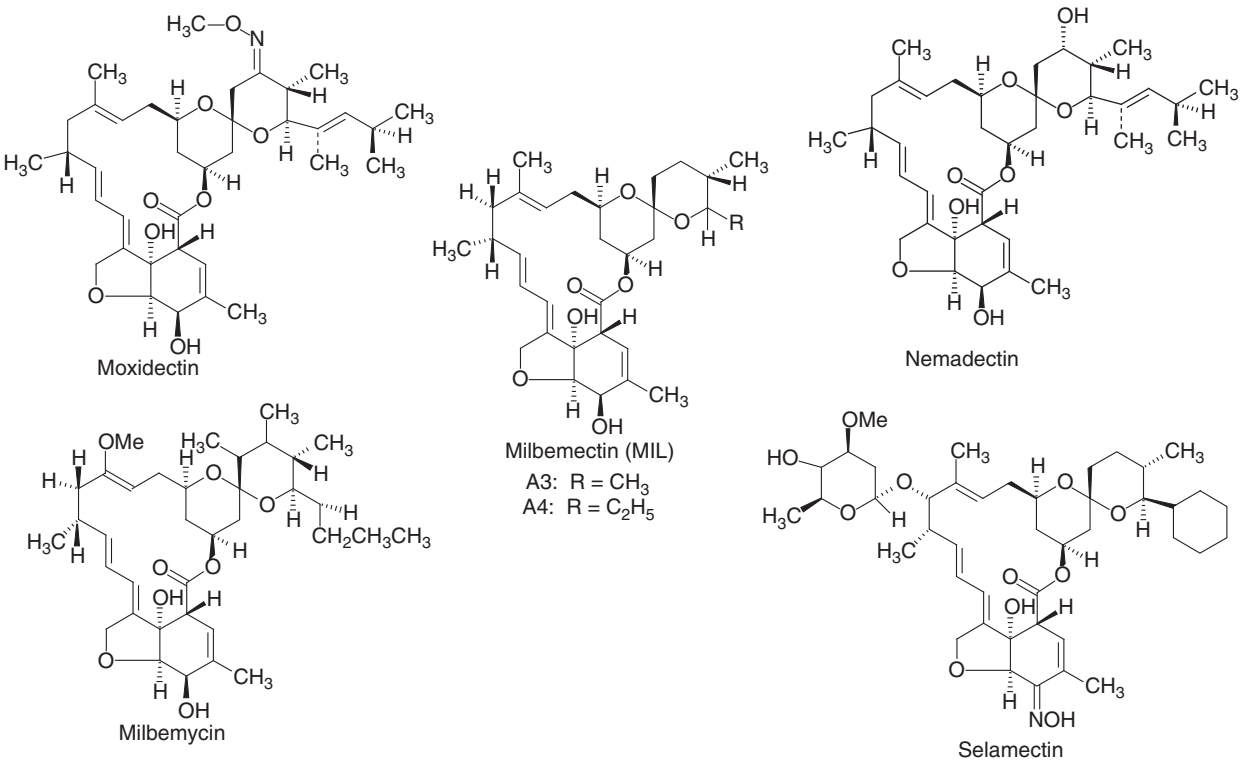


Figure 2 Structures of milbemycins and selamectin.

but no resistance in multihost ticks has thus far been reported. To date no data on the development of ectoparasite resistance is available for the MLs. In animal health resistance of ectoparasites against insect growth regulators are still rare.

Control of Drug Residues in Food of Animal Origin

Ectoparasiticides are commonly applied topically and are often lipophilic resulting in slow dermal absorption with long tissue and plasma half-lives. In addition, the natural grooming behavior of farm animals can result in significant oral absorption with increased systemic exposure in both treated and untreated animals. The chronic effects of ectoparasiticides from food intake on human health are not well defined, but there is increasing evidence of carcinogenicity, disruption in hormonal function, and genotoxicity. Restrictions are therefore applied to many of the ectoparasiticides indicated for use in food-producing animals to ensure that unacceptable residues are not present in products intended for human consumption. Consequently many international organizations and countries have issued their own pesticide maximum residual limits (MRLs) for the purpose of international trade. The Codex Alimentarius Commission (CAC), established by Food and Agriculture Organization and World Health Organization in 1963, develops harmonized international food standards, guidelines and codes of practice to protect the health of the consumers, and ensure fair trade practices in the food trade. Currently CAC has 185 member countries. Using MRLs as either criteria or guidelines many countries have mounted effective residue monitoring programs.

Analysis of ML Residues

Following administration, MLs are stored in the liver and fat tissue and slowly released, metabolized, and excreted. With the exception of eprinomectin, lactating cows or cows during the last 2 months of pregnancy cannot be treated with this drug class. MLs can be analyzed in biological matrices using a range of techniques including immunoassay, high-performance liquid chromatography (HPLC) with ultraviolet, or fluorescence detection (FLD) or liquid chromatography (LC) coupled to tandem mass spectrometry (LC–MS/MS). HPLC fluorescence has been the technique of choice for the analysis of ML residues for many years because of its excellent sensitivity and selectivity. However, MLs do not possess a native fluorophore and precolumn derivatization with non-fluorescent reagents is required before chromatographic analysis. A number of different derivatization approaches have been employed to reduce reaction time, enhance the stability of derivatives, and extend analysis to additional analytes. Eprinomectin is the most difficult ML to analyze and requires elevated reaction temperatures to produce a stable fluorescent derivative. In recent years, a number of groups have developed LC–MS/MS methods for detection of ML residues. In general, it has been shown that mobile phase additives have to be carefully controlled, with ammonium acetate or formate being desirable for production $[M+H]^+$ or $[M+NH4]^+$ ions, which are more suitable for low-energy collision-induced dissociation experiments. It has been shown by a number of groups that if formic or acetic acid are used in the mobile phase that $[M+Na]^+$ ions are predominate, which are difficult to fragment. ML residues can be analyzed down

to <1 ppb in meat or milk using HPLC–FLD or LC–MS/MS-based detection following simple sample preparation procedures. LC–MS/MS is becoming more popular because a wider range of drugs can be included in the analysis.

ML residues are occasionally detected in food, with ivermectin being the most frequently detected endectocide in bovine tissues, followed by milk and fish. Much attention has been placed on the analysis of ML residues down to low parts per billion levels in milk samples because of the perceived risk to developing neonates. This has been further fueled over reports that as much as 5% of the dose of some ML drugs such as ivermectin are excreted in the milk. In response, safer ML products such as eprinomectin and emamectin have been developed for applications in dairy cows and fish, respectively. Surprisingly in 2010–11, there were widespread reports of ivermectin residues in beef products exported from Brazil. At the time, no limit was set for ivermectin residues in muscle tissue in the European Union or the United States. In response, MRLs of 30 and 10 $\mu g\ kg^{-1}$ are now in place in these respective regions.

VETERINARY DRUGS RESIDUES

Control of Helminths

T de Waal, University College Dublin, Dublin, Ireland
M Danaher, Teagasc Food Research Centre, Dublin, Ireland

Glossary

Anthelmintics Drugs that acts against helminthic infections.
Anthelmintic resistance A heritable change in the susceptibility to the attack of an anthelmintic in a population of parasitic nematodes.
Cestodes Parasitic flatworms of the class Cestoda having a long flat body equipped with a specialized organ of attachment at one end. Also called tapeworms.
Endectocide A drug effective against both endo- and ectoparasites.
Nematodes Parasitic worms of the phylum Nematoda, having unsegmented, cylindrical bodies, often narrowing at each end, and including parasitic forms, such as the hookworm and pinworm. Also called roundworm.
Trematodes Parasitic flatworms of the class Trematoda that have a thick outer cuticle and one or more suckers or hooks for attaching to host tissue. Also called fluke.

Introduction

Domestic animals are affected by a large variety of helminth parasites which includes nematodes (roundworms), trematodes (flukes), and cestodes (tapeworms). Since the first discovery of the potent broad-spectrum anthelmintics, it has been widely used and has led to major changes in clinical parasitism, and millions of dollars are being spent annually in efforts to reduce the effects of parasitism in food-producing animals. Both cattle and sheep producers list internal parasites as a common cause of significant economic impact on animal production. Producers are inflicted by losses at the global level that run to many billions of dollars (liver fluke infestation alone causes losses of an estimated $3 billion worldwide).

Antiparasitic compounds are the dominant segment of the veterinary pharmaceuticals market with global sales of approximately $3.5 billion annually. Resistance to all major antiparasitic (anthelmintic) drug classes is now widespread in intestinal nematodes of sheep and goats. Modern anthelmintics generally have a wide margin of safety, considerable activity against immature (larval) and mature stages of helminths, and mostly a broad spectrum of activity (Table 1).

Summary of the Individual Drug Classes

Anthelmintics are separated into classes on the basis of similar chemical structure and mode of action. The major drug classes, their introduction onto the market and mechanism of actions are summarized in Table 2. After the introduction of the first benzimidazole molecule on the market, approximately 20 new benzimidazole compounds have been synthesized with potent anthelmintic activity, and are in use today to control helminths.

Levamisole is an anthelminthic and immunomodulator belonging to a class of synthetic imidazothiazole derivatives.

Macrocyclic lactones (ML) (including avermectin/milbemycin) are endectocides with broad activity against both external and internal parasites. Since the first introduction of ivermectin on the market (a semisynthetic derivative of avermectin), many

Table 1 Anthelmintic drug classes commonly used to treat helminth infections in food-producing animals

Chemical group	*Activity spectrum (Helminth group)*	*Food-producing animals*
Benzimidazole	Nematodes and some trematodes	Cattle, sheep, goats, pigs, and poultry
Imidazothiazole	Nematodes	Cattle, sheep, goats, pigs, and poultry
Tetrahydropyrimidine	Nematodes	Cattle
Avermectin/milbemycin	Endectocide	Cattle, sheep, goats, and pigs
Amino-acetonitrile derivatives	Nematodes	Sheep
Praziquantel	Cestodes and trematodes	Sheep and goats
Nitrophenolic compounds	Some nematodes and trematodes	Cattle and sheep
Salicylanilides	Some nematodes and trematodes	Cattle and sheep
Benzenesulfonamides	Trematodes	Cattle and sheep

Table 2 Spectrum of activity, mode of action, and toxicity of the different anthelmintic chemical classes, with comments on the appearance of resistance

Chemical group	*Discovery and first release onto market*	*Mode of action*	*Anthelmintic spectrum*	*Pharmacokinetics*	*Toxicity*	*Route of administration*	*Resistance situation*
Benzimidazole (BZ)	Thiabendazole was discovered in 1961 and subsequently a number of second generation BZ products had been commercially developed for use in domestic animals	Binds with parasite β-tubulin for subsequent disruption of tubulin-microtuble dynamic equilibrium	Broad-spectrum against lung and GI nematodes. Some activity against cestodes and trematodes. One compound (triclabendazole) only effects against *Fasciola*	Poor GI absorption	Low toxicity	Oral administartion	First reported in 1964. High resistance worldwide in sheep and goat trichostrongylid nematodes. Emerging resistance in cattle trichostrongylid nematodes reported
Imidazothiazole	The first veterinary product was tetramisole in 1967. Levamisole, the *l*-isomer of tetramisole is currently the only compound in this group available	Nicotinic acetylcholine receptor agonist	Broad-spectrum against lung and GI nematodes, mainly adult stages	Rapid absorption following parental administration. Limited absorption following oral or topical application. Rapid elimination	Narrow safety margin	Oral administration, pour-on or by injection	First reported in 1979. High resistance worldwide in sheep and goat trichostrongylid nematodes. Emerging resistance in cattle trichostrongylid nematodes reported.
Tetrahydro-pyrimidine	Pyrantel, introduced in 1966	Nicotinic acetylcholine receptor agonist	GI nematodes, narrow spectrum, mainly adult stages	Poor GI absorption in ruminants, good GI absorption in pigs	Good safety margin	Oral administration	No reports in food producing animals
Avermectin/ milbemycin	A series of macrocyclic lactone derivatives was introduced as an anthelmintic in 1981	Activity is mediated through γ-aminobutyric acid and/or glutamate gated chloride channels	Very broad-spectrum against ecto- and endoparasites (endectocide) – both GI and lung nematodes	Highly lipophilic and rapidly absorbed, but reduced absorption from GI (in ruminants)	Good safety margin in majority of target species	Oral administration, pour-on or by injection	First ivermectin resistance reported in 1988 and moxidectin in 1991. Resistance reported in sheep, goat, and cattle trichostrongylid nematodes. Ivermectin still effective in Europe and Canada. Moxidectin resistance so far only reported in goat trichostrongylid nematodes

Amino-acetonitrile derivatives	2010	Nematode-specific acetylcholine receptors	Broad-spectrum, recently introduced for use in sheep			Oral administration	–
Spiroindoles	2012	Nicotinic acetylcholine receptors	Narrow spectrum GI nematodes			Oral administration	–
Praziquantel	1978	Modulates cell membrane permeability and causes damage to parasite tegument	Narrow spectrum – adults cestodes in ruminants (at high dose rates) and schistosomes	Good GI absorption	Wide safety margin	Oral administration	–
Nitrophenolic compounds	Developed in the late 1960s as injectable fasciolicide for sheep and cattle	Intrinsic mode of action not established. Disrupts tegument of *Fasciola*	Narrow-spectrum, Highly effective against adult *Fasciola* and some abomasal nematodes	Rapid absorption following parental administration	Well tolerated in ruminants at recommended dose rates	Oral administration, but more effective when administered parentally	–
Salicylanilides	Rafoxanide was developed in 1969 and introduced for sheep and cattle in 1970	Complex. Uncouples oxidative phosphorylation in flukes but including other biochemical and physiological processes within the parasite	Narrow-spectrum. Effective against mature *Fasciola* with some compounds showing activity against immature flukes. Also activity against some adult nematodes and some compounds against cestodes and *Paramphistomum*	Well absorbed after both external and parenteral administration	Well tolerated in ruminants at recommended dose rates	Oral administration	–
Benzenesulf-onamides		Effect on gut and integument of flukes	Narrow-spectrum. Effective against adult *Fasciola*	Slow absorption following oral administration	Safe drug with high therapeutic index	Oral administration and injection	–

Abbreviations: BZ, benzimidazole; GI, gastrointestinal.

ivermectin analogs were introduced for the control of parasites, including: moxidectin, milbemycin oxime, doramectin, selamectin, abamectin, and eprinomectin. The MLs exhibit no activity against cestodes, trematodes, or protozoa. Fecal excretion is the main route of elimination of most of the ML; however, in lactating animals, up to 5% of the dose may be excreted in the milk.

Anthelmintic Resistance to Drugs and Impact on Public Health

The standards of anthelmintic efficacy usually demand that $\geq$95% of parasitic nematodes be removed with a single drug treatment, and below this level, the efficacy indicates the evidence of anthelmintic resistance. Drug resistance in parasites results from the selection of a subpopulation, which can tolerate the lethal effects of the drug that are normally effective against them. This resistance has a genetic basis due to target gene mutation/alteration of the drug receptor, but is often more complex involving other nonreceptor based mechanisms (Table 2). In livestock, anthelmintic resistance to the broad-spectrum drug, thiabendazole, was first reported by 1964. Today, significant levels of anthelmintic resistance have been recorded throughout the world to all three of the major anthelmintic classes used (benzimidazoles, imidothiazoles-tetrahydropyrimidines, and ML; see Table 2). Among sheep in particular, multidrug resistant nematode populations have become an important limitation for successful sheep production in many parts of the world. Anthelmintic resistance has also been reported in cattle and pig nematodes though not as widespread. Limited data is available on the resistance in cestodes against the drugs, but in the case of liver fluke, *Fasciola hepatica*, an important trematode infection of livestock in many temperate areas of the world, resistance (or decreased efficacy) to triclabendazole (a benzimidasole) has been reported.

The mode of action of the benzimidazole drugs can be directly linked to the interruption of microtubular function in the target parasite. Benzimidazole resistance is thus mainly caused by transversion mutations leading to specific amino acid substitutions in the β-tubulin protein at codon 200 (TTC to TAC; phenylalanine to tyrosine), codon 167 (TTC to TAC), or codon 198 (GAA to GCA; glutamate to alanine). To date, there is no convincing evidence of a role for tubulin mutations in *F. hepatica* resistance to triclabendazole; however, there is evidence to indicate that altered uptake and metabolism of the drug maybe involved.

A nicotinic acetylcholine receptor (ACh – the primary excitatory transmitter in nematodes) on the muscle cells of nematodes is associated with the sensitivity to levamisole. Levamisole, monepantel, and derquantel are cholinergic agonists that selectively produce depolarization and spastic contraction, followed by the paralysis of body muscle cells of nematodes. Monepantel, however, acts on a different class of nicotinic receptor than levamisole and derquantel. Resistance to levamisole is associated with mutation of the nicotinic acetylcholine receptor subunits, involved in forming the levamisole receptor.

Both classes of ML mediate their nematocidal effect by interacting with a range of ligand-gated ion channels of the muscles of the pharynx and somatic musculature. As a result, nematodes become paralyzed and starve to death. Resistance to ML is more complex and the mechanism of resistance to these compounds in parasitic nematodes seems to involve changes in the activity of multidrug ATP binding cassette (ABC) transporters such as P-glycoprotein.

Treatment regimens against nematodes in humans often do not achieve the same high level of efficacy and therefore it may be much more difficult to notice an anthelmintic failure. Current mass treatment campaigns against onchocercosis, lymphatic filariosis, schistosomosis, and soil-transmitted helminths in humans are based on the use of drugs being employed for decades in the veterinary field. Data suggestive of praziquantel resistance in *Schistosoma mansoni*, and ML resistance in both *Onchocerca volvulus* and soil transmitted helminths has been reported. The cost of developing a new class of broad-spectrum anthelmintic for use in food-producing animals is becoming prohibitive and very few new classes of anthelmintic have been developed in the past 40 years. New anthelmintic drug classes, such as monepantel, derquantel, and emodepside that have been developed do not seem to have the breadth of spectrum in terms of target hosts and parasite species as the MLs and benzimidazoles, and have not so far been developed for use in humans.

Control of Anthelmintic Drug Residues in Food of Animal Origin

Anthelmintic drug residues can potentially occur in food following the administration of veterinary medicinal products to farm animals or from cross contamination at feed mills. Maximum residue limits (MRL) have been set for the anthelmintic drug marker residues in edible tissues (namely, liver, muscle, kidney, and fat), eggs, and milk as markers of food safety. MRLs also play an important role in the harmonization of trade between regions worldwide including the EU, North America, Asia, Australia, and New Zealand. In addition, withdrawal periods have been set for veterinary medicinal products to ensure that residues have depleted below the MRL before tissues entering the food chain. A range of regulatory control measures to ensure food safety include the licensing of veterinary medicinal products, on-going national surveillance programs, networks of reference laboratories, and performance criteria for analytical methods.

To monitor food safety, analytical methods have been developed for analysis of anthelmintic drug residues in food. Most of the early methods for the analysis of anthelmintic residues were based on high performance liquid chromatography coupled to ultraviolet, fluorescence, or electrochemical detection. In recent years, there has been a move to liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) technology, which allows the analysis of a wider range of anthelmintic drug residues at parts-per-billion. LC-MS/MS is advantageous because simpler sample preparation approaches can be employed and the sample throughput can be improved vastly. Several analytical methods have been developed that can analyze as many as 40 anthelmintic residues in both milk and animal tissues. Kinsella et al. (2011) have recently reported the application of this technology to the analysis of the new anthelmintic drug,

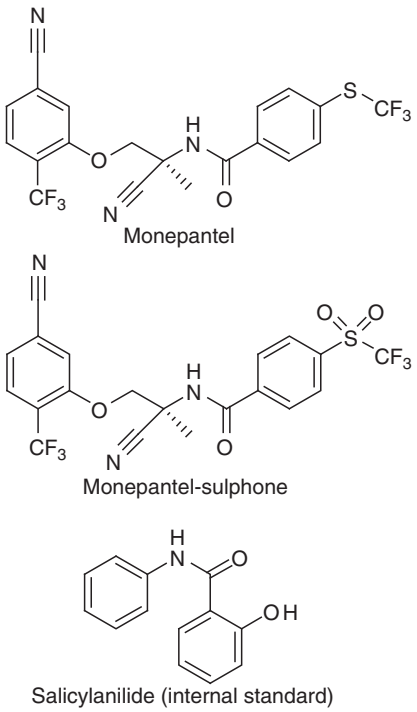

Figure 1 Structure of monepantel, monepantel sulphone, and the internal standard salicylanilide.

monepantel and its sulphone metabolite in milk and animal tissue. Figure 1 shows the chemical structures of monepantel, monepantel sulphone, and salicylanilide, which was used an internal standard in the method.

Residue Findings and Implications

Anthelmintic residues are occasionally detected in food samples and are typically found in $<1\%$ of tissue samples. The results of early residue surveillance indicate oxfendazole to be one of the most frequently detected anthelmintic residues, found mainly in ovine tissues. Many countries have commenced testing for triclabendazole residues in animal tissue, which has led to some reports of noncompliant residues in ovine tissue samples. Recently, anthelmintic analysis was extended to include the flukicide residues, namely, closantel, clorsulon, niclosamide, nitroxynil, oxyclozanide, and rafoxanide. From the inception of this testing, there have been some reports of MRL violations for closantel and rafoxanide residues in ovine tissue samples. However, in some countries, the most significant development has been the reported detection of low levels of closantel, nitroxynil, rafoxanide, and triclabendazole residues in milk samples. As a result of these positive milk samples, new MRLs have been established for four flukicide residues in milk.

Glossary

Dietary supplement A product that is taken orally and that contains one or more ingredients (such as vitamins, minerals, amino acids) that are intended to supplement the diet by increasing the daily dietary intake of such nutrients and cannot be considered as a food or a meal. Dietary supplements must be clearly labeled as such, indicating that they are only intended for oral administration.

Food biofortification Technologies for enhancing the micronutrient content of staple crops by means of biological processes such as conventional selective breeding and genetic engineering techniques.

Food fortification The addition of one or more essential nutrients to food, whether or not it is normally contained in the food, in order to prevent or correct a demonstrated deficiency of one or more nutrients in the population or specific population groups.

Nutrient bioavailability The amount of nutrient ingested dose that is absorbed and used for normal body functions. Nutrients must reach the site of action in their active form in order to exert their metabolic function; bioavailability of nutrients is governed by both external and internal factors.

Recommended dietary allowances The average daily dietary nutrient intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy subjects in a particular life stage and gender group.

Upper intake level (UL) The maximum intake from food that is unlikely to pose risk of adverse health effects from excess in almost all (97.5%) apparently healthy subjects in an age and sex-specific population group. ULs should be based on long-term exposure from food, including fortified food products.

Introduction

Food safety is an umbrella term for those conditions that ensure the availability of safe and healthy food when prepared and/or consumed according to their intended use. In Europe, and in general in the most developed societies, the availability of enough amount of food is not the main problem, so attention is addressed toward food safety.

To achieve an appropriate dietary regime in these societies, however, is not an easy task as most of the people believe that they have an adequate diet and an optimal nutrient contribution can be warranted by slightly varying food habits. Moreover, sedentary lifestyles and the current esthetic standards constrain to low calories ingestion, which is associated with an inferior nutrient intake. In addition, stress, smoking, pollution, drugs and alcohol consumption, etc., increase the nutrient requirements, which in many cases are not achieved with the usual diet. Furthermore, recommended intakes of some nutrients for pregnant and lactating women are virtually impossible to be fulfilled by standard diets. In fact, diets of more than two-thirds of the world's population lack one or more essential mineral elements. This problem can be overcome by dietary diversification, mineral supplementation, food fortification, or by increasing the concentration and/or bioavailability of mineral elements in place (biofortification).

In the case of fortified foods, it is essential to characterize and assess the risk of overconsumption, which must be regulated by food safety authorities. In other words, it is important to define which foods can be enriched, the fortifying substances and sources that can be used, maximum enrichment levels, and maximum daily allowance.

Nowadays, thanks to the scientific advances related to the analysis of food composition and the knowledge about the metabolic processes in human body, it is possible to define the concepts of nutritional normality, deficiency, and toxicity. Therefore, the reference values of nutrient intake are focused not only on the prevention of risks associated with nutrient deficiencies but also on the prevention of chronic and degenerative diseases, with the ultimate aim of health promotion. Various international organizations have established Recommended dietary allowances to be used as a basis for establishing appropriate dietary guidelines (Table 1).
