PREFACE

Why an Encyclopedia on Food Safety?

With the world's growing population, the provision of a safe, nutritious, and wholesome food supply has become a major challenge. To achieve this, effective risk management based on sound science and unbiased information is required by all stakeholders, including the food industry, governments, and consumers themselves. In addition, the globalization of the food supply requires the harmonization of policies and standards based on a common understanding of food safety among authorities in countries around the world.

Furthermore, reports of food safety incidents and foodborne disease outbreaks in one country are disseminated almost instantaneously through the 24/7 news cycle to consumers in other countries all over the world. Consequently, food safety managers in government and industry are sometimes called on to respond to queries from politicians, the media, and the general public even before they may be aware of the problem. Taking effective intervention measures and communicating the basis of their decisions and actions are essential for maintaining confidence in the safety of the food supply.

In all the above circumstances, sound scientific information is the key to effectively and efficiently assess, manage, and communicate on food safety risks. Yet, professionals and other specialists working in this multidisciplinary field are finding it increasingly difficult to keep up with developments outside their immediate areas of expertise. The time and staff needed to provide this information are beyond the resources of most individuals and organizations. Therefore, a single source of concise, reliable, and authoritative information on food safety has, more than ever, become a necessity.

This is the role that the Encyclopedia on Food Safety sought to fulfill by gathering all of the world's knowledge and expertise covering the entire spectrum of food safety topics into one comprehensive reference work. This was done with the objective of facilitating the work of those working in the field of food safety and related fields, such as nutrition, food science and technology, and environment. The Encyclopedia also provides a platform for experts to share their state-of-the art expertise and experience with the rest of the food safety community. Furthermore, the Encyclopedia's online feature is designed for rapid search and retrieval of relevant information.

Who Will Benefit from the Food Safety Encyclopedia?

The Encyclopedia will be useful for professionals and other specialists working in, but not limited to, the following institutions:

- Regulatory and enforcement agencies.
- Food industry.
- Trade and industry organizations.
- Audit and certification bodies.
- Academic institutions.
- Private and governmental scientific and research institutions.
- International and nongovernmental organizations with an interest in food.

What Does the Encyclopedia of Food Safety Contain?

With some 280 articles, the Encyclopedia provides comprehensive coverage a broad range of food safety topics, which may be grouped under the following general categories:

- History and basic sciences that support food safety.
- Foodborne diseases, including surveillance and investigation.
- Foodborne hazards, including microbiological and chemical agents.
- Substances added to food, both directly and indirectly.
- Food technologies, including the latest developments.
- Food commodities, including their potential hazards and controls.
- Food safety management systems, including their elements and the roles of stakeholders.

In developing the Encyclopedia, the editors and members of the Editorial Advisory Board have aimed to ensure that the Encyclopedia provides:

- Contributions by the foremost authorities in their fields.
- Unbiased and concise overviews on a multitude of food safety subjects.
- References for further information
- Specialized and general definitions for food safety terminology.

While the editors have made every effort to ensure that the Encyclopedia reflects the most complete and up-to-date information available, new scientific findings, and advances in food safety occur continuously. In undertaking a project of this scale and with the inevitably delays that occur during production, the editors acknowledge that some topics may have been omitted or insufficiently addressed. Therefore, the feedback of readers to point out any such errors or oversights will be greatly appreciated and will facilitate the development of future editions.

Acknowledgments

The lead editors would like to thank the Editorial Advisory Board members, section editors, and particularly, the authors who have generously contributed their time and talent to the development of this Encyclopedia. We are indebted to the Elsevier secretariat, which has assisted in the production of this work since its inception. Finally, a special note of thanks goes to our families whose patience and support are greatly appreciated.

Yasmine Motarjemi
Food Safety and Risk Management Consultant, Switzerland
Gerald G Moy
Food Safety Consultants International, Switzerland
Ewen CD Todd
Ewen Todd Consulting LLC, Okemos, MI, USA

DEDICATION

This Encyclopedia is dedicated to our children, our grandchildren, and all the world's future generations who we hope will enjoy the benefits of a safe and nutritious food supply, produced with fair management of people working in industry and ethical treatment of animals.

FOREWORD I

Today's food system is one of the humanity's great achievements. It includes millions of commercial actors all over the world who produce, process, transport, store, market, and serve food that feeds billions of people daily. The complexity, diversity, and scope of the food system are almost beyond comprehension – ranging from small producers and processors serving local communities to vast global enterprises producing food for millions and managing extended international supply chains – all aimed at meeting high consumer expectations for safe, nutritious, and affordable food.

For all of its successes, the food system is full of challenges. Food insecurity and hunger remain major problems worldwide, and, for those with ready access to the foods of their choice, it is too easy to choose products high in salt, fat, and added sugar. Food safety – the task of avoiding chemical and microbiological contamination of food that can make people sick – is another persistent and dynamic challenge. In fact, new products in the marketplace, new patterns of production and supply, new consumer behaviors and new bacterial and chemical hazards – coupled with high consumer expectations – conspire to make food safety one of the central challenges of today's food system.

People working in the food system know this. Prominent illness outbreaks and contamination incidents take a toll on the public's health and cause a loss of confidence that can steer consumers away from healthy foods, like fresh fruits and vegetables, and impose big economic losses on food producers and processors. And the food system is responding with a heightened awareness of food safety at all levels of the food system and tremendous effort across the system to improve food safety. Much progress is being made.

One of the most important food safety developments of the last quarter century has been the emergence of a widely shared, science-based understanding of foodborne illness, its causes, and how it can be prevented. This begins with the understanding that the current burden of foodborne illness is unacceptable because it is largely preventable. It is preventable if we see food safety as a food system issue and recognize that microbiological and chemical hazards can enter the food supply at any point in the system along the pathway from the farm through processing, transport, storage, and retail sale. Likewise, opportunities to minimize hazards and help prevent food safety problems exist throughout the system, which means that everyone in the system shares responsibility for the safety of the food we eat.

Fulfilling this responsibility requires that we understand as much as we can about food safety hazards and their causes, devise the appropriate, science-based preventive controls for particular hazards and food production settings, monitor their effectiveness, and adjust the controls as needed based on experience. In short, progress on food safety depends fundamentally on a strong base of knowledge and continuous learning to systematically prevent food safety problems. And participants across the global food safety community are actively seeking and applying the knowledge needed to produce safe food and meet high consumer expectations.

This food safety encyclopedia provides a comprehensive overview of what we know about food safety hazards and control measures. We have more to learn, but the knowledge compiled in this encyclopedia demonstrates that we know a lot and that what we know can help empower participants in today's food system to fulfill their food safety responsibility. Although the food safety challenge is global and continuing, and may seem daunting, it can be met if all who share responsibility for food safety take advantage of the knowledge we have, participate in continuous learning, and place first priority every day on protecting the safety of food. That will be good for the food system – and for the consumers it serves.

Michael R Taylor
Deputy Commissioner for Foods and Veterinary Medicine, US Food and Drug Administration (FDA), Silver Spring, MD, USA

FOREWORD II

Food is one of the most basic requirements to sustain life. However, the safety of food and water cannot be taken for granted. Owing to both manmade and natural processes, an array of chemical and microbiological disease-causing agents find their way into food through multiple routes. When contaminated, such food can endanger or even destroy life. Therefore, from time immemorial, humankind has waged a constant battle against foodborne disease. Over many centuries of human development, people invented technologies that helped them fighting this battle, such as cooking, smoking, sun drying, canning, and freezing, to mention but a few. But like any scientific advance, some of these technologies presented their own food safety issues.

In a number of holy books, religious proscriptions for handling food contributed to food safety. In addition, many centuries ago, some governments already recognized that they had responsibilities in this domain and many laws were enacted to ensure the purity of certain foods. But it was only at the end of the nineteenth century, following scientific developments in the field microbiology and other areas of food science, that 'modern' food regulatory activities started.

In 1948, the availability, accessibility, and affordability of food were recognized as a basic human right by the United Nations in its Universal Declaration of Human Rights (Article 25, 1948). Implicit in this concept is the assumption that the food is first and foremost safe to consume, i.e., absence of health damaging properties. It is therefore not surprising that in the same year, the World Health Organization (WHO) was established as a specialized agency of the United Nations with a broad health mandate that included the specific responsibility to "develop, establish and promote international standards with respect to food…". Subsequently in 1963, WHO together with the Food and Agriculture Organization of the United Nations established an intergovernmental body to develop international standards for food – the Codex Alimentarius Commission. Today Codex stands as a major achievement in the promotion of food safety worldwide with an extensive collection of health and safety recommendations for food that are international recognized and referenced by the World Trade Organization and its member countries.

Thirty years ago, in 1983, WHO, again jointly with FAO, convened an Expert Committee on Food Safety to review the global food safety situation and provide guidance for governments, the food industry and consumers on how to cope with the inherent hazards and risks of our food supply. Based on available data and evidence at the time, the committee concluded that "illness due to contaminated food is perhaps the most widespread health problem in the contemporary world and an important cause of reduced economic productivity."

Unfortunately, this rather alarming statement appears to be still true today. Recent studies examining the morbidity and mortality of foodborne diseases have confirmed the significant public health burden posed by these diseases. In developed countries, one-quarter to one-third of the population are made ill each year because of foodborne diseases. In the developing world, the burden is much more severe. For example, diarrheal diseases are now estimated to cause 2.43 million deaths a year. According to WHO statistics, this is the second leading cause of mortality in low-income countries and kills more people than human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), malaria, or tuberculosis.

In addition, the large number of food safety crises, which occur with increasing frequency, is contributing to the growing public demand for better health protection from contaminated food. This has prompted governments to strengthen their food safety legislation, improve capacities and infrastructure, and tighten control measures. Examples of governmental measures include the creation of European Food Safety Agency by the European Union in 2002, the Food Safety Modernization Act in the USA of 2011 and, most recently, 2013, the commitment of the Premier of the People's Republic of China, Mr. Li Keqiang, to act with an 'iron fist' to improve food safety.

These positive developments are, unfortunately, contrasted by the fact that in many other countries, mostly developing countries, food safety does not receive the attention it deserves. In this regard, the medical profession and public health community appear to be slow in accepting the role that contaminated food plays in the epidemiology of diarrhea, particularly in infants and young children. The treatment of hospitalized cases and outpatients is rarely seen as an opportunity for educating patients and their families on why foodborne diseases occur and how they can be prevented. Two publications published in WHO's Bulletin in 1993 and 2003 urged the health sector to take steps to correct this oversight. Yet even today progress has been disappointing. For example, in the 2009, United Nations Children's Fund (UNICEF) and WHO published a document entitled 'Diarrhea: Why children are still dying and what can be done,' that again overlooked food safety as one of the most important interventions for these diseases. Consequently, in a recent publication in a prestigious *Medical Journal of Gastroenterology*, the issue had to be raised again and omission corrected. It can only be hoped that the public health and donor communities will eventually adopt a more holistic approach for the prevention of diarrheal diseases, which includes essential food safety interventions.

It is for this and many other reasons that I enthusiastically welcome the initiative of Elsevier to publish this Encyclopedia of Food Safety under the editorial leadership of Drs. Yasmine Motarjemi and Gerald Moy (my former WHO colleagues) as well as Dr Ewen Todd, a world renowned expert in food safety. The laudable collaboration and support of the Editorial Advisory Board, Section Coordinators, and the many authors who have freely devoted their time to advance the cause of food safety through the development of this Encyclopedia is also acknowledged.

With such a collection of information, whoever needs first-hand, reliable, and authoritative information on food safety does not need to consult various books, periodicals, or

websites. All of what is presently known in this domain can be found in this comprehensive work. In particular, the Encyclopedia will be useful for decision-makers, managers, officials, and scientists working in government, the food industry, academia, and nongovernmental organizations.

This Encyclopedia may be particularly important for colleagues in developing countries to not only improve food safety for their people but also convince politicians and other policy makers of the pivotal role of food safety in health and development. Without this awareness, the ultimate goal of safe food for all cannot be achieved.

F Käferstein
Former Director, Food Safety and Food Aid Programme (1980–98), World Health Organization, Wiesbaden, Germany

EDITOR-IN-CHIEF

Yasmine Motarjemi holds a Masters degree in Food Science and Technology from the University of Languedoc, Montpellier, France (1978) and a Doctoral degree in Food Engineering from the University of Lund, Sweden (1988).

After her research and academic career at the University of Lund, in 1990, she joined the World Health Organization in Geneva as Senior Scientist. In WHO, she was responsible for the surveillance and prevention of foodborne illnesses (including education of professional food handlers and consumers), the development of the food safety assurance systems (e.g., Hazard Analysis and Critical Control Point system), and for assistance to the WHO Member States in strengthening their national food safety programme. She also contributed to the development of the risk analysis process. She has served in the Secretariat of various sessions of the Codex Alimentarius Commission and its Committees.

From 2000 to 2011, she held the position of Assistant Vice President in Nestlé where she worked as the Corporate Food Safety Manager. In this capacity, she has, among others, developed the Nestlé Food Safety Management system and managed various emerging food safety issues and crises.

She is the author, co-author, or editor of numerous peer-reviewed articles, books, training manuals, and other publications. Her latest books are Food Safety Management: A Practical Guide for the Food Industry (Elsevier 2014) and Invisible Things (original in French under the title: Les Invisibles), a book on food safety for children.

CO-EDITORS BIOGRAPHY

Dr Gerald G Moy, since his retirement from the World Health Organization in 2008, is a scientific adviser with Food Safety Consultants International working with numerous governments and international organizations. His expertise includes assessment of national food safety programs, risk assessment of chemical hazards in food, total diet studies, food safety during mass gatherings, and food defense. Dr Moy is the editor-in-chief for recently published book Total Diet Studies (Springer) and is currently preparing a chapter on food and water protection for a book on key public health considerations during mass gatherings. He serves on the International Scientific Advisory Committee of the China National Center for Food Safety Risk Assessment, the Technical Advisory Group of the World Food Program Technical Advisory Group, and the WHO International Virtual Advisory Group on Mass Gatherings. He is the author of numerous book chapters, articles, and publications and serves on the editorial boards for several food safety journals.

He received his BS in chemistry from the University of Wisconsin and his PhD in physical organic chemistry from Oregon State University, followed by a post-doctoral fellowship in biophysics at the University of New Mexico. He is a Fellow in International Academy of Food Science and Technology and a recipient of the 2009 Great Wall Friendship Award for his contributions to food safety during the Beijing Olympics.

Ewen CD Todd is the President of Ewen Todd Consulting and the former Professor in the Department of Advertising, Public Relations and Retailing, and he is also the Adjunct Professor in the Departments of Food Science and Human Nutrition and Large Animal Clinical Sciences at Michigan State University (MSU). He was former directors of the Food Safety Policy Center and the National Food Safety and Toxicology Center at MSU. At both these centers, Dr. Todd coordinated research in microbiology, toxicology, epidemiology, risk assessment, social science, and policy in the area of food safety, distance education programs, and outreach in the community. Previously, he was in the Bureau of Microbial Hazards, Health Products and Food Branch, Health Canada, Ottawa where he was a research scientist for 33 years working on methods development for pathogens in foods, foodborne disease investigation and reporting, costs and surveillance of disease, illnesses caused by seafood toxins, and risk assessment of foodborne pathogens. He also helped develop risk management strategies for the Department including producing videos and pamphlets on food safety education. Some of his recent research has been working on *Listeria* and *E. coli* O157 transfer coefficient and modeling projects, hygiene in child care centers, schools, and elder care facilities. He has also collaborated with government agencies and academia in Spain, Kuwait, Saudi Arabia, Lebanon, Cambodia, Korea, Japan, and China on food safety issues, and is an expert witness in legal suits involving food safety. He has published extensively on many different aspects of food safety, including 11 recent papers on food workers and hand hygiene. He is active in the International Association for Food Protection (IAFP) and other organizations, and speaks and organizes symposia at national and international meetings. He is the associate editor for the Journal of Food Science and is a frequent reviewer of manuscripts submitted to several different scientific journals.

He has received the Government of Canada Distinctive Service Award for extraordinary teamwork and support to the Science and Technology Community; Recipient of the Excellence in Science Award for 1998 by Health Canada; Deputy Minister's Award of Team Excellence for the work done in promoting the Fight BAC! Campaign in Canada; the Professional Institute of the Public Service of Canada Gold Medal for Pure and Applied Science; and he is Fellow of the American Association for the Advancement of Science, the IAFP, and the MSU University Outreach and Engagement. He is also an honorary life member of the IAFP. He is a graduate of Glasgow University with a BSc in Bacteriology and a PhD in bacterial systematics.

Protozoa

Organisms of Concern but not Foodborne or Confirmed Foodborne

Natural Toxicants

Mycotoxins

Environmental Contaminants

Toxic Metals

Foods, Materials and Risks

Safety of Food and Beverages

VOLUME 4 Food Safety Management

Food Safety Management

Public Health Measures

Food Safety Assurance Systems

Institutions Involved in Food Safety

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into five broad sections, presented in four volumes. The sections consist of:

1. **History, science, and methods**: this section includes papers which help in the understanding of basic sciences underpinning food safety and foodborne diseases and their historical development.
2. **Hazards and diseases**: this section addresses the features of major foodborne hazards be they chemical, microbial, parasitical or physical and their health consequence.
3. **Food technologies**: this section explains the various food technologies and aspects related to their safety, or risks in their application.
4. **Foods, materials, and risks**: similarly, in this section, various groups of food products are described in terms of their risks and measures needed to ensure their safety.
5. **Food safety management**: finally, in this part, the building blocks of food safety management in the private and public sector are explained. The role of major international organizations is also reported.

To help realize the full potential of the material in the Encyclopedia the authors have provided five features to help you find the topic of your choice: a preface giving an overview of the encyclopedia and its objectives, a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1 Contents List by Subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2 Alphabetical Contents List

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the alphabetical order. This list provides both the volume number and the page number of each entry. On the opening page of an entry a contents list is provided so that the full details of any articles within the entry are immediately available.

3 Cross-references

All of the entries in the Encyclopedia have been extensively cross-references. The cross-references, which appear at the end of the entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other entries.
iii. To indicate the material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry Characteristics of Foodborne Hazard and Diseases | Drug Resistant Pathogens.

> *See also*: Bacteria: *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli* and Other Pathogenic *Escherichia coli*; *Shigella*; *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. Characteristics of Foodborne Hazard and Diseases: Cost of Foodborne Diseases. Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings; Surveillance of Foodborne Diseases

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi, and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli*), parallel discussion in other entries (e.g., Other Pathogenic *Escherichia coli*), and reference to entries that broaden the discussion (e.g., Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings).

4 Index

The index provides you with the page number where the material is located. The index entries differentiate between materials that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5 Contributors

A full list of contributors is listed at the beginning of each volume.

GLOSSARY OF SELECTED TERMS

This Glossary of Selected Terms is a partial list of definitions for terms commonly used in the area of food safety. The terms selected are those that are important for communication among the various disciplines or are often subject to misunderstanding. Most of the definitions are taken from those recommended by international organizations or given by the authors contributing to this Encyclopedia. In cases where there are different definitions for a term, the Glossary presents the definition that is most consistent with usage by the majority of authors. Note that in some instances, slight differences between general definitions in this Glossary and those appearing in the individual articles may occur as the result of the specific context of the articles.

Acceptable daily intake The estimate of the amount of a substance in food or drinking water, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk to the consumer.

Acute reference dose The estimate of the amount of a substance in food or drinking water, expressed on a body mass basis, that can be ingested in a period of 24 h or less without appreciable health risk to the consumer.

Adulteration (economic) A fraudulent action which is intended to omit a valuable constituent or substitute another substance, in whole or in part, for a valuable constituent; conceal damage or inferiority in any manner; or add any substance to increase its bulk or weight, reduce its quality or strength, or make it appear bigger or of greater value than it is (Note that in the US, adulterated food is generally defined as impure, unsafe, or unwholesome food.).

Antiseptic A substance that inhibits the growth and development of microorganisms. For practical purposes, antiseptics are routinely thought of as topical agents, for application to skin, mucous membranes, and inanimate objects, although a formal definition includes agents which are used internally, such as the urinary tract antiseptics.

As low as reasonably achievable A risk management approach that aims to keep exposure to a substance at the lowest level that is realistically achievable.

Asymptomatic shedder A person who does not exhibit the symptoms of an illness but excrete the pathogen (*see also* carrier).

Benchmark Reference point or standard against which performance or achievements can be assessed. A benchmark refers to the performance that has been achieved in the recent past by other comparable organizations, or what can be reasonably inferred to have been achieved in the circumstances.

Biomarkers Indicators of changes or events in human biological systems. Biomarkers of exposure refer to cellular, biochemical, or molecular measures that are obtained from biological media such as human tissues, cells or fluids, and are indicative of exposure to a substance. Biomarkers of effect refer to biological changes that represent an alteration in endogenous body constituents (e.g., depression of cholinesterase levels as an indicator of exposure to pesticides).

Carrier A person or animal that harbors a specific infectious agent without discernible clinical disease and serves as a potential source of infection. The carrier state may exist in an individual with an infection that is unapparent throughout its course (commonly known as healthy or asymptomatic carrier), or during the incubation period, convalescence and postconvalescence of an individual with a clinically recognizable disease (commonly known as an incubatory or convalescent carrier). Under either circumstance the carrier state may be of short or long duration (temporary or transient carrier, or chronic carrier) (*see also* asymptomatic shedder).

Case-fatality rate Usually expressed as the percentage of persons diagnosed as having a specified disease who die as a result of that illness within a given period. This term is most frequently applied to a specific outbreak of acute disease in which all patients have been followed for an adequate period of time to include all attributable deaths. The case-fatality rate must be clearly differentiated from the mortality rate (Compare with mortality rate).

Colony-forming unit A measure of viable bacterial or fungal cells in which a colony represents an aggregate of cells derived from a single progenitor cell.

Contaminant Any biological, chemical, or physical agent not intentionally added to food, which is present in food as a result of the production, manufacture, processing, preparation, transport, or holding of such food (Compare with hazard).

Control (noun) The state wherein correct procedures are being followed and critical criteria are being met.

Control (verb) To take all necessary actions to ensure and maintain compliance with criteria established in the Hazard analysis and critical control point system (HACCP) plan.

Control measure Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Corrective action Any action to be taken when the results of monitoring at the Critical Control Point (CCP) indicate a loss of control.

Crisis A predicted or unpredicted event which represents an immediate or future significant threat to an organization, its employees, consumers, and the public at large.

Critical control point A step at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Critical limit (CL) A criterion which separates acceptability from unacceptability.

Detergent A chemical used to remove grease, dirt and food, such as washing-up liquid.

Disability adjusted life year (DALY) A metric used to express a health gap that extends the concept of potential years of life lost due to premature death to include equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. The DALY combines in one measure the time lived with disability and the time lost due to premature mortality. One DALY can be thought of as one lost year of 'healthy' life and the burden of disease as a measurement of

the gap between current health status and an ideal situation where everyone lives into old age free of disease and disability.

Disinfectant A chemical agent or a process that destroys, neutralizes, or inhibits the growth of pathogenic microorganisms (*see also* sanitizer).

Dose–response assessment The determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response) in the exposed organism, system, or (sub) population in reaction to the agent.

Endotoxin A toxin present in intact bacterial cells and released when bacteria die or the cells are disrupted. A notable endotoxin is lipopolysaccharide, which is a major constituent of the outer cell membrane of Gram-negative bacteria and can cause toxic effect on lysis of bacteria. The term 'endotoxin' is to be differentiated from 'exotoxin', which is a toxin secreted in the surrounding medium and environment of the bacterial cell.

Enterotoxin A cytotoxin produced by bacteria that is specific for the mucous membrane of the intestine and causes diarrhea and/or vomiting associated with foodborne disease. Many infectious microorganisms produce enterotoxins in the gut, but some are produced external to the host (*see also* exotoxin and endotoxin).

Exotoxin A toxin that is secreted by bacteria. There are many different types of exotoxins. They can be released into the susceptible host (after infection and growth) or into the environment, including food (after contamination and growth). Those released into the intestines are typically heat labile (but some *E. coli* strains can produce both heat labile (HL) and heat stable (HS) toxins). *Clostridium perfringens* produces a HL enterotoxin after completion of sporulation in the host's intestines. *Staphyloccocus aureus* and *Bacillus cereus* enterotoxins produced in food are HS and cause vomiting and diarrhea, whereas toxins of *Clostridium botulinum* toxin, also produced in food, are HL and cause systemic neurological symptoms (*see also* exotoxin and endotoxin).

Epidemic The occurrence in a community or region of a group of illnesses which are similar in nature and clearly in excess of normal expectancy, and derived from a common or from a propagated source (Compare with pandemic).

Equivalence The situation where the application of two different food safety management measures lead to the same, or equivalent, public health outcomes.

Equivalence of sanitary measures (import–export of food) Equivalence is the state wherein sanitary measures applied in an exporting country, though different from the measures applied in an importing country, achieve, as demonstrated by the exporting country, the importing country's appropriate level of sanitary protection.

Exposure assessment The qualitative and/or quantitative evaluation of the likely ingestion of a biological, chemical, or physical agent in food as well as exposures from other sources if relevant.

Fecal–oral route A means of spreading pathogenic microorganisms from feces produced by an infected host to another host, usually via the mouth; for example, contact between contaminated hands or objects and the mouth.

Flow diagram A systematic representation of the sequence of steps or operations used in the production or manufacture of a particular food item.

Food Any substance, whether processed, semiprocessed, or raw, which is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation or treatment of 'food' but does not include cosmetics or tobacco or substances used only as drugs.

Food additive Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport, or holding of such food results, or may be reasonably expected to result, (directly or indirectly) in it or its byproducts becoming a component of or otherwise affecting the characteristics of such foods.

Food allergy A form of food intolerance in which there is evidence of an abnormal immunological reaction to the food (Compare with food intolerance).

Food establishment Any building or area in which food is handled and the surroundings under the control of the same management.

Food handler Any person who handles, prepares, or serves food, be they domestic food handlers, such as preparing family food, or professional food handlers, such as those working in food service establishments (cooks and waiters), retail stores, supermarkets, etc. (*see also* food worker).

Food hygiene All conditions and measures necessary to ensure the safety and suitability of food at all stages of the food chain.

Food industry The term includes primary manufacturing and processing industry as well as some other establishments involved in the food chain.

Food intolerance A reproducible, unpleasant reaction to a food or food ingredient, including reactions due to immunological effects, biochemical factors, such as enzyme deficiencies and anaphylactic reactions that often include histamine release (Compare with food allergy).

Food poisoning (or acute foodborne intoxication) A disease caused by a toxin or a chemical in food with symptoms usually appearing within 24 h after ingesting the agent. This term is commonly misused as a synonym for foodborne disease, which covers both infections and intoxications.

Food safety Assurance that food will not cause harm to the consumer, when it is prepared and/or eaten according to its intended use (Compare with food suitability and food hygiene).

Food safety hazard A biological, chemical, or physical agent in, or condition* of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to property of a food.

Food safety objective (FSO) The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP) (Compare with Performance objective).

Food suitability Assurance that food is acceptable for human consumption according to its intended use (Compare with food safety and food hygiene).
Food worker Individuals who harvest, process, prepare and serve food, i.e., across the whole food chain to retail/foodservice; it is broader than that of a food handler, who typically works in foodservice establishments typically foodservice; however, the two terms are used interchangeably in the literature (*see also* food handler).
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of contaminated food, including drink.
Foodborne pathogens Disease-causing microorganisms that are transmitted to humans via foods.
Generally recognized as safe Status of a substance that is generally recognized, among qualified experts, as having been adequately shown to be safe under the conditions of its intended use (used mainly in the USA).
Genomics The study of an organism via decoding the entire genetic sequence of the organism.
Genetic modification A process of altering the genetic makeup of an organism by techniques of modern biotechnology.
Genetically modified organism (GMO) AGMO or genetically engineered organism is an organism whose genetic material has been altered using genetic engineering techniques.
Good animal husbandry practice A system of management controls that need to be adopted at the level of primary producers to ensure production of food of animal origin that is safe for human consumption and acceptable for trade in the world market.
Good hygienic practice A system of management controls that need to be adopted at production, processing, storage, distribution, and preparation to ensure safety and suitability of products of consumption.
Good laboratory practice A system of management controls for laboratories and research organizations to ensure the quality, integrity, consistency, and reliability of results.
HACCP plan A document prepared in accordance with the principles of HACCP to ensure control of hazards which are significant for food safety in the segment of the food chain under consideration (see also HACCP).
Hazard A biological, chemical, or physical agent in, or condition*; of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to a property of a food.
Hazard analysis The process of collecting and evaluating information on hazards and conditions leading to their presence to decide which are significant for food safety and therefore should be addressed in the HACCP plan.
Hazard analysis and critical control point system A preventive system which identifies, evaluates, and controls hazards which are significant for food safety.
Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with a biological, chemical, or physical agent which may be present in food. For a chemical agent, a dose–response assessment should be performed. For a biological or physical agent, a dose–response assessment should be performed if the data are obtainable.
Hazard identification The identification of the type and nature of adverse effects that a biological, chemical, or physical agent in food is capable of causing in an exposed population.
Incidence rate The number of new cases of a condition arising in a defined group within a given period or the number of new infections per unit of person–time at risk (Compare with prevalence).
In vitro In an artificial environment outside the living organism.
In vivo Within a living organism.
Lethal dose 50% The dose of a substance that would be expected to kill half of a population of exposed organisms.
Margin of exposure Ratio of the no-observed-adverse-effect level or benchmark dose lower confidence limit for the critical effect to the theoretical, predicted, or estimated exposure dose or concentration.
Maximum residue limit The maximum concentration of residues resulting from the use of a pesticide or veterinary drug that is acceptable in or on a food.
Minimum infective dose The lowest number of microorganisms required to cause an infection in the host.
Monitoring (CCP) The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a CCP is under control.
Monitoring (general) Continuous or repeated observation, measurement and evaluation of health, and/or environmental or technical data for defined purposes, according to prearranged schedules in space and time, using comparable methods for sensing and data collection.
Morbidity rate An expression of the number of illnesses in a population at risk over a given period of time (usually one year).
Mortality rate An expression of the number of deaths in a population at risk over a given period of time (usually one year).
Nanomaterials Materials engineered at the nanoscale to have novel functionality or properties. Such properties will typically, but not exclusively, be demonstrated in the size range 1–100 nm, but this size range should be considered approximate.
Nanoparticles Particles with one or more external dimensions in the range 1–100 nm, but this size range should be considered approximate.
Nanotechnology The manipulation or materials at the nano level.
Notifiable disease A disease that must, by law or by ministerial decree, be reported to a government authority.
Outbreak A group of at least two cases of a single illness that are demonstrated by epidemiological investigation to have a single common exposure or source.
Pandemic Epidemic occurring over a very wide area, crossing international boundaries (often more than one continent) and usually affecting a large number of people.
Pasteurization A process involving heat treatment at a prescribed time–temperature combination to kill vegetative forms of pathogens that may be present, while causing minimal changes in the composition, flavor, and nutritive value of food. However, with advances and the development

of new food technologies, the term is sometimes used for nonthermal technologies leading to the same effect.

Pathogen An organism capable of causing disease.

Pathogenesis The course of a disease from its origin to its manifestation; more specifically it refers to the cellular events and reactions, and other pathologic mechanisms occurring in the development of the disease.

Pathogenicity Ability of a microorganism to cause disease in a host (Compare with virulence).

Performance criterion The effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a performance objective (PO) or an FSO.

Performance objective The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable (Compare with Food Safety Objective).

Pesticide Any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production; storage; transport; and distribution and processing of food, agricultural commodities, or animal feeds or which may be administered to animals for the control of ectoparasites. The term includes insecticides, herbicides, fungicides, rodenticides and algicides as well as plant growth regulators, defoliants, desiccants, and agents for thinning fruit or preventing the premature fall of fruit.

Prerequisite program Practices and conditions needed prior to and during the implementation of HACCP and which are essential to food safety.

Prevalence The number of persons in a population who have a disease at a specified point in time or over a specified period of time (Compare with incidence rate).

Primary production Those initial steps in the food chain up to and including, for example, harvesting, slaughter, milking, and fishing.

Processing aid Any substance or material, not including apparatus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods, or its ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the nonintentional but unavoidable presence of residues or derivatives in the final product.

Processing contaminant Undesirable contaminants that are formed during the treatment of food as a result of the interaction of their natural components or their ingredients.

Provisional maximum tolerable daily intake (PMTDI) The health-based reference value used for contaminants with no cumulative properties. Its value represents permissible human exposure as a result of the natural occurrence of the substance in food and in drinking water. In the case of trace elements that are both essential nutrients and unavoidable constituents of food, a range is expressed, the lower value representing the level of essentiality and the upper value the PMTDI.

Provisional tolerable monthly intake The health-based reference value used for a food contaminant with cumulative properties that has a very long half-life in the human body. Its value represents permissible human monthly exposure to a contaminant unavoidably associated with otherwise wholesome and nutritious foods.

Provisional tolerable weekly intake The health-based reference value used for food contaminants such as heavy metals with cumulative properties. Its value represents permissible human weekly exposure to those contaminants unavoidably associated with the consumption of otherwise wholesome and nutritious foods.

Quality management Quality management includes all the activities that organization use to direct, control, and coordinate quality. These activities include formulating a quality policy and setting quality objectives. They also include quality planning, quality control, quality assurance, and quality improvements.

Recommended dietary allowance The average daily dietary nutrient intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy subjects in a particular life stage and gender group.

Reservoir An animal species that specifically harbors an infectious agent over long periods, often without harm to the host.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Risk analysis A process of decision making (usually government) for managing food safety, consisting of three components: risk assessment, risk management, and risk communication.

Risk assessment A scientifically based process for evaluating risks associated with foodborne hazards, consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization.

Risk assessment policy Documented guidelines on the choice of options and associated judgments for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties, including the explanation of risk assessment findings and the basis of risk management decisions.

Risk estimate The quantitative estimation of risk resulting from risk characterization.

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and, if needed, selecting appropriate prevention and control options.

Risk manager A person or an organization (usually government) with the authority to decide on the acceptability of risk and, if necessary, measures needed for their management.

Risk profile The description of the food safety problem and its context.

Safe (food) A level of risk that is deemed to be acceptable by some standard. The question of safety always involves the question of to whom the risk is acceptable, and by what criteria that party judges it so.

Sanitizer Type of antimicrobial (disinfectant) that kills or irreversibly inactivates microorganisms present on a surface, especially designed for use on food-processing equipment. The US Environmental Protection Agency further defines a sanitizer as providing at least 99.9% reductions of all microorganisms on a surface (*see also* disinfectant).

Shelf-life The predicted time at which a product will change from acceptable to unacceptable quality. It is influenced by factors such as raw ingredient quality, processing conditions, packaging practices, and storage conditions. Typically, shelf-life is determined by a combination of microbial, sensory, and chemical methods. 'Shelf-life' can be expressed on food labels by a variety of dates, including 'expiry', 'use by', 'sell by', 'best before', and 'consume by', depending on the applicable legislation.

Step (HACCP) A point, procedure, operation, or stage in the food chain including raw materials, from primary production to final consumption.

Strain An isolate of the same type of microorganism possessing different properties.

Surveillance The systematic, ongoing collection, collation, and analysis of data on specific diseases in a defined population, to guide public health decisions.

Surveillance (active) Public health surveillance that regularly reaches out to diagnostic laboratories or to clinicians to actively collect reports of specific diagnoses of infections.

Surveillance (passive) Public health surveillance that collects reports of specific diagnoses from clinicians or diagnostic laboratories, which they are required or requested to submit because of notifiable diseases regulations.

Time–temperature abuse A situation where food has not been cooked for long enough or at a sufficient high temperature to reduce contaminants to safe levels, or food has been stored for a time or at a temperature that permits bacteria to proliferate.

Traceability/product tracing The ability to follow, forward as well as backward, the movement of a food through specified stage(s) of production, processing, and distribution.

Uncertainty In risk assessment, imperfect knowledge concerning the present or future state of an organism, system, or (sub) population under consideration.

Validation (analytical methods) Practice undertaken to substantiate or confirm methods or procedures perform as expected and in a reliable manner and consistently meet expectations.

Validation (control measures) Obtaining evidence that a control measure or combination of control measures, if properly implemented, is capable of controlling the hazard to a specified outcome.

Validation (HACCP) Obtaining evidence that the elements of the HACCP plan are effective.

Variability Heterogeneity of values over time, space, or different members of a population. Variability implies real differences among members of that population.

Verification (general) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine whether a control measure is or has been operating as intended.

Verification (HACCP) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine compliance with the HACCP plan.

Veterinary drug Any substance applied or administered to any food-producing animal, such as meat or milk producing animals, poultry, fish, or bees, whether used for therapeutic, prophylactic, or diagnostic purposes, or for modification of physiological functions or behavior.

Virulence The degree of pathogenicity of a microorganism as indicated by case-fatality rates and/or its ability to invade the tissues of the host; the competence of any infectious agent to produce pathologic effects. The virulence of a microorganism is a measure of the severity of the disease it causes (Compare with pathogenicity).

Waterborne disease A disease resulting from the contamination of water either by pathogenic viruses, bacteria or protozoa, or by chemical substances. These agents are directly transmitted to people when the water is used for drinking, preparing food, recreation, or other domestic purposes.

Withdrawal period (veterinary drugs) The interval between the time of the last administration of a veterinary drug and the time of the collection of edible tissue or products from a treated animal that ensures the concentration of residues in food comply with the maximum residue limit for the drug.

Zoonosis A disease that can be passed directly or indirectly from animals, whether wild or domesticated, to humans. Also called zoonotic disease.

ABBREVIATIONS OF TECHNICAL TERMS

This is a nonexhaustive list of commonly used abbreviations in the area of food safety.

ADI	Acceptable daily intake.
ADME	Absorption, distribution, metabolism, and excretion.
AI	Adequate intake.
ALARA	As low as reasonably achievable.
ALOP	Appropriate level of protection.
ARfD	Acute reference dose.
BMD	Benchmark dose.
BMDL	Benchmark dose at lower confidence limit.
CCP	Critical control point.
CFR	Case fatality rate.
CFU	Colony forming unit.
CIP	Cleaning in place.
DALY	Disability adjusted life year.
DGGE	Denaturing gradient gel electrophoresis.
DNA	Deoxyribonucleic acid.
EAR	Estimated average requirement.
ED_{50}	Effective dose 50%.
ELISA	Enzyme linked immunosorbent assay.
EMRL	Extraneous maximum residue limit.
FSO	Food safety objective.
GAHP	Good animal husbandry practice.
GAP	Good agricultural practice.
GHP	Good hygienic practice.
GAqP	Good aquacultural practice.
GC	Gas chromatography.
GC–MS	Gas chromatography–mass spectrometry.
GHP	Good hygienic practice.
GLP	Good laboratory practice.
GM	Genetically modified.
GMO	Genetically modified organism.
GMP	Good manufacturing practice.
GPVD	Good practice in the use of veterinary drugs.
GRAS	Generally recognized as safe.
HAB	Harmful algal bloom.
HACCP	Hazard analysis and critical control point.
HPLC	High performance liquid chromatography.
HPLC–MS	High performance liquid chromatography–mass spectrometry.
HPP	High pressure processing.
HTST	High temperature short time.
HUS	Hemolytic uremic syndrome.
IEDI	International estimated daily intake.
IESTI	International estimated short term Intake.
LD_{50}	Lethal dose 50%.
LOAEL	Lowest observed adverse effect level.
LOD	Limit of detection.
LOQ	Limit of quantitation.
MFFB	Moisture on a fat free bases.
ML	Maximum level.
MLST	Multilocus sequence typing.
MLVA	Multiple locus variable number tandem repeat analysis.
MOE	Margin of exposure.
MRL	Maximum residue limit.
mRNA	Messenger ribonucleic acid.
MS	Mass spectrometry.
NEDI	National estimated daily intake.
NOAEL	No observed adverse effect level.
NOEL	No observed effect level.
OPRP	Operational prerequisite programme.
PC	Performance criterion.
PCR	Polymerase chain reaction.
PDCA	Plan do check act.
PEF	Pulsed electric fields.
PFGE	Pulsed field gel electrophoresis.
PMTDI	Provisional maximum tolerable daily intake.
PO	Performance objective.
PRP	Prerequisite program.
PrP	Protease resistant protein.
PTMI	Provisional tolerable monthly intake.
PTWI	Provisional tolerable weekly intake.
QPS	Qualified presumption of safety.
RDA	Recommended dietary allowance.
RNA	Ribonucleic acid.
SMEs	Small- and medium-sized enterprises.
SOP	Standard operating procedure.
SPS Agreement	Agreement on the Application of Sanitary and Phytosanitary Measures.
TBT Agreement	Agreement on Technical Barriers to Trade.
TDI	Tolerable daily intake.
TDS	Total diet study.
TEF	Toxic equivalency factor.
TEQ	Toxic equivalence.
TMDI	Theoretical maximum daily intake.
TSE	Transmissible spongiform encephalopathy.
UHT	Ultra high temperature.
UL	Upper limit.
UV	Ultra violet.

HISTORY OF FOOD SAFETY AND RELATED SCIENCES

Contents

History of Foodborne Disease – Part I – Ancient History

M Satin, Salt Institute, Alexandria, VA, USA

Glossary

Alimentary toxic aleukia High mortality intoxication characterized by massive immune deficiency, ulceration of the digestive tract, and pulmonary hemorrhaging.
Coprolites Desiccated or fossilized feces or intestinal contents.
Coturnism Suite of symptoms resulting from quail meat poisoning.
Methylmercury Highly toxic organic form of mercury that causes irreversible damage to nerve cells resulting in overwhelming neurological damage.
Paleogenetics The study and characterization of deoxyribonucleic acid (DNA) from ancient remains in order to determine their genetic origins.
St. Anthony's fire Gangrenous ergotism characterized by intense burning pain, followed by fingers, toes, or limbs.

Prehistory

It is difficult to say precisely which foodborne diseases our Stone Age ancestors suffered from because there is little or no direct evidence or records available. However, based on our understanding of their environment and lifestyles, we can assume with some confidence that they regularly ate contaminated meat and fish, poisonous mushrooms, toxic plants and raw, indigestible grains. Notwithstanding their hardy constitutions and continual exposure to a variety of contaminating organisms, it is likely that they routinely suffered and occasionally expired from, gastrointestinal-related diseases.

Our forebears were opportunistic eaters and consumed whatever they could gather or kill, and carrion, left over by large carnivores, would not infrequently be a part of their food. Aside from large and small mammals, fish, amphibians, and reptiles, they ate insects, snails, shellfish, and a great variety of plants, tree nuts, mushrooms, fruits, grains, and roots. Tribal experience would have knowledge of the most toxic of these to be avoided such as certain berries and mushrooms, either at all times or during specific seasons. Like all other predators, they consumed the sickest or weakest animals because they were the easiest to kill. Because of the limited opportunities for regular kills, it would typically be feast or famine for tribes, and so the members also probably ate decomposing meat, stored after a large kill. With the advent of fire, cooking would eliminate many microbial and toxin risks but not completely. It would be logical to assume that these people had stronger constitutions than ourselves but nevertheless suffered regularly from the widest possible range of foodborne illnesses. Although certain societies may have grown more tolerant to certain toxic or other pathogenic challenges, the available evidence indicated our ancient prehistoric ancestors generally died in poor health at an age of 20–30 years.

In examining the history of foodborne diseases, we must occasionally take a small leap of faith because conventional evidence from ancient times can be quite rare. For the most part, foodborne disease organisms exert their effects on intestines and other soft organs, which are highly biodegradable and seldom survive for long in dead bodies; however, under natural conditions. But that does not mean there are no other clues scattered along the path of history. Much can be learned through ancient paintings, hieroglyphics or writings, which depicted ancient life in exquisitely animated and detailed ways. These primitive pictorial works, rock paintings, and carvings can be found on every continent and from the Arctic to the South Pacific. The images include local plants, animals, and people. From these records, we have learned what people ate and the experiences they had in obtaining food.

As time progressed, improved historical records provided much *in lieu* of physical evidence.

Accidental and intentional preservation of bodies have provided us with additional evidence of foodborne diseases. Mummification has resulted in bodies so well preserved that they continue to be useful for in-depth forensic examination in the present day.

Coprolites (desiccated or fossilized feces or intestinal contents) can be extremely valuable artifacts for the archeologist, particularly in the study of intestinal including foodborne diseases. Few, if any foods are digested completely, coprolites contain the residual contents of the diet as well as the remains of pathogenic organisms. Although soft tissue cannot generally survive through the ages, coprolites can, and the organisms they contain are often robust enough to remain intact throughout the centuries.

The new discipline of Paleogenetics seeks to characterize the deoxyribonucleic acid (DNA) of ancient remains in order to determine their genetic origins. As an example, the DNA from the bacteria responsible for tuberculosis was recently extracted from a 1000-year-old Peruvian mummy.

Ancient societies suffered from a great many food- and waterborne parasites. Egyptian mummies were found with beef and pork tapeworms, liver flukes, whipworms, guinea worms, huge intestinal roundworms, *Trichinella*, *Ascaris*, and many other food and waterborne parasites. Although Egypt of the Pharaohs is generally considered to be a highly structured and sophisticated society, the hygienic and sanitation practices were very rudimentary, resulting in continual fecal–oral reinfection cycles experienced by all classes of the population.

Legends, myths, religious prohibitions, and taboos were originally transferred orally and only later put into a readable form or a more lasting and extensive form of communication. Primitive pictorial works, rock paintings, and carvings can be found on every continent and from the Arctic to the South Pacific, created many tens of thousands of years ago up to the present. The images include local plants, birds, animals, and people. From these records, we have learned what people hunted and ate and the experiences they had in obtaining food. Pictographs and petroglyphs were reminders of key events in a community's history, and only later were ideas and words expressed through symbols, such as hieroglyphics in Egypt, considered to have originated approximately 6000 BCE. Other forms of primitive writing have been found in ancient Crete and Central America. Cuneiform writing, made up of thin, wedge-shaped strokes impressed on clay tablets, some opportunely baked and preserved through intense destructive fires, were developed by the Sumerians around 4000 BCE. Much of these texts are limited to royal proclamations, store inventories, and business agreements, but some include references to the contemporary diet, the way foods were prepared and the diseases that occurred.

By the time we get to the glory of ancient Greece, writings evolved to a highly detailed record. The ancient Greeks and Romans also described food consumption habits and food poisoning. Hippocrates, Horace, and Ovid all wrote about the poisonous effects of certain plants, and history records the tragic destruction of Euripides' entire family by poisonous mushrooms.

The Greek, Theophrastus, made many references to poisons in his book on plants, and Xenophon stated that intentional poisoning was so common that tasters were employed to check foods before they were presented to royalty – a practice that continued for another two millennia! The Greek and Roman writers also went to lengths to describe the practice of food adulteration – a trend first started from the time that foods and food ingredients became items of trade.

During the medieval period, records show that accidental and intentional food poisonings along with food adulterations were commonplace. Diseased animals were slaughtered together with animals that had previously succumbed to disease. Many were treated with adulterants to hide any evidence of their poor quality, and one of the most popular uses of the newly imported spice, nutmeg, was to hide the smell and taste of spoiled meat. The taste of nutmeg became so common and so closely associated with meat that up until in the present day, it is the overriding spice used in modern hot dogs and sausages!

From the sixteenth century onward, the origin and basis of diseases slowly began to become established on a scientific basis. It was a slow process, and the annals of science are littered with the remains of quack disease theories and equally useless treatments that were proffered up until those that passed objective scientific scrutiny were eventually discovered.

Taken together, the physical and historical evidence tells us that foodborne disease has been a constant companion of mankind throughout history. Indeed, these diseases and the elements that cause them have been associated with some of the most dramatic episodes of history, even though the victims were totally unaware of their presence.

This article has been written in order to give readers an idea of the incredible impact that foodborne and waterborne diseases have had on human history. As it would be impossible to describe all major events, only those events, which have had a powerful impact on shaping our great ages, have been highlighted.

The Biblical Period

The Bible's first texts were documented in the tenth century BCE, including Genesis, although often referring back to events almost 1000 years earlier, with the remaining books of the Old Testament completed over the next 800 years. The Old Testament has several references to foods, their consumption, prohibitions, and the pathological conditions that could result from improper consumption. Based on descriptions in the Old Testament, the foods available to the ancient Hebrews were generally similar to that of the ancient Egyptians. The main differences in consumption patterns between the two peoples resulted from the strict prohibitions enshrined in the Jewish dietary laws.

It is interesting that the very first law quoted in the Bible is a dietary law,

Genesis:

> ***2:16-17:*** *God gave the man a commandment, saying, 'You may definitely eat from every tree of the garden. But from the Tree of Knowledge of good and evil, do not eat, for on the day you eat from it, you will definitely die.*

The reference to 'every tree of the garden' makes it appear that God initially intended its inhabitants to be vegetarians. This is further confirmed by a previous passage:

Genesis:

> ***1:29-30:*** *God said, 'Behold, I have given you every seedbearing plant on the face of the earth, and every tree that has seedbearing fruit. It shall be to you for food. For every beast of the field, every bird of the sky, and everything that walks the land, that has in it a living soul, all plant vegetation shall be food. It remained that way.*

However, after the world was apparently destroyed in the Flood, God permitted Noah and all his dependants to eat the meat of animals, under certain conditions, where Genesis 9:4 sets out the first stricture on blood consumption that served as the moral basis of the Jewish dietary laws.

Genesis:

> ***9:3-4:*** *Every moving thing that lives shall be to you as food. Like plant vegetation, I have now given you everything. But nevertheless, you may not eat flesh of a creature that is still alive.*

Leviticus, chapter 12, describes in great detail the animals that God permitted to be consumed. Chapter 15 of the same book illustrates the phenomenon of contamination and goes on to describe the necessity to clean and wash those who are ill. The purpose for the kosher laws was to aspire to holiness and perfection by emphasizing certain moral and ethical obligations – they had nothing to do with hygiene – nevertheless, the dietary laws also happened to make good sanitary sense, and the ancient Hebrews who strictly followed them generally suffered from fewer gastrointestinal diseases than their neighbors. Subsequent Halal dietary laws were very similar and served to protect Islamic followers in the very same way. Much of this information can be used as a basic guideline for hygienic practices in the present day. Note that in the Book of Acts Peter is advised to give up on these dietary laws and eaten anything not sacrificed to idols; this explains why most of the western world see little limit to food choices.

Within the Bible, however, a number of instances where foodborne and waterborne poisoning incidents occurred are depicted. Even though much of the text is allegorical in nature, both the circumstances and symptoms are described in sufficient detail to allow a credible disease diagnosis to be made. Even more important is the fact that identical poisonings have occurred in the same geographical region for millennia and still occur in the present day.

Quail Poisoning

One of the greatest epics narrated in the Bible is the Book of Exodus, the flight of the Hebrews from Egypt and their wanderings through the desert to Mount Sinai in the 'Promised Land'. The story is a genuine classic with as much drama as any modern adventure can have. It describes not only the trials and tribulations of Moses and the Hebrews but also illustrates the many weaknesses of human character that surface under conditions of stress. The book is full of heavenly miracles from the plagues to the dramatic parting of the Red Sea. The story holds such fascination for us that we continually attempt to provide rational explanations for all these miracles.

The Book of Numbers describes how God was infuriated with the wandering Hebrews' desire for meat and promised to punish their animal passions!

> ***11:31*** *G_d caused a wind to start blowing, sweeping quail up from the sea. They ran out of strength over the camp, and (were flying) only two cubits above the ground for the distance of a day's journey in each direction.*

> ***11:32*** *The people went about all that day, all night, and the entire next day, and gathered quail. Even those who got the least had gathered ten chomers (A chomer is a little over six bushels).*

> ***11:33*** *The meat was still between their teeth when (the people) began to die. G_d's anger was displayed against the people, and He struck them with an extremely severe plague.*

What a series of events! A miracle is created in order to bring the Israelites the meat they craved, but after they set on the quails to eat them, they begin to die immediately – *while the meat was still between their teeth!* What actually happened? Was it a mass food poisoning?

This could not have been a foodborne infection like our modern *Escherichia coli* O157:H7 or *Salmonella* poisoning. Pathogenic foodborne bacteria take anywhere from 8 to 24 h to develop an infection sufficient for symptoms to be noticed. In this case, however, death occurred while the meat was still between their teeth – during or immediately after eating. There was no time for any type of infection to develop! The only thing that can make people ill that quickly is a foodborne toxin. How could quails flying in from the sea contain enough toxins to kill people?

Quail hunting has been a common practice in the Mediterranean region from time immemorial. The European migratory quail (Latin: *Coturnix coturnix*) is found in Europe, Africa and as far to the east as Pakistan and India. These little birds carry out a migratory flight twice every year. From August to October, as winter approaches, the birds leave Europe and fly south across the Mediterranean Sea and North Africa, all the way to equatorial Africa. After they fatten up over the winter, they begin to migrate back northward from late winter through early spring. The quail breed in Europe from late spring through summer and then begin the cycle all over again.

The ancient Egyptians caught large numbers of quail when they landed after crossing the Mediterranean. Fishermen spread their nets out on the ground and quickly trapped them as they landed on the shore, before the exhausted birds had an opportunity to lift off again. This tradition, carried out for millennia, still goes on in the present day despite the fact that the occasional food poisoning occurs.

The first intensive study of the phenomenon was carried out by Dr. Edmond Sergent, the Director of the Pasteur Institute in Algeria. Using the considerable facilities of his Institute, Sergent carried out several experiments to determine the effect of feeding quail with the hemlock seeds his literature studies suggested. He observed that the birds did not suffer

from the paralysis that was so typical of hemlock poisoning. He then fed the same quail to dogs, which immediately exhibited hind leg paralysis, the classical symptom of hemlock poisoning. In Sergent's mind, this experiment categorically solved the mystery of how the Israelites had died from consuming the quails.

Since the time of the original publication, Sergent's work was questioned by several other scientists and physicians. Some say the work was not conclusive and may have been technically flawed. They feel that other toxic plants or insects consumed by the quail were the materials responsible for making the birds poisonous. Based on recent studies carried out in Greece and the Mediterranean islands, still others felt that the ancient Israelites may possibly have had a genetic predisposition that made them particularly sensitive to some other type of quail toxin.

Regardless of the type of toxin involved or the genetic predisposition of the Israelites, none of the scientists dispute that the story in the Bible is a vivid description of a mass food poisoning incident.

A Serpent Returns

At a later time during their long sojourn in the wilderness, the Israelites find yet another excuse to complain as recounted in Chapter 21 of the Book of Numbers.

Numbers

> ***21:5*** *And the people spake against G_d, and against Moses, Wherefore have ye brought us up out of Egypt to die in the wilderness? For there is no bread, neither is there any water; and our soul loatheth this light bread.*

> ***21:6*** *And the LORD sent fiery serpents among the people, and they bit the people; and much people of Israel died.*

> ***21:7*** *Therefore the people came to Moses, and said, We have sinned, for we have spoken against the LORD, and against thee; pray unto the LORD, that he take away the serpents from us. And Moses prayed for the people.*

> ***21:8*** *And the LORD said unto Moses, Make thee a fiery serpent, and set it upon a pole: and it shall come to pass, that every one that is bitten, when he looketh upon it, shall live.*

> ***21:9*** *And Moses made a serpent of brass, and put it upon a pole, and it came to pass, that if a serpent had bitten any man, when he beheld the serpent of brass, he lived.*

This story is unique not only because it describes the disease but the cure as well. What were the fiery serpents and how could a brass representation of a serpent on a pole manage to cure this dreadful affliction?

Many of the signs point to the drinking of water infected with *Dracunculus medinensis* as a valid explanation for the fiery serpents mentioned in the Bible. With limited water resources for drinking and bathing, infections with Guinea worms, which are endemic to the region, could easily occur. It does not take a great leap of imagination to equate the long, slim Guinea worm with a serpent as vividly described in Verse 6. Incredibly, Verses 8 and 9 describe the curing of the disease by setting the serpent on a pole – the very same cure recommended in the present day by the US Centers for Disease Control and Prevention (CDC), the world's most advanced center for disease control – and the cure that originated the symbol of the Staff of Asclepius (Figure 1) – the icon of modern medicine.

A particularly nasty example of a long, slim parasitic worm common to the Bible region is appropriately named *D. medinensis*, Latin for the Dragon of Medina, and commonly known in the present day as the Guinea worm. A female of the species can measure from 3 to 8 feet in length but is less than an eighth of an inch in diameter. Males are only an inch or so in length. People become infected with these worms by drinking water containing minute *Cyclops* water fleas, which have consumed the *Dracunculus* larvae.

People who are infected with *Dracunculus* experience great pain and often try to relieve the fiery, burning sensation by soaking the infected part of their body in a pond or well. This stimulates the female to emerge and expel hundreds of thousands of larvae into the water, where they are consumed by the *Cyclops* to start the entire cycle over. The life cycle of *Dracunculus* is shown in Figure 2.

This disease continues to exist in many parts of the tropical world (mainly Africa) in the present day, and there still is no cure. If you visit the website of the US Centers for Disease

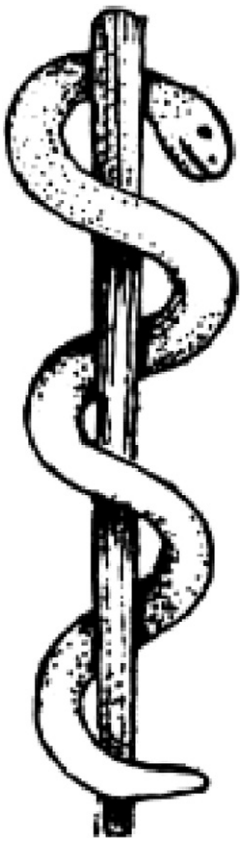

Figure 1 Staff of Asclepius.

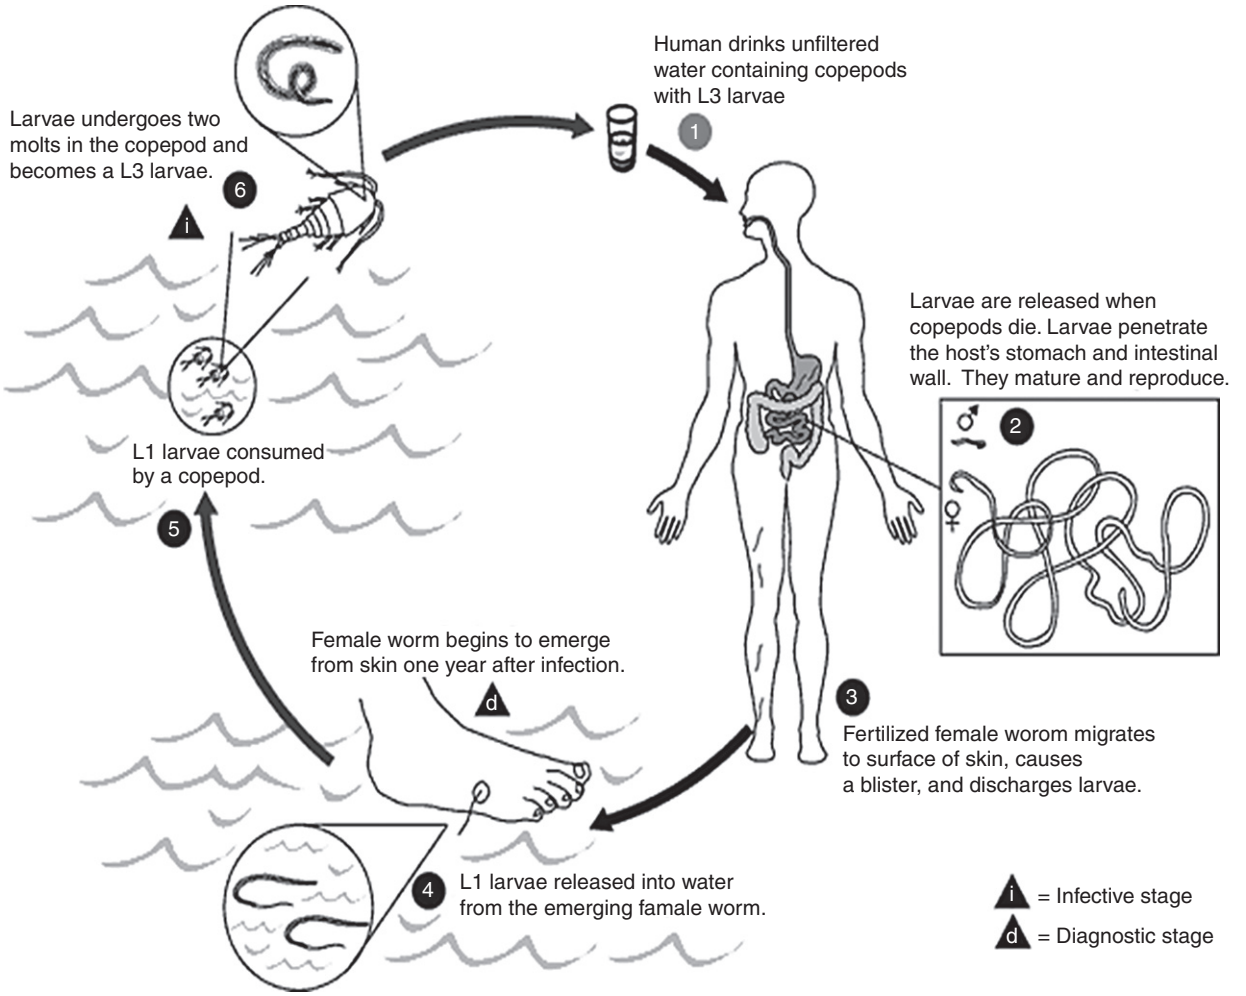

Figure 2 Life cycle of *Dracunculus*.

Control, you will find only a minor variation of the ancient treatment prescribed.

In this day and age, it seems an incredibly archaic remedy, but that is all that can be done. If the worm happens to break during the extraction, a severe secondary bacterial infection can occur. So, prevalent was the disease in ancient times, and so common the treatment that physicians advertised their services by displaying a sign with the worm on a stick or a serpent encircling a staff – a sign that eventually became the archetypal symbol of medicine.

Could the fiery dragons mentioned in Numbers be Guinea worms? We now know that the typical Guinea worm symptoms take many months to manifest themselves and deaths are rare with *D. medinensis*, but we also have a tendency to give the unnamed authors of the Biblical verses considerable poetic license. Let us leave the Dragon of Medina as a definite and very interesting possibility.

History of Foodborne Disease – Part II – The Greek and Roman Periods (1200 BCE–CE 500)

M Satin, Salt Institute, Alexandria, VA, USA

Glossary

St. Anthony's fire Gangrenous ergotism characterized by intense burning pain, followed by fingers, toes, or limbs.

Not-so-Funny Honey

In his chronicle The Anabasis, the Greek historian and army general Xenophon provided the Western world's first detailed eyewitness account of a great military campaign. He describes how, in 401 BCE, an army of 10 000 undisciplined Greek mercenaries traveled east to fight for Cyrus the Younger in the Persian prince's attempt to usurp the throne from his brother. The disastrous campaign ended in defeat, followed by a retreat characterized by the murder, rape, robbery, and enslavement of countless innocent villagers in the lands through which the Greek mercenary army passed.

The disheartened soldiers looted whatever they could from the local inhabitants, including food; honey in particular was considered a tasty prize. In the territory of Colchis, by the Black Sea, Xenophon's men raided the local supply of beehives. After gorging themselves on the honey, they became intoxicated and were seized with fits of vomiting and nausea. Xenophon finally caught a break because the pursuing Colchian army decided not to attack the mercenaries who were completely incapable of defending themselves. It took some days to recover, and the ragtag army moved westward as quickly as possible to get to more hospitable territory.

In 67 BCE, Rome, perceiving a threat to its territories, sent out the great general Pompey to conquer King Mithridates IV of Pontus. After a number of battles, Mithridates retreated until his army was forced to face off with the Romans near the city of Trabzon on the Black Sea coast of Turkey. Pompey, certain that Mithridates' retreat was chaotic and illogical, was totally unaware that it had been carefully planned.

All the forces were in honey country, and it did not take them long before Pompey's men plundered the regions' hives. After gorging themselves on honeycombs, the Roman army became intoxicated. This time, Mithridates did take advantage of the situation and massacred three squadrons of Pompey's troops while they were under the influence of the honey's toxins.

Despite this setback, Rome eventually gained full control of the area around the Black Sea but had never before come so close to 'sweet surrender.'

Back in Rome, the typical foods consumed were nearly all fresh, in-season, produce, stews or gruels, bread, and occasional meat. The facilities for saving food were limited to drying, smoking, pickling, or salting. The great expanse of the Roman Empire allowed it to import a wide variety of foods, spices, and herbs giving the population a taste for exotic dishes with highly flavored and spicy sauces. In high Roman society, feasts lasting many hours had many ready-to-eat delicacies, like dormice or lark's tongues prepared ahead of time, and probably many guests went home to suffer from some form of foodborne disease. It was the Greek and Roman bacchanalian love of food and particularly drink that served to initiate of the world's longest bout of chronic poisoning – one that plagued the Western world for 2 millennia.

Lead Adrift

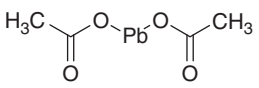
Of the seven famous metals of antiquity (gold, copper, silver, lead, tin, iron, and mercury), the ready availability of lead and the ease of casting it into useful products made it extremely widespread. Lead is normally found in nature as the lead sulfide ore called Galena, which was first used to make ornaments or as eye paint. Metallic lead is easily produced simply by heating Galena in a camp fire. By 3500 BCE, lead was used widely as a material for containers and lead pipes. The chemical symbol for lead is Pb from the Latin word plumbum, which also happens to be the root of the word for the tradesmen that worked with pipes – plumbers.

Most people believe that it was the lead pipes that carried their water supply that led to the downfall of the Roman Empire. Although there is no doubt that lead pipes slightly increased the risk of lead poisoning, pipes represented a relatively minor hazard to health. Both the Greeks and the

Romans discovered a more insidious application of lead that exposed them to a far greater risk.

They found that when they coated the interiors of their copper or bronze cooking pots with lead, many of the food and beverages they prepared tasted much better. Nowhere was this more evident than in the preparation of acidic products such as wines. Popular recipes of the day called for the boiling concentration of grape must in lead-lined vessels in order to prepare a liquid additive that enhanced the color, flavor, and shelf life of wine. The resultant thick, syrupy liquid was called 'sapa.'

When the must was boiled in lead vessels, there was a reaction between the acetic acid from the grape ferment and the lead of the pot to form a compound called lead acetate, also called 'lead sugar' because it is so sweet. This compound added just the right type of sweetness to bring out the best in wines and corrected many of the souring problems wine-makers routinely encountered. Sapa prepared using the ancient formulas contained between one-fourth and one gram of lead per liter! A single teaspoon of liquid sapa was more than enough to cause lead poisoning, but no one understood this at the time. In fact, because its effects were long term rather than immediate, the relationship between lead and disease were not well understood for another 2000 years!



Lead acetate

Hippocrates (460–377 BCE) was the first physician to link the excess consumption of food and wine with lead-based gout and Nicander of Colophon (197–130 BCE), a renowned botanist and physician of the time, wrote the first undisputed account of lead poisoning in the 2nd century BCE. He described symptoms of intense intestinal pains and tissue swelling. Several other ancient notables such as Pliny the Elder (CE 23–79) and Dioscorides (CE 40–90) specifically warned that the consumption sapa-corrected wine would result in severe nervous disorders but to no avail. The practice of consuming wine corrected with lead sugar continued unabated and was exacerbated by the consumption of several other foods that were sweetened with sapa.

This continual ingestion of lead by large segments of the population resulted in a series of epidemics throughout the Roman Empire. The average consumption of wine in ancient Rome was estimated to be more than a liter per day. The results were inevitable. A whole list of Roman Emperors was considered to be heavy drinkers and mentally disturbed enough to be considered as prime candidates for lead poisoning. For instance, Emperor Claudius limped, slurred his words, had fits, and slobbered. One publication goes so far as to suggest that more than two-thirds of the leading Roman aristocrats who served between CE 30 and 220 were most likely victims of lead poisoning. The disease eventually became endemic throughout most of Europe, particularly among the wealthy, who could afford to consume a good deal of sapa-corrected wine. When a rib bone of Pope Clement (who died in 1047) was analyzed, it revealed enough lead to conclude that he, too, had died of chronic lead poisoning.

During the course of these epidemics, chroniclers wrote of painful stomach colic, epilepsy, and paralysis as typical symptoms. The disease became variously known as the Huttenkatz of Germany (the foundry cat, because it tore at the entrails like a cat) and the Colic of Devonshire, however, the most common term used in the medical literature from the seventeenth century onward was the Colic of Poitou, so named in 1639 by Francois Citois, the personal physician of Cardinal Richelieu.

The disease proceeds when circulating lead ions are attracted and bound to the natural sulfhydryl groups that are common to most of our proteins. In the case of enzymes, this binding interferes with their normal action and results in a wide range of symptoms, the most important being those of the nervous system. Paralysis slowly develops with the greatest pain resulting from the inaction of the intestine causing cramps and constipation.

The first clues to uncovering the cause came in the German city of Ulm in 1694. Dr. Eberhard Gockel, a very astute observer, noted that monks who did not drink wine did not suffer from the colic, whereas those who did became sick. He spoke to a local manufacturer who described how the recent productions of wine were treated to overcome the sourness resulting from the past number of poor grape-growing years. Litharge or lead oxide was routinely added to the region's wines as a sweetening agent. Gockel successfully duplicated the process and was able to instantly turn an undrinkable acidic wine into the best of products. He deduced that the wine was the source of the colic problem and 2 years later published a medical paper describing the great harm that can befall anyone drinking 'corrected' wines.

Other physicians in the area confirmed Gockel's conclusions, and the matter came to the attention of Salomon Reisel, the personal physician of Duke Eberhard Ludwig. On 10 March 1696, the Duke issued an edict forbidding the adulteration of wine with litharge on pain of death – not only for the adulterators but also for anyone who knew of them but did not turn them in! A few years later Johanne Ehrni, a barrel maker from Eisslingen, was tried and convicted of the crime of adulterating wine with lead and publicly beheaded in Stuttgart!

In 1703, shortly after Gockel published his work on the colic of Poitou, a well-known British physician named Musgrave published a treatise on gout. It was Musgrave's contention that attacks of gout were precipitated by the colic. He was particularly concerned with the colic of Devonshire, the region that was well known for the conspicuous consumption of a rough and acidic cider and the region wherein the colic was endemic. He stressed that in those years when the apple harvests were small and manageable, the colic never appeared. However, he did not make the connection to the consumption of lead in the cider, even though his patients' symptoms were similar to the colic of Poitou.

John Huxham, a colleague of Musgrave's continued to work on the Devonshire colic and published a large essay on the subject in Latin in1739. Like Musgrave before him, Huxham did not associate the Devonshire colic with the colic of

Poitou, and hence the relationship to the consumption of lead was not made. Nothing further was done to mitigate the impact of the Devonshire colic until 1767, when Sir George Baker, the eminent court physician published a pamphlet warning his countrymen of the dangers of drinking the local cider. He kindly gave credit to the publications of Musgrave and Huxham but went on to say that he believed they missed the mark in discerning the cause of the disease. He stated that there was nothing wrong with pure cider, and that the cause of the colic was cider adulterated with lead.

Baker found out that the apple presses of Devonshire uniquely used lead sheeting as an inner lining to prevent leaking. Further, analytical experiments proved that cider from Devonshire was heavily contaminated with lead, whereas those from the other counties were not. The centuries old endemic colic of Devonshire was finally over.

Middle Ages (CE 500–1500)

The period of time between the fall of the Roman Empire and the middle of the fifteenth century is commonly referred to as the Middle Ages. The established society went through changes in law, culture, religion, and patterns of property ownership. The rule of Roman law (Pax Romana) with its guaranteed benefits was replaced by the rule of local warlords and kings, resulting in a dramatic change in the economic and social norms and infrastructure. This evolved to a feudal system wherein the overlord (usually a King), awarded land grants or 'fiefs' to his most important cronies, and the prelates of his church. At the bottom of society's ladder were the peasants or serfs who worked the lord's land, in exchange for his protection.

St. Anthony's Fire

Most people have never heard of ergotism, much less the mold that causes it, *Claviceps purpurea*. This fungus starts life out as a small, black rind-covered tube called a sclerotium. Barely, more than half an inch long and an eighth of an inch wide, this harmless looking tube is easily mistaken for a broken piece of stock and would likely go totally unnoticed lying on the winter ground. Within its thick walls, a compact mass of mycelium lies dormant awaiting the proper time to awake.

With the arrival of spring, the sclerotium awakes and sprouts a dozen or more stocks that looked like many tiny Enoki mushrooms. The heads of these stocks produce and discharge spores that are light enough to be carried by the passing winds. If these settle on cereals, they quickly colonize them and produce a new sclerotium at every infection site.

The word ergot is derived from the French for a rooster's spur on its foot, which the sclerotia resemble.

The cereals that are most commonly affected are wheat, barley, rye, and oats – all common staples of the Western diet. As can be seen from the illustration, it is quite easy for the sclerotium to be harvested along with the rest of the grain. According to agricultural records, in cold, damp periods, as much as a quarter of the harvest could be ergot sclerotia!

Manually culling out these contaminants is a very time-consuming job, and it is not surprising that a considerable amount of ergot eventually become mixed in with the rest of the cereal grains. What makes matters worse is that the *Claviceps* continues to thrive if the moisture content exceeds 14% – a situation not uncommon in grain storage. Once it is all removed from storage and milled into flour, it is very difficult to tell that a product is toxic. Aside from some very slight discoloration, ergot-contaminated flour looks exactly like normal flour.

Ergot toxins are alkaloids (nitrogenous plant chemicals) that have profound effects on the central nervous system. Many of them are very powerful hallucinogens, including lysergic acid diethylamide (more commonly known as LSD). Aside from hallucinations, these toxins can severely contract arteries (vasoconstrictor) and smooth muscles, causing numbness, extreme sensitivity, and irritability.

Ergotism manifests itself in two distinct ways. The first is called gangrenous ergotism, whereas the second is known as convulsive ergotism. Sometimes, both conditions can be found in the same incident.

Historically, gangrenous ergotism is more prominent, having been responsible for the infamous affliction, St. Anthony's fire. In this terrible manifestation of ergot-induced vasoconstriction, the limbs and their extremities (fingers and toes) becomes swollen and highly inflamed. Victims experience sensations of extreme heat (the 'holy fire'). Within a few weeks, gangrene sets in and the fingers, toes, or limbs become necrotic and fall off. As can be imagined, this whole process was agonizingly painful because the limbs felt like they were consumed by fire.

Ergotism has been a regular curse to rye- and other grain-eating populations for millennia. It was first described in an Assyrian tablet as a 'noxious pustule in the ear of grain.' The ancient Egyptians were aware of a disease caused by eating certain grains that produced both convulsions and hallucinations.

The first large European ergot epidemic appeared in the eleventh century and was christened ignis sacer (Latin for holy fire). Although less common in England than the rest of Europe, a number of major outbreaks of ergotism were recorded in 1762 and 1734. In Russia, ergotism was a major health hazard particularly in times of famine when little choice was left but to consume even-blighted grain.

Out of desperation, victims prayed to their various Saints for relief. One of the most popular Saints to appeal to was St. Anthony whose remains were interred in the Church of La Motte near Vienne, France. In 1089, there was a terrible plague of ergotism in the town of La Motte. A nobleman and his son were among those stricken but in time were miraculously cured by what they believed were the magical powers of the ancient relics of St. Anthony housed in their local church. The nobleman, Gaston, and his son, Girond, soon pledged themselves and their estate to establish a hospital near the Church. Since that time, gangrenous ergotism, previously called the holy fire, became commonly known as St. Anthony's fire.

More than 100 major outbreaks of St. Anthony's fire have been reported with as many as 40 000 deaths attributed to a single incident that occurred in the year 944 in France. Despite our knowledge of the disease and the toxins that cause it, outbreaks continue to occur in recent history; in

the twentieth century, at least four major outbreaks occurred (Soviet Union, 1926; Ireland, 1929; France, 1951; and Ethiopia, 1978).

History of Foodborne Disease – Part III – The Renaissance and the Enlightenment (CE 1300–1750)

M Satin, Salt Institute, Alexandria, VA, USA

Glossary

Alimentary toxic aleukia High mortality intoxication characterized by massive immune deficiency, ulceration of the digestive tract, and pulmonary hemorrhaging.

The Constant Menace of Mold

During this period, grains supplied the basic carbohydrate calories and legumes (peas and beans) provided the complementary proteins required to sustain life. The two technological developments that allowed these commodities to be produced in large quantities to support the growth and development of a prosperous Europe were the moldboard plow and a new system of crop rotation, which significantly boosted agricultural output.

Unfortunately, this population explosion was cut short in the early fourteenth century as a result of several disastrous events. Political instability led to a European-wide recession toward the end of the thirteenth century. This was quickly followed by the onset of sustained poor climatic conditions in the opening years of the fourteenth century. Cold, damp weather dramatically reduced the yields of grain and initiated a series of calamitous famines from 1315 to 1317, which ravaged all of Europe.

The wet spring of 1315 saturated the soil, making it impossible to plow the fields that were ready for cultivation. To make matters worse, the heavy rains rotted a large portion of the seeding grains before they could germinate properly. Throughout the spring and summer, the rains continued and the temperature remained cool. Not surprisingly, the annual harvest was much smaller than usual, resulting in a rapid depletion of the very meager food reserves kept by most families.

To survive, peasants gathered whatever forest food they could find; roots, mushrooms, ground plants, grass, nuts, and even bark to supplement their meager and moldy grain supplies. Ravaged by malnutrition, the rural populations, who did almost all the work, were severely weakened. The following spring and summer of 1316 were once again cold and wet. Peasant workers, depleted of the sheer physical energy needed to till the heavy, wet soil, went through their food supplies to a point where it could no longer sustain them until the next harvest.

It has been estimated that more than 10% of the population perished during these famines. This was soon followed by the bubonic plague or Black Death, which broke out in 1347. Within 90 years, from 1340 to 1450, the population of Europe decreased by 30%.

Professor Mary Kilborne Matossian has constructed a well-documented and plausible theory that mold poisoning played a critical role in repressing population growth in England (and perhaps elsewhere in Europe) between the sixteenth and nineteenth centuries. Basing her research on factors such as population figures, child mortality, and fever epidemic, she convincingly argues that ergotism and alimentary toxic aleukia (ATA) were critical factors in child mortality and the consequent reduction in European population growth with all its consequent social impacts.

Another fungal contaminant of grain is the *Fusarium* mold, a filamentous fungi that is widely distributed in soil and closely associated with plants. Like *Claviceps*, *Fusarium* has a long and prominent place in the history of European morbidity and mortality. *Fusarium* species are responsible for blights, root rots, and cankers in legumes, grains, and grasses.

The role of fusaria as a potent producer of mycotoxins remained unsuspected until the 1970s. Since that time, however, research has firmly established its role in major episodes of human mycotoxicosis. Its prominent position in the fungal Rogue's Gallery is a result of the three different kinds of toxins it produces.

The first toxin, zearalenone, is a chemical that causes severe deformations to reproductive organs by imitating the estrogen hormone. Another toxin, fumonisin, can cause severe and irreversible damage to organs and has been implicated in esophageal cancer. Undoubtedly, the most deadly toxins produced by *Fusarium* mold are called trichothecenes, with one of them dubbed T-2, the most notorious of all.

If consumed by humans, the T-2 toxin can result in a condition first described by the Russians in 1943 as ATA. When infected by *Fusarium*, a wide range of grains including rice, rye, wheat, barley, corn, and millet can produce T-2 toxins capable of causing ATA. An epidemic in the Union of Soviet Socialist Republics (USSR) killed an estimated 100 000 people

between 1942 and 1948. It is now known that ATA also occurred in Russia in 1932 and before that in 1913, and there is little doubt that outbreaks occurred in earlier years as well.

The pathological course of ATA development in humans is both strange and terrible. When infected grain is consumed, victims first experience headache, vomiting, throat inflammation, and gastroenteritis. Then, the symptoms subside even if contaminated grain continues to be a part of the diet.

But the T-2 toxin acts like a time bomb. Victims can continue consuming infected grains without noticing overt symptoms for anywhere from 2 weeks to 2 months – all during that time, the T-2 toxins continue to exert their effects. The T-2 toxin kills bone marrow stem cells causing the destruction and shrinkage of bone marrow. The end result is a massive immune deficiency characterized by considerable ulceration of the digestive tract, as well as pulmonary hemorrhages. Once diagnosed, the body has suffered too much damage to be able to fight back. Mortality rates from ATA are very high.

During World War II, tens of thousands of Russians, most located in the Orenburg district, close to the Caspian sea, perished from ATA because they were forced to consume grain infected with *Fusarium* mold. Recently, in the Zhejiang Province of China, a small epidemic broke out after people ate rice contaminated with *Fusarium* toxins. As in all the outbreaks, it was rainy weather and poor storage conditions that led to the *Fusarium* contamination.

Silent, unobtrusive, and seldom the focus of our thoughts, the lowly fungus among us has had a far greater impact on our history and social evolution than most of our most famous historical figures and events.

Royal Parasites

Louis XIV (the Sun King) ruled France for 72 years (1643–1715) – longer than any other major European monarch. To get away from the swarm of courtiers and advisors at Versailles, he built a country retreat called Marly-le-Roi. The French Revolution destroyed Marly-le-Roi so completely that nothing remains to be seen. Recent archeological excavations managed to discover the site of Marly-le-Roi's latrines, originally constructed in 1680 and used until Louis XIV death in 1715. The unique construction of the latrines did not allow contamination from other sources, and so any parasite remains found in the sediments are specifically associated with the excrement of the King and his courtiers.

Parasitology researchers from the Faculty of Medicine at Reims, together with a team of experts from France's National Center for Scientific Research, investigated the remnants in Marly-le-Roi's latrines and their meticulous analyses provided an excellent insight into the parasitic diseases that the Sun King and his courtiers suffered from.

The two types of parasite eggs that were found to be most prevalent were the roundworms *Ascaris* and *Trichuris*, species that continue to be a problem in the present day. *Ascaris* is a large roundworm found in humans, pigs, and some other animals. They normally range from 6 to 12 in. in length and are usually approximately quarter inch in diameter. The spread of *Ascaris* is through the ingestion of their tiny eggs. Female *Ascaris* worms may contain as many as 25 000 000 eggs at any time and can eliminate as many as 200 000 per day into the host's intestine. The eggs are then spread in human and animal waste.

Trichuris trichiura (human whipworm), a roundworm that is fairly common in Europe, is notable for its small size compared to *Ascaris lumbricoides*. The worm derives its name from its characteristic whip-like shape, with adults reaching a length 1.5–2 in. The *Trichuris* buries its thin front end into the intestinal mucosa and feeds on tissue secretions, not blood. This worm does not migrate through the tissues like the *Ascaris* and therefore does not cause as much damage although heavy infections can result in similar symptoms.

Trichuris is found in other animals, which can serve as alternate sources of infection. The use of unsterilized 'night soil,' which contains both types of parasite eggs, as a fertilizer, is a definite cause of reinfection and the reason why this parasite is found on fresh vegetables. Humans are infected with this type of produce if it is consumed raw.

In addition to *Ascaris* and *Trichuris*, researchers found encapsulated tapeworm embryos but were unable to differentiate between beef- and pork-derived varieties (*Taenia saginata* and *Taenia solium*). Humans are usually infected by ingestion of undercooked or raw meat. The symptoms of infection with beef tapeworms (*T. saginata*) are variable. Many infections are completely asymptomatic, but in other cases they can be serious as a result of intestinal blockage.

Pork tapeworm (*T. solium)* infections are more problematic. The embryos hatch in the intestine and bore their way into the tissues to form cysts known as cysticerci. This cysticercosis state is the most dangerous form of tapeworm disease because of the tissues the larva invades and damages. The hatched tapeworm embryos burrow their way to the eyes, lung, liver, heart, and brain of the victim, wreaking inflammatory havoc and infection all along the way. The most serious form of this disease experienced is cerebral (neurocysticercosis), which often leads to epilepsy and death. The annual worldwide cysticercosis mortality has been estimated at approximately 50 000 cases.

Another parasite found, which infested the King's court was *Fasciola hepatica*, the liver fluke, most probably the result of consuming fresh watercress and dandelion greens. Adult parasites have a flat leaf-like body that is about 1 in. long and a 0.5 in. wide. After ingestion the cysts hatch in the small intestine and release the young parasite. They then penetrate the gut wall entering the peritoneal cavity. The *F. hepatica* then migrates directly to the liver where they penetrate and damage the tissue. The infection is rarely fatal and causes fairly nonspecific symptoms including an intermittent fever, mild jaundice, and in some cases anemia.

Fresh vegetables were the privilege of the wealthy and were very rarely consumed by the common people. The presence of *Ascaris*, *Trichuris,* and *Fasciola* are strong indicators of poor hygiene during the preparation of the fine vegetables and salads, not particularly surprising because the knowledge transmission of pathogenic organisms was very limited. Interestingly, human fascioliasis is a serious health problem in the present day in many countries and is acquired in the present day mostly by eating watercress, other vegetables, or by drinking water contaminated with metacercariae. The presence of *Taenia* cysts confirms the contamination of meat and consumption in an

uncooked or almost raw state. Poor people did not suffer in the same way because they had so little meat that it was usually boiled in a soup with coarse grains and starchy vegetables. As a result, the royal court and aristocracy were far more prone to chronic parasitic infections than the poor.

Part V: The Industrial Revolution (CE 1750–1900)

The Perils of Discovery

The beginning of the industrial revolution was characterized by the development of mechanized agriculture, which drove many rural laborers off the farm and into the squalid workhouses of the cities. The increased demand for food to feed urban workers and for raw materials to keep the factories running resulted in a total realignment of production and trade patterns. In particular, the concentration of agricultural production, processing, and trade migrated into the hands of fewer and larger enterprises. This established the conditions for the mass food poisonings that were to be regularly experienced over the next centuries.

The increasing demand for foods that would not readily spoil prompted the development of new processing technologies such as canning that remain in use in the present day. Initial efforts to preserve foods were accompanied by a great deal of food poisoning simply because no one understood the mechanism behind successful preservation. It was only in the last half of the nineteenth century that the scientific basis for food and beverage spoilage became understood, largely because of the work of Louis Pasteur. This knowledge quickly ushered in an era of understanding that led to new technologies that revolutionized food production and processing in the twentieth century.

Perhaps the most significant development in the history of food preservation was the process of canning. By the middle of the eighteenth century, it was generally accepted that it was possible to slow down the spoilage of certain foods through the use of heat. Unfortunately, no one had any idea why heat worked so well because the concept of microbial spoilage still remained undiscovered.

Toward the end of the eighteenth century, Napoleonic France was the powerhouse of Europe. The Society for the Encouragement of National Industry (Société d'Encouragement pour l'Industrie Nationale) was extremely influential in fostering practical developmental research and encouraged the public to submit their ideas and discoveries. They made sure to reserve a prominent place for deserving entries in their famous 'Bulletin.' This not only ensured the rapid dissemination of new ideas and information but also solicited an increasing input of more sophisticated experimental work.

Nicholas Appert (1749–1841), a Parisian confectioner, had developed a method to conserve certain foods in the 1790s. By the turn of the century, he had an operational factory at Massy (Seine-et-Oise) that employed 50 people. It was the world's first canning plant, but it did not use tin cans – it used glass bottles instead.

Using this technique, he produced the world's first canned foods and had even sent them around the world with the French Navy in 1806. His results were so impressive that the Société nominated a Special Committee just to review his process and products. This blue ribbon Committee passed Appert's work and products with flying colors, their only reservation being that glass containers might not be practical because they were so easily broken. Appert, however, insisted that glass was the purest material he could use. He was rewarded a prize of 12 000 Fr and asked to publish his work. In 1810, his now famous classic *Le Livre de tous les Ménages ou l'Art de Conserve pendant Plusiers Années Toutes les Substances Animales et Végétales* (The Art of Preserving All Kinds of Animals and Vegetable Substances for Several Years) was published.

In 1818, the French competition for food conservation by the Appert method sponsored by Ministry of the Interior's Board of Arts and Manufactures only allowed for products in metal containers ushering in the true age of canning.

Canned foods were a great boon to the increasingly prolonged voyages that were made to explore the vast reaches of the globe. The first of the Arctic explorers to bring canned goods along with him in 1815 was the Russian, Otto von Kotzebue who felt the new products 'too important not to be made use of for the expedition'. In 1818, the English company of Donkin, Hall, and Gamble supplied the British Admiralty with close to 30 000 cans of various meat, vegetable, and soup products and went on to supply Sir William Parry's famous voyage to discover the Northwest Passage in 1819.

Stephan Goldner was a businessman who set up canning factories near London and in Galatz (Moldavia, Romania) offering a great variety of canned foods including milk, soups, turtle meat, carrots, ox tongues, and several others. He claimed to be able to supply canisters ranging in size from 1 to 500 lbs each. (A 500 lb canister would be equivalent to a 60 gallon drum!)

The British Empire was at the zenith of its power and regularly demonstrated this in the arts, sciences, engineering, military, and commercial trade. The indomitable Navy wanted to discover a Northwest Passage from the Atlantic to the Pacific and sent out expeditions to achieve that goal. In 1819–20, Sir Edward Parry sailed further west than anyone had previously and further than anyone else would for the remainder of the century. At the same time, the British Admiralty sent John Franklin overland from Hudson Bay to the mouth of the Coppermine river on the Arctic ocean where he was to link up with Parry and then proceed together to Alaska. This did not work as planned, but Franklin did map a significant portion of Arctic coastline. Franklin ventured again to the Arctic in 1825 and carefully mapped a significant amount of territory and was knighted for his efforts in 1829.

Once again, in 1845, Sir John Franklin accepted the Admiralty's invitation to lead a new expedition to discover a Northwest Passage. No expense was spared, and by this time, canned foods had proven to be products that were highly acceptable to all mariners. Goldner's company obtained a major order to supply the canned foods for the Franklin expedition, but within 2 weeks of the expedition's departure had only supplied 10% of the contracted amount. Under tremendous pressure, Goldner promised that all the canned meat and soup would be ready on time. More importantly, he asked to be allowed to supply the soup in larger canisters than originally agreed and received approval. Two days before departure the products finally arrived.

On 19 May 1845, outfitted with 5 years of supply of food provisions, Franklin triumphantly sailed down the Thames river as head of the biggest, best-equipped, and most costly naval expedition ever mounted. Two months later, British whalers in the seas north of Baffin Island sighted the expedition ships. Neither other sighting was ever made nor a word heard from the expedition – a crushing blow to the Empire.

Because of the high number of faulty cans and spoiled products he delivered to the Navy, Goldner was refused further orders in 1849. A year later, the first traces of the Franklin expedition were found on Devon Island. Three graves were discovered lying in the shallow permafrost on nearby Beechey island together with stacks of abandoned tinned foods. Analysis carried out showed that the cans contained spoiled meat indicating that the expedition's supply of provisions had been critically compromised.

Several attempts were made to find the remains of the expedition without any success.

Charges were leveled at Goldner for selling the Navy substandard products making it clear that a major factor contributing to the demise of the expedition was the state of the canned provisions. Not only was a large proportion of their food supply unavailable but also it was possible that the limited consumption of the products resulted in widespread food poisoning.

It has been speculated that the cans were contaminated with botulism, which resulted in the ultimate demise of the expedition, but this premise, while theoretically possible, is unlikely.

Botulism poisoning symptoms usually begin to appear from 12 to 36 h after eating contaminated foods. The descending paralysis begins with blurred vision and dizziness, followed by difficulty in swallowing and speaking. The muscles experience weakness and breathing becomes difficult because the diaphragm can no longer compel the lungs to fill with air. Once this happens, death proceeds quickly.

Because they were considered to be superior to other provisions, canned products would have been consumed throughout the voyage from England to the Arctic. If that was the case, there should have been some record or note describing the death of sailors or officers during the first leg of the voyage. No evidence of any kind indicates that this occurred.

Finally, death from botulism is a rapid and dramatic process that can affect a great many people because of the potency of the toxin. Until the expedition unloaded their store of canned goods on Beechey Island, the only indication was that of a very limited number of deaths – certainly nothing compared to what one might expect from a large crew suffering from a botulism outbreak.

More than a century later, in 1981, Owen Beattie, an anthropologist at the University of Alberta, Edmonton, AB, Canada, found the skull and bones of two expedition crewmen and analyzed them. The results showed very high levels of lead. Three years later, he collected additional material for analysis from the body of the crewmen that had been well preserved in the permafrost. The hair samples (which can provide an excellent indication of what was consumed during the previous few months) showed lead levels that were 120 times above the normal.

Beattie also examined the tin cans that were found on Beechey Island. He noticed that the inside seams had large gobs of solder protruding – an indication of sloppy construction. The solder originally used to seal can seams contained more than 50% of lead. When the food made intimate contact with lead, the possibility of lead contamination increased. This increase would be dramatic if the food was acidic enough to actively leach the lead out of the solder – a common occurrence in spoiled products.

Heavy metal poisoning, such as that from lead, routinely result in symptoms of mental instability and lead to lapses in judgment (the former Roman Emperors being an example). Beattie's analysis showed that the lead solder in the cans and the lead content of the hair samples were the very same isotope – convincing proof that the lead poisoning the men suffered from came from the cans made by Goldner.

Although many factors played a hand in challenges faced by the Franklin expedition, there can be little doubt that food poisoning and canned products contributed a large part to the ultimate disaster of one of history's great expeditions.

Glossary

Methylmercury Highly toxic organic form of mercury that causes irreversible damage to nerve cells resulting in overwhelming neurological damage.

Based on the knowledge of food and beverage spoilage gained in the latter half of the nineteenth century, an explosion of technological improvements set the stage for a revolution in the production and processing that redefined the foods we eat and the manner in which we consume them. The twentieth century started with the average consumer eating home-cooked fresh foods that relied heavily on locally available products such as meat, potatoes, dairy, and seasonable vegetables. Rapid advances in food preservation technology made a wide variety of foods much more convenient and available throughout the year. Consumer acceptance of these products allowed very large quantities to be processed during a single growing season, which, in turn, encouraged mass production of agricultural products because of the obvious economies of scale. Likewise, the marketing of foods was carried out in much larger retail outlets that offered consumers convenience because of the great variety of goods one could buy at a single location.

By processing more and more foods and beverages in large production facilities, products became cheaper and more convenient. As processed foods proliferated, home cooking declined. The responsibility for safe foods passed from the homemaker to the commercial processor. Because of the shameful and corrupt behavior of several companies, new food safety legislation was promulgated and mechanisms were developed to enforce the new laws. Although this was a great leap forward, major scandals continued to occur.

Mercury in Minamata

One of the most touching images seen appeared as the 'Picture of the Week' in the 2 June 1972 edition of *Life* magazine. The black-and-white image by renowned photographer Eugene W. Smith portrays a mother holding up her daughter in a traditional Japanese chamber bath. The caption on the photograph reads:

> This is Tomoko Uemura. She was maimed by mercury poisoning in her mother's womb. Blind, speechless, crippled and deformed since birth, she must be bathed, fed and cared for like an infant. She is now 17.

The story of Tomoko Uemura is a tale of shame and disgrace. It involves the unconscionable behavior of a giant Japanese chemical corporation, the complicity of an uncaring government and an indifferent public that simply decided to look the other way.

The story unfolded in the tiny fishing village of Minamata on the western coast of southern Kyushu Island. Minamata Bay was blessed with a natural reef and the traditional village economy was based on fishing. At the start of twentieth century, the company Nippon Chisso (Japan Nitrogen) located a chemical factory to produce fertilizer there. In 1930s, the company perfected a process to make acetaldehyde by passing acetylene over a mercury sulfate catalyst. As the markets grew, so did Chisso and Minamata evolved from a quiet fishing village to an industrial city.

In Chisso's acetaldehyde process, a small amount of methylmercury is formed, and as this and other organic mercury compounds had no value to the company, they were dumped together with the rest of Chisso's waste products into the once pristine Minamata Bay.

During the Second World War, Chisso greatly prospered because it was a major supplier of strategic chemicals to the government. Unfortunately, Minimata Bay's stock of fish and shellfish dwindled dramatically making life very difficult for the local fishermen who felt that Chisso's practice of dumping its wastes into Minamata Bay was responsible. The local fishermen went to Chisso asking for compensation and were given a pitiful one-time payment on the condition that no other demands would ever be made in future.

At the close of the War, Chisso lost all its offshore assets but made an incredible comeback because it produced the fertilizer required for Japan's massive agricultural efforts to produce food. Right after it started up fertilizer production, it went back into the acetaldehyde. As Chisso grew, so did its toxic effluents, which it continued to dump into Minamata Bay

without any treatment. By the mid-1950s, schools of dead or dying fish could be seen floating on the Bay's surface. The reduced harvest impoverished the fishermen forcing them to eat more of the very products they caught. Out of desperation, they went back to Chisso asking for some type of compensation. The company, not wanting to incur any publicity, offered another pittance on condition that the fishermen promised to cease all further claims.

But Minamata's inhabitants began to notice a strange occurrence. Cats would get into a frenzied state and start dancing and jumping awkwardly toward the Bay where they threw themselves in and drowned. Although they were dubbed 'dancing suicide cats,' no one laughed because people felt it was a premonition of bad things to come.

In May 1956, Minamata City Hospital (owned by Chisso) admitted four patients exhibiting convulsions, agitated mental states, lapses into unconsciousness, coma, and death. The hospital's director, Dr. Hosokawa did a quick survey of the other medical facilities in the vicinity of the Bay and found 17 more fatalities, which had exhibited the same symptoms. The local medical community felt this was not a new disease but one that had been going on for some time. Hosokawa began a record of it and asked Kumamoto University in Kyushu to investigate. They very quickly came to the conclusion that the fish and shellfish in Minamata Bay were poisonous.

It was obvious to everyone – Chisso was poisoning the Bay with its industrial wastes, but how could anyone say anything against the chemical colossus that was the city's economic base? So, no one did. Kumamoto's medical research group determined that organic mercury in the waste stream was the primary cause of the disease, but Chisso quickly denied everything and severely criticized the quality of the University's research.

Some fishermen were so incensed, they broke into Chisso's facilities and destroyed a few pieces of office equipment. This type of behavior was unprecedented in Japan, and Chisso immediately brought in the police. For the first time the tragedy came to the country's attention, a full 4 years after the initial cases were admitted to Hospital.

The fishermen received very little sympathy from the public and even less from the government. No one had the right to criticize an industrial giant that played a critical role in Japan's new economy. Such things were unheard of and everyone immediately went into a form of denial speculating on all sorts of other causes that might be responsible for Minamata disease.

Dr. Hosokawa soon proved beyond doubt that Chisso's effluent was the singular cause of Minamata disease but as the Director of the Minamata Hospital, he was also the Chisso company doctor. When he presented his results to company executives, they instructed him to immediately stop all research and ordered him hide all information. As he was an employee in the old tradition, Hosokawa bowed his head and sealed his lips until his deathbed.

By October 1959, Chisso did not doubt its responsibility for the sickness and death of so many of the area's inhabitants and the collapse of the local fisheries, but this did not stop them from continuing to dump their toxic wastes as always.

Although metallic mercury (unless vaporized) and inorganic mercury salts have fairly low toxicities, organic mercury compounds are extremely dangerous. They are readily absorbed into the body and can easily cross the blood–brain and placental barriers. These two body mechanisms evolved to prevent toxins from entering our nervous systems and to protect a growing fetus. Unfortunately, methylmercury combines with one amino acid (cysteine) and tricks these defense mechanisms into thinking it is another amino acid (methionine). Once it crosses these defensive barriers, it is in the brain and central nervous system where methylmercury does its greatest damage through the destruction of nerve cells, resulting in devastating neurological problems.

In the fetus, methylmercury interferes with nerve cell development by binding to DNA. It also interferes with normal brain development. Exposure while in the womb can result in small misshapen heads, mental retardation, cerebral palsy, blindness, deafness, and seizures. As in the case of Tomoko, children can be born to mothers who exhibited no symptoms of methylmercury poisoning at all during pregnancy.

Methylmercury bioaccumulates as it moves up the food chain so that the levels in animals and people can be several million times higher than in the waters that the consumed fish were taken from. Like the rest of Japan, the diet of the people in Minamata depended largely on fish and shellfish for protein. The levels of mercury in their bodies climbed steadily because they had no other options but to eat the fish from the Bay.

So many people were affected and so many babies were born disabled that by the end of 1959, the Governor of the Prefecture had no choice but to intervene and ordered Chisso to pay out ¥100 million to the fishermen's associations. It sounds like a lot of money, but it was only $28 000 in 1959 rates. The Minamata Disease Association paid $830 for each confirmed death and $280 for survivors, regardless of how grievous their symptoms were.

Chisso insisted that their payments in no way reflected any responsibility on their part and added a clause prohibiting any further claims against the company. If anyone else got ill, the government would have to compensate them. In the meantime, Chisso's toxic effluent continued to pour into the Bay and surrounding waters.

Kumamoto University continued to study the subject and in 1962 demonstrated publicly that methylmercury was produced as a result of Chisso's acetaldehyde process – a fact that was long known by the company but kept secret. As soon as Kumamoto's results were made public, Chisso immediately objected and claimed that the university's research was bogus. Chisso managed to keep a lid on things until 1965 when a rash of new cases was reported in Niigata City, far from Minamata. Kumamoto University researchers quickly found the problem to be the toxic waste discharge from another acetaldehyde plant owned by the Showa Denko Company. As with Chisso, Showa Denko denied all responsibility.

In 1968, a dozen years after it was first uncovered, the Japanese government finally gave recognition to the direct relationship between methylmercury in the toxic waste streams and Minamata disease. After protracted negotiations,

the victims received a more reasonable compensation package, most paid by the government, not Chisso. The *Japan Times* recently reported on government plans to financially assist 3000 Minamata disease victims of the 1950s and 1960s. This decision was finally made in April 2005, 50 years after the first victims entered Minamata City Hospital.

On his deathbed, Dr. Hosokawa testified that all his research proving the link between methylmercury and Minamata disease was kept secret or destroyed by the Chisso Corporation. Tomoko Uemura died in 1977, 5 years after Eugene Smith produced the stunning image that is considered to be one of the 100 most influential photos ever taken.

Tainted Oil in Spain

On 1 May 1981, an 8-year-old boy, Jaime Vaquero Garcia, died on the way to Madrid's La Paz children's hospital. Soon afterward five of Jaime's brothers and sisters were examined at the same hospital and found to be very ill. They were initially diagnosed as having atypical pneumonia. The doctors immediately put one of the girls into intensive care and the other four children were transferred to the Hospital del Rey, Madrid's well-known institution for infectious diseases. Within days, the number of patients admitted to hospitals all over Madrid began to rise meteorically!

Because of the victims' symptoms, the hunt for some type of infectious agent was immediately commenced. The acute phase of the disease was characterized by noncardiogenic pulmonary edema with headaches, asthenia, itchy scalp, rash, abdominal pain, and fever. Severe muscle pain and cramps marked the end of the acute phase. After the first 2 months, patients began an intermediate phase, which seemed to last another 2 months. The clinical features of this phase were characterized by abnormalities of the sensory nervous system and intense muscle pain. Other findings were difficulty in swallowing, pulmonary hypertension, deposition of blood clots in the large vessels, marked weight loss, increased levels of peripheral blood eosinophils, and elevated triglycerides/cholesterol were also observed.

Almost 60% of the patients went on to a chronic phase with pathological thickening and hardening of the skin, motor and sensory nerve degeneration, carpal tunnel syndrome, and muscle pain and cramps. Problems such as memory loss and depression were also reported during the chronic phases.

A pediatrician at the Hospital Infantil de Niño Jesus, soon informed the government that he had finally determined the cause of the epidemic. He had investigated 210 of the children under his care and found that all had consumed cooking oil. This study established that consumption of oil sold in unlabeled 5-l plastic containers as the risk factor for developing this epidemic syndrome.

Following this finding, oils were collected from affected households and open-air markets and analyzed by the government laboratory. It was found to be rapeseed oil rather than the olive oil, the poor people who bought it thought it was.

Traditional rapeseed oil contains high levels of erucic acid, which has been linked to the formation of fatty deposits in heart muscle and the consequent negative cardiac events. It also contains high levels of glucosinolates, which are toxic antinutritional compounds. After extensive research, Canadian plant breeders were able to develop rapeseed oil that had extremely low levels of both these compounds – a product we now know as Canola oil.

But it was the old rapeseed oil that was implicated in the Spanish outbreak. In fact, erucic acid had excellent lubricating properties and made the traditional rapeseed oil ideal for industrial uses – but bad for food use. This was why the potent toxin, aniline, was added as a denaturant – so people would not use it in food. But, like the alcohol strippers of the prohibition days, there were operators who made a living at stripping the aniline out of rapeseed oil so that it could be used as a cheap food oil substitute.

The rapeseed oils that the Madrid medical researchers found were originally denatured with 2% aniline, but now contained other aniline-derived compounds, indicating they had been reprocessed and reheated. (It was later learned that the Spanish customs laboratory had known of the importation of aniline-denatured rapeseed oil for several months.) On 10 June 1981, exactly 40 days after the epidemic started, an official announcement was made by the Ministry of Health and Consumer Affairs on late-night television, informing the public that the widespread epidemic had been the result of contaminated, unlabeled cooking oil.

Referring to the outbreak as toxic oil syndrome or TOS, the announcement stated that the hospitals remained full of victims, but that new admissions had dropped precipitously. All suspected supplies of toxic oil would be recalled. Overnight, the panic that had gripped the country for weeks subsided.

The number of cases began to drop precipitously after the oil recall was instituted. By October 1981, almost no cases were reported. By the time the outbreak was quelled, more than 20 000 persons were diagnosed with acute TOS. Approximately 59% of those affected progressed to a chronic stage of the disease and were hospitalized with symptoms including neurological deficiencies, carpal tunnel syndrome, and muscle cramps. Approximately 375 deaths were reported, but that jumped to 1663 after further analysis.

Victims took the government to court and in 1997 the Supreme Court established indemnities at a cost that amounted to more than €300 million by 2002. Current regular payments to beneficiaries come to approximately €20 million per year.

A number of oil merchants were arrested, tried, and convicted in 1989, even though the judges stressed that the actual toxin was not fully known. Despite all the controversy, research continues into finding the most likely toxic compounds that might have caused the disaster – but there are no definite answers as yet.

The Birth of a Beast

Escherichia coli bacteria were first described by the German pediatrician and bacteriologist, Dr. Theodore Escherich, in an article he published in 1885. They were very common in the intestine (colon) and eventually called *E. coli* in his honor. For more than 100 years, these microorganisms were not

considered to be very harmful but were used as indicators of contamination in water, and in the food industry, it was considered a sign of poor employee sanitation.

The varieties of *E. coli* that are considered to be pathogenic to humans are those that cause diarrhea. The most common one is called enteropathogenic *E. coli* (EPEC) and is most often implicated in infant diarrhea – a condition that could end up being chronic unless great care is taken to ensure that the baby bottles, diapers, linens, and toys are kept scrupulously clean in order to prevent reinfection by passing or direct contact with a baby's feces. Two other types of pathogenic *E. coli* are known as enteroinvasive (EIEC) and enterotoxigenic (ETEC) forms.

Historically, the most well-known form of pathogenic *E. coli* is the enterotoxigenic type. This occurs most commonly in developing countries where sanitation remains a very low level. It is responsible for the range of diarrheal symptoms experienced by travelers such as Monteuma's Revenge, Delhi Belly, Rangoon Runs, Tokyo Trots, and the more generic Gringo Gallop.

The way bacteria evolve certain pathogenic characteristics depends on their nuclear structure. Unlike the cells of higher organisms, which carry their chromosomes within a well-defined nucleus, bacterial cells usually contain a large circular chromosome that is not enclosed by a membrane of any sort and is free to move around within the cytoplasm. In addition, bacterial cells may contain several smaller circular strands of DNA called plasmids that can operate independently from a microorganism's main chromosome.

A microbe's characteristics are defined by the DNA in both its large chromosome and its plasmids. Very often characteristics such as antibiotic resistance are carried in plasmids. It is a quirk of nature that bacteria, which may not be related to one another, are able to share characteristics through a process of plasmid transfer. That is why antibiotic resistance can spread so quickly between various species of bacteria.

Another way is through bacteriophage transfer. A bacteriophage is a small virus that can infect bacteria. Because all viruses are essentially DNA, bacteriophages infect bacteria and incorporate their own DNA into that of the bacteria. The bacteriophage begins to replicate itself until the bacterial cell bursts and disperses a cloud of young new bacteriophages ready to infect a great many more bacteria. At times, these bacteriophages are able to incorporate the DNA from one bacterium and pass it on to others that they infect.

E. coli's prevalence in the colon stems from its basic ability to attach to the inner surface of the intestines, causing the lining cells to rupture. This particular characteristic is carried in the bacteria's plasmids and can easily be transferred to other bacteria such as nonpathogenic *E. coli*. The results are greater number of *E. coli* types that can cause diarrhea.

In another case, EIEC inherited the characteristic of being able to actually invade the surface cells of the intestine by picking up genetic material from another bacterium called *Shigella dysenteriae*. Although they are from two completely different families of bacteria, both species exhibit the very same symptoms – because they share identical pathogenicities. In this case, the bacteriophage passed on the DNA that coded for the deadly Shiga toxin, and thereby created a new enterohemorrhagic (EHEC) *Escherichia coli* O157:H7.

It is thought that this bacteriophage-moderated DNA transfer may have been accelerated by the use of antibiotics in cattle feed, however, this has not yet been proven with any certainty. What is certain is that *E. coli* O157:H7 is one beastly, very deadly superbug. Our traditional perception of the quasibenign nature of *E. coli* changed dramatically in the 1990s when the first well-publicized cases of EHEC occurred.

It is thought that the *E. coli* O157:H7 originally evolved as early as 1955 because hemolytic uremic syndrome (HUS) – a typical characteristic of *E. coli* O157:H7 was first described by a Swiss pediatrician while examining a dairy-related outbreak. It occurred again in 1975, when doctors took a stool sample from California-based female naval officer who had a severe case of bloody diarrhea. They cultured a rare form of *E. coli* and sent it to the Centers for Disease Control (CDC) in Atlanta where it was promptly placed in storage. In December 1981, a severe outbreak of hemorrhagic diarrhea occurred in White City, Oregon. Local physicians were unable to identify the responsible organism and called Dr. Lee Riley, a California-based epidemiologist, who was associated with the CDC. No specific microbial agent was immediately found, but shortly thereafter, two simultaneous outbreaks occurred in Michigan and Oregon, both involving McDonald's restaurants. By this time, Joy Wells, a microbiologist at the CDC isolated *E. coli* O157:H7 from stool samples of the victims. However, it was not until two months later that investigators discovered the same *E. coli* O157:H7 in a processing plant that had supplied the suspected burgers to McDonald's. It was then that Dr. Wells took it one step further and canvassed the thousands of *E. coli* samples maintained at the CDC and found the one that had been responsible for the hemorrhagic diarrhea episode that took place in 1975. They were finally on to something conclusive and in 1982, they published the results in the *New England Journal of Medicine*.

When *E. coli* O157:H7 was first discovered, it was a true rarity among pathogenic bacteria because no one could accurately estimate the minimum infectious dose (the minimum number of organisms required to cause an infection). For most bacteria, the average infectious dose ranged from 100 to 1 000 000 000, however, for *E. coli* O157:H7, its infectivity (rather than pathogenicity) was so great that the ingestion of one single cell was thought to be sufficient to cause an infection. Even then, its true potential was not fully known because the outbreaks had been so limited.

In early January 1993, a Seattle pediatrician noticed what he thought was an unusual spike in the number of children coming down with bloody diarrhea. He immediately alerted the Washington State health officials about a possible foodborne outbreak.

In less than a week, the health department staff successfully identified hamburgers contaminated with *E. coli* O157:H7 bacteria from the Jack in the Box restaurant chain as the cause. More than 70 Jack in the Box restaurants located in the Washington, Nevada, California, and Idaho were involved in the outbreak, and their remaining ground beef inventories were immediately recalled.

Seven hundred people, many small children, became very ill and four children died. The staff epidemiologists at the

CDC quickly concluded that the outbreak resulted from errors in meat processing at the plant that made the burgers in addition to incorrect cooking at the restaurants that served them up. Ultimately, this incident turned out to be a defining moment in the history of food safety in the USA.

This was certainly not the first large-scale foodborne disease outbreak to be recorded. More than 10 years earlier in 1982, two large outbreaks of Norwalk gastroenteritis occurred in Minnesota. The first one involved 3000 cases and was related to eating bakery items with contaminated frosting, whereas the second implicated 2000 cases and was associated with eating bad coleslaw. In 1988, a large outbreak of *Shigella sonnei* infections occurred among the unfortunate individuals who ate what was supposed to be healthy, raw tofu salad at an outdoor music festival in Michigan. In that episode, 3175 persons became ill and 117 were serious enough to require hospitalization. In case numbers, the Jack in the Box paled in comparison to the national outbreak of *Salmonella enteritidis* infections from Schwan's ice cream that occurred a year later, where almost one quarter of a million people were infected.

What made the Jack in the Box incident a watershed event was that four children died an unusually cruel and agonizing death – from the simple act of eating a hamburger. Hamburgers are the quintessential icon of American fast food. By 1992, McDonald's alone had sold more than 80 billion hamburgers around the world. There is no other food as ubiquitous throughout America as the hamburger.

One of the saddest comments made following the outbreak was by Michael Nole of Tacoma, the father of one of the victims. "I don't care how long I live, I will never believe that my son died from eating a cheeseburger. Never." His son, Michael James, died at Children's Hospital and Medical Center in Tacoma. He died from complications resulting from HUS – a condition in which platelets start to clump up within the kidney's tiny blood vessels resulting in reduced blood flow and eventual kidney failure. The partial blockage of the blood vessels also leads to destruction of red cells. Michael was 25 months old.

Although it is unusual to take a very long quote from another source, the testimony of Michael Nole's mother appears so touching that it is reproduced in large part here, as it is no longer available on the Safe Tables Our Priority (STOP) website:

> …My son had bouts of diarrhea, which rapidly became runny, painful and eventually bloody…and later all blood.
>
> He was admitted to Mary Bridge Children's Hospital in Tacoma, Washington. I had no idea what was soon to follow.
>
> The bloody diarrhea continued throughout the night, every 3–5 min with screams of pain and terror with each one. We went through a diaper with each one because the blood burned his skin.
>
> In the morning, he was transferred to the pediatric I.C.U. unit. Unknown to us, there were already children there with *E. coli* O157:H7.
>
> By this time his kidneys had shut down and he was becoming very lethargic, his abdomen began to swell to an unbelievable size. He had hemorrhoids and was unable to eat or urinate.
>
> I remember the last time my husband and I saw our son responding and sitting up with our help. Due to his swollen tummy and tubes in his arms, he ate an orange Popsicle and I kept trying to tell myself he was going to be okay.
>
> Dialysis was needed and the decision was made to transport him to a children's hospital in Seattle that had the machines for this purpose.
>
> Before they transported him I had asked to rock him in my arms in a chair next to his bed. With the help of 3 nurses and his physician, they carried him over to me with all of his tubes, IV's and other monitoring devices and set him in my arms.
>
> I rocked him and sang our favorite songs together. One of our favorites was "Jesus Loves Me". To this day, I cannot bear to hear this song.
>
> This was the last time I held my baby in my arms.
>
> He was transported to Children's Hospital in Seattle, I rode in the ambulance with him and two other transport nurses. We made the hour trip in 22 min.
>
> …
>
> Michael had dialysis one or two times a day. There were so many other children arriving daily that needed dialysis that the machines were becoming very popular. Nurses, physicians and all other specialists were working around the clock, many sleeping at the hospital to provide the best possible care for our children.
>
> As Michael's meds increased and tried to help his pains, things got even worse.
>
> The physicians thought we might lose him at several different times, and several times we were rushed into say our last good-byes and prayers. This was so very painful.
>
> As our family members started to arrive to kiss his cheek and stroke his golden hair and say prayers I just sat back in complete helplessness, thinking "I'm his mommy…why can't I fix this? Make everything better? Trade him places?" This was such a hopeless, powerless feeling. After physicians noted he had red patches on his tummy, they thought something might have burst inside him. The suggestion was made to rush him into surgery to see if they could stop or identify the internal bleeding.
>
> Papers were signed and we kissed him good-bye one more time in the hallway on his way to surgery.
>
> I cannot remember how long it took…1, 2, 3 hours, seemed like 2 days.
>
> When he returned they said they "lost" him once during surgery but were able to revive him.
>
> When we were allowed to go in to see him he had an incision from his neck to his groin area. This was so difficult to see.
>
> He did not do well after this, he opened his eyes once, and we were able to see the blue of his eyes and barely a twinkle. I told him he was mommies big boy and that I would love him forever and someday would be with him forever in heaven. My husband and I spent several hours with him before he died. The nurses gave me a lock of his golden hair to cherish.
>
> I left the hospital with his blanket, shoes, choo-choo train, sweats I made for him, and a bag of toys.

As his father said, all Michael did was eat a cheeseburger.

Based on documents filed in the US District Court in Seattle, the Jack in the Box restaurant chain had made a decision to cook their hamburger patties at a temperature below that which was recommended by state regulations (155 °F). Had they done so, in all likelihood, the *E. coli* O157:H7, which contaminated their hamburgers, would have been killed. The Jack in the Box restaurant chain purchased this batch of frozen hamburger patties from Vons Companies Inc. Not surprisingly, the Jack in the Box parent company Foodmaker blamed and eventually sued Vons claiming that they were responsible for the outbreak.

The Jack in the Box outbreak in 1993 made *E. coli* O157:H7 a household word. The devastation it brought to families whose children died or ended up with lifelong disabilities, served as a rude wake-up call to a nation that took the safety of its favorite food for granted.

No sooner had the Jack in the Box outbreak subsided, than another national outbreak hits the press. This time, it was an upscale, unpasteurized apple juice that carried the deadly *E. coli* O157:H7 bacteria, and another child died. Although it was not difficult to understand how ground up hamburger could be contaminated, how was it possible that apple juice could carry the same bacteria? It was eventually linked to apples dropped from the trees contaminated with deer feces being squeezed to make the cider.

The stream of unanswered questions at the time began to mount up. What were we doing to allow such things to happen? What were the changes that have been made to standard quality control procedures? If it could happen in products differing as widely as hamburger and apple juice, where might it strike next? Were the laws that we worked under no longer sufficient to deal with this new threat? The increasing number of negative media articles dictated that some radical changes had to be made before the industry could restore the consumer's confidence in the food supply.

The National Food Safety Initiative began with President Bill Clinton's radio address on January 1997:

> We have built a solid foundation for the health of America's families. But clearly we must do more. No parent should have to think twice about the juice they pour their children at breakfast, or a hamburger ordered during dinner out.

The goal of the Initiative was to identify all possible contamination points along the farm-to-table continuum and implementing process controls for preventing problems that might affect our nation's food supply.

For the first time, representatives from Agriculture, Health and Human Services, the Food and Drug Administration, the Centers for Disease Control and Prevention, the Department of Defense, the Environmental Protection Agency, the Council of State and Territorial Epidemiologists, the Association of Food and Drug Officials, the Association of Public Health Laboratories, the National Association of City and County Health Officers, the Association of State and Territorial Health Officials, and the National Association of State Departments of Agriculture were put together to solve the problem. No one was to be left out.

The resulting Farm-to-Table approach clearly recognized that food safety began at the production level and included all the steps in the process from the farm to the ultimate consumer's table. Likewise, the key government agencies recognized the importance of a seamless interagency approach to food safety problems.

To test how effectively interagency cooperation worked, a joint program was set up for a method to be developed for the rapid detection of *E. coli* O157:H7. The Centers for Disease Control and Prevention published a list of all those diseases that could be transmitted by the food supply. Various state public health agencies began to publish their own food safety initiatives.

The National Food Safety Initiative began an overhaul of food safety programs that continues to the present. It has resulted in some of the most integrated food safety and surveillance systems in the world. In the present day, this pathogen is a major concern around the world and there is growing concern about closely related EHEC strains like O111 and O145, which have also caused outbreaks.

Conclusion

Food poisoning whether unintentional or deliberate has always had an impact on the course of human events. Going back to Biblical time, civilized society has been regularly plagued by it. In some cases, the very same diseases exist in the present day and strangely enough, the most up-to-date cure for one of them is take almost verbatim from the Bible.

Certain food and beverage poisonings have had a continual run of 2000 years and throughout that time have not only affected the daily lives of countless societies but have also had an impact on the thinking and behavior of influential leaders. Who knows how different the world would have turned out had lead poisoning not reduced the intellectual capacities of some of the great Greek and Roman leaders? Empires may have been lost over a few unsuspected molecules.

In every major historical era, foodborne diseases have altered the course of human events. It was not until the last quarter of the nineteenth century that we began to understand the nature of spoilage and disease. Even after we gained this knowledge, we were powerless against the forces of nature exerted through her tiniest beings.

Microorganisms, too small to be seen, have constantly evolved in order to survive. In pursuit of survival, they have evolved unique and opportunistic mechanisms that often exceed our technical abilities to control them.

The combination of industrialized food production, communal eating in fast food chains, and terrorists committed to using any means to destroy our lives and lifestyles resulted in a cocktail of risks such as we have never seen before. However, a risk is only a risk and not an outcome. Thus far, we have been reasonably effective or remarkably lucky in avoiding the consequences of these risks. Let us hope we continue to do so.

History of Foodborne Disease in Asia – Examples from China, India, and Japan

GG Moy, Food Safety Consultants International, Geneva, Switzerland
F Han, China National Centre for Food Safety Risk Assessment (CFSA), Beijing, China

Introduction

With more than half of the world's population, the cultural, climatic, and geographical diversity of Asia is so vast that one might expect to find few commonalities among them. However, what is striking is that the basic commodities that make up the diet in India and China as well as of many other countries in the region are quite similar. Although diet will influence the nature and incidence of foodborne diseases, food-handling practices also play a role. For example, the consumption of raw or under-cooked fish and water plants is a tradition in many countries of Asia. Not surprisingly, many of the estimated 40 million people who are infected with foodborne trematodes live in Southeast Asia. In 1988 along the northern coast of China, inadequate cooking of 'hairy' clams contaminated with hepatitis A virus caused one of the largest foodborne disease outbreaks ever documented with more than 300 000 cases.

However, certain food safety practices have a long tradition in Asia although, as in the West, the underlying causes of foodborne illness were not understood. With the early development of large populations and urban centers in Asia, the problems of adulteration and fraud were among some of the first problems addressed by those societies. However, the concept that good wholesome food leads to good health was well appreciated even in the earliest times. This chapter discusses the history of food safety in China, India, and Japan, which begins with mythology and ends with modern times. Significant incidents involving foodborne disease are also discussed. It is recognized that many countries with long food safety traditions are not represented because much of the literature has been lost or in some cases, not translated.

Food Safety in Chinese Mythology

From the time of the first civilizations, the ancient peoples of Asia recognized that contaminated food can be the source of illness. Some of the earliest writings from China refer to food safety although from a traditional medicine perspective. In Chinese mythology, the legendary figure Shennong (*ca.* 3000 BCE) whose name means 'Divine Farmer' is said to have taught the Chinese a number of agricultural inventions that changed society, such as the axe, hoe, and plow and practices such as preserving seeds with boiled horse urine, irrigation and the weekly farmers markets. He is also considered the father of Chinese traditional medicine.

In about 200 BCE, the 'Divine Farmer's Herb-Root Classic' was the first compilation of Shennong's teaching that was based on oral traditions going back several millennia. Although the original text has been lost, it said to have been comprised of 365 entries on the safety and efficacy of medications that were divided into three categories. The first category included 120 foods and herbs with health-giving properties that were safe enough to be used as foods, including ginseng, jujube, orange, cinnamon, and liquorice. The second was comprised 120 herbs used for specific diseases, but which (were thought to have) possessed greater toxicity, such as ginger, peonies, and cucumber. The last category contained 125 medicinals that were acutely toxic and included rhubarb (oxalic acid) and the pits of certain fruits, such as peaches (cyanogenic glycosides). This insight into the relationship between toxicity and dose predated Paracelsus by several thousand years and laid the foundation for the development of traditional medicine in China.

Shennong is believed to have carried out much of his research by self-administering unknown plants and plant parts, and observing the effects. According to some accounts, his death was the result of consuming a yellow flower of a toxic weed (perhaps tansy). He died of intestinal hemorrhage before he had time to take the universal antidote, tea, which he also discovered. Shennong has been revered for his sacrifice and gifts to the Chinese people and even today many temples exist to honor him. While mythology is always a mixture of facts and fiction, the ancient heritage of traditional medicine continues to make important contributions to public health today. For example, the Chinese traditional medicine artemisinin (*Qinghoasu*) is now the standard treatment for malaria and saves millions of lives a year. Beyond traditional medicine, Shennong's influence on the Chinese culture can also be seen today in beliefs of many Chinese that foods have specific medicinal properties and perhaps explains why 'functional' foods are more widely accepted in Asia.

Food Safety in Ancient Times

China

One of the earliest accounts of food safety in the marketplace comes from the Zhou Dynasty (1046–256 BCE). 'The Book of

 doi:10.1016/B978-0-12-378612-8.00017-2

Rites' codified a range of requirements for commerce. One of the rules for food trade prohibited the entry of unripe fruit into the market. During the Tang Dynasty (618–907), the Two-Year Laws required that foodstuffs that could cause food poisoning due to spoilage should be burnt immediately and the violators and associated officials should be severely punished. For example, the food owner would be sentenced to imprisonment for one year if a condemned food was not destroyed. If a food that was known to be harmful was sold and was the cause of death, the food owner would be hung. In the context of consumer education, it should be noted that in about 500 BCE, the Chinese philosopher Confucius warned against eating 'sour rice.'

The Song Dynasty (960–1279) witnessed a period of prosperity and a doubling of the population made possible by a great expansion in rice cultivation and the use of short-ripening rice cultivars from Southeast Asia. This was also a time of scientific and cultural advancements, including the discovery of the compass, gunpowder, and movable wooden type. With the great expansion of the food trade, the government adopted the Famous Sages of the Capital, which were specific laws that required all trade associations to be registered. The law carried on the regulations of Two Year Laws, which included severe punishment for merchants who sold spoiled food. The exceptional growth of the economy also gave rise to many fake and inferior commodities being sold in the market. According to the record of Xi Hu You Lan Zhi Yu, unscrupulous traders in Hangzhou adulterated food using such practices as putting ash into wine and sand in chickens, filling geese and sheep with air and injecting water into fish.

During the Ming and Qing Dynasties (1368–1911), the government decreed that when deaths are caused by food safety problems, crime would be considered equivalent to a homicide and assault resulting in severe penalties, including death.

India

During the Vedic period in India (1700–500 BCE), a sophisticated culture and cuisine developed in the Indus Valley. The Vedic Indians believed that mental health was linked to the purity of food and washing of the hands, feet, and mouth was undertaken before consuming morning and evening meals. Ancient texts also prescribe that chefs should bathe before preparing food and refrain from speaking, coughing, or spitting when facing the food. They should also wash their hands with water after touching their hair, limbs, or clothes. Other food handlers in the kitchen were also required to bathe as well as to shave their hair and beards and cut their nails. In regard to food handling, it was required that rice should be well washed before boiling. Indo-Aryans were also particular about the cleanliness of utensils. For example, a previously used earthenware plate had to be baked in a fire before it would be used as a plate to serve meals. Similarly, an iron plate had to be scrubbed with ashes before it could be reused. Various metals were used for utensils and for cooking, including iron, copper, and even gold. While lead utensils were also used, these did not appear to have had a significant impact on health.

As in China, food also plays a role in the system of traditional medicine in India, called Ayurveda. The basic texts date from around 300 BCE, but are thought to have been authored by the physician Sushruta who lived in the sixth century BCE. Although little is known about him, later Ayurvedic texts present him as a descendant of Dhanvantari, who was the physician of the gods in Hindu mythology. The text includes reference to 700 medicinal plants, 64 mineral preparations, and 57 preparations made from animal products. However, it should be noted that in modern times, many Ayurvedic herbal preparations have been found to contain heavy metals, including lead and mercury compounds.

One of the most famous cases of foodborne disease occurred in India in 483 BCE. According to tradition, Gautama Buddha died near the town of Kushinagara in Northern India near the border with Nepal allegedly after consuming contaminated food that was offered to him by a blacksmith named Cunda. Different texts do not agree on the content of the meal. However, given the short time to onset, one possible cause could be *Bacillus cereus* toxin, which is a commonly present in cooked rice that was subject to time–temperature abuse. In some countries today, Buddhist monks and initiates still receive offerings of food from the local inhabitants in the morning, which can pose risks if the food is stored at ambient temperatures.

Japan

In Japan, a new study has added more evidence to the theory that the decline of the samurai class during the Edo period (1603–1867) was due to mental and physical developmental problems in the warriors' children caused by lead contamination of their mother's breast milk. Studies show that the bones of young children who died near the end of the Edo period had extremely high levels of lead. Those children that survived would be expected to suffer from the known adverse effects of lead, including learning disabilities, behavioral problems, and mental retardation. It has been suggested that the cause of the problem was fashion for women to wear white make-up, which contained white lead ($(PbCO_3)_2 \cdot Pb(OH)_2$). Although it may be argued that the ruling Tokugawa family was already in financial and political decline, historical evidence indicates that weak leadership was a factor bringing the Tokugawa dynasty to an end. If this is substantiated, it would have an eerie resemblance to the fall of the Roman Empire, which was also partially attributed to the consumption by the elite of wine sweetened with lead acetate.

Even into the twentieth century, cases of lead poisoning in young children in Japan have been documented although its toxicity was well known. During the early Showa period (1926–89), some Japanese women were still using white lead make-up, which resulted in adverse effects in their children. However, it should be noted about the same time, the USA introduced the use of tetraethyl lead in fuel for automobiles and began what was probably the most significant and widespread lead pollution in history.

From 1910 to 1945 cadmium from mining waste contaminated irrigation water used in rice cultivation. Illness known as Itai-itai disease (which translates to 'pain-pain') was estimated to affect more than 20% of women over the age of 50 years. In 1968, another outbreak of Itai-Itai disease was again traced to cadmium-contaminated rice.

Food Safety in Asia in Modern Times

The danger of food-related outbreaks is particularly acute in Asia because of the instances in which animals and people live in proximity and the way in which some food is produced and distributed. The avian influenza epidemic, as the most recent example of a disease linking animals and human health, has been historically unprecedented and of great concern for human health as well as for agriculture. First reported in Hong Kong in 1998, the epidemic has now spread to every continent, which now appears to be due to both legal and illegal trade in poultry rather than wild bird migration as was initially thought. Hundreds of human cases in Cambodia, China, and Vietnam have been caused by direct exposure to infected birds and by consuming inadequately cooked poultry. Although transmission to humans is low, the disease is extremely deadly in domestic flocks and hundreds of millions of birds have died or been culled.

However, in the region, more than a million people die and many more are debilitated every year from single cases and small outbreaks of foodborne disease that are most often downplayed by governments and overlooked by the international media. Even though disruptions in food exports due to problems in food safety have been on the increase and are attracting greater attention. Since 2001, unacceptable pesticide residue levels in fruits and vegetables, chloramphenicol and other antibiotic residues in seafood and poultry, pathogens in seafood, and mycotoxins in crops and peanuts have been the cause of rejection of food exports from the Asian region. After one incident, a ban on fish imports into the European Union (EU) cost one Asian country US$335 million in lost export opportunities. The export of peanut meal by another Asian country to the EU dropped by more than US$30 million per year since the EU introduced new mycotoxin regulations in the early 1980s.

China

With a greatly expanding economy and the mass migration of over 100 million people from the western provinces to the lucrative jobs of its eastern seaboard, China has experienced phenomenal changes in the past three decades. With all of the societal benefits, including the lifting of millions out of abject poverty, the social costs in terms of environmental degradation and food safety problems have also grown. The following incidents are cited as only examples of the food safety problems in China that have resulted. In 2003, to meet the growing demand, producers of Jinhua hams operated out of season during warmer months and to prevent spoilage, hams were soaked in dichlorvos, which is an acutely toxic organophosphate insecticide.

In April 2004, an incident involving infant formula that was deficient in protein occurred in Anhui Province. An estimated 60–70 infants died of protein malnutrition and another 100–200 were hospitalized but survived. Local officials arrested 47 people who were responsible for making and selling the substandard formula, but further investigation revealed 45 other brands of infant formula from over 140 factories also failed to meet the standard. By mid-April, officials had closed many of the factories and seized most of the substandard products. In May 2004, the State Food and Drug Administration ordered an investigation and the government agreed to cover the medical costs for affected families.

In June 2004, the government monitoring data in Chengdu report that three-quarters of the pickled vegetables produced in the city had levels of toxic chemicals that exceeded maximum limits. On investigation, many factories in Sichuan Province were found to be using industrial-grade salt in the pickling process and some were spraying dichlorvos onto their products before shipment.

In 2005, the presence of Sudan I in food products in the UK resulted in a global search for contaminated products, as well as in China. However, the investigation in China resulted in the discovery of the widespread use of Sudan I in Chinese food products despite a ban that had been in place since 1996. This lapse of enforcement was the beginning of the recognition that the Chinese food control system needed reform.

In 2006, pigs were illegally fed clenbuterol, an anabolic steroid, to enhance fat burning and muscle growth. Over 300 persons consuming the contaminated pork became ill. Clenbuterol is not approved for use in China, but remains a persistent problem.

In late 2006, Shanghai chemists from the Shanghai Food and Drug Administration found traces of carcinogen nitrofuran in turbot fish and at the same time, Beijing authorities found other antimicrobial drugs, including malachite green, in the fish. Other cities, including Hangzhou, have begun testing turbot fish and banning turbot shipped from Shandong Province.

In 2008, one of the most notorious cases of food adulteration occurred in China resulting in about 300 000 infants being affected with 52 000 hospitalizations and 6 deaths. The cause was infant formula made from powdered milk containing melamine. The melamine was added to milk by producers to cover up their dilution of milk with water. The standard test used for monitoring milk only measures total nitrogen and melamine, which is high in nitrogen, was used to falsify results. Later in 2008, melamine was also found in eggs and other food, which was traced to contaminated animal feed. Melamine contaminated wheat gluten used in pet food had earlier caused the death of many cats and dogs in the US raising the international profile of this problem.

In 2009, an outbreak involving clenbuterol occurred in Guangzhou where 70 persons were hospitalized with stomach pains and diarrhea after eating contaminated pig organs. In 2010, snakes used for food became contaminated with clenbuterol when fed frogs treated with the substance. Thirteen people who consumed the contaminated snakes required hospitalization. Overall, there were 113 prosecutions in 2011 relating to illegal use of clenbuterol with sentences ranging from 3 years imprisonment to death.

Also in 2009, a company in Qingdao was found to be marinating duck meat in goat or sheep urine to give the duck the smell and taste of lamb. The duck was then sold as lamb to customers. In Wuhan inspectors discovered that most of the pork blood pudding sold in the local markets contained little actual blood, but was made with formaldehyde, corn starch, industrial grade salt, and food coloring.

In 2011, 11 people died in Xinjiang and 120 became ill after consuming vinegar stored in tanks that contained antifreeze made with ethylene glycol.

India

Like China, India is a large populous country (1.2 billion) experiencing rapid economic growth. In particular, a growing middle class (approximately 15% of the population) is demanding more and better food. However, the problems faced by domestic consumers appear to be more serious as India has many more micro-, small-, and medium-size enterprises that generally pay less attention to food safety. The following are examples of some of the problems encountered. Many of these examples are the result of findings by importers of Indian food products, but serve as indicators of the types of problems that may be encountered in the domestic economy.

India has had many food safety problems with exports. In 1997, the European Commission found Indian fish processing industry to be noncompliant in maintaining hygiene standards. Because of continued detection of salmonella, all exports of fish and fishery products to the EU from India were banned. Problems of heavy metals and other contaminants are emerging issues that could further threaten trade. Other rejections by the EU include: raw peeled shrimp, prepared Indian breads (paratha and roti), basmati rice, sesame seeds, pepper, and coriander and chili powder for salmonella and filth; lentils for excessive pesticide residues; and processed food products with undeclared or unapproved coloring matter. From 1998 to 2000, Indian dry chili exports to Germany, Italy, Spain, and the UK were rejected due to the presence of aflatoxin.

In 1998, adulteration of edible mustard seed oil with the highly toxic oil from the seed of the Mexican poppy caused an epidemic of dropsy that affected thousands of people in New Delhi even though the level of contamination was only 1%. Over 3000 people were hospitalized and 60 persons died. Even after this incident, further similar epidemics were reported in Gwalior in 2000, Kannauj in 2002 and Lucknow in 2005.

In 2003, Indian grape exports suffered a setback when Dutch authorities discovered the insecticides methomyl and acephate on Indian grape samples. However, the more serious problem for India is spices because India is the world's largest producer, consumer, and exporter of spices. One of the most widely publicized food safety incidents occurred in 2005 when Indian chilies containing the banned coal tar dye Sudan I was imported into the UK and used to make Worcester sauce that was subsequently added to over 600 food products. This resulted in a massive global recall of contaminated products and a major loss of confidence in food safety controls in India by both domestic and foreign consumers.

In July 2007, the European Commission issued a health warning after high levels of dioxins were found in guar gum from India, which is a thicken agent used in many processed foods. In 2011 adulterated alcohol in West Bengal sold illegally resulted in an estimated 126 deaths. The alcohol was thought to have contained methanol or nitrite, but it was not confirmed.

Japan

One incident of particular sensitivity occurred in 1954 when a Japanese tuna fishing boat was operating near the Bikini Atoll. Subsequently, tuna in Tsukiji fish market was found to contain extremely high levels of radionuclides. In 1955, another incident involving arsenic-contaminated infant formula caused illness in 11 718 patients and 113 deaths. Then in 1956, the infamous Minamata disease outbreak occurred as a result of methyl mercury contamination of fish harvested in Minamata Bay. By 2010 over 14 000 victims had received some type of financial compensation. This outbreak, which resulted in irreversible neurological damage to the developing fetus and nursing infant gained international attention and raised awareness of the potential impact of environmental pollution on health and food safety. For a more detailed discussion of this outbreak, see other article. It should be noted that in 1965, a second cluster of Minamata disease was identified among people living along the Agano River.

In July 1996, a massive outbreak of *Escherichia coli* O157:H7 infection occurred among schoolchildren in Sakai City and was associated with consumption of white radish sprouts. Of the 12 680 cases, 121 children developed hemolytic uremic syndrome and 3 children died.

On 11 Mar 2011, an earthquake and tidal wave struck the Fukushima Daiichi nuclear facility resulting in the release of radioactive materials. Atmosphere releases were estimated to be significant, but still only about one-tenth of that released during the Chernobyl disaster. Significant amounts of radioactive material were released into the marine environment. The sale of food grown in affected areas has been banned. Fishing in the waters around the site is prohibited and fish caught for monitoring purposes still show high levels of cesium-134 and -137, indicating that marine contamination is still occurring.

Food Safety Legislation in Modern Times

As the world's food supply became global, most countries of Asia have moved to adopt modern food safety legislation, which often conforms to the standards, guidelines, and other recommendations of the Codex Alimentarius Commission. Certain countries are making great strides in raising the priority of food safety as an essential public health function. For example, the Korean Food and Drug Administration, which was established in 1998, is due to be elevated to the ministerial level under direct supervision of the Prime Minister. More detailed descriptions of the development of food safety legislation in China, India, and Japan are provided in the following sections.

China

With the establishment of the People's Republic in 1949, food safety became the responsibility of the Ministry of Health. Initially, the focus of the government was on recovering from the war and ensuring food security. However, in 1965, the first comprehensive food hygiene law and regulations at the national level were enacted as 'Food Hygiene Management – Proposed Regulations'. In 1982, 'Food Hygiene Law of the People's Republic of China (Trial Implementation)' was promulgated in China, which gave the main responsibility for the

management of food hygiene to Health Administrative Departments at various levels of government (local, provincial, and national).

In 1995, 'The Food Hygiene Law of the People's Republic of China' became effective, which was China's first food safety law (FSL). Since 1998, the Chinese government adopted a food safety regulatory model composed of multiple regulatory authorities based on the existing administrative structure. The responsibilities of overseeing food safety were shared by the following authorities: Ministry of Agriculture was responsible for the production and processing of farm products, General Administration for Quality Supervision, Inspection, and Quarantine for the production and processing of food, State Administration for Industry and Commerce for food in markets, and Ministry of Health (MOH) for food catering services. However, this posed some problems in that there was an overlap of management activities in some area, unclear responsibilities in other (gaps) and a general lack of coordination that hampered response to food safety emergencies.

Subsequently in 2003, the State Food and Drug Administration (SFDA) was established under the State Council with a broad remit for the coordination and supervision of the management of food safety, including the investigation of serious outbreaks of foodborne disease. In 2004, the SFDA was given additional instructions concerning the food safety regulatory system. While improved, the system still suffers from overlapping responsibilities and lack of effective means of coordinating.

At the provincial/municipal level, food safety controls have been improving. Beginning in 2005 the Beijing Olympic Food Safety Committee made great efforts to strengthen food safety in the city in preparation for the 2008 Beijing Olympic Games. Eight new technological measures were put in place, including a food tracking and monitoring systems, as well as mobile laboratories. As a result, not a single incident of foodborne disease was reported during the Olympic Games. Moreover, the residents of Beijing have continued to benefit from this legacy of improved food safety.

In 2009, the FSL of the People's Republic of China was enacted by the Standing Committee of the Eleventh National People's Congress in 2009 to replace the Food Hygiene Law of 1995. The FSL takes an evolutionary approach in adopting a legislative framework that gradually modernizes approaches to food safety. As China's first law was devoted solely to the subject of food safety generally, the new FSL takes a broader perspective by providing principles and guidance for food safety regulators on how to evaluate risks and conduct inspections.

In 2010, the State Council has established the Food Safety Committee as the highest level of coordination and supervision for implementing food safety efforts of the different authorities as well as provincial and local governments. The oversight system was reconfigured and expanded to include the Ministry of Industry and Information Technology and Ministry of Commerce. This increased the effectiveness for coordination and reduced overlap and gaps in management.

In October 2011, the MOH established the China National Center for Food Safety Risk Assessment (CFSA) to provide risk managers with sound scientific evaluations of chemical and microbiological hazards in foods, including assessment of new chemicals that are proposed for use in food in China. CFSA is expected to play a major role in building up the country's food safety research and scientific regulatory capacity, enhancing food safety quality, protecting public health, and strengthening international cooperation and communication in this field.

India

With increasing income, urbanization, literacy, and awareness of international trends, the people of India are giving greater attention to food safety issues. India is the world's leading producer of milk, sugarcane, cashew, and spices, and the second largest producer of rice, wheat, pulses, fruits, and vegetables. Consequently, the domestic food market with 1.2 billion consumers is one of the largest, and the potential for food exports is enormous. However, the problems of assuring food safety in this society undergoing rapid transition have proved to be a formidable challenge.

With the adoption of the Food Safety and Standards Act in 2006 and the establishment of the Food Safety and Standards Authority of India (FSSAI), India now appears to be rising to this challenge. The act consolidates various pieces of legislation that were implemented by different departments and ministries. Under the Ministry of Health and Family Welfare, FSSAI has been designed to provide a harmonized food safety environment using science-based requirement for food and modern 'inprocess' approaches for the manufacture, storage, distribution, sale, and import of food.

Although adoption of the latest technology, farming practices, and modern breeding techniques is essential for assuring food security and promoting exports, the FSSAI will focus on assuring food safety in the context of the Indian climatic and other relevant physical and cultural conditions. One area of particular concern is developing basic requirements for street food vendors because of the significant growth in this sector. Street foods are an accessible and affordable option for a sizeable percentage of our working population. The requirements must not be too complex or burdensome, but must be a channel for assisting street vendor to recognize their food safety problems and for finding practical solutions to these.

For example, one major problem is the use of calcium carbide to ripen fruit. The practice is ingrained in the food supply system because the poor transportation system makes it nearly impossible to market ripe fruit. Consequently, unripe fruit is picked and shipped. Although calcium carbide is a known carcinogen, vendors do not see any obvious health effect on their customer nor do they see any alternative to the practice itself.

Japan

Immediately following the end of World War II, the population faced shortages of many foods items. This resulted in a many cases of fraud, which in some cases caused illness and death. For example, a number of fatal cases were associated with the consumption of methyl alcohol, which was being

sold as ethanol. In 1947, the Food Sanitation Law was published and the following the administrative structure, including an inspectorate, was established. In 1969, Japan banned the production of benzene hexachloride and DDT and in 1973 banned the use of polychlorinated biphenyls (PCBs). The 1971 Amendment of the Agricultural Chemicals Regulation Act enhanced the regulation of pesticides by requiring toxicological testing and establishing limits for residues in food. In 1972, approval of irradiation for potatoes to prevent germination was granted. In 1974, furyl furamide (AF2) was banned as a food additive after reports of its potential carcinogenicity were published. In 2001, the first BSE case in Japanese cattle, which resulted in the mandatory testing for bovine spongiform encephalopathy (BSE) for all the slaughtered bovine. In 2002, the Food Safety Basic Act was established, and in 2003, the Food Safety Commission was established as the government's food safety risk assessment body. In 2013, Japan reduced its restrictions on imported beef.

Conclusion

In many countries of Asia, awareness of the importance of safe wholesome food has long traditions. Some of the earliest civilizations in Asia established standards and norms for assuring the safety of the food supply. Although many of these measures contributed to food safety, the true nature and impact of foodborne diseases were not recognized. As a result, governments were slow to act and problems became acute during the period of industrialization. In the modern era, globalization of the world's food supply has meant that all countries are involved in the international food trade in some capacity, either as food exporters or importers, and often both. At the same time, the 24/7 news cycle and the access to information and social networks by many consumers, including those in developing countries, has significantly raised awareness of food safety problems. Consequently, the response of many governments has now become swift and decisive, not only to promote their trade but, most importantly, to protect their people.

DISCIPLINES ASSOCIATED WITH FOOD SAFETY

Contents

Food Microbiology

MR Adams, University of Surrey, Guildford, UK

Introduction

Food microbiology is concerned with the activity of microorganisms in the production, preservation, and safety of foods and encompasses topics as diverse as the molecular basis of pathogenesis through to the development of food quality management systems. It is, by its very nature, an applied subject and one of, enormous economic and social importance.

Unfortunately, food microbiologists can take little credit for the many great advances in food safety, preservation, and fermentation prior to the mid nineteenth century. Methods of conserving food based on drying, salting, smoking, acidic fermentation, and combinations of these were developed empirically thousands of years ago. Even more recent developments such as canning preceded knowledge of the thermal stability of microorganisms and their role in food spoilage. Seeking to explain Appert's original heat preservation process, eminent scientists of the day such as Gay-Lussac held the view that the exclusion of oxygen was responsible for the preservative effect. It was not until much later, and an extensive applied research program in the 1920s, sponsored by the National Canners Association in the USA, that microbiologists established the safe practices in food canning that have been applied with considerable success for nearly a century. In fact, it is only since the twentieth century that newly developed food processing techniques such as food irradiation and high hydrostatic pressure have been able to benefit from the food microbiologist's input from their inception.

Foodborne Illness

It is clear that an association between foods and the transmission of some illnesses was noted long before the advent of the germ theory of disease and may well account for some of the longstanding dietary taboos and religious priscriptions relating to food. Diarrhea and vomiting have been observed and reported since the earliest times and, though they are not invariably the result of microbial activity, associating them with the activities of eating and drinking would be natural. The link between foods and illness would be particularly apparent in those illnesses that are more severe or more distinctive in their symptoms, such as botulism.

Botulism or sausage poisoning was a distinctive syndrome recognized by German physicians in the eighteenth century with the first recorded case in 1735 and others in 1755 and 1789. The first well-recorded outbreak was in Wurttemberg in 1793 when 13 people were affected and 6 died. This was caused by *Schweinsmagen* or *Blunzen*, a sausage consisting mainly of blood packed in a pig's stomach which was then boiled, smoked, and stored at room temperature for weeks giving an ideal opportunity for surviving *C. botulinum* spores to germinate, grow, and produce toxin. Alarm at the increasing number of cases of sausage poisoning led to some early explicit attempts to control foodborne illness. Justinius Kerner, as district medical officer in Wurttemberg, promoted a law requiring all cases of sausage poisoning to be registered and in 1802, a warning was issued against eating spoiled sausages, describing the correct method for preparing sausages and the symptoms of botulism. It was correctly believed to be an intoxication, although it was not known that the toxin was microbial in origin. Subsequent investigations by Kerner established a range of conditions that were necessary for botulism to occur, all consistent with establishing conditions suitable for the survival of spores, their germination, anaerobic growth, and toxin production.

With increasing knowledge of microorganisms and their role in disease, an early theory on foodborne illness, developed in the late nineteenth century, ascribed pathogenicity to microbial production of ptomaines or cadaveric alkaloids during putrefaction of organic material: In effect making all foodborne illness the result of an intoxication. This theory has long since been superseded in the light of our increasing knowledge of the different mechanisms of pathogenesis

 doi:10.1016/B978-0-12-378612-8.00022-6

involved in foodborne illness, although there are certainly echoes of the ptomaine theory in our modern understanding of scombroid fish poisoning.

Food Fermentation

Appreciation of the more positive aspect of food microbiology, the use of microorganism in the production of food also increased in the second half of the nineteenth century. Like traditional food preservation techniques, fermented foods had been developed empirically, without any knowledge of the presence or activity of microorganisms. They did, however, make an important early appearance in the development of microbiology. In 1680, Leeuwenhoek described brewing yeast in his 32nd letter to the Royal Society but made no allusion to its living nature or involvement in the fermentation process, although he does describe his work as "observations of the yeast from which beer is made."

The nature of yeast and its role in alcoholic fermentation became embroiled in the frequently told tale of the, sometimes acrimonious, controversy over spontaneous generation featuring such luminaries as Pasteur and Liebig: A dispute which also included a negative aspect of food microbiology: Spoilage and putrefaction. Pasteur expounded the view that contaminating bacteria were responsible for defects (diseases) in wine and beer and he developed methods to improve brewing and winemaking by reducing the incidence of bacteria. Success was only partial however and it needed the later seminal work of Hansen at the Carlsberg laboratories where he demonstrated the role of wild yeasts in beer fermentations and developed the technique of producing pure yeast cultures from a single cell to lay the foundations modern brewing microbiology.

The Advent of Food Microbiology

It is clear that the growth of microbiology as a subject was based primarily on investigation of what microorganisms did rather than what they were. In that context, an early focus of food microbiology was on the safety, cleanliness, and perishability of one particular food commodity, milk, an area of continuing importance to this day. Many of the leading learned and professional societies currently active in food microbiology started life as organizations concerned with the safety and quality of milk but have since broadened their remit to encompass all food commodities. For example, around 1910 a number of US cities and states had passed laws regulating dairies, to protect the consumer from problems such as adulteration but also to protect their health as it had been shown that if a city supervised the production and sale of milk efficiently, the infant mortality rate could be greatly reduced. This led in 1911 to the formation of the International Association of Dairy and Milk Inspectors which eventually became the International Association for Food Protection. Similarly in the UK, in 1925, the Ministry of Agriculture started to appoint Advisory Dairy Bacteriologists who in 1931 recommended the foundation of the UK's first microbiology society, the Society of Agricultural Bacteriology, which later became the Society for Applied Microbiology. The importance of animal products both as a perishable food product and as potential carriers of disease also led to the early involvement of veterinarians in the development of food microbiology – a theme that was most marked in continental Europe.

Analytical Techniques in Food Microbiology

Progress on understanding microorganisms was for a long time constrained by the limited practical techniques available. Early light microscopy revealed the presence of the microbial world in the seventeenth century when van Leeuwenhoek, working with simple microscopes and magnifications up to 200 ×, famously described, in letters to the Royal Society, his observations of protozoa, yeast, and what may well have been bacteria. It was not until the 1880s, however, with the introduction of lenses corrected for both chromatic and spherical aberration by Abbe, the use of aniline dyes for staining and the development of methods for isolating and culturing organisms by Koch, that the pace of advance quickened. This still centered largely on medical microbiology where a number of pathogens were isolated and identified. These included some bacteria that were later recognized as food poisoning organisms, although they were first identified as the causative agents of very different conditions. For example, *Clostridium perfringens* was described as a cause of gas gangrene in 1892 but was not unequivocally associated with foodborne illness until 1943; *Staphylococcus aureus* was described as a pyogenic (pus forming) organism in 1882 but its role in food poisoning was not discovered until 1914. The identification of food and waterborne microbial hazards has been a continuing process throughout the last 130 years with *Cryptosporidium*, *Campylobacter jejuni*, norovirus, and verotoxin producing *E. coli* first being reported in 1976,1977, 1978, and 1982, respectively.

Compared to other analytical sciences, the techniques of food microbiology have changed relatively little in the century following the introduction of cultural techniques and solid media. Though there have been great strides in some areas such as molecular and serological detection methods, it is probably true to say that most of the methods used in a routine practising food microbiology laboratory today would not be too unfamiliar to Robert Koch.

As an analyte, microorganisms have the unique property of self amplification; given the right conditions, a single organism can multiply exponentially over time and produce a detectable signal, traditionally a visual indication such as a colony on solid media or turbidity in broth media. Our improved understanding of the biochemistry and physiology of microorganisms has allowed an increasing range of organisms to be cultured (although molecular studies suggest that we are still some way from growing all microorganisms) and for growth media to be formulated so that growth gives additional signals, such as color changes, or fluorescence, that are of diagnostic value.

To be able to distinguish not only between microbial species, but also between strains of the same species is a powerful tool in tracing pathogens through the food chain and in the investigation of outbreaks of foodborne illness. To do this requires focusing on properties that differ between closely related organisms rather than those they share in

common and techniques have been developed in recent years to high levels of refinement. Procedures based on phenotypic characteristics such as antimicrobial resistance (antibiotyping, phage typing), metabolic activities (biotyping), and antigenic properties (serotyping) have been around for almost a century now. The Kauffman–White serotyping scheme for *Salmonella* based on somatic (O) and flagellar (H) antigens was originally established in 1929 and phage typing schemes were developed shortly after for the same genus. In the ensuing 80 years numerous phenotypic schemes have been produced for a range of other organisms (usually pathogens).

The development of molecular (nucleic acid based) techniques employing restriction enzymes and the polymerase chain reaction (PCR) has revolutionized microbial typing – improving strain differentiation, enhancing reproducibility, and standardization. Although techniques such as gene probes were used previously, their utility was limited by the lack of material available and it was not until the advent of the PCR technique, patented in 1985, that molecular approaches to the identification and typing of bacteria took off. We now have a battery of techniques, described in detail elsewhere in this book, that focus on small differences in genetic composition of cells to achieve high levels of discrimination such as pulsed field gel electrophoresis (PFGE), ribotyping, random amplification of polymorphic DNA (RAPD), and amplified fragment length polymorphism (AFLP).

The use of instrumental methods based on electrical detection of microorganisms either directly using the principles of flow cytometry or as a result of changes in electrical properties of a medium produced by their growth has proved particularly valuable in handling large numbers of samples of particular foods. The huge progress made in understanding the molecular basis of microbiology has led to molecular and immunological techniques which have had a dramatic effect improving the accuracy and precision of diagnostic techniques.

Microbiological Criteria

Once analytical techniques were available, it seemed reasonable to use them as a tool to determine and thus control the microbiological quality of foods. This approach was similar to that adopted with chemical contaminants but suffered from a number of drawbacks. Microorganisms do not behave as most chemical contaminants in foods: Their levels are subject to change as organisms die, grow, or simply survive, depending on the properties of the food, its processing and storage. Their behavior will vary depending on their location in an inhomogeneous food matrix so, as a result, microbes will not be distributed randomly. This means that taking a representative sample, one that gives an accurate picture of the quality of the whole lot, is either practically infeasible or hobbled by a high degree of uncertainty in the results from a limited number of samples. The need for sound statistically based sampling plans rather than casual sampling prompted the establishment of a leading international body in food microbiology, the International Commission on Microbiological Specifications for Foods (ICMSF). This was set up as a standing commission of the International Union of Microbiological Societies in 1962 in response to the need for international microbiological specifications for foods. It is made up of leading food microbiologists from around the world and has expanded from its initial focus on methodology and sampling plans to produce a series of high-quality publications on food safety management including Hazard Analysis and Critical Control Point (HACCP) (see below).

Quality Control at Source and HACCP

Recognition of the limitations of relying on product testing as a control measure led to more effective strategies based on intervention at source, well summarized by Sir Grahame Wilson at a meeting on quality control held in 1969:

> Bacteriologists are better employed in devising means to prevent or overcome contamination than in examining more and more samples…. Control of processing…is of far greater importance than examination of the finished article.

Initially this philosophy involved the production and propagation of codes of good manufacturing practice by bodies such as the Codex Alimentarius Commission, trade associations, and national regulatory bodies. These described the equipment, layout, and operating procedures and testing that would deliver high-quality products on a regular basis. However, to achieve wide applicability they tended to lack specificity in terms of their requirements and recommendations. This deficiency was later remedied by the development of what became known as the HACCP concept. HACCP originated by the effort of the National Aeronautical and Space Administration (NASA) and the Pillsbury Corporation in the US to apply the same kind of zero defects approach used in engineering the hardware of the US space program to the foods that the astronauts would eat. Its value was seen beyond the immediate concerns of space travel and was taken up by the food industry, national and international regulatory bodies. As a result, it was refined and codified into the now internationally agreed approach based on the seven principles:

1. Hazard Analysis
2. Critical Control Points
3. Critical Limits
4. Monitoring Procedures
5. Corrective Actions
6. Record Keeping
7. Verification

Application of a full HACCP approach can be a time consuming and costly exercise and has found its greatest application in larger scale food production and processing, but the emphasis of HACCP on identification of where and how hazards can be controlled has now become the universal basis for food control/inspection down to the smallest scale of food operation.

The Physiology and Ecology of Foodborne Microorganisms

Control of microbiological quality at source, during production, required a sound appreciation of how microorganisms

behave in different foods and under different conditions of processing and storage. This knowledge, which makes it possible to understand the effect of control measures and to establish effective critical limits for them, had developed over the years since cultural techniques were first developed. Using them it was possible to analyze the microbial flora associated with foods and determine how population levels changed under different conditions. This work did not confine itself to pathogens but examined all components of the microflora including spoilage organisms.

It was an early observation by Beijerinck in 1908 that a specific type of spoilage arises in a food under its normal conditions of storage, anticipating the current concept of specific spoilage organisms (SSOs) by many years. This observation that food materials serve as an ecological niche wherein particular groups of organisms are able to thrive led to an ecological approach to microbial growth and survival in foods, applicable to pathogens and spoilage organisms alike. This was formulated by Mossel and Ingram in the 1950s in a seminal article in the *Journal of Applied Bacteriology* where they outlined the different factors that determine the microbial association that develop within a particular food.

1. The initial infection of the substrate.
2. Factors depending on the properties of the food material (intrinsic factors): nutrient content, pH, a_w, redox potential…
3. The conditions of storage (extrinsic factors): temperature, relative humidity, and gaseous atmosphere.
4. The properties of the organisms (implicit factors): physiological properties such as growth rate, K_s…
5. Processing factors: washing, comminution, heating, freezing, irradiation…

A huge published literature developed describing the various factors affecting the growth and survival of microorganisms, particularly pathogens, and the limit values of various parameters beyond which growth or survival is not possible. It was an early observation that these factors often act in concert; microbial behavior being determined by the aggregate effect of a combination of factors. This idea was formulated as the hurdle or multiple barrier concept of food preservation. It had been applied unwittingly in the past in a whole range of traditional foods such as cured meats and conserves but now also gave guidance to the developers of new food products for the market.

Predictive Microbiology

Although the mass of published experimental data available helped support the formulation of expert opinion as to the likely fate of a pathogen in a particular food, it was rarely possible to make quantitative predictions and there was frequent recourse to challenge trials where the fate of an organism was followed in the situation under investigation. Quantitative predictions were possible where a simple mathematical model was available as in the case of thermal death, but models predicting growth were not a practical proposition until the advent of modern accessible computing power. This new potential soon stimulated research programs around the world generating mathematical models that predict microbial growth (principally pathogens) over a whole landscape of conditions, combining factors such as pH, temperature, and water activity. Much of this activity has now been consolidated within a single program – the ComBase initiative. This is a collaboration between the Institute of Food Research in the UK, the USDA Agricultural Research Service in the USA, and the Food Safety Center in Australia which has used a massive library of quantitative data as the basis for ComBase Predictor – freely available web-based predictive microbiology software.

The availability of such models and the predictions they generate are an invaluable tool for food microbiologists. They do however remain models of microbial behavior. They are formulated so that their predictions err on the side of safety, i.e., overpredicting growth or survival. The predictions give the microbiologist useful guidance though ultimately some limited challenge testing remains the gold standard for confirming how a pathogen will actually behave in a particular situation.

Microbiological Risk Assessment

Sophisticated tools such as ComBase bring us nearer to a position where we can assess accurately the risks associated with foodborne microbial hazards. They support what has been described as the third wave of food safety – microbiological risk assessment: a scientifically based process that produces an estimate of risk. This is performed in four steps

- Hazard identification
- Hazard characterization
- Exposure assessment
- Risk characterization

Risk assessment takes place within the broader framework of what is known as Microbiological Risk Analysis and brings food microbiology into the sphere of public policy. In addition to risk assessment, the other aspects of risk analysis are risk communication – the interactive exchange of information on risk between interested parties such as consumers and risk managers (regulators) and risk management – the weighing of different policy options with regard to public health in the light of the risk assessment and its communication. Recognizing the impossibility of eliminating risk entirely, the outcome of the risk analysis would be an agreed Appropriate Level of Protection (ALOP): The level of risk (incidence of illness) a society is prepared to accept. In order for this to link with food safety management programs it has to be translated into a Food Safety Objective, defined as the maximum frequency or level of a hazard in a food at the time of consumption that gives the appropriate level of protection. It is then up to good manufacturing practice (GMP) and HACCP systems to deliver this objective in practice.

Conclusion

Food safety is not a goal that can be achieved and maintained without continuing effort to improve our knowledge and keep pace with changes in the food chain, microorganisms, and

consumer behavior. In the foregoing, the author presented a concise picture of the development and scope of food microbiology and shown it to be a discipline that draws on many areas in pursuit of safe, stable, reliable, and nutritious food. The author hopes that it provides some setting for the numerous topics that will be explored in greater depth elsewhere in this volume.

DISCIPLINES ASSOCIATED WITH FOOD SAFETY

Parasitology

GW Esch, KE Luth, and MR Zimmermann, Wake Forest University, Winston-Salem, NC, USA

Glossary

Cercaria An immature trematode, usually free-swimming, produced by an intramolluscan larval stage.
Definitive host The host in which a parasite reaches sexual maturity.
Geohelminth A helminth parasite transmitted via soil.
Intermediate host A required host in a parasite's life cycle in which morphological change in the parasite will occur.
Metacercaria An immature trematode, usually encysted, in the open or in an intermediate host; develops from a cercaria.
Microfilaria The larval stage of a nematode (round worm) produced by an adult female that temporarily resides in the blood or another tissue of its vertebrate definitive host.
Reservoir host A host in which a parasite can mature and reproduce, then pass infective stages to hosts that are typically not part of the normal life cycle.
Trophozoite The active, feeding stage of a protozoan or myxozoan parasite.
Vectorborne The mechanism for transmission of a parasite into its host via a blood-sucking insect.
Zoonosis A disease produced by a parasite in a human that would normally occur in another animal host.

Historical Perspectives and Introduction

To most working parasitologists, a parasite is any eukaryotic organism that lives on, off, and at the expense of its host. Generally, this means that viruses, bacteria, and even the eukaryotic fungi are excluded from consideration by traditional parasitologists. Unfortunately, this approach was created irrationally. It is largely based on historical convention begun in the seventeenth century when Antonie van Leeuwenhoek began grinding glass lenses and using them to look at just about anything he could find, ranging from his own semen, to his own feces (and, in the latter case, he discovered and described *Giardia lamblia*, a widespread, and particularly unseemly, water- and foodborne protozoan parasite). Although Leeuwenhoek also observed bacteria, he did not know what they were, referring to them as 'animalcules.' The serious study of bacteria as causes of infectious disease was begun by Robert Koch and Louis Pasteur in the late nineteenth century.

Accordingly, conventional parasitology focused on eukaryotic organisms and essentially stayed that way until the parasite population dynamics models created by Roy Anderson and Robert May in 1970s. These models shaped an approach that eliminated the historic and artificial barriers separating the epidemiologic qualities of virtually all infectious pathogens. During an interview (by Gerald W. Esch) with Roy Anderson, he was adamant that the artificial distinction between virology, for example, and traditional parasitology was just that, artificial! Anderson was asked if he and May had to make an adjustment in their thinking when they moved from traditional parasitology to include viruses and bacteria in their models. He replied, "No, studies on infectious diseases at that time were quite Balkanized. There were departments of virology, microbiology/bacteriology, and parasitology." Continuing, he said, "Despite this, the ecological concepts and evolutionary issues faced [in any of these areas] were identical. They are all identical." Accordingly, it is important to understand that the ideas and views presented here regarding the ecology of parasitic organisms transcend the synthetic separation created by approximately 350 years of bad practice.

Parasites, whether eukaryotic or otherwise, have most likely been with humans since the appearance of *Homo sapiens* some 200 000 years ago in Africa. However, it would be difficult to say which of these parasites predominated in early humans, i.e., soil-, food-, water-, or vectorborne. Based on early Chinese writings, however, it is known that humans were definitely affected by malaria, a vectorborne disease, more than 4500 years ago. It is also known from the Ebers papyrus (1550 BC) that people in Egypt were infected with at least one species of *Taenia*, a foodborne tapeworm. The Old Testament forbade Jews from consuming pork, an agent for transmitting *Taenia solium*, as well as the foodborne nematode, *Trichinella spiralis*, although it is unclear if these parasites actually had anything to do with the ban. Numbers 21: 6–9 tells of the Fiery Serpent being sent among the Jews during the long migration with Moses out of Egypt. The Fiery Serpent is most likely *Dracunculus medinensis*, a waterborne parasite transmitted by microcrustaceans.

It was not until the nineteenth century that substantive discoveries were beginning to be made in understanding the

basic biology of parasitism. In part, this progress was due to the development of better microscopy. However, the significant forward movement in the nineteenth century was also made because the ideas of evolution and natural selection displaced the notion of spontaneous generation in 1859 with the publication of Darwin's, On the Origin of Species. With these changes also came the concepts of alternation of generations and of parasite life cycles. Louis Pasteur, Robert Koch, and others, promoted the notion of the germ theory for many diseases. In fact, Koch won a Nobel Prize in 1905 for his work on the germ theory. A great deal of the parasite research accomplished in the late nineteenth century, and even into the middle of the twentieth century, can be considered within the context of natural history.

Parasite life cycles are complicated, with many species requiring more than one host to complete. In definitive hosts, parasites reach sexual maturity. Intermediate hosts are required for the life cycle to be completed, and, generally, morphological change in the parasite will also occur in intermediate hosts. For many parasite species, insects that feed on blood are required to complete the life cycle. Insect vectors, in fact, play a significant role in the transmission of some of the world's most dangerous diseases, for example, malaria, African sleeping sickness, American trypanosomiasis (also known as Chagas disease), leishmaniasis, etc. Some parasites also employ paratenic hosts, an intermediate host in which the parasite does not change morphologically and which is used by the parasite to bridge a trophic gap between an intermediate and a definitive host. Paratenic hosts, accordingly, carry foodborne parasites.

Among the first parasite life cycles resolved was that of the foodborne cestode, *T. solium*. The German parasitologist, Friedrich Küchenmeister, fed cysticerci, a larval stage of the tapeworm, to the prisoners who were to be executed. Following their demise, the corpses were autopsied and adult tapeworms were found. The life cycle of *Taenia saginata*, the so-called beef tapeworm (another foodborne tapeworm) came soon after. Rudolf Leuckart and A.P.W. Thomas, working independently, are both credited for resolving the comparatively more complex life cycle of *Fasciola hepatica*, a plant- or foodborne trematode, which infects the liver and bile ducts of humans and livestock, primarily sheep. Life cycles for many of the important helminths infecting humans, for example, *Ascaris lumbricoides*, the hookworms, *Wuchereria bancrofti*, schistosomes, etc., were determined during roughly the same time frame. The zenith of the life cycle efforts came with Ronald Ross' studies on malaria and his pronouncement to the world in 1897 that he had worked out the *Plasmodium* life cycle. So significant was his discovery that he received the Nobel Prize for Medicine and Physiology in 1902.

Studies on the ecology of parasitic organisms began in natural history, most of it associated with life cycles, and was then followed with more sophisticated aspects of epidemiology and epizootiology. The main emphasis at first was on infectious diseases affecting humans and domesticated animals. Eventually, however, the scope of parasitology/ecology began to change. At first, the research was focused on the diversity of parasites that were to become the models for later work, for example, cestodes such as *Hymenolepis diminuta* and *Echinococcus granulosus*, trematodes like *F. hepatica* and *Echinostoma revolutum*, and nematodes such as *T. spiralis* and a tiny free-living species named *Caenorhabditis elegans*. *Toxoplasma gondii* and *Trypanosoma cruzi* were described and would eventually become protozoan models. As time passed into the twentieth century, parasitology began to take on a new face. Most of this change was related to rapidly developing technology in the last half of the century that was to lead into so many new fields of biology and a complete diversification of research efforts, for example, biochemistry, molecular biology, immunology, quantitative systematics (cladistics), etc.

One of the fields to emerge early in the twentieth century dealt with the ecology of animal parasites, which can be appropriately associated with species that infect humans (epidemiology) and those that infect other animals (epizootiology). As noted earlier, parasite transmission to humans can occur in a number of ways, and may, or may not, involve an intermediate host. Thus, parasite life cycles that involve humans and other animals can be direct (monoxenous) or indirect (heteroxenous). Immersed within these categorizations are a number of conceptualizations that are concerned with the dynamic qualities of host–parasite relationships, i.e., the regulation of parasite population dynamics (and predictive models), the distribution of parasites with host populations (and dispersion), transmission strategies, etc. Each of these concepts may, in one way or another, be linked to parasites that are foodborne.

Obviously, the consumption of food is basic to life, and parasites have exploited this necessity beautifully. A number of eukaryotic protistan species, commonly known as protozoans, access humans directly, via food/water consumption. Several parasitic flatworm species, commonly known as trematodes (flukes) or cestodes (tapeworms), have evolved indirect life cycles that require one, or more, intermediate hosts to successfully complete their life cycles. In many instances, humans also acquire these parasites via consumption of food. In most of these cases, the food is almost always raw, or poorly cooked. Finally, there are numerous parasitic nematodes (roundworms) that have either direct or indirect life cycles. In the former species, the infective vehicle is an egg, which is accidentally ingested, usually in soil. In the latter, the infective stage is called an L3, or filariform larva, and is usually associated with the tissues of an intermediate host. As with the trematodes and cestodes, flesh of the intermediate host for the nematode is almost always eaten raw, or poorly cooked.

Parasite infective stages that are acquired directly by the human hosts are almost always resistant to desiccation, and can usually remain viable for extended periods of time, ranging from several days for protozoans, to months for cestodes, trematodes, and nematodes, depending on the species. A large number of helminths employ vertebrate intermediate hosts, and some can survive in these hosts for many years. In almost all parasite species using a vertebrate animal as an intermediate host, the larval stages will be sequestered inside a cyst of host origin. The taeniid cestodes, for example, *T. saginata* (beef), *T. solium* (pork), and *E. granulosus* (a wide range of hoofed mammals) are all foodborne and possess larval stages that are sequestered inside cysts. The nematode, *T. spiralis*, and metacercariae of many trematodes are also encysted in vertebrate hosts, and all are foodborne parasites.

Transition Parasite Ecology

Parasite ecology was to parallel the changes in other disciplines of biology but there was a transition period. Probably the first significant breakthrough in the ecology of animal parasites came with the publication in 1964 of *General Parasitology*, written by the Russian, V.A. Dogiel. The content of the book was largely sophisticated natural history. However, it was also the first major effort to codify ecological parasitology. It represented a way in which the ecology of parasitism could be developed as a 'stand-alone' subdiscipline of parasitology.

Perhaps one of the most significant pieces of transitional work cited by Dogiel was W.L. Wisniewski's (1958) research dealing with eutrophication and parasitism in Lake Druzno, Poland. This effort was fundamental in food chain biology, with indirect, but real, meaning for the ecology of many foodborne parasites in aquatic ecosystems. In effect, what Wisniewski proposed was that with cultural eutrophication, a rapid and man-made form of ecological succession, significant changes in hypolimnetic oxygen concentration in lakes could affect food web dynamics simply through the addition of excess phosphorus, a limiting factor in aquatic habitats. Accordingly, the parasite fauna would be significantly altered and assume a characteristic quality, i.e., dominance by allogenic parasites. A number of investigators became involved in similar research in the rest of Europe and North America. Collectively, their efforts supported the central thrust of Wisniewski's thesis regarding man-made environmental changes and their consequences for parasite ecology.

Modern Quantitative Ecology

The first breakthrough in modern parasite ecology was purely quantitative and came with the publication of two papers by Harry Crofton of the University of Bristol, Bristol, UK. Most people working in the area of parasite epidemiology and ecology consider these papers as seminal. He ascribed four basic qualities to the notion of parasitism. First, he asserted that parasites are physiologically dependent on their hosts. Second, he said that heavily infected hosts would be killed by their parasites. Third, the reproductive capacity of parasites is always greater than that of their hosts. Finally, parasites exhibit what he termed an overdispersed frequency distribution within their host populations (it should be noted here that this concept only applies to helminth parasites that do not reproduce asexually in their hosts).

So, what is overdispersion? If one examines the manner in which free-living populations are distributed in space, there are basically three patterns of dispersion, each of which can be described mathematically simply by statistically comparing the mean population density per unit area with the variance of the mean. If the variance equals the mean ($S^2 = X$), then the distribution is said to be random. About the only time this frequency distribution can be seen is early, during parasite recruitment, which also means that this kind of frequency distribution is always ephemeral. A second kind of frequency distribution occurs when the variance is significantly less than the mean population density per unit area ($S^2 < X$). This distribution can also be described as regular, but it is rarely observed in host–parasite systems. Finally, most organisms, whether free-living or parasitic, exhibit overdispersed frequency distributions, where variances are greater than population means per unit area ($S^2 > X$). These distributions are also described as being aggregated, clumped, or contagious.

Now then, another question can be asked, what makes overdispersion unique because the distributions of most organisms, whether parasitic or not, are overdispersed? The answer to this question is simple. If one examines the distribution patterns of, let's say, enteric helminths in humans, most of the parasites of a given species within an African village will occur in relatively few hosts. For example, roughly 80% of all of the helminth parasites within the village may occur in just 20% of the human hosts. This kind of frequency distribution has a number of important consequences, and several are crucial for understanding the nature of host–parasite interactions. For example, most of the potential for morbidity/mortality in a population will be associated with just a few hosts. This implies a differential effect by parasites on host fitness. There is some evidence, albeit somewhat ambiguous, that aggregation can also affect sex ratios among some parasite populations. Despite the overriding nature of overdispersion, Poulin argued that, "The variance in [parasite population sizes] appears a much more important characteristic than their average size." He continued, "The failure of many studies to address this [issue] will need to be corrected if parasite evolution is to be placed in the proper context of highly variable" sizes of parasite populations within individual hosts.

The second major quantitative contribution to the study of parasite ecology came with the publication of two papers by Roy Anderson and Bob May. In these two papers, they merged several ideas and concepts, including those of Crofton regarding frequency distributions and dispersion, the classic ideas of Lotka and Volterra dealing with predator–prey interactions, and the notion that viruses, bacteria, protozoans, and helminths can be bundled together, under a single umbrella. In other words, their model applies to viruses and bacteria, as well as the classic eukaryotic protozoans and helminths.

Nonquantitative Contributions

Population Ecology

In general terms, a population can be defined as a group of organisms of the same species occupying the same space at a given point in time. It is not believed that anyone would strongly object to this definition as it applies to free-living organisms. As noted by Esch, Gibbons, and Bourque in a paper published in 1975, however, there are problems with defining just exactly what represents a parasite population. For example, should a population of parasites correspond to all individuals of the same species within a single host? Or, should it include all individuals of the same parasite life cycle stage in all hosts within a given habitat, or all life cycle stages of a parasite species within a given habitat? In other words, the definition of a free-living population does not fit the structure of a parasite population. For example, gene flow within a contiguous free-living population has no real physical

restrictions. However, consider the adult nematodes of the same species within the intestines of sunfishes in a single pond. Within a single host, these parasites can freely interact with each other, but not with adult nematodes of the same species in another sunfish in the same pond. So, the question is, what constitutes a population of these parasites?

To resolve this enigmatic problem, Esch *et al*. suggested that all of the individuals of a given species of parasite within a single host should be considered as an infrapopulation and that all of the parasites of a given species, including all life cycle stages, within a given ecosystem should be considered as a suprapopulation. Subsequently, Bush *et al*. introduced the idea of a component population as representing all of the parasites of a specified life history phase at a particular place and time, i.e., the adults of a given nematode species in all of the hosts within a single habitat.

It is clear that each individual within a host population is unique in terms of its age, size, genetic makeup, immunocompetence, etc. It is known that these factors can potentially influence the infrapopulation dynamics of a parasite species differently within various individuals of a given host population in a single habitat. Another of the important factors that must be considered when undertaking any sort of study on the population biology of parasites is the phenomenon of overdispersion. Why do just a few individuals in a population possess 80% of the parasites, whereas the majority has just 20%? Moreover, if the villagers are dewormed and a year later the same host population is examined again, the parasites will be overdispersed again, but are the same villagers wormy the next time around? Some investigators say yes, and some say no. The implications here are clear, but the reasons for discrepancies in understanding the manner in which overdispersed frequency distributions are not clear.

In the very first study using Crofton's ideas regarding overdispersion as applied to the epidemiology of human parasites, Croll and Ghadarian examined the frequency distributions of *Ancylostoma duodenale*, *Necator americanus*, *A. lumbricoides*, and *Trichuris trichiura* in a series of Iranian villages. They found that all four species of geohelminths were overdispersed. They dewormed the residents, returned a year later, and examined the same villagers. The parasites were overdispersed again, but the second time, a new set of persons was 'wormy.' Their conclusion was that certain people in these villages were not predisposed to infection. They contended that, "in this population of mixed ages, sexes, and social histories, the 'wormy' persons before treatment were not reliable predictors of subsequent intensities of infection." Continuing, they stated, "Risk factors are much more subtle than the classic categories we are considering or that 'wormy' persons in these communities result from superimposition of otherwise random events."

In contrast to the results and conclusions of Croll and Ghadarian as well as Schad and Anderson, working on hookworm disease in several villages in West Bengal, India before drug treatment, asserted that genetic predisposition to infection was important because the same people were found to acquire heavy infections after treatment. The subsequent literature regarding this aspect of epidemiology and overdispersion is mixed with respect to the influence of predisposition and the transmission of geohelminths in humans. Genetic differences between component parasite populations and host populations in separate geographic localities may be reflected by disparities in life cycle variations, population dynamics, and other biotic, as well as abiotic phenomena, whether dealing with human parasites, or not.

Antibody titers for *T. gondii* in human populations are highly variable on a worldwide basis, ranging from as low as 4% in areas of Korea to 92% in parts of Brazil. Cats are the primary reservoir hosts for the parasite in nature. This protozoan can have a fecal–oral route of infection (soil- or waterborne), or it may be acquired by consumption of poorly cooked meat (foodborne); it is even known to have a transplacental path of recruitment by a fetus still in the womb. Fortunately, only rarely clinical manifestations of toxoplasmosis can be seen. Interestingly, New World monkeys and Australian marsupials are highly susceptible to toxoplasmosis, whereas Old World monkeys, rats, cattle, and horses are very resistant. Dubey, perhaps the world's foremost expert on the parasite, suggests that a combination of evolution, genetics, and ecology are in many ways involved in this apicomplexan's epidemiology/epizootiology.

Community Ecology

Bush and Holmes adapted the approach of Esch *et al*. by applying the latter's hierarchical organization of parasite populations to parasite communities. The Bush and Holmes study of parasites in lesser scaup thus employed the notion of infra-, component, and supracommunities, which are parallel to analogous conceptualizations at the population level.

The Crowding Effect (Competitive Exclusion)

In 1951, Read published a paper that dealt with the crowding effect of parasites in a host. Since then, this paper and another published by Read in 1959, have become two of the most frequently cited parasitology papers ever published. The premise of both papers is based on what is commonly termed the Gaussian principle, or the Principle of Competitive Exclusion. In essence, the idea is a simple one. It says that no two species can occupy the same niche at the same time. If a conflict between two species should arise in this regard, then the outcome will fall into one of three categories, i.e., one of the species must move, one species must become locally extinct, or one species must change (evolve).

Read initially asserted that the options for the crowding effect among parasites were dictated by a single limiting factor, i.e., oxygen. Subsequently, he altered his position and stated that the limiting factor in crowding was more likely involved with the quantity and quality of dietary carbohydrates, which directly influenced parasite growth. Roberts as well as Bush and Lotz published summary commentaries on the crowding effect as it involved parasites. The latter authors noted that the seminal research on the crowding effect from an ecological parasitology perspective was published by Holmes in 1961 and 1962, using the cestode *H. diminuta* and the acanthocephalan *Moniliformis dubius* as models for his investigations. He was able to clearly demonstrate competitive exclusion of *H. diminuta* with respect to its normal attachment location

during simultaneous infections with both species of helminth. These results were so apparent that Bush and Lotz placed the work of Holmes into the same class as Gause's classic 1934 experiments using two species of *Paramecium* and Park's equally impressive study using two species of *Tribolium*.

Parasite/Host Behavior

Parasite behavior cannot be divorced from their ability to successfully locate and infect their hosts. Furthermore, the routes for parasite transmission are deeply rooted in several ecological traits, for example, the nature of environmental and host cues, parasite and host abundance, population structure, and evolutionary processes. MacInnis noted that host-finding techniques employed by macroparasites (ecto and endoparasitic insects, nematodes, trematodes, cestodes, and parasitic crustaceans) will include either active or passive means. In active transmission, either the parasites respond to cues from their environment or host, or hosts respond to the parasite. In either case, parasite behavior is oriented toward increasing their chances of encountering (and subsequently infecting) a host. In passive modes of transmission, no response by the parasite or the host is seen. This mode of transmission can occur via several methods, for example, randomly, or in response to a variety of environmental cues, through food web dynamics, predation, or accidental ingestion. Thus, parasite behavior can, at the very least, be attributed to indirectly influencing transmission in some passive modes, for example, by maintaining a high reproductive output, or by infecting intermediate hosts that are likely to be consumed by the definitive host in the parasite's life cycle. As with ecological aspects of parasite transmission, evolutionary processes will ultimately increase the fitness of the parasite by enhancing direct and indirect parasite behaviors that amplify the probability of increased transmission success.

Site and Host Specificity

One of the most remarkable attributes of most parasites is their very strong fidelity for both their host(s) and their site of infection in a host. *Dicrocoelium dendriticum* and *Fasciola hepaticum* are both trematodes (flukes) of sheep, are distributed worldwide, and are occupants of the bile ducts of sheep as adults. However, the similarities between the two parasites stop here. *Dicrocoelium dendriticum* is acquired inadvertently. Although a sheep forages in the pasture, it may accidentally ingest *Formica fusca* (an ant), where *D. dendriticum* metacercariae reside in the hemocoel. On arrival in the sheep's duodenum, the metacercariae are freed by digestion from the ant and excyst; the parasites then move directly into the bile duct where they mature sexually into adults. *Fasciola hepatica* is acquired when succulent emergent vegetation on which cercariae have encysted (metacercariae) is consumed as the sheep forages. Metacercariae excyst in the duodenum just like those of *D. dendriticum*. However, the excysted larvae of *F. hepatica* penetrate the gut wall of the sheep, then locate the liver and penetrate it from the outside. After wandering in the liver for 50–60 days, consuming tissue in the liver parenchyma, and generally causing significant tissue damage, the parasite leaves the liver and takes up residence in the bile duct. Thus, even though the two species occupy the same site of infection, they get there in completely different ways.

The remarkable point regarding the two parasites and their migration inside sheep is that initially they are both exposed to precisely the same set of environmental conditions. However, they respond in completely different ways to specific, but unknown, physical and/or chemical cues. It can, therefore, be said that everything that occurs inside the sheep with respect to migration by the two parasites operates within the context of the proverbial 'black box.' The same thing can be said for virtually every parasite species in terms of site location behavior. The nature of the stimuli to which parasites respond in order to find a given site of infection is largely unknown.

Most importantly, successful internal migration is almost always dependent on the parasite being in the correct host. If the wrong host becomes involved, one of the two things will happen to the parasite. On the one hand, the parasite will be killed immediately, or it will be killed in short order, by the host's immune response while migrating. On the other hand, there are many examples of a parasite evading, or at least surviving, the host's immune response for an extended period. In these cases, the parasite will almost always induce severe pathology, sometimes even death of the host.

Host specificity is another constant for most species of parasites. For some parasites, specificity is broad, for example, *E. revolutum* is known to successfully infect some 40 species of birds and mammals. In contrast, there are some species of parasites that will infect a single host species, and no more. In some of these cases, where specificity is narrow, parasites can actually be used as 'markers' as a way of understanding the origins of host stock. Along the northwest coast of North America, for example, certain species of helminth parasites are used to 'mark' (identify) specific migrating salmon in the northern Pacific Ocean and, thereby, can be employed to recognize the geographic origins of various fish stocks.

Host specificity translates into certainty with respect to a parasite's life cycle. For many human parasites, this predictability is related to cultural mores of the human host. If one wanted to find a human population with a high seroprevalence of *Trichinella spiralis*, a foodborne nematode found in pork, the Middle East would not be a good place to look. Why? Because both Jews and Muslims are forbidden to eat pork. (It should be noted here that this does not necessarily preclude the presence of *T. spiralis* in these areas. It has been reminded that relatively large outbreaks of trichinosis have occurred in both Lebanon and Turkey in recent years, and that the presence of *T. spiralis* has even been noted in pigs raised for foreign trade in Cairo, Egypt!)

Nonetheless, a high degree of host predictability by parasites has been honed over many thousands of years. Some of this predictability is related to parasites adapting certain behavioral qualities that match those of the host. Thus, for example, if you wanted to find a certain species of snail in eastern Africa that is shedding infective cercariae of *Schistosoma haematobium* (a waterborne pathogen that infects humans by skin penetration), you need not look between 18.00 and 06.00 h, because cercariae shedding by this trematode occurs between 06.00 and 18.00 h. Similarly, if you want to see shedding of *Schistosoma rodhaini* cercariae, check the snails

between 18.00 and 24.00 h. The explanation for these shedding patterns rests with adaptive characteristics of the parasite developed over long periods of coevolution by both the parasite and host. The definitive hosts are most active during these periods of cercariae shedding, and the probability of success in infecting their hosts is enhanced if cercariae are shed during periods of activity on the part of their hosts.

Another example of a biological clock is displayed by the appearance of *W. bancrofti* microfilariae (mf) in peripheral blood of humans in many areas of eastern Asia. The mf begin circulating in the peripheral blood around 22.00 h and stop around 02.00 h, moving deep into the blood vascular system. This 4-h sequence in peripheral blood coincides with the time during which the correct mosquito vectors take their blood meals.

Most host-matching behavioral phenomena are also parsimonious, i.e., the direction of coevolution over time ensures that the encounter probability between the two hosts is enhanced, not diminished. These behavioral characteristics represent just a few of the many examples that increase the probability of a parasite's success in completing a complicated step in its life cycle, as well as help in identifying an important aspect of host specificity by the parasite for a given host.

Emerging Infectious Disease

Over the past 30 years or so, certainly a rather short period of time considering the evolutionary history of the human race is at least 200 000 years old, a spate of new infectious disease problems have emerged. Clearly, the leader of this group must be acquired immune deficiency syndrome (AIDS). Approximately 30 million people are infected with the human immunodeficiency virus (HIV), greater than 1.7 million deaths occur per year, and nearly 75% of the cases are in sub-Saharan Africa. Although this is among the leading infectious diseases affecting mortality and morbidity in humans, it is not considered as a 'classic' parasite, and it is certainly not foodborne, so it will not be considered further from this point.

A rapidly spreading emergent disease of humans is cryptosporidiosis, caused by *Cryptosporidium parvum* that infects humans and other mammals, and *Cryptosporidium hominis* that infects primarily humans (both parasites are water- or foodborne). Massive outbreaks of this disease were, for example, reported in Carroll County, GA, USA in 1987, with an estimated 13 000 cases of diarrhea, and in Milwaukee, WI, USA in 1993, where it is variously estimated that 300 000–400 000 cases of the disease occurred, virtually all at the same time. In both localities, there were functional water treatment facilities present, yet the outbreaks still took place (chlorine treatment of infective oocysts is ineffective). Transmission in the latter case was traced to a cattle feedlot that overflowed into the primary water source for the city. Tragically, there were many hospitalizations and even several deaths among immunocompromised individuals. Even though this parasite is primarily a waterborne problem, it can also be transmitted via oocysts present on contaminated vegetables.

Cyclosporosis is strictly a human pathogen that produces a mild and self-limiting form of diarrhea. Originally, it was thought to be a blue–green alga, or perhaps a large form of *Cryptosporidium* sp. Presently, *Cyclospora cayetanensis* is the only cyclospora species known to infect humans. Cyclosporosis is clearly a newly emergent disease, having been recognized for the first time in 1977 in Papua New Guinea. Since 1990, outbreaks have been reported several times in North America, usually in a large gathering of people in conjunction with a special luncheon/dinner. On more than one occasion, the source of the parasite was traced to raspberries imported from Guatemala. According to Mansfield and Gajadhar, *C. cayetanensis* may also be transmitted via contaminated and untreated water.

As noted above, a significant recent problem has been the near pandemic associated with HIV-induced AIDS, an increase in the number of immunocompromised people, and the resulting acquisition of certain parasites that might not otherwise be a serious problem. Included among these parasites are *Entamoeba histolytica*, *C. parvum*, and *T. gondii*, all of which may produce lethal diseases in people who have AIDS, or those who may be taking immunosuppressive drugs for the treatment of cancer, for example.

Several species of what are normally considered as free-living amoebae, i.e., *Acanthamoeba* and *Naegleria*, are known also to infect humans, causing granulomatous amebic encephalitis and amebic keratitis. The former condition is frequently fatal and the eye problem is considered a progressive disease that can ultimately cause permanent blindness. The free-living stages of these parasites occur as trophozoites or as cysts in both soil and water. Keratitis is an emergent disease because there is an increase in the use of contact lenses on a worldwide basis. The disease is usually associated with a corneal abrasion and/or contaminated water in the lense storage case.

Food Webs and Trophic Dynamics

Food webs are used by ecologists to track energy flow in ecosystems. Parasites have been shown to play an integral role in these food webs, even to the point of acting as an indicator regarding the health of an ecosystem. Although there is a relatively small amount of energy transfer in parasite life cycles, they may have a significant impact viz-a-viz their effect on host life histories and behavior. Their influence on energy flow in an ecosystem is enhanced by the fact that at least half of all animals in an ecosystem are infected by parasites, and that close to 100% of all species present are parasitized. Accordingly, parasitism can have a significant impact on community structure, even to the extent that some parasites may act as keystones species in certain ecosystems. Within food webs, species in the highest trophic levels (including humans in this group) are most vulnerable to infection by parasites due to accumulation of parasites in the food of top predators.

In general, parasite life cycle dynamics can involve direct or indirect, and active or passive, action by the parasite. There are some species and life cycle stages in which the parasite can actively penetrate the surface of a host, for example, a schistosome cercaria, thereby requiring an expenditure of energy by the parasite. The venue for schistosome cercariae is water and these kinds of parasites are described as waterborne (although unlike most waterborne parasites, they are not ingested, they

penetrate the skin directly). In some cases, an inactive form of the parasite, for example, an egg of *A. lumbricoides*, will be directly ingested by the host, and not require an expenditure of energy by the parasite for transmission purposes. These sorts of parasites are usually soilborne, or have a fecal–oral route of infection. It must be emphasized, however, that many of these so-called soilborne parasites of the fecal–oral kind may also be transported into one's body through ingestion of contaminated food or water, or via unclean food handlers. In many cases, the parasite thus 'catches a ride' and is carried into the host via trophic, or feeding, activity of the host. These constitute the foodborne group of parasites.

Virtually any foodstuff that passes through the mouth into the digestive system can be a source of infection by a eukaryotic parasite. Some of these parasites are associated only with the human host. Others are more closely associated with other animals, so-called reservoir hosts, but humans 'get in the way' and can acquire them, usually in the same manner as reservoir hosts. These species are also referred to as zoonotic parasites and the diseases they produce as zoonoses. Variety in this latter group is thought to be increasing (in the form of emerging, or reemerging, diseases). The explanation for the expansion can be traced to the increasing exposure to reservoir host habitats as humans expand their reach into new habitats. Others claim that climate change is causing some species to expand their natural range and intrude on the normal human habitat. Finally, as travel by humans becomes more frequent, they are exposed to a much wider array of 'exotic' food experiences in Third World countries and, as a result, to a great many new and different parasites.

When it is spoken of foodborne parasites and foodborne disease, what are the possibilities of acquiring parasites that cause these problems? Somewhere, it has been said that, 'you are what you eat,' from a parasite's perspective. Accordingly, there is virtually nothing that can be eaten that is not capable of carrying a parasite, or parasites. For example, depending on where one goes in the world, parasites may be associated with leafy vegetables or salads, for example, metacercariae of *F. hepatica* or *Fasciolopsis buski* may be present on watercress or water caltrop. Consumption of this sort of vegetation in the Far East may thus lead the unsuspecting traveler to severe digestive problems or liver disease. Ingestion of lettuce in third world countries may also lead to dysentery caused by *E. histolytica*. Similarly, a special kind of intestinal problem, called steatorrhea, is induced by another protozoan, *G. lamblia*. The infective cysts of the latter parasite can occur on vegetation, or will more likely be in water contaminated with infective cysts of the parasite. In fact, giardiasis is a rather common parasitic disease in several so-called advanced countries, where it can spread from reservoir hosts, for example, beaver, to the unsuspecting hiker or picnicker who might be enticed to drink the cold and clear water of a nearby mountain stream.

The parasites briefly highlighted to this point are mostly protozoans, and most have alternative transmission routes, i.e., fecal/oral (soil or water), or foodborne, pathways. There are also a substantial number of helminths that infect humans, many of which are strictly foodborne. They almost always involve complex life cycles, with two, or more, hosts necessary for completion. Most, but not all, require consumption of raw, or poorly cooked, meat, or fish. Several are transmitted via vegetation of some sort, whereas others employ crabs, crayfish, lobsters, etc.

Both gnathostomiasis and anisakiasis are caused by parasitic helminths and are also typical emerging diseases; they should be mentioned together because their similar life cycles are connected with the consumption of sushi or sashimi, which really means the same thing, i.e., eating raw fish. Both of these diseases in humans are caused by eating raw fish containing larval nematodes, which should normally infect felids/canids, or marine mammals, respectively. In each case, the larval parasite in humans will wander 'aimlessly' in the host's body cavity/subcutaneous tissues, seemingly searching for the appropriate site of infection, which is the stomach in the normal definitive host (fish-eating marine mammals). One or both are common in parts of the world where raw fish are consumed on a regular basis, for example, Scandinavia, the Far East, and coastal areas of Central and South America.

As previously mentioned, *F. hepatica* and several closely related zoonotic trematode species employ primarily aquatic vegetation, for example, watercress/water caltrop, on which metacercariae of the parasite will occur. On ingestion, metacerariae excyst in the small intestine and the parasites migrate into the liver, gall bladder, liver, or bile ducts, where they develop into relatively large adults. *Opisthorchis* (*Clonorchis*) *sinensis*, the so-called Chinese liver fluke, and *Opisthorchis viverrini* are frequently (estimated at 10 million infections) seen in the bile ducts of humans in southeastern Asia. The latter has even been associated with cancer of the bile duct epithelium (cholangiocarcinoma). The intermediate hosts are freshwater/marine fishes in which metacercariae occur in the flesh. Several other zoonotic trematodes are also known to infect humans. These species, for example, *Metagonimus yokogawi*, *Heterophyes heterophyes*, *Watsonius watsoni*, *Haplorchis* spp. etc., are mostly associated with the gastrointestinal tract and employ a number of different fish species as second intermediate hosts. These parasites, along with the liver flukes mentioned above, commonly occur in association with the flourishing aquaculture industry. Their numbers within a given host can be quite high, for example, from several hundred to several thousand, and are capable of inducing gastric pain, typically accompanied by diarrhea.

Human paragonimiasis is another zoonotic disease caused by at least 10 species of *Paragonimus* in several parts of the world, but primarily in Central and South America and the Far East. The parasites become encapsulated in the lungs, usually in pairs, and cause tuberculosis-like symptoms. Eggs are coughed up in sputum and swallowed. Ectopic sites of infection, for example, brain, spleen, subcutaneously, etc., confirm that humans are not the normal definitive hosts. Intermediate hosts include marine and freshwater crabs, crayfish, and shrimp. Because these hosts are frequently eaten raw in many parts of the world, the disease is fairly common (estimated at 22 million cases) in endemic areas.

As noted earlier, foodborne parasites in humans are frequently 'cultural' in character. However, most of these same parasites are also closely related to poor socioeconomic conditions, i.e., poverty. Some say that parasites cause poverty, whereas others believe that parasites and poverty simply go hand-in-hand. The cestode, *T. solium*, is quite unusual in that humans can serve as both the definitive and intermediate

hosts for the cestode. The normal life cycle should include pigs as the intermediate host where bladder worms, technically known was cysticerci, encyst in skeletal and cardiac muscle, as well as subcutaneously. When humans consume inadequately cooked pork, they will acquire the cysticerci, which will develop into a robust tapeworm, reaching 10–12 feet in length. Segments (proglottids) that can enclose up to 10 000 eggs drop-off of the tapeworm strobila and are shed in the feces. Once outside, proglottids dry up and disintegrate, releasing the eggs. Foraging pigs then ingest the eggs by accident. The problem is that in many impoverished countries, humans and their pigs live in very close proximity to one another, which makes it likely that humans can also accidentally consume the eggs. If this happens, then the eggs will hatch and cysticerci will develop in the same sites of infection as in pigs, as well as in the brain (neurocysticercosis) where they can cause epileptic-like seizures.

Foodborne parasites are a bane for mankind. They can be exotic and limited in geographic dissemination, or they can be common and have a near worldwide distribution. Many are dependent on cultural mores, involving the choice of food, or the way it is prepared for human consumption, or both. Once eating habits have been established for a particular group of humans, and these eating habitats have become ingrained for many hundreds, if not thousands, of years, cultural tradition is difficult, if not impossible, to change.

Generally, most of these parasites and the diseases they cause are well known. For many of these parasites, there is adequate treatment or prophylactic drugs. Adequate cooking, or freezing, will take care of most species. A change in food consumption behavior would take care of others. Nonetheless, the likelihood of their total eradication, especially those with reservoir hosts, is very small. Depending on the parasite, humans can be the definitive host, or a dead-end intermediate host. Although most foodborne parasites rarely kill human hosts, morbidity is common. Although effective drug treatment is presently available for most helminth parasites, the risk of eventually developing resistance by parasites is real. For most of the protozoan parasites affecting humans, the same thing can be said. However, as was just noted, because so many foodborne parasites ultimately come from reservoir hosts, the likelihood of forced extinction is virtually nil. Moreover, the probability of severing their association with humans is near zero because of entrenched cultural mores.

DISCIPLINES ASSOCIATED WITH FOOD SAFETY

Food Virology

RM Goulter-Thorsen and L-A Jaykus, North Carolina State University, Raleigh, NC, USA

Glossary

Hepatitis A virus A 27–32 nm, nonenveloped, positive-sense single-stranded RNA virus with a 7.5-kb genome and a capsid with icosahedral symmetry. This virus is classified in the Picornaviridae family under the genus *Hepatovirus*. The virus causes a classic hepatitis syndrome that is less severe than hepatitis A and B and does not result in subsequent chronic disease. Nonetheless, it is one of the more severe of the foodborne viral illnesses.

Hepatitis E virus A positive-sense single-stranded RNA virus, hepatitis E virus is transmitted by the fecal–oral route and is endemic in the developing world. Clinical symptoms are very similar to those of hepatitis A virus infection, but with more severe consequences to infected pregnant women. Its increasing recognition in industrialized countries suggests that hepatitis E virus may be an emerging foodborne pathogen.

Human enteric viruses A functional, rather than taxonomic, group of viruses that infect humans by ingestion of infectious particles. Many virus families are represented by the enteric viruses, which are most commonly transmitted by the fecal–oral route.

Norovirus One of four genera within the Caliciviridae family. Human noroviruses are the most common cause of acute viral gastroenteritis in industrialized countries, and also the leading cause of foodborne illness. These are nonenveloped icosahedral viruses approximately 27 nm in diameter and having a genome consisting of a single strand of positive-sense RNA of 7.4–8.3 kb in length. Based on amino acid homology of the viral capsid protein, the *Norovirus* genus can be further subdivided into five genogroups.

Positive-sense RNA Single-stranded RNA molecule that can be translated directly, without need for modification.

Reverse transcription-quantitative polymerase chain reaction (RT-qPCR) A modification of the DNA amplification method qPCR intended to be applied to RNA. This is accomplished by preceding the qPCR with a RT step that produces a double-stranded DNA copy of the RNA. RT-qPCR is a commonly used method to detect the genomes of human enteric viruses, as these typically consist of single-stranded RNA.

Virus A small infectious agent that can only replicate in a live host cell, i.e., an obligate intracellular pathogen. Viruses consist of one or more nucleic acid molecules (genome) surrounded by a protective protein coat (capsid); some viruses are further surrounded by a lipid bilayer or envelope.

Introduction

Human enteric viruses are the most common cause of foodborne illness worldwide. These viruses comprise a functional, rather than taxonomic group, almost all of which are nonenveloped (lacking a lipid outer layer) and transmitted by the fecal–oral route. From an epidemiological perspective, human noroviruses (HuNoV) are now considered the most important of the foodborne viruses, causing 58% of foodborne illnesses of known etiology in USA. Hepatitis A virus (HAV) is also important as it causes perhaps the most severe of the viral foodborne diseases. There are other important viruses that can be transmitted by foodborne routes, although their significance is less well characterized.

Viruses are obligate intracellular parasites that require the metabolic machinery of the host cell to replicate. They are tissue tropic (enteric viruses infect the gastrointestinal tract) and species specific, so human enteric viruses infect humans but not other animals, and vice versa. Enteric virus particles are shed in extremely high numbers in the feces of infected individuals, and hence their transmission is usually due to the fecal–oral route. However, epidemiological evidence suggests that NoV particles are also shed in vomitus and this may significantly increase transmissibility of these viruses, especially if virus particles become aerosolized during vomiting events. In general, enteric viruses are highly infectious and typically disease can be caused by a small number (perhaps 10–100) of infectious virus particles.

Human enteric viruses are spread in a number of ways: by person-to-person contact; through contact with contaminated inanimate objects (fomites); or by consumption of contaminated food or water. Most cases of foodborne viral disease are caused by consumption of foods that have been handled or prepared by infected food handlers who have not practiced adequate hygiene, particularly after using the restroom. Contamination can also occur preharvest, as a consequence of exposure to human feces (sewage) during irrigation or fertilization of fresh produce, or during production of molluscan shellfish.

Although the disease caused by the common foodborne viruses is rarely life threatening, the sheer volume of cases places severe burden on the public health system. This article will summarize the early days of food virology, outline key characteristics of important and emerging foodborne viruses, and discuss epidemiological surveillance and control of these important agents of foodborne disease.

The History of Food Virology

Poliovirus was the first enteric virus to be widely recognized, causing foodborne disease outbreaks in the early 1900s associated with the consumption of contaminated raw milk. Raw milk outbreaks of poliomyelitis continued until the 1950s, when an effective vaccine was introduced. Molluscan shellfish-associated outbreaks of hepatitis were also reported in the 1950s and 1960s. The cause of this disease was HAV, which was identified as an enterically transmitted infectious agent when Dr. Saul Krugman intentionally fed mentally disabled children purified fecal extracts prepared from symptomatic patients; the children subsequently developing classic hepatitis symptoms. During the same era, foodborne outbreaks of nonbacterial gastroenteritis were recognized and although a viral etiology was suspected, it remained difficult to confirm.

This changed when, in 1972, Dr. Albert Kapikian identified the first virus to be associated with acute nonbacterial gastroenteritis. Appropriately named 'Norwalk virus' because of its association with an outbreak in Norwalk, OH, in USA, this virus was the first of many that would ultimately be identified as members of the genus *Norovirus* (*NoV*) within the Caliciviridea family. Electron microscopy was used to identify the Norwalk virus, and this method, which requires virus loads $>10^6$ particles per g of stool, is still used to this day.

The absence of culture methods for both HuNoV and HAV was a major impediment to further study of these agents. In 1987, Dr. Theresa Cromeans developed a method to propagate HAV, ushering in a new era for studying this virus. This method, as well as cultivation methods for the vaccine strain of poliovirus, eventually allowed for the quantification of infective virus plaque forming units and facilitated studies on detection and control of enteric viruses in water and foods, with a particular focus on molluscan shellfish. Dr. Dean Cliver, who served as a professor at the University of Wisconsin in Madison and at the University of California in Davis, provided much of the foundation on which current principles in food virology are based.

In 1990, Dr. Mary Estes team at Baylor College of Medicine sequenced the full Norwalk virus, and many other NoV genomes have been characterized since then. With knowledge of nucleic acid sequence and the rapid adoption of molecular biological methods, scientists were suddenly presented with new tools to study human enteric viruses. Particularly important was the nucleic acid amplification method polymerase chain reaction (PCR), which was readily adapted to the detection of RNA viruses by preceding PCR with a reverse transcription (RT) step, hence the designation RT-PCR. Conventional RT-PCR methods, followed by Southern hybridization were quickly developed for the detection of these viruses in clinical (fecal) samples and foods, particularly molluscan shellfish. These were later replaced by more rapid and sensitive quantitative real-time RT-PCR (RT-qPCR) methods.

Although promising, the utility of these molecular amplification methods for virus detection in food and environmental samples was limited by low levels of contamination; high levels of matrix-associated inhibitory substances that interfered with nucleic acid amplification; and the lack of broadly reactive primers and probes for HuNoV. In addition, the development of an *in vitro* cultivation system for HuNoV has remained elusive. Cultivable surrogate viruses (e.g., feline calicivirus and murine norovirus) have been used in a variety of studies but their behavior does not always mimic that of HuNoV. These impediments to the study of HuNoV continue to this day.

The epidemiological importance of HuNoV came to the forefront in 1999 when Mead *et al.* (1999) suggested that viruses, not bacteria, were the leading cause of foodborne illness of known etiology. This study prompted expanded epidemiological surveillance activities in Europe. The Mead *et al.* (1999) publication, along with some high profile outbreaks in the late 1990s and early 2000s, also focused attention on foods other than molluscan shellfish as significant causes of foodborne viral gastroenteritis. In fact, we now know that foods such as salads, bakery products, and sandwiches are responsible for more NoV and HAV infections than are molluscan shellfish. Fresh produce (berries and green onions) have also emerged as important vehicles of infection. The association of disease with foods such as these suggest that the hands of infected food handlers are arguably the most common source of the virus contamination for many if not most foods. Recent epidemiological data continue to support the fact that viruses, particularly HuNoV, are the most common cause of foodborne disease of known etiology in USA.

HuNoV

HuNoV are the most common cause of acute gastroenteritis in industrialized countries. Scallan *et al.* (2011b) estimate that these viruses are responsible for approximately 58% of foodborne disease of known etiology in USA. This amounts to 5.5 million infections per year, resulting in approximately 50 000 hospitalizations and 300 deaths. These numbers reflect only those diseases of known etiology; if foodborne disease of unknown etiology were included, as well as other transmission routes, these estimates would be staggeringly high. For example, of the more than 170 million cases of gastroenteritis that occur in USA each year, the etiology of only about one-fifth of them is confirmed, leaving an estimated 140 million cases of gastroenteritis caused by unspecified agents. Owing to the frequency of NoV infection, it is likely that a large proportion of these are also caused by HuNoV. Similar data are available from Europe.

The taxonomy of NoV has changed substantially over the past 15 years, and what was originally called the 'Norwalk-like' virus group is now classified as the *NoV* genus, one of four genera within the Caliciviridae virus family. The other genus in this family causing disease in humans is *Sapovirus*, also shown to cause gastroenteritis. HuNoV are a nonenveloped icosahedral

viruses approximately 27 nm in diameter and having a genome consisting of a single strand of positive-sense RNA of 7.4–8.3 kb in length. The genome encodes three open reading frames (ORF); ORF1 encodes a nonstructural polyprotein that contains the genes for p48, NTPase, p22, VPg, protease, and RNA polymerase; ORF2 encodes the viral capsid protein; and ORF3 encodes a small basic structural protein of unknown function.

Based on nucleic acid sequence analysis, the *NoV* genus can be further classified into five genogroups, designated GI, GII, GIII, GIV, and GV, based on >60% amino acid homology of the viral capsid protein. Human infections are caused almost exclusively by genogroups GI and GII, with the vast majority caused by GII strains. Each genogroup can be further classified into genotypes, based on a >80% amino acid homology in the capsid protein. Currently, 8 GI strains and 19 GII strains have been identified. The genetic cluster GII.4 is the most significant of the genotypes, having predominated in outbreaks around the world for over a decade. However, strains other than GII.4 are most often the cause of foodborne disease outbreaks.

Outbreaks of NoV have involved food products including molluscan shellfish, fresh fruits and vegetables, and 'ready-to-eat' (RTE) foods. Epidemiologically speaking, it appears that RTE foods are the most common cause of foodborne NoV outbreaks, although high-profile outbreaks have occurred in produce items such as berries. In healthy adults, the incubation period for NoV infection ranges from 24 to 48 h, with symptoms lasting 12–72 h. The disease is gastrointestinal in nature, typically presenting with vomiting (hallmark symptom), diarrhea, and abdominal cramps that may or may not be accompanied by fever. In certain at-risk groups, particularly the elderly, NoV infection can result in a much more severe disease, with symptoms lasting as long as 6 weeks. The hospitalization rate for HuNoV infection is estimated to be 0.03% and the mortality rate is less than 0.1%. Nonetheless, the shear numbers of cases make these viruses one of the leading causes of foodborne disease hospitalizations and deaths. No antiviral strategy exists for prevention or treatment of NoV illness. As is the case for all enteric diseases, infected individuals should be treated to maintain hydration and electrolyte balance.

Although some immunologically based commercial methods are available for detection of HuNoV in clinical samples, they are licensed in only some parts of the world. This is largely because of poor sensitivity due to the lack of broadly reactive antibodies that will detect all HuNoV strains. The high degree of genetic diversity for the NoV has historically complicated the development of broadly reactive RT-qPCR methods. Four 'regions' of the NoV genome have been used for primer design (designated regions A, B, C, and D). These regions are generally conserved among HuNoV strains of the same genogroup. The ORF-1–ORF2 junction (just downstream of region B) seems to be the most conserved and is frequently used for genogroup-specific detection. For strain comparison (as might be appropriate in outbreak investigation), primers corresponding to the NoV capsid region (region D) are usually used. Commercial RT-qPCR method detection methods are available for use in the food and environmental sector, but in all cases, substantial sample preparation to concentrate the viruses and remove the sample matrix is required before the application of RT-qPCR for detection. Taken together, HuNoV detection in clinical, food, and environmental samples is not done routinely and there are wide regional variations in protocols. This highlights the need for standardized methods of detection and consistency of surveillance and disease reporting across countries.

HAV

HAV is a 27–32 nm, nonenveloped, positive-sense single-stranded RNA virus with a 7.5-kb genome and capsid having icosahedral symmetry. This virus is classified in the Picornaviridae family under the genus *Hepatovirus*. Unlike other RNA viruses, the HAV genome is highly conserved, with only 1–4% amino acid variation. Human isolates of HAV comprise a single serotype, but sequence heterogeneity within the VP1/2A can be used to differentiate HAV into seven unique genotypes. Of these seven genotypes, genotypes I and III predominate in human disease. Transmitted primarily by contact with the blood of infected individuals or through male homosexual relations, only approximately 5% of HAV cases are foodborne, with transmission almost always in keeping with the fecal–oral route. Once infected, the disease incubation period averages 4 weeks (range of 2–6 weeks). Disease initially presents with a prodrome that includes fever, headache, nausea, vomiting, and diarrhea. These symptoms progress 1–2 weeks later into inflammation of the liver and jaundice. Hospitalization occurs in 31.5% of cases, with mortality rates estimated at 2.4%. Infected young children are frequently asymptomatic, while disease severity increases with age. Hepatitis A infection is endemic in developing regions of the world, and foods imported from third world countries where sewage treatment and hygiene advancements are still developing pose an increased risk to naive consumers in developed countries.

Like NoV, outbreaks of HAV have involved food products including molluscan shellfish, fresh fruits and vegetables, and RTE foods. For example, in 1988 approximately 300 000 people in China contracted HAV from consuming partially cooked clams that had become contaminated by release of raw sewage in the proximity of the harvest area. Within the fresh produce category, products such as raspberries, strawberries, lettuce, and green onions have caused outbreaks, some quite sizable. A good example is the 2003 US outbreak when green onions served at a single Pennsylvania restaurant resulted in more than 600 HAV cases, with 124 hospitalizations, and 3 deaths. Fresh produce most likely becomes contaminated by the use of human sewage-contaminated irrigation water, because of human defecation in production fields, and/or from the hands of infected food handlers during harvest or preparation phases of the farm-to-fork continuum. Still, the most common cause of HAV foodborne outbreaks in general is poor personal hygiene of infected food handlers. Fortunately, an effective vaccine that provides lifelong immunity is now available suggesting that as the immunized population grows the disease will eventually go the route of poliovirus, although it may take decades before this is realized.

Because HAV has a degree of genetic and antigenic homogeneity, its detection is much easier than that of HuNoV. Clinical assays that detect antibodies against HAV are commercially available, and for food and environmental samples,

RT-qPCR using primers targeting the highly conserved VP1/2 A junction or 5′ untranslated region of the viral genome are used. As is the case for NoV, substantial preanalytical sample processing must be done when applying these methods to complex sample matrices and this remains the limiting factor in the routine detection of HAV in foods.

Rotaviruses

Rotaviruses are the leading cause of infantile diarrhea worldwide and are responsible for more than 500 000 deaths annually, the majority of which occur in developing countries. These viruses are 70–75 nm in diameter and contain 11 segmented double-stranded RNA molecules encased in a double-layered protein coat of icosahedral symmetry. The 11 genome segments range in size from 667 bp (segment 11) to 3302 bp (segment 1), for a total of 18.5 kb. Each of the segments encodes a single protein, with the exception of segments 9 and 11 which encode two proteins. A total of six structural viral proteins form the virus particle (termed VP1, VP2, VP3, VP4, VP6, and VP7), whereas a further five nonstructural proteins (termed NSP1–NSP5) are responsible for RNA replication, packing, and other functions. Interestingly, NSP4 is an enterotoxin that induces diarrhea. At least seven different rotavirus groups exist (A–G) based on VP6 reactivity with monoclonal antibodies.

Waterborne and person-to-person transmission are the most common causes of rotavirus infection; however, transmission via food products has been documented, with infant populations under 5 years of age most often affected. The incubation period preceding disease is approximately 2 days, and symptoms of disease include vomiting, diarrhea, and fever; dehydration is the most common cause of death. Hospitalization rates in USA are estimated at 1.7%, with a mortality rate of less than 0.1%. The World Health Organization (WHO) now recommends the use of second generation rotavirus vaccines worldwide in an attempt to reduce the burden of disease in developing countries.

Emerging Foodborne Viruses

A number of enteric viruses have the capacity to be transmitted by foodborne routes, although this is rarely documented or has not yet occurred. A few of these are described briefly in this section.

Hepatitis E virus (HEV)

HEV is a positive-sense single-stranded RNA virus that is transmitted via the fecal–oral route, generally through the consumption of water and sometimes food that has become contaminated with human feces. This virus is endemic in developing countries, particularly those locations having hot climates. Large waterborne outbreaks have been recorded in many countries, and it is also possible that the virus is transmitted by the consumption of raw or undercooked pork and deer meat. Interestingly, cases of HEV have recently been reported in USA, UK, and Japan, leading to speculation that the geographic range of this virus is increasing and that HEV may become an emerging food and waterborne pathogen in the developed world.

The incubation period for HEV infection ranges from 3 to 8 weeks, with disease symptoms generally lasting several weeks. Frank disease occurs more often in adults, with children often spreading the infection without displaying symptoms. Clinical symptoms are very similar to those of HAV infection, but unlike HAV, the disease is quite severe in pregnant women for whom mortality is approximately 20%. Clinical diagnosis of HEV involves detecting antibodies specific to the virus in the blood of patients displaying the symptoms of hepatitis, or by RT-PCR.

Other Human Enteric Viruses

Other human enteric viruses also have the potential to be transmitted by contaminated food products, although their epidemiological significance is not well understood. The human enteroviruses, including poliovirus, coxsackie, and echoviruses, are nonenveloped particles containing single-stranded positive-sense RNA, with particle diameter of approximately 27 nm. Poliovirus has been all but eradicated in the developed world, coxsackie and echoviruses, which cause a variety of symptoms that can range from gastroenteritis, neurological, and skin manifestations, can be transmitted by foodborne routes, albeit infrequently. Like HuNoV, they are resistant to harsh conditions, making them environmentally persistent.

Astroviruses are 28 nm single-stranded RNA viruses with a star-shaped capsid structure. These viruses cause sporadic disease and outbreaks of diarrhea in children and the elderly, particularly in venues such as day care centers and hospitals. Transmission of these astroviruses by food is uncommon but has been documented for molluscan shellfish. Human adenoviruses are nonenveloped double-stranded DNA viruses that range from 80 to 110 nm in diameter. They can cause gastroenteritis, conjunctivitis, and most frequently, respiratory symptoms. The presence of these viruses in environmental samples such as wastewater, sludge, and drinking water has been reported, and for this reason, their use as an indicator for the presence of human enteric viruses has been proposed. However, the transmission of adenoviruses by foodborne routes has not yet been documented.

Nipah Virus

Nipah viruses belong to the genus *Henipavirus* in the family Paramyxoviridae, and are relatively large (120–150 nm diameter), enveloped, single-stranded RNA viruses. The Nipah virus was first recognized in 1999 in Malaysia in association with pig farmers who contracted the disease by contact with infected animals. It can also be transmitted by person-to-person contact and can be carried by fruit bats. There have been recorded outbreaks where the vehicle of infection was fruits and vegetables contaminated with the saliva of bats. Other outbreaks have involved direct contact with contaminated pigs or their tissues. Disease symptoms usually include

fever, headache, muscle pain, vomiting, and sore throat. These can progress to pneumonia and other respiratory illnesses. In severe cases, seizure and encephalitis can occur, often resulting in death. Currently, there is no vaccine or treatment for Nipah virus infection, so control of foodborne disease relies on cleaning and disinfection of pig farms, culling animals suspected of being infected, and controlling bat populations.

Highly Pathogenic Avian Influenza (HPAI) Viruses

HPAI viruses are large (300 nm diameter), negative sense RNA viruses having a segmented genome and belonging to the Orthomyxoviridae family. Domestic and wild birds are the major reservoir for these viruses. There are virtually hundreds of HPAI strains, however, only four have been shown to cause infection in humans; H5N1, H7N3, H7N7, and H9N2. Disease in humans is typically mild, except for the H5N1 virus, which has been responsible for a number of human deaths following outbreaks. The potential for spread of this virus through the food chain has been of concern because the virus appears to survive on imported meat. There is also concern for the risk of fecal contamination of water that is subsequently used in production agriculture or even for food preparation. However, it has been documented that HPAI is susceptible to thermal processes, meaning that the consumption of properly cooked food poses little risk for HPAI infection.

Coronavirus

Coronaviruses are enveloped viruses with positive-sense single-stranded RNA that belong to the family Coronaviridae. The coronavirus that causes sudden acute respiratory syndrome (SARS-CoV) was first recognized as a human pathogen in 2002 in association with an outbreak in China. The virus was subsequently detected in more than 30 other countries, infecting more than 8500 people with a 10% mortality rate. Although generally thought to be spread exclusively by respiratory routes, there is evidence that SARS-CoV can replicate in the small and large intestines, causing diarrhea that results in fecal shedding of the virus. Thus, the fecal–oral transmission route cannot be excluded. However, SARS-CoV are sensitive to fairly mild heat treatment and commonly used disinfectants, suggesting that attention to proper food handling and preparation measures should control foodborne transmission of the virus. Taken together, the spread of SARS-CoV via contaminated food products remains possible but is now considered unlikely.

Lassa Virus (LV) and Hantavirus (HV)

LV and HV are RNA viruses that belong to the Arenaviridae and Bunyaviridae families, respectively. LV, which is endemic in sub-Saharan Africa, causes a viral hemorrhagic fever; HV initially presents as a flu-like syndrome that can progress to severe pulmonary disease. The natural reservoir for both of these viruses is the mouse, and although rare, food can potentially be a vehicle of infection if it becomes contaminated with urine and/or feces of mice.

Epidemiological Surveillance and Burden of Disease

The US Centers for Disease Control and Prevention (CDC) conducts surveillance of foodborne disease outbreaks, including those caused by HuNoV and HAV, through the National Outbreak Reporting System (NORS). Because the program relies on individual states reporting their data, which is quite variable, the database is incomplete. The NORS system provides some important information that can be used relative to epidemiological attribution estimates, but it only reports on epidemic disease. In the absence of routine clinical diagnostics, it is very difficult to get estimates for endemic HuNoV disease. The CDC has also recently launched CalciNet, a national HuNoV sequence database that may eventually have utility similar to that of the PulseNet system for bacterial foodborne pathogens.

Surveillance for HuNoV illness in Europe has been done by the European Centre for Disease Control and Prevention (ECDC) and the Foodborne Viruses in Europe (FBVE) Network. In Australia, the notification of individual NoV infections is not required, however, the reporting of two or more infections having a time, place, and/or person association, suggesting an outbreak, is required.

In many other countries, foodborne viral disease surveillance is not conducted, making it difficult to estimate the global impact of disease. In a UK study, it was estimated that only 1 in 1562 HuNoV infections was actually reported. This is not surprising due to the mild nature of most infections and the lack of routine clinical diagnostics. Of particular interest is the proportion of HuNoV infections that are caused by contaminated foods as compared to other transmission routes. Getting at these estimates will undoubtedly require targeted epidemiological efforts such as active surveillance and/or case control studies, both of which are expensive and time-consuming. Further, until standardized reporting at the country and international level is established, the true burden of foodborne viral disease will remain unknown.

Control of Foodborne Viruses

As obligate intracellular parasites, enteric viruses cannot replicate in foods or water. In general, if wastewater is adequately treated through primary, secondary, and tertiary steps, and including chlorination, the risk of viral contamination is minimal. When it comes to foods, many measures classically applied to control bacterial growth are not very effective against viruses. For example, exposure to extremes of pH (2.0–10.0) and water activity will have little or no effect on the infectivity of enteric viruses. Refrigeration and freezing actually help to preserve virus infectivity. The efficacy of standard thermal inactivation treatments is dependent on the food matrix and virus studied. As a general rule of thumb, NoV and HAV appear to be less sensitive to heat than are typical Gram-negative bacteria, and more sensitive to heat than spores. High hydrostatic pressure has been recognized as an emerging processing technology for inactivating viruses in molluscan shellfish, however, similar to thermal inactivation, the effectiveness of the treatment is variable and virus specific. Enteric viruses are also notably resistant to ionizing radiation.

Many studies have demonstrated the ability of enteric viruses to survive on abiotic surfaces commonly found in food processing and preparation environments, including stainless steel, aluminum, and polystyrene. Viruses also persist in foods, having been found to survive in shellfish for weeks or months and on the surface of fresh produce for days to weeks. To make matters worse, it is well documented that many common sanitizers used in food processing environments have poor efficacy against nonenveloped enteric viruses, at least when used at manufacturer-recommended concentrations.

It is for this reason, current control measures focus on the prevention of contamination, rather than treatments to inactivate viruses after a contamination event has occurred. The central tenets of control are good hygiene practices in food processing and handling environments, and prevention of contamination in the preharvest environments. Because the decontamination of hands and surfaces in food processing and preparation is critical to preventing virus contamination, an important effort is assuring effective hand decontamination. The best method remains the traditional soap and water wash followed by towel drying. Commercial alcohol-based hand sanitizers should not be used in place of adequate hand washing. Of course, hand washing compliance in retail, institutional, and home settings remains a challenge and must be continuously advocated. There has been interest in further promoting the need for infected food handlers to report illness symptoms and abstain from work during periods of time in which they are actively shedding virus. However, the latter may be difficult in light of emerging evidence suggesting that shedding of HuNoV may persist for weeks after symptom resolution. Adequate cleaning and disinfection of surfaces is also important to preventing virus contamination of foods, but the availability of disinfecting agents with specific activity against the nonenveloped enteric viruses is a pressing need. Also needed are better microbiological indicator systems that have a more direct correlation with virus contamination of water in production environments, as the fecal coliforms and *Escherichia coli* remain poor indicators for this application. This is particularly relevant for molluscan shellfish and fresh produce production.

Conclusion

Food virology is a relatively young field, at least from the perspective of food safety. The development of molecular techniques during the 1990s, in combination with increased epidemiological surveillance, have raised awareness of the importance of viruses to foodborne illness. Although methodological advancements have been made, much still remains unknown. The lack of a culture system for HuNoV is probably the single most important limiting factor to studying and controlling these viruses. With availability of such a method, or in its absence, availability of better cultivable surrogates or more sensitive detection methods for complex sample matrices, scientists would be able to tackle the challenges associated with trying to control foodborne viruses. Likewise, the availability of routine clinical assays would result in greater awareness of these diseases and improvements in reporting and epidemiological surveillance. The field of food virology is set to grow rapidly in the coming years as scientists tackle these problems with the aid of developing technologies.

DISCIPLINES ASSOCIATED WITH FOOD SAFETY

Epidemiology

E Scallan, Colorado School of Public Health, Aurora, CO, USA

Glossary

Agent A factor that is essential for a disease to occur.
Endemic A disease that is habitually present within a given geographic area.
Epidemic The occurrence of a group of illnesses in a community or region, which are of similar nature and clearly in excess of normal expectancy and derived from a common or from a propagated source.
Epidemic curve A histogram that shows the course of an outbreak or epidemic by plotting the number of cases of a disease by the date or time of illness onset.
Epidemiologic triad The traditional model of infectious disease causation, which has three components: an external agent, a susceptible host, and an environment that brings the host and agent together so that the disease occurs.
Host A person or other living organism that is susceptible to an infectious agent under natural conditions.
Pandemic A worldwide epidemic.
Portal of entry A pathway by which an agent enters the host allowing it to multiply or act.
Portal of exit A pathway by which an agent can leave its source or reservoir.
Prospective study An epidemiologic study in which the groups of individuals (cohorts) are selected on the bases of factors that are to be examined for possible effects on some outcome.
Retrospective study An epidemiologic study in which participating individuals are classified as either having disease or other outcome (cases) or not having the disease or outcome (controls) and the persons' histories are examined for specific factors that might be associated with that outcome.

Introduction

Epidemiology is the study of patterns of disease in the population. Foodborne diseases often have seasonal and geographic patterns, are reported disproportionately among people with certain demographic characteristics, or are associated with eating specific foods. By understanding these patterns, we can learn about the factors that affect the disease occurrence. This understanding provides critical information that can help direct prevention and control efforts. This article describes the science of epidemiology and its importance to food safety and the study of foodborne disease.

Disease Transmission

Epidemiologists view disease as the result of complex interactions between an agent, a host (person or other living animal), and an environment, which includes food and water, as illustrated by the epidemiologic triad (Figure 1). The agent can be a bacteria, virus, parasite, or a toxin that causes disease by infecting or injuring the host. The presence of the agent is essential but whether disease occurs also depends on characteristics of the agent, host, and environment. For example, the amount of toxin or number of microorganisms ingested (infective dose), the ability of the agent to produce disease (pathogenicity), and the degree of pathogenicity (virulence) will influence the occurrence and severity of disease. Host factors, such as age and ethnicity, influence exposure to disease, whereas other factors, such as the host's immune status, can influence host susceptibility and disease severity. Environmental factors are extrinsic factors that affect both the agent and the opportunity for exposure and may include: physical factors, such as climate, geology, and physical surroundings (e.g., childcare center and nursing home); and

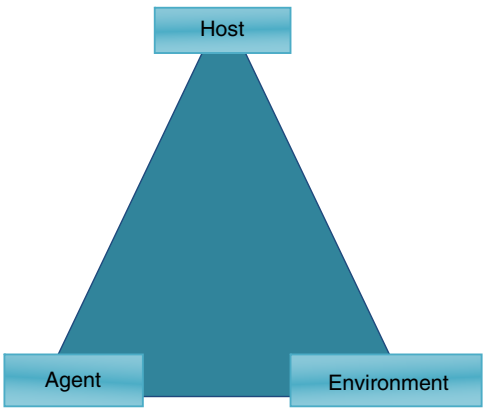

Figure 1 Epidemiologic triad.

socioeconomic factors, such as crowding and sanitation. When studying the distribution and causes of a disease in a population, it is important to consider all the three components of the epidemiologic triad and how they interact with the disease under investigation. Some key epidemiologic concepts related to disease transmission are described in the following sections.

Modes of Transmission

The mode of transmission is the mechanism by which an agent interacts with the host. Infectious agents can be transmitted directly from one person to another or indirectly by a vector (e.g., a fly or other insect) or through a vehicle, such as food or water. Foodborne diseases are by definition transmitted by a food vehicle. However, it is important to note that many agents that cause foodborne illness may also be transmitted by other modes. Infectious foodborne agents must have a human, animal, or an environmental reservoir to live. Because many involve the gastrointestinal tract, causing diarrhea or other gastrointestinal symptoms, they typically leave the human or animal reservoir through the feces (portal of exit) and are ingested (portal of entry) by the host via contaminated food.

Incubation Period

An incubation period is the time between infection or contact with the agent and the onset of symptoms or signs of infection. The incubation period for foodborne diseases can range from hours for bacterial food intoxications (e.g., *Bacillus cereus* and staphylococcal enterotoxins) to days for infectious agents (e.g., *Salmonella* and *Escherichia coli* O157) or weeks (e.g., Hepatitis A virus, *Listeria monocytogenes*, and *Toxoplasma gondii*) and even years for cancer-causing chemicals or toxins. Infectious diseases typically require an incubation period that allows for the multiplication of the agent to a threshold necessary to produce symptoms. Variation in the incubation period may occur for a variety of reasons, including the dose and rate of replication of the organism.

Disease and Carrier States

People who are infected often show clinical symptoms, such as diarrhea or vomiting, whereas some may be asymptomatic showing no obvious sign or symptoms of disease. The term 'carrier' is used to describe a person who is infected by a pathogen and is capable of disseminating that pathogen but shows no signs of clinical disease. Asymptomatic carriers infected with a foodborne pathogen who handle food present an important threat to public health and may shed organisms intermittently over a long period of time.

Patterns of Disease

Epidemiologists classify three patterns of disease – endemic, epidemic, and pandemic. A disease is endemic if it is habitually present within a given geographic area. An epidemic is the occurrence of a group of illnesses in a community or region, which are similar in nature and clearly in excess of normal expectancy and derived from a common or from a propagated source. A pandemic refers to a worldwide epidemic.

Disease Outbreaks

The term outbreak is synonymous with the term epidemic, although the former is used more frequently and can refer to more localized epidemics. The term cluster may also be used when describing a group of cases that are clustered in time or place but require further investigation to determine if they constitute an outbreak. If a group of people become ill after eating the same contaminated food, the outbreak is referred to as a 'common-vehicle exposure.' In these outbreaks, there is a sudden and rapid increase in the number of cases among the people exposed, followed by a more gradual decline. A histogram, called an epidemic curve, is used to show a disease outbreak by plotting the number of cases by the time of symptom onset (Figure 2). The index case is the first person who indicates the existence of an outbreak, whereas a primary case is any person who acquires the disease directly from the contaminated food. Secondary cases acquire the disease from exposure to a primary case and may result from a foodborne

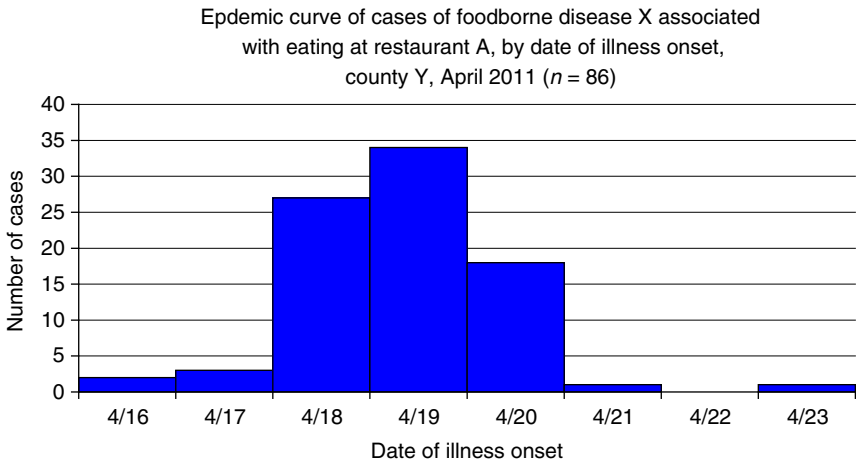

Figure 2 Example of epidemic curve.

outbreak if the pathogen can also be transmitted from one person to another (e.g., *E. coli* OI57).

Measures of Disease Occurrence

To describe the patterns of disease, epidemiologists use standard measures of disease occurrence. Each measure is calculated by dividing a numerator (counts of cases) by a denominator (population at risk), where the population at risk is defined as the population considered capable of acquiring the particular disease within the population being studied. A clear case definition and a good understanding of the population at risk are essential when calculating measure of disease occurrence. Cases of foodborne disease are usually defined using laboratory-based criteria (e.g., culture-confirmed cases of *Salmonella enteritidis*), although clinical criteria (i.e., signs and symptoms, such as diarrhea) may be used.

Incidence Proportion

The incidence proportion (also called cumulative incidence) measures the average risk of disease in a population (ranging from zero to one) and is defined as the number of persons who develop disease divided by the total number of persons at risk. For example, if we study 1000 people (population at risk) over a 2-year period and two people are diagnosed with *Campylobacter* spp. (cases), then the incidence proportion is 2 in 1000 or 0.002 (0.2%). To get an accurate measure of the incidence proportion, it is important that all persons at risk are monitored for the entire time for which the risk is being measured. To interpret the measure correctly, it is also important to know the length of the time period over which the risk applies (e.g., 3 months or 2 years).

$$\text{Incidence proportion} = \frac{\text{Number of persons who develop disease during a time period}}{\text{Number of persons followed for this time period}}$$

The incidence proportion is called an attack rate when used in the context of infectious disease outbreaks. An attack rate may be calculated for all persons exposed during an outbreak. For example, if 30 of 100 people became ill with *E. coli* O157 after attending a church supper, the overall attack rate would be 0.30 (30%). Attack rates can also be calculated for groups with different exposures, for example, attack rates among people who ate a certain food. Another version of incidence proportion is the case-fatality rate. Here, the numerator is the number of deaths and the denominator are people who have already developed the disease, or population at risk. For example, if 2 of the 30 people with *E. coli* O157 infection die, the case-fatality rate would be 0.07 (7%).

Incidence Rate

Similar to the incidence proportion, the numerator for the incidence rate is number of persons who develop a disease. However, the denominator is not the number of persons initially followed but the total time experienced by the people being followed (person-time) during which the disease or event being studied could have occurred. Person-time can be calculated by summing the time that each person is followed for every member of the group (e.g., 100 persons followed for 2 years equals 200 person-years). The incidence rate assumes that the risk on an event is constant over the observed time interval.

$$\text{Incidence rate} = \frac{\text{Number of persons who develop disease}}{\text{Total time experienced for persons followed}}$$

The incidence rate is used for reporting data on the number of individual cases of disease (e.g., from foodborne diseases surveillance) over a specific period of time. Here, the population at risk is often estimated using census data. It is common to find incidence rates expressed as the number of cases per 1000 or per 100 000 persons in the population. Incidence rates are typically described as an annual basis. For example, in 2009, the annual incidence of culture-confirmed nontyphoidal *Salmonella* infections in USA was 14 per 100 000 population.

Prevalence

The incidence proportion and the incidence rate measure the frequency of disease onset. Prevalence (also called prevalence proportion) is a measure of disease status at a given moment in time. For example, the prevalence of nontyphoidal *Salmonella* infections is the number of people ill at a specified time point. For acute diseases of short duration such as nontyphoidal *Salmonella*, the prevalence of disease will be low even if the incidence of disease is high because most people recover from the disease within a week and are therefore no longer in a diseased state. For chronic infections, such as the parasite neurocystercercosis, the prevalence of disease is greater than the incidence. The greater in incidence or duration of disease, the more people will be effected.

$$\text{Prevalence} = \text{Incidence rate} \times \text{Average duration of illness}$$

Measures of Excess Risk

To determine if there is an association between exposure and disease, epidemiologists measure the excess risk of disease among people exposed to a certain risk factor, where risk is defined as the probability of a disease occurring. This can be done by comparing the risk of disease (e.g., culture-confirmed *Campylobacter* spp. infection) between people who were exposed to a specified risk factor (e.g., chicken) and those who were not by subtracting the risk of disease in the unexposed group from the risk of disease in the exposed group (risk difference) or calculating the ratio of disease risk among exposed and unexposed people (e.g., relative risk and odds ratio).

Relative Risk

The relative risk (also called risk ratio) is a ratio of the incidence proportion. The relative effect of a risk factor is measured by dividing the incidence proportion (or average risk of disease) in the exposed group by the incidence proportion in the unexposed group (Table 1). For example, if 23 people

Table 1 Calculating relative risks in a cohort study

Exposure (or risk factor)	*Number of people*	
	Ill persons	*Well persons*
Present	a	b
Absent	c	d
Total	$a+c$	$b+d$
Relative risk $=\dfrac{\text{Incidence proportion in exposed}}{\text{Incidence proportion in unexposed}}$		$\dfrac{(a/(a+c))}{(b/(b+c))}$

Table 2 Calculating odds ratios in a case–control study

Exposure (or risk factor)	*Number of people*	
	Cases	*Controls*
Present	a	b
Absent	c	d
Odds ratio $=\dfrac{\text{Odds of being exposed among cases}}{\text{Odds of being exposed among controls}}$		$\dfrac{(a/c)}{(b/d)}=\dfrac{ad}{bc}$

became ill with campylobacteriosis after attending a church supper, including 20 of 50 people who ate chicken and 3 of the 30 people who did not eat chicken, then the relative risk of illness among chicken eaters (exposed) compared with nonchicken eaters (unexposed) is $(20/20+30)/(3/3+27)$ or 4, meaning that the people who ate chicken were 4 times more likely to become ill than the nonchicken eaters. A relative risk of 1 means the exposed and unexposed people were equally likely to develop disease, whereas a relative risk less than 1 indicates that the exposure was protective against the disease. The rate ratio is a similar measure that uses the incidence rate rather than the incidence proportion.

Odds Ratio

The odds ratio is a relative measure of association typically used in case–control studies. It compares the odds of being exposed among cases (persons with disease) with the odds of being exposed among controls (persons without disease) (Table 2). For example, if we interview 50 people with campylobacteriosis (cases) and 20 confirm that they ate chicken in the week before illness onset compared with only 10 of 50 controls, then the odds ratio is $(20/30)/(10/40)$ or $(20\times 40)/(10\times 30)$ or 2.7. Therefore, cases were 2.7 times more likely than controls to have eaten chicken. Like a relative risk, an odds ratio of 1 indicates no association and less than 1 indicates that the exposure was protective.

Causal Inference

It is important to note that because most epidemiologic studies are observational rather than experimental, an association between an exposure and a disease does not necessarily indicate that the exposure caused the disease. The observed association may be due to chance (random error appearing to cause an association between an exposure and a disease), bias (systematic error in the design, conduct, or analysis of a study that results in a mistaken estimate of an exposure's effect on the risk of disease), or confounding (error in the interpretation because of a third factor that is associated with the exposure and an independent risk factor for the disease). These factors need to be carefully considered in the design and analysis of any epidemiologic study before we can draw conclusions about causality.

Types of Epidemiologic Studies

Epidemiologic studies can be descriptive or analytical. Descriptive studies focus on describing people who develop disease in terms of their personal characteristics and where and when they were exposed to the agent causing disease – person (e.g., sex, age, and race/ethnicity), place (e.g., location and geography), and time (e.g., season and year). Descriptive studies have no fixed hypotheses about the relationship between exposure and disease, although the results of these studies can suggest hypotheses. Most investigations of foodborne disease begin with a descriptive study and may use existing data from surveillance, surveys, or medical records. For example, surveillance summaries often describe cases of illness by person, place, and time. In an outbreak setting, counts of illnesses are frequently organized in a line list (Table 3), which allows for a counting of cases by their various characteristics (Figure 3).

Analytical studies, unlike descriptive studies, start with a hypothesis (or hypotheses) about the association of disease with possible exposures or risk factors and the purpose of the study is to test the hypothesis. To measure excess risk, we would have to make comparisons between groups of people with and without the exposure of interest. The study design

Table 3 Example of line list

ID	*Date of birth*	*Sex*	*Ill*	*Date of illness onset*	*Fever*	*Diarrhea*	*Chills*	*Abdominal cramps*	*Vomiting*	*Headache*
1	08 April 1990	Male	Y	18 April	N	Y	Y	N	N	N

Y, yes; N, no.

Figure 3 Mary Mallon (1869–1938), nicknamed 'Typhoid Mary,' was the first person in USA to be identified as an asymptomatic carrier of typhoid fever. Over the course of her career as a cook, she infected 47 people, three of whom died from the disease.

must compare exposed and unexposed groups with similar risk characteristics and minimize the opportunity for bias or confounding. The major analytical studies used in the investigation of foodborne disease are cohort studies and case–control studies; other types of analytical studies include cross-sectional studies, case crossover, experimental, and randomized controlled trials.

Cohort Studies

Cohort studies evaluate the occurrence of disease in a carefully defined group of people. Cohort studies can be prospective or retrospective. Prospective cohort studies monitor a group or groups of persons over time for the development of disease in the presence or absence of suspected risk factors that are measured at the start of the study. The cohort is followed until the effect of the exposure occurs or until the end of the study period. Conversely, retrospective cohort studies identify a group of persons at some point in time in the past when they were presumably free of the disease under investigation. The cohort is then followed to the present. Large population-based cohort studies are typically time and resource intensive but have been used to estimate the incidence of foodborne pathogens in the community and to investigate the risk factors for the development of sequelae from foodborne disease. Cohort studies are frequently used in outbreak investigations when the outbreak has been linked to a specific group of people (e.g., wedding party or church supper). Statistical methods used in a cohort study involve the calculation of a relative risk.

Case–Control Studies

Unlike cohort studies, case–control studies begin with people who have the disease and compare their characteristics with a control group free from the disease for the presence or absence of potential risk factors. Because total population at risk is not known, case–control studies cannot be used to estimate the incidence of the disease. Advantages of case–control studies include the relatively small number of subjects and the shorter time frame needed to complete the study, which increases their suitability for the study of low-incidence diseases. Nested case–control studies are a variation on case–control studies and encompass the concept of a cohort study. In a nested case–control study, a large cohort is prospectively or retrospectively followed for the occurrence of a specific disease. These cases are then matched by age and sex with persons in the original cohort who did not develop the disease. This

approach is useful for diseases of low frequency, where analyzing the entire cohort would be overwhelming. Case–control studies have been used to examine risk factors for sporadic foodborne pathogens and are frequently used in foodborne disease outbreak investigations.

The main biases that occur in case–control studies are selection bias and recall bias. Selection bias means that cases or controls have different probability of being selected according to exposures or outcomes of interest, creating a biased measure of association. To minimize selection bias, cases should be representative and, optimally, include all diagnosed cases. Controls are selected from the same population group as cases in some symptomatic fashion (e.g., reverse directory or random digit dialing) and are usually matched to cases by age, sex, or other characteristics. Sometimes people diagnosed with a foodborne disease other than the one under study may be used as controls. Recall bias can occur when cases or controls recall exposures differently. For example, cases may try harder than controls to recall everything that they ate in the week before onset of the illness because they think what they ate might be related to their disease.

Conclusions

Epidemiology is a cornerstone of public health. It is only by gaining a rigorous and systematic understanding of patterns of disease that we are able to design rational interventions to reduce foodborne infections and improve human health. The basic tools of measuring disease occurrence and quantifying risk are through epidemiologic studies core skills with applicability to nearly all facets of foodborne disease.

DISCIPLINES ASSOCIATED WITH FOOD SAFETY

Food Safety Toxicology

FGR Reyes, University of Campinas, Campinas, Brazil
PC Binsfeld, Ministry of Health, Brasilia, Brazil

Glossary

Contaminant Any substance not intentionally added to food that is present in such food as a result of the production (including operations carried out in crop husbandry, animal husbandry and veterinary medicine), manufacture, processing, preparation, treatment, packaging, transport or holding of such food or as a result of environmental contamination. The term does not include insect fragments, rodent hairs and other extraneous matter.
Dose–response assessment Analysis of the relationship between the total amount of an agent administered to, taken up by or absorbed by an organism, system or (sub)population and the changes developed in that organism, system or (sub)population in reaction to that agent, and inferences derived from such an analysis with respect to the entire population. Dose–response assessment is the second of four steps in risk assessment.
End-point Qualitative or quantitative expression of a specific factor with which a risk may be associated as determined through an appropriate risk assessment.
Exposure assessment Evaluation of the exposure of an organism, system or (sub) population to an agent (and its derivatives). Exposure assessment is one of the steps in the process of risk assessment.
Hazard Inherent property of an agent or situation having the potential to cause adverse effects when an organism, system or (sub)population is exposed to that agent.
Risk The probability of an adverse effect in an organism, system or (sub)-population caused under specified circumstances by exposure to an agent.
Risk analysis A process for controlling situations where an organism, system or (sub)population could be exposed to a hazard. The risk analysis process consists of three components: risk assessment, risk management and risk communication.
Risk management Decision-making process involving considerations of political, social, economic and technical factors with relevant risk assessment information relating to a hazard so as to develop, analyze and compare regulatory and non-regulatory options and to select and implement appropriate regulatory response to that hazard.
Uncertainty factor Reductive factor by which an observed or estimated no-observed-adverse-effect level or other reference point, such as the benchmark dose or benchmark dose lower confidence limit, is divided to arrive at a reference dose or standard that is considered safe or without appreciable risk.

Introduction

Food safety is a public health issue, with the microbiological and chemical contamination of food being important causes of diseases. In addition to improving public health, effective food safety systems are also essential in maintaining consumer confidence in the food system, as well as to provide the basis for food trade regulation, which supports economic development. Food safety is a responsibility of everyone involved in the food chain. However, governments are responsible for providing an institutional and regulatory framework of food control. The Food and Agriculture Organization (FAO) of the United Nations, along with the World Health Organization (WHO), has played a leadership role in the development of risk analysis in food safety, which has demonstrated its capacity to improve the processes of decision making regarding food safety and the development of improvements in public health. Nevertheless, it should be mentioned that the paradigm of risk analysis is only part of an effective food safety system. Risk analysis, as defined by the Codex Alimentarius Commission is a process consisting of three components: assessment, management, and communication of risk (Figure 1).

Risk assessment is a scientific process intended to characterize the nature and likelihood of harm resulting from human exposure to agents in the environment, and provides the scientific basis for the decisions that may be taken at the stage of risk management necessary to protect human health, based on all relevant scientific data (including toxicological data), as well as identifies the uncertainties inherent to the food safety evaluation. For food, the focus is on the nature and likely harm related to the ingestion of food-associated toxicants. It consists of four steps (Figure 2).

The assessment of risk to human health resulting from exposure to food toxicants is one of the central activities of the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and the Joint FAO/WHO Meeting on Pesticide Residues (JMPR).

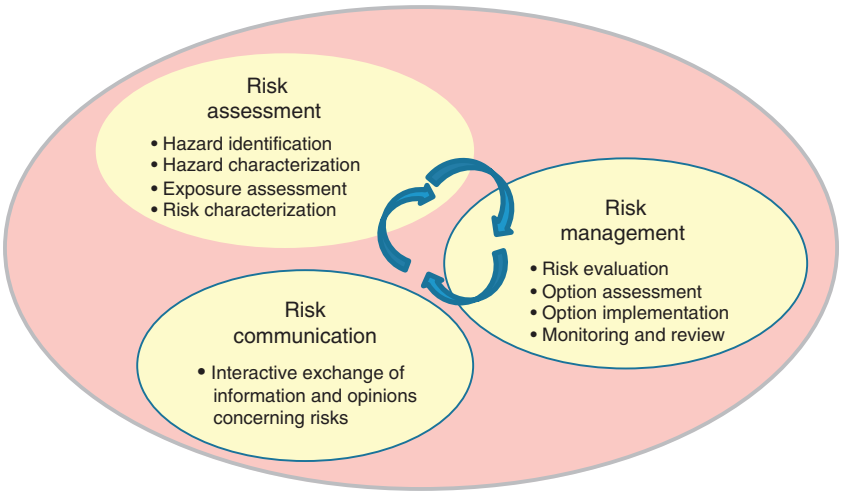

Figure 1 Components of risk analysis. Adapted from FAO/WHO (2009b).

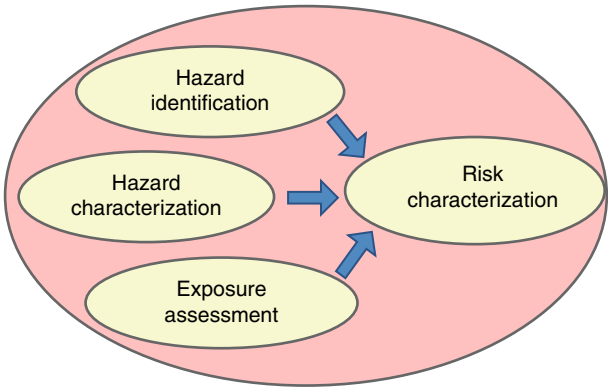

Figure 2 Steps of risk assessment. Adapted from FAO/WHO (1995) Application of risk analysis to food standards issues. *Report of the Joint FAO/WHO Expert Consultation*. Rome, Italy. Available at: http://www.fsc.go.jp/sonota/foodsafety_riskanalysis.pdf (accessed on 14 April 2013).

Classification of the Main Groups of Foodborne Toxicants

The main groups of potentially hazardous chemicals in food, including some representative examples, are shown in Table 1.

Analytical Methods and Development of Specifications

Validated analytical methods are needed for determining the concentration of food toxicants and its biotransformation products, in pharmacokinetic and toxicokinetic studies; residue depletion; and for the determination of additives, contaminants, and residues of veterinary drugs and pesticides in foods. The specifications for identity, purity, and chemical and physicochemical characteristics are essential in safety assessment of food toxicants. It must be ensured that any substance that is to be evaluated is well characterized for the presence of any impurity. It also should describe the manufacturing process of the target substance. It is worth mentioning that the safety assessment is only valid for products that do not differ significantly in their identity and quality profile used to generate confident data.

When necessary the form of application and distribution of residues that result from each application mode (e.g., pesticides and veterinary drugs) should be determined. For veterinary drugs the depletion of residues should be studied in each species, as well as, in the edible tissue and food of animal origin.

Toxicological Preclinical and Clinical Studies

The toxicological studies for hazard identification and characterization can be divided into:

- *In silico* studies: performed to denote computer simulations that model a laboratory or natural process.
- *In vitro* studies: performed in laboratory cultured cells, tissues, or organs of animals or humans.
- *In vivo* studies: performed in laboratory animals or humans.

These studies are applied in hazard identification, definition of the exposure conditions necessary to observe the adverse effects, and in the dose–response evaluation (hazard characterization). Both JECFA and JMPR consider the data from *in vitro* and *in vivo* studies for risk assessment. However, despite the recent advances in *in vitro* studies, these approaches do not currently allow the replacement of animal testing for most of the adverse effects of concern (endpoints). No animal species is an ideal experimental model; there are evidences that preclinical studies generally provide an effective evaluation of the toxicity potential of the toxicants, as well as provide data for a critical interpretation. Further, all studies used in risk assessment of food toxicants shall be conducted in accordance with the principles of good laboratory practice.

Table 1 Main groups of foodborne toxicants

Agricultural chemicals: insecticides, herbicides, fungicides, and fertilizers
Veterinary drugs and feed additives: antibiotics, hormones, and other veterinary drugs
Environmental and industrial pollutants: arsenic, selenium, fluorine, mercury, radionuclides, polychlorinated biphenyls, polychlorinated dibenzodioxins and dibenzofurans, and polybrominated biphenyls
Chemicals migrating from packaging materials and containers: lead, tin, copper, and zinc
Unintentional toxicants from food processing: polycyclic aromatic hydrocarbons; alcohols; bacterial toxins; biogenic vasoactive amines; nitrates, nitrites, and nitrosoamines; acrylamide; chlorinated propanols; phthalates; and bisphenols
Mycotoxins: aflatoxins, ochratoxins, sterigmatocystin, zearalenone, fumonisins, trichothecenes, patulin, citrinin and citreoviridin, ergot toxins, and many other mycotoxins
Bacterial toxins: staphylococcal enterotoxins, *Clostridium botulinum* toxins, *Bacillus cereus* toxins, Bongkrek acid
Endogenous plant toxicants: lectins or hemaglutinins, ricin, enzyme inhibitors, alkaloids, cyanogenic glucosides, phytoestrogens, glucosinolates, coumarin, thujones, anisatin, toxic amino acids, toxic lipids, oxalates, fluoroacetates, bracken toxins, saponins, grayanotoxin, and mushroom toxins
Animal endogenous toxins: prions, phytanic acid, avidin, and tetrodotoxin (puffer fish poisoning)
Food additives: natural and artificial colorants, artificial sweeteners, acidulants, anticaking agents, antimicrobial agents, antioxidants, emulsifying agents, sequestrants, stabilizers, flavorings, and others

The safety evaluation is not a standardized process. Thus, not all toxicological tests must compulsorily be conducted. In general, pharmacokinetic studies (absorption, distribution, metabolism, and excretion) of a substance are important to the extent that they assist in the selection of species to be tested and the choice of doses for toxicity studies. The short- and long-term tests are performed to assess systemic toxicity. They identify target organs for toxicity and may indicate the need for additional or more specific tests (e.g., neurotoxicity or immunotoxicity). The effects of the test on a range of parameters indicative of toxicity are assessed, including observational, functional, biochemical, and pathological parameters. Generally, studies are conducted in two species, one rodent and one nonrodent, or in two rodent species, and in both the sexes to maximize the chance to verify any effect (hazard identification). Often, the tests also include long-term carcinogenicity tests in two species of rodents. Preferably, testing should be conducted in a manner that best relates to the scenarios of human exposure. The choice of dose should take into account anticipated human exposure, and the frequency and duration of exposure. For food toxicants, their administration in repeated doses in experimental animals is usually done through diet, by gavage, or via drinking water.

The doses have to be chosen so that toxic effects are produced at the highest dose level tested, with lower dose levels producing graded responses, and with no adverse effects at the lowest level. The study should be adequate to allow for determining a reference point for hazard characterization, also known as point of departure (POD), such as a no observed adverse effect level (NOAEL) or a benchmark dose (BMD) which is a dose that produces a low but measurable adverse response (**Figure 3**).

In the studies of carcinogenicity and developmental toxicity, comparison of the data obtained in the test with historical control data may be needed to understand the meaning of a particular result. Positive results in carcinogenicity studies in rodents require careful interpretation in relation to mode of action, the possible interspecies differences, and to extrapolate from high doses to low doses. Genotoxicity studies can provide information about the mode of action of substances that are carcinogenic.

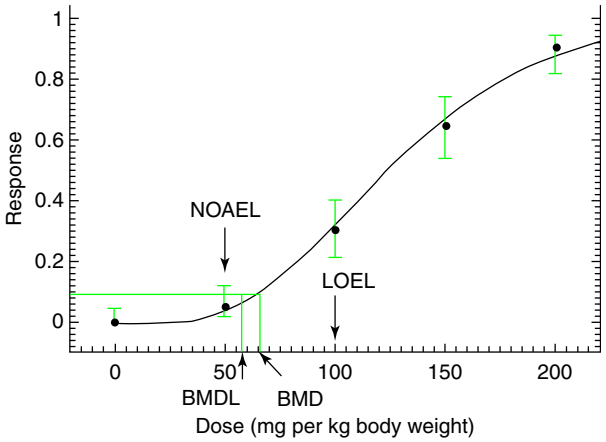

Figure 3 PODs in toxicological studies. Adapted from FAO/WHO (2004) *Technical Workshop on Residues of Veterinary Drugs without ADI/MRL*. Bangkok, Thailand, 24–26 August 2004. Available at: http://www.fao.org/docrep/008/y5723e/y5723e00.htm#Contents (accessed on 14 April 2013).

Acute toxicity studies as a result of short exposure, for example, metals, mycotoxins, veterinary drugs, and agricultural chemicals, may be useful. The JMPR establishes the acute reference dose, which is an estimation of the quantity of a specific substance in the food, normally expressed on body weight basis, which can be ingested in a period equal to 24 h or shorter without appreciable health risk for the consumer.

Information obtained from clinical studies in humans are of great importance in risk assessment of food toxicants. These information may be obtained from epidemiological or clinical studies. The crucial points of the clinical studies in humans are ethics, professional and legal controls for human studies, and the circumstances in which the study should be adequately developed.

Dose–Response Assessment

The dose–response evaluation is an essential part of hazard characterization. It is used to derive health-based guidance

values, such as the acceptable daily intake (ADI) or tolerable daily intake (TDI), which are levels considered to be 'without appreciable health risk.' The interpretation of dose–response data usually requires knowledge of exposure levels that do not produce a measurable adverse effect, and of the relationship between the increase in incidence, severity, or the nature of the effect and increased exposure.

Extrapolation is a essential part in all risk assessments. In most cases, data from the dose–response evaluation results from preclinical experiments using doses that significantly exceed human exposure. For the dose–response analysis, two aspects of extrapolation need to be considered:

1. Extrapolation from animal exposure data to humans (interspecies extrapolation).
2. Extrapolation to allow for possible differences in response between humans (intraspecies extrapolation).

The methods employed in the extrapolations range from the use of uncertainty factors to models based on differences in toxicokinetics and toxicodynamics between humans and experimental animals, as well as variability among different individuals.

Derivation of Health-Based Guidance Values

The setting of these parameters provides quantitative information of risk assessment used for risk management. These values arise from the dose–response evaluation for the most relevant endpoint, on the more relevant species in the preclinical studies.

Usually, the first step is to set the NOAEL (which is the highest concentration of a toxicant expressed as mg per kg body weight per day, which does not cause dysfunctions in animals) or, sometimes, the lowest observed adverse effect level as the POD.

The BMD has also been used as the POD to derive health-based guidance values. BMD is defined as the lower confidence limit of the dose calculated to be associated with a given incidence (e.g., incidence of 5% or 10%) of an estimated effect based on all toxicological data concerning the effect in the study.

The dose–response evaluation can also be used to establish a dose associated with a negligible increase of an adverse response (e.g., one in a million) relative to its background. Also, for substances that do not exhibit a safe threshold of exposure to adverse effects (e.g., genotoxic and carcinogenic substances) the calculation of a margin of exposure (MOE) is conducted, which is the ratio of POD (lower one-sided confidence limit of the BMD) with the theoretical or estimated exposure level (Figure 4).

ADI values are established for food additives, pesticides, and veterinary drugs used in food production. It is established based on the lowest relevant POD in the most sensitive species, and it is defined as the amount of a substance, expressed in mg per kg body weight and as a range of zero to an upper limit, which may be ingested daily for even a lifetime without any damage to human health, based on toxicological data available at the time of the evaluation.

$$\text{MOE} = \frac{\text{Carcinogenic dose for 10\% of rodents (mg kg}^{-1}\text{ day}^{-1})}{\text{Average human exposure (mg kg}^{-1}\text{ day}^{-1})}$$

Figure 4 Example of calculating the MOE for genotoxic and carcinogenic substances.

TDI values are established for unavoidable contaminants in foods. The principles in establishing TDI values are the same as those used for the ADI. Both NOAEL and BMD approaches can be used as POD to establish the health-based guidance values for tolerable contaminants.

Assessment of Exposure to Foodborne Toxicants

For the assessment of exposure to toxicants via diet, the data on food consumption and the concentration of the food toxicant are considered. These data on exposure are compared with the ADI or TDI value, or with the POD (NOAEL; benchmark dose lower confidence limit (BMDL)) of the chemical of interest present in the food. Evaluations can be made for either acute or chronic exposures. Assessments of exposure via diet should cover the general population, as well as critical groups who are vulnerable, or whose exposure is expected to be significantly different from that of the general population (e.g., infants, children, pregnant women, the elderly, or vegetarians).

Characterization of Risk

This stage of the risk assessment integrates information from hazard characterization and their exposure assessment. Historically, different approaches have been used for risk characterization of food toxicants that have a threshold for adverse effects observed, and those that do not have a threshold. The health-based guidance values (ADI and TDI) are established for substances producing adverse effects that exhibit a threshold of toxicity. In the risk characterization for these types of substances, the ADI or TDI values are compared with the estimated or determined human exposure.

Where exposures exceed the health-based guidance values, it does not allow to infer the extent of the risk to those individuals exposed to these higher levels, as the ADI and TDI values incorporate uncertainty factors. An exposure that occasionally exceeds the ADI or TDI value does not necessarily imply that adverse health effects will occur in humans. The risk characterization shall consider the uncertainty and variability. Uncertainty refers to the limitations of the information available to the risk assessor about the data and models used. The variability reflects the inherent biological heterogeneity, either in exposure or response. The uncertainty can be reduced when the quantity or quality of the information is improved. The characterization of exposure variability via diet may be improved by better information, but the variability cannot be eliminated.

For toxicants that are genotoxic and carcinogenic, the traditional hypothesis is that there is no threshold dose and that some degree of risk may exist in any exposure level. Thus, ADI or TDI values are not established for this type of compounds. The substances that are both genotoxic and carcinogenic

are not accepted for use as food additives, pesticides, or veterinary drugs.

Principles Related to Specific Groups of Substances

Many toxicants evaluated by JECFA are present in food in low concentrations, such as flavorings, extraction solvents, enzymes, and others. In these cases, the concept of Threshold of toxicological concern (TTC) is applied. The TTC concept considers that toxicity is a function of both the chemical structure and exposure time. Thus, by knowing the chemical structure and low exposure via diet it is possible to provide guidance based on scientific evidence, when there is negligible probability that damage will be induced. This concept does not propose the replacement of risk assessment used for toxicants for which complete toxicity data are available.

The TTC approach uses threshold values of exposure for which there is a very low probability of any appreciable risk to human health. These TTC values are derived from existing data on toxicity of toxicants classified into three classes – I, II, and III – for 1800, 540, and 90 mg per person per day, respectively. As the threshold values for human exposure are compared with known or anticipated exposure, the TTC approach requires adequate estimates of human exposure.

The safety assessment of substances that are consumed in relatively large amounts, such as modified starches, nutrients and related substances, as well as nontraditional food, presents additional problems. In assessing the safety of these substances, secondary constituents or processing impurities may assume a greater importance than usual.

Interactions of Toxic Substances

Interactions between chemicals administered to humans at high doses have been known for many years in the field of pharmacology. However, these experiences may not be directly useful for predicting toxic effects of mixtures of food toxicants given that exposure levels of the general population are relatively low. However, the main emphasis has to be laid on the identification of the basic principles for combined actions and interactions of toxicants and on the current knowledge on effects of exposures to mixtures of food additives, feed additives, veterinary drugs, agricultural and industrial chemicals, and environmental contaminants.

There are many possibilities for interaction between toxicants because of the complex structure and functions of the cellular systems. Recently, a number of examples of endocrine-disrupting chemicals, reproductive toxicity, and neurotoxicity have been described. The strongest interaction found in the literature was a 5-fold increase in the neurotoxicity of hexane when methyl isobutyl ketone was coadministered. It is therefore evident that interaction might be a real phenomenon and not just a theoretical possibility.

Although an expressive number of studies have concluded that toxicants can act additively, very few quantitative studies have been performed. Interaction has not been studied systematically, and the present state of knowledge does not allow general conclusions.

Conclusions

The use of Codex standards as a reference for the construction of national standards assists in harmonizing the overall implementation of food safety measures. Thus, it is suggested that countries consider the Codex criteria of risk analysis as an important normative reference. However, despite the adoption of harmonized standards, in many countries the main limitations for risk analysis is the lack of information regarding the quality of food products, resulting in deficiency of available data necessary to assess the risk.

The risk assessment of exposure to toxicants should make optimal use of the toxicological databases, in order to assess the safety of foods. The POD should be based on studies using the oral route of exposure.

Despite the difficulties and limitations that still exist, in our perception, there is an ongoing virtuous progress of risk analysis in food, both the global harmonization of the regulatory framework as well as the technological capacity and consciousness of the health authorities for the consumer needs for safer and quality food.

RISK ANALYSIS

Contents

Risk Analysis of Hazards in Food: An Overview

GG Moy, Food Safety Consultants International, Geneva, Switzerland

Glossary

Hazard A biological, chemical or physical agent in, or condition of food with the potential to cause an adverse health effect.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Risk analysis A process consisting of three components: risk assessment, risk management and risk communication.

Risk assessment A scientifically based process consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization.

Risk assessment policy Documented guidelines on the choice of options and associated judgements for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization and exposure assessment.

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions among risk assessors, risk managers, consumers, industry, the academic community and other interested parties, including the explanation of risk assessment findings and the basis of risk management decisions.

Risk management The process, distinct from risk assessment, of weighing policy alternatives in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and, if needed, selecting appropriate prevention and control options.

Risk profile The description of the food safety problem and its context.

Introduction

Risk analysis is a logical framework that underlies decision-making concerning all kinds of risks and not just those that pertain to food safety. The origins of risk analysis can be traced back to the era of atmospheric nuclear testing when health physicists in the United States first used risk analysis to assess the potential adverse health impact posed by the presence of

radionuclides in food and water. In 1983, the National Research Council of the US National Academy of Sciences in a report entitled *Risk Assessment in the Federal Government: Managing the Process* described the approach.

One of the most important advantages of the risk analysis approach is that it provides a clear and transparent framework for objective and structured decision-making in food safety. It delineates the responsibilities of governmental authorities and, in particular, fosters the separation of risk assessment from risk management functions. It also facilitates communication and interaction between risk assessors and risk managers as well as among all stakeholders, including industry, consumer organizations, and civil society.

Each of the four components of risk assessment and management are presented. However, only a cursory mention of risk communication is given because a full discussion would go beyond the scope of this article. Risk communication is an essential function that encompasses the whole process, but is particularly important between the risk manager and risk assessor. Although the principles and process of risk analysis are similar, the differences between chemical and microbial risk analysis are great enough to warrant separate discussions.

Background

Growing public concern for food safety and challenges posed by the modern food supply system, including globalization and new technologies, have underlined the need for more objective and transparent methods for decision-making based on the concept of risk analysis. Subsequently, governments are increasingly adopting the risk analysis framework as a tool for managing potential risks to human health posed by hazards in food. Risk analysis is a process that consists of three main components as shown in **Figure 1**.

The ever-increasing global trade during the past few decades in both raw commodities and processed foods has also led to the need for an intergovernmental body to protect the health of consumers and ensure fair trading practices. In 1963, the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO) established the Codex Alimentarius Commission (Codex), which has 184 member countries, including all of the main food exporting and importing countries. Codex has become a model for international cooperation and has adopted 186 food standards, 46 codes of practice and related texts, and maximum limits covering 292 food additives, 218 pesticides, and 49 veterinary drugs. These are collectively referred to as the *Codex Alimentarius*. The work of Codex relies basically on risk assessments performed by WHO and FAO scientific committees, such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA), Joint FAO/WHO Meetings on Pesticide Residues (JMPR), and the Joint FAO/WHO Meetings on Microbiological Risk Assessment (JEMRA) as well as other *ad hoc* expert meetings. Although compliance with Codex Alimentarius was voluntary, much of the international trade in food met Codex requirements. However, trade disputes over health and safety requirements continued. In some cases, such requirements constituted nontariff barriers to trade.

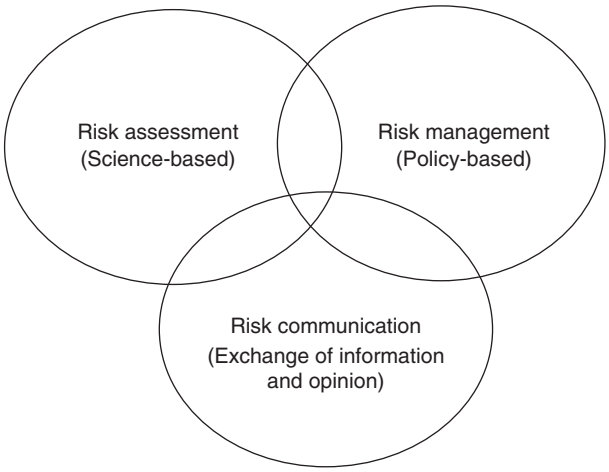

Figure 1 Components of risk analysis.

Under the General Agreement on Tariffs and Trade (GATT), countries negotiated reductions in tariff barriers to trade, including food, and it was recognized that nontariff barriers based on reputed health and safety requirements could undermine such negotiations. To address this concern, the World Trade Organization (WTO), which succeeded GATT in 1995, adopted as part of its founding texts the Agreement on the Application of Sanitary and Phytosanitary Measures (often referred to as the SPS Agreement). This agreement sets forth principles regarding the establishment of health and safety regulations for food and, in particular, that they be based on sound scientific assessment of the risk.

In addition, the SPS Agreement imposes other disciplines on countries in developing their food safety requirements, including nondiscrimination, transparency, and acceptance of equivalent approaches to achieve the same level of health protection. In this regard, WTO referred to the standards, guidelines, and other recommendations of the *Codex Alimentarius* as representing the international consensus regarding health and safety requirements for food and countries in compliance with Codex Alimentarius were assumed to meet the requirements of the SPS Agreement.

The impact of the SPS Agreement on the Codex Commission and countries would be game changing. Countries would be obligated to follow the Codex Alimentarius unless they could scientifically justify their need for their divergence using risk analysis. The effect was twofold, namely that *Codex Alimentarius* became essentially mandatory and that risk analysis became the foundation for standard setting at both the international and national levels. In response, Codex has made the use of risk analysis explicit in its work and has developed several guidance documents to promote its application at the national level.

Currently, risk analysis has become the internationally agreed model for the formulation of policies and legislation to manage foodborne hazards. The risk analysis process is now used to guide the development of a range of risk management options, including both mandatory and voluntary measures. Risk analysis has had a significant impact on the regulation of the food industry as well as on the information and advice provided to consumers. In many countries, consumers have

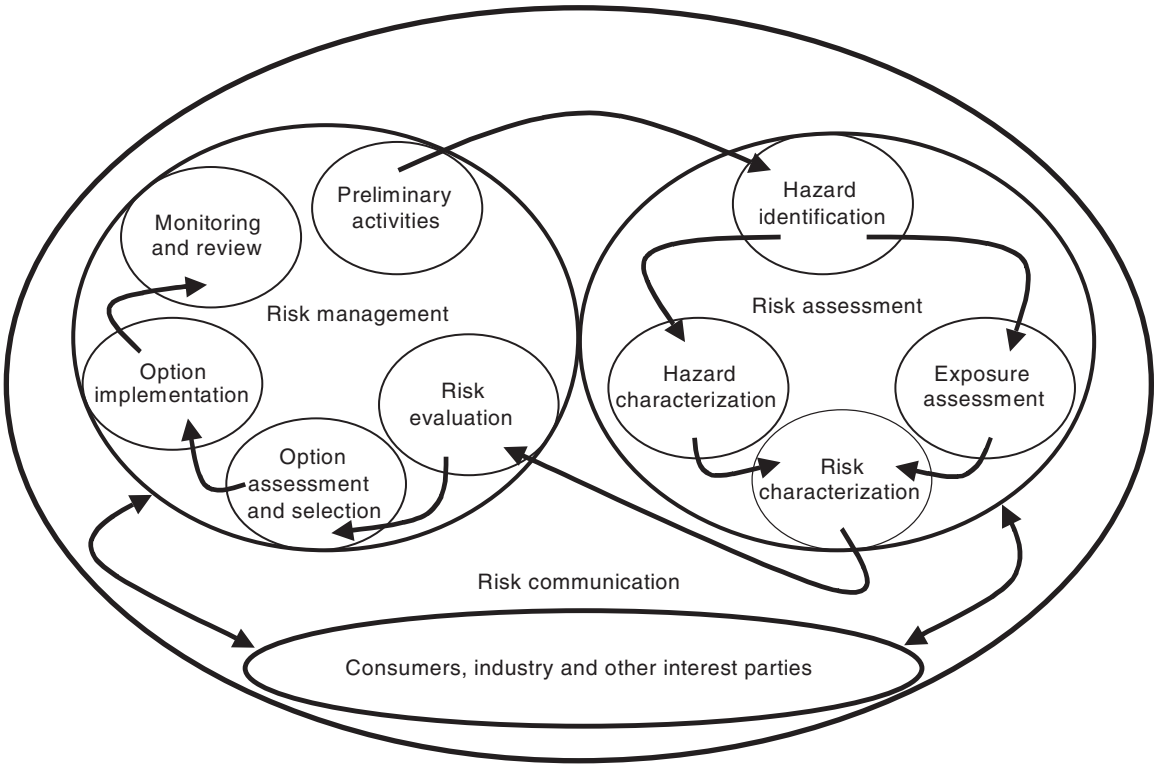

Figure 2 Risk analysis process.

benefited from greater protection from hazards in food afforded by the application of risk analysis. However, harmonization of risk analysis procedures has not been fully achieved and many developing countries are only now beginning to routinely apply it. In addition, the socio-economic and cultural differences among countries often lead to different consumer opinions about safety. The SPS Agreement recognizes the right of countries to establish their appropriate level of protection (ALOP) provided that it does not unjustifiably impede trade.

Risk Analysis Process

Risk analysis is a tool used by the risk manager in making complex decisions concerning the safety of the food supply. Risk analysis can also be used in preventing fraud and unfair trading practices based on contrived health and safety claims. As the legal authority designated to protect the food supply, risk managers in government have the overall responsibility for the risk analysis process. In many countries, more than one risk manager may be designated to cover different parts of the food supply network, such as primary production, processing and manufacturing, wholesale and retail markets, and food service establishments. As food safety is an essential public health activity, conflicts of interest by the risk manager should be avoided in order to assure integrity and confidence in the process.

Each of the components of risk analysis, namely risk assessment, risk management, and risk communication, has been the subject of an FAO/WHO expert consultation in 1995, 1997, and 1998, respectively. Each consultation elaborated further details of each component. For example, the risk assessment process has been defined as consisting of four elements, namely hazard identification, hazard characterization, exposure assessment, and risk characterization. Similarly, risk management also consists of four elements, namely risk evaluation, option assessment, option implementation, and monitoring and review. However, risk communication links all of the processes together from the critical exchange between risk assessors and risk managers to the important on-going dialog with industry, consumers, and other stakeholders. Figure 2 provides a schematic overview of the risk analysis process with the steps in the process shown with arrows.

Note that the risk assessment process is initiated by preliminary activities carried out by the risk manager. Although these activities normally precede the risk analysis process, they are particularly important in crisis situations where the experience and judgment of the risk manager is necessary in the face of uncertainty. Based on available information of the risk posed by hazard–food combination, the risk manager may (or may not) decide to commission a risk assessment. The purpose and scope of the risk assessment, including relevant risk assessment policy and the preferred form of the output, need to be communicated clearly to the risk assessor by the risk manager. Although the function of risk management and risk assessment should be separated to the extent possible, maintaining effective and continual communication between the risk manager and risk assessor is essential during all steps of the risk analysis process.

Risk Assessment

Hazard Identification

The first step in a risk assessment process is hazard identification, which identifies agents capable of causing adverse health effects, which may be present in a particular food or groups of foods. In this regard, epidemiological, biological, and other pertinent information and expert knowledge are used to link potential hazards and their sources in food to illness in consumers. Obviously, a chemical that produces toxic effects shortly after ingestion of small amounts can be easily identified as a hazard. Similarly, biological agents that produce disease in humans can be identified as potential hazards. However, for both chemicals and biological agents, the long-term adverse health effects may be difficult to determine. This is particularly a problem for chemicals that can produce adverse health effects, such as cancer, after long-term low-level exposure. Physical hazards, such as stones, glass, or metal fragments, can produce serious injuries, but are usually not routinely found in food.

Hazard Characterization

Hazard characterization considers the dose level at which a specific adverse effect or disease can occur in order to establish an exposure level considered to be acceptable or tolerable. For example, the standard health reference value used at the international level to indicate the safe level of intake for a chemical, such as a food additive, pesticide, and veterinary drug, is the acceptable daily intake (ADI), which is the estimate of the amount of a substance in food and/or in drinking water, expressed on a body weight basis, which can be ingested daily over a lifetime without appreciable health risk to the consumer.

For microbial hazards, the hazard characterization consists of estimating the lowest infectious dose for the general population and for any vulnerable groups.

Exposure Assessment

For intentionally added chemicals, methods have been developed to predict the likely exposure to populations based on the intended use of the chemical. Other methods to assess short-term exposure have also been developed for those chemicals that pose acute risks. For contaminants, monitoring data on such chemicals in the food supply are used in conjunction with food consumption patterns to estimate exposure.

For biological hazards, exposure assessment attempts to model the level of contamination at the various steps in the food production to consumption continuum, i.e., farm to fork.

Risk Characterization

Risk characterization is the last of the four steps of risk assessment. It is defined as an estimation of the probability of occurrence and severity of known or potential adverse health effects in a population based on the preceding steps of hazard identification, hazard characterization, and exposure assessment. It comprises the results of the risk assessment in the form of risk estimates and risk descriptions and provides the best available science-based evidence to support food safety management. If requested by the risk manager, it may also provide information on a range of possible decisions for ensuring consumer safety.

Risk Management

As discussed earlier, the risk manager will prepare a preliminary risk profile based on available information. After the risk assessment is completed, the risk manager will weigh policy alternatives in the light of the risk assessment and other factors and, if necessary, select and implement an appropriate risk management measure. The risk manager will also establish relevant surveillance and monitoring activities so that the effectiveness of the risk management measure can be assessed and, if necessary, modified. These risk management activities are part of the four-step risk management process, namely risk evaluation, option assessment and selection, option implementation, and monitoring and review (refer to Figure 2). Each component is briefly discussed in the following sections.

Risk Evaluation

After the risk has been characterized, the risk manager will use this and other information to complete the preliminary risk profile, which is the main task of risk evaluation. Typically a risk profile consists of a description of the food safety situation, including the hazard, the product or commodity involved, how and where the hazard enters the food supply, frequency, distribution and levels of the hazard in food, pathways by which consumers are exposed, possible adverse health effects, the quantitative (or qualitative) estimate of the risk, the distribution of the risk in the population, perception of consumers of the risk and values involved, and information on the prevention and control measures undertaken by other various countries, including recommendations from Codex. The evaluation may also consider other factors, such as the nature of the hazard or food that might affect the availability and feasibility of risk management options.

Option Assessment and Selection

Option assessment includes the identification of risk reduction measures and the selection of the preferred option based on the policies, goals, and priorities of risk management. Risk management measures may range from mandatory to voluntary and may be implemented by the government, the food industry, or consumers. The efficiency and effectiveness of an option and its cost to the industry and the government are important considerations in option assessment and selection.

The establishment and enforcement of maximum limits or levels is the most common risk management option. For certain other hazards, guideline levels are recommended for use by industry. Setting a ‘zero’ or ‘negligible’ tolerance for a hazard in food appears to be a simple option, but the method of analysis used to determine ‘zero’ must be specified. If not, ‘zero’ or ‘negligible’ will continual go down as methods of

analysis become more sensitive. These limits are often used in the absence of an agreed-upon acceptable risk as in the case of ALARA, which stands for 'as low as reasonably achievable'.

In considering possible health and safety requirements for food, countries are obligated to use Codex standards, guidelines, and other recommendations unless they can justify that a more stringent standard is necessary to protect their populations based on a sound scientific assessment of the risk. WTO members are also required to observe other disciplines, including transparency and consistency. Furthermore, the option selected should not be unnecessarily restrictive to trade. Decisions on appropriate levels of protection should be determined primarily by human health considerations even when consideration of other factors (e.g., economic costs, health benefits, technical feasibility, and societal preferences) may be relevant in some risk management contexts.

In other cases, codes of practice at various levels of the food supply network may be appropriate. Some risk management options involve changing consumer behavior through product labeling or public education programs. Education programs may be targeted to specific subgroups of the population, such as pregnant women, and may include specifically tailored risk management messages. As such, they rely to a great extent on professional risk communicators. Risk managers need to be good risk communicators given their overall responsibility for maintaining a dialog with all stakeholders.

Option Implementation

Once a decision is taken, the option should be implemented in a uniform and consistent manner within the country and with regard to both domestic and imported products. As the primary responsibility for the safety of food rests with the food industry, the implementation of food safety measures is often carried out by industry. For example, the levels of contaminants in food must conform to the limits prescribed by food safety regulations. To meet these requirements, the food industry will often incorporate appropriate prevention and control measures into their codes of practice and quality management systems. In particular, the application of the Hazard Analysis and Critical Control Point (HACCP) system should use maximum limits and levels as the basis for setting critical limits for hazards in the HACCP plan.

It should also be noted that both the government and the food industry have major roles to play with regard to consumer education. Obviously, product labeling is important for the safe handling of specific packaged foods. For broader food safety concerns, the government and consumer organizations can promote safe food practices in the home through a number of channels, which can be targeted toward various members of the family, especially school children.

Monitoring and Review

Finally, risk managers need to establish means for monitoring the effectiveness of the selected option in reducing the risk. For an adverse health effect that occurs shortly after exposure, disease surveillance and related epidemiological techniques may be used to assess the disease burden for a particular hazard. For chemicals, however, adverse effects resulting from long-term, low-level exposures are often expressed only after long induction periods, in some cases decades. Although epidemiological studies may reveal the current disease burden posed by previous exposures, they are insensitive to recent exposures. Therefore, monitoring of chemicals in food and total diet is the most practical way of assuring the safety of the food supply. In some special cases, biomonitoring can be useful in assessing exposure and the impact of risk management measures. Based on the review of monitoring information, the risk manager may commission a further risk assessment or consider alternative management options.

Risk Communication

Risk communication is the interactive exchange of information and opinions throughout the entire risk analysis process concerning risk. It is important not only between risk assessors and risk managers, but also with consumers, the food industry, and other stakeholders. Providing meaningful, relevant, and accurate information in clear and understandable terms tailored for specific audiences is usually the responsibility of the risk manager. Obviously, good risk communication skills are important for obtaining cooperation and support of stakeholders, particularly in the implementation of a risk management measure. Risk communication is also important in crisis situations and the risk analysis framework provides a useful structure when there is uncertainty about the extent and nature of the risk.

Conclusion

The introduction of risk analysis in food safety has provided governments with a powerful tool for assessing and managing risks posed by potentially hazards in food. The approach provides a logical framework for making complex public health decisions in context of economic, social, and political considerations. The risk analysis approach can foster better and more interactive communication among all parties involved in risk analysis, including industry and consumers. Food safety risk analysis has been recognized by global health and trade organizations as the primary basis for establishing health and safety requirements for foods. As a consequence, food safety authorities at the international, national, and local levels should make greater efforts to understand and apply the principles and procedures of risk analysis, particularly those used by relevant international organizations.

Glossary

Appropriate level of protection (ALOP) A metric advocated by the World Trade Organization reflecting the level of public health protection achieved in a country; competent authorities may establish a similar metric on the basis of relevant policy decisions on public health protection (then more appropriately referred to as a public health goal).
Exposure assessment Exposure assessment is an activity within risk analysis that establishes the dynamics of a hazard in a food and food environment up to the point of consumption of the food and assesses exposure of a consumer population to that hazard through the food.
Food Safety Objective (FSO) A metric advocated by Codex Alimentarius and established by a competent authority that represents the maximum level of a hazard in a food at the point of consumption that may be tolerated in the light of an ALOP or relevant policy decisions on public health protection.
Hazard characterization Hazard characterization is an activity within risk analysis that establishes the inherent properties of a hazard and the consequences for a consumer population being exposed to that hazard.
Hazard Identification Hazard identification is an activity within risk analysis that evaluates the likely association between a particular hazard and a food and the causal relationship of this association with the concerned risk to a consumer population.
Risk Risk is a measure of an undesirable outcome; in food safety, risk is a combination of the impact that a hazard may have on consumers following exposure and the probability of actual exposure.
Risk analysis Risk analysis is a systematic framework advocated by Codex Alimentarius to determine the level of risk to a consumer population due to hazards possibly associated to foods.
Risk characterization Risk characterization is an activity within risk analysis that combines knowledge derived from hazard characterization and exposure assessment into a measure of the level of risk to a consumer population due to a particular hazard possibly associated to a food.
Sensitivity analysis Sensitivity analysis is a systematic assessment of the impact of individual input parameters used in risk characterization for the purpose of determining the influence of such parameters on the risk characterization outcome relative to insight in their robustness.
Uncertainty Uncertainty of input parameters may relate to either their natural variability (aleatory uncertainty) or lack of specific knowledge on the side of the risk assessor (epistemic uncertainty). The latter may be reduced by gathering more knowledge.
Variability Variability (aleatory uncertainty or natural variability) relates to inherent variability in the physical world; it can be better described but not reduced by gathering more knowledge.

Introduction

The management of product safety can be performed using a number of different approaches, falling in one of two categories: hazard-based or risk-based decision making. In hazard-based decision making, the mere occurrence of a hazard in a food product is the basis for decision making, whereas in risk-based approaches, the basis for decision making is likely the exposure of a consumer to a hazard present in a food combined with the degree of severity of the impact of exposure on a consumer. Although there is possibly a place for both types of approaches when managing food safety, in the public context, there is a move toward the consistent use of risk-based management within an overall framework referred to as risk analysis. Risk analysis consists of risk management, risk assessment, and risk communication. In this framework, risk managers are responsible for making the ultimate decision about product safety and risk assessors are responsible for bringing together the scientific information in support of decision making. This article discusses risk assessment as the science-based process within risk analysis, explaining the concept of risk, the principles underlying risk assessment, and the generic process followed in risk assessment. Examples of the application of risk assessment for different potential hazards, such as chemicals and microorganisms in food, are given where it serves to illustrate key differences.

Risk

Risk is a measure of the probability and consequence of uncertain future events. It is the chance of an undesirable outcome.

That outcome could be a loss or a potential gain that is not realized. It is often described by the expression:

$$\text{Risk} = \text{Probability} \times \text{Consequence}$$

This conceptual model is not conveying the complexity of models with which risks are actually calculated; clearly, few are this simple. Instead, it conveys the fact that both elements must be present for a risk to exist. If an event of any consequence has no probability of occurring, there is no risk. Likewise, when there is no unfavorable consequence, there is no risk no matter how likely the event is. Risk assessment tends to focus on assessing the probability and consequence of specific events.

In food safety, the risk model can for instance be translated as follows:

$$\text{Risk} = \text{Exposure to hazard} \times \text{Consequence of exposure}$$

The probability is reflected in the likely exposure of a consumer to a hazard in food, with exposure being determined by the hazard concentration and prevalence in the food as well as the amount and frequency of the food consumed. The consequence is characterized by the resulting outcome of exposure for the consumer, which usually is an adverse health effect, i.e., illness. There are many opportunities for potential gain concerning food, but they tend to be more properly considered as nutritional concerns rather than food safety concerns.

Risk Assessment

Risk assessment is the science-based component of risk analysis that concerns itself with characterizing the probability of exposure to a hazard and the consequences of exposure for the consumer. It is a set of logical, systematic, evidence-based, analytical activities designed to gain an understanding of specific risks and to measure and describe them to the fullest extent possible. A risk assessment intends to answer risk manager's questions about the identified risks and provides the objective information needed for decision making. It describes and addresses uncertainty in intentional ways and then characterizes the relevant uncertainty encountered in the assessment that could influence the decision or change decision outcomes.

Risk assessments may address all relevant dimensions of risks in a decision problem. These may include:

- Existing risk
- New risks
- Future risk
- Risk reductions
- Residual risk
- Historical risk
- Geographical risk
- Transferred risk
- Transformed risk.

Informally, risk assessment is the work needed to answer the following questions:

- What can go wrong?
- How can it happen?
- How likely is it?
- What are the consequences?

In food safety, these questions help risk assessors (often referred to as analysts) to identify hazards and the sequence of events by which consumers become exposed to them, as well as the likelihood and consequences of exposure.

Risk Assessment Principles

The main principles underlying a good risk assessment include: following a systematic and structured approach, being objective and transparent, providing appropriate documentation, allowing for peer review and communication suitable for different stakeholders, and ensuring that the responsibilities of risk assessors and risk managers are separated. A good risk assessment meets a risk manager's information needs for decision making. It provides an objective, unbiased treatment of the available evidence and clearly links the evidence to its conclusions. It is also transparent, which relates to clearly detailing the rationale for the evidence selected and being honest about what is not known and how that affects an assessment's conclusions. Risk assessment is a structured and systematic process. It follows a methodology consisting of specific steps that provides for a thorough and consistent approach to the assessment of risks. Good risk assessment documents the details of the work to support current decision making as well as for future consideration. Documenting the assessment is important to peer and stakeholder review of the assessment and decisions based on it. In food safety, stakeholders include the risk manager, risk managers in other countries, consumers or consumer organizations, industry, and academia. A good risk assessment requires substantial interactions among risk managers and risk assessors, whereas the responsibilities associated to these two roles are kept separate. The functional separation of responsibilities is a key principle, which is difficult to adhere to where resources are limited and the two roles are only found in a single person. However, generally, the risk assessors should not influence the risk manager's decision for instance by altering the scope of the work, specific selection of evidence, or through the way that the results of the risk assessment are presented. Conversely, risk managers should not influence the integrity or objectivity of the risk assessment.

Defining Risk Assessment

No definition is going to meet the needs of the many and diverse uses of risk assessment, given the wide range of hazards found in the world and the many differences in the context that risk assessments can be utilized. Even within the food safety community of practice, multiple definitions can be found. The first formal attempt to provide a description of the risk assessment process was for cancer risk associated with the chemicals in the environment and it is usually traced to *Risk Assessment in the Federal Government: Managing the Process*, a report of the National Research Council in 1983. Although originally setup for chemicals, the principles in this early work have proven

robust for a wide range of chemical, microbial, and physical risks. It defined risk assessment as follows:

"Risk assessment can be divided into four major steps: hazard identification, dose–response assessment, exposure assessment, and risk characterization."

The steps were defined by the National Research Council as follows:

- Hazard identification: the determination of whether a particular chemical is or is not causally linked to particular health effects.
- Dose–response assessment: the determination of the relationship between the magnitude of exposure and the probability of occurrence of the health effects in question.
- Exposure assessment: the determination of the extent of human exposure before or after application of regulatory controls.
- Risk characterization: the description of the nature and often the magnitude of human risk, including attendant uncertainty.

The spirit of these definitions is also found in the Codex Alimentarius definition of risk assessment as it applies to a food context:

"Risk Assessment: A scientifically based process consisting of the following steps: (1) hazard identification, (2) hazard characterization, (3) exposure assessment, and (4) risk characterization."

The risk assessment steps, noticeably expanded to a wider range of hazards, have been defined by Codex as follows:

Hazard identification: The identification of biological, chemical, and physical agents capable of causing adverse health effects and which may be present in a particular food or group of foods.

Hazard characterization: The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents which may be present in food. For chemical agents, a dose–response assessment should be performed. For biological or physical agents, a dose–response assessment should be performed if the data are obtainable.

Exposure assessment: The qualitative and/or quantitative evaluation of the likely intake of biological, chemical, and physical agents via food as well as exposures from other sources if relevant.

Risk characterization: The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Notably, these definitions use the term 'hazard' similarly for chemicals and microorganisms, namely to specify the chemical or the microbial agent (infectious cell or toxin). However, in toxicology, the term 'hazard' may rather be used to describe the adverse health effect to consumers, for instance which specific illness is caused or which particular organ is affected.

Hazard Identification

Hazard identification is primarily a qualitative process that describes the association of hazards to foods. The main hazards of concern are microorganisms or chemicals. The chemicals can be naturally occurring; food additives or colorants; or contaminants, such as pesticide residues. When construed broadly, food safety may include hazards, such as antimicrobial-resistant microorganisms, genetically modified (GM) organisms, too little or too much of a nutrient, nanotechnology hazards, and even plant and animal diseases. This discussion focuses on microbial and chemical hazards.

Why is hazard identification needed? In some cases, it is not known if the agent in question is indeed a hazard, i.e., capable of harm. For example, does a specific chemical cause cancer in humans? In other cases, the potential for harm is well established, as for well-known human pathogens for which there is ample epidemiological evidence. In any case, the purpose of the hazard identification step is to confirm that there is an association of the hazard of concern to the food(s) or food group considered. In formulating the risk manager's questions and in compiling the necessary scope and background for the risk assessor (which often is done by providing a so-called risk profile), risk managers may already bring together key details for hazard identification. The hazard identification step is an opportunity for risk assessors to signal to risk managers that the association assumed by the risk manager may not be correct or that there are other hazards to be considered. Every risk assessment begins with hazard identification, but hazard identification need not result in taking further steps in risk assessment. For instance, where the results of hazard identification lead to the conclusion that the hazard–food association is incorrect or that other hazards are more significant, the risk manager may decide to discontinue the particular risk assessment.

Hazard Characterization

Hazard characterization describes the adverse health effect or effects to the consumer that may result from exposure to the hazard. This step therefore considers demographics and health status information among other characteristics of the consumer or specific consumer groups in the population related to their vulnerability to the hazard. For chemical hazards, this step develops detailed information regarding the nature of the chemical and how it causes adverse health effects, for example, which organ(s) might be affected. For microbial hazards, hazard characterization considers characteristics of the pathogen related to adverse health effects, such as infectivity and toxin production, as well as possible impacts of the food matrix on their ability to cause adverse health effects. When possible, this step includes quantitative information in the form of a dose–response relationship between hazard concentration and the level of consumer health effect as well as probabilistic estimates of adverse outcomes. Data sources for hazard characterization include animal toxicity studies, cell line studies, clinical human exposure studies, and epidemiological data from investigations of outbreaks and illness.

The relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response) defines the dose–response relationship. This relationship is often represented as a curve, such as the stylized dose–response curve shown in Figure 1. The dose–response

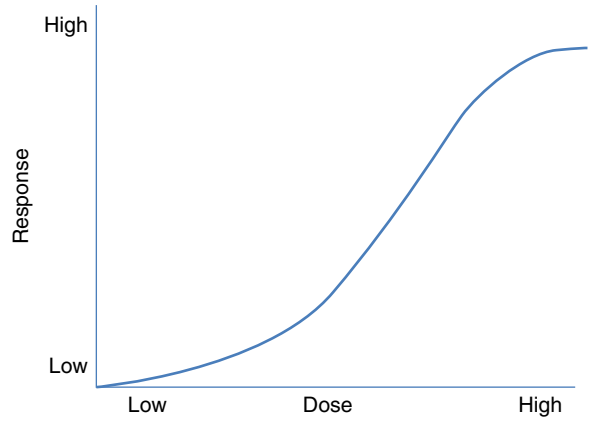

Figure 1 Conceptualized dose–response relationship.

curve is the primary health-consequence model used to characterize the adverse human health effects of chemicals, toxins, and microbes in food, but specific data may not always be available. When data are available, they are often characterized by variability and uncertainty. Exposure to chemicals typically leads to chronic adverse health outcomes, whereas exposure to microorganisms most often may cause acute effects. This difference has a major impact on the way dose–response relationships can be constructed and the data required.

A dose–response relationship may be used to describe the effect of a hazard on a typical individual or a large population. In the first case, a low response might be a low probability of illness, and a high response might be a high probability of illness. In the latter case, the response may vary from no detectable effects at low doses to subtle effects (such as tumors) in some subjects, severe effects in some to many subjects to death at high doses. The dose may be milligram per kilogram of bodyweight daily for a lifetime in the case of a chemical, such as a pesticide or the number of colony forming units (CFUs) ingested in the case of a pathogenic microorganism. Dose–response relationships involve consideration of the elements or factors related to the pathogen or chemical, the host and the matrix, insofar as they may modulate the response to exposure.

It is important to categorize the adverse health effects to meet the requirements of risk managers. Adverse health effects include such possible responses as infection, illness, hospitalization, fatalities, and/or long-term sequelae. Although individual sensitivity to a chemical hazard can vary, the types of adverse effects are generally similar for all members of a population. This is less the case for microbial hazards, for which significant differences have been noted in health responses of individual consumers to different hazard levels, and also specific subpopulations of particularly vulnerable consumers may exist within the overall population. Dose–response curves for subpopulations are highly desirable, but rare due to a general lack of data to develop these relationships.

In the absence of dose–response data, it is sometimes possible to relate the incidence of disease or other adverse health effects to eating occasions. This method requires extensive surveillance data that are also not always available. Qualitative characterizations are acceptable when there are insufficient data to support quantitative work.

Exposure Assessment

The exposure assessment step provides an estimate of the level of a hazard the consumers may be exposed to through food consumption. The exposure assessment integrates information about the hazard (e.g., prevalence and/or concentration, growth, and survival characteristics for microbial hazards), the food product (e.g., production methods, presence, ability to support growth of microbes, and food chain handling), and the consumer (e.g., the quantity and frequency of consumption, and handling practices) to produce the required estimates of the exposure in units that vary from per serving or per (sub)population for microbial hazards, to average daily intakes and lifetime exposures for chemical hazards.

Exposure assessments vary significantly between chemical and microbial risk assessments not only because chemicals are often concerned with lifetime exposures and microbial hazards with a single acute exposure but also because the microbial hazard is alive. Growth, attenuation, death, and cross-contamination possibilities over the life of a food product make microbial exposure assessments challenging. Chemical levels in foods often change little throughout the production process. Exposure assessments may be quantitative or qualitative. Quantitative assessments are preferred when practical. Exposure assessments and hazard characterizations can be done in any order, including concurrently.

Risk Characterization

In the risk characterization step, risk assessors integrate the evidence gathered in the previous steps. A characterization often includes one or more estimates of risk, risk descriptions, evaluations of risk management options, and estimates of changes in risk attributable to the management options.

A risk estimate is an estimate of the likelihood and severity of the adverse health effects, with attendant uncertainties, for a given hazard–food combination in a specified population. It may be quantitative or qualitative. The risk description is a narrative that bounds and defines a risk for decision-making purposes. The evaluation of risk management options requires the estimation of 'baseline' risks, understanding the public perception of the hazard, as well as inequities in the distribution of benefits and risks. The evaluation should include the effects of substitution risks (i.e., transformed and transferred risks) as well as an estimate of expected risk reductions under alternative mitigation strategies. The practical feasibility and monetary costs of alternative mitigation strategies must also be taken into account, although some consider this to be a part of risk management, whereas others consider it to be a part of risk assessment.

Roles and Responsibilities in Risk Assessment

The risk manager has a critical role in the risk assessment process. Although the management and assessment tasks are to be kept functionally separated, regular communication, cooperation, and collaboration between these two functions

are essential for success. Some specific examples of the risk managers' involvement in the assessment process include:

- assembling the risk assessment team,
- identifying the questions to be answered by risk assessors,
- providing sufficient resources and time to complete the risk assessment,
- understanding the risk assessment results and using them appropriately, and
- seeing that the purpose statement, scope, conduct, results, and use of the risk assessment is properly communicated to all interested parties.

Qualitative and Quantitative Assessments

Risk assessments can be qualitative or quantitative. When sufficient data and resources are available, a quantitative assessment is preferred, except where the risk manager's questions can be adequately answered in a narrative or categorical fashion. Quantitative risk assessment relies on numerical expressions of risk, which are generally more informative than qualitative estimates. They can be deterministic or probabilistic. The choice depends on the risk manager's questions, available data, the nature of the uncertainties, the skills of the assessors, the effectiveness of outputs in informing and supporting decision makers, and the number and robustness of the assumptions made in the assessment.

When quantitative risk assessment is not possible or necessary, nonnumerical qualitative risk assessment can be a viable and valuable option. It is especially useful:

- for noncontroversial and routine tasks,
- when transparency and consistency in handling risk are desired,
- when theory, data, time, or expertise are limited,
- for broadly defined problems, where quantitative risk assessment is impractical, and
- as a first iteration of a risk assessment, when uncertainty is great.

Qualitative risk estimates rely primarily on ratings (high, medium, and low), rankings (first, second, and third), and narrative descriptions. There is no internationally agreed approach on how to conduct a qualitative risk assessment. However, the better qualitative assessments include both a narrative descriptions of the risk and a qualitative risk estimate, which together provide a descriptive or categorical treatment of risk information in a formal, organized, and reproducible manner. Much of the relevant evidence in any given risk assessment is not numerical. Thus, a qualitative assessment compiles the available evidence and combines it in a logical and transparent manner that supports a statement of risk. Qualitative assessments reveal data gaps and can be useful in directing resources to productive areas of research. Their value stems from the ability to inform and support risk management decision making in complex situations.

Uncertainty and Variability

Risk analysis is for making decisions under uncertainty and in the face of variability. Risk assessors lack information because there are facts that they do not know, data that they do not have, the future is fundamentally uncertain, and because the universe is inherently variable. Uncertainty about the probability and consequence of a risk may be due to either or both 'epistemic uncertainty' (knowledge uncertainty) and 'aleatory uncertainty' (natural variability).

Epistemic uncertainty is due to a lack of knowledge on the part of the observer. Epistemic uncertainty arises from incomplete theory, incomplete understanding of a system, modeling limitations, and/or limited data. It reflects the risk assessors' level of knowledge about the components of the risk assessment. Assessors can be uncertain about what a true value is (e.g., the specific prevalence of *Salmonella enteritidis* in shell eggs). They may be uncertain about risk scenarios, i.e., the sequence of events that produce the risk. The model(s) used to estimate the risk may also be uncertain. Epistemic uncertainty is reducible in principle; more study, research, finding someone who knows what the assessors do not, and expert elicitation are common means of reducing this uncertainty. In some circumstances, it may be expensive, difficult, or even impossible to do so.

Aleatory uncertainty deals with the inherent variability in the physical world. Eggs are not all the same size, they may carry a varying numbers of *Salmonella enteritidis* cells, and people eat varying quantities of eggs prepared in a variety of ways. Natural variability is often attributed to a random process that produces variability among members of a population or of a quantity over time and/or space. It is, in principle, irreducible. In other words, natural variability cannot be altered by obtaining more information. More data may improve the characterization of the variability, but the variability will not be reduced.

Ideally the effects of uncertainty and variability should be separated in a risk assessment so that their effects on the risk estimate(s) and the answers to the risk manager's questions can be explicitly described for the risk manager. Risk assessment should address the potential for uncertainty to affect the outcomes of risk management options. It is the risk assessors' job to address uncertainty in models and their inputs and the risk manager's job to address uncertainty in the risk assessment outputs. To do this effectively, risk managers must understand the significant uncertainties and their implications for the risk assessment and the efficacy of risk management measures.

Sensitivity Analysis

Sensitivity analysis is an essential part of every risk assessment, quantitative and qualitative. The gaps in our knowledge are bridged by assumptions, probability distributions, expert opinion, best guesses, and a variety of other techniques. Sensitivity analysis is a systematic investigation of the means by which assessors bridge these uncertainty gaps. It includes 'what if' analysis of uncertain model parameters and inputs, as well as all significant assumptions. Sensitivity analysis seeks to learn such things as how sensitive model outputs are to changes in inputs and how that sensitivity might affect decisions. A good sensitivity analysis increases overall confidence in a risk assessment.

Risk Assessment Applications

The first risk assessment methodologies were developed for chemical risks. Chemical hazards may be naturally present in

foods, they can enter into food products via raw materials and ingredients, can be formed during certain processing steps (e.g., acrylamide), or enter in later stages of the food supply chain (e.g., packaging migrants). The amount of a chemical present in a food product is often the result of a choice made along the food chain, for example, food additives, and residues of veterinary drugs and pesticides used on crops.

Microbial hazards are markedly different because they are alive and biologically active. They can enter foods at any point in the farm-to-table food chain. The prevalence and concentration of a hazard can change dramatically as the food moves along that food chain. Despite intentional efforts to manage the risk, the hazard is often present at the point of consumption. Individual consumers exhibit a wide variety of health responses to different levels of the hazard. Microbial hazard health risks tend to be acute and may result from consuming a single portion of contaminated food.

There are a growing number of different areas for application of risk assessment, covering microbial, chemical, antimicrobial resistance, nutrient, functional food components, biotechnology, and nanotechnology. Generally, in all application areas, analysts keep to the four basic steps in risk assessment, although tailored methodologies have been developed for individual areas.

A good source for risk assessments conducted around the globe is foodrisk.org (http://foodrisk.org/rarepository/), and the following examples of qualitative risk assessments and risk assessment procedures can be found there:

- Opinions on the geographical risk of bovine spongiform encephalopathy in various countries.
- Evaluations of the safety of new antimicrobial animal drugs with regard to their microbiological effects on bacteria of human health concern.
- Regulatory procedure for health risk assessment of GM foods.
- Safety assessment of GM food.
- Example of a qualitative exposure assessment in a microbial risk assessment.
- Qualitative risk assessment of the risk of introduction and transmission of H5N1 HPAI virus for 1-km buffer zones surrounding compartmentalized poultry farms in Thailand.

Safety Assessment

Safety assessments are a commonly used tool in the assessment of acceptable levels of risk. These assessments generally compare an estimated level of a hazard to a science-based safety standard. Hazard levels in excess of the standard are considered unacceptable and are subject to risk management measures aimed at reducing the hazard levels below the standard.

Traditionally, chemical risks, such as food additives and pesticide residues, have been subjected to safety assessments. These safety assessments were considered risk assessments by many in the early days of food safety risk assessment. It is perhaps more appropriate today to consider that they are a combination of risk assessment because they are based on science, and risk management because the technique relies on the subjective derivation of a 'safe level of exposure,' which in current terms would be a risk management responsibility.

In the process of a safety assessment for a food additive, the potential hazard is characterized by establishing an acceptable daily intake (ADI), which reflects a level of exposure to the hazard that is considered to be without undue public health effect. This is done by first establishing a no-observed-adverse-effect level (NOAEL) of exposure to a chemical, often through animal feeding studies. To extrapolate from animal feeding studies to humans, an overall factor of safety or uncertainty factor is used. For example, a factor of 10 may be used for extrapolation from animals to humans, another factor of 10 to account for variable susceptibility among humans, and a third factor of 10 to account for sensitive populations. The product of the selected factors $10 \times 10 \times 10 = 1000$ yields the overall safety factor. The NOAEL, say 5 mg per kg of bodyweight daily for a lifetime, is divided by the safety factor to yield the ADI (0.005 mg per kg of bodyweight daily for a lifetime) for the human population of interest.

The estimated daily intake (EDI) of the substance is then estimated and compared with the ADI. An EDI/ADI > 1 is considered unacceptable and levels of the toxic substance must be reduced. Other levels are considered safe.

For chemical contaminants, a so-called tolerable daily intake (TDI) is derived following a comparable process. In the case of pesticide residues, the exposure assessment relies on identification of a suitable index of residue levels that can be used to predict residue intake. This level is usually the maximum residue limit (MRL). The MRL is used to estimate the dietary intake of the residue, which is compared with the TDI.

Linking Risk Assessment to Food Safety Management

On the basis of a risk assessment, risk managers make decisions in the light of public health protection policies. They may decide to implement particular risk management options to mitigate a risk they deem unacceptable. They may also determine a tolerable number of adverse health effects in their population that can result from a specific hazard associated with a particular food. Such a level of public health effects may be called a 'public health goal' stipulated in regulatory policy for the protection of public health in a country. In the context of international trade in food, it is often referred to as the 'appropriate level of protection' (ALOP). A public health expectation is normally determined for a sovereign nation by a competent authority. It may be based on a decision made considering epidemiological evidence in a country; but in the international context, it is advocated to be set using the risk analysis framework. In the latter case, a risk assessment is commissioned by the risk manager in the responsible regulatory body to provide the required estimate of prevailing risk from which to derive the public health goal or the ALOP. The ALOP then states the number of illnesses per year from a particular pathogen–food pair that can be tolerated; for the

purposes of providing an example, say, the ALOP is 100 illnesses per total population per year. Working backward from this number of illnesses using the exposure assessment data of the risk assessment, now suppose that 100 or fewer illnesses can be expected to occur if the probability of illness is 10^{-6} or less. The ALOP translated into this probability of illnesses is shown in Figure 2.

To realize a probability of illness of 10^{-6} or less, the dose–response relationship of the figure indicates that the food at the time of consumption must have 10^5 or fewer pathogenic cells per gram (or more practically: CFUs of the pathogen per gram, CFU g^{-1}) at the time of consumption. Considering the results of the risk assessment, such as the vulnerability of subpopulations, or variability and uncertainty associated with the dose–response data, the risk manager may wish to lower this value to a level deemed more appropriate. In any case, this value would then be a target to be met by the food industries involved in the food supply chain for the particular food product. Codex Alimentarius refers to this target value as the food safety objective (FSO) and defines it as 'the maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the ALOP.' If the food industries manage to meet the FSO, then the ALOP will be realized. Codex Alimentarius provides guidelines on the ALOP and FSO concepts specifically for risks due to microbial hazards. Both the ALOP and FSO are determined at the national level by competent authorities.

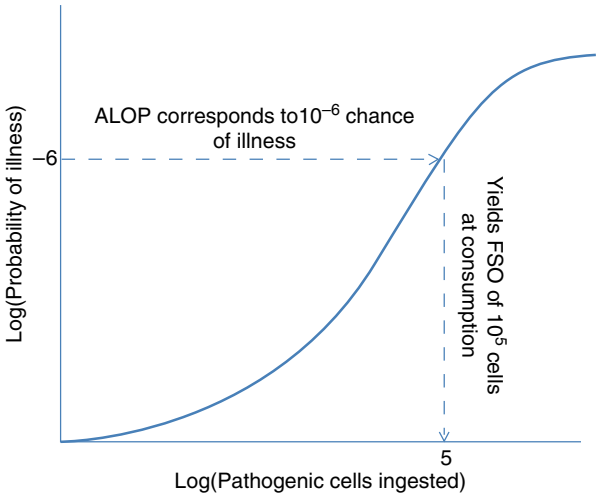

Figure 2 From ALOP to FSO with a dose–response relationship.

Armed with this information, the individual firms can establish the appropriate design of their food safety management systems, which generally are based on employing good practices (such as good agricultural practice, good hygienic practice, and good manufacturing practices) and following the principles of hazard analysis critical control points. Figure 3 shows a simplified food supply chain. Codex Alimentarius advocates ALOP and FSO to drive the design of food safety management systems targeting microbial hazards.

Raw ingredients are received and processed, there is a kill step of some kind and the product is stored until sold to the consumer. Notice that the ALOP influences health outcomes by limiting the number of illnesses. The FSO is set at the point of consumption. As one of the risk management options, a performance objective (PO) may have been issued by the competent authorities to aid industries that lack resources to design appropriate food safety management systems to meet the FSO. Other industries may be setting PO values by their own means. The concept of a PO is identical to that of the FSO, but it occurs at an earlier stage in the food chain, not at consumption. The PO expresses the level of a microbial hazard at a particular point in the food chain that must not be exceeded in order to meet the FSO at the point of consumption. To meet the PO, industries must consider in detail their production and/or handling of the food products and arrange their food safety management systems accordingly. In particular, industries will have to determine how much of the hazard is coming into the food they produce through for instance raw materials, ingredients, and processing environment. They will then know how much they will need to change the hazard level in order to meet the PO. This change is called a performance criterion (PC) by Codex Alimentarius and it relates to the complete stage in the food chain for which an industry is responsible. Codex Alimentarius defines the PC as the effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a PO or an FSO.

Suppose that a PO is set at 10^3 CFU g^{-1} of a particular pathogen at the time of storage and that this will deliver the FSO set for the particular food–pathogen combination.

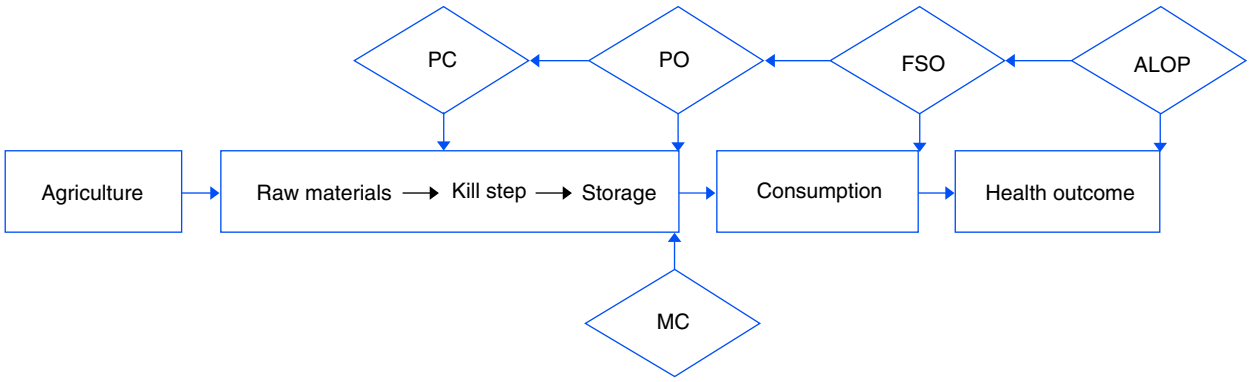

Figure 3 Linking risk assessment to food safety management.

However, raw materials, ingredients, and the production environment may all be sources of the hazard that together bring in a level of the hazard to the food at 10^5 CFU g^{-1}. To meet the PO of 10^3 CFU g^{-1}, there is then a need to reduce the hazard level before storage of the finished product 100-fold, which is the PC value. To achieve a 100-fold reduction, the kill step (for instance pasteurization or other thermal process) will be essential, but also limiting hazards coming into the food through ingredients added after the kill step or from the food production environment will be required to ensure that the PO is not surpassed. For enforcement purposes, competent authorities may establish microbiological criteria (MCs) specifically related to the FSO they have set or to a PO they derived from it. An MC is defined by Codex Alimentarius as the acceptability of a product or a food lot, based on the absence or presence, or number of microorganisms, including parasites, and/or quantity of their toxins/metabolites, per unit(s) of mass, volume, area, or lot. When industries meet the MC, this provides evidence to the regulatory body that they are meeting the PO thus, ultimately the FSO and the ALOP.

Although no competent authority has implemented the FSO approach to date, a significant advantage of this approach for food safety, and the reason why it is advocated by Codex Alimentarius and considered by national competent authorities, is that it does not prescribe how industries should meet food safety expectations without necessarily an integrated view across the food chain, as has been done in the past by governments issuing performance standards for specific operations such as pasteurization. It empowers individual industries to design their products and the associated food safety management systems to their own capabilities. It fosters innovation and helps meet public health expectations in the most efficient manner possible for both governments and industries.

Who Does Risk Assessment?

Many sovereign nations have central food authorities that conduct their own risk assessments. A variety of ministries and agencies, like the US Food and Drug Administration and the US Food Safety Inspection Service conduct food-safety risk assessments. Where such expertise is not available in competent authorities, risk managers in regulatory bodies may have access to specific risk assessment experts and expertise from other relevant public organizations, such as Universities. Academicians have certainly contributed to the growing literature on risk assessment. At the regional level, dedicated risk assessment bodies have been established, such as the European Food Safety Authority of the European Union, which functions as the risk assessment and risk communication body. At the international level, Codex Alimentarius represents the risk management function taking advice from risk assessment specific committees set up under the auspices of FAO and WHO. The Joint FAO/WHO Expert Committee on Food Additives (JECFA) is an international scientific expert committee that has been meeting since 1956. They began by evaluating the safety of food additives. That work has grown to include the evaluation of contaminants, naturally occurring toxicants, and residues of veterinary drugs in food. The Joint FAO/WHO Meeting on Pesticide Residues (JMPR) is an international expert scientific group that has been meeting regularly since 1963. JMPR establishes TDIs and acute reference doses for pesticides they evaluate. They use scientific evidence to recommend MRLs for pesticides in food commodities that follow good agricultural practice. The Joint FAO/WHO Expert Meetings on Microbiological Risk Assessment (JEMRA) began their work in 2000 with the objective of conducting risk assessments for the Codex Committee on Food Hygiene and member countries. JEMRA focuses on providing pathogen commodity combination risk assessments for selected pathogens and on developing guidelines for risk assessment of microbiological hazards in food and water.

Estimating the Burden of Foodborne Disease

RJ Lake, Institute of Environmental Science and Research Ltd, Christchurch, New Zealand
CE Stein, World Health Organization, Regional Office for Europe, Copenhagen, Denmark
AH Havelaar, National Institute for Public Health and the Environment, Bilthoven, The Netherlands, Utrecht University, The Netherlands

Glossary

Burden of disease A measure that combines prevalence or incidence of health states with indices of severity, disability from long-term complications, and duration.
Cost of illness Monetary value of the effect of illness on individuals and society.
Disability adjusted life year A lost year of 'healthy' life. The sum of these across the population is a measurement of the gap between current health status and an ideal health situation.
Disability weight A value between 0 and 1 reflecting the relative desirability of a health state, where 0 indicates perfect health and 1 worst possible health status; assigned by a panel of judges including medical and/or lay people, used in the calculation of disability adjusted life years.
Foodborne Disease Burden Epidemiology Reference Group (FERG) An expert group advising the WHO initiative to estimate the global burden of foodborne diseases.
Global burden of disease (GBD) A series of studies producing comprehensive estimates of the burden of diseases, injuries and associated risk factors.
Reporting pyramid A quantitative or semiquantitative depiction of the underascertainment of cases at each step of the pathway (general practitioner (GP), clinical laboratory, notifiable disease system) leading to a case that is reported to a disease surveillance system (the top of the pyramid). The base of the pyramid represents the total number of cases which occur in the population.

Introduction

Making choices about the allocation of resources to address health issues requires a consistent quantitative assessment of the relative magnitude of diseases. Burden of disease estimates provide such a metric, which can act as a transparent criterion for the relative importance of specific diseases. This provides opportunities not only to allocate resources and to target interventions, but also to monitor their effects.

Burden of disease is defined as a measure that combines prevalence or incidence of health states with indices of severity, disability from long-term complications, and duration.

Foodborne disease encompasses acute and chronic syndromes caused by a multitude of hazards. In this article, the authors describe the application of burden of disease estimates as a tool to prioritize or rank food safety risks. There are numerous publications that discuss burden of disease concepts and alternate metrics. The authors will focus on issues specific to the burden of foodborne disease and summarize existing and 'in progress' estimates.

Burden of disease metrics represent one component of analysis for (regulatory) decision making. Health policy analysis takes the perspective of maximizing population health (rather than individual preferences), so summary measures of population health are required.

Burden of Disease Metrics

A number of metrics to quantify the burden of disease as a summary measure of public health have been put forward. These relate to differing approaches to the economic evaluation of health care programs. In the context of foodborne disease, such evaluations compare the costs of an intervention to improve food safety, with the consequences of the intervention, in terms of illnesses avoided.

Cost–Benefit Analysis

Cost–benefit analysis is an economic evaluation that attempts to value the consequences or benefits of an intervention in monetary terms, rather than in 'units of health'. This approach requires monetary values for the effect of illness on individuals. Although this approach has difficulties, it does have the advantage of being able to compare health programs with nonhealth programs.

There are two main approaches to the monetary valuation of health outcomes. The 'cost of illness' (COI) approach sums the medical and nonmedical costs of the disease along with productivity losses from associated morbidity or premature mortality. Direct costs are those for medical services such as visits to a general practitioner (GP) or physician, specialist,

and costs associated with medicines. Nonmedical direct costs are incurred by the case in accessing medical services (e.g., travel costs).

Indirect costs are those resulting from the inability of a case (or a caregiver) to perform normal life activities. This principally concerns an inability to perform paid work, valued as lost income (usually on a daily basis, and regardless of whether the case actually loses that income). For some analyses, the period during which a case is unable to perform normal activities is valued, regardless of whether the case is employed, i.e., the cost includes both work and leisure activities. For illnesses where patients die prematurely, or are unable to return to work, the lost productivity may be represented by estimates of foregone earnings.

The second approach, 'willingness to pay' (WTP), attempts to measure the value an individual places on reducing risk. In the absence of market pricing mechanisms, several alternatives have been developed to provide WTP values. The most common approach is 'contingent-valuation studies' in which individuals are surveyed in the context of a hypothetical market situation. Examples related to food safety include WTP, over and above current expenditure, for poultry meat treated to eliminate the risk of foodborne illness, and experimental auctions to reduce the risk of campylobacteriosis from consuming poultry. For illnesses where patients die prematurely, or are unable to return to work, WTP estimates of the value of a statistical life can be used.

Inherent in the analysis of this COI is a choice of 'perspective,' which guides the costs that are included. The most common choice is to take a societal perspective, which includes all costs to the individual case and society as a whole, in providing medical services and lost production through inability to work. However, alternative perspectives, such as the individual patient, or the medical system, could be chosen.

Additional nonhealth costs may be borne by the food industry and governments. Industry costs include control measures, recalls, and loss of product and brand name credibility; whereas for regulators there are costs associated with the generation of standards, monitoring, and surveillance. However, these costs are estimated infrequently.

Cost–benefit analysis is discussed in more detail in another article.

Cost–Utility Analysis (Cost-Effectiveness Analysis)

Cost–utility analysis incorporates changes in the quantity of life (mortality) and changes in the quality of life (morbidity) into a single 'unit of health' metric. The concept of health adjusted life years (HALYs) has been developed by health economists, and the two most common metrics of this type are the quality adjusted life year (QALY, broadly useful as a measure of health gain from interventions) and the disability adjusted life year (DALY). The DALY is a measure of the gap between an existing health state and a hypothetical ideal, and thus is a metric suited to burden of disease.

To incorporate both the quantity and quality of life into a common unit of measurement, it is necessary to use a set of values or weights, sometimes called utilities. These reflect the relative desirability of the health state, with perfect health and death representing the opposite extremes. There are a variety of methods for eliciting these preferences from individuals or health experts, including scaling methods (rating scales category scale, visual analog scale, and ratio scale) and choice methods (time trade-off, paired comparison, equivalence, person trade-off, and standard gamble).

DALYs were originally developed by the World Health Organization (WHO) for the Global Burden of Disease (GBD) Study. Since then, they have been extensively used for burden of disease estimation, including foodborne disease.

The fundamental calculation for DALYs is:

$$\mathrm{DALY} = \mathrm{YLL} + \mathrm{YLD}$$

YLL is the number of years of life lost due to mortality and YLD is the number of years lived with a disability, weighted with a factor between 0 and 1 for the severity of the disability.

The YLL due to a specific disease in a specified population is calculated by the summation of all fatal cases (n) due to the health outcomes (l) of that specific disease, each case multiplied by the expected individual life span (e) at the age of death.

$$\mathrm{YLL} = \sum_{l} n_l \times e_l$$

YLD is calculated by accumulation of overall health outcomes (l), the product of the number of cases (n), the duration of the illness (t), and the severity weight (w) of a specific disease. It should be noted that the calculation for YLL implicitly includes a severity weight factor. The severity weight or disability weight factors are in the range 0–1, with the severity weight for death being equal to 1.

$$\mathrm{YLD} = \sum_{l} n_l \times t_l \times w_l$$

An example calculation, for an infection with a microbial foodborne hazard that has a variety of outcomes, is illustrated in Table 1. In this example, $\mathrm{YLD} = 55 + 200 + 8 = 263$ and $\mathrm{YLL} = 607$, hence $\mathrm{DALY} = 263 + 607 = 870$.

Table 1 Example DALY calculation for a specific disease

Burden calculation	*Outcomes*			
	Do not visit a GP and recover	*Visit a GP and recover*	*Hospitalized and recover*	*Fatal*
Cases per year	59 000	18 300	570	46
Duration	5 days (0.014 years)	10 days (0.028 years)	14 days (0.038 years)	13.2 years[a]
Disability weight	0.067	0.39	0.39	1
Disease burden	55	200	8	607

[a]Fatality occurred on average 13.2 y before normal life expectancy.

A number of methodological choices have to be made when calculating DALY values for burden of disease.

Although a prevalence approach may be taken to the calculation of DALYs (i.e., calculating the current burden of disease in a population, considering previous events), more commonly an incidence approach is taken. This includes both current and future health outcomes. Future outcomes include sequelae and mortality resulting from the initial infection with pathogens within a defined time period.

To calculate YLL, life expectancy must be defined. Some studies have used life expectancy tables for the population being studied. A more universal approach would be to use life expectancy that reflects an ideal of human potential. The greatest potential for the life-span of humans is currently the life expectancy of the Japanese population (82.5 years for females). This ideal is used to choose appropriate values from the Coale–Demeny regional model life tables (West level 26 for females, and 2.5 years less for males, using the West level 25 for females).

When calculating YLL, the 1990 GBD study weighted a year of healthy life lived at younger and older ages lower than years lived at intermediate ages. This was a reflection of societal choices, particularly in nonindustrialized countries where individuals at intermediate age tend to be the main breadwinners for dependents among several generations within one family. However, the concept of such weighting (and the appropriate weighting to be applied) has been controversial. On equity grounds, it has been argued that every year of life should have equal value.

The discounting of future benefits is a standard practice in economic analysis. However, opinion is divided as to whether future health, such as future DALYs avoided, should be discounted.

The 2001 GBD Study results were generally presented without age weighting, but using a 3% discount rate, although the effect of varying these settings was also discussed. A Dutch study of foodborne pathogens presented both undiscounted and discounted estimates (using a discount rate of 4%), whereas a New Zealand study applied no discounting to DALY estimates.

Comorbidity, when multiple conditions coexist in an individual, presents particular difficulties. This is particularly relevant for foodborne disease, because a preexisting condition (e.g., diseases affecting the immune system) or a risk factor (e.g., old age) may make a person more susceptible to infection, or at greater risk of more severe consequences. Questions arise of how a comorbid condition might affect the disability weight for the disease of interest and how the burden of disease can be apportioned, particularly when mortality occurs. These issues have yet to be addressed on a population health basis by existing foodborne disease burden estimates, although national burden of disease studies have examined the issue.

Methodological Choices Particular to Estimation of Foodborne Burden of Disease

Foodborne diseases are those commonly transmitted through food and include illnesses caused by microbial pathogens, parasites, chemical contaminants, and biotoxins. They also include food allergies. There are a number of particular methodological issues which must be resolved for foodborne burden estimates to be generated. These are not entirely specific to foodborne disease; similar challenges would apply to estimating the burden of waterborne disease.

Incidence

One approach to estimating the burden of disease for foodborne hazards is to estimate the incidence of specific relevant syndromes or outcomes (as clinically defined by International Classification of Diseases codes), such as acute gastrointestinal illness (AGI), which is important for foodborne microbial pathogens. This is sometimes called the 'top down' approach. A number of studies estimating the incidence of AGI have been published including prospective studies in England and the Netherlands, as well as retrospective telephone surveys in Australia, Canada, Ireland, the US and New Zealand. Global estimates of the incidence of diarrheal illness have been published for children younger than 5 years of age as well as older children and adults.

The next step in this approach is to assign proportions of the incidence to etiologic agents relevant to foodborne transmission. This may be achieved by direct analysis of clinical samples provided by surveyed cases, as in the prospective infectious intestinal disease study in England. Alternatively, proportional estimates may be extrapolated from surveillance data generated by clinical laboratories, with an additional proportion assigned from the remaining cases of unknown etiology.

A complicating issue in assigning such proportions is that asymptomatic carriage of pathogens may occur in a proportion of people. In a standard approach to estimating the etiological fraction, the prevalence in symptomatic individuals should be corrected for the prevalence in asymptomatic individuals. However, for infectious diseases this approach may not be applicable because asymptomatic carriage may be associated with acquired immunity and less virulent subtypes of the pathogenic microorganisms.

An alternative approach is to estimate the incidence of illness from agent-specific diagnoses. This so-called 'bottom up' approach uses the concept of reporting pyramids, where data may be obtained from a variety of levels. The base of the pyramid is all community cases, with higher levels being those that present to the health system, those that provide samples and an agent is diagnosed, with those that are reported to surveillance being the top of the pyramid. Data may be provided by notifiable disease surveillance systems, hospitalization, and mortality records, and incidence at other levels of the pyramid can be estimated using 'multipliers.' Well-known examples of such studies include estimates of the incidence of foodborne illness in the USA, which were updated in 2011.

To capture all the relevant outcomes associated with a particular agent, 'outcome trees' or 'disease models' are usually constructed, which describe the progression of health states potentially resulting from ingestion of a hazard through food. For microbial infections, the most common outcome is an acute disease followed by recovery. A small proportion of cases

will go on to develop sequelae, and a smaller proportion will result in mortality. The conditional probabilities of each branching pathway are assigned in the tree as far as possible.

The development of these trees requires choices about which outcomes to include and exclude. An international consensus on these choices has not yet been reached; links between initial infections and sequelae are often difficult to establish and quantify. Frameworks such as those developed by the Institute of Medicine to assess scientific evidence for causation can be helpful.

By including not only the initial illness caused by the ingestion of the hazard in food, but also longer term effects as sequelae, this approach integrates the burden from a number of syndromes. In doing so, it is important that the outcome burden components fit within the syndrome-specific burden envelopes estimated by overall public health burden of disease estimates. For example, the burden of disease assigned to Guillain-Barré syndrome (GBS) as a sequel of campylobacteriosis would be a component of the overall burden from this syndrome within a population.

Attribution for Foodborne Transmission

Hazards relevant to foodborne disease usually have multiple pathways of exposure for humans. Once a burden of disease estimate has been generated, a proportion needs to be assigned to foodborne transmission. The GBD Study assigns burden of disease estimates to risk factors using a comparative risk assessment approach (CRA). The CRA approach estimates the burden of disease and injuries due to risk factors based on a counterfactual exposure distribution that would result in the lowest population risk, irrespective of whether this is currently attainable in practice. The counterfactual is referred to as the theoretical minimum-risk exposure distribution. Reviews of the literature are used to provide suitable counterfactual exposure distributions, and the stratified estimates for existing exposures.

The corresponding counterfactual exposure distribution for foodborne hazards would be zero exposure. To estimate current exposure requires knowledge of food consumption, hazard prevalence, and concentration. However, it is often not possible to conduct exposure estimates for foodborne hazards, either because of limited data, or the dynamic nature of the hazard (i.e., microbial hazards, which may grow or decline depending on factors through the supply chain). A number of alternative approaches exist for attribution of the burden of illness from hazards that may be foodborne, including the analysis of microbial subtyping data, epidemiological studies, outbreak analysis, and expert elicitation.

Severity and Duration: Disability Weights Relevant to Foodborne Disease

The disability weight is a value elicited from a panel of judges that reflects the relative desirability of particular health states. The value ranges from zero (best possible health state) to one (worst possible health state). The members of the panel may be persons suffering from the illness in question, their carers, medical experts, or lay people. Numerical values may be elicited by asking panel members to simply provide a score across a range, or else specify a period of healthy life that would be sacrificed to avoid the illness (a 'time trade-off' approach).

The health state needs to be described to the panel. This may be done using generic tools that describe a range of health states using sets of specific attributes describing how the disease affects a person. The panel assigns values to a number of health conditions with different combinations of these health attributes. These are then disaggregated (e.g., by regression modeling) to produce a formula to calculate disability weights for any combination of attributes. This approach has been used to generate the large number of disability weights needed by the GBD Study.

Alternatively, disease-specific descriptions may be used to indicate both the cause and the health effects of the condition. Such descriptions may adopt a period profile approach, where the health state is considered to be constant over time, and duration information is not included (i.e., duration and disability are independent). Alternatively, the annual profile approach is taken, where the duration of the disease is indicated in the disease presentation (as a portion of a year), which removes the need to estimate duration of acute, self-limiting diseases for DALY calculations.

The annual profile approach has been applied to short-term AGIs and sequelae, which are particularly relevant to foodborne disease, in a Dutch study using lay person panels to assign disability weights. This study also considered the use of a relevance criterion. Using the 'time trade-off' method to generate disability weights, panel members had the option of refusing to sacrifice any days of healthy life to avoid the illness. A threshold was established that half the panel had to be willing to sacrifice a period of healthy life, in order to consider the illness relevant. If the threshold was not achieved, then the illness was considered trivial in terms of burden and excluded from the DALY estimate. For example, fewer than half the panel members were willing to sacrifice any period for mild gastrointestinal illness (one day). Excluding these cases reduced the burden estimate for all pathogens, particularly norovirus for which the burden was reduced by 94%.

Global Burden of Disease

The global burden of disease project grew out of work by the World Bank to prioritize control of specific diseases in developing countries. Cost-effectiveness analysis for this purpose required an assessment of the relative magnitude of diseases, injuries, and risk factors. The original GBD Study was commissioned by the World Bank in 1991 to provide a comprehensive assessment of the burden of 107 diseases and injuries and 10 selected risk factors for the world and 8 major regions estimated for the year 1990. A major update, for the year 2001, was published in 2006. In 2008, WHO published a further update, for the year 2004.

Since 2007, the Global Burden of Diseases, Injuries, and Risk Factors Study (the GBD 2010 Study) has been working to produce comprehensive and comparable estimates of the burden of diseases, injuries, and risk factors for two time periods, 1990 and 2005. The core team for this initiative

includes scientists from the University of Washington, Harvard University, the University of Queensland, Johns Hopkins University, and the WHO, and will use improved methods and data that have been developed since the original GBD 1990 Study. The project is expected to produce its estimates in 2011.

Global Burden of Foodborne Disease

In 2006, the Department of Food Safety and Zoonoses (FOS) in WHO conducted an international consultation on estimation of the burden of foodborne diseases. This consultation resulted in the launch of the WHO Initiative to Estimate the Global Burden of Foodborne Diseases and a strategic framework to guide the task. An external advisory group was required, so the Foodborne Disease Burden Epidemiology Reference Group (FERG) was set up, under the leadership of WHO/FOS, with the following specific functions:

1. Assemble, appraise, and report on the current, the projected, as well as the averted burden of foodborne disease estimates.
2. Conduct epidemiological reviews for mortality, morbidity, and disability in each of the major foodborne diseases.
3. Provide models for the estimation of foodborne disease burden where data are lacking.
4. Develop cause attribution models to estimate the proportion of diseases that are foodborne.
5. Use the FERG models to develop user-friendly tools for burden of foodborne disease studies at country level.

A dedicated website for the FERG initiative has been developed by the WHO.

FERG has established five task forces to address elements of the global burden. Three of these are hazard based (Enteric, Parasitic, Chemical) whereas a fourth is concerned with Source Attribution. Through the commission of systematic reviews addressing specific hazards, global estimates of incidence will be gathered and used for DALY calculations.

The fifth task force, Country Studies, was established in 2008 and is intended to foster a series of national foodborne disease burden studies in specific countries, particularly developing countries. The studies will be conducted according to a specific protocol, developed partly through adaptation of the National Burden of Disease Studies protocol published by WHO. These studies will have several objectives, in addition to filling data gaps for the FERG global estimate. Besides capacity building within each country, the task force has also taken on the challenge of providing tools for the translation of burden of disease information into food safety policy. This novel objective is being addressed by a knowledge translation subgroup of the Country Studies Task Force.

FERG has a 5-year mandate, with reporting to begin in 2012. The Country Studies will begin in 2011 and are likely to be completed in 2013–2014.

A number of publications have already emerged from this project, including global estimates of the incidence and etiology of diarrheal morbidity and mortality in older children and adults and estimates of the global incidence of specific parasitic diseases.

National Burden of Microbial Foodborne Disease Studies

Economic Estimates

Cost of illness estimates have been extensively investigated in the US. A series of estimates have been published by the USDA Economic Research Service (ERS), beginning with a 1996 estimate of the cost of foodborne illnesses from six bacterial pathogens of $2.9–6.7 billion (US). This estimate was based on a COI approach, including foregone earnings of affected individuals, and productivity losses. More up-to-date estimates have been provided at the ERS website.

A 2009 estimate of the cost of foodborne illness for six major foodborne enteric diseases in New Zealand of $162 million (NZ$) has been published. The estimate of the value of personal and lifestyle costs (pain, suffering and disruption, including the possibility of premature death) was based on a WTP estimate for the value of a statistical life. This estimate also included costs for treatment and lost production, as well as industry and regulatory costs.

An Australian estimate of the cost of foodborne illness, published in 2006, also incorporated industry and regulatory costs, although these were modest compared with productivity and lifestyle costs. The overall cost was estimated as $1249 million with productivity and lifestyle costs being $772 million (AU$), largely based on WTP by individuals to avoid illness.

DALY and Cost of Illness Estimates

The Netherlands

A series of studies performed by the National Institute for Public Health and the Environment (RIVM) for the Dutch government have generated both burden of disease and COI estimates for a range of pathogenic microorganisms that may be foodborne. The first study, for the year 2004, described the burden of disease for norovirus, rotavirus, thermophilic *Campylobacter* species, *Salmonella* spp., Shiga toxin-producing *Escherichia coli* O157, *Listeria monocytogenes*, and *Toxoplasma gondii*. For the first four of these, COI was also estimated. A second study published in 2007, applied the same methods to estimate the disease burden and COI of *Giardia lamblia* and *Cryptosporidium* spp.. Most recently, an update for 2006 has been published. In addition to using updated data, this report expanded the range of pathogens to include hepatitis A and E virus, and the toxin-producing pathogens *Clostridium perfringens*, *Staphylococcus aureus*, and *Bacillus cereus*.

A significant change in the DALY estimates in 2006 for some pathogens was due to the addition of postinfectious irritable bowel syndrome (IBS) as a sequel for infectious diarrhea. The effect of this added sequel was to increase the DALY estimates by 86, 92, and 151%, respectively, for *Campylobacter*, *Salmonella*, and *Shigella*. This illustrates the potential importance of choices about sequelae for burden of disease estimates.

The attribution component of this analysis was taken from an expert elicitation study. A strength of this study was that it asked experts to estimate environmental, human (person-to-person), and animal contact proportions of the

attributable fraction, as well as the foodborne proportion, providing a total of 100%.

The DALY burden estimated for 2006 in the Netherlands was highest for infections with *Campylobacter* spp., followed by *Salmonella* spp. and norovirus.

New Zealand

Estimates of the burden of foodborne disease caused by six selected enteric pathogens in New Zealand have been reported. Illnesses were selected based on considerations of incidence and clinical severity in the New Zealand context:

- Campylobacteriosis.
- Salmonellosis.
- Listeriosis (invasive, perinatal, and nonperinatal).
- Infection with Shiga toxin-producing *E. coli*.
- Yersiniosis.
- Infection with norovirus.

The estimation of disease burden closely followed the approach taken in the Netherlands. New Zealand specific attribution estimates were derived from an expert elicitation process. The elicitation was carried out as a two-pass modification of the Delphi method. The base year for these estimates was 2005, although some data (especially for rare outcomes like mortality) were taken from a wider time span.

In addition to the DALY burden, COI estimates were generated for direct and indirect medical costs. Direct health-care costs included GP consultations and medication for AGI, GP and specialist consultations for sequelae, hospital, and rehabilitation costs. Indirect costs included lost production resulting from illness. For fatalities and long-term disability, lost production was estimated using discounted future income (instead of the friction cost approach used in the Netherlands estimate).

As would be expected for New Zealand, having a high reported incidence of this illness compared with other developed countries, the greatest burden of foodborne disease estimate was for campylobacteriosis and sequelae. The DALY estimates ranking for the remaining illnesses (and relevant sequelae) were at least four-fold lower. The reported incidence of campylobacteriosis in New Zealand has declined by approximately 50% over the period 2006–2010. This will substantially reduce the burden estimate for this disease.

After the production of these estimates, alternative disability weights for AGI outcomes were published. The New Zealand burden estimates were revisited using these new weights. The revised estimates, using a relevance criterion, provided the same ranking of the bacterial pathogens. However, when the relevance criterion was not applied, then the DALY estimate for the foodborne burden of infection with norovirus was higher than that for campylobacteriosis and sequelae.

National Burden of Chemical Foodborne Disease Studies

Some estimates of the foodborne disease burden from chemical contaminants in food have been published. In the Netherlands, estimates of the burden attributable to chemical contamination (mycotoxins, nitrates, processing contaminants) and allergens in food have been reported by RIVM, although these were described as probably overestimates. Estimates of the disease burden from neurodevelopmental toxicity of methylmercury have also been published by WHO, based on seafood consumption.

Future Challenges

Several aspects of the estimation of the burden of foodborne disease are well established and dependent on the availability of sufficiently robust incidence data and the ability to attribute a proportion of that incidence to foodborne transmission. This is the case for most of the relevant bacterial, viral, and parasitic microbial pathogens.

The estimation of the burden of disease caused by chemical hazards in food is the most pressing area for methodological development. Like the linkage between microbial infections and potential sequelae, linkages between exposure to chemicals and health effects are often circumstantial. Another complicating factor is the multiplicity of exposure routes for many chemicals.

As described above, the use of age weighting and discounting presents important methodological choices. Adjustment for comorbidity also remains to be addressed by foodborne disease burden estimates.

There is a need to standardize the outcome trees used by agent-specific foodborne disease burden estimates, so that results can be compared across countries and regions. As illustrated by the inclusion of IBS in the Netherlands burden estimates, these decisions can have a major effect on the size and ranking of burden.

The extrapolation of disability weights developed for a single country to other countries or regions is an issue that requires further study. This is particularly important for extrapolation between developed and developing countries, where illness caused by the same agent may have different courses of disease (e.g., campylobacteriosis). The GBD Study 2010 has set up an interactive website with the aim of soliciting value judgments on disability weights from a large number of individuals around the world.

Finally, there is a need to consider how burden of disease information might be used by decision makers, particularly governments and other regulatory organizations. The quantification of the disease burden itself, and ranking of individual hazards, could assist in the allocation of food safety resources. However, the DALY metric is probably less familiar to policy makers, and arguments based on economic value may be applicable in the wider policy arena. WHO is mindful of this issue and has asked the FERG to advice on this through the Knowledge Translation and Policy Group within its Country Studies Task Force.

Where a range of interventions to improve food safety are available, a cost-effectiveness analysis would be useful. Use of nonmonetary burden of disease metrics for cost-effectiveness analysis requires a weighting of costs (in $) against improvements in public health (usually in some other metric, often DALYs). In a ranking situation, where there is a requirement to

rank options for risk management, a league table of costs and benefits/effectiveness could be sufficient (ranking based on cost-effectiveness ratio). However, if the choice is whether to take action or not, then some threshold of the amount of expenditure for a unit of health gain is required. Exploration of this issue can probably only be achieved after a number of cost and burden estimates have been produced. It is possible that such criteria may emerge after ranking exercises that encompass a variety of transmission routes (especially if options to reduce waterborne disease can be included).

RISK ANALYSIS

Risk Assessment: Microbiological Hazards

T Ross, University of Tasmania, Hobart, TAS, Australia

Glossary

Equivalence The demonstration that one set of food safety management measures leads to the same public health outcome as another, and are accepted as such by both jurisdictions.

Exposure assessment The qualitative or quantitative evaluation of the likely intake, both amount and frequency, of a defined hazard in a specified food by a defined population.

Farm-to-fork A term to describe the conditions of processing, storage, distribution, etc., of a food from the point of harvest to the point of consumption.

Harmonization (of law) The process of creating common standards across diverse jurisdictions.

Hazard A thing that could cause harm; in microbiological food safety risk assessment, the hazard will be a microbial pathogen, parasite, or toxin produced by a microorganism that could be present in food.

Hazard characterization Description and evaluation of the adverse health effects associated with ingestion of a pathogen or microbial toxin that may be present in food; it should include a dose–response assessment, i.e., a (quantitative) description of the relationship between the amount of the hazard ingested and probability and/or symptoms of illness caused.

Hazard identification The identification of known or potential health effects associated with a particular microbial hazard in a particular food.

Risk A function of the probability of illness to a consumer(s) and the severity of the illness, and number of people affected, due to a hazard in food.

Risk characterization Integration of the hazard identification, exposure assessment, and hazard characterization stages of risk assessment to produce an estimate of the likelihood and magnitude and severity of adverse health effects in a defined population due to a specified hazard in a specified food.

Stochastic simulation modeling A form of mathematical modeling in which variables in the calculation are described by distributions of values, rather than a single representative value. Because calculations involving distributions can become very complex, it is usually easier to use simulation modeling approaches, involve computer software to automate the repetitive calculation of the model for many thousands of combinations of different values of each variable, to generate a distribution of the possible results.

Introduction

Historically, regulations governing the microbiological quality and safety of foods were developed empirically, and independently, by nations. Over time, this leads to various problems.

During the 1980s and 1990s, increased awareness of microbial foodborne disease led national governments to seek better ways to manage food safety, and prioritize the allocation of resources for food safety management to the greatest risks, and where most benefits might result. The systematic analysis of the sources of risk that occurs in formal risk assessment approaches was promoted as a way to optimize food safety outcomes from the (often) limited available resources by focusing regulatory actions on the control of those steps in a 'farm-to-fork' food chain that most contribute to consumer risk. Related to this were concerns about appropriate sharing of responsibility for food safety along the 'farm-to-fork' chain so as to ensure the safety of the product at the time of consumption. Responsibility for food safety had usually been imposed on food processors despite their efforts being thwarted by others, for example, by mishandling their products further along the supply chain. Food safety management approaches based on risks, rather than perceived hazards, were proposed to be more rational, equitable, effective, and defensible.

Similarly, increasing focus in some nations on the overall impost (on industry and national productivity) of government regulation led to the idea that such regulations should be justified, i.e., by proving that their benefits outweighed the costs (to government, industry, and consumers) of their implementation. Concurrently, with increasing international trade in foods, inconsistencies in the food regulations of trading nations began to cause tensions between trading partners: Exporting nations considered that the importing nations sometimes imposed unfair, or unrealistic or unnecessary regulations on the imported products (including food) to protect their domestic industries from international competitors able to supply products of equivalent quality and integrity at lower cost. The ability to compare the efficacy of

Box 1 Applications of microbial food safety risk assessment (MFSRA)

At its most basic level, risk assessment is a systematic analysis of the likelihood and severity of some undesirable event. Although the most extensively documented MFSRAs have generally arisen from large national or international projects to establish and justify new food safety regulations, the approach is useful for many applications including:

- assessing equivalence of food safety management systems in different jurisdictions,
- assessing the risk from different foods to establish priorities for risk management and for the allocation of resources to the management of that risk,
- comparing the public health burden of foodborne diseases to other diseases for the apportionment of resources,
- attribution of the burden of foodborne microbial illness to different foods (ranking of relative risk of foods for different pathogens),
- to better understand the relative contributions of various factors that affect a specific foodborne microbial risk and thereby to identify and select the most optimal risk management options including sharing of responsibility for food safety at all points along the farm-to-fork food chain,
- assisting in the development of effective hazard analysis critical control points (HACCP) plans for food businesses,
- establishing relevant microbiological criteria for food that achieve an appropriate level of protection (ALOP) to consumers,
- verifying that a Food Safety Objective (FSO), related to an ALOP, is achievable, and
- evaluation of the relevance/efficacy existing regulations

different risk management approaches to food safety in different trading nations, and to have objective means of setting food safety standards for international trade in foods, respectively termed equivalence and harmonization, were also advocated as benefits of formalized food safety risk assessment (see Box 1).

Until the 1990s, however, microbial food safety risk assessment (MFSRA) had been considered a daunting task because of the apparent randomness of microbial contamination of foods and the subsequent consequences, i.e., because microbial contamination levels can increase or decrease dramatically (due to microbial growth and inactivation) according to the handling of foods along the farm-to-fork chain. With the advent of predictive microbiology, the ability to monitor temperature continuously throughout the food supply/distribution chain, and quantify the probability (and severity) of illness from different doses of pathogens, the ideas of risk analysis have begun to be applied to microbial food safety management and food safety standard setting.

Many MFSRAs have now been conducted and presented. As discussed in the section Methods for Risk Characterization, they differ in scale and complexity and the risk questions addressed. They include academic examples from diverse researchers and organizations in various nations and presented in the published scientific literature, studies conducted for industry organization in various countries and presented as internal reports, those initiated by provincial or national governments, and others undertaken by international organizations such as the European Food Safety Authority, Codex Alimentarius Commission (CAC), International Life Sciences Institute, etc. They consider a variety of pathogens and foods; for some food–pathogen combinations, the risk has been assessed by different organizations. Results from these risk assessments have been translated into government policy concerning priorities in public health management, or changed food safety management strategies and regulations that have affected industry practices and technologies, have resulted in changed international regulations and guidelines (including relaxation of standards in some cases), and changes to recommended industry practices. The list of useful websites at the end of this entry provides a guide to many of these reports. The Joint Institute of Food Science and Applied Nutrition (JIFSAN) site is particularly useful because it provides access to a wide range of published food safety risk assessments, resources and related information, and is actively maintained and updated.

This article describes the principles of microbiological risk assessment, and development of 'best practice' methods for microbiological risk assessment.

Risks and Hazards

Humans have used various forms of empirical risk assessment since antiquity, and continue to do so on a daily basis. The development of formalized, objective, and science-based assessment of risks may be traced to the need to improve, and defend, various regulations introduced by government agencies, particularly in the US. Catastrophic accidents in the space program, failures in nuclear power facilities, and unforeseen environmental and health effects of industrial developments all accentuated the need for a more wholistic analysis of the likelihood and consequences of possible failures in complex systems. In the frameworks for risk analysis that arose, a hazard represents the potential for harm, i.e., the thing that could 'go wrong' to cause an undesirable effect, but risk considers both the likelihood and consequences of the hazard occurring. In the context of microbial food safety, risk involves:

- the potential presence of a microbial hazard, i.e., a pathogen or microbial toxins in foods at levels that could cause harm to the consumer,
- the likelihood that the hazard will arise, i.e., how often consumers are exposed to the hazard at disease-causing levels, and
- the severity and magnitude of that exposure, which will depend on the severity of the illness caused by the specific pathogen, the number of people exposed, and to a lesser extent, the dose ingested.

Risk Assessment Within the Risk Analysis Paradigm

Microbiological risk assessment is one aspect of the 'risk analysis' paradigm proposed by the CAC, an international body

convened under the United Nations (UN). The other two elements are risk management and risk communication.

Risk analysis involves:

1. objectively determining risks and sources of risk ('risk assessment'),
2. conceiving appropriate actions and strategies based on the risk and societal expectations to limit the risks to acceptable levels ('risk management'), possibly including imposition of food safety regulations, and
3. understanding the interests, concerns, and level of tolerance of the stakeholders to risks to which they are exposed ('risk communication') and explaining the costs and consequences of alternative risk management options to them and why the selected risk management strategies are the most appropriate options.

Food safety risk assessment is intended to objectively assess (as quantitatively as possible) the risk faced by a defined group of consumers of a specific food, or group of foods. Determining whether that risk is acceptable, and defining an acceptable level of risk from a food product, are societal decisions and require 'risk communication.' Risk communication is described as an interactive exchange of information and opinions concerning the risk between those likely to be affected by the risk and/or risk management decision. Notably, risk communication is not only limited to explain (to those affected by the risk) what will be done to manage the risk but also to understand their concerns about the risk, tolerance of the hazard, preferences for potential risk management options, etc.

Determining the most appropriate action, or actions, to ensure that the risk remains below some tolerable level is the function of 'risk management,' and must include consideration of cost versus benefit, technical feasibility, cultural acceptability, the willingness of consumers to accept some responsibility for management of the risk, etc. Thus, risk assessment is intended to be as objective and quantitative as possible, whereas risk management must consider subjective aspects to determine the best options for managing the risk in the context of the culture in which they arise. The risk analysis paradigm and risk management are considered in greater detail in other entries.

Within this overall risk analysis framework, the main function of risk assessment is to provide support to risk managers for decisions that they are required to make.

Principles of MFSRA

The CAC is a UN-based organization established under the joint Food Standards Program of the UN's Food and Agriculture Organization (FAO) and World Health Organization (WHO). The main purposes of the Food Standards Program are protection of the health of consumers, ensuring fair trade practices in the international food industry, and promoting coordination of all food standards work undertaken by international governmental and nongovernmental organizations, i.e., to achieve 'harmonization' of regulations so as to facilitate international trade in foods. An underlying ideal of this work is to assist developing nations to build their economies through the development of export agriculture, considered as an important first step along the path to national development.

Codex Principles and Guidelines for the Conduct of Microbiological Risk Assessment

Development of internationally agreed principles of microbial food safety risk analysis, including those for risk assessment, fell to CAC (see Box 2). In practice, most of the work has been coordinated by FAO/WHO's Joint Food Standards Program and undertaken not only through a series of expert consultations that have become known as Joint FAO/WHO Expert Meetings on Microbial Risk Assessment (JEMRA) but also through the Codex Committee on Food Hygiene. Arguably, the most fundamental of the CAC risk assessment documents is Guideline CAC/GL 30 (1999): "Principles and Guidelines for the Conduct of Microbiological Risk Assessment" which establishes high-level desiderata for the conduct of transparent, defensible, science-based estimates of the magnitude and severity of foodborne microbiological risks. Importantly it does not specify methods for risk assessment, but describes the qualities of defensible and informative risk assessments. The guidelines (summarized in Box 3) reflect principles articulated in 1990 by Morgan and Henrion as the 'Ten Commandments' of risk assessment in the context of policy decision making.

It is useful to elaborate on some of the principles articulated in CAC/GL (1999), as discussed further below.

Functional Separation Between Risk Assessment and Management

The need for functional separation between risk assessors and managers is to maintain objectivity in the risk assessment process. Risk managers, due to their familiarity with the risk and its potential sources, may have preconceived ideas about the magnitude of the risk and how it is best (or most pragmatically) managed. A risk assessor should be more 'removed' from the situation, and also be able to view the risk from different, and more holistic, perspectives and to evaluate it from more diverse sources of information, (e.g., a simple approach to risk assessment is to review illness incidence data and reports to quantify the magnitude of the risk; however, that information is often not systematically collected and is often biased toward known problems or pathogens for which established test methods are available). The intention is that a systematic risk assessment approach will lead to more reliable estimates of actual risk, rather than perceived risk, and thereby to better risk management strategies and actions.

Any Constraints that Impact Upon the Risk Assessment … Should be Identified and Their Possible Consequences Described

As noted in the section on Transparency, risk assessment should be 'transparent,' meaning that the data, methods and calculations used, and assumptions made, should be thoroughly

Box 2 International development of formalized microbial food safety risk assessment

The General Agreement on Tariffs and Trade (GATT) was an international forum established in 1948 by the UN to liberalize and 'harmonize' international trade. GATT was established as an interim measure due to inability of the UN at that time to agree on the establishment and operation of an 'International Trade Organization' (ITO). The ITO was envisioned as a UN-based body that would establish equitable rules for international trade.

From 1948 to 1995 GATT met periodically as a body of national representatives at various locations around the world. The Uruguay Round of GATT, initiated in 1986 and finalized in 1995, led to the creation of the World Trade Organization (WTO) to fulfill (at least some aspects of) the role originally conceived for the ITO and also because GATT had become effectively unworkable due to changes in the world economy, especially 'globalization,' as it was first convened.

In 1995, the WTO introduced the Sanitary–Phytosanitary Agreement and Technical Barriers to Trade Agreement that:

1. mandated (in effect) demonstrable, and unacceptable risk to human, plant, or animal populations in an importing nation as the only basis on which import of foods from other nations could be restricted,
2. sought to establish the 'equivalence' of efficacy of disparate (food) safety regulatory systems in trading nations by comparing the level of protection that each system afforded. The aim was to facilitate international trade without being prescriptive about methods and strategies to achieve required levels of consumer, agricultural, and ecological protection.

Both agreements required internationally accepted methods to assess risks and the efficacy of diverse risk management approaches. Thus, science based, risk assessment methods were proposed by the WTO as the means for evaluating risk from imports and 'equivalence' of risk management systems. However, whereas several nations had begun to adapt risk assessment methods to microbial foodborne hazards for the establishment of domestic regulations and food safety management strategies, at the time of introduction of the WTO agreements there were no internationally accepted methods for the objective assessment of foodborne microbial risks.

The task of developing those methods fell to Food and Agriculture Organization (FAO) and World Health Organization (WHO), through the Codex Alimentarius Commission. FAO and WHO have convened a series of international expert consultations, which have become known as the Joint FAO/WHO Expert Meetings on Microbial Risk Assessment (JEMRA), to develop agreed principles for food safety risk analysis. JEMRA was intended to become a dynamic body analogous to the Joint Expert Committee on Food Additives (JECFA), established in 1956. Well-defined procedures for assessing the safety of chemical food additives, and for determining tolerable levels, had been established by JECFA but were considered to be inappropriate to microbiological hazards. The work of JEMRA has included the development of guideline documents and the conduct of a number of risk assessments employing those guidelines for specific hazards and food combinations. The JEMRA risk assessments have usually been done in response to questions from Codex committees for the purposes of establishing international guidelines and standards. Further information and copies of documents can be found at: http:www.who.int/foodsafety/micro/jemra/en/

Box 3 Principles for the conduct of microbiological risk assessment (CAC/GL, 1999)

1. Microbiological risk assessment should be soundly based upon science
2. There should be a functional separation between risk assessment and management
3. Microbiological risk assessment should be conducted according to a structured approach that includes hazard identification, hazard characterization, exposure assessment, and risk characterization
4. A microbiological risk assessment should clearly state the purpose of the exercise, including the form of risk estimate that will be the output
5. The conduct of a microbiological risk assessment should be transparent
6. Any constraints that impact the risk assessment such as cost, resources, or time, should be identified and their possible consequences described
7. The risk estimate should contain a description of uncertainty and where the uncertainty arose during the risk assessment process
8. Data should be such that uncertainty in the risk estimate can be determined; data and data collection systems should, as far as possible, be of sufficient quality and precision that uncertainty in the risk estimate is minimized
9. A microbiological risk assessment should explicitly consider the dynamics of microbiological growth, survival, and death in foods and the complexity of the interaction (including sequelae) between human and agent following consumption as well as the potential for further spread
10. Wherever possible, risk estimates should be reassessed over time by comparison with independent human illness data.
11. A microbiological risk assessment may need reevaluation, as new relevant information becomes available

documented so that the reliability and limitations of the assessment can be evaluated by others. If there were resource constraints, the risk assessment may not be based on all, or the best, data available, or not using the most complete and objective methods. For example, if time is limited, simpler methods for data analysis might be employed than would be possible with more time, or computing power. These limitations might affect the generality of the results, or might not reveal all aspects of the sources of risk. As such, any constraints that might limit the validity or generality of the assessed risk should be documented and, preferably, their potential consequences discussed. Simple risk assessments do not necessarily produce results significantly different than those derived from more complex ones if they are based on the same data and knowledge, but complex analyses are likely to provide more subtle insights about the 'range' of

risk, its sources, and the sets of circumstances under which unacceptable levels of risk arise.

Sources of Uncertainty Should be Documented and Their Influence on the Assessed Risk Estimated

Similar to that discussed in section Any Constraints that Impact Upon the Risk Assessment…, if data or knowledge required to estimate the risk is unavailable or incomplete, then the influence of that uncertainty (or those 'data gaps') on the estimated risk needs to be evaluated and documented. This principle is important because MFSRA is used to support decisions about the most effective ways to manage and minimize risk, and consequent risk management actions can affect individuals, companies, organizations, or nations, i.e., the 'stakeholders.' Risk management decisions derived from results of a risk assessment that is based on incorrect or inadequate data could adversely affect some 'stakeholders' without producing a real, net benefit.

Transparency

Related to the above two sections a risk assessment should be presented in a way that enables its validity to be critically evaluated by others, i.e., to enable expert or 'peer' review. Risk assessments are often complex in structure, with voluminous supporting data, and can produce nonintuitive results. Given the complexity of the systems being modeled (see section A Microbiological Risk Assessment Should….) and the possibility of correlations (either positive or negative) between factors influencing risk, logical errors in risk assessment models can occur. A common example is to forget to include the negative correlation between shelf life of foods and the storage temperature of foods – if this correlation is not included, pathogen growth to very high levels can be predicted and can skew the risk estimate (i.e., in practice, foods that are held at higher than recommended temperature spoil earlier and are usually discarded without eating; this can ameliorate the probability that high pathogen loads will be encountered by consumers if storage temperatures are inappropriately high). These considerations require comprehensive documentation of data sources, methods of data synthesis and analysis, calculations, assumptions, inferences, etc., so that errors and oversights, and incomplete understanding of limitations in the risk estimate do not lead to inappropriate risk management decisions. As discussed above, incorrect decisions can adversely affect some stakeholders without any real benefit being achieved.

A Microbiological Risk Assessment Should Explicitly Consider the Dynamics of Microbiological Growth, Survival …

Microbial contamination of foods is often a more-or-less random event, but the consequences of such contamination can be magnified enormously by microbial growth or eliminated completely by microbial inactivation processes. Microbial populations present in foods respond dynamically over time to processing conditions, product formulation, and storage and distribution conditions. It was not until the advent of 'predictive microbiology' that microbiological risk assessment became feasible, because predictive microbiology enabled those dynamic responses to be quantified. Microorganisms are living, selfreplicating entities. Severe conditions can kill microbes but, because some can reproduce asexually, even a single surviving cell can recover and grow to produce sufficient cells or toxins to cause illness in a consumer. There is considerable variability in virulence and tolerance of stressful conditions between strains of the same species. Moreover, microbial susceptibility to inimical conditions can be modified by earlier exposure to stressful conditions, as can microbial virulence. Equally, microbes are discrete entities and less likely (than chemical contaminants) to be homogenously distributed in foods. Thus, at low levels of contamination in a batch of foods, some units of the food may harbor a cell that could grow to disease-causing levels although most of the units remain free from risk. To fully characterize the risk of microbes in foods requires a detailed knowledge of microbial ecology and physiology in foods and particularly the dynamics of the microbial ecology of foods.

Microbiological Risk Assessment Should be Conducted According to a Structured Approach that Includes Hazard Identification, Hazard Characterization, Exposure Assessment, and Risk Characterization

Risk characterization describes the process of estimating the magnitude of risk by assessing:

1. how often consumers experience the hazard (termed 'exposure assessment'), and
2. the relationship between the magnitude of the hazard (e.g., numbers of pathogens in the food at the point of consumption, or levels of toxin) and the effect on the consumer (termed 'hazard characterization' or 'dose–response assessment').

Hazard identification involves (1) presentation of the evidence for a relationship between the presence of the hazard in food and human illness, (2) information about the hazard that will assist in determining exposure, and (3) identification of other data that is available to support the risk assessment.

In more established fields of risk assessment, for example, toxicology and/or environmental health, often the major focus of the hazard identification step is to determine if there is sufficient evidence to implicate a substance (e.g., a chemical) as the cause of an adverse health effect (e.g., cancer). In contrast, the hazard in microbial risk assessment is often already known to be capable of causing human illness before the initiation of the risk assessment. The cause-and-effect relationship for microbial hazards can often be measured over short periods of time (hours, days, or weeks) due to the acute nature of foodborne infections or intoxications. Conversely, the consequences of chemical hazards are often only manifest after prolonged exposure, often in the order of years or lifetimes, and leading to chronic disease. Some microbial toxins, for example, aflatoxins, lead to chronic effects after prolonged, low level, exposure.

In the following sections, the four elements of MFSRA are discussed in greater detail.

Hazard Identification

In MFSRA, hazard identification involves the presentation of evidence that a microbe is capable of causing adverse health effects if present in a particular food or group of foods, and that it can be present in those foods. Unlike chemical hazards in foods, the evidence for pathogenicity of foodborne microbes is often stronger because microbes usually cause acute disease (infections or intoxications) and there is often clear epidemiological evidence linking the food, pathogen, and human illness. Because pathogens, or their toxins, are usually able to be isolated from victims, Koch's postulates provide a mechanism for demonstrating cause and effect. There are, however, exceptions. Not all pathogens can be readily cultured and identified from the patient's intestines, stools or their blood, and from the food implicated in illness. Foodborne enteric viruses, for example, are difficult to cultivate. Similarly, *Mycobacterium paratuberculosis* causes Johne's disease, a wasting disease, in sheep and cattle. Crohn's disease is associated with similar symptoms in humans and it has been suggested that Crohn's disease may be caused by *M. paratuberculosis*, possibly acquired from meat or milk from animals affected by Johne's disease. The onset of symptoms is very slow however and, at the time of writing, the causative link between *M. paratuberculosis* and Crohn's disease is not established, let alone whether infection can be acquired from food. A hazard identification would present the evidence that such links may exist as the justification for undertaking a risk assessment. Sometimes MFSRA is undertaken to test the strength of the evidence implicating a relationship between human disease, a suspected pathogen, and food.

Hazard identification in MFSRA also describes the severity of the outcomes of exposure. For example, the consequences of intoxication with staphylococcal enterotoxin (i.e., vomiting for several hours) are far less severe than the consequences of infection of a pregnant women with *Listeria monocytogenes* (i.e., potentially fetal death or miscarriage). A useful measure of the severity of consequences is the disability adjusted life years (DALY) concept, which is a measure of the time that the symptoms of the disease persist (measured in years of fractions of year) and the extent to which the victim's normal activities are compromised, assessed as proportional loss of normal life activities. For example, if a person were infected with *Salmonella* for 3 days, and it prevented them from attending their normal work, the loss of function might be assessed as 50% for 1/120th of a year. In this case the DALY would be 0.0042. Conversely, if an adult were intoxicated by botulin from *Clostridium botulinum* in a food, and required hospitalization involving life support for 12 months, the DALY might be calculated as 90% loss of function for 1 year, i.e., the DALY would be 0.9. If a pregnant woman contracted listeriosis and lost her unborn child, the DALY would be 100% times the life expectancy of the unborn child, for example, 80 years. In this case the DALY would be 80. In this way systemic listeriosis in a pregnant women would be considered to be tens of thousands of times more severe than salmonellosis, and 90 times more severe than nonfatal botulism.

Exposure Assessment

'Exposure assessment' in MFSRA is the qualitative and/or quantitative evaluation of the likely intake (both frequency and amount) of pathogens or their toxins via food as well as exposures from other sources if relevant. In other words, it aims to answer the questions: How often, and at what levels, is the hazard ingested in a specific food or group of foods of interest?

To assess exposure one needs to consider:

- how much of the food is eaten, by whom, and how often,
- how often the food is contaminated and how heavily contaminated it is,
- how the contamination arose, for example, at what point in the farm-to-fork pathway, and
- changes in the hazard level between the point of harvest or processing and consumption, and by how much it changed.

To answer these questions, data from many sources are combined.

Questions about the route of contamination and change in contamination level usually require the development of a 'conceptual model' that describes in text or mathematical equations the 'farm-to-fork' pathway, including all points where contamination could occur. It also includes detailed description of the factors that could change the hazard level, such as processing operations and conditions, and times and temperature of storage and transport. In the case of bacterial and fungal hazards this will also include knowledge of the food's composition (pH, water activity, preservatives, etc.) so as to be able to estimate microbial growth (or death) and toxin production, i.e., using predictive microbiology models. Processes such as:

- mixing, leading to dilution;
- drying, leading to concentration or decreased water activity; and
- separation of fatty components from water components that might lead to concentration or reduction in the levels due to preferential partition of the hazard into the oil or aqueous phases, etc.,

also need to be described.

For consumption estimates, data sources include national nutrition/diet surveys, production figures for various food industries, import and export statistics, data from supermarkets or market survey companies that estimate the sales of various types of products and foods, etc. National dietary surveys also often include breakdown of consumption into different age and gender classes and geographic regions. Food categories used in those surveys, however, are often based on nutritional considerations, rather than categories that relate to the probable presence of foodborne hazards.

Prevalence and concentration of pathogens (or their toxins) in foods at the time of consumption are required to estimate risk. Available data describing levels and frequency of the hazard in the food, however, almost always relate to times in the farm-to-fork chain much earlier than the point of consumption, requiring the application of predictive microbiology as discussed below. Sources of data relating to prevalence, and

concentration, of microbial hazards at selected points in the farm-to-fork chain include industry organizations, and hazard analysis critical control points (HACCP) and quality assurance records of individual companies. Some government agencies also conduct routine and random monitoring of selected hazards in foods. Additionally, there are many small studies published in scientific journals.

Predictive microbiology (*q.v.*) models facilitate the estimation of change in pathogen levels between various stages in the farm-to-fork chain and point of contamination. Essentially, predictive microbiology models summarize the ecology of microbial hazards in foods. To use predictive microbiology for estimating hazard levels at the time of consumption requires knowledge of food-processing operations, physicochemical properties of the food, and times and environmental conditions (particularly temperature) experienced by the food from harvest and during processing, usually available from companies that process foods. Formulation data may also be available from the published literature. In addition, several large studies have been undertaken in recent years that determined temperatures of foods during storage, transport, retail display, and home storage. Some data are available from industry groups and others have been published in the public domain.

Hazard Characterization

Hazard characterization describes and, ideally, quantifies the adverse health effects associated with the various microbial hazards that may be present in food. This requires that a 'dose–response assessment' be performed if the data are obtainable. In practice, the relationship between pathogens and consumer illness is better described as a dose versus probability of infection or probability-of-illness relationship because, unlike chemical contaminants, the symptoms of infection do not usually change qualitatively as a function of dose although they may change in severity or duration.

Data to define human microbial 'dose–response' relationships are not readily available, for ethical reasons, although limited older data from volunteer trials do exist. These are usually derived from healthy, young adults, however, and do not reflect the susceptibility of the general population accurately; it is known that the very young and the elderly are more susceptible to foodborne infections because of their undeveloped or waning immune responses. Equally, in many nations there are increasing numbers of consumers whose immune system is weakened by underlying illness or medical treatments (e.g., immunosuppressive therapies for organ transplant recipients). Given these limitations, many of the available dose–response relationships for foodborne pathogens are derived from the analysis of collations of outbreak data. The limitations of outbreak data (e.g., difficulty in determining doses ingested from foods possibly ingested days earlier) are also recognized and acknowledged. Animal models have also been used to gain information about dose–infection relationships for some pathogens but animal models do not always reflect accurately infection processes in humans, or the consequences of toxin ingestion by humans, due to the specificity of the pathogen–host interactions leading to infection and differences in biochemical pathways in different species.

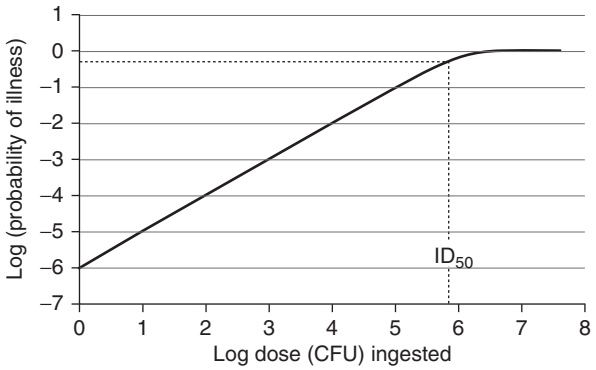

Figure 1 An illustration of the predictions of an exponential 'dose–response' model. The exponential model is often used in MFSRA to relate the probability of illness to a given dose of a pathogen. The intercept of the model with the *y*-axis gives the '*r*' value of the exponential model, which is effectively the probability that one cell of the pathogen could cause illness (i.e., in this example, 1 in a million). The dotted lines illustrate the calculation of the ID_{50}, i.e., that dose that would be expected to lead to illness in 50% of the population which, in this example, is approximately 70 000 cells.

There is also debate concerning the nature of the infection process and how this can be modeled mathematically. A JEMRA consultation concluded, however, that models that are based on the single-hit hypothesis of infection are the most biologically plausible. Of this class of models the 'exponential' and 'Beta-Poisson' models are the most widely used, with the exponential model being simpler and relying on fewer assumptions. The Beta-Poisson model includes the possibility of variability in infectivity of individual cells in the dose ingested and that for some organisms some proportion of the exposed population will never become no matter what the dose. Both models predict that the probability of infection is a simple function of the dose of cells ingested, up to some upper limiting dose, above which the probability of illness does not increase further. An example of a dose versus probability of illness relationship is shown in Figure 1.

Risk Characterization

Risk characterization synthesizes the exposure assessment with the dose–response relationship to generate an estimate of human health risk. To do so, however, one has to understand all the factors that contribute to, or affect, the risk to the consumer, and the interrelationships between these factors. This involves the articulation of our understanding of how the risk arises, and changes in the level of the hazard from the point of contamination to the point of consumption. This description, whether expressed in words or as mathematical equations, may be referred to as the 'conceptual model.' An example is shown in Figure 2.

The estimated risk can be expressed in many ways including risk per serving, risk to an individual or to an entire population and over some defined time interval, etc., and may be expressed in absolute or relative terms. The use of relative measures of risk can often simplify the risk assessment process

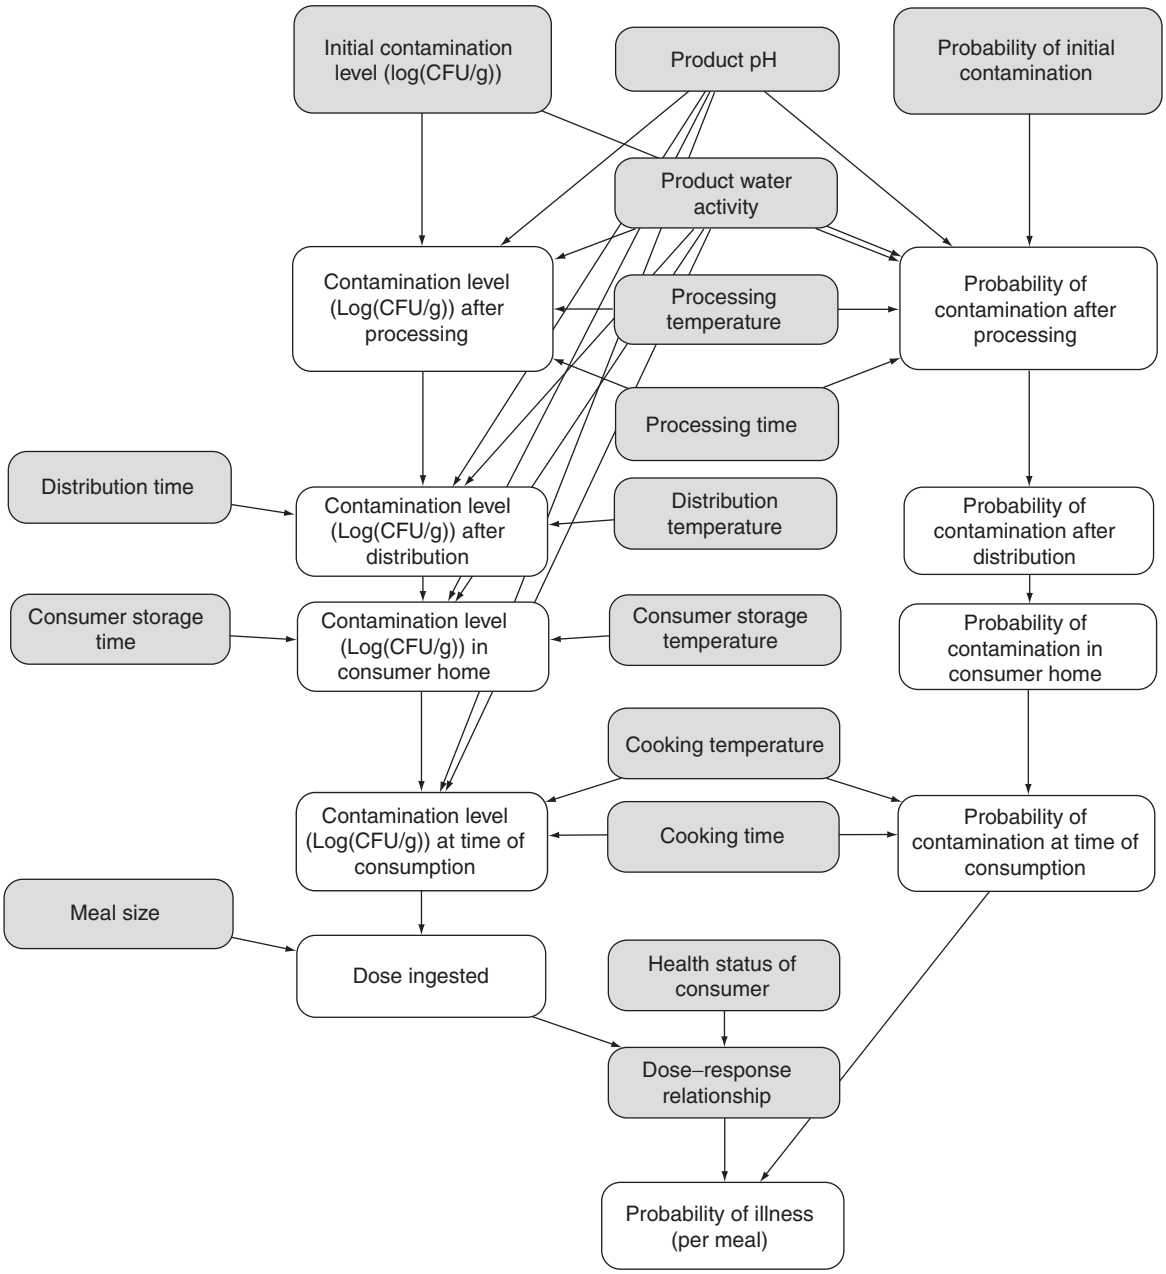

Figure 2 An illustration of a simple 'conceptual model' for assessing risk of microbial foodborne illness from a factory-to-fork food supply chain. The model shown is also described as an 'influence diagram' because arrows in the diagram indicate the influences that various factors have on other variables that affect the final risk to the consumer at the point of consumption. Variables that must be described by data (i.e., obtained by studies or surveys) are shown in shaded boxes whereas variables that are derived from knowledge of other factors, including the final estimate of risk (i.e., probability of illness per meal), are shown in unshaded boxes. In a quantitative risk assessment, the relationships depicted by the arrows are defined and quantified by mathematical equations. The model is a form of 'process risk model' and at each stage in the factory-to-fork process the model calculates both the concentration of pathogen (or toxin) in the food and also the likelihood that the pathogen is present at all in the food.

and yet still provide adequate advice to risk managers. For example, if risk managers determine that the only viable risk management alternatives to manage the risk of pathogen growth in a product are:

1. to reduce the nominal shelf life of the product by 10 days, or
2. to reduce the microbial growth rate in the product by a reduction of pH by 0.5.

A simplified model that estimates the proportional risk reduction arising from either of those alternatives would be sufficient to answer the risk management question (i.e., which alternative would be more effective) without

having to determine the absolute risk to consumers or detail all other risk-affecting factors because they would stay the same. In this case, the risk assessment might devolve to calculation, using predictive microbiology models, of the expected reduction in the extent of growth of the pathogen by either of the alternatives. Conversely, if the purpose of the risk assessment were to identify and rank all possible risk management alternatives, the conceptual model would need to detail the effects of all risk-affecting factors, and their interrelationships, to provide the additional insights needed to support for the decisions of the risk manager.

Methods for Risk Characterization

JEMRA have presented guidelines for the conduct of risk characterization. The recommendations are not prescriptive but recognize that the most appropriate risk characterization approach may depend on the problem being addressed, as illustrated above. Thus 'qualitative' (descriptive) methods may be useful and adequate in some cases, and use terms or rankings like 'higher' or 'lower' to describe the relative risk. This provides limited guidance for decisions, however, so that terms like 'much' higher or 'significantly' higher, etc., may be required. Clearly, however, such terms are subjective and could be interpreted in different ways by different people. In most cases a risk assessment will need to 'quantify' the magnitude of the risk, or magnitude of differences in risk (or relative risk). In essence, risk is a quantitative concept, and mathematical approaches to risk assessment are usually needed. In those cases the conceptual model is expressed as a series of mathematical equations.

In a quantitative risk assessment each of the values that contribute to risk can be defined as a single, representative, value. This is termed a 'deterministic' approach. But such values are rarely constant and the question arises, what is the best representation of the value of each factor? The average value is an obvious choice, but can lead the risk assessment to underestimate or ignore risks. For example, if the average storage temperature and time were used to estimate the potential growth of *Salmonella* in a salad sandwich, it might be concluded that there would never be a problem because any *Salmonella* present would never grow to unacceptable levels. In reality, it is likely that sandwiches are occasionally kept too warm or kept for too long. Such conditions may lead to an unacceptable risk, and need to be included in the risk assessment because they are the scenarios of most interest for identifying risk management needs. An alternative approach is to use the worst-case levels for each factor contributing to the risk, but this will lead to an overestimation of the risk because a situation in which each factor is at the most hazardous level will almost never occur.

In practice, the risk from a particular food and process will be variable, depending on many variable factors. Given this, one approach to characterize the risk would be to calculate the risk for a range of scenarios, with different values for each of the risk-affecting factors. From this, an estimate of the 'range' of the risk, and extreme levels of risk, and some representative measures (e.g., average, mode, etc.) could be determined. The more such scenarios are calculated, the more complete the risk estimate will become. The process of calculations would be tedious, however, unless it could be automated. Stochastic simulation modeling using computer software does this and, for reasons outlined above, currently is often the preferred method for MFSRA though other methods are equally valid, if not preferable, depending on the risk assessment question. An example of the difference between insights obtained from deterministic compared to stochastic approaches is presented in **Box 4**, and discussed further below.

In stochastic simulation modeling each factor in the conceptual model is described by a 'distribution' of possible values, i.e., the full range of values that the variable could take, as well as the probability that any given value in that range will be observed. The software systematically evaluates the model tens or hundreds of thousands of times, each time taking a different combination of values from each of the distributions and calculates the expected outcome according to the conceptual

Box 4 Example of the differences in deterministic and stochastic risk assessment

Stochastic models are usually more informative than deterministic models because most processes leading to foodborne risk are variable, and not readily defined by a single representative value. As an example, **Figure 3** presents a very simple 'farm-to-fork' food safety risk assessment model for an infectious pathogen. The conceptual model is presented as an influence diagram on the left side of the figure. The right hand side of the figure shows the distributions of values of factors that contribute to the risk, namely:

1. the initial contamination level on the food,
2. the potential growth that occurs between farm and consumption,
3. the size of the meal consumed (which affects the dose ingested), and
4. the dose–response relationship or, in the case of the deterministic model, the ID_{50} as a representative value for the average dose required to cause illness.

In the deterministic model, the average value of the distributions was used for calculations, i.e., 1 cell per 50 g (i.e., below the reliable detection limit), 100-fold increase in cell numbers (i.e., 2 logs of growth), 100 g meal, and $ID_{50} = 700\,000$ cells. Using these values, the dose ingested never exceeds a dose that is typically expected to cause illness and no cases of illness are predicted even in 1 million meals consumed.

Conversely, when distributions of values and a dose–response model are used, the expected number of illnesses from 1 million meals is 254. Most risk managers would consider that this level of illness is too high and would implement actions to further reduce the risk to consumers so that an appropriate level of consumer protection was achieved. Note that in this comparison, the average of values contributing to the risk (i.e., the initial contamination level, potential for pathogen growth, and size of the meal) are identical in the two approaches to the risk assessment, but the stochastic approach shows that in some cases an unacceptable risk occurs, whereas the deterministic approach predicts that the risk, 'on average,' is acceptable. Thus, the stochastic approach leads to a very different risk management decision than the deterministic approach.

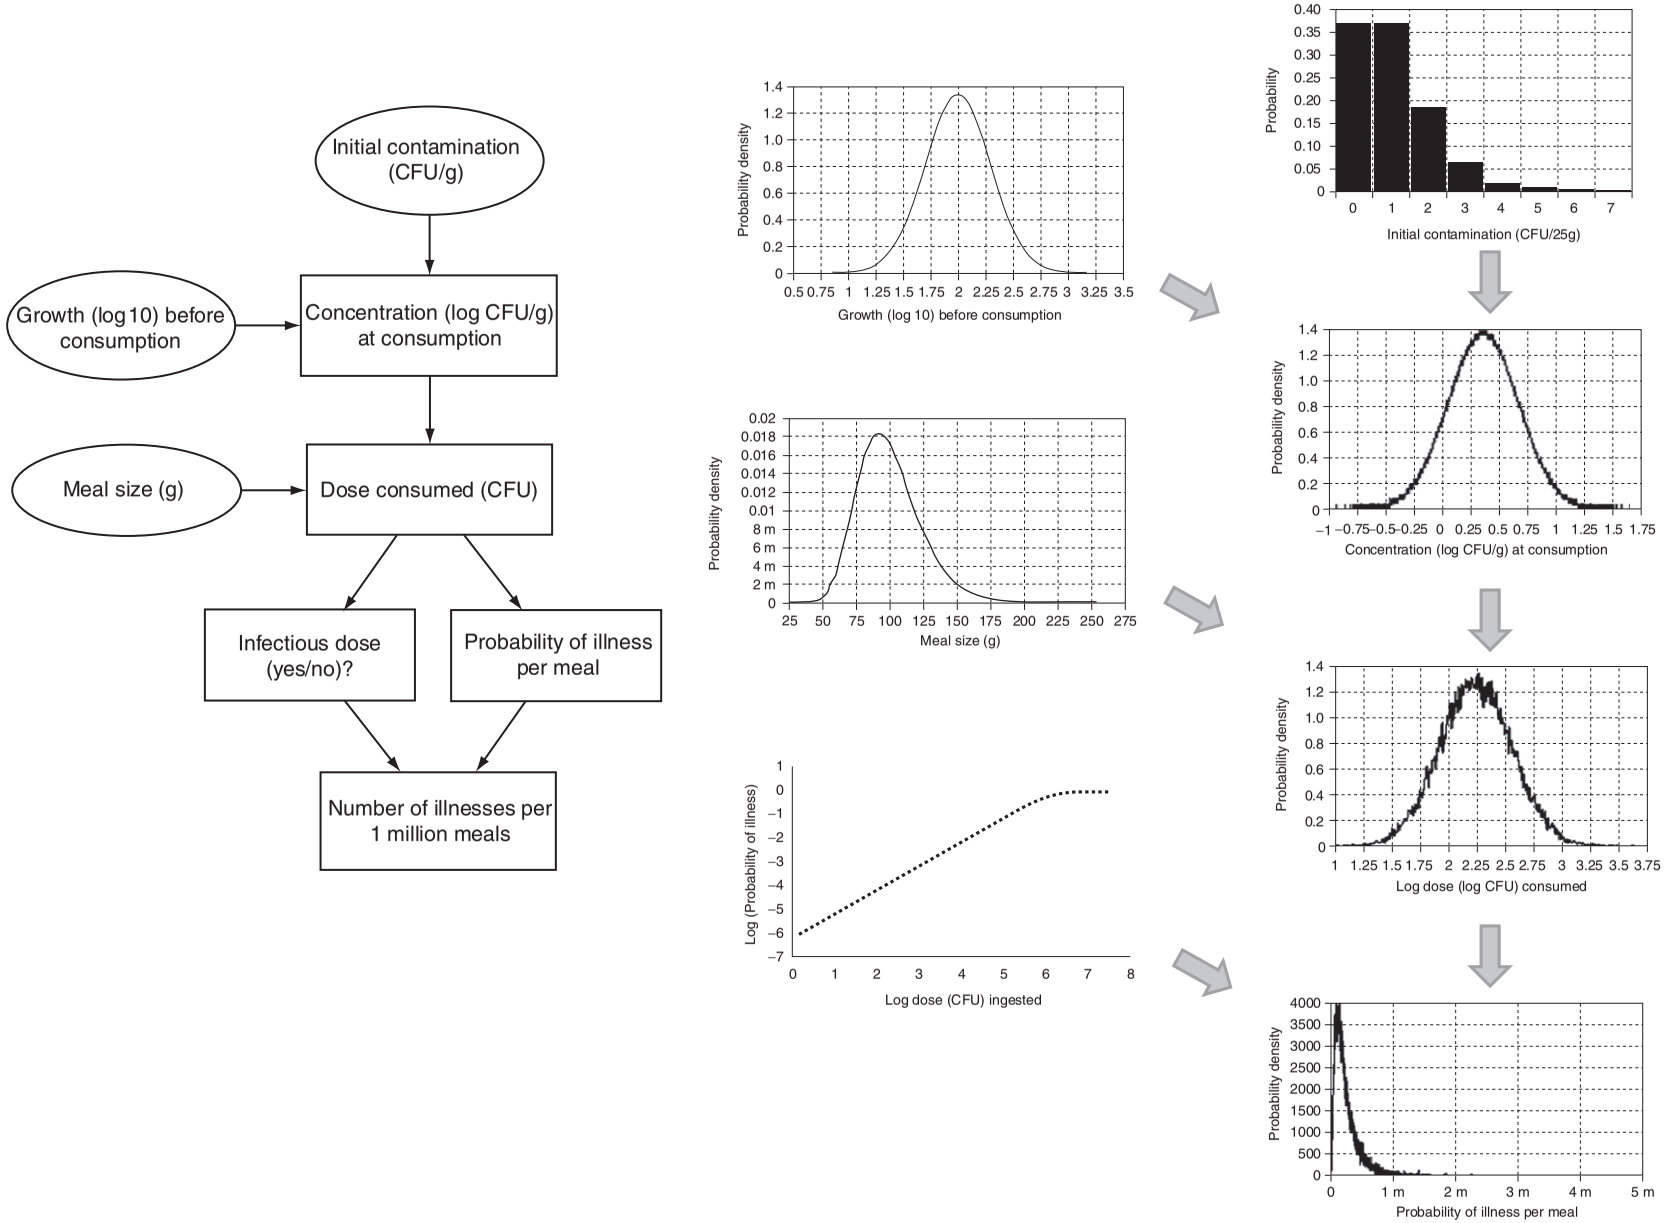

Figure 3 A simple risk assessment model illustrating a stochastic risk estimation process (see text for details).The graphs on the right represent the distributions of values for the variables in the model (oval shapes) and results derived from them (rectangular shapes). When distributions of values are used for calculations, the estimated risk is 254 illnesses per 1 million meals. When the average values of the distributions are used for the estimation of the risk, no illness is predicted.

model. Each calculation is termed an 'iteration' and represents one possible meal scenario, i.e., the risk from one unit of food under a particular set of circumstances. As more iterations are performed a distribution of possible levels of risk is generated, representing more and more possible sets of circumstances for that food and its consumers. In some cases the sets of circumstances will lead to an unacceptable risk to the consumer that would not have been revealed by calculations that considered only typical, or average, sets of conditions.

The four steps of risk assessment are conducted sequentially, i.e., hazard identification must precede the other steps in the risk assessment process because it is a precursor to the risk assessment. Similarly, the risk characterization step is undertaken last because it is the synthesis of the exposure assessment and hazard characterization steps, but those two steps can be conducted in parallel. Sources of more detailed and practical information about the conduct of the four steps of MFSRA are listed in the 'Further Reading' section.

Uncertainty and Variability

Complete and perfect information and knowledge is rarely available for the conduct of risk assessments. As such, a risk assessment provides an imperfect estimate of risk and the significance of the various factors that contribute to it. Risk assessments are used to assist decision making and, accordingly, the level of confidence in the accuracy of the risk estimate, or the range of the risk estimate, needs to be explained to risk managers so that they can balance the risk assessment information against other information and considerations when making risk management decisions.

Uncertainty and variability both affect the confidence one can have in the risk estimate. Uncertainty describes information that is required, but is not available, or that one cannot have much confidence in the data that is available. Variability reflects the fact that in many systems slight differences in conditions affect the outcome of the process, for example, the amount of food that different consumers eat, the health status of an individual consumer, etc. Although uncertainty can be reduced by gathering further data, usually variability cannot. It may be possible to decrease variability by making the model more detailed, for example, specifically modeling individual differences in consumer susceptibility to infection due to their individual health status. This approach is sometimes described as 'disaggregation,' and refers to differentiating average values for larger groups into estimates specific to subcategories within those larger groups. Doing so, however, may make the conceptual model more complex because disaggregation may lead to the need for other related data, specific to the individual cases. For example, if a model discretely considered differences in individual susceptibility to infection by virtue of health status, it might be necessary to also recognize corresponding differences in consumption amount, or meal preparation methods, that might also affect risk to those subgroups, and thus require more data. If that data were not available, the net effect of the decreased variability in dose–response could be to increase uncertainty overall.

Mathematical methods for systematic treatment and evaluation of variability and uncertainty are considered in JEMRA publications, and the published literature. In many MFSRAs variability is estimated by the stochastic simulation modeling process, but it is also important to document sources of uncertainty in the risk assessment (e.g., missing/unavailable data or knowledge, assumptions that were made) and the potential consequences of that uncertainty for the estimate of risk. Such an evaluation can be undertaken by calculating the conceptual model for different assumptions, or different values of uncertain factors, and comparing the new risk estimates with those under the original set of assumptions. If the risk estimate is little affected by the new set of assumptions, it suggests that the missing or uncertain information is not critical to the risk estimate and risk management decision.

Other Methods for Risk Assessment

MFSRA has become almost synonymous with stochastic modeling of the entire farm-to-fork food chain and, for some kinds of risk management decisions, these approaches may be the most appropriate. This perception may, however, have inhibited the uptake of risk assessment principles for food safety management decisions because of concerns about the cost, time, and expertise required because those approaches to MFSRA can be very time- and labor-intensive.

As noted, risk assessment is intended to improve the quality of decision making. JEMRA does not specify methods for risk assessment but rather emphasizes principles. The actual methods used for a risk assessment should be appropriate to answer the specific questions of a risk manager. Accordingly, for some risk management questions (as illustrated earlier), simpler approaches can provide equally rigorous support for decisions, particularly when the decisions are more specific, for example, what is the relative public health burden of salmonellosis compared to listeriosis, which might be addressed by considering the number of cases of each and the typical severity of each infection using the DALY concept. Similarly, epidemiological data and exposure assessment (based on consumption data and predictive microbiology) have been used to rank the relative risk of illness from listeriosis in a wide variety of ready-to-eat foods but without having established a dose–response relationship for listeriosis.

There is also a desire for risk assessment methods that are quicker, for example, for questions that require only a 'first estimate' to determine whether the apparent risk warrants further, more detailed, investigation. Accordingly, risk assessors are attempting to define simpler, less resource demanding, methods that are appropriate to different types of risk assessment questions. To this end, various types of 'risk matrices' have been presented in which users select categories that describe hazard severity, effects of processing, sensitivity of exposed populations, etc., and then use a decision matrix (often a series of tables) to generate a risk estimate. These approaches can suffer from the limitations of qualitative risk assessments because it is difficult to achieve logical consistency when combining subjective categorical/descriptive terms to generate an essentially quantitative risk estimate, or risk ranking. Several simplified MFSRA models have been presented and adopted, however, that lead risk assessors through relevant questions, requiring that the user selects descriptive terms (that are equated to values or ranges of values), and that

then combine the numerical response via a generalized conceptual model. The models are presented as interactive software that, once values are selected or entered, automates the risk calculation. Their effectiveness, however, requires that reliable data or knowledge are available to enable the various questions to be answered correctly.

Summary

The systematic, objective, and science-based approach of risk assessment can support decisions about food safety management at all levels, from individual businesses, to local and national governments, setting international rules for trade in food. At the international level, MFSRA was advocated by the World Trade Organization as a means to harmonize international trade in foods by providing a framework to establish objective regulations. This impetus led to the development of guideline documents for the conduct of MFSRA by the UN's FAO and WHO to provide advice to the CAC and also to assist member nations to develop capacity in MFSRA. Within individual nations MFSRA can be used, among other applications, to prioritize resources to those hazards with the greatest public health burden, to establish risk management approaches relevant and achievable within that nation and culture, etc.

It is widely recommended that MFSRA follow a systematic approach involving four steps that describe (1) the hazard and consequences of its ingestion, (2) the likely exposure of consumers to that hazard in food, (3) the relationship between the amount of the hazard ingested and the probability and severity of illness, and (4) this information is synthesized to generate an estimate of risk (i.e., likelihood, severity, and magnitude of harm to consumers) that can be compared to the risk under other circumstances or proposed management strategies, thus enabling the elucidation of the most effective risk management strategies, or comparison of different risk management systems in different regions, etc.

Although stochastic simulation modeling is generally regarded as the method of choice for risk assessment, there are no internationally agreed methods for MFSRA. This is because different methods will be appropriate to different types of risk management questions, and because time, data, and/or resource limitations may preclude the development of fully quantitative, stochastic, farm-to-fork risk assessment models. Instead, FAO/WHO through the CAC have articulated a series of guidelines that represent 'best practice' in MFSRA. Paramount in those guidelines is the need for transparency of the MFSRA process, in terms of the data and knowledge used, assumptions made, resource or other limitations on the conduct of the risk assessment, and where uncertainty exists. These elements should be documented as part of the risk assessment.

Transparency is needed to gauge the reliability of the risk assessment and estimate derived because risk assessments are used to support decisions concerning food safety management. Those decisions will often have both positive and negative consequences for the food industry and risk managers need to ensure that a net benefit results from the risk management strategies they implement. Risk assessments combine data and knowledge from diverse sources and often require complex mathematical treatments and logic, but they are also often based on imperfect data and knowledge and rely on various simplifying assumptions. Transparency and documentation enable peer review and open evaluation of the risk assessment and its conclusions by those that may be affected by the risk management decisions arising from the MFSRA. The review process also contributes to better and more effective risk management decisions and strategies.

Risk Assessment: Chemical Hazards

GG Moy, Food Safety Consultants International, Geneva, Switzerland

Introduction

Over the past century, the use of natural and synthetic chemicals has largely created our modern world, which has improved the lives of many billions of people. Some of these chemicals have been used by the food industry to improve food safety and quality and reduce spoilage and wastage, thus increase its availability, accessibility, and/or affordability. As with any technology, the use of such chemicals are not without certain risks; therefore these need to be addressed and actively managed. Besides these intentionally added chemicals, there are also chemical contaminants that are inadvertently present in food that may also pose risks to health. These include chemicals that are naturally occurring toxins or that are produced during handling, storage, and processing, including cooking. Chemical contamination of food can also arise from the environment through polluted air, water, and soil. Finally toxic chemicals may be illegally introduced into food to defraud consumers or for other criminal purposes.

With the development of risk analysis principles and procedures in the US, the approach to managing chemical hazards has become more methodical and to some extent, harmonized. In the risk analysis paradigm, the scientific evaluation of a chemical is based on an assessment of the potential risk, consisting of hazard identification, hazard characterization, exposure assessment, and risk characterization. Since 1995, the use of risk assessment for food safety has been required by all member countries of the World Trade Organization (WTO) under the WTO's Agreement on the Application of Sanitary and Phytosanitary Measurers (SPS Agreement). Note that the SPS Agreement explicitly recognizes the standards, guidelines, and other recommendations of the Codex Alimentarius Commission (Codex) as representing the *de facto* international reference for risk assessment and management for food safety. In this regard, Codex has developed definitions and principles for risk analysis that should be consulted to ensure compliance with the SPS Agreement.

In relation to risk assessment, Codex has provided guidance on risk assessment policy and risk assessment as follows:

> *"RISK ASSESSMENT POLICY*
>
> *Determination of risk assessment policy should be included as a specific component of risk management.*
>
> *Risk assessment policy should be established by risk managers in advance of risk assessment, in consultation with risk assessors and all other interested parties. This procedure aims at ensuring that the risk assessment is systematic, complete, unbiased and transparent.*
>
> *The mandate given by risk managers to risk assessors should be as clear as possible.*
>
> *Where necessary, risk managers should ask risk assessors to evaluate the potential changes in risk resulting from different risk management options.*
>
> *RISK ASSESSMENT*
>
> *The scope and purpose of the particular risk assessment being carried out should be clearly stated and in accordance with risk assessment policy. The output form and possible alternative outputs of the risk assessment should be defined.*
>
> *Experts responsible for risk assessment should be selected in a transparent manner on the basis of their expertise, experience, and their independence with regard to the interests involved. The procedures used to select these experts should be documented including a public declaration of any potential conflict of interest. This declaration should also identify and detail their individual expertise, experience and independence. Expert bodies and consultations should ensure effective participation of experts from different parts of the world, including experts from developing countries.*
>
> *Risk assessment should be conducted in accordance with the Statements of Principle Relating to the Role of Food Safety Risk Assessment and should incorporate the four steps of the risk assessment, i.e. hazard identification, hazard characterization, exposure assessment and risk characterization.*
>
> *Risk assessment should be based on all available scientific data. It should use available quantitative information to the greatest extent possible. Risk assessment may also take into account qualitative information.*
>
> *Risk assessment should take into account relevant production, storage and handling practices used throughout the food chain including traditional practices, methods of analysis, sampling and inspection and the prevalence of specific adverse health effects.*
>
> *Risk assessment should seek and incorporate relevant data from different parts of the world, including that from developing countries. These data should particularly include epidemiological surveillance data, analytical and exposure data. Where relevant data are not available from developing countries, the Commission should request that FAO/WHO initiate time-bound studies for this purpose. The conduct of the risk assessment should not be inappropriately delayed pending receipt of these data; however, the risk assessment should be reconsidered when such data are available.*
>
> *Constraints, uncertainties and assumptions having an impact on the risk assessment should be explicitly considered at each step in the risk assessment and documented in a transparent manner. Expression of uncertainty or variability in risk estimates may be qualitative or quantitative, but should be quantified to the extent that is scientifically achievable.*
>
> *Risk assessments should be based on realistic exposure scenarios, with consideration of different situations being defined by risk assessment policy. They should include consideration of susceptible and high-risk population groups. Acute, chronic (including long-term), cumulative and/or combined adverse health effects should be taken into account in carrying out risk assessment, where relevant.*
>
> *The report of the risk assessment should indicate any constraints, uncertainties, assumptions and their impact on the risk assessment. Minority opinions should also be recorded. The responsibility for resolving the impact of uncertainty on the risk management decision lies with the risk manager, not the risk assessors.*

 doi:10.1016/B978-0-12-378612-8.00034-2

> *The conclusion of the risk assessment including a risk estimate, if available, should be presented in a readily understandable and useful form to risk managers and made available to other risk assessors and interested parties so that they can review the assessment.''*

On behalf of Codex and member countries of the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO, the risk assessment for chemicals is carried out mainly by two international expert bodies, namely the Joint WHO/FAO Expert Committee on Food Additives (JECFA), which evaluates food additives, contaminants and veterinary drug residues in food, and the Joint FAO/WHO Meetings on Pesticide Residues (JMPR), which evaluates insecticides, herbicides, fungicides and related chemicals. At times special *ad hoc* expert committees are convened by FAO and WHO to address urgent issues, as was the case with the first evaluation of acrylamide. The methods and procedures used by JECFA and JMPR for evaluating chemicals in food have been recently updated in 2009.

Although there are some similarities, with chemical risk assessment the risk assessment of microbiological hazards has a number of significant differences. It should also be noted that health risks may also be posed by nutritional hazards, such as the inadequate intake of essential micronutrients, including vitamins and minerals. Within Codex, the responsibility for nutritional hazards is under the Codex Committee on Nutrition and Food for Special Dietary Needs. Whereas JECFA reviews the potential risk of excessive consumption of food fortification agents, the establishment of minimum intake levels is handled by other FAO and WHO expert committees.

Risk Assessment and Risk Management Interface

One of the earliest communications between risk assessor and risk managers involves the preparation of the risk profile upon which the risk manager decides whether a full risk assessment is appropriate. The potential toxicity of a chemical is based not only on its chemical structure, but also its likely levels in the diet. Therefore, even a chemical with low toxicity can be harmful if exposure is sufficiently high.

Obviously, a chemical that produces toxic effects shortly after ingestion of the food can be easily identified as a candidate for risk assessment. However, most cases are not so clear. In the early 1900s in the US, for example, the public health risks posed by the widely used, but unregulated food additives benzoic acid and boric acid were hotly debated. At one point, human volunteers were recruited to actually test the toxic potential of these chemicals, although laboratory animals are now used for this purpose.

Today in most countries, food safety legislation requires that any chemical intentionally added to food be shown to be safe through appropriate tests in animals, usually rats, mice, and sometimes dogs. Consequently, risk assessments are systematically carried out in the case of food additives. Premarket risk assessments are also required for pesticides and veterinary drugs. In some countries, chemicals added indirectly to food, such as processing aids and chemicals that can migrate from food contact materials, are also required to undergo risk assessment. Premarket evaluation is also required for new technologies that may introduce a new chemical or increase the exposure to a known toxic chemical. For example, food irradiation was evaluated for 'unique radiolytic products' and genetically modified plants are evaluated for possible immunoactive proteins.

Many of contaminants and toxins would fall under the traditional term 'poisons' because the time between ingestion and onset of adverse effects is short, in most cases in the order of minutes and hours. For example, certain heavy metals, mycotoxins, and biotoxins are easily recognized as potential foodborne hazards. However, certain chemicals cause adverse effects only after many days, months, or even years of exposure. These so-called 'slow poisons' have proved more difficult to identify. Whereas some chemicals are inherently more toxic than others, delayed effects can be difficult to identify because of the nature of the toxic effects in humans are not known. This is particularly difficult for effects with a large baseline of cases, such as cancer. Sometimes chemicals can cause behavioral changes that are subtle and difficult to measure. Some chemicals, such as endocrine disruptors, can cause adverse effects at extremely low levels and for short durations of exposure. Furthermore, effects may not be manifested for decades, such as in the case of diethylstilbestrol. Consequently, these chemicals are currently the subject of scientific and policy debate.

The presence of some toxicants in food has been revealed by new analytical methods, which have steadily become more sensitive over the years. However, the adverse effects of low-level, long-term exposure to many toxic chemicals remain unknown. Each year approximately 1500 new chemicals are brought onto the market, adding to the approximately 70 000 existing ones. The United Nations Environment Program has estimated that production of chemicals is likely to increase at the rate of 15% a year. Few of these chemicals have been rigorously tested and many of them could potentially contaminate food. Consequently, the food safety database for many chemicals of potential concern may be inadequate. If exposure is expected to be significant, governments and/or industry should undertake the necessary studies to support a risk assessment of these chemicals.

Based on preliminary information from risk assessors along with other information in the risk profile, risk managers may decide that the potential health risk warrants the completion of the full risk assessment paradigm. In that case, the risk manager would usually formulate the questions that the risk assessor needs to answer. The risk manager will also provide the risk assessment policy to be followed, such as default assumptions and procedures for addressing uncertainty (see the Codex recommendations above). In many countries, the risk manager also provides the resources to conduct the risk assessment, but a functional separation between the risk manager and risk assessor is necessary to ensure integrity of the process. The next step is hazard identification, which mainly focuses on certain aspects of toxicology.

Hazard Identification

The first step in a risk assessment process is hazard identification. Hazard identification is the process of determining

whether the nature of potential adverse health effects caused by exposure to a chemical and whether adverse health effects are likely to occur in humans. It examines the available scientific data for a given chemical and uses a weight of evidence approach to characterize the link between the adverse health effect and the chemical exposure. Note that exposure to a chemical may generate many different or multiple adverse effects in humans, including various diseases, organ failure, cancers, reproductive defects, developmental deficits, or other effects. These may occur after high level short-term (acute) exposure or low-level long-term (chronic) exposure.

A wide variety of *in vitro* and animal studies are used to support hazard identification, including toxicokinetics, which involve how the body absorbs, distributes, metabolizes, and eliminates specific chemicals and toxicodynamics, which focus on the effects that chemicals have on the human body. Models based on these studies can describe mechanisms by which a chemical may impact human health, thus providing insights into the possible effects of a chemical.

Epidemiological studies of human populations to examine whether there is an association between exposure to a chemical and a human health effect are preferred, but are often not available because accurate exposure information is lacking, especially for diseases with long induction periods. For many of these chemicals, there is a paucity of reliable data to identify the potential health effects and the populations at risk. Results from animal studies can be used to extrapolate observed adverse effects to humans. *In silico* and *in vitro* test are also useful for identifying toxic potential. In some cases, predictive models based on structure–activity relationships can be used to assess potential toxicity for reproductive and developmental toxicity, genotoxicity, and carcinogenicity.

Hazard Characterization

Hazard characterization may include some of the toxicity studies considered under the hazard identification component and in this regard, it should be noted that risk assessment is an iterative process as new data can alter previous conclusions or raise new concerns. The toxicological evaluation of a chemical for regulatory purposes is based on a principle first identified in the sixteenth century by Philippus Paracelsus, a Swiss chemist and physician. He recognized that 'all chemicals are toxic; the dose makes the poison.' For example, even water can cause death if consumed in large enough amounts that cause an electrolyte imbalance. However, a corollary to the Paracelsus Principle might be 'all chemicals are harmless at some low dose,' which is true for most chemicals with the notable exceptions of so-called 'nonthresholdable' toxicants. The concept of a threshold (with appropriate uncertainty factors) below which exposure is 'safe' underlies the risk assessment, or more precisely, the safety assessment of chemicals. Therefore, besides understanding the dose–response characteristics of a chemical, the practical goal of regulatory toxicology is to find the dose of a chemical, which poses no appreciable risk to health over a lifetime of exposure.

To accomplish this, hazard characterization relies on standard toxicity tests performed according to internationally accepted protocols, such as those published by the Organization for Economic Cooperation and Development. Hazard characterization considers the dose levels at which no adverse effects occur in order to establish a dietary exposure from all sources that is acceptable (intentionally used chemicals) or tolerable (contaminants and naturally occurring chemicals). The standard reference value used at the international level to indicate the safe level of intake of an intentionally used chemical is the 'acceptable daily intake' (ADI) which is defined by JECFA as the estimate of the amount of a substance in food and/or in drinking water, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk to the consumer. Note that because the adverse effects are thresholdable, these safety assessments employ a standard of risk that is virtually zero. The ADI is usually derived from establishing a No Observed Adverse Effect Level in the most sensitive animal species and then apply a 100-fold uncertainty factor (sometimes referred to as a safety factor) to take into account the extrapolation from animals to human and variability among humans.

For contaminants and naturally occurring chemicals, the corresponding reference intake value is the 'provisional tolerable intake (PTI),' which can be expressed on a daily, weekly, or monthly basis. The PTI is referred to as 'provisional' because there are often insufficient data on the consequences of human exposure at low levels, and new data may result in a change to the tolerable level. For contaminants that may accumulate in the body over time, such as lead, cadmium, and mercury, the provisional tolerable weekly intake is used as a reference value in order to minimize the significance of daily variations in intake. For contaminants that do not accumulate in the body, the provisional tolerable daily intake is used. For dioxins and dioxin-like PCBs, the reference is the provisional monthly tolerable intake, which is used to emphasize the long half-lives of these chemicals in the body. These tolerable intakes are the primary health reference limits that apply to chronic low-level exposures.

For 'non thresholdable' toxicants, the lower one-sided confidence limit of the bench mark dose (BMDL) is used as the point of departure for the determination of a margin of exposure (MOE), which is defined as the BMDL divided by the actual or estimated exposure. The bench mark dose (BMD) is determined from the dose–response curve to represent the dose that causes a specific incidence of adverse health effects in test animals. The MOE is not itself a health-based reference value, but can be used by the risk manager in setting priorities and selecting interventions, if necessary. Such dose–response assessments are occasionally used to define the dose associated with a negligible response, such as one case in a million population.

The principles and methods for the risk assessments carried out by JECFA and JMPR for chemicals are described in Environmental Health Criteria 240 prepared by the International Program on Chemical Safety (IPCS) and published by WHO. The use of animal studies for assessing toxicity and their consideration for public health purposes are also described by a number of national agencies. In most cases, a tiered approach is used based on the potential toxicity of the chemical

and the likely levels of exposure of the population. For chemicals of lowest concern, only a battery of genotoxicity studies and short-term toxicity study in the rodent would be required. For chemicals of intermediate concern, genotoxicities study, two subchronic toxicity studies in the rodent and nonrodent species, a developmental/teratogenicity study and metabolism and toxicokinetics study would need to be performed. For chemicals of highest concern, chronic toxicity and carcinogenicity studies in two rodent species, usually the mouse and rat, would need to be performed in addition to those required for chemicals of intermediate concern. Other specific studies may also be required depending on the nature of the chemical and the specific requirements of the national authority, including neurotoxicity, immunotoxicity, and acute toxicity studies.

The ability of certain chemicals to cause disease through a similar mechanism of action has been incorporated into most risk assessments. Metabolites formed in the bodies of humans or in food-producing animals from the parent molecule have to be considered in the risk assessment for both hazard characterization and exposure assessment. For some structurally-related chemicals, a group ADI will be established. In cases where the toxic potentials of related chemicals are different, toxic equivalence factors will be assigned to each isomer. In this regard, the endocrine disruption potential of dioxins and certain polychlorinated biphenyls (PCBs) has been estimated with toxic equivalence factors, such factors have not been assigned to the many other chemicals that also possess such potential, including pesticides, packaging materials, industrial pollutants, and even products commonly found in the home. In addition, the impact of mixtures of chemicals with different toxicities remains largely unknown although some evidence indicates that this may be a concern.

In regard to chemicals present in the diet at very low levels, JECFA has applied another approach mainly for flavorings. The approach, called the threshold of toxicological concern (TTC), recognizes that risk can be predicted based on chemical structure and exposure. For example, if a chemical possess a structure that is not associated with genotoxicity or other nonthresholdable toxicity, there is a high probability of negligible harm if dietary exposure to the chemical is sufficiently low, for example, below 1.5 mg per day. TTC is not intended to replace established risk assessment procedures, but rather to be applied to certain structural classes. The approach might also be useful for evaluating processing aids, packaging migrants, and other chemicals present at low levels in the diet, given the large number of chemicals involved and significant resources that would be required to prepare a complete toxicological profile for each.

Finally, some chemicals need to be assessed for potential acute toxicity. For example, certain pesticides, mycotoxins, veterinary drugs, and metals can give rise to acute health effects after short periods of exposure, usually within 24 hours or less. JMPR routinely considers the need to set an acute reference dose (ARfD) for all pesticides it evaluates. JECFA also includes consideration of acute effects, including the possibility of acute effects in sensitive individuals. JMPR has developed guidance for a single-dose study in experimental animals to enable a more accurate derivation of the ARfD.

Exposure Assessment

For intentionally an added chemical, methods have been developed to predict the likely exposure to populations if the chemical was allowed on the market. In its simplest form, the estimated exposure is the amount of a chemical in a food multiplied by the amount of the food consumed. If the chemical occurs in more than one food, then these exposures need to be added together. If the chemical occurs in multiple media, such as, air, water, and soil, then these exposures need to be included in the exposure assessment, which is referred to as an aggregate assessment. If the chemical involves other chemicals with similar mechanisms of toxicity, for example, organophosphorus pesticides, then the amount of each chemical needs to be taken into account. These assessments are referred to as cumulative and it is possible to have an aggregate, cumulative exposure assessment.

Estimation of exposure to a chemical depends on knowledge of the level of the chemical in a food coupled with knowledge of that food consumed. Most countries use a tiered approach that makes the best use of resources in estimating exposure. For example, if an ADI is high, only a crude exposure estimate is necessary in most cases. However, if a more refined exposure estimate is necessary, additional resources are needed to obtain a more realistic assessment, either through better estimates of concentration levels or consumption amounts. The level of contamination of food can also be influenced by a variety of factors, such as food preparation and storage practices as well as geographical and climatic conditions, agricultural practices, and industrial pollution. The level of contamination of food can be determined from food monitoring data when available, but this data has a number of deficiencies. Different methods of dietary intake modeling combine data on contaminant levels in food with food consumption data to provide estimates of the daily, weekly, or monthly dietary exposure. The models may be either deterministic or probabilistic. In the deterministic model, the mean and high percentile are usually calculated, whereas with the probabilistic model, a more complete picture of the distribution of intakes is calculated to take into account all sections of the population for which food consumption data are available. In some models, distributions of levels of contaminants are also used.

In the case of pesticides and veterinary drug residues, appropriate levels of use are first established to ensure the efficacy of the chemicals and then the safety of those levels is assessed. As a first estimate, a theoretical maximum daily intake (TMDI) is often used to provide a rapid and resource-efficient assessment of exposure, which is compared to the ADI. The assessment assumes that the entire consumed commodity is treated with the chemical and that residues are present at the proposed maximum residue levels (MRLs). Although this first tier is a significant overestimate of exposure, it is often sufficient to resolve any exposure concerns for the chemical under the proposed conditions of use. However, the JMPR routinely applies a more realistic assessment using the median residues instead of the MRLs. Further refinements of the exposure assessment may also be applied, such as processing factors for cleaning, peeling, and cooking. Reducing the number of foods considered for approval may also

be used to reduce exposure to an acceptable level, i.e., the ADI. In the case of veterinary drug residues, the withholding period from the time of administration of the drug to the time of slaughter or collection of eggs or milk for human consumption is used to reduce residues to acceptable levels.

For food additives, various screening methods, like the budget method, have been devised based on the proposed maximum levels permitted in the foods or food categories in which the additive would be used. For some additives, such as flavors, the exposure is based on annual production and assuming that 10% of the population consumes the chemical. If any of these screening methods indicate that the ADI may be exceeded, national exposure assessments are consulted because these offer more precise estimates of consumption and use levels in specific foods.

Another approach is to use total diet surveys to estimate the exposure of selected contaminants that is already present in the food supply. These surveys are a direct measure of the level of dietary exposure to contaminants and other chemicals in food as consumed. When periodically repeated using the same protocol, such data provide useful time trends in exposure, which is very useful for evaluating control measures and anticipating potential problems. WHO considers total diet studies to be the most cost-effective method for generally assuring the safety of the food supply from hazardous chemicals. Many countries share information on the levels of contaminants in their food supply with the WHO GEMS/Food Program as part of internationally coordinated efforts to build national capacities, provide data for international risk assessments, and promote confidence in safety of the global food supply.

In some cases, biomonitoring may be used to measure integrated exposure from all media, including food, air, water, and soil. Biomonitoring is particularly useful for chemicals that bioaccumulate and whose toxicity is related to the body burden of the accumulated chemical. Various tissues may be used for biomonitoring including blood, hair, urine, adipose tissue, and human milk. Such monitoring may measure the chemical or an adduct directly or another substance that serves as a marker of exposure.

In the case of emergencies, the risk assessor will need to use any and all available information to formulate a preliminary risk characterization. To protect public health, the WTO allows the establishment of standards based on partial information, but such measures can only be temporary and are subject to other disciplines, for example, not be discriminatory.

Risk Characterization

Risk characterization brings together the information on the level of exposure to the chemical for various population groups and compares this with health-based reference values for health effects. If the exposure does not exceed the health-based reference value, then it is generally assumed that the chemical does not pose a health concern. For nonthresholdable chemicals, the risk assessment will provide an MOE. This information allows a decision to be made regarding necessary management action, if any. At times, the risk manager may ask the risk assessor to provide additional information related to the risk assessment. For example, the likely health outcomes of various maximum permitted levels of a contaminant in food may be requested by the risk manager to allow balancing of the risk of a chemical with health benefits of food availability. Finally, it should be noted that any risk assessment is based on the scientific evidence available at the time of the assessment and that whenever significant new information warrants, the chemical should be reevaluated.

RISK ANALYSIS

Risk Management: Application to Chemical Hazards

SA Slorach, OIE Working Group on Animal Production Food Safety, Älvsjö, Sweden

Glossary

Chemical hazard A chemical in food with the potential to cause an adverse health effect.

European Food Safety Authority (EFSA) The European Union body responsible for risk assessment of and risk communication on risks associated with food and feed, as a basis for European policies, legislation, and measures to manage such risks.

JEFCFA Joint FAO/WHO Expert Committee on Food Additives. An expert body that carries out toxicological evaluations of chemical hazards, including food additives and contaminants and residues of veterinary drugs, in food and proposes specifications for food additives.

JMPR Joint FAO/WHO Meetings on Pesticide Residues. An expert body that carries out toxicological evaluations of pesticide residues in food and proposes maximum residue limits (MRLs) for such residues in foods.

Risk assessment A scientifically based process consisting of the following steps: (1) hazard identification, (2) hazard characterization, (3) exposure assessment, and (4) risk characterization.

Risk assessment policy Documented guidelines on the choice of options and associated judgements for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk estimate The quantitative estimation of risk resulting from risk characterization.

Risk profile The description of the food safety problem and its context.

SPS Agreement The World Trade Organization Agreement on the Application of Sanitary and Phytosanitary Measures.

Introduction

This article describes how the general principles of food safety risk management are applied to chemical hazards in food. Examples are given of different risk management options and their application in dealing with the risks posed by the wide range of chemical hazards that may be present in food.

Chemical Hazards in Food

Many different kinds of chemical hazards may be introduced into food at different points in the food production to consumption continuum. Some hazards are well characterized, single compounds (e.g., basic elements and simple organic molecules), whereas others are complex mixtures of varying composition (e.g., polychlorinated biphenyls (PCBs), polychlorinated dibenzodioxins (dioxins), and many biotoxins). Some are added intentionally to foods (e.g., food additives) or are residues of products used in primary production (e.g., pesticides and veterinary drugs) and others occur naturally in foods or are formed during food processing. Still others are a derived from environmental contamination.

Although bacterial toxins can be regarded as chemical hazards, they are not dealt with here, but instead in the article dealing with the management of biological hazards. Likewise, although genetically modified organisms (GMOs) used as food may contain chemical hazards, they are not dealt with here but in the article on GMOs .

The following are some of the most important types of chemical hazard that may be present in foods.

Environmental Contaminants

Contamination of the environment with persistent organic pollutants, such as PCBs, dioxins, DDT, and several other pesticides and brominated fire retardants, has led to contamination of foods of animal origin, in some cases via contamination of animal feed. Similarly, methylmercury derived from industrial pollution or natural sources accumulates in some predatory fish species. Toxic metals, such as cadmium, lead, and arsenic can be taken up by food plants, for example, cadmium in rice from grown in volcanic soils. Food may also become contaminated with radionuclides as a result of releases from nuclear power plant incidents.

Naturally Occurring Toxins

A wide range of chemical hazards may be present naturally in some foods, for example, cyanogenic glycosides in cassava, caffeine in coffee and tea, solanine in potatoes, hydrazine derivatives in mushrooms, safrole in flavors, and lectins in legumes. In addition, algal toxins present in the aquatic

 doi:10.1016/B978-0-12-378612-8.00036-6

environment can accumulate in mussels and other shellfish and give rise to a range of intoxications, such as diarrhetic shellfish poisoning (DSP) and paralytic shellfish poisoning.

Food Allergens and Other Components of Food

Chemical components, especially proteins, of many common foods, for example, eggs, milk, fish, shellfish, nuts, legumes, and cereals, may give rise to allergic reactions in sensitive individuals. In addition to atopic allergy, some food components (e.g., lactose) may give rise to hypersensitivity or intolerance reactions.

Mycotoxins

Growth of certain molds on foods can lead to the formation of mycotoxins, for example, aflatoxins in nuts and maize, ochratoxin A, fumonisins and trichothecenes in grains, and patulin in certain fruits such as apples and pears. The presence of mycotoxins in animal feed can result in contamination of foods of animal origin, for example, aflatoxin M_1 in milk derived from aflatoxin B_1 in feed.

Residues of Pesticides

A wide range of pesticides, including herbicides and fungicides, are used in agriculture and horticulture to protect plants from insects, molds, etc. and to control weeds. This can result in residues in foods of plant origin. Several different pesticides may be used on the same product, resulting in multiple residues in the same food. Pesticide residues present in animal fodder, such as hay, or feed ingredients, such as citrus pulp, may result in the contamination of foods of animal origin, for example, meat and milk.

Residues of Veterinary Drugs, Including Feed Additives

Veterinary drugs are used to prevent or treat diseases in food-producing animals and for growth-promotion and other purposes and residues of such drugs may be present in foods of animal origin. In addition to the risks arising from residues, the use of antimicrobials in animal husbandry may increase the risk of development of antimicrobial-resistant microorganisms.

Intentional Food Additives, Including Flavoring Substances and Enrichment Substances

Certain chemicals are added to foods to improve their quality and shelf-life (e.g., preservatives and antioxidants) or organoleptic properties (e.g., colors, sweeteners, and flavoring substances) or for technological and other reasons (e.g., emulsifiers, acidity regulators, and anticaking agents). Other substances, for example, vitamins and minerals, are added to foods to enhance their nutritional value or to replace nutrients lost during processing.

Substances Formed During Food Processing/Preparation

Industrial food processing and food preparation in catering establishments or at home, for example, heat treatment, such as baking, frying, grilling, and smoking, can result in the formation of chemical hazards in some foods, for example, acrylamide in French fries and bread, polycyclic aromatic hydrocarbons (PAH) in smoked foods, nitrosamines in nitrite-treated meat products, and 3-monochloropropane-1, 2-diol (3-MCPD) in acid-hydrolyzed vegetable protein. In addition, some substances used as processing aids may become part of foodstuffs.

Substances Derived from Materials Coming into Contact with Food

During their production, processing, storage, and preparation foods often come into contact with materials from which chemicals can migrate or be leached. For example, monomers and plasticizers can migrate from plastic packaging materials, tin can contaminate foods stored in tin-plated cans, and lead and cadmium can be leached from ceramic tableware.

Intentionally Added Contaminants/Adulterants

Dishonest food business operators may add chemicals to foods in order to deceive the purchaser as to their identity, quality, or other properties. Examples of such practices in recent years include the addition of melamine to milk to give the impression of higher protein content and the adulteration of spices with the color Sudan Red.

Generic Framework for Food Safety Risk Management

Food safety risk management can be divided into the four steps shown in Figure 1.

Step 1: Preliminary Risk Management Activities

The first step of the risk management process, preliminary risk management activities, comprises the following:

- Identify the food safety issue.
- Develop a risk profile.

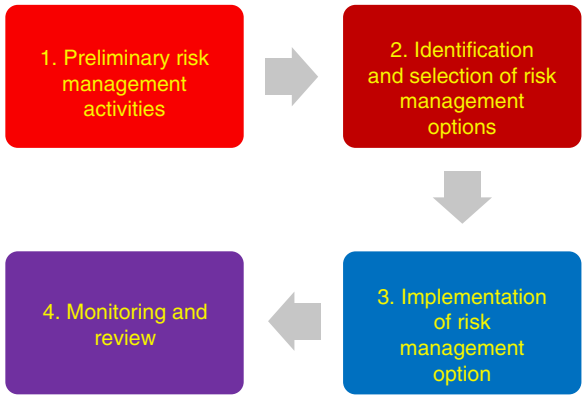

Figure 1 The four steps of food safety risk management.

- Establish broad risk management goals.
- Decide if a (new) risk assessment is needed.
- Rank risks, if necessary.
- Establish a risk assessment policy.

Identify the Food Safety Issue

Identifying and describing the nature and characteristics of food safety issue is an essential first step in its management. In some cases the issue will already have been recognized as a food safety problem and a considerable amount of information about the risks involved is available, whereas in others the hazard may not have been identified earlier and little information on its toxicity or human exposure is available. Food safety problems may be identified in many different ways, for example, by food inspection and monitoring programs (e.g., dioxin contamination of foods of animal origin in Ireland and Germany arising from feed contamination), biological and environmental monitoring, human and animal disease outbreak investigations (e.g., humans affected by methylmercury in Minimata and animals affected by dioxin contamination of feed in Belgium in 1999) and clinical and toxicological studies (e.g., studies on processing contaminants such as acrylamide and 3-MCPD). Industrial incidents, for example, the Chernobyl and Fukushima disasters, may also result in food safety problems from radionuclides. Potential problems may also be identified by academic and scientific experts, the food industry, consumer organizations, and the media. For example, the problems with 2-isopropyl thioxanthone and semicarbazide were first reported by industry.

A brief initial description of the food safety issue provides the basis for developing a risk profile, which in turn generates a context and guide for further action.

Develop a Risk Profile

A risk profile is a description of a food safety problem and its context. Its main purpose is to assist risk managers in assessing if and what further action may be required. Essentially, it is a summary of what is known, and not known, about the food safety issue in question. A risk profile is usually developed by risk assessors in cooperation with others who can provide complementary background information, for example, on production and trade aspects of the foods involved. The contents of a risk profile can vary widely, depending on the amount of information available on the specific issue. However, the following are examples of the types of information that may be included in a risk profile:

- Broad statement of the food safety issue.
- Description of the hazard and food(s) involved.
- Chemical characteristics of the hazard involved.
- Scientific information on possible health risks, including descriptions of potential adverse effects on human health.
- Gaps in and uncertainties in scientific knowledge.
- How and where the hazard enters the food chain.
- Levels of the hazard in relevant foods and intake of these foods by different population groups, providing the basis for estimating exposure.
- Nature of values at risk (human health, economic, ethical, etc.).
- Distribution of risk (who produces, benefits from, and bears the risk).
- Current risk management practices, including any regulatory standards and control measures.
- Information about possible risk management measures.
- Public perceptions of the hazard and possible risks.
- Implications for international agreements, for example, the World Trade Organization (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement) and the International Health Regulations 2005.

Examples of risk profiles of caffeine in beverages, ciguatoxins in seafood, and natural toxins in New Zealand crop plants can be found on the website of the New Zealand Food Safety Authority.

Establish Broad Risk Management Goals

Risk management goals are statements of the intended purpose and the end result that risk management is intended to achieve. The goals can be expressed in different ways, for example, to ensure that the intake of a certain chemical hazard by a vulnerable population group does not exceed a defined acceptable daily intake (ADI) or provisional tolerable weekly intake (PTWI) or to achieve a specified reduction in exposure of a population group to a chemical hazard within a certain time period. For example, Germany has set a goal to reduce acrylamide exposure via food by taking an as low as reasonably achievable (ALARA) approach (see Evaluate the Options).

Decide if a (New) Risk Assessment is Necessary

A risk assessment is a scientifically based process to develop an understanding of and characterize the human health risk associated with a particular hazard. It consisting of the following steps: (1) hazard identification, (2) hazard characterization, (3) exposure assessment, and (4) risk characterization. The process is described in more detail in the article on risk assessment of chemicals. A risk assessment can be qualitative (e.g., when data on toxicity and exposure are inadequate) or, preferably, quantitative and should answer specific questions posed by the risk manager on likely risk, including the likelihood and severity of a particular adverse health effect and any population groups that are at particular risk. The degree of uncertainty in the risk estimate should be clearly communicated to the risk manager.

Full risk assessments require considerable scientific resources and are also time-consuming and it is, therefore, necessary for the risk manager, in consultation with risk assessors, to decide whether such a risk assessment is needed or not. In some cases, sufficient information will already be available from risk assessments carried out internationally or nationally. Risk assessments of many chemical hazards in food have already been carried out by expert bodies such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA), the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) and the Scientific Panels of the European Food Safety Authority (EFSA). These assessments can be accessed via the

FAO, WHO, and EFSA websites (see Further Reading). It is desirable to carry out a risk assessment in cases where the issue is of significant concern to risk managers and other stakeholders, including consumers, and where little scientific data exists and there is considerable uncertainty about the nature or magnitude of the risk. However, it may not always be necessary (or, due to time constraints, possible) to carry out a risk assessment before taking action. For example, when sufficient scientific information on likely risks is already available, where an issue is of minor food safety concern or when rapid action is needed in an emergency. In such cases, the information in the risk profile can be used as a basis for identifying and selecting risk management options. If, in an emergency, preliminary action is taken on the basis of a risk profile, this should be reviewed when further scientific evidence becomes available to enable a risk assessment to be performed.

Rank Risks, if Necessary

In cases where resources for risk assessment are insufficient to meet immediate needs, it may be necessary for the risk managers to prioritize risks for risk assessment. This ranking should be based on a preliminary assessment of the risks by risk assessors, but other factors, such as consumer, political, or trade concerns are often taken into account.

Establish a Risk Assessment Policy

Many of the risk assessments of chemical hazards in food are based on the results of studies carried out on experimental animal receiving relatively high doses of the hazard. When assessing health risks for humans based on such studies, it is often necessary to make certain judgments to bridge gaps in scientific knowledge. This may concern, for example, extrapolating results seen at high doses in cancer studies in animals to low exposure in man and choice of appropriate animal species to test for teratogenic effects. Another issue is the use of default safety factors or uncertainty factors in estimating ADIs for man for chemical hazards from no adverse effect levels determined from animal studies. Many risk assessment bodies follow the practice developed by the JECFA, in which a factor of 10 is used to account for any variation within species (e.g., higher susceptibility in the very young) and an additional factor of 10 in case there is any interspecies variation when extrapolating from experimental animals to man. Additional safety factors may be applied if the underlying scientific data are deficient in some way. Risk assessment policies are usually established by risk managers in consultation with risk assessors well in advance of the risk assessment. These are often incorporated into guidelines or standard operating procedures for conducting risk assessment, such as Environmental Health Criteria 240, which is used by JECFA.

Commission a Risk Assessment

If it is decided to conduct a risk assessment, then the scope of the assessment and the questions to be answered must clearly be defined and the time frame and resources to be allocated agreed. In some cases, where considerable knowledge about the toxicity of a hazard is already available, the risk assessment may be restricted to assessing the risk of a particular health effect, for example, cancer.

Consider the Results of the Risk Assessment in the Context of Risk Evaluation

It is important that risk managers clearly understand the results of the risk assessment and the associated uncertainties. An executive summary is useful for this purpose. For communication with other stakeholders, it is also useful to have a lay summary of the risk assessment.

Step 2: Identification and Selection of Risk Management Options

The second step of the risk management process, identification and selection of risk management options, comprises the following activities:

- Identify risk management options.
- Evaluate the options.
- Select the preferred option or options.

In this second step of the risk management of chemical hazards in food, the risk manager leads the process of identifying and selecting risk management options, taking into account the size and severity of the risk together with the likely effectiveness and costs of the different options for risk reduction and, where relevant, any social, ethical, and political aspects.

Identify Risk Management Options

There are several options available for managing risks associated with chemical hazards in food: in some cases, two or more approaches are used to tackle a problem. The identification of risk management options can be facilitated by close cooperation and good communication between the food authorities, food business operators, technical and academic experts, and other stakeholders.

The modern farm-to-fork approach to food safety requires that good practices (good agricultural practice, good veterinary practice, good hygienic practice, good manufacturing practice, etc.) and be applied along the whole of the food chain in order to minimize the risk of contamination with chemical and other hazards. Food manufacturers should base their internal control systems on hazard analysis and critical control point (HACCP) principles. Traceability, at least the ability to trace feed/foods/ingredients one step forward and one step back in the food chain is important in managing food safety risks, especially when the risks have only been detected in the later parts of the food chain. For instance, in the case of the dioxin incident in Belgium in 1999, lack of traceability was a major constraint in managing the crisis. Later incidents in Ireland and Germany caused by dioxin-contaminated feed also show the importance of traceability of feed and feed ingredients.

The following are some examples of different risk management options and areas in which they can be applied.

- Introduce legislation to require prior approval of a substance/product before it may be used in connection with food production or handling and set conditions for its use. Examples of chemical hazards that are managed in this way are intentional food and feed additives, pesticides, and veterinary drugs. When positive lists of approved substances/products have been established, the use of other products is prohibited. In some cases negative lists of substances/products that may not be used, i.e., are banned, in connection with food production and handling are established.
- Set and enforce maximum levels (MLs) for the substance in various foods and animal feed. Examples of this are setting and enforcing maximum residue limits (MRLs) for residues of pesticides and veterinary drugs, and for MLs for food additives and food contaminants such as heavy metals (lead, cadmium, mercury, etc.), mycotoxins (aflatoxins, ochratoxin A, etc.), persistent organic pollutants (PCBs, dioxins, etc.), and PAH. For operational reasons, food business operators may establish MLs that are below the existing legal limits. These may be used as critical limits in conjunction with HACCP-based internal control systems to ensure the timely correction of processes and to ensure that noncomplying products do not leave the plant.
- Set and enforce maximum limits for migration or leaching of substances from food contact materials. Examples of this approach are setting limits for global migration and migration of specific monomers from plastic food packaging materials and leaching of lead and cadmium from ceramic tableware. Specifications may also be set for metal, for example, stainless steel, equipment coming into contact with food.
- Intensify control and enforcement activities in cases where MLs have already been established and experience shows that these levels are often exceeded.
- Recommend the relevant authorities to take action to reduce or eliminate emissions from sources of environmental pollution with, for example, heavy metals or persistent organochlorine compounds such as PCBs and dioxins.
- Ban food or animal feed that presents an unacceptable or imminent risk. For example, prohibit the sale of foods from a specified geographical area known to be heavily contaminated with a chemical hazard or foods (e.g., certain fungi) known to regularly contain unacceptably high levels of certain chemical toxins.
- Establish specific food labeling requirements so that persons that are allergic or hypersensitive to or intolerant of certain food components can identify and avoid foods that can cause untoward reactions. For example, in some countries there is a requirement to label products containing the sweetener aspartame with information that it is a source of phenylalanine, which is important information for persons suffering from phenylketonuria.
- Introduce legislation requiring food business operators to develop, operate. and document internal control systems based on HACCP principles and to ensure that their staff receive adequate training to prevent contamination of food with chemical hazards.
- Promote voluntary action by food business operators to adopt new production or handling methods, selection of ingredients, etc.
- Issue recommendations, such as codes of practice, on the handling of certain foods in order to keep the levels of chemical hazards at acceptable levels. For example, advice on smoking and grilling of foods to keep down the levels of PAH (see Further Reading).
- Issue dietary advice to consumers, especially vulnerable groups such as pregnant women, to restrict their intake of foods known to regularly contain relatively high levels of certain chemical hazards, for example, to restrict the intake of fish species with elevated levels of methylmercury.
- Develop specific compliance programs to focus on food producers and traders who do not comply with food safety legislation.
- Prosecute food producers and traders who do not comply with food safety legislation, in particular those intentionally adulterating foods with chemical hazards.
- Take no action because it is considered that the risk is negligible or that the current control measures are adequate. A decision to take no action is also a risk management decision and should be documented.

Evaluate the Options

The risk management options should be evaluated against a set of criteria linked to the broad risk management goals established (see Establish Broad Risk Management Goals) and related to public health, economic, social, political, environmental, ethical, and legal issues. The primary goal is to provide an appropriate level of protection of public health (see below) and the options considered should be compared with the status quo in order to consider whether any changes are in fact needed to achieve this goal.

For WTO members (i.e., most countries of the world), it is important to remember that, according to the SPS Agreement, the chosen level of sanitary protection and the measures introduced to protect public health should be as least trade restrictive as necessary to achieve the established goal.

The criteria to be considered in selecting various options include:

- Likelihood that the measure(s) will lead to the achievement of the established public health goals. The risk assessors should be asked to estimate the risk reductions that can be achieved by various options considered.
- The feasibility of implementation, verification, and enforcement of the measures proposed.
- Possibility to evaluate if the public health goal has been achieved.
- Consistency with government policy.
- Consistency with the legal powers of government agency, if legal powers are delegated.
- Costs of compliance for food business operators and other stakeholders.
- Impact on international trade and consistency with the country's international obligations, for example, WTO membership and, in particular, the SPS Agreement.

- Impact on the availability and affordability of the foods concerned and any nutritional implications for the population.
- Acceptability to stakeholders, bearing in mind that some stakeholders may have competing interests.
- Possibility to communicate recommendations, advice, etc. to the population group(s) concerned.
- Any ethical or religious considerations.

One of the most important factors to be considered when evaluating the various risk management options is the human health protection goal. In the SPS Agreement this is referred to as the appropriate level of sanitary protection (ALOP) and it is up to each WTO member to set this level. There are various approaches to setting an ALOP and in selecting the best risk management option(s), including:

- Notional zero risk approach. Hazards are kept at or below levels that correspond to a predetermined negligible or notional zero risk, based on a risk assessment that indicated that such low exposure levels are reasonably certain not to cause harm to human health, even with lifetime exposure. This is the approach used by JECFA in setting ADIs for food additives and veterinary drug residues and PTWIs for chemical contaminants in food. Similarly the JMPR uses this approach in setting ADIs for pesticide residues. The MLs for food additives and contaminants and pesticide and veterinary drug residues adopted by the Codex Alimentarius Commission for various foods are based on JECFA and JMPR evaluations.
- ALARA approach. MLs for hazards are set at the lowest levels technically achievable and economically feasible under the circumstances. These MLs may vary over time and from country to country, due to agro-climatic conditions, technical developments and capabilities and economic feasibility.
- Threshold approach. According to this approach, risks must be kept below a certain specified numerical level that is deemed to represent a finite, but acceptable, risk. This approach may be used for chemical carcinogens, but up to now very few countries have established or applied such levels.
- Benefit–cost approach. Both a risk assessment and a benefit-cost assessment are carried out and the risk managers then weigh the expected risk reduction against the estimated cost of achieving this reduction.
- Comparative risk approach (risk–risk comparison). In some cases, reducing a risk from one hazard using certain measures has to be compared with the risk that may be generated as a consequence of the decision. For example, prohibiting the use of nitrite as a preservative in certain meat products to reduce the formation of carcinogenic nitrosamines may increase the risk of growth of *Clostridium botulinum*. Prohibiting the sale of fish with moderate levels of methylmercury may have nutritional consequences for populations for which fish is an important source of protein and other nutrients.
- Precautionary approach. When information exists to suggest that a hazard in food may pose significant risks to human health, but the scientific data are insufficient for a full risk assessment, interim measures may be adopted to limit the risk while steps are taken to obtain the necessary information to carry out a full risk assessment. This approach (sometimes referred to as the precautionary principle) is included in the basic food legislation in the European Union and some other countries.

Select the Preferred Option(s)

Although final selection of risk management option(s) is the responsibility of the risk manager, it is important to involve other stakeholders, for example, food business operators and consumer representatives, and to document and explain the rationale behind the decision made. The selected option(s) should result in the achievement of the desired level of public health protection at reasonable cost, without causing unwarranted barriers to international trade and, as far as possible, be acceptable to all stakeholders. Where possible, a preventive approach to food safety should be used, i.e., problems should be tackled at source, because this is generally more effective and less costly than other approaches (see Further Reading). Requiring prior approval (including setting conditions for use) of food additives, veterinary drugs and pesticides is an example of this approach.

In managing the risks posed by food additives, pesticides and veterinary drugs, the commonest approach is to establish positive lists of such substances/products and to set conditions for their use and maximum limits for their presence in foodstuffs, such as MRLs for pesticides and veterinary drug residues. WTO members are required by the SPS Agreement to base their national food safety measures on Codex standards, where they exist, although they may set more stringent requirements based on a risk assessment for their population and the appropriate level of protection they have set. Thus most countries base their national legislation on food additives and pesticide and veterinary drug residues on Codex standards.

A number of food safety risks arise due to contamination of animal feed with chemical hazards, such as dioxins and aflatoxins. Management of such risks requires regulation and control of feed ingredients and feed manufacturing processes and recommendations to farmers and other primary producers. Additives added to feed are regulated in most countries.

Managing risks arising from environmental contamination (e.g., methylmercury and PCBs and dioxins in fish) is more complicated. For example, some countries have set maximum limits (e.g., 1 mg kg^{-1}) for the levels of these hazards in fish that can be offered for sale, issued fish consumption recommendations to vulnerable population groups (e.g., pregnant women and young children) and taken measures to reduce or eliminate sources of pollution (e.g., from waste incinerators).

Food safety risks arising from food contact materials can be managed by establishing positive lists of substances that may be used to produce such materials, setting limits for global or specific migration or leaching of chemicals from such materials and regulations or recommendations on the appropriate use of certain materials in contact with specific groups of food, for example, acidic or fatty foods.

Management of risks associated with natural toxins can be achieved by setting limits for their presence in food (e.g., aflatoxins in peanuts and DSP in mussels), advice to consumers

on treatment of some foods before consumption (e.g., treatment of cassava to remove cyanogenic glycosides) or that consumption of certain foods should be restricted or even avoided altogether by vulnerable population groups.

The main method of managing risks from food allergens and other substances causing intolerance or hypersensitivity reactions is through detailed regulations on food labeling, information to affected population groups and voluntary action by food business operators to provide further information on their products in food stores and via the Internet and other channels.

Food safety risks due to substances formed during food processing or commercial or domestic food preparation (e.g., acrylamide and PAHs) can be tackled by regulations or recommendations to food business operators and advice to consumers concerning, for example, grilling and smoking of foods.

Management of risk arising from intentional contamination/adulteration of foods with chemical hazards and gross negligence on the part of food business operators is best achieved by legal action to remove contaminated products from the food supply and prosecution of the offenders. Good coordination with foodborne disease surveillance programs is also essential in detecting such problems as early as possible so that recalls and remedial action can be taken. In this regard, incidents of international public health concern must be reported under the WHO International Health Regulations, which serves to protect the world community in this era of globalized food supply. The European Union has also established the Rapid Alert System for Food and Feed (RASFF) for the rapid communication of information about food and feed safety incidents. Publication of the results of food control and, in particular investigations of malpractices, will often encourage compliance with legal requirements.

Step 3: Implementation of Risk Management Options

The third step in risk management, Implementation of risk management options/measures, consists of the following activities:

- Validate control(s) where necessary.
- Implement controls.
- Verify implementation.

The measures chosen to manage risks arising from chemical hazards must be effectively implemented if the desired risk reduction is to be obtained. Food control authorities and the food and feed business operators have the main responsibility for implementation, but consumers and other stakeholders may also play an important role in some cases.

Validate Controls, Where Necessary

When it has been decided to introduce new or revised official control measures, these should be validated before being introduced. This may be done by the food control authorities or by independent bodies working under contract to the authority. Food business operators should also ensure that their internal control measures are validated.

Implement Controls

Controls may be introduced at various points along the food production to consumption chain, depending on the source of the chemical hazard and an assessment of where controls are likely to be both practical and most effective.

Responsibility for introducing and enforcing legal requirements rests with the food safety authorities. This includes standard setting and inspection and other measures to ensure compliance with existing standards. In some countries inspection of food production establishments and analysis of food samples is carried out by qualified independent bodies working under contract to the food control authorities. Analysis of food samples for control purposes should be carried out by suitably qualified laboratories, preferably accredited for the type of analysis in question. The food safety authorities are also responsible for providing consumers, food business operators, and other stakeholders with information, recommendations, and advice on food safety matters.

Major responsibility for food safety rests with food business operators, who must ensure that they have in place appropriate internal control systems based on HACCP principles, that the control results are documented and that their staff has adequate training in food safety. Furthermore, business operators should have in place systems to ensure traceability, at least one step forward and one step back in the food chain. In other words, they should have records of where they obtained the ingredients, etc., for their products and to whom their products were sold.

Consumers have a responsibility for food safety in the home, including domestic food preparation and storage. Although consumer education programs tend to focus on microbial hazards, consumers can also reduce exposure to certain chemical hazards, such as acrylamide and PAHs, through better food preparation in the home. It is also important that consumers, especially vulnerable population groups such as pregnant women, follow the recommendations of the food safety authorities on restrictions on the intake of certain foods that may contain elevated levels of chemical hazards.

Verify Implementation

The food safety authorities are responsible for verifying that measures that have been introduced in order to manage a food safety problem have been implemented by food business operators. This may be done either by the authorities themselves or by qualified independent bodies working under contract to them.

Step 4: Monitoring and Review

The fourth, and last, step in the risk management process, monitoring and review, comprises the following activities:

- Monitor the outcomes of the control measures.
- Evaluate the results.

- Review controls if the risk management goals are not achieved.

Monitor the Outcomes of Control Measures

When deciding on the measures to be introduced to tackle a food safety problem, it is important to plan how to monitor the outcome of the control measures. Depending on the problem and the desired outcome, this can include, for example, monitoring the levels of pesticide or veterinary drug residues in specific foods before and after introducing the measures, measuring human exposure to chemical hazards (e.g., PCBs, dioxins, lead) or control of food labeling of especial importance for persons who are allergic or hypersensitive to certain food ingredients. For instance, it is through such a monitoring program that the Irish authorities discovered contamination of pork meat with dioxin in 2008. Such monitoring programs are important for biotoxins and radionuclides.

When the control measures have been aimed at producing improvements in food production processes and handling by food business operators, food inspection should monitor and confirm that the desired improvements have been made.

Where the measures introduced comprise mainly information and recommendations to consumers, this should be followed up by surveys to establish if the message has reached the target group and whether it has resulted in the desired changes in food safety behavior.

Many countries periodically carry out total diet studies to assess the exposure of their population to a range of chemical hazards. Such studies can provide assurance that the food supply is safe from such hazards and can identify problems or potential problems based on time-trends. Total diet studies are considered to be an important management tool for addressing the multitude of potentially toxic chemicals that may be present in food.

Evaluate the Results

The results of monitoring after the introduction of measures to reduce human health risks from chemical hazards in food should be evaluated to see if the desired outcome has been achieved. This is the responsibility of the food safety authorities and the results of the evaluation should be made public.

Review Controls if the Risk Management Goals are not Achieved

If, following the evaluation, it is found that the measures introduced have not achieved the established risk management goals, the controls should be reviewed and possibly intensified. If the controls introduced have been found to be ineffective, then the list of risk management options should be reexamined and other or further measures introduced in order to reach the desired food safety outcomes. In some cases, the risk manager may request that the risk assessment be reviewed in order to take into account the latest science and knowledge.

RISK ANALYSIS

Risk Management: Application to Biological Hazards

Y Motarjemi, Food Safety and Risk Management Consultant, Switzerland
GG Moy, Food Safety Consultants International, Geneva, Switzerland

Glossary

Food Safety Objective (FSO) The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP).

Performance criterion (PC) The effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a performance objective (PO) or an FSO.

Performance objective (PO) The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable.

Risk assessment policy Documented guidelines on the choice of options and associated judgments for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk estimate The quantitative estimation of risk resulting from risk characterization.

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and if needed, selecting appropriate prevention and control options.

Risk manager Governmental food safety organization with the authority to decide on the acceptability of risks and measures needed for their management.

Risk profile The description of the food safety problem and its context.

Introduction

In the late 1990s, the approach to prevention of foodborne illness and management of food safety was thoroughly revisited and drastic changes were brought to the process of decision-making. This paradigm shift was the result of the application of risk analysis to food safety. Risk analysis consists of three elements, namely risk assessment, risk management, and risk communication. Risk management is the core element of the risk analysis process, as risk managers have the responsibility and leading role in managing risks.

For the purpose of this text, the term risk manager refers to a governmental food safety organization with authority to decide on the acceptability of risks and measures needed for their management. Here, the definition does not include all of the individuals who are involved in the implementation phase and activities associated with risk management, such as industry and consumers. However, the risk management process can also be used in by large food companies as a model for decision-making process on food safety matters.

This article presents the principles and procedures for risk management of biological hazards and is based on those recommended internationally by the Codex Alimentarius Commission (see Further Reading section). Risk assessment and communication aspects of risk analysis are addressed in other articles of this encyclopedia.

Background

The need for the risk analysis process emanated from an increasing incidence of foodborne illnesses, such as salmonellosis, campylobacteriosis, enterohemorrhagic *Escherichia coli* infections and listeriosis, in industrialized countries. In addition, epidemics of food- and waterborne diseases in the developing countries, such as cholera and other diarrheal diseases, were becoming more recognized for their adverse impact on health and development. At the same time, the globalization of the world's food supply raised awareness of risk managers that a foodborne disease outbreak in any country had the potential to become an international issue. Even if the contaminated food was not exported, 24/7 media coverage could have a negative effect on consumer confidence. The deteriorating situation raised a large number of questions and called for strengthening of the food safety management system including:

- Reviewing existing management practices, including the efficacy of preventive measures;
- Revising the approach to decision-making based on the risk analysis paradigm, which had already been successfully applied to chemical hazards in food;
- Developing concepts which would make management of food safety (including evaluation) more quantitative; and

 doi:10.1016/B978-0-12-378612-8.00037-8

- Clarifying responsibilities and accountability along the food supply chain.

Concomitantly, in 1995 the World Trade Organization (WTO) was established and two agreements came into force that had implications for food safety. Although liberalizing trade in food and animal feed among WTO countries, these agreements were intended to safeguard the right of countries to protect their population against import of unsafe food. The Agreement on the Application of Sanitary and Phytosanitary Measures (SPS) and the Agreement on Technical Barrier to Trade were devised to harmonize safety and other technical aspects (e.g., labeling) of foods entering in international trade. According to the SPS agreement, the work of the Codex Alimentarius Commission (Codex) (i.e., its standards, guidelines, codes of practice, and other recommendations) became the international reference for food safety requirements. Countries that accepted Codex standards were considered to be incompliance with the SPS agreement. However, countries wishing to adopt a stricter standard than Codex were required to provide scientific evidence of the risk that the imported food would present for their population. Consequently, Codex became the benchmark for the national legislation.

Among the various SPS articles, the Article 4 on equivalence states:

> Members shall accept the sanitary or phytosanitary measures of other Members as equivalent, even if these measures differ from their own or from those used by other Members trading in the same product, if the exporting Member objectively demonstrates to the importing Member that its measures achieve the importing Member's appropriate level of sanitary or phytosanitary protection. For this purpose, reasonable access shall be given, upon request, to the importing Member for inspection, testing, and other relevant procedures.

This is of importance to risk management of biological hazards as this has a major impact on the principles of risk management. This article stipulates that an importing country ought to accept the control measures of a trading partner as equivalent, even if these measures differ from their own, if the exporting country can objectively demonstrates that through its control measures it can achieve the same degree of risk reduction, and consequently health protection.

Thus, exporting countries had to prove that their control measures were equivalent to those required by the importing country. To facilitate the process, there was a need to introduce a more quantitative approach to the management of food safety. In regard to microbiological risk management (MRM), new concepts were developed, including appropriate level of protection (ALOP) or tolerable level of risk, as low as reasonably achievable, food safety objective (FSO), and performance objective (PO).

The above developments were the background for a new risk-based approach to management of biological hazards in the food supply chain. Although the risk analysis process did not change the basic control measures per se, it had major consequences such as:

1. Improved the process of decision-making by the provision of a structure for the different governmental activities (legislative, enforcement, education, surveillance, etc.) and increased transparency and objectivity;
2. Allowed for a more evidence-based approach to decision-making considering both scientific facts as well as economic and sociocultural factors;
3. Fostered the development of new concepts (e.g., ALOP, FSO, and PO) to make management of safety more measurable; and
4. Increased the interaction between risk managers, scientists, and stakeholder as well as between stakeholders within the food chain.

Definition and Concept

Strictly, risk management is defined by Codex as the process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and if needed, selecting appropriate prevention and control options. This definition underlines that risk management consists of the evaluation of public health policies. It is a societal process and the risk management decision should be seen as a societal decision as how risks should be managed.

Risk management is not a new concept as historically many measures required to prevent foodborne illnesses were types of risk management. Chlorination of water supply, provision of sanitary services, pasteurization of milk, health surveillance of food handlers, and education of consumers are all examples of risk management measures that has been implemented for a number of years. However, under the modern approach to food safety management, risk managers are encouraged to take their risk management decision in the context of risk analysis process. A set of guiding principles for MRM have also been laid down (Figure 1). As stipulated by the Principle 3, risk manager should follow a more structured approach to ensure that decisions are taken objectively and, as far as possible, based on scientific facts and consideration of socioeconomic factors as well as other risks (e.g., nutritional or chemical risks).

Microbial risk management (MRM) process consists of the so-called preliminary MRM activities, followed by identification, evaluation, and selection of MRM options, implementation of the selected option, and monitoring and review of the impact. What is particularly new in the process is that the decisions are not taken arbitrarily or based on the perception of risk managers, political pressure, or to erect nontariff barriers to trade. They should be based, on the one hand, on a scientific evaluation of risk (risk assessment) and, on the other hand, on weighing different policy alternatives to ensure that both scientific factors as well as feasibility, economic, social, and cultural factors are considered in the decision-making process. Decisions taken during such process will not always lead to an action, as it may be that the level of risk is tolerable or the risk is not a priority at the time. Thus, a risk management decision may be to not take action.

General Principles for Microbiological Risk Management

During the MRM process, the risk manager has the leading role. The main responsibilities consist of setting public health

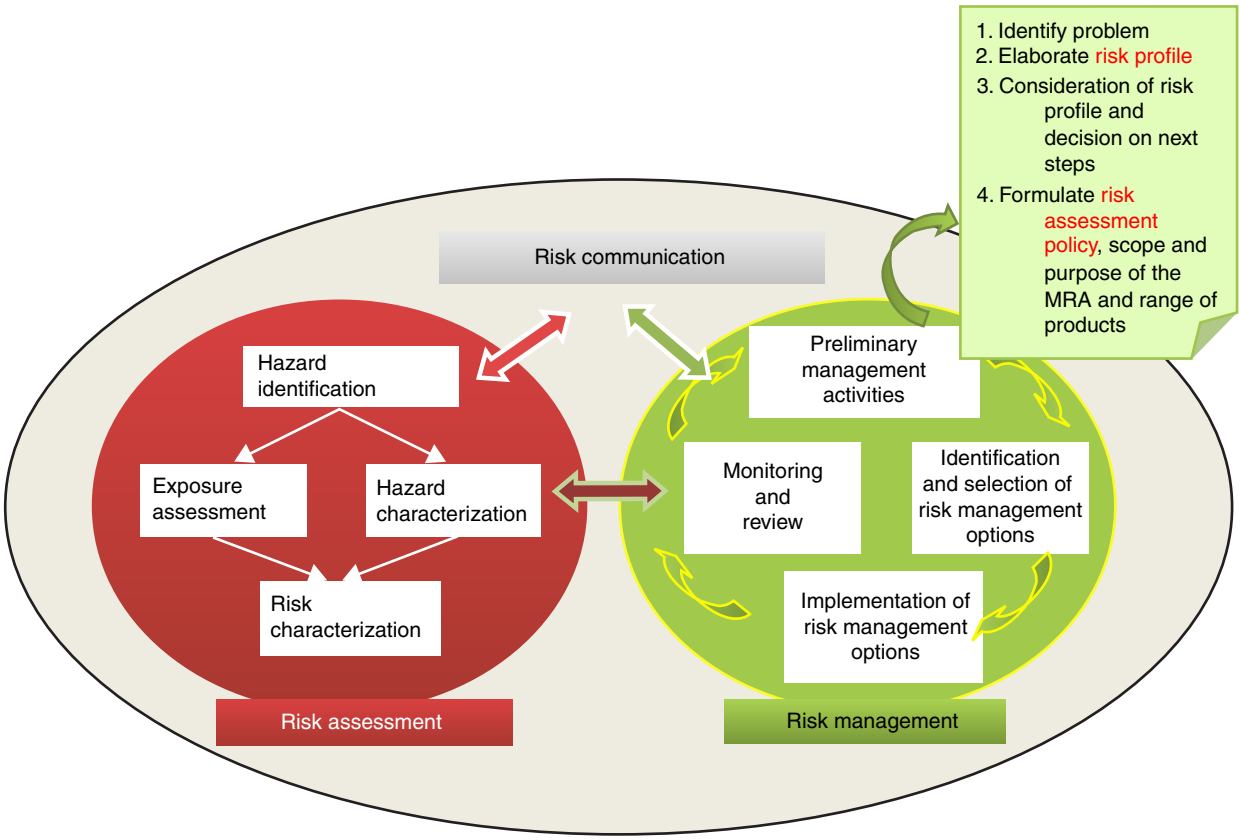

Figure 1 Process of risk analysis, including risk management, assessment, and communication.

goals and priorities, initiating the risk assessment process, and managing the overall risk management process. In MRM, a number of principles need to be observed (see Box 1). These principles result from years of experience in management in food safety and lessons learned from successes as well as failures.

Principle 1: Protection of human health is the primary objective in MRM. The management of biological hazards, particularly when it involves international trade or major economic costs, should recognize that public health is the first priority. For instance, the compulsory pasteurization of milk was initially opposed because of its cost. This principle is to ensure that human health is not compromised for economic reasons.

Principle 2: MRM should take into account the whole food chain. This principle conveys the concept that the entire food supply chain should be considered in the decision-making process. This continuum should cover primary production (including feeds, agricultural practices, and environmental conditions that may lead to the contamination of crops and animals), product design, processing, transport, storage, distribution, marketing, preparation, and consumption. Also, it should include both domestic and imported products to the extent feasible.

The principle ensures that efforts to control foodborne pathogens are implemented, where most feasible and effective, ensuring maximum health protection. For instance, in managing risk of salmonella in poultry, risk managers will have to take the decision as to which measures, or combination of measures, and at which level of the food chain, will be most effective in reducing the risk of illness, e.g. vaccinating flocks, culling infected flocks, irradiating poultry meat, monitoring and recalling contaminated poultry meat, educating consumers to cook poultry thoroughly, or a combination of these,

Box 1 General principles for microbiological risk management (MRM)

Principle 1: Protection of human health is the primary objective in MRM.
Principle 2: MRM should take into account the whole food chain.
Principle 3: MRM should follow a structured approach.
Principle 4: MRM process should be transparent, consistent, and fully documented.
Principle 5: Risk managers should ensure effective consultations with relevant interested parties.
Principle 6: Risk managers should ensure effective interaction with risk assessors.
Principle 7: Risk managers should take account of risks resulting from regional differences in hazards in the food chain and regional differences in available risk management options.
Principle 8: MRM decisions should be subject to monitoring and review and, if necessary, revision.

Principle 3: MRM should follow a structured approach. As mentioned above, this includes preliminary MRM activities, identification and selection of MRM options, implementation of MRM activities, and monitoring and review of the options taken. This principle prevents bias and arbitrary decisions and directs risk managers to follow a consistent process of interaction and consultation with scientists and stakeholders.

Principle 4: MRM process should be transparent, consistent, and fully documented. Transparency and documentation will foster a broader understanding of issues and rationale for decisions among interested parties. Thus, it will minimize conflict among stakeholders.

Principle 5: Risk managers should ensure effective consultations with relevant interested parties. This principle underlines the need for consultation with stakeholders while keeping the independence of the decision-making process. The extent and nature of public consultation will depend on the urgency, complexity, and uncertainties related to the risk and management strategies being considered. Effective and timely consultation with all relevant interested parties provides a sound basis for decision-making to ensure that decisions are feasible, effective, and where applicable, enforceable. Also, it provides an opportunity to consider potential implications and to explore if the considered options are practicable and culturally acceptable by consumers. This is important when they will have to play a role in their application. The acceptability of risk management options depend on the perception of risk and other factors underlying risk communication of biological hazards. For instance, the reduction of the risk of listeriosis by a ban of cheese made from raw milk may not be culturally acceptable in certain European countries. However, education of pregnant women and other vulnerable populations to avoid consuming such products may be more feasible.

Principle 6: Risk managers should ensure effective interaction with risk assessors. This principle is to ensure that the decisions are based on science and where necessary, on a formal risk assessment. This principle recognizes that risk managers and risk assessors should have an iterative dialog so that the risk assessment meets the needs of the risk manager. However, a separation of functions between risk assessment and management helps to prevent conflicts of interest and ensures the integrity of the process.

Principle 7: Risk managers should take account of risks resulting from regional differences in hazards in the food chain and regional differences in available risk management options. This principle recognizes that there may be regional differences in the spread of microbiological hazards, or conditions of production, processing, food handling practices, and food use or consumption patterns; subsequently exposure of consumers may vary. Risk perception may also vary among countries. Thus, risk management options should be adapted to local or regional conditions. For instance, in regions where hepatitis A is highly prevalent and personal hygiene may not be respected, it may be decided to vaccinate professional food handlers against hepatitis A.

Principle 8: MRM decisions should be subject to monitoring and review and, when necessary, revision. Risk management should be a dynamic and an iterative process. Through a process of monitoring and review of verification or newly available data, the efficacy of implemented measures should be examined and evaluated; where necessary risk management decisions should be revised. This principal embodies the concept of continuous improvement, i.e., to strive to continuously reduce risk of illness. A case in point is that the review of the efficacy of routine medical examinations of food handlers working in food service establishments. A World Health Organization expert committee recommended that such practices be discontinued as they only could confirm the health of the food handler on the day of the examination. Instead, it was recommended that food handlers should not directly handle food when they have symptoms of foodborne disease. However, in line with the Principle 7, some countries with high prevalence of typhoid and paratyphoid fevers have decided to continue periodic physical examinations.

Public Health Goals

A prime responsibility of risk managers is to decide on the public health goals. In the context of foodborne diseases, ideally, the public health goal should be prevention of all foodborne diseases, i.e., no cases. However, for most diseases, this is not possible to achieve and a more attainable goal must be decided. In practice, this means that a certain level of risk is tolerable. The concept of ALOP mentioned in the SPS agreement is a type of public health goal and expresses the idea that in managing food safety risk managers should have clear objectives on what they want to achieve, what would be the tolerable target level for the incidence of foodborne diseases, and manage the safety of their food supply so that this is not exceeded. In the SPS agreement, it is defined as ''*The level of protection deemed appropriate by the member establishing a sanitary or phytosanitary measure to protect human, animal or plant life or health within a territory*.'' Sometimes the concept is referred to as 'acceptable or tolerable level of risk.' For instance, an ALOP can be an expression of the yearly incidence of foodborne disease that may be accepted in the population. As an example, it may be decided that the annual incidence of listeriosis should not exceed 2.5 cases per 100 000 of population.

Managing the Risk Management Process

Another responsibility of the risk managers is to manage the risk management process. This consists of the following steps:

Preliminary MRM Activities

See **Figure 2**. These activities consist of:

Identification of a Microbiological Food Safety Issue

Risk managers are responsible for the identification of food safety issues and their communication to risk assessors and stakeholders. The information may reach the risk managers from different sources (e.g., scientists, trading partners, stakeholders, and media). Examples of issues may include:

- Emergence of a new pathogen that is foodborne or suspected to be (e.g., avian influenza or *Mycobacterium paratuberculosis*, the etiological agent of the Johne's disease

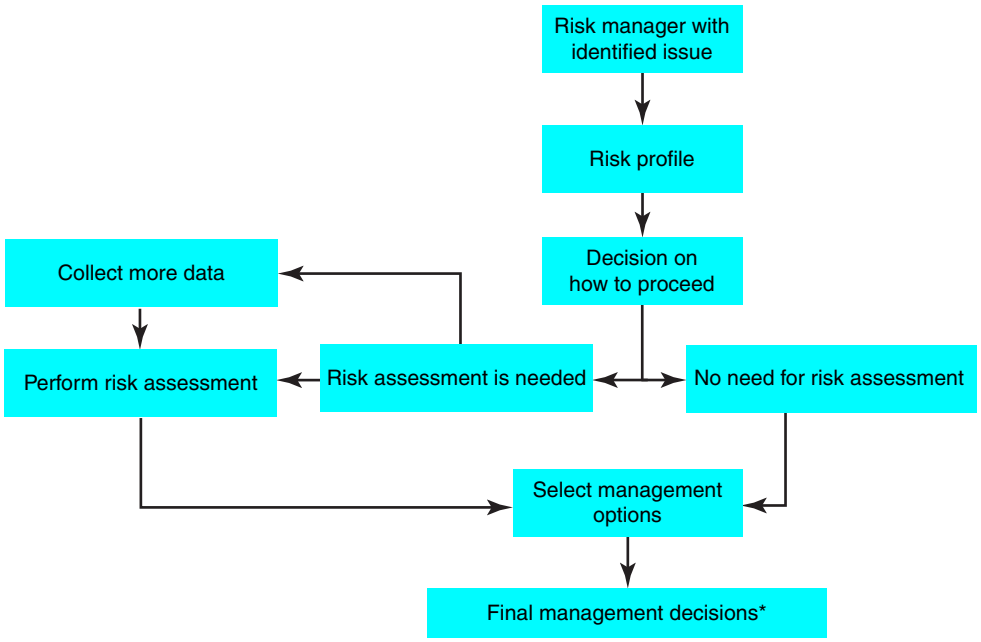

Figure 2 Risk management process. (*Includes the decision that no specific action is required). Adapted from FAO/WHO 2002 Principles and guidelines for incorporating microbiological risk assessment in the development of food safety standards. Guidelines and related texts. Report of a Joint FAO/WHO consultation, Kiel Germany 18–22 March 2002. FAO, Rome, 2002.

in cattle). Although the latter is not yet confirmed as foodborne, a food safety risk management decision was initially required);

- An unexpected outbreak of a serious foodborne illness (e.g., Shiga-like enteroaggregative *E. coli* O104:H4 outbreak in Germany and France in 2011);
- Recurring incidents in industry (e.g., chocolate contaminated with *Salmonella*);
- Frequent food contamination recalls (e.g., beef contaminated with *E. coli* O157 in USA);
- Data on the prevalence and concentration of hazards in the food chain or environment (e.g., surveys of campylobacter in poultry showing a high degree of contamination);
- Trends in human and/or animal disease surveillance data showing increase in a foodborne or zoonotic illnesses;
- Epidemiological or clinical studies, laboratory studies, and scientific, technological, or medical advances; and
- Lack of industry compliance with regulatory requirements.

In emergency situations where there is an imminent public health concern, risk managers may not have time to wait for a full fledged risk management process and may need to take immediate precautionary risk management measures. For instance, in case of an industry-associated incident which may expose large population, even if the source of the outbreak is not yet confirmed or the scientific data on the epidemiology of the pathogen are not fully available, temporary measures such as withdrawal or recall of a product may be justified. However, the provisional and precautionary nature of the information and decision should be communicated to stakeholders and general public and care should be taken to not cause undue panic. Therefore, as part of emergency preparation and crisis prevention, a concise risk profile on various pathogens needs to be compiled beforehand so that it can be readily available to risk managers. As further information becomes available, the decision should be reviewed and, if warranted, revised. Another issue to be addressed is the need for setting priorities and public health goals, or in the context of SPS agreement, comparing the impact of different risk management options in order to demonstrate equivalence of measures.

Risk Profile

If not available, the risk manager will initiate the development of a risk profile. In some cases, these may be available internationally or from another country and can be used as a starting point. A risk profile is a description of a food safety problem and its context in a concise form; it includes the state of knowledge on the subject, potential risk management options, and the food safety policy context that will influence further possible actions. A risk profile provides information on a range of elements that are relevant to the risk management decision. Box 2 provides a list of suggested elements to be included in a risk profile.

The purpose of risk profile is to provide risk managers with an information base that can enhance their understanding of a food safety issue. Through the analysis of this initial data, the risk profile can help managers to decide whether a full microbial risk assessment (MRA) or more limited assessment (e.g., exposure assessment and hazard characterization) is needed. In some cases, the risk profile could provide enough information for the risk manager to make an immediate decision to take precautionary measures. However, the preliminary information may also persuade the risk manager to decide to take no further action.

Box 2 Elements suggested for inclusion of a microbiological risk profile

A risk profile should present, to the extent possible, information on the following:

1. Hazard–food commodity combination of concern:
   - Hazard of concern;
   - Description of the food or food product and/or condition of its use with which problems (foodborne illness and trade restrictions) due to this hazard have been associated; and
   - Occurrence of the hazard in the food chain.
2. Description of the public health problem:
   - Description of the hazard including key attributes that are the focus of its public health impact (e.g., virulence characteristics, thermal resistance, and antimicrobial resistance);
   - Characteristics of the disease, including;
     - Susceptible populations;
     - Annual incidence rate in humans including, if possible, any differences between age and sex;
     - Outcome of exposure;
     - Severity of clinical manifestations (e.g., case-fatality rate and rate of hospitalization);
     - Nature and frequency of long-term complications;
     - Availability and nature of treatment; and
     - Percentage of annual cases attributable to foodborne transmission.
   - Epidemiology of foodborne disease
     - Etiology of foodborne diseases;
     - Characteristics of the foods implicated;
     - Food use and handling that influences transmission of the hazard;
     - Frequency and characteristics of foodborne sporadic cases; and
     - Epidemiological data from outbreak investigations.
   - Regional, seasonal, and ethnic differences in the incidence of foodborne illness due to the hazard.
   - Economic impact or burden of the disease if readily available:
     - Medical and hospital costs;
     - Working days lost due to illness, etc.
3. Food production, processing, distribution, and consumption:
   - Characteristics of the commodity that are involved and that may impact on risk management;
   - Description of the farm to table continuum including factors which may impact the microbiological safety of the commodity (i.e., primary production, processing, transport, storage, and consumer-handling practices);
   - What is currently known about the risk, how it arises with respect to the production, processing, transport, and consumer-handling practices of the commodity, and who it affects;
   - Summary of the extent and effectiveness of current risk management practices including food safety production/processing control measures, educational programs, and public health intervention programs (e.g., vaccines); and
   - Identification of additional risk mitigation strategies that could be used to control the hazard.
4. Other risk profile elements:
   - Extent of international trade of the food commodity;
   - Existence of regional/international trade agreements and how they may affect the public health impact with respect to the specific hazard/commodity combination(s);
   - Public perceptions of the problem and the risk; and
   - Potential public health and economic consequences of establishing Codex MRM guidance document.

Risk Assessment Policy

Another responsibility of risk managers is setting a risk assessment policy. However, it should be established in full collaboration with risk assessors and possibly with other stakeholders. The MRA policy is a document providing guidance to the risk assessors on the scope and range of the risk assessment, for example, sector of the food chain, types of food, products to consider, population to cover, source and type of data to be considered, default decisions for data gaps and uncertainties encountered during the course of the assessment, and how to present the data, particularly the types of assumptions and uncertainties that should be mentioned. The purpose is to protect the scientific integrity of the risk assessment, ensure that risk assessment is systematic, unbiased, and transparent, and to offer guidance for balancing value judgments and policy choices and weighing of adverse health parameters in evaluating risks to human health. The risk assessment policy could be of a generic nature or specific to a planned MRA and should be documented to ensure consistency, clarity, and transparency.

Commissioning a Microbiological Risk Assessment

Figure 2 presents the process of risk management and commissioning MRA. It shows that the process can be complex

and can follow different pathways. MRA does not follow a single model, especially as it is a lengthy and expensive exercise. Therefore, risk managers may decide to commission an MRA only when absolutely needed. The purpose of an MRA is to provide an objective systematic evaluation of relevant scientific data to help risk managers to make an informed and science-based decision. An MRA can also be instrumental in deciding whether public health goals are realistic by estimating the resources that would be needed to achieve them. Furthermore, it can be used to compare the efficacy of management interventions. In relation to the SPS agreement, it can be used to demonstrate that different measures are equally effective and thus equivalent.

In commissioning an MRA, the mandate should be as clear as possible. Risk assessors must inform risk managers of any constraints, data gaps, uncertainties, and assumptions and their impact on the risk assessment. Where there is a disagreement among the risk assessors, the risk managers should be informed of the minority opinions and these differences should be documented. Risk assessors have to also ensure that the result of the MRA is relevant to the questions raised by the risk manager. Through an iterative communication process, risk assessors should further clarify their mandate and fine tune the results to meet the needs of the risk managers. The results of the MRA should be presented by risk assessors in a way that it is comprehensible to risk managers. It can be in different forms such as:

- Risk of illness by consumption of specific product/pathogen combination (e.g., risk of botulism from canned products is 1 in 10^{-12});
- Estimated number of illnesses (e.g., per year in a country) due to consumption of specific food-hazard combination (e.g., listeriosis from smoked fish is 0.5 cases per 100 000 inhabitants);
- Risk estimates for different processing, distribution, and consumer-use scenarios; and
- Efficiency of control measures (e.g., incidence of egg-borne salmonellosis can be reduced by 80% by changing preparation practices).

For the best use of a risk assessment, risk managers should be fully informed of the strengths and limitations (key assumptions, key data gaps, and variability in the data and their influences on the outcomes), especially a pragmatic appreciation of uncertainties associated with an MRA and its outputs.

Identification of MRM Options

Risk management options are control measures that risk managers may consider to manage the microbiological risks and prevent or control foodborne diseases. The identification of management options should be based on the consideration of the ability of the control measures to mitigate the risks to desired level of health protection and on the practical feasibility, acceptability, and consequences of the options. An MRA can help in determining the efficacy of different control measures in achieving the desired objectives.

One category of risk management options is legislation. For managing biological hazards, a number of options are possible, including:

- Introducing a microbiocidal treatment or a temperature control (e.g., refrigeration) to prevent growth of pathogens. For instance, pasteurization of milk is a legal requirement in many countries to prevent milk-borne infections;
- Labeling of products with a safety warning or with instructions for safe handling and preparation of products by consumers;
- Specifying microbiological criteria (MC). For example, following emergence of *Cronobacter sakazakii*, the MC of infant formula was revised;
- Establishing requirements for certification or approval procedures. Such measures can be important when safety is based on hygienic practice during production, processing, or manufacturing (e.g., cheese made from raw milk);
- Requiring import certificates for certain products. Such measures were required at the time of bovine spongiform encephalopathy epidemic;
- Banning sale of certain foodstuffs. For example, many countries ban the sale of raw milk to prevent milk-borne diseases; and
- Inspecting. Many countries require the inspection of slaughtered animals to prevent parasitical diseases.

Another option for managing biological risks is strengthening the food safety assurance system. For example, new measures may be recommended as part of good agriculture practice or in the application of the Hazard Analysis and Critical Control Point (HACCP) system. Following the outbreak of avian influenza, specific measures were recommended by many countries as part of good animal husbandry. Another example is an outbreak of botulism associated with pasteurized carrot juice in 2006 in the USA. As a result, the US Food and Drug Administration (FDA) recommended that firms incorporate validated control measures for *C. botulinum* spores into their HACCP plans. To ensure that growth and toxin production does not occur, the US FDA required that the juice be kept refrigerated in distribution channels and by consumers. Similarly, after outbreaks of *E. coli* O157:H7 associated with unpasteurized apple cider in 1996, the US FDA required the pasteurization of the product.

Another risk management option is the establishment of a FSO for a particular food safety issue. This approach offers flexibility to industry to select appropriate control measures that meet the FSO.

For certain problems, the risk management option of choice is the education of food handlers and consumers in hygienic handing of food. This is perhaps one of the key control measures applicable to most biological hazards, and particularly important for the preparation of food for infants and young children.

In the cases of a food safety emergency, the withdrawal/recall of a food product may be warranted. The effective use of this risk management option often depends on the ability of the producer to trace the distribution of the product. Requirements for traceability, both forward and backward, have now become common for food producers in many countries.

Evaluation and Selection of MRM Options

The primary responsibility for evaluating and selecting appropriate risk management options lies with the risk manager. However, risk assessors and stakeholders play an important role in this process by providing information that permits the evaluation, comparison, and selection of the most suitable options. When evaluating the various options, the risk managers need to consider a number of factors including:

- Efficacy of the measure in reducing risk to the ALOP. For instance, if cold storage of eggs can reduce the risk of egg-borne salmonellosis to a set target;
- Feasibility, economic cost, and culturally acceptability. These need to be assessed from the perspectives of the industry, consumers, and other stakeholders; and
- Any practical issues regarding the implementation of the selected risk management options (e.g., enforceable, verifiable, and additional resource needed).

In selecting among risk management options, it should be remembered that prevention is always better than cure. Moreover, preventive approaches, such as HACCP, have largely replaced test and release system because the level of protection afforded by the latter is no longer considered appropriate.

Implementation of MRM Options

Implementation involves communicating the selected risk management options to stakeholders, if applicable, providing training and education, and assuring that the risk management option is implemented as intended. Implementation may involve different interested parties, including competent authorities, industry, and consumers.

Where a risk management option involves industry, the industry may need time to introduce the measures in their food safety management system and establish performance metrics such as PO or performance criteria (PC), which validate the efficacy of control measures and the contribution to the achieving FSOs or other regulatory requirements.

Where control measures relate to consumers practice, information should be provided to consumers on their responsibilities. It is essential that their education is based on an understanding of their risk perception and socioeconomic conditions and culture.

Monitoring and Review

Implementation of risk management options requires continuous monitoring and surveillance of implementation of MRM options as well as criteria that will be used for evaluation of the impact of MRM measures on the foodborne disease of interest. These can include:

- Surveillance of foodborne diseases in humans or related zoonotic diseases in animals. This can include outbreak data, notification data, epidemiological surveys, or laboratory data on human, animal, and food isolates;
- Monitoring of environmental contamination in food processing establishments;
- Monitoring of contamination of the food supply for a specific pathogen or a food–pathogen combination. Food contamination data collected at different point of the food chain allow a better understanding of where failures occur. Where monitoring data indicate a gap in achieving expected results, consultation with the stakeholders and root cause analysis of the gaps can help in understanding how the implementation of control measures can be improved; and
- Surveying of practices, habits, and behavioral risk factors of food workers and consumers.

As for any management process, the relevance and effectiveness of the selected MRM measures need to be periodically reviewed. The purpose of review is to ensure that expected consumer health protection is achieved. Review of MRM activities should be seen as an integral part of the MRM process, and criteria for the review should be considered when monitoring plans are made.

Ideally, reviews should take place at a predetermined time but may also be triggered by the availability of relevant new information such as new information on the virulence of a pathogen, prevalence of the disease, occurrence of the pathogen in foods, changes in dietary intake patterns, and sensitivity of subpopulations.

The outcome of a review could be the confirmation of appropriateness of the existing measures or a decision to amend the selected MRM option. Industry and other interested parties (e.g., consumers) can also suggest the review of MRM options. For transparency, the results of the review process and the actions that risk managers are considering to undertake should, where appropriate, be made public and communicated to interested parties.

Microbiological Risk Management Metrics

Although various risk management options are presented in greater depth in other articles, a few words should be said about the risk management metrics for microbiological hazards. Traditionally, food safety management and prevention of foodborne illness involved control measures which, although effective, were generally based on metrics that were not directly related to specific levels of public health protection. Therefore, it was often difficult to evaluate the efficacy of such control measures.

To develop risk-based management approaches that can directly and transparently relate the stringency of control measures to achievement of specific levels of public health protection, there was the need to relate the performance of a control measure, or a series of control measures, to the level of control needed to manage a food safety risk. In other words, there was a need to translate the desired level of health protection to the tolerable level of a hazard in a food to achieve the public health goals.

For this reason, a number of metrics for the MRM were developed (see Table 1). These metrics serve various purposes. As explained above, they translate public health goals (e.g., ALOPs) into values which can help industry to design more precisely their food safety control systems to meet

Table 1 Microbiological risk management metrics

Public health goal (e.g., ALOP)	A public health goal can be an expression of acceptable yearly incidence of foodborne disease or expected reduction in incidence during a given period of time
Food safety objective (FSO)	The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP)
Performance objective (PO)	The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable
Performance criteria (PC)	The effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a PO or an FSO.
Process or product criteria (PcC and PdC)	PcC specify conditions of treatment that a food must undergo at a specific step in its manufacturing to reduce the level of a hazard to meet PC. PdC specify chemical and physical characteristic of a food to prevent or limit growth of bacteria
Microbiological criteria (MC)	MC specify the conditions of acceptability of a product or a food lot, based on the absence or presence or number of microorganism per unit(s) of mass, volume, area, or lot

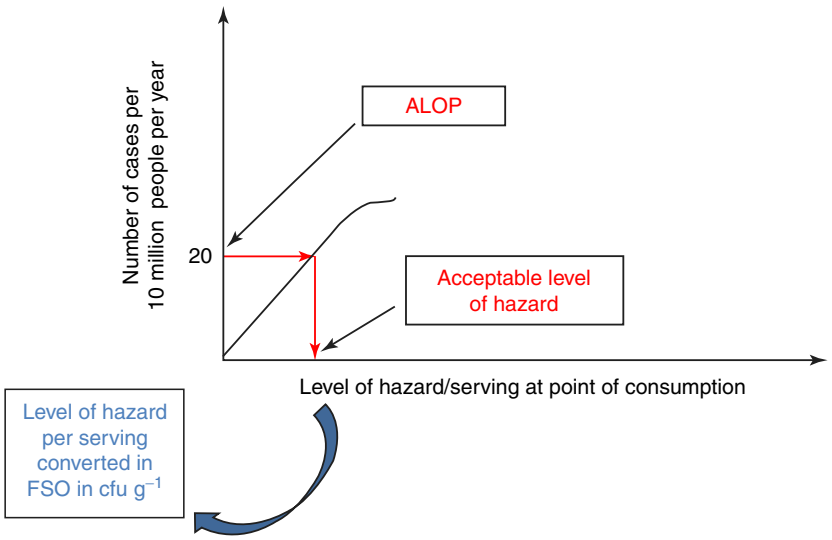

Figure 3 Schematic presentation of relationship of ALOP and FSO.

public health goals. They also provide a conceptual framework that fosters a dialog with all stakeholders on the efficiency and efficacy of control measures. In this way, they can be used to evaluate whether the existing food industry control measures are adequate to support public health goals. In the context of the SPS Agreement, they can be used to demonstrate equivalence of control measures.

To explain these concepts, the term control measures, which is defined by the Codex, should be referred to as the actions and activities that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level. The question is then "What is an acceptable level?" At the point of consumption, the acceptable level of hazard is expressed by the term FSO (see Figure 3).

An FSO is defined as the maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the ALOP. For instance, for a given product, it may be required that the level of *Listeria monocytogenes* at the point of consumption should not exceed 100 cfu g^{-1} or *Salmonella* be absent in a ready-to-eat (RTE) product.

As explained above, in establishing an FSO, the acceptable level of a hazard is considered at the moment of consumption. However, this level can also be extrapolated to other points in the food chain. These levels are then referred to as POs. The PO is defined as the maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable. Because a PO is conceptually linked to the FSO and ALOP, the impact of various steps in the food chain both before and subsequent to the PO should be considered in setting its value. If the microbial level of a food is likely to change during the steps of the food chain, the POs may be different from each other and from the FSO.

FSO can also be transformed into PC which express the effect of a control measure on the level of a hazard (for instance the effect of a cooking step). A PC is defined as the effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a PO or an FSO.

A PC is most often applied in association with various measures to eliminate the pathogen, such as heat processing and irradiation, or to control their growth, such as use of antimicrobial agents, refrigeration, or lowering water activity. A PC for elimination will specify the reduction of the microbial population that will occur as a result of the treatment (e.g., 12-log reduction in the levels of *Clostridium botulinum* spores). A PC for preventing growth will indicate the maximum acceptable increase in number of pathogens during the application of the control measure (e.g., less than a 1-log increase in *L. monocytogenes* during refrigerated distribution of a RTE food).

The microbial acceptability of a product is described by MC that can be applied as a direct control measure to accept or reject each lot of food or as a means for verifying that a food safety management system, such as HACCP, is functioning as planned. Other control measures may be characterized by a number of process parameters (e.g., time and temperature) or product parameters (e.g., water activity and pH). In turn, these need to be specifically designed to ensure that the set PC is achieved. These conditions are referred to as process criterion (PcC) and product criterion (PdC), respectively.

A PcC specifies the conditions of treatment that a food must undergo at a specific step in its manufacture to achieve a desired level of control of a microbiological hazard. For example, to achieve a PC of 12D reduction in the number of *Clostridium botulinum* spores (so-called 'bot cook') for canned meat products, the PcC is typically designed to be 2.5 min at 121 °C, or parameters that allow the same degree of reduction. However, the PdC specifies a chemical or physical characteristic of a food (e.g., pH and water activity) that, if met, contributes to the food safety of the product.

In general, PCs are established by individual food companies. However, a PC may also be set by national governments for a specific control measure such as the case with low-acid canned food. The advantage of a government PC is that all food businesses are applying the same safety standards regardless of their size and resources. It also facilitates the validation of control measures in industry.

Conclusion

In conclusion, the modern approach to food safety management calls for a more risk based, quantifiable, and transparent approach to food safety and increased accountability of regulatory authorities and stakeholders.

To ensure that management of the safety of the food supply meet the set public health goals, the control measures at different steps of the food chain, from farm-to-fork, should be designed such that the overall reduction or increase in the level of hazards does not exceed the FSOs at the point of consumption.

Although the modern approach to risk management of biological hazards present multiple benefits for the society, a key question remains its implementation as it will require incalculable amount of resources and expertise. Most developing countries and small, or less developed, business may not be able to follow this trend. Nevertheless, this should not undermine the importance and validity of the guidance and its application where feasible.

RISK ANALYSIS

Risk Communication

LJ Frewer, Newcastle University, Newcastle upon Tyne, UK
ARH Fischer, University of Wageningen, Wageningen, The Netherlands

Glossary

Attitude A hypothetical construct that represents an individual's degree of like or dislike for an item.
Nanotechnology Focuses with structures sized between 1 and 100 nanometers in at least one dimension, and development of materials or devices within that size range.
Risk assessment Risk assessment is the determination of quantitative or qualitative value of risk related to a concrete situation and a recognized threat (or hazard) from genetically modified (GM) food. GM foods are foods derived from genetically modified organisms.
Risk communication The exchange of information about health or environmental risks among risk assessors and managers, the general public, and other interested stakeholders and end-users.
Risk management A process to identify, assess, manage, and control potential events or situations.
Risk perception The judgment, underpinned by psychological determinants, that people make about the characteristics and severity of a risk.
Stakeholder Any person or group affected by an event or activity, for example the occurrence of a food risk.

The Historical Background of Risk Communication and Food Safety

Risk communication has been a focus of academic study for the past 35 years. Initially, research in this area aimed to translate risk assessments into messages for the general public, in order to align their views with expert opinion, and to facilitate understanding on the part of nonexperts. However, today risk communication forms an integral part of the practice of risk analysis as defined by FAO/WHO. Food risk analysis comprises three components: risk assessment, risk management, and risk communication. Risk communication is now established as an interactive exchange of risk information among stakeholders. Stakeholders include the food industry, farmers and food producers, food risk assessors, communicators and managers, and other regulators, representatives of civic society (e.g., consumer and environmental organizations, and other nongovernmental bodies), and, perhaps most importantly, food consumers. It is risk communication which will be the focus of discussion in this article.

A series of food safety crises has occurred over recent decades. These include, for example, bovine spongiform encephalopathy (BSE), dioxin contamination in different food chains, the debate about the effects of acrylamide on human health, the US *Salmonella* peanut contamination incident, cases of deliberate fraud, such as the melamine contamination of milk in China, and accidental contamination of food at different stages of the food chain, such as the case of Sudan red colorant. These incidents have resulted in a widespread public concern about food safety, emerging food risks, and adequacy of risk management measures. One consequence has been the decline in consumer confidence in regulatory measures and activities associated with consumer protection in the agrifood sector, as well as strengthened regulations and their enforcement (e.g., traceability).

Unsuccessful and successful examples of food risk communication can be identified. Unsuccessful communication efforts typically fail to take into account the concerns and perceptions of the public. For example, in the case of genetically modified (GM) foods, European consumers were concerned that the resulting products were unnatural, and had potential for long-term bioactive consequences. Consumer control over consumption was not possible as products were untraced and unlabeled. Communication was based on the premise that the novel foods were 'substantially equivalent' to the existing ones. Not only did risk communication not address consumer concerns, but also conveyed the unintended message that regulators and industry had dismissed consumer concerns as irrelevant and potentially trivial, increasing societal distrust in the motives of communicators. In contrast, communication about the potential dioxin contamination of the milk supply following the 2001 foot and mouth crisis was effective. Potential contamination resulted from the close proximity of animal cremation sites to milk-producing areas. The UK Food Standards Agency communication was open about the potential uncertainties (signaling honesty) and it also contained information about what was being done to reduce these uncertainties in scientific terms. In contrast, both these types of information had been omitted in communication from the UK Ministry of Agriculture, Fisheries, and Food (MAFF) about BSE a few years earlier, which contributed to public outrage and an international crisis.

 doi:10.1016/B978-0-12-378612-8.00038-X

In addition, as a consequence of the increasing globalization of the food supply, food safety problems may have impacts across broader geographical regions than before in terms of human and animal health, or environmental protection. It is at this broad level that the issues of risk assessment, management, and communication must be addressed. As part of this, it is important to understand cross-cultural differences and similarities in consumer risk perceptions, and how these influence consumer behaviors. This information is essential to understanding how these influence best practice in risk communication targeting the needs of consumers in different socio-political contexts.

One aim of risk communication is to influence potentially risky end-user behaviors. Another aim is to enhance transparency and inform consumer choice through the provision of relevant risk information. As part of this, it is important to understand the risk perceptions of the individual, who is the target of the communication, as this will influence what information is perceived to be relevant to the individual, as well as provide the basis for further interactive exchange of opinions and ideas.

Risk Perception and Communication

Research focused on understanding risk perception identified different psychological dimensions of risk between lay and experts, which explained why societal reactions to risk differed from those of experts. This research demonstrated that factors that are not included in technical risk estimates may nevertheless influence people's perception of risk. The extent to which a risk is perceived to be unnatural, potentially catastrophic, or to which an individual perceives exposure to be involuntary influences risk perceptions. These psychological dimensions are excellent predictors of people's responses to potential risks associated with hazards across different hazard domains, including that of food hazards.

Various methodologies have been used to study peoples risk perceptions. These may be both qualitative and quantitative. For example, focus groups (qualitative planned discussions that facilitate detailed analysis of an issue within groups of individuals) or semi-structured interviews may be used as a 'stand alone method,' or provide the foundation for the development of quantitative surveys, for example, those sampling the opinion of representative samples of a population of interest. Although survey based methods for identifying risk perceptions is amenable to comparison across different demographic segments of the population, or in time and space, the use of fixed questions results in the method being inflexible, and unable to incorporate new concerns and issues into comparisons. More interactive methods such as interactive workshops or consensus conferences (classified as deliberative public engagement or public participation) facilitate discussion between members of the public and experts in the area of food risk. The advantage is that an in-depth insight into public concerns and values about food risk can be identified, at the expense of gaining an understanding of the priorities and preferences of the overall population, as only small and unrepresentative groups of the public can be included in such workshops. Expert stakeholder views are frequently elicited using several rounds of a survey (the 'Delphi method'). Delphi methodology provides feedback from the initial rounds of expert responses (e.g., through statistical aggregation), which allows some degree of interaction between experts, even if they are dispersed geographically, or if expertise from a broad range of disciplines, where participants are unlikely to be members of the same scientific or policy networks, is required.

Consumer trust in different actors and institutions responsible for guaranteeing and controlling food safety, as well as trust in the information provided by different information sources that communicate about food safety or food-related risks, is an important determinant of consumer food risk perceptions, and reactions to risk communication. In addition, trust in food chain stakeholders may influence consumer evaluations of the efficacy of food risk management practices.

Individual differences in consumer responses to food hazards, and communication about the associated risks, have also been a focus of empirical investigation. Risk perceptions, food safety related behaviors, consumer responses to food safety incidents, and consumer use of food risk information may be dependent on consumer characteristics such as an individual's tendency to anxiety, their tendency to engage in habitual food choices, or their perceptions that their own health is amenable to influence by their own behaviors.

One important barrier to effective communication about food safety issues, which may vary across individuals, is that of optimistic bias which refers to an individual's judgment that negative events are less likely to happen to the person making the judgment in comparison to the risks experienced by an average member of society or other people in general. The importance of optimistic bias in developing an effective risk communication strategy will be discussed in the context of domestic food hygiene practices in the next section.

Behavioral Change through Effective Risk Communication

Many health-related behaviors, such as home preparation of foods, may determine whether an individual is at high or low risk from a particular hazard. In such cases, risk communication efforts may be specifically aimed at behavioral change of the consumers. In the example of food safety, domestic food hygiene practices are of particular concern.

The Case of Improving Domestic Food Handling Practices

Foodborne illness remains an issue of concern in terms of potentially negative consequences for public health. The overall aim of food safety objectives is to reduce the number of cases of foodborne illnesses, and hence reduce the consequent burden on public health. Although legislative changes may improve food safety up to the point of retail of food products, it is far more difficult to legislate for risky consumer behavior. Inappropriate storage, food preparation, and cross-contamination by end-users may result in illness, despite foods being safe at the point of sale, necessitating implementation of appropriate and effective information interventions. Improved public health is dependent on food preparation practices by the consumer (as well as other stakeholders in the food chain)

implying that effective ways have to be developed to communicate about the risks of food safety and inappropriate food-handling practices with the consumer.

Domestic food preparation tends to be lifestyle-related risk, in particular involving frequently repeated behaviors, where individuals think they have a lot of control over the risks associated with their behavior. Perceived personal control over the risk diminishes perceptions of risk. As a lifestyle risk, domestic food preparation represents an example where optimistic bias may be influential in acting as a barrier to effective risk communication. Optimistic bias has been observed for a range of food-related hazards, but tends to be more pronounced for that which can be described as 'lifestyle' related as opposed to 'technological' in origin. Influenced by optimistic bias, consumers may perceive that the risk information in risk messages is directed toward more vulnerable and less knowledgeable members of society.

People exhibiting optimistic bias may not take precautions to reduce their risk from a particular hazard. Risk communication interventions have been developed which have succeeded in reducing optimistic bias, including increasing perceived accountability associated with individual's risk judgment. This can be achieved through providing information about actual risk-taking behaviors or through making people compare themselves with an individual similar to themselves or an identified individual similar to the receiver of the risk information. Targeting information to those individuals most at risk may optimize use of available resources. An important first step is to differentiate or segment consumers who are most at risk, as a consequence of both attitudinal factors and their vulnerability to the risks.

Developing effective risk communication interventions (e.g., targeted risk communication or information campaigns focused on the needs of those consumers most at risk), is contingent on understanding what constitutes safe behavior as well as consumer beliefs about what constitutes safe behavior. Understanding social psychological factors which determine behavior is likely important if people are to make changes in domestic food preparation practices in order to minimize the risks of foodborne illness. Furthermore, although people may actually possess the information needed to reduce food risks associated with food preparation, they may not use this knowledge at the moment they need it most. For example, most consumers know that cross-contamination should be avoided, and heating should be adequate, if food safety problems are to be reduced, but they may only be aware of this information when prompted. This knowledge is not always applied when consumers are actually preparing food. Differences in the likelihood of conducting safe domestic hygiene practices across the population suggest that stratified risk communication strategies represent an important element in targeting risk communication to those most at risk, designing both message content and using information delivery systems so that vulnerable individuals will utilize the information. Various factors have been shown to increase consumers' receptivity to food safety risk communications focused on domestic hygiene practices. The first involves adding relevant emotional content to food safety messages, (e.g., imagery designed to elicit the emotion disgust). This increased consumer awareness and motivation to behave in such a way is to reduce the problem of food poisoning. Another approach to increase safe behavior, involves introducing a risk message into recipes used as part of food preparation practices. This not only reminded consumers of the relevance of the food safety message included in the recipe, but also activated their existing knowledge about other aspects of food safety related behaviors that consumers already possessed, but were not putting into practice. Research of this type demonstrates that consumers possess more knowledge about safe food preparation than they use, and breaking behavioral habits and activating this knowledge at the moment the behaviors are actually conducted may represent a useful approach to developing risk communication strategies to reduce the incidence of food safety problems.

Communication about Food Technologies

Besides those risks that can be controlled by consumers through their own behaviors, some consumer concerns may focus on production processes of food technologies, which are not under the consumers' control. These types of risks require a different type of communication as it is not end-user food handling, but end-user food choice that determines the risk. This type of communication is, for example, suited for communication about new food technologies. Communication about such risks should deal with a number of factors that may influence risk perception including dealing with uncertainty in risks and trust in relation to risk management structures.

Communicating Uncertainty Associated With Food Risk

There is increasing societal and political pressure directed toward greater transparency in risk management practices. For this reason, the uncertainties associated with technical risk assessments, on which risk management decisions are founded, need to be explicitly communicated to all end-users and stakeholders, including the public. Public response to communication of uncertainty may also need to be taken into account by decision-makers.

Historically, it has been assumed by experts that the public is unable to conceptualize the scientific uncertainties associated with technical risk estimates, and that providing the public with this information will have a negative impact on public risk perceptions and related attitudes. However, the effects of different types of uncertainty on lay people's understanding of technical risk estimates have been investigated. A minority of individuals experience difficulties with the concept of uncertainty *per se*. For others, discussion of uncertainty appears to signal more honestly on the part of the communicators, although may, at the same time, result in reduced competence ratings attributed to the communicator or risk manager. From a risk communication perspective, it is also interesting to note that graphical presentations of uncertainty to lay people seem to result in higher comprehensibility ratings, but lower trustworthiness ratings.

Different types of uncertainty have been found to be associated with different levels of concern on the part of the general public. These are related to perceptions of lack of knowledge on the part of relevant stakeholders (e.g., lack of

scientific information regarding a specific risk, or conflicting scientific information or opinion), scientific uncertainty about the potential impact or extent of a particular hazard should it occur, and the perceived need by consumers for further research to be conducted in order to reduce the uncertainty. Perceptions that regulatory institutions are withholding uncertainty information from the public tend to have a negative impact on public trust in those institutions. The public is more accepting of uncertainty resulting from inadequacies in scientific process (e.g., associated with risk estimates) *per se* compared to uncertainty associated with the failure of institutions to reduce scientific uncertainty through conducting appropriate empirical investigations. Individuals appear to have difficulties in interpreting low probabilities and tend not to seek out probabilistic information under conditions of uncertainty. Other heuristics (or 'decision-rules') may exert influence on lay interpretations of uncertainty information, although it is not known how different individuals, or indeed people with different levels of expertise, are influenced by these heuristics. Example of heuristics relevant to the discussion of uncertainty includes the availability heuristic, where the people find it is easier to recall a past event, the greater they estimate the probability of the event occurring in the future, and representativeness, where the likelihood of an event is estimated according to the similarity to the class of events of which it is seen as an example. Developing effective communication about uncertainty is important if it is to be presented in the public domain as part of the risk analysis process. For example, there is evidence that public preferences for information about proactive risk management increases as uncertainty about a particular risk also increases, although this effect may be prone to cross-cultural variation.

Communicating about Risk Management Strategies

Consumer trust in different actors and institutions responsible for guaranteeing and controlling food safety is as important as trust in the information provided by these different institutions. In particular, trust may act as a proxy for extensive consumer scrutiny of food risk messages or communications. For example, although many people do not want to receive detailed information about the risks and benefits of food technologies, they may accept these same food technologies if they perceive that they are able to trust those institutions with responsibility for consumer and environmental protection. From this, it is arguable that risk communication should not only focus on food-related risks, but also provide information about risk management activities in an accessible form, which can then be made available to consumers. The question arises as to what constitutes optimal risk management practices from a consumer perspective. Results from qualitative and quantitative research have provided insight into which underlying factors have the potential to influence consumer evaluations of risk management practices. The research demonstrated that initiation of preventative risk management activities by risk regulators, strict enforcement of, and communication about, relevant regulations, transparency associated with regulatory activities, and information provision about the application of control systems and their performance were shown to be essential indicators for consumer perceptions of high-quality food risk management. Country-specific factors included skepticism regarding the practice of risk assessment and management. One conclusion is that communication with the public about how risks are managed is an important part of effective risk communication. Making such information available also enhances perceptions that food risk governance is transparent.

Communicating about the Risks (and Benefits) of Food Technologies

Research into consumer attitudes to emerging food technologies, such as GM foods, food irradiation, or highly technological food-processing practices has demonstrated that consumer acceptance of these technologies and their applications is driven not only by perceptions of potential personal benefits and health effects, but also by concerns and beliefs such as ethical and moral considerations, and values such as concern about the integrity of nature. For example, the (European) public perception that institutions and industries were pushing the introduction of GM foods in order to protect their own vested interests, rather than to provide societal benefits, did little to alleviate societal concerns. In the future, emerging technologies applied to food production (e.g., nanotechnology), may give rise to other public concerns. This may be exacerbated by increased complexities and uncertainties regarding both risks and benefits associated with food-production processes and food products. In response to public concerns, institutions may adopt a precautionary approach in terms of regulation, although greater regulatory attention may be paid to the trade-off between risks and benefits associated with these novel foods.

From this, it seems likely that consumer responses are contingent on perceptions of both risk and benefit associated with specific applications. An example is provided by Schenk *et al*. (2008), who examined the trade-offs consumers make between perceived risks and benefits regarding genetic modification applied to mitigating allergies (e.g., applied to the development of hypoallergenic foods, or birch trees with hypoallergenic pollen). Allergic patients perceived greater benefits associated with the birch application compared to nonpatients, an effect which correlated with increased perceived allergy severity. However, no differences were found between patients and nonpatients for the hypoallergenic food applications, possibly because the severity of the allergic response experienced by apple allergy sufferers is rather low. Thus it appears that the personal relevance of a particular benefit associated with a technology application will influence whether a particular consumer perceives the application of a technology to be acceptable.

The problems associated with consumer acceptance of GM foods in Europe will not be discussed in depth in the present article. However, a summary of the risk communication issues associated with GM foods is relevant at this juncture. Consumer values such as concern about the integrity of nature, and trust in the regulatory system, were an important part of societal and consumer acceptance. Communication efforts (from international institutions, national governments, and the industry) focused on the concept of 'substantial equivalence,' in other words that GM foods were in no way 'substantially different' in terms of food safety to foods that consumers were already consuming, and which had been

produced using conventional production techniques. As a consequence, developing communication about substantial equivalence did not address consumer concerns. In addition, control over consumption of GM foods was important to European consumers, necessitating the labeling of GM foods (as an additional form of communication) and implementation of effective traceability systems, as well as communication about how both the risks of genetic modification were managed and controlled.

Once established, consumer attitudes to technologies appear difficult to change, and consumers are unlikely to attend to further risk communication about a specific issue. For example, it has been shown that providing additional information about food-production technologies associated with established attitudes has little impact on these attitudes, independent of whether the information is about potential benefits or benefits and risks. Negative attitudes become slightly less negative, and positive attitudes become slightly less positive, although the actual extent of the change may be rather small.

In the case of nanotechnology, however, there is evidence to suggest that the provision of balanced risk–benefit information has a differential effect on different consumers. In this case, consumer attitudes to the technology still remain inchoate. Some consumers do not change their attitude at all (i.e., they remain indifferent or ambivalent to the use of nanotechnology in food production). These consumers are likely to be convinced either by the benefit they perceive to be associated with specific products, or by the views of opinion leaders with whom they perceive to share values, or whom they trust. A large minority appear to differentially process, and react to the risk information, and a smaller minority process the benefit information, developing more positive attitudes toward nanotechnology and its agrifood-related applications.

It is likely that many consumers are less interested in information about the risks and benefits of novel agrifood technologies, but will accept these technologies if they trust those perceived to be responsible for consumer health and environmental protection. To some extent this will be contingent on the extent to which these institutional and organizational stakeholders are perceived to be both honest (telling the truth) about risks and benefits, other salient issues associated with emerging technologies applied in the agrifood sector, as well as presenting accurate information which addresses risks, benefits, and uncertainties. In the case of nanotechnology, much of the debate about risk communication relates also to whether appropriate risk assessments have been conducted. In addition, trust might be developed through communication about proactive risk management strategies adopted by regulators and industry to ensure that the products of emerging technologies are safe.

Future Research Needs

Although there is a need to develop effective risk–benefit communication with consumers, historically, communication with consumers about food issues associated with health and environmental impact has focused almost exclusively on food risks, whereas health benefits have been communicated separately, as nutritional information. Other areas relevant to consumer food choices (e.g., innovations in food-production technologies) may also involve consumers trading off perceived benefits (e.g., improvements to consumer health, or more sustainable production) against perceived risks, for example, uncertain long-term effects associated with production processes, or ethical concerns about the integrity of nature negatively impacted by the production process. In reality, consumer food consumption decisions frequently involve weighing risks against benefits. Indeed, integrated assessment of risk and benefit is increasingly forming an integral part of the assessment phase of risk analysis.

It is increasingly recognized that benefit assessment should be considered in the risk analyses process. Risk--benefit assessment again is a science-based process, and can be divided into analogous steps: problem formulation, risk–benefit identification, dose–response relationships, exposure assessment, and risk–benefit characterization. Risk–benefit management involves the same process of consideration of societal interests in the issue as dose risk management. Similarly risk–benefit communication has proven to be more complex than simply delivering a health message. At the present time, it is not understood how to effectively communicate to end-users about the combination of both inherent food risks and benefits associated with a particular food product. This will be especially challenging when a specific hazard may differentially harm or benefit subgroups of the population (e.g., pregnant women or the immune-compromised, or those suffering from specific illnesses that can be prevented or would benefit from specific nutritional interventions). In addition, quantitative approaches to risk–benefit assessments may provide information on the associated uncertainty and variability, which can be particularly difficult to communicate. There is an increasing interest in the provision of personalized information, which contemporary communication strategies assume is more effective than those focused on the population more generally. All these types of information (risk–benefit communication, and its impact on consumer decision-making, differential information needs and preferences of specific population groups, discussion of uncertainty associated with both risks and benefits, and development of personalized information) have great potential for better informing consumer choices and food governance activities, but require very careful design and evaluation to avoid the risk of provoking unwarranted alarm, or ill-informed consumer decision-making. An important part of this is investigating what information consumers actually want, and how they may respond to it. At the present time, there is little theoretically underpinned and empirically tested information available on which to develop a pan-European risk–benefit communication strategy associated with foods. Scientific understanding regarding how consumers perceive risks and benefits associated with foods is urgently required, together with further understanding of the cognitive processes underlying risk–benefit communication, and associated decision-making regarding food choices. This knowledge will form the basis of an effective pan-European risk–benefit communication strategy associated with nutritional and technological food issues.

The need to conduct research in this area is particularly timely, given recent and ongoing advances within the natural sciences, for example, regarding the development of integrated risk–benefit assessment measures associated with food consumption, and their consideration by food authorities and innovations in the agrifood sector such as those associated with genetic modification of food production animals and innovations associated with emerging technologies, such as nanotechnology.

Risk Communication: Chemical Hazards

M Dreyer, DIALOGIK Non-Profit Institute for Communication and Cooperation Research, Stuttgart, Germany
O Renn, University of Stuttgart and DIALOGIK, Stuttgart, Germany

Glossary

Knowledge deficit model A concept addressing lay–expert discrepancy in the perception of risk; in this view the discrepancy exists because lay people lack the experts' knowledge and understanding of the issues; the main objective of risk communication is to educate the public in terms of aligning its views to those of the experts.

Latency Concealed or dormant risks. Latency refers to those risks where the harm emerges a considerable time after exposure.

Qualitative risk factors Factors that describe properties of risks (e.g., naturally occurring or human-induced) or risky situations (e.g., degree of ability of self-control) by which people judge risks, beyond the two classic components of risk analysis (i.e., level of probability and extent of possible harm).

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties, including the explanation of the risk assessment findings and the basis of risk management decisions (Codex definition).

Risk perception The outcome of the processing, assimilation, and evaluation of personal experiences or information about risk by individuals or groups in society.

Synopsis This contribution highlights insights gained from research in the areas of risk communication and risk perception showing both the relevance and challenge of communication about chemical food hazards. It points out the importance of perceived unnaturalness, involuntariness, delayed effects, and lack of control for judging chemical risks as high compared to natural, voluntary, and controllable risks. Effective risk communication requires addressing these qualitative characteristics. The particular role of public trust of authorities in this context is emphasized. This exposition is preceded by a clarification of the risk communication concept in the field of food safety and followed by an outline of research needs.

Chemical Contamination in the Context of Food Risk Communication

The World Health Organization (WHO) identifies the contamination of food by chemical hazards as a worldwide public health concern and a leading cause of trade problems internationally. Chemical hazards may result from chemicals that were added to food intentionally or from food contaminants that are present in food inadvertently. Residues of pesticides, veterinary medicines, and other agrochemicals, as well as food additives such as coloring and preservatives can lead to adverse health effects if the chemicals are not applied to food in an appropriate manner. One way in which hazardous chemicals can accidentally enter the food chain refers to indirect absorption via environmental pollution of the air, water, and soil, for instance by toxic metals, dioxins, or polychlorinated biphenyles (PCBs). Another possible source of food contamination is naturally occurring toxicants such as mycotoxins. These chemical hazards may arise at various points of the food chain. Contamination may also occur through chemicals used in food contact materials, from which they migrate into the food.

Although exposure to heavy metals such as lead has decreased in developed countries, this problem is still high on the public health agenda of developing countries. Heavy metals and other inorganic substances pose a constant threat to low income population in developing countries with respect to water and food safety. Despite strict regulatory standards and practices chemical food hazards remain a major concern of stakeholders and the public at large also in the industrialized countries. Public health concerns that have evolved here in the recent past include concerns about risks for foods contaminated by dioxins and dioxin-like PCBs (in wild and farmed fish and shellfish, for instance), increased levels of heavy metals in seafood, effects of cumulative exposure (to different pesticide residues in foods, for instance), and impacts on particularly vulnerable parts of the population such as fetuses, pregnant women, children, and the elderly (in relation to exposure to chemicals used in food contact materials, for instance). Although these are public health concerns widely shared by all industrialized countries, controversies arise over the concentrations that are deemed dangerous to human health or the environment (dose–effect relationships) and on the nature of what constitutes a food chemical hazard.

 doi:10.1016/B978-0-12-378612-8.00039-1

One illustration of different hazard concepts can be found in the so-called transatlantic beef dispute. On the contrary to the US and Canada, which consider meat produced from cattle treated with certain growth-promoting hormones as safe for consumption, the competent authorities in the European Union (EU) regard it as a risk to human health. A long-running dispute between Europe and the US, and Canada on the import of such meat has been the result of these different views.

Over the past 15 years food safety and public health authorities in the Western industrialized world have increasingly come to recognize that there is a need for purposeful and targeted communication about these and other food safety-related hazards. Although communication of food safety issues is still a developing field of practice, there are a growing number of national and international agencies that offer documentation and advice on the functions and forms of food risk communication and its role within their institutions and for other actors in the food safety field (e.g., WHO, the Codex Alimentarius Commission (CAC), the Organization for Economic Co-operation and Development (OECD), the US National Research Council, the European Food Safety Authority (EFSA), and many of the European national food safety authorities). They can build on a growing body of literature of academic research on the subject of communication on risk in general and on food risks in particular. The repercussions of the series of food-related scares and controversies that afflicted Europe between the late 1980s and the late 1990s (besides mad cow disease, most notably dioxin contamination, beef hormones, and genetically modified organisms) have promoted the expansion of food risk communication research. This expansion occurs in line with the development of the overall risk communication area, which builds greatly on risk perception research.

In this contribution, we will highlight some major insights offered by this overall body of knowledge, which indicate both the relevance and challenge of communication about chemical food risks. We will point out that people tend to worry more about unnatural (i.e., human-induced) and externally imposed risks, that their concerns are often multidimensional, and that the role of trust in risk management is pronounced under circumstances typical of many chemical food hazards. Finally, we will point to some major current research themes deserving further investigation. As the field of food risk communication research is currently dominated by scholars from the Western World concentrating on the situation in Europe, we will use mainly the European situation when we draw on examples.

The Concept of Risk Communication in Food Safety

Food risk communication is widely seen as an integral component of the entire food safety regulation process. The risk analysis framework as outlined by the WHO and the Food and Agriculture Organization (FAO) is comprises three interrelated. But functionally separated components, risk assessment, risk management, and risk communication. Nowadays this framework underlies and informs food safety regulation at the EU-level (and at national level in many European countries) as well as in the US and also at the global level in the form of standard-setting activities of the CAC, a joint WHO and Food and Agricultural Organization standard-setting body. The CAC defines risk communication as the 'interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties, including the explanation of the risk assessment findings and the basis of risk management decisions.' In this view, food risk communication includes exchanges between those who are central to the risk analysis process (i.e., the risk professionals responsible for framing, assessing, evaluating, and managing risks) and exchanges between these and other actors outside the immediate risk analysis process (mainly experts in food-related research, stakeholders in the food supply chain, and consumers). It has been suggested to refer to the former communicative exchanges as internal risk communication and the latter as external risk communication. By including risk-related factors and risk perceptions as subjects of communication the CAC defines food risk communication as not being strictly about risk. Instead it acknowledges that there is a need to communicate factors other than the technical estimates of a risk, i.e., the probability of an adverse effect and the severity and magnitude of that effect.

Risk perception research has been shown that understanding and communicating risk is influenced by a number of additional factors, such as whether the risk is voluntary or involuntary. Food risk understanding and communication has shown to be also influenced by the particular concerns that groups and individuals might link with a certain food hazard. These are not necessarily restricted to immediate impacts on human health or the environment but might include issues of perceived equity violations, symbolic associations, and attributions with the respective ingredient, or concerns that relate chemical risk with other negative evaluations such as 'big business.'

Attributes of Chemical Hazards that Increase Concern

Many chemical food hazards have attributes or are associated with attributes that risk perception research has identified as factors likely to increase the perception of risk. One of these factors is unnaturalness. From risk perception studies highlighting the importance of both quantitative and qualitative risk factors it is well known that natural hazards are seen as more acceptable than human-induced hazards. Anything that is seen as natural tends to be considered familiar and therefore less fearful and dangerous. Anything that is seen as chemical or artificial tends to be regarded as foreign, unnatural, and thus more threatening and dangerous. Therefore, everything chemistry does to our food tends to be considered as particularly risky. Although this dualist perspective does not withstand scientific examination, it is an expression of the longing of many people in highly industrialized countries for a contemplative refuge from society, technology, industry, and capitalism, and nature has come to represent such a refuge.

Another important qualitative characteristic of most chemical food hazards is involuntariness. People tend to

worry more about risks caused by external factors, i.e., imposed from the outside. This applies particularly in those cases in which the hazard-causing substances are used intentionally in the production of consumer goods, and this is the case for instance with potentially hazardous agrochemicals and food additives.

As shown by the 2010 EU-wide public opinion survey commissioned by the EFSA, European consumers persist in being concerned primarily about chemical contamination in food. Unnaturalness and involuntariness are attributes of the chemical hazards that consumers are most concerned about and likely to be among the top concern-producing factors (besides context-dependent factors such as the level of trust and distrust in the actors of the food supply chain and food safety authorities, social exclusion from risk governance processes, or social amplification effects caused by the media or nongovernmental organizations). This assumption takes into account that in Europe (as opposed to the US, for instance) it is a widely held belief that food should be produced in the most natural way possible and the criterion of naturalness enjoys great popularity.

Research in the areas of risk perception and risk communication links the two risk attributes with a basic difference between expert and public food risk perception. Although food safety experts judge microbiological hazards to be the main risk to human health from food, the public is much more concerned about chemical hazards with residues from pesticides and veterinary drugs ranking especially high. In contrast, acrylamide considered as a natural hazard in relation to food and at least partly under one's personal control has not developed into a major public concern in Europe (acrylamide in food is a natural byproduct of exposing in particular starch to high temperature, which is not related to alien ingredients or additives in food). When public authorities or food producers assess the need and the required design for communication to stakeholder organizations and consumers about chemical food hazards, it is essential that both the major quantitative and qualitative risk attributes and the particular role that these risk attributes might play in a specific social and cultural context are taken into account and explicitly addressed.

Multidimensionality of People's Risk Concerns

Research looking at the psychology of risk perception and the social factors governing eating behavior has further shown that in many cases people link various concerns with food-related hazards. Often the fear of immediate or long-term adverse health effects is not the only or the decisive component in the position that people take towards potentially hazardous aspects of food production. For instance, concerns about the environment and animal welfare have been found to be important in people's judgment about the use of pesticides and not only worries about health risks. Concerns about animal welfare form also part of the skepticism or opposition of people towards what appears to them as an unreserved use of veterinary medicines in animal husbandry. Risk perception studies have further found that people do not always clearly articulate worries about largely invisible hazards such as food additives and chemical residues. Instead, such worries were sometimes expressed more indirectly through indication of a general uneasiness about food quality and general reservations about contemporary social trends such as a progressive industrialization of food production. This unease with industrialization of food processing is often looked at as a threat to the traditional or nutritional value of foods.

The multidimensionality of people's risk perception has immediate implications for risk communication. In many instances, a narrow focus on human health will not suffice. The possibility for effective risk communication significantly increases when risk messages address the specific concerns that individuals, social groups, and different cultures might link with specific food hazards. If the use of growth-promoting hormones in meat production in Europe is opposed partly (or by some consumers even mainly) on the grounds of skepticism towards an ever increasing industrialization of animal husbandry, information campaigns simply explaining or discussing the safety of the meat for human consumption are highly unlikely to be effective; campaigners and addressees would talk at cross-purposes. The effectiveness of risk communication to a large part rests on the knowledge of what matters to the targeted audience and also on the willingness of the risk managers to incorporate the revealed concerns of affected and interested public groups into the design of risk management policies.

The Pronounced Role of Trust in Chemical Risk Management

A prominent topic in risk communication research is trust in the ability of food producers or public food safety authorities to maintain adequate levels of food safety. Trust has been found to be particularly important under circumstances where risks are considered as an early indicator of insidious danger and people feel that they have very little personal control over these risks. Many chemical food hazards are perceived in these terms, most notably food additives and pesticide residues. The perception of these hazards is closely linked with the need to find clear causes for seemingly inexplicable effects such as allergies or cancer in children. Knowledge of the possibility of cancers caused by certain food additives or pesticide residues does at least legitimize the suspicion that any cancer can be explained by the consumption of certain foods. For those suffering from cancer (assumed) knowledge about a concrete reason (such as consumption of foods contaminated with carcinogenic agrochemicals) can help to accept the disease because its occurrence provides a meaning to the affected person. This coping strategy is often linked with the tendency of people to focus on the hazard, the potential for harm, and ignore or downplay exposure and dose–response relationships. Empirical research on intuitive toxicology has shown that people tend to underestimate uncertainties and ignore exposure or dose when they are informed about a potential causal relationship between an agent and an effect.

For dealing with risks belonging to the category of early indicators of insidious danger, affected people depend on information provided by third parties. As a rule these risks cannot be perceived with the human senses. Moreover, these

risks are highly complex, i.e., there are usually many years of latency between emission and effect. Research in the fields of risk perception and risk communication has argued that people will be willing to make a balanced judgment between risks and benefits only if they trust the information providing party (regardless if whether this party advocates the food or warns about it). If there is lack of trust, risk–benefit tradeoffs will not be accepted but zero exposure will be demanded. A basic prerequisite for effective communication about chemical hazards perceived as early indicators of insidious dangers is therefore public trust in the performance of those institutions responsible for dealing with these hazards. Trust cannot be produced or manufactured but only earned in terms of performance and targeted communication. To (re-)gain trust implies to be sensitive to public concerns and to organize communication as a two-way process, i.e., from and to the target audience.

In summary it can be stated that risk communication by those responsible for assuring food safety is particularly difficult, if chemical food risks are invisible to the consumer and may cause negative health effects after a long incubation time. These risks are particularly frightening for the consumer: they are associated with involuntariness, delayed effects, inability to be sensed by human organs, lack of control, and unfamiliarity. To address these negative risk characteristics, it may be helpful to point to functional equivalents of these characteristics in a broader societal context. Potential equivalents are the assurance of a democratic decision-making process to counteract the impression of involuntariness and, as a replacement for personal control, the independence and impartiality of operating and regulating agencies. This may produce trust in their capability to monitor food items on the shelves, check composition and durability of goods, and intervene if safety in the risk-producing facility is not managed properly. In addition, familiarity can partially be compensated for by better functional knowledge about the risk and the associated procedures.

Need for Further Research

Recent risk communication research has indicated and largely supported a general trend towards understanding and performing risk communication as a two-way communication process. In this process it is not only the members of the public who are expected to engage in a social learning process, but also the risk assessors and risk managers. Although risk communication implies a stronger role for risk professionals to provide information to the public rather than vice versa, it is increasingly regarded as a mutual learning process. Concerns, perceptions, and experiential knowledge of the targeted audience(s) should guide risk professionals in their selection of topics and subjects. In contrast to the so-called knowledge deficit model, it is not the task of the communicators to decide about what people need to know but to respond to the questions of what people want to know. The question of what are basic requirements and major challenges of moving beyond the education- and persuasion-based approach to risk communication and towards a more discursive approach based on mutual learning deserves further investigation.

This is not a trivial task. Many scholars of risk communication emphasize that there is not a single homogenous public with one lay view of risk that needs to be taken into consideration. Rather there are a number of differentiated publics with varying values and concerns and also different levels of technical expertise and involvement with a given food issue. When communicating about the effects of cumulative exposure to different pesticide residues in foods, for instance, it needs to be recognized that communication demands of stakeholders along the food chain (such as farmers, producers, caterers, and retailers), environmental and consumer organizations, public authorities involved in risk regulation and public health, and the average consumers are very different. More research is required on what are the pros and cons of the various available methods and tools to achieve understanding of this variability (such as focus groups or mental models approaches) and on appropriate ways to incorporate these insights into the design of risk communication (in terms of content and tools, which can be oriented towards information, dialog and/or participation).

One issue that researchers have been dealing with since the field of risk communication was born is how one communicates uncertainty. This is a major research topic in the food risk area too and a communication challenge for food safety authorities with many chemical food hazards. Uncertainties about the possibility of adverse human health effects at low doses of Bisphenol A, for instance, have led to controversy in the scientific community about the safety of the use of the industrial chemical in food contact materials. This has resulted in different risk management decisions taken by national authorities and received much attention in the media and in the general public. Under these circumstances, food safety authorities are faced with the question of whether they should communicate about the uncertainty issue also to the wider public. Empirical research of the recent past has indicated that communicating uncertainty does not in all cases increase public trust of authorities and help consumers make informed choices but may also lead to public distrust and confusion. The nature of the relationship between uncertainty communication and trust-building is in urgent need of further investigation.

A subject of research that has emerged only recently is the composition of communication messages under circumstances where there is both risk and benefit associated with consuming a particular food. A prominent example is consumption of fish. From a nutritional perspective, increased fish consumption is likely to be beneficial for human health by helping to prevent the occurrence of cardiovascular diseases. From a toxicological perspective, however, it might be a risk to health as fish is associated with environmental contaminants such as methyl mercury, PCBs and dioxins. The challenge for risk communicators addressing the wider public here is to select messages that do not induce consumers to fully eliminate fish from their diet (and, what would make it even worse, switch to increased consumption of red meat), instead of including moderate fish consumption (defined in relation to their potential specific vulnerability) in a well balanced diet. Future research in the area of risk communication on chemical hazards should include further investigation of the potential and conditions for effective risk–benefit communication.

Glossary

Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of contaminated food, including drink.
Foodborne pathogens Disease-causing microorganisms that are transmitted to humans via foods.
Food safety Assurance that food will not cause harm to the consumer, when it is prepared and/or eaten according to its intended use.
Hazard A biological, chemical or physical agent in, or condition of, food with the potential to cause an adverse health effect.
Pathogen An organism capable of causing disease.
Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.
Risk analysis A process of decision-making (usually at government level) for managing food safety, consisting of three components: risk assessment, risk management and risk communication.
Risk assessment A scientifically based process for evaluating risks associated with foodborne hazards, consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization.
Risk assessment policy Documented guidelines on the choice of options and associated judgments for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.
Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community and other interested parties, including the explanation of risk assessment findings and the basis of risk management decisions.
Risk manager A person or an organization (usually government-related) with the authority to decide on the acceptability of risk and, if necessary, measures needed for their management.
Risk profile The description of the food safety problem and its context.
Uncertainty Uncertainty refers to lack of knowledge of a variable, or effect, or lack of certainty that a measured value is correct. Uncertainties include those that might arise in the extrapolation of information obtained from epidemiological, microbiological and laboratory animals, or complete lack of data for some variable that affects consumer risk.
Validation Obtaining evidence that a control measure or combination of control measures, if properly implemented, is capable of controlling the hazard to a specified outcome.
Variability Variability refers to differences in values of the same variable (e.g. the initial level of microbial contamination, the amount of food eaten in a single meal) that are not readily related to some known cause that could also be measured. It also includes biological variation such the difference in virulence that exists in microbiological populations and the variability in susceptibility within the human population and particular subpopulation.

Introduction

Risk communication is defined as 'the exchange of information and opinions concerning risk and risk related factors among risk assessors, risk managers, consumers, and other interested parties.' This definition emphasizes that risk communication is a two-way process and can occur among different sectors of society.

The goals of risk communication are:

1. exchanging information on the knowledge, attitude, values, practices, and perceptions of interested parties concerning risks associated with food and practices,
2. raising awareness and understanding of the specific health issues under consideration during the risk analysis process,
3. providing a sound basis for risk management decisions,
4. communicating the reason for the risk management decisions proposed,
5. contributing to the development and delivery of effective information and education programs, when they are considered as a risk management option (including when industry views that consumers have to control the risks), and
6. fostering public trust and confidence in the food supply.

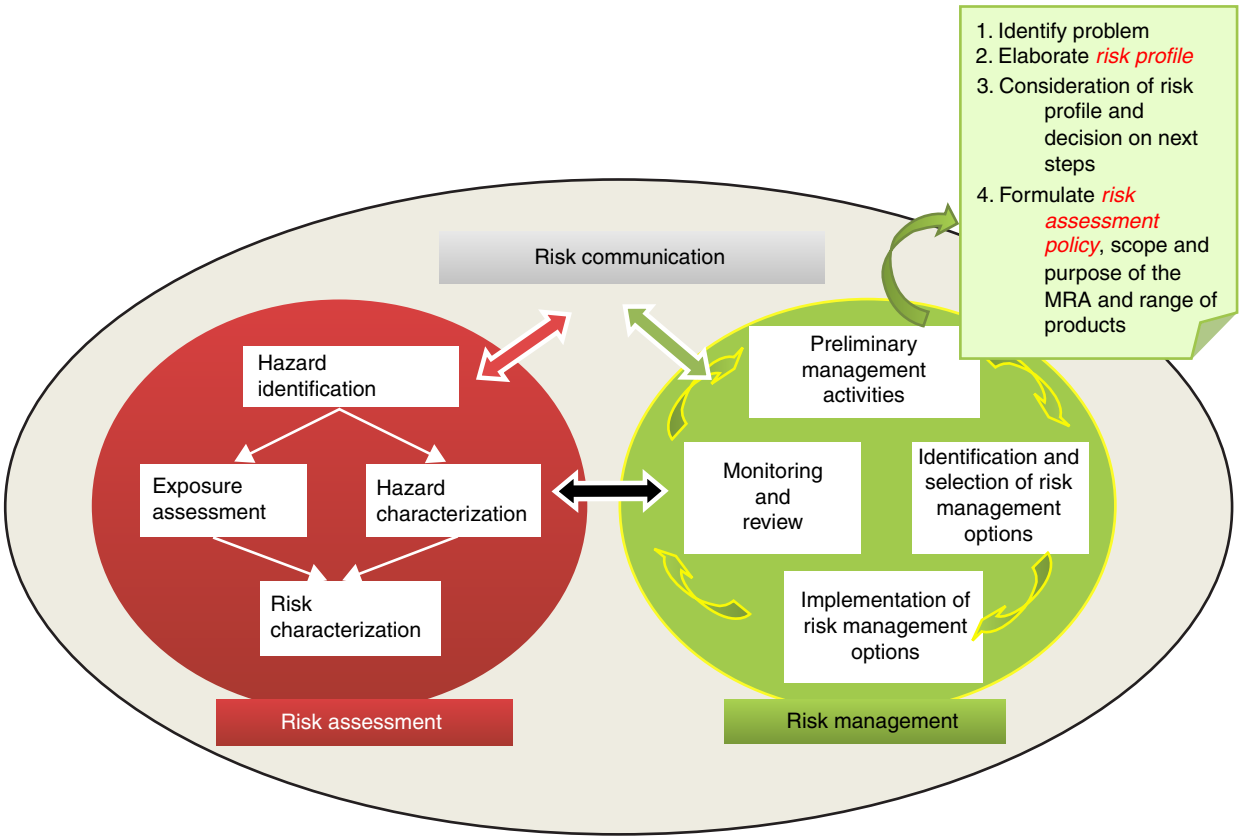

Figure 1 Risk communication in the context of risk analysis process.

In this article, risk communication is examined from two perspectives:

1. Risk communication as part of the risk analysis process.
2. Risk communication as part of health education in food safety (which itself is a risk management measure for prevention of foodborne diseases).

The focus of this article is on risk communication as applied to biological hazards. The principles of risk communication to chemical hazards or food technologies are addressed in other articles of the encyclopedia. The principles of risk communication are similar for all potential hazards in food.

Risk Communication as an Integral Part of Risk Analysis

Since the mid-1980s, the increase in incidence of foodborne diseases and a greater awareness of their health impact, together with a series of food safety incidents and crises causing public outrage, led public health authorities to revisit the process of decision making and the management of food safety at international, national, and local level. The outcome was the advance of the risk analysis process, consisting of risk assessment, risk management, and risk communication, as a model for risk-based food safety management (Figure 1).

Because, there has been an increasing attention to the science of risk communication and the associated concept of risk perception. Risk communication is a dynamic concept, which applies at different levels, for instance between:

1. Scientists involved in risk assessment and risk managers (e.g., regulatory authorities) and *vice versa*.
2. Internationally, between trading partners, i.e., importing and exporting countries.
3. Risk managers and stakeholders involved in the 'farm-to-fork' food chain; such food producers, processors, distributors, retailers, consumers, and others involved in assuring food safety and protecting public health, for example, health professionals.

In the context of risk analysis, be it at national or at international level, risk communication involves processes such as:

1. Understanding the concerns of the stakeholders.
2. Commissioning a risk assessment, and articulating the question that the risk assessment should address and including a risk assessment policy by a risk manager.
3. Communicating the outcome of risk assessment to risk managers at national or international level.
4. Communicating (e.g., explaining or justifying) risk management decisions to stakeholders.

Risk Communication Between Risk Managers and Risks Assessors

Risk managers have a leading role in driving the risk analysis process. As part of the risk communication process, they may:

1. require that the risk assessors advise on issues such as the 'impact' of foodborne disease, their relative importance (e.g., the public health burden they impose), and develop a risk profile for a preliminary appreciation of risks, or
2. commission a full-fledged risk assessment exercise to advise on risk management options. These may, for instance, involve:
    1. the efficacy of various control measures,
    2. points in the food chain where controls can be most effective (e.g., comparing efficacy of vaccination of poultry at the farm, cold storage of eggs in retail stores, or cooking of the eggs at the consumer level for preventing eggborne salmonellosis),
    3. evaluate the acceptability of risk as compared to public health goals, for example, risk of illness by consumption of specific product/pathogen combinations,
    4. risks associated with different processing, distribution, and consumer use scenarios, etc.

In commissioning a risk assessment, the interaction between risks managers and risk assessors starts with commissioning a risk profile, and in the eventuality of a full risk assessment, with preparing and communicating a document referred to as risk assessment policy. This is a document, initiated by the risk manager, specifies the context and objectives of the risk assessors' work. The preparation of the risk assessment policy should take place jointly with risk assessors, and is, of itself, a risk communication exercise. In the risk assessment policy, the risk managers will communicate to risk assessors:

1. the purpose and the scope of the risk assessment, i.e., what should be included and what should be disregarded, such as the segment of the food chain to examine, target population (general population or, e.g., a focus on pregnant women, the elderly, or a minority ethnic group), the data that could be relevant as evidence (outbreak data, sporadic cases, consumption patterns, industry monitoring data, etc.);
2. the procedure to be followed, the required documentation and the form of the risk estimate or the output to be presented (e.g., an estimate of the prevalence of illness, an estimate of the annual rate, or an estimate of the rate of human illness and severity per eating occurrence);
3. interpretative aspects, for instance, guidance on acceptable assumptions, how variability and uncertainties need to be addressed, the acceptable level of protection as a basis for acceptance or rejection of a risk, uncertainty in the risk estimate, transparency in the constraints that impact on risk assessment such as costs, resource, or time.

Risk communication between risk assessors and risk managers is a dynamic process during which iterative exchange of questions and information occurs, and the risk management questions are refined until the risk assessment exercise is focused to a point that risk assessment addresses the issue for which the risk managers need additional advice in an optimal manner.

The communication between risk assessors and risk managers includes the documentation of the risk assessment to ensure transparency and consistency as a reference for the future. Such documents can be important in case a risk reassessment is needed by other experts or when new information becomes available, or if the risk assessment is to be applied to different scenarios or to changed situations.

However, as stated above, a risk analysis process does not always start with a microbiological risk assessment. A starting point is the preparation of a risk profile, and this may in some cases suffice for decision making. At times, the risk profile may indicate the lack of data, in that case the risk managers may need to interact with scientists for the collection of additional data to enable a risk assessment to proceed.

Risk Communication Between Risk Managers and Stakeholders

As for communicating with risk assessors, risk managers should hold a two-way communication with stakeholders to consider the feasibility, the financial or cultural constraints, or preferences of stakeholders in the risk management options. Understanding these, as well as understanding the stakeholders' perceptions of risks, is important for effective communication of risks and risk management options. Even if the risk management option is a decision to accept the status quo and not implement further measures or reinforce the existing measures, it would be important to explain to the stakeholders the reason behind these decisions.

Risk management measures may be targeted to industry, for example, setting microbiological criteria, requiring specific processing such as pasteurization of the product, labeling and instructions for consumers, an inspection or certification process, development of a code of practice, training of food-handlers, or risk communication and health education of consumers and perhaps explaining to consumers the benefits of accepting responsibility for some management of the risk. In the latter case, the communication with consumers can range from simple information to specific educational programs (e.g., school health education, education of pregnant or breast-feeding mothers) or health education campaigns. **Box 1** shows the type of information that could be included in a risk communication message, as needed.

Risk Communication Between Risk Assessors and Stakeholders

As scientists, risk assessors also have a responsibility to alert and advice risk managers, and/or the stakeholders, on emerging pathogens, or conditions leading to potential increase in risk of illness, for example, contamination of environment where food is produced, change in practice or food habits, or to an increase in trend of foodborne illnesses. Such communication to risk managers will, as explained above, initiate the risk analysis process. However, scientists need to be particularly careful in risk communication to the general public

Box 1 Content of risk communication. Depending on what is to be communicated, and to whom, risk communication messages may contain the information described in this box

The nature of the risks

1. The characteristics and importance of the hazard of concern;
2. The magnitude and severity of the risk;
3. The urgency of the situation;
4. The trend;
5. The probability of exposure;
6. The distribution of exposure;
7. The amount of exposure that constitutes a significant risk;
8. The nature and size of the population at risk;
9. Who is at greatest risk.

The nature of the benefits

1. The actual or expected benefits (magnitude, importance) associated with each risk.
2. Who benefits and in what ways.

How the risk was assessed

1. The method used for risk assessment;
2. The assumptions on which estimates are based;
3. The effect of changes in estimates on risk management decisions;
4. Uncertainties in the risk assessment;
5. The weaknesses of, or inaccuracies in, the available data;
6. The sensitivity of estimates to change in assumptions.

Risk management options

1. The actions taken to control or manage the risk;
2. The actions individual's may take to reduce personal risk;
3. The justification for choosing a specific risk management option;
4. The effectiveness of a specific option;
5. The benefits of a specific option;
6. The cost of managing the risk, and who pays for it;
7. The risks that remain after a risk management option is implemented.

in order not to generate panic among the population or to wear out their trust because, in times of crisis, the attention of the general public will be essential for managing risks. Therefore, as far as possible, it is important to coordinate any communication to the general public with the risk managers, for example, the public health authorities.

Risk Communications Between Stakeholders

Risk communication can also take place between the stakeholders of the food chain and this is reflected in the definition of food safety, which is 'Assurance that food will not cause harm to the consumer when it is prepared and/or eaten according to its intended use.' Therefore, in trading foods, businesses are liable to inform their customers and/or consumers about the conditions for the use or handling of their products, and declare or warn of any counterindication. With regard to allergic reactions to food ingredients or food additives used, this is usually done through labeling as required by the legislation of the country where the product is marketed.

With regard to biological risks, food businesses will have to provide clear instructions for conditions of transport, storage, cooking, etc. While doing so, it is important that the information be provided in a format that is visible and clearly understood by the customer/consumers. Also, businesses should not make any assumption about the knowledge of the consumers and should try to understand the possible perception of consumers and/or their habits as well as the feasibility of the recommended measures. In other words, businesses should communicate in a way that not only are they understood, but also are not misunderstood. Therefore, for measures expected to be taken by customers that are critical for food safety, the coverage, and clarity of the communication should be validated by a representative group of consumers (focus group). There have been several outbreaks where misunderstanding of the conditions of transport, or use of products, have led to outbreaks of foodborne diseases. For example, in 2006, four cases of botulism linked to refrigerated carrot juice occurred in the US and two cases occurred in Canada. The implicated product was pasteurized carrot juice contaminated with spores of *Clostridium botulinum*. The carrot juice was distributed under refrigeration and was labeled with statements 'Keep Chilled,' 'Keep Refrigerated.' Nevertheless, it is believed that the juice involved in these outbreaks may have been left unrefrigerated for an extended period, either during distribution or while being held by consumers, allowing *C. botulinum* spores to grow and produce toxin.

In another outbreak in 2009, cookie dough contaminated with *Escherichia coli* O157 was eaten raw. The label indicated that the product contained raw ingredients. However, consumers did not realize that this was a safety instruction, as the statement was presented as a general information, and not as an instruction or a warning. Seventy people from 29 States in the US fell ill. These cases illustrate the importance of communication with the stakeholders and of validation of the information for clarity. This is particularly important when consumer actions are considered as a critical control point for controlling the hazard in question.

Risk Communication Between Trading Partners Internationally

Communication on risks between importing and exporting countries also occur occasionally. A case in point was the epidemic of cholera in 1993 in Peru. The epidemic led to food export restrictions causing major economic losses for Peru. In this context, World Health Organization (WHO) issued a policy on cholera and international trade in food that eased the situation. Similarly, in the crisis of bovine spongiform encephalopathy (BSE), the communication of WHO in relation to the safety of bovine products paved the way for managing the risk at national and international levels, and reassuring consumers on the safety of products on the market, in particular milk.

Other trade disputes between the European Union and the US involving risk communication have concerned cheese made with raw milk and meat produced with growth hormones.

Understanding Risk Perception as Basis for Risk Communication

Whether communication targets stakeholders of the chain with the purpose of explaining a risk management decision, or for providing guidance on what they will need to do, as mentioned above, understanding the intended audience's perception of the risk is essential. Experience has shown that acceptance of risks varies according to the factors influencing the perception of risk. This depends on a number of factors (these are also discussed in other articles).

Voluntary Versus Imposed

Voluntary risks, i.e., those that are experienced knowingly and by choice, are tolerated more readily than those that are imposed. For instance, in many European countries, there is the cultural habit of eating 'steak tartare' (raw minced beef), although this practice can expose consumers to a wide range of pathogens such as *Salmonella* spp. or *E. coli* O157. Some consumers also prefer raw milk, although it has been repeatedly demonstrated that raw milk can be the source of many illnesses. In Asian countries, consumption of raw freshwater fish is common, even though these are frequently the source of trematode infections. The risks associated with such foods are accepted because they are voluntary, while the same persons may be outraged with industrially produced foods that will expose them to the same level of risk. With regard to their own practices and food choices, consumers are often overoptimistic that nothing will happen, or even in the eventuality of an event, that the illness will be benign and self-limiting, an inconvenience they often qualify as 'simple diarrhea.'

Risk That are Under Individual's Control

Similarly, where risks are under individual's control, they are accepted more readily than when consumers need to rely on governments and/or industry for their protection. A case in point is the risk associated with poultry contaminated with *Salmonella* or *Campylobacter* versus risks of avian influenza (AI) and BSE. In the former, consumers can manage the risk themselves by cooking, whereas in the latter case they perceive the risk as greater or unacceptable due to their lack of control. In the AI and BSE epidemics, sales of products were significantly affected.

Risks That Seem Fair

Risks that seem fair, i.e., where the benefits of accepting the risk are fairly distributed between producers and consumers.' In such conditions, risks are better accepted than when the private sector would be the main or sole beneficiary. For instance, one of the reasons that food irradiation is not accepted by consumers, in spite of the record of proven safety, is because of the perception that the technology is introduced to cover up the poor hygienic practice of producers.

Natural Risks

Natural risks seem more acceptable to consumers than man-made risks. Although scientific evidence shows that where the food control system is well developed and implemented, the risks from food additives and residues of agrochemicals are comparatively lower than foodborne pathogens consumers perceive the contrary. Exposure to microbes is generally seen as a natural risk and as part of life.

Exotic risks Seem Greater Than Familiar Risks

Similar to the section Natural Risks, as people frequently recover from foodborne diarrhea, they are more tolerant of risks associated with the causative agent. In some regions of the world, where infectious diarrhea is a common health problem, it is even perceived as normal part of life. Consequently, such consumers may be more relaxed with their own malpractices, whereas, at the same time, they will be more concerned about an unknown or less familiar illness, even if it is of lower risk, such as AI.

Dread Factor

The second BSE crisis in the year 2000 demonstrated the importance of the outrage factor in the acceptance of risk. Even though with the measures taken by food control authorities, the risk of variant Creutzfeldt–Jakob disease (vCJD) was not particularly high, the fact that new cases of BSE were due to failures in control measures and that the consequences of an eventual vCJD infection were particularly dreadful (i.e., incurable, lingering, and terminal illness), the situation led to outrage and panic among consumers who lost trust in the safety of meat and meat products.

The Authority and Credibility of the Source of Information

Experience and surveys have shown that the trust of the general public in the information they receive depends on the credibility of the source. Generally, public health institutions and professionals, for example, physicians, are the most trusted source of information and consumers may more readily accept a risk when the communication is made by this professional group (because they are perceived to have no vested interest).

Risk Communication in the Context of Health Education

Health education is one of the essential public health functions and, in preventing foodborne illnesses, it is one of the most important risk management measures. In educating the general public and motivating them to adopt healthy practices, more economic constraints, public health authorities must also consider the perception of risk and the social and cultural factors that can influence consumer behavior and their acceptance of risk. Thus, in this context of health education, risk communication and understanding risk perception are also fundamentally important.

Similar to other risk management decisions, health education should be based on two types of considerations:

1. Scientific and technical information on factors leading to foodborne illness, and

Box 2 Causes of diarrhea as perceived in different cultures

1. Foods that are fatty, not cooled adequately or heavy.
2. Imbalance of heat and cold associated with food.
3. Exposure to draughts or seasonal changes.
4. Poor quality of breast milk.
5. Physical factors such as a fall or poor care of a child.
6. Supernatural causes, including possession, sorcery, or the evil eye.
7. Pollution or exposure to inauspicious contact with ritually impure persons or things.
8. Moral misbehavior, including the deeds of the sick persons or a sick child's parents.
9. Natural consequences of development milestones, especially teething, crawling, and walking.
10. Infection which may be associated with hygiene and sanitation (but which may be thought due to pollution).

Source: Adapted from Weiss, MG (1988) Cultural methods of diarrheal illness: Conceptual framework and review. *Social Science and Medicine* 27: 5–16.

2. Sociocultural and economic factors, including risk perception, which may impede the change of behavior or adoption of good practices.

For instance, an educational message on safe foodhandling will have little impact if people do not even believe that foodborne pathogens are the source of diarrhea (Box 2), or that diarrhea can have serious sequaele. Therefore in health education activities, it is important to understand the perception of risks of the population which is often a reason for their practices.

Therefore, in any health education activity, before advising any good practice, it is important to explain the scientific and technical reasons for the recommended measure and their importance. As explained in the article on health education in this encyclopedia, the recommended measures should also be adapted to the cultural and economic conditions of the society, and where necessary, policies and services be provided to ensure the feasibility of the measures. As an example, when promoting breast-feeding, it would be important to explain to parents the risk associated with infant formula, for example, *Cronobacter sakazakii* (formerly known as *Enterobacter sakazakii*), and that these products are not sterile and surviving pathogens may grow if the product is left at room temperature. Newborn babies are particularly sensitive as their immune system is not fully developed. Products may also be recontaminated during preparation by water or the environment, and feeding infants with infant formula will deprive them of the physiological and immune protective functions of breast milk. Naturally, breast-feeding would be feasible only if maternity leave or other type of facilities are provided to mothers.

Unfortunately, misperceptions are also common in the medical and public health community and many public health workers ignore the role of food in the transmission of infectious diarrhea and its chronic sequaele, or judge the extent of the problem by statistics on reported outbreaks, while most cases of illness occur sporadically and are not reported. Therefore, in any strategy for effective communication of risks, education of health professionals on the job and/or education of medical and public health students should be the starting point.

Conclusion

Risk communication is an integral part of food safety management. Understanding the science of risk communication, in particular, factors influencing risk perception, is important for effective management of food safety.

Although the regulatory authorities have the key role in communicating risks and control measures to industry and consumers, public health professionals remain the most trusted source of information, thus the most competent authority to advise the general public on preventive measures. Education of the public health professionals in risk communication and health education is the first stepping stone in the prevention of foodborne illnesses.

Risk Communication: Novel Foods and Novel Technologies

CG Brunk, University of Victoria, Victoria, BC, Canada

Glossary

Risk It is usually defined as the magnitude of a potential harm multiplied by the probability of that harm actually occurring.

Risk management The activities and strategies undertaken to maintain risks within the limits of what is judged to be acceptable for that risk. It is built upon a reliable scientific assessment of the risk and an appropriate standard of risk acceptability (safety).

Safe A level of risk that is deemed to be acceptable by some standard. The question of safety always involves the question of to whom the risk is acceptable, and by what criteria that party judges it so.

Uncertainty The situation created when firm scientific conclusions cannot be drawn because of insufficient or conflicting data, disagreements among scientists on the interpretation of data and other potential sources of misjudgment.

Distinctive Challenges Presented by Novel Technologies and Food

Risk communication around new technologies presents unique challenges because of the special concerns they raise in the public mind. This is especially true in the case of food. The concerns that are raised by food risks stem from the very intimate relationship all people have with food. It is one of only a few truly intimate interactions with our environment, in which we take into our bodies parts of that environment, they become part of us. Sexual activity is the other most typical way in which we do this. So, eating, like sex, raises distinctive concerns about the security of one's person. We are no more protective of our health and welfare than when we ingest food into our bodies.

Food and water are the source of the basis of life. They are the fundamental symbols of nourishment and nurture. Those foods that are the 'staples' of diet in a culture – bread, milk, rice, beans, and maize – usually carry added symbolic significance and, also added concern. When that which is the essential source of life turns into a perceived threat to life or health, it is not surprising that this should trigger much greater aversion to risks than might be tolerated from other sources.

The introduction of a new or unfamiliar technology also triggers concerns and sensitivities that need to be given special consideration in risk communication. Risk perception studies uniformly find that people are more accepting of risks that are familiar and present long term in their environment than of risks perceived as new and unfamiliar. There should be nothing surprising in this fact; that which is a regular part of our lives we accept as the normal conditions of life, and even if they are relatively risky, they are acceptable.

We also learn, or think we have learned, how to control our lives in the face of the familiar risks. The sense of control of the risks one faces is another highly important factor at work in the acceptability of risk for most people. This explains the widely observed fact that people are accepting very high levels of risk if they feel they exercise some measure of control over them. It is one reason why people generally accept the risks of driving automobiles, skiing, and extreme sports (relatively high risk), whereas at the same time may be unwilling to fly in commercial airplanes or eat foods grown with pesticides (relatively lower risk).

Studies also show that people generally are much more accepting of the risks they consider inherent in nature itself than they are of risks created by human activity. They trust 'God' or 'Mother Nature' more than their fellow humans. Thus, the risks posed by foods, food ingredients, or health products thought of as 'natural' do not raise nearly the level of concern as those considered artificial, technologized, or otherwise 'unnatural.' Even though the concept of 'natural' is ambiguous and contested, it plays a significant role in the perception of acceptable risk. There is a close link between the 'familiar' and 'natural' – those things with which we are entirely familiar are more likely to be seen as natural.

New foods and technologies often present new and previously unknown or unexpected risks. For example, a new food or food production process can be the vehicle for new diseases to appear (e.g., bovine spongiform encephalopathy (BSE) and variant Creutzfeldt–Jakob disease (vCJD)) or for old diseases to suddenly emerge as threats to human health on much larger scales (e.g., *Listeria* in processed meats, *Escherichia coli* in vegetables, etc.). When the media reports crises in food safety, public trust in the management of the food system is seriously eroded and notoriously difficult to reestablish. Major food crises and technological failures produce long memories. Competent risk communication practices cannot prevent these reactions to risk

 doi:10.1016/B978-0-12-378612-8.00041-X

management failures, but it is an essential tool in the restoration of public confidence in food and technology after these failures occur.

The Importance of Understanding Risk Perception

Risk perceptions like these are often judged to be irrational by risk experts, because they appear to defy the scientific assessment of the actual risks. It is often clear from the scientific point of view that relatively higher risks (e.g., the microorganism risk in organic vegetables) are of less concern to many people than relatively lower risks (e.g., risk of pesticide residue in nonorganic vegetables). This is irrational if the only reasonable consideration in the acceptability of a risk is its magnitude (the probability and severity of the potential harm).

But, as nearly every account of risk acceptability acknowledges, the concept of 'safety' is best understood as 'the level of risk that is acceptable.' This being so, the question becomes one of determining the criteria people use for deciding that different types and levels of risk are acceptable or unacceptable. Different people, and groups of people, will understandably make different judgments about what is acceptable to them, depending upon how risk averse or risk-accepting they are in general, and where they stand with respect to the risks and benefits. There is no one objective standard of safety that can be determined by scientific or other means, for the simple reason that safety is a subjective judgment, relative to the values and interests of those parties who face the risk (or stand to benefit from it).

The factors that have been shown to be most salient for people in their evaluations of risk acceptability are the following:

- The magnitude of the risk and benefits.
- Distribution of the risks and benefits (who gets the benefits and who bears the risk?).
- Familiarity/unfamiliarity of risk (including levels of uncertainties in the science).
- Ability to control/manage the risk.
- 'Dread' factors associated with risks (e.g., dreaded diseases).
- Risk threatens children or other vulnerable populations.
- Catastrophe scenario attached to risk (loss of control and of potential remediation/recovery).
- Voluntary/nonvoluntary (imposed) risk.
- Trustworthiness of the risk manager.

Only the very first factor on this list involves empirical criteria measurable by scientific means. All of the others are primarily value judgments of various kinds, including personal preferences, ethical standards (e.g., 'I have a right to choose the risks I take,' 'You do not have the right to harm me without my consent,' etc.), and deep-seated psychological tendencies within human beings. As value judgments, they illustrate clearly the fact that the question of what constitutes a 'safe' level of risk in food or technology is very complex. It is not just a matter of knowing the magnitude of the risk, because even a very low risk can be unacceptable if it is imposed on persons without any consent and benefit to them, if it is uncertain, and if there is little ability to control it. However, a very significant risk might nevertheless be acceptable if voluntary, controllable, familiar, and highly beneficial to the one taking the risk.

The question of safety cannot be answered except by looking carefully at the actual judgments people (especially those who are the potential bearers of the risk) make about what is acceptable to them. There are no widely agreed criteria, ethical, philosophical, or psychological, for deciding which of these value judgments are 'rational,' 'irrational,' or which should form the basis for a risk management decision.

Basics of Risk Communication

Science is the essential basis for the assessment and management of risk. The most important aspect of risk management of novel foods and technologies is the scientifically reliable assessment of the risks they pose. Judgments about the safety of these foods and technologies that are based on significant underestimates or overestimates of the actual risk are flawed, and where such misunderstandings occur it is appropriate for risk communicators to try to correct them.

Often, however, risk communicators assume that educating the public about the correct scientific assessment of the risk is the primary, or even the sole, objective of risk communication. When this assumption is conjoined with the further assumption that the public's view of the acceptability of a risk can be changed if people can be properly educated about the science, it produces a view of risk communication that is rarely successful in practice, and it often has precisely the opposite effect by undermining public trust in the risk communicators and managers they represent.

This view of risk communication is that its primary objective is to persuade the public to accept the safety views of the risk assessment and management experts, and that the most effective means to achieving this goal is to address the lack of scientific understanding, or 'knowledge deficit,' or the public. Recent research has demonstrated that the 'knowledge deficit' view of risk communication is fraught with serious problems. Attempting to fill in the gaps in the public's scientific understanding of food and technology risks has less impact on its attitudes toward the safety of these things than is commonly supposed. The reason for this is not difficult to see, if one understands the factors, outlined above, that are most important in shaping people's view of acceptable risk, most of which are not matters of scientific understanding of risk magnitudes. Many studies have shown that risk experts generally view safety issues quite differently from lay people. Thus, when they try to persuade the public of their own (nonscientific) views, they move well beyond their own scientific expertise.

The fundamental aim of risk communication is to provide the public and consumers with the most accurate and reliable information they need to judge the acceptability of a risk according to their own standards. To do this the risk communicator needs to respond accurately and sensitively to the safety concerns of stakeholders and the public, helping them to put these concerns together with the most accurate

understanding of current science. Success in this task is the most likely way to build public understanding of, and confidence in, the safety of food and novel technologies. It creates public confidence that the risk managers are competent, truthful, and serious about public safety because they are implementing responsible management strategies.

The fundamental tasks of risk communication include the following:

- Providing the most accurate account of current scientific knowledge. This includes being clear about what is known (by general scientific consensus), and also about what is unknown or controversial within the scientific community.
- Engaging all stakeholders in the risk in an open discussion of perceptions of the risk and standards by which it is judged acceptable or nonacceptable.
- Demonstrating that public concerns and risk perceptions about risk acceptability are understood and are being taken seriously.
- Demonstrating that risk management strategies are appropriate for the type and level of risk.
- Demonstrating that risk management strategies are competent – that they meet or exceed standards and best practices of other respected parties.

These points illustrate graphically that risk communication can never substitute for good risk management, because it is most effective when it is about competent risk management. If the approach to risk management is appropriate and defensible, the risk communication is easier. It is simply being clear about what is being done to protect the public from risks they find unacceptable.

Common Errors of Risk Communication

Identifying the factors that lead to successful risk communication is a complex and uncertain task. There is no guarantee of success. It is much easier to identify the mistakes that often lead to its failure. These mistakes are often made by risk communicators, especially in crisis situations.

'Zero-Risk' Messages

There is a widespread view among scientists and risk experts that lay people generally expect food and technology to be risk-free. This is part of a more general assumption that lay people do not understand the concept of safety as 'acceptable risk' rather than 'zero risk.' This assumption is far from valid in the case of many lay people, and certainly in the case of the more informed portion of the public that involves itself in the public debates about risk and safety. Often, risk experts confuse public resistance to what are viewed as increases in the risks imposed upon it by new practices as a demand for 'zero-risk' in these practices. These are not the same thing.

It is neither surprising nor unreasonable in any way that most people are resistant to increases in the risk burdens they share. Consequently, not only do risk communication claims that a new food or technology is 'risk-free' fail to convince (they are not plausible), but they also serve as traps in the long run that can be devastating to an industry or practice. All it takes to disprove a 'zero-risk' claim is one instance of the potential harm occurring, and when this happens, public trust in the risk managers and communicators is seriously undermined and very difficult to restore. When trust is undermined, risks, however small, will be viewed with much greater suspicion.

Reluctance to Admit Scientific Unknowns and Uncertainties

Another common error in risk communication is the failure to be entirely transparent about the science underlying the assessment of risk. Risk assessment is an inexact science at the best of times, as every risk assessor knows. It is often full of uncertainties and disagreements among scientists themselves. However, because of the high demand in many sectors of society for 'science based' decision making, many scientists, when speaking in public, are reluctant to admit the uncertainties in the science they are willing to admit among themselves. This is, ironically, a very 'unscientific' stance, because it misrepresents the real nature of science to the public. Scientists themselves often create high expectations in the public of the accuracy and objectivity of science, and when scientists turn out to be wrong, or change their view in light of new evidence, the credibility of science itself is undermined in the public eye.

A common form of this risk communication error is the reliance on what is essentially lack of any serious scientific data to support claims that a food product or technology does not pose any threats to human or environmental health. This is known widely as the fallacy of confusing 'absence of evidence (of risk)' with 'evidence of absence (of risk).' A good risk communicator carefully respects this distinction, being ready to admit that where there is little scientific evidence regarding risks posed by a food or technology, this should be admitted. The best risk communication message in this situation is transparency about the state of the scientific understanding, and clarity about what precautions are being taken with respect to human health and the environment in light of the unknowns.

Invoking Standards of Safety that are not Sensitive to Public Concerns

Risk experts tend to rely on standards of acceptable risk that are unpersuasive to the lay person, and appeal to them is usually unpersuasive. The preferred safety standards for risk experts are risk–benefit standards and comparative risk standards. In the first case, the argument made is that the benefits derived from the novel food or technology outweighs the risks, and should therefore be acceptable. In the second case, the argument is that, in comparison with other risks most people already take, the one associated with this food or technology is lower or no greater.

Neither of these arguments has proven to be very effective in risk communication. There are some very easily understandable reasons why this is so. In the first case, pointing out that certain risks are outweighed by the benefits often ignores

the vitally important question of how the risks and benefits are distributed. Often the benefits of a particular novel food or production process accrue to the producers rather than the consumers. They may legitimately feel that they are being exposed to risks in order that others enjoy the benefits – and this is not likely to be persuasive.

In the second case, comparative risk arguments are also notoriously ineffective. This too, is understandable: People often reason, quite legitimately, that the fact that one risk is no greater than another they already take, does not account for the fact that the new risk is being added to the one they already take. Most people are reluctant to add additional risks to what they perceive as an already heavy risk burden. In addition, the comparative risk argument serves to remind people that they are already exposed to risks they did not realize were there.

Assuming that the Primary Objective of Risk Communication is Communicating the Scientific Evidence of Low Risk

The reasons for the ineffectiveness of this strategy should be evident from the previous discussion of the factors that inform attitudes to acceptable risk. Although information about the best scientific assessment of the risk is crucial to risk communication, it is rarely definitive. The question in the mind of the audience is not only that of how great the risk is but also what aspects of the risk make it acceptable or unacceptable, in addition to its magnitude. Emphasizing that the risk assessors and communicator believe the risk to be low, whereas failing to address the other aspects of acceptable risk, simply make them both appear to be insensitive to public safety concerns.

How does this Apply to Novel Foods?

When new food products, food processes, and new foodborne risks are introduced into the market, it is not difficult, given what we know about risk perception, to predict what concerns will need to be addressed in effective risk communication. Recent examples of these concerns include food products from genetically modified organisms (GMOs, plants and animals), cloning of animals, the BSE crisis in beef and the associated vCJD in humans, the use of the pesticide Alar in apples, and the debate about irradiation of food for sanitation. In all these examples we see the following concerns raised in the public mind:

- This is something entirely new in my experience. I do not know whether to trust it. I do not know how to deal with it. It does not seem 'natural.' Should we be 'tampering' with our food in this way?
- What is the state of the science which assures us that the food product is safe? Has sufficient research been done? How much uncertainty is there in the science? Why do some scientists say there are serious risks? Can the science be trusted?
- Who benefits most from this new food product or process, and who is most exposed to the potential risks? Why should I accept the risk if others (e.g., the producers) are the primary beneficiaries? Why should I voluntarily accept this risk anyway?
- If there are risks in this product, is there anything I can do to identify them? There does not seem to be anything I can do (e.g., food preparation) to control my exposure to the risk.
- I do not trust the people who are producing these potential risks (e.g., the scientists and industries). I remember that they assured us that other products were 'proven safe' (e.g., drugs that were later removed from the market because of serious side effects). Why should I trust them to manage this risk?

The debate about GM foods involved each one of the concerns above. The technology of gene splicing was new and difficult to understand by lay people. It appeared to be a significant way of bypassing the familiar processes of 'nature,' which, being familiar, are largely trusted. This raised the questions about the reliability of the science in assessing the potential health risks to humans (e.g., allergenic foods) and environmental risks (e.g., outcrossing of pesticide-resistance into weeds, biodiversity), and trust in the science–industrial complex that profited from the development of the technology.

A commonly acknowledged factor in consumer apprehension about GMOs was that the first generation of these products modified the organisms to serve producer interests (e.g., lower production costs and easier transportation) rather than consumer interests (e.g., better food quality and lower prices). Thus, the question naturally presented itself, 'Why should I accept any level of risk in this technology, if I do not receive any real benefit?' Because several of the companies behind the major GMOs introduced to the market were companies associated with chemical pesticide production (and issues of chemical pesticide residues in food were very much in the news), there were serious issues of public trust in the producers of GM food.

In the early days of the serious public debate that swirled around GM food technology, especially in those countries in Europe and Africa that were forced to adopt restrictive legislation about their production and importation, the communication from the industry, government, and other promoters of the technology largely failed to address these concerns about the acceptability of the risks. Instead, they focused on the scientific assessment of the risk, arguing that the science had not identified any serious risks about which the public should be concerned. This argument was of limited effectiveness, and for obvious reasons, given the nature of public concern, which was focused on other issues. Failure to take these concerns seriously led to weak risk communication about GM foods.

Conclusion: What does the Public Need to Know?

Good risk communicators know that they have succeeded in their task if their intended audience is left with a sufficient understanding of the relevant issues surrounding the risks of a new food or technology to make reasonable judgments about the acceptability of these risks (which they are entitled to

make according to their own values) and about the appropriateness and effectiveness of the risk management strategies in place with respect to these technologies. The keys to this success can be summarized as follows:

- The best and latest scientific information has been communicated in ways that the public can understand sufficiently to make informed judgments;
- The nature and extent of the uncertainties and unknowns in this science have been communicated honestly and transparently, as well as the steps that are being taken to fill in the gaps in scientific knowledge;
- The risk managers and communicators have engaged in the necessary consultation with the various stakeholders in the issue to have developed an understanding and appreciation of the factors that influence their attitudes toward the acceptability of the risk; and
- The communicator is able to address the public sensitivities with respect to this risk, and make a convincing case that these are being addressed responsibly by appropriate risk management strategies.

To the extent that these tasks can be carried out, public confidence and trust in the safety of novel foods and technologies can be sustained.

Glossary

Attentional bias The tendency of individuals to direct attention selectively toward specific information in one's environment, resulting in less attention to other relevant information when making decisions.
Attitude Enduring systems of beliefs that represent individuals' affective feelings of like or dislike of an object.
Credence attributes Attributes of a product that cannot be verified by consumers or can be verified only after a long time period.
Food labeling A panel attached to a package of food that gives a variety of information about the nutritional value and safety of a food item.
Health halo effect One positively perceived feature of a food (such as claim or logo) extends to the broader product evaluation, leading to an overestimation of the overall healthfulness of the food.
Health locus of control A theoretical construct developed to assess individuals' beliefs regarding personal control over one's health. A person may believe that internal forces have control over health or that health primarily is determined by outside forces, such as physicians and chance.
Nutrition education A set of educational strategies to encourage specific dietary choices and behaviors in order to improve health and reduce the risk of diet-related diseases.
Optimistic bias The tendency of 'unrealistic optimism' in which an individual judges that negative events are less likely to happen to the person making the judgment compared to the risks experienced by an average member of society or comparative individual within that society.
Self-efficacy The extent to which a person believes in his or her ability to overcome the difficulties inherent in performing a specific task in a particular situation.
Self-regulation Individual's capacity to change behavior to the attainment of personal goals.

Introduction

Good and safe nutrition are closely connected with good health. Consumers have various concerns about the influence of food on their health, ranging from food safety issues (e.g., additives and foodborne illnesses) and concerns related to longer term health risks because of unhealthy food choices (e.g., overweight, micronutrient deficiency, chronic heart diseases, and cancer). As a consequence, the provision of information about diet, health, and nutrition is increasing. Information is rapidly spread by the (mass) media, which includes social media. But it also includes communication developed to reach consumers at the exact place where they make their food decisions, for example, through food labels, at the supermarket or in catering outlets.

Communication regarding diet, health, and nutrition is about the provision of knowledge and skills so that consumers are better able to select and consume healthy and safe foods. Various barriers to effective communication about diet, health, and nutrition can be identified. Before people can process information they need to be aware of it, either because they are exposed to it or actively search for it. This requires a certain degree of motivation. Even if consumers process this information, it may not subsequently lead to changes in behavior. Hence, communicators in the area of nutrition, diet, and health deal with a variety of issues, ranging from reaching the right target population to making sure that the message is understood and implemented in daily life. In this chapter some relevant consumer behavior issues facing the communication of risk in the field of nutrition and diet will be examined.

Consumer Awareness and Motivation to Process Information

Information about diet, health, and nutrition can only influence consumers if they are exposed to it. Exposure can be intentional when consumers search for information relevant to their goal or problem. Accidental exposure occurs when consumers unexpectedly encounter the information. Attention is influenced by both environmental factors, and those related to the consumer, such as motivational and time constraints. The location of information on a food package, or the novelty of the information presented, potentially influence the likelihood that a message becomes salient and captures a consumer's attention.

Nutrition education has gradually shifted to include food retailers. As a consequence, consumers are confronted with an

 doi:10.1016/B978-0-12-378612-8.00042-1

extremely rich information environment with competing choices being made available. Consumers are often too rushed to intentionally search for all types of information in retail environments such as supermarkets which are noisy and provide many other types of information. People are more likely to look for information when they have a specific health problem (e.g., trying to lose weight or food allergies). Owing to cognitive limitations in the extent to which multiple messages can be simultaneously processed, consumer attention is focused on what matters the most to them, and so diet, health, and nutrition information potentially competes with information about price, brand, convenience, and taste.

Research has suggested that health is reported by consumers to be a key choice criterion when making food choices. However, even when consumers are aware of health information associated with particular foods, they are not necessarily motivated to spend energy and time to process this information and adapt their behavior if needed. In persuading individuals to perform or refrain from certain behaviors, the emphasis has typically been on developing uniform education materials for the general population. Although these materials may provide accurate and understandable information, they may not be processed by individuals and hence be less likely to motivate behavior changes. Information processing is influenced by the level at which an individual is involved in its content, and considers the information to be personally relevant. For example, 'optimistic bias' (or 'unrealistic optimism') is where an individual judges that negative events are less likely to happen to the person compared to the risks to which an average member of society or comparative individual within that society is exposed. Optimistic bias has been observed for a range of food related hazards, but tends to be more evident for 'lifestyle' hazards (e.g., alcohol and fat intake) compared to hazards of 'technological' origin (e.g., pesticides and genetic modification). For these lifestyle risks, consumers' optimistic bias may stem from the 'illusion of control' whereby consumers are confident that they are able to prevent the risk from occurring, or the 'illusion of knowledge' where they perceive they know more about the risk than others. Optimistic bias may hinder educational efforts to motivate consumers to change risky behaviors, because they perceive that information is directed towards more vulnerable and less knowledgeable members of society.

Attentional biases influence what kind of information people are likely to focus on, and – in particular – what kind of information they tend to neglect. In the research field of persuasion, some approaches to improving compliance with 'good' behaviors have been identified. For example, people naturally like to behave in line with others. The likelihood that people will adopt a good behavior can be increased by providing them with the information that other people also show similar behavior. If the aim of information provision is to persuade people to eat, for example, more fruits and vegetables, it would be helpful to stress the number of people who are already doing so or to supply a testimonial from someone who eats fruits and vegetables. It also suggests that, if one wants to persuade people not to do something, for example, eating too much saturated fat, one should not focus on the number of people who are engaging in such bad behavior. In this case, the message that people will remember is that others are also acting badly (i.e., eating too much saturated fat) and thus it is normal to do the same. Research shows that providing people with normative information (i.e., information about how others are behaving) is more effective when the bond between the reference group and receiver of the message is closer. For instance, a message like 'many people living in Amsterdam eat sufficient amounts of fruits' should be more persuasive for an inhabitant of Amsterdam than the simple message 'many people eat sufficient amounts of fruits these days.' Some studies have even shown that strong affiliation with the reference group is needed for normative information to be persuasive.

People also differ in the degree to which they believe they possess control over their own personal health. This so-called 'health locus of control' theory categorizes people into 'internals' if they believe that they themselves are in control of their health and 'externals' if they believe that their fate is controlled by external forces such as powerful others or chance. 'Internals' have been shown to be more likely to carry out health-promoting behaviors, such as exercise, and to take responsibility for their own actions. As such, the theory is closely related to the construct of self-efficacy which reflects a person's belief in his or her ability to overcome the difficulties inherent in performing a specific task in a particular situation. Self-efficacy has been shown to be a powerful predictor of many health behaviors. For example, people tend to pursue tasks in which they feel competent and are confident of accomplishing and avoid challenging tasks which involve complex behavior changes (e.g., eat less fat). Messages that boost self-efficacy focus on reasons and skills that make people believe they will be able to carry out the behaviors successfully. Research has shown that messages consistent with the locus of control of individuals are more effective than general messages.

Potential Misinterpretations of Communication about Risks, Health, and Nutrition

Once consumers are exposed to information, whether accidently, or because they deliberately searched for it, the interpretation and comprehension process begins. Comprehension is a precondition of correct interpretation of information. Various studies have shown that individual differences, such as food safety and nutrition knowledge, and health status influence the interpretation of related information. In general, consumers, and some researchers and policy makers, feel that health and nutrition information is often conflicting and confusing. To prevent confusion, it is often stressed that information should be simple without adding too many details. When asked for their opinion, for example, in group discussions or personal interviews, consumers tend to express a preference for simple and understandable information. However, the more information is summarized, for example, in a single logo front-of-pack, the more it is lost, which may make misinterpretations more likely to occur. Information about food often produces inferences (beliefs that are not based on information directly presented to an individual). Consumers are heavily influenced by existing knowledge that is activated during comprehension. Consumers can make

interferences from small amounts of information. For example, some consumers might infer that a food is healthy because the advertisement emphasizes the naturalness of the product. Research on the effect of positive descriptive food names on food showed that these descriptions might create a 'halo effect' such that the food consumed becomes more attractive and liked.

Closely related to this is that healthy and safe eating messages typically stress only one particular risky or beneficial aspect of foods. People tend to rely strongly on one piece of information when making decisions, the 'anchoring bias.' Moreover, faced with information overload, individuals tend to just categorize foods as good or bad and do not evaluate a food or message about the food in the context of the total diet. This is also called 'dichotomous thinking'; the oversimplification of information in either bad or good. Consequently, messages that aim to change undesirable behaviors may be not well received if consumers think that they have to give up their favorite 'good' foods. Restricting the amount of information provided, and presenting a balanced view of risks and benefits, may reduce this tendency.

Food decisions of consumers are based on both the expected benefits and risks. When people are concerned, they typically desire more information about the object of their concern and want to be taken seriously. Risk perceptions of consumers have been found to increase when a potential food risk is perceived to be unnatural, potentially catastrophic, or unfamiliar. Understanding these psychological drivers of risk perceptions are of key importance. For example, research has shown that food additives were rated as more harmful when their names were difficult rather than easy to pronounce, indicating unfamiliarity. The trade-off between risks and benefits involves weighing the benefits of a food (e.g., the health benefits of consuming fatty fish in relation to heart diseases) with the safety risks (e.g., contamination of fish with heavy metals). Perceived risk and benefit seem to be inversely correlated. In case the benefits clearly outweigh the risks associated with a food, risks become more acceptable. This implies that when something is perceived as highly risky, it is correspondingly only acceptable when there are high benefits. This suggests that certain trade-offs between risks and benefits are being made by consumers. The information processing of consumers in terms of perceived benefits is to a large extent the result of cognitive processes. For risky information, consumers process that type of information in a more heuristic way which refers to people's fast and intuitive responses to dangers.

Consumer Trust in Information

Consumer responses to communication are influenced by more factors than the information itself, such as the trust in the source of information. This concept of trust has been extensively studied in relation to consumer perceptions of the risks and benefits associated with the consumption of different foods (for example, in relation to the efficacy of regulatory assessment and governance practices) and information about the risks and benefits of consuming different foods. For example, when consumers judge information to be overcomplicated and difficult to comprehend, they will use their perceptions of the motives of the information source in providing the information to make decisions about the value of the information. They may also adopt the attitudes of groups with whom they perceive that they share values, rather than process the information directly.

To evaluate the healthiness and nutritional value of specific food products, consumers have to resort to the use of credence attributes. Credence attributes are those product characteristics that cannot be verified by the consumers or can be verified only after a long time period. Consequently, consumers have to believe that these attributes deliver without proof at the moment of purchase or consumption. Hence, consumers have to rely on their trust in food manufacturers or regulators. Generally it has been observed that trust in scientific governance has increased across Europe in recent years. Industry sponsored initiatives (such as front-of-pack nutrition labeling) may or may not be subject to regulation, depending on local or regional legislative frameworks in force. For example, in Europe, nutritional labeling must be 'evidence-based,' whereas in South East Asia no such legislation has been enacted. In a global society this may result in different messages being delivered to consumers which vary across regions, causing further consumer confusion about dietary choices. From an industry perspective, such labeling may be used voluntarily to indicate the industry is responsive to societal concerns about food and nutrition.

Changing Consumer Behavior in a Desired Direction

Even under circumstances when people process nutrition information correctly and are motivated to change their diet accordingly, they still often fail to do so. Choices regarding the purchase and consumption of food are made on a daily basis and most of the time is performed in the same context. This repetition in behavior and context means that eating behavior is largely habitual and consequently difficult to change. Habits can be understood as learned sequences of acts that have been reinforced by rewarding experiences in the past and that are triggered by the environment to produce behavior, largely outside of people's conscious awareness. This automaticity means that educational interventions attempting to change behavior by fostering deliberate intentions towards healthy eating are often ineffective. Instead of promoting healthy eating intentions by means of informational campaigns, habit theory suggests that interventions may be more effective when they target environmental cues that trigger automatic behavior. Habits may be easier to break when there is a change in context. Therefore, attempts to change or create eating habits may be more effective when they coincide with a change in someone's situation, such as starting with a new job or moving to a new neighborhood.

Another, related, reason why people often fail to implement their good intentions has to do with their limited self-regulation capacity, or in more popular terms 'willpower.' To enact a healthy food choice when tempted with unhealthy, but hedonically attractive, alternatives requires a high level of self-regulation. People need to be able to resist the reward of short-term gratification over the long-term health benefits associated

with healthy food choices. In particular, in moments of low self-control, for instance when one is tired or hungry, self-regulation often fails. Education interventions that include self-regulation techniques have shown to be more effective than interventions that are based on information provision only. These interventions often include a component that encourages people to make specific plans as to when and how to implement the desired behavior. These so-called implementation intentions have shown helpful in enacting positive intentions.

A major question in research and policy making is whether communicating about diet, health, and nutrition will actually lead to healthier and safer food choices and less nutrition-related diseases. To date, little empirical and consistent evidence exists to support that education improves eating habits. Research on actual impact on diet and health is complex and time consuming. Traditional consumer research approaches based on self-reports are valuable but limited as consumers tend to give socially desirable answers (and besides may not be aware of the factors that underlie their habitual food choices.

Concluding Remarks

Educational campaigns and health interventions are widely used to promote healthy and safe eating practices. Despite these initiatives, consumers do not always notice and act on information provided, particularly when they are overwhelmed with high levels of information. Hence it is important to target messages according to different consumer needs and preferences, for example by referring to other people's action with which the target group closely identifies. Careful segmentation of different population groups may lead to more readily engagement in health-promoting behaviors.

Easy accessible and understandable information is needed to enable consumer to make informed choices about risks and benefits. To increase the likelihood of acceptance, information is increasingly provided at the place where it is most needed. For example, food preparation information should reach the kitchen by putting clear instruction labels on particular foods. Nutrition information 'front-of-pack' or on shelf tags in retail support consumers make in-store decisions.

Information that is not personally relevant and generic is less likely to attract attention and influence attitudes or behavior. Messages that are closely tailored to individuals' interests are more likely to be internalized. Over the previous decade, there has been growing interest in the role of the internet, including social media. Developments in communication technology have enabled efficient delivery of information to large number of individuals. The increased availability of the internet and new social media tools facilitate interactive communication that can help inform the public and create a dialog between communicators and consumers. In particular, one characteristic of social media is that consumers themselves play an important role in sharing and 'cocreating' information. At the same time these additional communication channels are a relatively unfamiliar domain leading to new challenges for researchers, risk managers, and communicators and may create groups of excluded individuals who do not have access to these new media.

In the current food environment, consumers are regularly confronted with relatively cheap, tasty, and unhealthy foods. This is supposed to be a strong contributor to the increase in nutrition-related diseases such as obesity. As a consequence, environmental interventions are highly needed as a complementary strategy to improve healthy and safe eating habits among consumers. In addition, for effective communication to be developed, it is important to understand the factors that influence consumer trust in information about diet, health, and nutrition.

Food Safety Training and Health Education: Principles and Methods

C Griffith, Von Holy Consulting CC, Bellville, South Africa
E Redmond, Cardiff Metropolitan University, Cardiff, UK

Glossary

Food safety competence The ability to perform a food preparation task safely and to the required standard (this may be legislative, in-house or external).
Food safety culture The aggregation of the prevailing, relatively constant, learned, shared attitudes, values, and beliefs contributing to the hygiene behaviors used in a particular food-handling environment. It provides staff with a common sense of food safety purpose.
Food safety management Coordinated activities to direct or control food safety. The attainment of business food safety goals in an effective and efficient way through planning, staffing, organizing, directing, and controlling organizational resources.
Food safety training One way to deliver/achieve learning, a planned process to modify knowledge, attitudes, skill, or behavior relating to food safety through a learning experience. In work, to develop the abilities of an individual to work effectively and efficiently.
Formal training Successful completion of a widely recognized, independent food safety training program.
Health education Range of definitions; a simple one is: a communication activity designed to enhance positive health or diminish ill health in individuals or groups. Considered in a broader work and social framework than training – not necessarily in a limited field of activity.
Informal training Usually undertaken at work, can be theoretical or more usually practically based on the specific needs a company has, for a food handler to produce food safely.
Learning Acquisition and understanding of new skills, knowledge, or attitudes (with respect to food safety). Ability to do something the person was previously unable to do. A relatively permanent change in behavior as a result of tuition, practice, or experience.
Management systems All the documented procedures, practices, and operating procedures which influence food safety.
Operational food safety performance The collective food safety practices used within an organization.

Introduction

The World Health Organization (WHO) at its 126th Executive Board meeting in January 2010 highlighted concerns over food safety and described it as "a continuing public health concern" that required a global solution. Whether actual cases of foodborne disease are increasing or whether there are just more being reported is uncertain, but what is clear is that the number of cases and the associated levels of morbidity and mortality are far too high. The global nature of food safety relates to the world trade and movement in food and raw materials, the mobility of labor from one country to another with the possible risk of infected food handlers moving from countries where some intestinal pathogens may be endemic, coupled with the fact that pathogens spread easily and do not respect international barriers.

The responsibility for food safety involves governments, industry, and consumers working together. Governments should undertake surveillance to establish the level of food contamination and the patterns, risk factors, and organisms involved in foodborne disease at a local level. They should draft and then enforce relevant food safety legislation, but this should be linked to good communication and support for industry. The food industry should construct and use appropriate management systems which need to be implemented within the context of a positive food safety culture. Consumers themselves must also play their part although many recent studies indicate nonimplementation of known food safety practices within the domestic kitchen.

It has been said that in spite of millions of words being written about food safety, coupled with the expenditure of large sums of money, levels of foodborne disease have not decreased significantly. There may be a number of explanations for this including the evolving nature of food pathogens. Many of the organisms causing problems today have been described as emerging pathogens, having been identified as problematic over the past 40 years. *Campylobacter*, identified as causing only foodborne disease in the early 1980s, is thought by WHO to be the most common cause of bacterial food related illness with possibly more than 300 million cases a year. However, even this is likely to be far fewer than the burden of illness caused by norovirus which

 doi:10.1016/B978-0-12-378612-8.00043-3

maybe one of the world's most infectious organisms with many cases spread by food handlers. However, focusing only on the microbial nature of foodborne disease is never going to reduce its burden to an acceptable level. Another major contributory factor as, or even more important than pathogen emergence, is the role played by food handlers. The controls necessary to manage foodborne disease are not new, but their full implementation by food handlers is a stubborn problem. Concerted efforts to reduce the burden of foodborne disease must, therefore, understand and address issues of food handler compliance with food safety practices.

Understanding Food Safety Behavior

Research over the past 20 years has attempted to quantify, understand, and improve food handler behavior in both the home and the food industry. Although food handlers in industry are also likely to prepare food in the home (although clearly the reverse may not always be true), a key difference is that practicing good food hygiene is a legal requirement in industry, and desirable, but only optional, in the home. Other differences include the facilities available to practice hygiene and food handler knowledge about safety practices. Many countries have legislation requiring food handlers to be informed about food safety and to be trained. However, strategies to inform and educate consumers about food safety are far more variable or even nonexistent. This may in part contribute to the large number of cases of foodborne illness thought to be acquired in the home.

The need to understand the human aspects of food handling with the involvement of behavioral scientists, has been recognized. In one recent study of food handlers' beliefs, 62% of food handlers admitted to sometimes not carrying out all known food safety behaviors on every appropriate occasion with 4% admitting that they often did not. Lack of time was the most quoted reason for failure to implement relevant practices. In food service operations, this may be due to the need for food handlers to be hygienic when a large number of customers are waiting to be served. This need to serve to order, as opposed to supply stock, which is more common in food manufacturing, can lead to greater food handler noncompliance. Possible factors influencing human food safety behavior are summarized in Figure 1. However, it must be realized that food handlers, especially consumers, are not a homogeneous group, they are individuals and will not behave in the same way or necessarily in a way food safety experts might expect.

In attempting to interpret, study, or even predict behavior it may be helpful to use existing theoretical behavioral models. The simplest of these is the knowledge, attitudes, practice (KAP) model, and this has been used as the basis for much hygiene training. This relies on the provision of information (knowledge) to modify a food handler's attitudes, which would in turn change behavior. The approach takes no cognizance of the conditions, culture, and environment in which the food handler may be working.

More sophisticated and successful models try to consider many more of the factors which can influence behavior. Social cognition models start from the assumption that an individual's behavior is best understood in terms of his or her perceptions of their social environment. Two of the most widely used models are the theory of planned behavior and the theory of reasoned action (TRA). These theories aim to measure behavioral intentions, recognizing that certain uncontrollable factors can inhibit implementation and thus prediction of actual behavior, for example, an individual intends to wash their hands, but arrives at the sink to find there

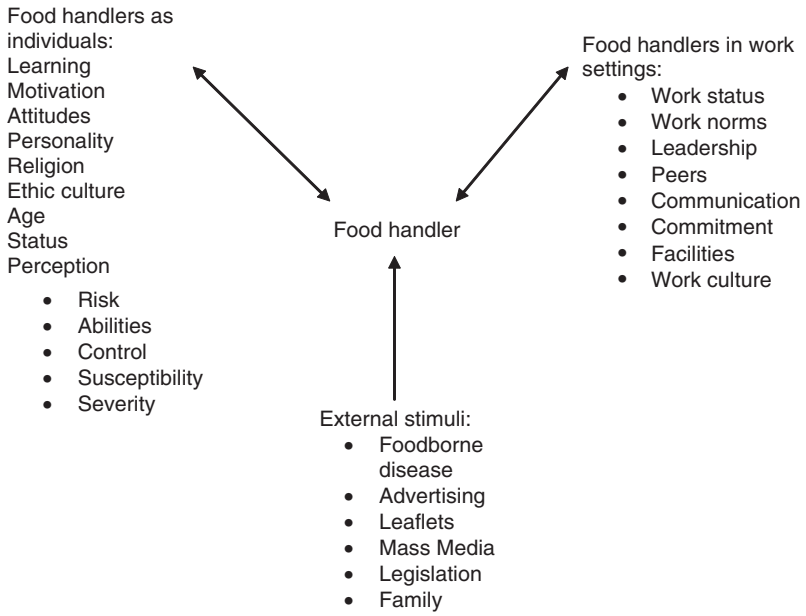

Figure 1 Factors influencing food handlers behavior. Reproduced from Blackburn CW and McClure PJ (eds.) (2009) *Foodborne Pathogens: Hazards Risk Analysis and Control*, 2nd edn. Boca Raton: WP/CRC Publishing.

is no soap. These models include the element of subjective norm, which considers the perceived beliefs of others and the individual's desire to comply with those beliefs.

One model that has been applied to food hygiene behavior is the health belief model (HBM). However, this model has been criticized as being more a catalogue of variables rather than a model. The health action model combines elements of the HBM with the TRA. Other models exist and, although they vary in structure, they can provide a basis for understanding and studying food hygiene behavior and a list of target areas for interventions to focus on. Considering these at the time of hygiene training could help to make the training more effective.

Another model that has attracted interest for use in consumer health education is the transtheoretical model developed by Prochaska and Diclemente. This model is considered to be suitable for social marketing applications and suggests that behavioral change is not usually instantaneous but is part of a series of five stages of change comprising precontemplation, contemplation, preparation, action, and maintenance. Use of this model for audience segmentation at an appropriate stage of change has been proven successful for a variety of health-related behavioral initiatives. What is clear is that food handlers (commercial or consumers) need to know about food safety practices and the underlying reasons for their implementation in order to prepare food safely. This usually requires knowledge transfer of some description which is usually by formal or informal learning/supervision or education.

Training and Commercial Food Handlers

In an attempt to improve food safety practices, legislation in a number of countries requires that all food handlers are supervised, instructed or trained in food hygiene matters commensurate with their work activities. This has in part resulted, in the UK, in an estimated 5 million food handlers receiving formal or certificated training over the past 10 years. This may only represent a fraction of all food handlers and there is evidence that businesses are still not complying fully with training requirements. Some countries are keen to encourage standardized food hygiene training. However, there is debate concerning the most appropriate type and nature of the training and whether introducing competence-based training is more, or less appropriate, than that delivered to meet the needs of various external awarding bodies. The latter are often private organizations and maybe international in nature. Endorsement of their courses may be seen as giving commercial advantage or preference to one organization or one country. However, some countries are less concerned with examinations and assessing the training and are more concerned with proof of attendance on training courses. Certificated formal training is preferred by auditors and inspectors because they can easily assess the level and content of the learning. Employers often prefer this approach because in some ways it is easier and allows them to display hygiene certificates and present a positive image. There is some evidence that employees prefer more specific internal, bespoke on-the-job training or supervision, believing it is more likely to lead to competence than more formal classroom-based training. Buddying can be used as part of on the job training/supervision, especially if based on a training-needs analysis.

Food service establishments are the main location for reported outbreaks of foodborne disease. It has also been implied that many outbreaks of foodborne disease result from faulty food-handling practices with one study suggesting that food handlers' malpractices contributed to 97% of foodborne illness in food service establishments and the home. This may be due to a lack of knowledge or nonimplementation of known food safety procedures. Effective training requires planned and systematic efforts to modify or develop knowledge, skills, and attitudes through learning experiences to achieve an effective performance in an activity or range of activities. Applied to food safety, this means people will receive, know, and understand food safety advice and be motivated to practice it. This is not just about sending people on a training course and hoping they will behave hygienically afterwards. To achieve behavioral change, people need to be motivated and be provided with the resources, including time, to act hygienically. The potential importance of training has been recognized over a number of years and recommended in many influential reports. Effective training offers, potentially, the best way to reduce cases of foodborne disease, yet it is often not well documented, managed, or supported, is taken for granted, and it is often seen by some enforcement officers and management as an end in itself rather than a means to an end.

Food handlers constitute a constantly changing and dynamic workforce, and some businesses may be reluctant to train staff fearing that they might leave and work for the competitors. Evidence of successful training can be seen in the form of hygiene certificates displayed in many food service establishments and small retailers, where they may be perceived to have a marketing potential and provide reassurance to customers. However, there is uncertainty regarding who should be targeted and the efficacy of current food hygiene training in changing handling practices and reducing foodborne disease. Many training initiatives have targeted the ordinary food handler rather than supervisors/managers, although there is evidence that businesses with better trained managers (who set standards and devise procedures) may sell food of better microbiological quality and are more likely to perform better in hygiene inspections. In a number of countries, training the supervisor or person in charge is seen as the most appropriate strategy. Training in food safety should involve all levels, not just food handlers and supervisors but also senior/top managers. They may need slightly different information with strategies designed to promote positive attitudes and culture as opposed to knowledge of specific practices. It is important for managers and supervisors to show food safety leadership. Statistics, although difficult to interpret, have not shown significant reductions in notified cases of foodborne disease as a result of all the training that has taken place. It is however possible that if the training had not been delivered, the number of cases could be even higher.

Catering or food service locations may be responsible for up to 70% of general outbreaks and it may be more difficult to ensure training is effective, i.e., behavioral change may be more difficult to achieve in this sector than in larger food manufacturers. Particular problems with ensuring training is effective in food service are summarized in Table 1.

Table 1 Characteristics of the food service industry that leads to training difficulties

Characteristics of food service industry	*Problem*
Industry dominated by small businesses	Small businesses have less time, flexibility, and resources for training combined with fewer/no opportunities for in-house courses. Need to conform to wishes of training providers
High turnover of staff	Requires new people to be constantly trained, time, and cost implications
Large number of part-time workers	Greater numbers of people with limited time available to be trained
Low staff pay	Poor morale, little incentive to implement training
Low staff status/poor career structure	Poor morale, little incentive to implement training
Staff language problems and/or low educational standards	Food service often employs larger number of overseas workers or ethnic minorities who may have poor language skills. Some who do speak a language well may be unable to read or write. This can make it difficult to find appropriate food safety training aids and can cause embarrassment for people being trained
Poor access to food safety information	No technical departments, little back up and support and many small bodies do not even belong to trade or professional bodies. Owners, of small catering business may have no hygiene or business training, with little or no knowledge and appreciation of food safety
Nature of business	Food manufacturers work to stock and there is more time available to be hygienic, food service works to order and this creates lack of time to practice hygiene when demand is heavy and customers are waiting. This creates attitudinal ambivalence, although hygiene may be considered important workers feel it is more important to serve customers quickly. Large volumes of food are handled within short periods of time – uneven work patterns. This makes it more difficult to practice food hygiene consistently
Premises design and construction	The ability to be hygienic cannot be divorced from the environment in which the food is handled. Food service premises, may be in nonpurpose built, poorly designed, and constructed premises – or even no premises (street vending). Premises maybe cramped and inadequate – greater opportunity for cross contamination

It is now well recognized that the KAP approach to training is incomplete and greater use of other social cognition models is advocated. These argue that behavior is the outcome of an interaction between cognitive processes and environmental events, both of which can be affected by the overall training need and the views of interested parties. A model for effective transfer of training (**Figure 2**) and the role and influence of interested parties is presented. What people learn and whether they learn is influenced by training design and delivery, i.e., the course structure, information contained, physical learning environment, and quality of training. In addition, it is also influenced by their own internal motivation to learn and how this may be influenced by others, and their desire to comply with the wishes of others. The outcome from this is the individual's intention to behave hygienically, which can be again influenced by both the physical and social environment, the availability of the necessary facilities to practice hygiene, the operating procedures and the management systems they have to comply with, and whether there is a prevailing business culture to be hygienic. The latter are very important in determining whether the acquired learning is, or not, implemented. The sum of the individual food handler's practices gives rise to the collective operational food safety performance, which is an integration of the food safety management systems and food safety culture.

The likely effectiveness of training is a dynamic between the employer and the trainee. Employers should not automatically assume training will be implemented. The role of the food industry is not just about providing training, but it has very important functions in helping to create the desire for learning within their employees as well as providing the right culture/climate for this learning to be transferred into practice. This consists of identifying and maintaining behavioral food safety norms and standards, i.e., the level of hygiene expected. This is related to rewards for compliance and sanctions for noncompliance, as well as the provision of appropriate and adequate facilities to allow its implementation. Employers, and in turn employees, may display attitudinal ambivalence. Alternatively, employers may display a positive general attitude to hygiene and food safety, but they may be more negative toward the implementation of specific hygiene practices and be more concerned about making money. One of the greatest enemies of a positive food safety culture maybe an opposing economic culture where saving money is considered more important. For example, although good hygiene may be valued, managers may feel specific practices are too time consuming or inconvenient. In turn, food handlers themselves may perceive this desire to serve customers quickly or save money.

Another dilemma that may face industry concerns the type of training and who will deliver it. Options included work-based training, usually delivered in-house, or a more formal certificated training which can be delivered in-house or contracted out to one of the many training providers/consultants available. One of the concerns experienced by industry in the past, particularly with respect to externally accredited courses, has been their generic nature. This has often resulted in food handlers from manufacturing being trained with caterers or butchers and following the same general syllabus. The lack of specificity of this type of approach has been cited as one of the reasons why training can fail to change behavior. As a consequence, some countries now offer sector-specific syllabus and exams. In practice, the different sections may or may not be taught together. All trainers should provide relevant examples showing application of knowledge to specific sector work practices, although this may be difficult with large mixed

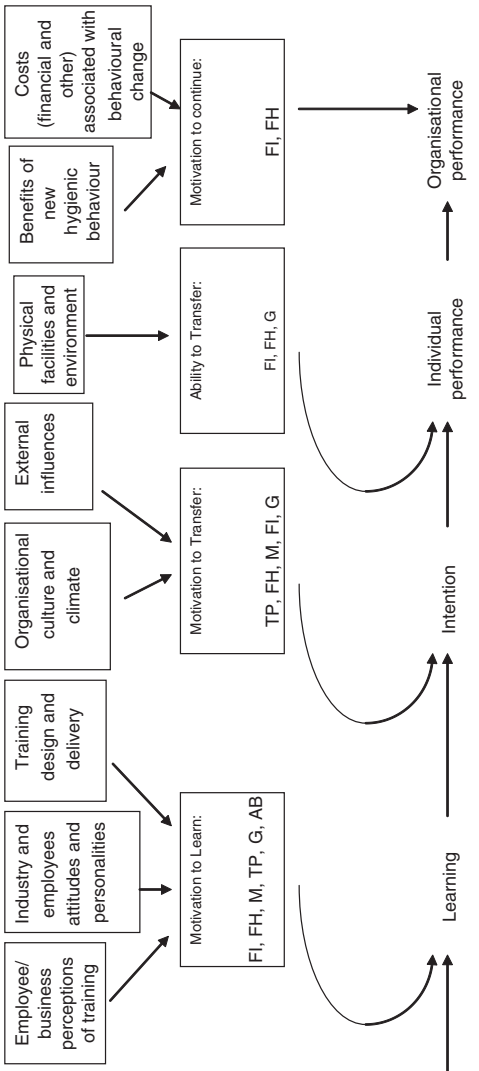

Figure 2 A model for training and behavioral change (see also **Table 2**).

classes. Some awarding bodies/training providers have attempted to provide bespoke courses for larger companies who can provide sufficient student numbers. Tables 2 and 3 provide a self-assessment checklist for employers to try to ensure maximum benefit from the training their employees receive.

A frequently neglected component of training is the requirement for refresher/remedial or update training. Most training focuses on the critical need for food handlers when they start work. Yet for longer-term compliance especially in the light of new information, refresher/remedial training is essential.

Health Education

Given that zero risk with regard to food safety is unlikely, governments and the agrifood industry have a responsibility for communicating information on risk and risk management to consumers. However, until recently, educating the consumer about food safety has been largely ignored. Consumers have an important role to play in handling food safely, yet increasingly hygiene and cooking skills are no longer taught in schools. Parents may not teach their children hygiene skills. Consumer food hygiene education and risk communication are important elements of the work of governments or their agencies, for example, the Food Standards Agency (FSA) in the UK. It is vital to ensure transparency and, where possible, consumer's participation in decision making. It is important to inform and advise them about risks in a way which makes it clear that they have the ability to manage or control those risks.

This latter aspect could be of concern to specific sectors of the food industry. If there is a problem with presence of pathogens in raw foods, for example, *Campylobacter* in poultry, the risk needs to be communicated to consumers in a way which both alerts them to the problem and informs them of how they can reduce/manage the risk. This is known as the reassurance/arousal paradox. Failure by a sector of industry to inform consumers about risk associated with a food could lead to an increase in consumer outrage. What is clear is that risk is not just about science but is heavily influenced by psychology, and experts and the public perceive risk in very different ways.

In general terms, risk communication should enable the recipients to understand the nature of the problem, help or support decision making and be unbiased. There is debate over the precise role of the government in this process – should this be restricted merely to provision of information and raising hygiene awareness or should it extend to modifying or influencing behavior? A detailed study of risk communication is beyond the scope of this article, however, it is worthwhile considering some of the pitfalls/barriers in effective risk communication for raising general consumer awareness of food safety.

Consumers acquire food safety information from a variety of sources including the home, school, and others, for example, the media including television, printed materials, and food safety campaigns. The role of the mass media for informing consumers about food safety risks is of critical importance, and the media have a responsibility to ensure that advice they provide is accurate and adequate. Although media coverage of food safety issues in recent years has heightened consumer awareness of microbiological safety, it has also increased consumer concern and confusion. The media have been responsible for sensationalizing so-called food scares whereby consumers' initial anxieties regarding the issue are commonly amplified. For example, in response to the *Salmonella* in eggs scare in 1980s/90s, consumers' risk perceptions rose to a level far greater than the actual risk. Consumers need to receive correct and consistent food safety information not only to prevent panic instigated by careless communications, but also to promote the safe food-handling behaviors in a manner that is accurate and credible.

Channels and sources generally used in public food safety communication include a variety of formats such as television, radio, posters, leaflets, newspapers, cookery books, magazines, and reminder aids. Although limited research has been conducted to evaluate the effectiveness of different intervention types, it has been reported that the potential effectiveness of different media elements, despite having common characteristics, does vary considerably. Research in the UK evaluating consumer perceptions of different sources of food safety information has shown that Environmental Health Departments and the Food Standards Agency were perceived to be the most trusted and credible organizations providing food safety information. The most preferred source of food safety information was identified as food packaging, followed by advice from a medical doctor.

Parents may not have the correct information to give to their children and there is evidence that consumers' (parents) knowledge about food safety maybe inadequate. Schools are acknowledged as important places for influencing health-related behaviors – including hygiene practices. Hygiene teaching in schools has suffered, certainly in the UK, as a result of a packed school curriculum. Recently, food safety material specially designed for schools has been produced in a number of countries and its usage could help to initiate good practice at an early age. Elements of the mass media, especially TV, offer a powerful means of influencing behavior; unfortunately they do not always project the correct message and TV cookery programs, with highly respected or admired chefs acting as a role model, can illustrate bad practices. One such show in the US even caused an outbreak of foodborne disease. Furthermore, there are suggestions that the media present conflicting advice causing confusion in consumers. In spite of this in the USA, the majority of consumers depend on the media as their primary information source. Initiatives designed to inform the consumer need to use a wide variety of strategies. Traditionally, food safety health education has excessively depended on the use of leaflets, although this is changing.

Educating the Consumer

Publicity concerning foodborne disease in the UK in the late 1980s led to the widespread distribution of standardized knowledge-based leaflets with food safety advice. Although acquisition of knowledge must precede behavioral change,

Table 2 A model for training and behavioral change: factors influencing effective training

Model component	*Interested party*	*Influence*
All stages	All parties	Business survival depends on safe food and consumers want to eat safe food. The food industry has a legal obligation to produce safe food, with government and society accepting their responsibilities. Industry has to contribute to providing the required knowledge for food safety and stimulating the desire to learn and transfer this knowledge into practice
Food safety knowledge	All parties	Accurate information on risk-based food safety practices and efficacy of control measures needs to be available. However, there is still some confusion over how some key practices should be best implemented, for example, defrosting, cooling, handwashing. Needs to cover theory and practice and promote understanding
Learning/motivation to learn	Food handlers	Individual desire for continued learning and acquiring knowledge, desire to succeed and do well, organizational commitment. Language and educational ability. Recognition of key role in food safety, and the ability and need to do things properly. Recognition of specific learning needs, response to feedback at work. Peer values. Perceived importance. Customer expectations
	Industry (management)	Recognition of importance of food safety. Job specific training. Attitudes of managers and supervisors. Assessment of specific hazards and risk and food safety management systems. Promotion and incentive schemes. Access to training. Provision of a training culture
	Training providers	Quality of delivery and training materials, role and enthusiasm of individual trainer. Quality of course materials, visual aids and learning environment . Flexibility of delivery and breadth of provision. Involvement of trainees in the learning process. Extent of precourse preparation
	Media	Adverse publicity about businesses/foodborne disease. Communication of risk. Demands for higher standards. Awareness of food borne illnesses
	Government	Stick and carrot approach to training: legislation, coupled with provision of support materials and finance for training initiatives
Intention/motivation to transfer	Food handlers	Positive reactions to training/enjoyment of learning process. Rewards, for example, enhanced status or salary for succeeding in training followed by its implementation
	Food industry	Food safety and organizational culture and climate: Appropriate cultural norms: Expression of what is desirable and acceptable. Influence of peers, managers, and supervisors, clear statement of hygienic values. Appropriate management systems to be available and in use. Customer expectations
	Training providers	Quality of course delivery. Emphasis given to the need to implement practices rather than just knowledge and rote learning and passing tests. Identification of likely barriers to hygiene implementation coupled with provision of coping strategies during course delivery
	Media	External cues toward hygiene implementation, for example, publications concerning named businesses and foodborne disease outbreaks
	Government	Overarching legislation. Communication that poor hygiene unacceptable, provision for closure of unhygienic operations and other sanctions
Individual performance/ability to transfer	Food handlers	Time to be hygienic, adequate knowledge in sufficient detail concerning theory and practices, i.e., why it needs doing and how it is to be done. Support and approbation from supervisors and peers
	Industry	Provision of all necessary facilities and equipment to practice/implement all food safety measures, for example, cleaning equipment, handwashing facilities, monitoring, design of work environment, etc.
	Government	Environmental health officers (EHOs) ensure premises of appropriate standard

(*Continued*)

Table 2 Continued

Model component	*Interested party*	*Influence*
Organizational performance/ motivation to continue	Food handler	Benefits of greater hygiene (moral and ethical values) greater consumer safety, better status and/or pay, greater job security, and satisfaction. Evaluation and eradication of personal negative aspects, for example, time, possible drying of skin from additional handwashing. Evaluation of peer values, positive feeling of doing things properly, self-satisfaction from understanding what to do and why it is necessary
	Food industry	Profitability, evaluation of cost of implementing hygiene, review, and recognition of failure costs if foodborne disease occurs (also no fines, bad publicity, compensation). Feedback from public and/or EHOs (compliance with legislation). Job description and appraisal, feedback from employees. Reduction in food waste (through better management and control), cleaner premises, integration of training, and hygiene into business management

Table 3 Employer's self-assessment checklist for effective training

Employer activity before the course	*Yes*	*No*
1 Inform the trainer of the type of food business you run and the role of the trainee		
2 Inform the training provider of any language or learning difficulties the trainee might have		
3 Check the qualifications/credentials/background/reputation of the training provider and the individual trainer		
4 Check that you have chosen the best course for your trainee. Get advice from your environmental health officer (EHO), or other food safety professional		
5 Check that the training sessions are not too long		
6 Ensure that training is not scheduled directly after work shifts		
7 Check that your trainees know how to get to the training venue. Consider the option of training at your premises		
8 Tell your trainee about the course content before training		
9 Explain how the course will be assessed. Show them sample questions		
10 Tell your trainee that he/she is expected to make an effort to learn on the course		
11 Ensure your trainee understands that training is important and is a necessity in your business		
12 Tell the supervisors about the training arrangements and encourage them to support the trainees during and after training		
13 Provide your trainee with consistent good examples of hygiene performance		
14 Devise a reward scheme for successful completion and implementation of training – based on increased status or pay		
15 Ensure all facilities are in place for hygiene implementation		
16 Ensure you provide sufficient time for trainees to attend and do any coursework.		
17 Ensure flexibility in time provision and job cover		
Employer activity during the course		
1 Encourage the supervisor to debrief the trainee		
2 Tell the training provider if the trainee has experienced any problems		
3 Recognize the course is maybe more theoretical than practical. Trainees will need to practise the hygienic behaviors at work.		
Employer activity after the course		
1 Debrief your trainee after training		
2 Collect his response to the training on an evaluation form		
3 Praise/reward your trainee for success on the course		
4 If they fail the test, mentor the trainee and encourage them the achieve success in the future		
5 Get the supervisor to check training effectiveness – hygiene knowledge and behavior		
6 Provide safety notices, and other visual aids, in the workplace to reinforce training		
7 Provide written work procedures with performance standards		
8 Check that facilities for hygiene performance are still adequate		
9 Check that work schedules (especially during peak demand) allow time for hygienic behavior		
10 Get the supervisor to provide encouragement and praise for demonstration of hygiene practices		
11 Give newly trained staff opportunities to perform trained tasks on the job		
12 Give extra responsibility to those who demonstrate competence and who motivate others		
13 Criticize and investigate hygiene failures. Learn from them, especially why. Implement corrective actions		
14 If hygiene performance is unsatisfactory, retrain on the job		
15 Carry out frequent refresher training sessions and maintain training records		
16 Encourage staff to discuss hygiene issues and make suggestions for improvements		

Table 4 The 4 Ps of marketing – marketing mix

Product	What is being offered must be acceptable and as tangible, accessible and attractive as possible. The changed behavior must not be excessively expensive, time consuming, totally impracticable, painful, etc.
Price	Decisions to act are a result of consideration of costs and benefits. Ways to minimize the cost as well as the benefits need to be addressed in strategies for behavioral change
Place	The means to implement new behavior must be readily available and convenient, for example, availability of soap for handwashing
Promotion	The message needs to be advertised in the most appropriate way. This could include leaflets/TV/cook books/magazines or individual advice, for example, health visitors

Source: Reproduced from Blackburn CW and McClure PJ (eds.) (2009) *Foodborne Pathogens: Hazards Risk Analysis and Control*, 2nd edn. Boca Raton: WP/CRC publishing.

and knowledge of the consequences of unsafe food-handling practices can enhance consumer motivation to change behavior, findings from other areas of health education suggest that although leaflets can play a role in raising awareness and supporting communication initiatives, they generally do not result in behavioral change. Leaflets can provide people with the information enabling them to change, if they are motivated and want to change. In the UK, the FSA, the Food and Drink Federation (FDF), and the Food Safety Promotion Board (FSPB) (Ireland) are the largest providers of consumer food safety information. The UK campaign was based on increasing awareness and understanding of 'The 4 Cs' (cleanliness, cooking, chilling, and cross-contamination). In the USA, a National Food Safety Initiative was set up to provide targeted information for consumers. The Fight BAC! Campaign was a product of the Partnership for Food Safety Education, which is a unique public–private partnership of government and consumer groups dedicated to increasing awareness of food safety and reducing the incidence of foodborne illness. The Campaign is based on four food safety messages ('Clean' – wash hands and surfaces often, 'Separate' – do not cross-contaminate, 'Chill' – refrigerate properly, and 'Cook' – cook to proper temperatures), and 'BAC!', a big, green bacterium character, has served as the focal point to the campaign. A recent addition to the Fight BAC! initiative has been the introduction of 'Thermy,' a cartoon thermometer. Such a character has been used to support the Fight BAC! message of 'Cook,' based on studies that have indicated there is significant risk of foodborne illness when color is used to judge if a food has been cooked to a safe temperature. Intervention materials have not only been targeted at specific food safety behaviors but also aimed at specific groups of consumers, and they have included a wide range of media formats, some of which have been interactive.

To improve food safety at an international level, The World Health Organization has developed a food safety initiative entitled 'The Five Keys to Safer Food', to teach safe food-handling practices. This initiative has been developed from the 'Ten Golden Rules for Safe Food Preparation' in the early 1990s but is simpler and generally more applicable to food handlers, especially those in high-risk groups and their caregivers. Implementation of this initiative has been undertaken by WHO regional offices, and interventions have been translated into more than 40 languages.

In addition to national educational initiatives, a number of countries undertake research initiatives for collecting information concerning consumer food safety. However, they mostly rely on self-report of behavior. A few studies have focused on actual behavior, and these have indicated that consumers often do not know or understand hygiene advice but more importantly, they often may not implement known hygiene practices. Other behavioral and attitudinal studies have identified that consumers may believe they implement adequate safe food-handling behaviors, but their perception of what is adequate has been frequently observed to be inadequate.

It has been suggested that the future of hygiene promotion should be based on the analysis of the specific needs of the target audience. A contemporary approach to structured behavioral change for health education initiatives has been the application of social marketing to a variety of public health-related disciplines including consumer food safety. Social marketing is a social change strategy that uses traditional marketing techniques from the commercial sector. The approach focuses on voluntary behavioral change to benefit the individual and society, rather than coercing consumers to adopt healthy behaviors. Use of the social marketing approach facilitates the development of a consumer-orientated strategy whereby the needs and wants of targeted consumers are actively sought and acted on in program planning, management, and evaluation. This approach requires a careful evaluation of consumer behavior and the identification of target risk groups using market segmentation. A precise message is identified and the target audience's response to, and beliefs about, the message is assessed as well as the likelihood that they will change behavior. Results from these preparatory stages are then used to plan the initiative based on marketing principles (involving the 4 Ps or marketing mix, see **Table 4**). After implementation, the initiative is evaluated, preferably based on assessment of actual behavior.

This type of approach, which has been used in both the UK and the USA (e.g., for certain cheeses eaten by the Spanish speaking community in California), is more comprehensive than an ordinary health educational approach. The latter is generally more concerned with imparting and receiving messages and with people learning facts. Social marketers argue that learning is only important if it results in the desired behavioral change. Although there are differences in marketing commercial products compared to improved safety in food-handling, not least in terms of budgets available, there are potential benefits in adopting the approach. The social marketing approach was successful in one UK campaign, but change was only achieved in the short term and concerted efforts need to consider a longer time scale. Relatively small improvements/changes in behavior could significantly reduce the costs and consequences of foodborne disease.

ANALYTICAL METHODS

Contents

Overview of Methods of Analysis for Chemical Hazards

H Senyuva, FoodLife International Ltd, Ankara, Turkey

Glossary

Analyte Residue or contaminant being targeted for analysis.
Analytical quality assurance Measures taken in the laboratory to demonstrate the validity of analytical data.
Cleanup Laboratory procedure involving concentration and purification of analyte.
Chromatography Analytical technique used for separation of analytes in gas phase (gas chromatography) or liquid phase (high-performance liquid chromatography).
Data systems Computerized means of processing outputs from analytical instruments.
Digestion Heating a food sample with strong acids to remove organic material(s).
Mass spectrometry (MS) Instrumental technique used to identify analytes by fragmentation to form unique fingerprints known as mass spectra.
Method validation The process undertaken in the laboratory to establish a set of performance parameters for any analytical method.

Introduction

Agricultural and food products are extensively tested in the laboratory to ensure they meet compositional requirements, that they are authentic, free of adulteration, and comply with regulatory limits for residues and contaminants. Additionally, processed foods need to be analyzed so they can be labeled for nutritional purposes, checked for levels of food additives, and finally any packaging system used to provide protection during transport and storage must be checked so that it does not lead to trace levels of contamination. Sophisticated techniques have been developed to facilitate this food testing ranging from field-tests used for rapid screening to complex multitarget instrumental analysis to be used in the analytical food laboratories.

Analytical chemistry has made tremendous advances over the last 10–15 years with dramatic improvements in methods of analysis exemplified by significantly higher sensitivity and vastly improved specificity of detection. The improved sensitivity has meant that detection of residues and contaminants in foods at parts per billion (ppb) levels (ng g^{-1}) is now carried out routinely. Improved specificity means that complex food matrices can be analyzed, with a high degree of confidence in the correct identification and accurate quantification of the targeted residue or contaminant. With increased specificity, the time spent on sample extraction and cleanup has been reduced and many multimethods have been developed enabling screening for a large number of analytes in a single analytical run.

Despite these significant developments in trace analysis, one should not underestimate the degree of difficulty in testing foods for residues and contaminants. First, foods are complex and diverse in composition making it difficult to develop a single method to cover all food types. Second, the limits for permitted levels of residues and contaminants in foods that are required by regulations in some instances are exceedingly low. This means that high concentration factors are required and sample preparation of necessity means removing as much of the background co-extractives from food as possible, before instrumental analysis.

A trend that has been apparent in recent years has been an increased emphasis on ensuring the quality of analytical data. It is now generally accepted that to demonstrate reliability of data, food laboratories should be accredited to the International Organization for Standardization's (ISO) Standard 17025, should only use validated methods of analysis, and should prove analytical competence through participation in proficiency testing.

 doi:10.1016/B978-0-12-378612-8.00047-0

Sampling

It is widely acknowledged, but frequently forgotten, that any analytical result is only as good as the sample that has been taken and submitted to the laboratory. The sample submitted must be representative of the batch or lot from which it was taken. It is well established that for various reasons, residues and contaminants are rarely evenly distributed throughout a large batch of material. This lack of homogeneity is extreme in the case of mycotoxins, where fungal infection is a random process and individual nut kernels or individual grains can be highly contaminated, whereas the bulk of the material might be essentially free of contamination. This same variability has been found with pesticides, where uneven spraying can result in some individual fruit or vegetables having higher residue levels, as a result of their location within an orchard or agrochemical treated field.

Generally sample sizes of only 50–100 g are required for analysis in the laboratory, but for that sample to be representative a significantly larger sample must be initially taken, thoroughly homogenized, and then a subsample taken for laboratory testing. Protocols known as 'Sampling Plans' have been developed that must be followed, and these dictate the total sample weight comprising a minimum number of subsamples and the points from which samples should be taken from throughout a food consignment.

Sample Preparation and Homogenization

When a sample is received by the laboratory, it is necessary that it undergoes appropriate preparation before subsampling for analysis. The type of preparation will depend on the specific matrix. Liquid foods like oils require only mixing, whereas dry foods like cereals can be blended to a fine powder in a hammer mill. Some products such as oily nuts can be blended to a paste, but in other instances (e.g., dried figs) it may be necessary to add water (or another solvent) to form a slurry during blending. If any of the target analytes are volatile, it may be necessary to blend the sample at low temperatures to avoid losses and this is known as cryogenic milling. This procedure is frequently used for sample preparation for the analysis of volatile pesticides in fruit and vegetables.

Screening Methods (Field Tests)

In some situations, it is highly desirable to test raw materials for residues or contaminants before transport, from the point of production to the factory for subsequent food processing. For example, it is desirable to test milk at the farm for veterinary drug residues or aflatoxin M_1 before mixing milk from a number of sources in a tanker. It is also desirable to test individual animals at the point of slaughter for illegal substances. In these instances, rapid field tests which do not require sophisticated laboratory facilities are employed. Also, many raw materials are produced in developing countries, which do not have access to sophisticated laboratory facilities, but nevertheless need to ensure that products are free of contaminants before export.

Screening Methods

Screening for Single Compounds

There are a wide range of different screening assays targeted at measuring individual analytes. These 'test kits' are simple and 'easy to use' and can be semiquantitative or can be developed to give 'YES' or 'NO' answer above or below a predetermined regulatory limit. These kits are invariably based around antibodies and the format can range from classical enzyme linked immunosorbant assay (ELISA) style through to dipsticks, test cards, and lateral flow devices. The majority of this type of test kits have been developed for screening for individual mycotoxins (aflatoxin B_1, ochratoxin A, deoxynivalenol, and zearalenone) and for individual veterinary drug residues (e.g., chloramphenicol). Results are read visually or using simple reading devices which can be battery operated and suitable for field use.

Multianalyte Screening

Some screening tests are widely used to indicate the presence of classes of compounds rather than individual analytes. Microbial inhibition assays such as Premi® Test (R-Biopharm AG, Darmstadt, Germany) or Delvotest® (DSM Food Specialities, Delft, The Netherlands) can be used to test for the presence of classes of antimicrobial substances in various matrices such as fresh meat, fish, eggs, honey, urine, and feed. The CALUX® assay (BDS Biodetection Systems b.v., Amsterdam, The Netherlands) is a dioxin/PCB screening test categorized as a reporter-gene assay. It can measure levels of dioxins and polychlorinated biphenyls (PCBs) faster and is less expensive than traditional instrumental methods, and gives total concentrations of the regulated biologically active dioxins/furans and PCBs.

Portable Instruments

There is considerable interest in miniaturization of laboratory instruments to develop portable hand-held devices that can be used in the field or food factory. This is still an area of development, but already handheld Raman and Fourier transform infra-red (FTIR) spectrometers have been designed for rapid and accurate identification of unknown chemicals directly in the field. Handheld X-ray fluorescence (XRF) analyzers have been purpose-built for measuring levels of metals anywhere and anytime with accurate results available in seconds, rather than the hours or days it can take for traditional laboratory testing. The feasibility of using portable devices for testing has been clearly demonstrated, but improvements in sensitivity and handling diverse food types remain as challenges.

Instrumental Methods

Sample Extraction

Although some new approaches are being developed to directly analyze foods, in general an extraction step is normally

required. This involves blending the foodstuff with a suitable solvent, then filtering or centrifuging to separate solid material from the blended extraction mixture. Although various innovative approaches to improve extraction such as use of supercritical fluids (SFE), microwave-assisted extraction, accelerated solvent extraction (ASE), or cloud point extraction have been developed, these have never really superseded classical solvent extraction, which remains the most widely used approach.

Sample Ashing Techniques (for Metals)

Sample preparation techniques for the analysis of metals of food safety concern such as mercury, cadmium, and lead involve removal of the organic matrix and dissolution of the metals of interest in acid solution. The destruction of organic matter can be achieved by dry ashing in a muffle furnace at 450–500 °C, but this risks loss of several elements by volatilization. Wet ashing is preferred by digestion of the organic material, for example, in *aqua regia* (three parts nitric and one part hydrochloric acid) by heating in an open or closed vessel (digestion bomb). In the past 10 years, microwave techniques have largely replaced conventional heating in most laboratories. Here the sample is digested in a polytetrafluoroethylene bomb and the process can be completed much more quickly than with conventional digestion/ashing techniques.

Sample Cleanup

Sample cleanup involves purification of the initial crude extract to remove background co-extractives, and at the same time selectively concentrating the target analytes(s) in the extract. The efficiency of the extraction and cleanup steps is measured as 'recovery' which should generally be better than 70% for an analytical method to be acceptable.

Solid-Phase Extraction

Traditionally, small glass columns packed with silica gel or another adsorbent were used for sample cleanup. However, these have now been largely replaced with plastic prepacked cartridges, which are commercially available containing a wide choice of different solid phase materials. Careful choice of a suitable solid-phase extraction (SPE) cartridge and development of appropriate conditions for loading the sample extract and eluting the target analyte(s) remains at the heart of most analytical methods. Reverse phase C-18 SPE cartridges are probably the most widely used, with anion exchange (SAX) and cation exchange (CAX) columns being selected for more polar analytes.

Quick, Easy, Cheap, Effective, Robust, Safe Method for Pesticides

One of the biggest developments in sample cleanup for pesticides in fruits and vegetables has been the introduction of the 'Quick, Easy, Cheap, Effective, Robust, Safe' (QuEChERS) method. This dispersive SPE method involves weighing the food sample into a tube, shaking with acetonitrile, adding magnesium sulfate and sodium chloride, followed by internal standards before centrifugation. An aliquot is taken and further purified with sorbent, centrifuged again, and diluted with acetic acid and 'analyte protectants' before direct instrumental analysis. This simple procedure can be carried out rapidly in a single tube and has been demonstrated to give good recoveries for a wide range of pesticide residues.

Immunoaffinity Column Cleanup

Probably the most effective cleanup technique is based on the use of antibodies which have been raised against the target analyte. The antibodies are linked to a gel matrix and contained in a small plastic column known as an immunoaffinity column (IAC). The crude sample extract or even liquid foods themselves (such as milk) are passed directly through the column, and the analyte is selectively extracted and becomes tightly bound to the antibody. The column can be washed to completely remove any potential interferences, and finally the analyte–antibody bond is broken and the target analyte is eluted in solution. These columns have found widespread acceptance as the definitive cleanup method for analyzing mycotoxins. Immunoaffinity columns are commercially available for individual mycotoxins or combinations of two or three mycotoxins which commonly co-occur. Immunoaffinity columns have also been employed for the cleanup of samples for the analysis of veterinary drugs, pesticides, marine biotoxins, process and environmental contaminants as well as vitamins.

Size-Exclusion Chromatography

Size-exclusion chromatography (also known as gel-permeation chromatography) is a cleanup technique that is useful as it can facilitate collection of a fraction from the sample below a predetermined molecular weight. This technique is not widely used for sample cleanup, although for analysis of oils and fats it is very useful for removal of the bulk of the lipids which is difficult with alternative cleanup methods.

TurboFlow Technology

A recent innovative development in sample preparation employs a combination of size exclusion and SPE in a reusable column operating under 'turbulent flow' conditions. This technology (ThermoFisher Scientific, Franklin, USA) is used in an automated mode, which is directly coupled to the detection system, and provides a very cost-effective approach for routine analysis of large numbers of sample.

Separation Techniques

Despite extensive sample cleanup, it is normal in the final stage of trace analysis to carry out chromatographic separation by either gas chromatography (GC) or liquid chromatography (LC). Lower molecular weight analytes that are sufficiently volatile or can be derivatized to increase volatility are generally analyzed by GC, whereas for nonvolatile analytes LC is the chosen approach.

Gas Chromatography

Gas chromatography involves injecting the sample extract (0.2–10 μl) via a heated injection system onto a capillary column with an internal diameter of typically 0.25 mm and a

length of typically 25–50 m. The column is coated internally with a thin film (e.g., 0.1–0.25 μm) of nonvolatile liquid (stationary phase) and gas is passed through the column at a flowrate of typically 1–2 ml min^{-1}. Separation of a mixture injected into the column takes place by partition between the gas and liquid phases, with the more soluble compounds being retained and the less soluble passing more quickly through the column and eluting first. The column can be operated at a fixed temperature (isothermal run), but more normally the temperature is raised from a starting temperature to such a point as all injected compounds have been eluted from the GC column (temperature programming). A detector (see Sections Nonspecific Detection – Gas Chromatography and Mass spectrometry – Gas Chromatography Mass Spectrometry, Liquid Chromatography Mass Spectrometry, and Inductively Coupled Plasma Mass Spectrometry) is connected to the column outlet so that compounds, which have been separated, can be monitored one by one as they elute. Capillary GC has a high separating power with a wide choice of the column stationary phases enabling the GC analysis to be tailored to engineer the desired separation of analyte from other compounds.

Liquid Chromatography

Liquid chromatography involves injecting an aliquot of the sample extract (typically 10–50 μl) onto an LC column with an internal diameter of 3–5 mm (columns ranging in internal diameter from 0.050 to 4.6 mm or even larger are used for performing large-scale preparative chromatography) and a length of typically 50–250 mm. The column is packed with solid support (3–5 μm particle size) coated with a film of stationary phase. A liquid solvent (mobile phase) is passed through the column at high pressure at a flowrate of typically 0.5–2 ml min^{-1}. Separation of any mixture injected into the column takes place by partition between the liquid phase on the high-performance LC (HPLC) column and the mobile phase, with the more soluble compounds being retained and the less soluble passing more quickly through the column and eluting first. The column is held at a fixed temperature. A detector (see Sections Nonspecific Detection – Gas Chromatography and Mass spectrometry – Gas Chromatography Mass Spectrometry, Liquid Chromatography Mass Spectrometry, and Inductively Coupled Plasma Mass Spectrometry) is connected to the column outlet so that compounds, which have been separated, can be monitored one by one as they elute. The stationary phase is generally made up of hydrophobic alkyl chains ($-CH_2-CH_2-CH_2-CH_3$) that interact with the analyte. Such reverse-phase C-18 LC columns are the most widely employed, although there are a wide range of columns which can be used depending on the desired separation.

Detection and Measurement Systems

Nonspecific Detection – Gas Chromatography

The most widely used detector in GC is the flame ionization detector (FID) which gives a mass response depending on the carbon content of the eluting compound. This is a very robust detector, but is nonspecific in that it responds to all compounds and lacks sensitivity. Other detectors are available with varying degrees of specificity such as the nitrogen/phosphorus, flame photometric, and electron capture detectors, which respond to specific elements such as nitrogen, phosphorus, sulfur, and halogens in the target analyte. However, for additional specificity most analysis for contaminants and residues would normally nowadays be conducted by GC mass spectrometry (GC/MS).

Nonspecific Detection – Liquid Chromatography

In LC, the UV detector is a general purpose detector equivalent to the FID. The diode array detector is similar to UV detector but can operate at a number of different wavelengths thereby providing increased specificity. The LC fluorescence detector offers both high sensitivity and good specificity, but its use is limited to a relatively small number of contaminants that have native fluorescence. The fluorescence detector is the detector of choice for routine analysis of mycotoxins such as aflatoxins, and can also be used for the analysis of polycyclic aromatic hydrocarbons (PAHs).

Atomic Spectrometry for Metals

There are a variety of different instrumental techniques which can be employed to analyze an acid solution containing dissolved elements. The most commonly used technique is known as atomic absorption spectrometry (AAS) in which a flame is used as an atomizer into which the liquid sample is aspirated. There are other variations used to atomize the sample, such as graphite furnace atomization (GFAAS) or electrothermal atomic absorption spectrometry (ETAAS). Analyte species are introduced into a thermally or electrically energetic medium such as a flame, arc, or plasma where molecular bonds are broken. Once the analyte species are converted into free atoms and atomic ions, their determination may be carried out by atomic absorption or atomic emission.

Mass spectrometry – Gas Chromatography Mass Spectrometry, Liquid Chromatography Mass Spectrometry, and Inductively Coupled Plasma Mass Spectrometry

In trace analysis, for the determination of low levels of residues and contaminants, the preferred identification and detection system is undoubtedly the mass spectrometer. The mass spectrometer can be directly coupled to either a GC (GC/MS) or an LC (LC/MS) system. In both cases, the analyte(s) can potentially be identified from its full scan spectrum or the instrument can be used as a sophisticated detector in a mode known as selected ion monitoring (SIM). When several ions are monitored simultaneously in SIM, this offers a reasonably high degree of specificity. This can however be further enhanced by using what is known as tandem mass spectrometry (MS/MS). In this mode of operation, the analyte is initially fragmented in the source of the mass spectrometer to form a characteristic pattern of ions. One or more of these fragment ions are then selected and subjected to conditions to induce further fragmentation (known as collision-activated decomposition). The process whereby these decomposition ions are subsequently monitored is known as multiple reaction monitoring (MRM).

Most MS involve measurement of the nominal mass of the ions (low resolution) which takes no account of the small

differences in mass due to different isotopic abundances of the constituent elements. High resolution MS takes account of these differences enabling accurate mass measurement to be undertaken providing an even greater degree of specificity from the instrument. Typically, dioxin analysis needs to be carried out using high resolution GC/MS in order to separate congeners of the same nominal mass which cannot be separated chromatographically. A resolution of 10 000–15 000 in GC/MS is usually adequate for dioxin analysis. A more recent development has been in LC/MS where time of flight (TOF) and Orbitrap instrumental configurations have become commercially available. LC-TOF/MS instruments offer approximately 20 000 resolution, whereas Orbitrap instruments can offer resolution up to 100 000. Both instruments (Thermo-Fisher Scientific, Bremen, Germany) are still relatively expensive and are still the province of research rather than routine food control laboratories.

A mass spectrometer can also be used for metal analysis by combining a high-temperature inductively coupled plasma (ICP) source with a mass spectrometer (ICP-MS). The ICP source converts the atoms of the elements in the sample to ions. These ions are then separated and detected by the mass spectrometer. Inductively coupled plasma-mass spectrometry has many advantages over other elemental analysis techniques such as AAS and optical emission spectrometry with detection limits for most elements equal to or better than those obtained by GFAAS and its ability to obtain isotopic information. In addition, ICP-MS is a fast, multielemental technique. It is however important to acknowledge that several elements including S, Se, B, Si, P, Br, I, K, and Ca have high detection limits via ICP-MS. In the case of I and Br, this is due to the fact that very few positive ions are formed in the ICP for these elements.

Data Systems and Data Analysis

Modern instruments are normally computer controlled, and this computerization covers optimization of instrumental parameters, control of auto-samplers (for running unattended) through to capture, and handling of data. The simplest of systems such as an LC with a UV detector may only require electronic recording of a chromatogram and integrating one or more peak areas. By comparing the area of the analyte peak with that of a standard, the concentration of the analyte can be estimated. More complex analysis might involve screening of 200 or more pesticides in a sample extract by LC/MS/MS. For each retention time, for each pesticide, two or more ion ratios need to be checked and compared with standards, and MRM areas of ions need to be measured. The more sophisticated the detection system, for example, high-resolution LC/MS, the more complex the data sets that are generated, and the more processing required to check the data quality and to compute the results into concentrations.

Chemometrics

In some situations, the complex datasets generated from instrumental analysis are used to characterize food samples, as being part of a certain population rather than making a simple analytical determination. Statistical techniques known as chemometrics are used to examine a dataset of known samples and to select those parameters which 'characterize' samples in terms of their 'sameness,' and those parameters that can be used to distinguish samples in terms of their 'differences.' These statistical techniques recognize that no two food samples within the same population are identical, but by understanding the natural variability within a population it is possible to estimate a probability that two samples in fact come from different populations. These techniques might be used to distinguish geographical origin of honey or distinguish organic from conventional produce or distinguish wild from farmed fish. In all these three examples for the same food product, no single parameter can distinguish the different types, but multiple variables processed with chemometrics can distinguish one from another.

Laboratory Information Management Systems

Running a modern food testing laboratory is a complex management challenge, as large numbers of samples are received daily, each may require different measurements, there are complex calculations, and reports and certificates must be generated. Quality assurance checks need to be undertaken and recorded for accreditation purposes and all data need to be archived. A Laboratory Information Management System (LIMS) is a customized database that serves multiple needs for sample and data handling. A LIMS typically is used to track samples throughout the laboratory from receipt to storage and archiving (bar-coding is effective). LIMS is usually set up to process the huge amounts of electronic data that are generated by modern instruments and to make suitable calculations of concentrations of residues and contaminants. The LIMS can even be used to automatically generate a certificate using a template for specific customers. Although there can be a high initial set-up cost to customize LIMS, the business case is not difficult to make in terms of cost savings to the testing laboratory.

Method Validation

Once any method of analysis has been developed to determine a food additive, residue, or contaminant, it is necessary to establish how well that method actually performs in practice. This process, whereby the performance characteristics of the method are established, is known as method validation. Method validation can be carried out in a single laboratory (the method originator's laboratory) or preferably should be tested among a number of laboratories.

In-House Method Validation

In-house or single-laboratory method validation is the most basic validation that must be carried out to establish the method performance and is the minimum required for accreditation purposes. Spiked and naturally contaminated samples are employed to establish the limit of detection (LOD), limit of quantification (LOQ), recovery, and between-day repeatability.

Inter-Laboratory Method Validation

Although a method may appear to perform well in the hands of the originator and the performance characteristics from in-house validation may be acceptable, in practice it is frequently the case that some steps in the method may be badly described or the method itself may be instrument specific and thereby difficult to reproduce elsewhere. For this reason, the recommended way to demonstrate that a method has widespread acceptability is to carry out a full inter-laboratory method validation (sometimes known as a collaborative study). In such a study, a group of a minimum of 12 laboratories is requested to scrupulously follow the proposed method and is required to analyze coded blind duplicate samples (both naturally contaminated and spiked at different levels). The results from individual participants are usually kept confidential by the study organizer, although the study results are normally published if acceptable performance characteristics are obtained. A minimum of eight sets of acceptable results are necessary after outliers have been removed during statistical analysis of the validation data.

A number of international bodies such as AOAC International and European Committee for Standardization publish validated methods as their own Official Methods or Standards, respectively. In such cases, the validation data have to be submitted to the organization, where it is closely scrutinized to ensure compliance with the AOAC/International Union of Pure and Applied Chemistry/ISO harmonized protocol, and to decide if the performance of the method itself justifies acceptance. In a number of countries, only prescribed official methods can be used for food-control purposes. In the EU, a criteria-based approach is used. This approach means that the minimum performance characteristics of the enforcement method are published in a Directive, and food control laboratories have a 'free choice' of methods provided the chosen method performs as well or better than the published standards.

Method Performance Characteristics

Method performance characteristics form an objective basis by which methods can be selected to ensure they are 'fit for purpose,' and can be used to compare the relative merits of different approaches. These parameters, however, do not provide any insights into costs, speed, or robustness of methods which have to be separately assessed.

Limit of Detection

The LOD is the smallest signal from the analyte that can be reliably seen against the background noise from the instrumental system. There are various ways of establishing the LOD based on different statistical measures, but the simplest and most commonly used approach is to estimate the amount of analyte which can give a signal three times the average background noise.

Limit of Quantification

The LOQ is the smallest signal from the analyte that can be reliably measured against the background noise from the instrumental system. There are various ways of measuring the LOQ based on different statistical measures, but the simplest and most commonly used is a signal 10 times the average background noise.

Recovery

The method recovery is the amount of analyte measured as a percentage of the amount present in the initial food sample. Usually spiking of blank food samples is carried out with known amounts of analyte(s), and the sample is taken through the complete analytical procedure and then the amount in the final extract is measured. Losses of analyte(s) can occur throughout the analytical procedure, for example, incomplete extraction or during cleanup. In general, acceptable methods should have recoveries from 70 to 110% and this range for recoveries is used as the target range in criteria-based approach.

Accuracy

The method accuracy is the closeness of the measured value to the true value. Although spiking gives some indications of accuracy, spiked samples may behave differently from naturally contaminated ones. Therefore, wherever possible accuracy is measured by comparing 'given values' for the analyte(s) with one's own 'determined values' for the test material. The given values for the test material might be those obtained by a number of expert laboratories in the case of a certified reference material, or consensus value in the case of surplus proficiency test material. In either case, one would expect to obtain measured values within the 95% confidence interval for the prescribed values of the test material.

Method Precision (RSD_r and RSD_R)

The method precision is expressed as both repeatability (r) and reproducibility (R). The repeatability is the within-laboratory precision, which can be determined from a single-laboratory validation and reflects variation when the method is performed in the same laboratory by the same analyst using the same equipment. The reproducibility (R) is the between-laboratory precision which can only be determined from a full inter-laboratory validation and reflects the variation when the method is performed by different analysts in different laboratories using a range of different equipments. Both r and R are frequently reported as percentage relative standard deviations (RSDs). The RSD_r is invariably less than the RSD_R and both are dependant on the amount of analyte being determined. In general, the lower the amount of analyte being determined the higher the method precision. Typical requirements for an analyte which is regulated at levels between 1 and 10 ng g^{-1} (ppb) would be that the RSD_r should be better than 20% and the RSD_R should be better than 30% with a recovery from 70to 110%.

Conclusions

Food analysis has made tremendous advances in the past 10–15 years and we can now measure more and more chemicals in

foods at incredibly low levels. Not only has sensitivity improved, but there has also been a focus on analytical quality, and there is a far greater confidence that analytical results are more meaningful than was the case some years ago. For the future the focus will probably not be on achieving lower limits of detection, but on improving the speed of analysis and reducing costs of analytical measurements.

Transmissible Spongiform Encephalopathy Diagnosis

B Oesch, Neurotune AG, Schlieren-Zürich, Switzerland

Glossary

Bioassay A scientific test in which the effect of a substance on a living organism is investigated. Bioassays are commonly used to measure the relative strength of a pharmaceutical substance or the toxic effects of environmental pollutant in an animal species. Bioassays in animals are the 'gold standard method' for estimation of the concentration of prions causing transmissible spongiform encephalopathies (TSEs).

Enzyme-linked immunosorbent assay (ELISA) A biochemical test by which antigen (e.g., prion protein (PrP)) can be detected and measured by reaction with an antibody directed to the antigen. Often it is also possible to detect antibodies against the pathogen, produced by the host, however, for prions this is not possible as the prion does not seem to be recognized by the host as foreign.

Histology Histological examination of thin sections of formalin fixed and paraffin embedded tissue has revealed the presence of pathological changes (in particular vacuolation also known as spongiform changes) in the brain tissue. The preserved tissue is often stained, usually with haematoxylin and eosin (H&E), before examination by light microscopy.

Immunohistochemistry Immunohistochemistry builds on the preparation of sections of fixed tissue as described for histopathology, by identifying deposits of PrP with the application of antibodies to PrP followed by secondary antibodies allowing the visualization of staining patterns that are indicative of infection. By using a range of antibodies that target different PrP epitopes as well as different pretreatments of the tissue, this approach can offer a degree of discrimination between strains of prion.

Western immunoblot/effect of glycosylation Western immunoblotting is an analytical technique for the study of proteins, which, after appropriate extraction and preparation of the protein to be examined is subjected to electrophoresis through a gel. This enables molecules to be separated according to their rate of migration through the gel, and these are subsequently detected by the application of antibodies to the protein (here PrP), usually after transfer of the protein from the gel to a membrane that will permit such treatment. Sugar molecules are normally found attached to the PrP, but when studied by the use of biochemical tests, such as immunoblotting, the protein is normally cleaved by incubation with proteases. When the ensuing mix is visualized after electrophoresis through gels, the digested protein becomes segregated by molecular weight in the gel, and visualization by combination with antibodies to PrP usually highlights three distinct bands. The high molecular weight band has two sugar molecules attached (diglycosylated), the middle band has one (monoglycosylated), whereas the lowest has none (unglycosylated). The position of this lowest band, relative to control material from known isolates, is increasingly used to discriminate between isolates, and may potentially represent strain differences. The di- and mono-glycosylated bands are also used to discriminate between isolates, but result in more complex interpretations that are particularly influenced by differences in methodologies between laboratories.

Introduction

The appearance of bovine spongiform encephalopathy (BSE) in the middle of the 1980s immediately prompted the (unpleasant) question regarding the distribution and frequency of the disease in individual countries, Europe, or other parts of the world. This led to the development of various diagnostic tests. Initially the disease was discovered because of its clinical symptoms, yet it became clear that more accurate and more rapid diagnostic methods would be needed in order to control the spreading of the disease as well as to limit the exposure of humans to BSE contaminated meat. However, diagnosis was also a political issue as the detection of BSE cases in a country often led to severe trade restrictions by other, presumably BSE-free countries. This also led to the specification that BSE tests should be 100% specific and sensitive, something which is technically hardly achievable. With progressively better diagnostic methods and extended surveillance, it became clear that BSE was more widespread than originally admitted by the veterinary authorities and that carcasses from BSE-infected animals would enter the human food chain. These findings lead to a culmination in November 1999 with the introduction of the "over 30 months"-rule, that is, animals over 30 months had to be tested with an European Union (EU) approved rapid

BSE test before entering the food chain. As this mandatory testing lead to a strong surge of BSE cases, testing was not questioned for the next 6–8 years. In 2008, 15 EU member states requested a relaxation of the BSE monitoring program based on a favorable risk assessment by the European Food Safety Authority (EFSA) and subsequently these countries received permission to raise the age limit for healthy slaughtered cattle from 30 to 48 months. In 2009, the age limit was raised to 72 months and in 2013 testing of healthy slaughtered cattle was stopped and the EU BSE monitoring program was revised to testing only at risk sub-populations of cattle. In hindsight it is clear that diagnostic tests have been accentuating the BSE crisis but in the end also provided the data to re-assure consumers and to point to residual sources of infection.

Clinical Diagnosis

Historically, transmissible spongiform encephalopathies (TSEs) were diagnosed clinically following examination of suspicious animals with abnormal neurological behavior and the disease was confirmed postmortem by histopathological examination of brain tissue (passive surveillance). With the introduction of routine monitoring programs using rapid screening tests in healthy slaughtered cattle (active surveillance) in the EU and other countries, BSE could be diagnosed also in apparently healthy cattle in the preclinical stage. Classical BSE affects adult cattle and manifests from as early as 20 months to 22 years of age with a peak incidence in animals aged 4–6 years. Like in all TSEs, the clinical picture of BSE is characterized by a slowly progressive course with early signs consisting of subtle behavioral changes, hyperreactivity, and incoordination. As the disease progresses, frequent signs include apprehension, hypersensitivity to touch and sound, abnormalities of posture, and gait involving low head carriage, arched back, abducted, stiff, straight and straddled hind limbs, hind limb ataxia, swaying, trotting, hypermetria, and falling as often shown in videos (http://www.defra.gov.uk/vla/science/sci_tse_rl_video.htm). Further signs described include overreaction to tactile, visual or auditory stimuli, startle response to new objects or small gaps in the ground, excessive licking of the nose or tremors of the head. Individually many of these signs may not be diagnostic, however a combination of clinical signs becomes highly accurate. Frequently observed extraneurological signs in the clinical phase include deterioration in body condition accompanied by weight loss and reduced milk production. The clinical course usually extends over weeks or months and can be as short as 2 weeks or as long as a year or more.

Bioassay

Animal bioassays have been used extensively in TSE research to determine the amount of infectivity and as a gold standard for diagnostic testing. However, bioassays are severely limited in their widespread use by the length of time it takes to obtain results (e.g., cattle material into cattle takes at least 3 years) and for the often used rodent models (hamsters, mice) there is a species barrier effect apparently reducing the amount of infectivity in a given sample. Yet animal bioassays remain the only method to measure directly the infectious agent and are, therefore, the most sensitive assay available for the detection of TSE agents. Although ruminants were used early on to assay for infectivity in sheep and goats, bioassays for research purposes improved dramatically with the introduction of rodent-adapted scrapie strains and their titration by intracranial inoculation of mice and hamsters. A further breakthrough in the detection of TSE agents by bioassay was achieved by the genetic engineering of PrP-deficient (knockout), mutant and transgenic mice. In particular, transgenic mice expressing high levels of heterologous PrP^{C} (e.g., human or bovine) on an otherwise PrP knockout background have been very valuable as a diagnostic tool for the detection of human or bovine prions. Transgenic mice expressing high levels of bovine PrP are approximately 10 times more sensitive than cattle and more than 1000 times as sensitive as wild-type mice to infection with BSE prions.

Histology

With the uncertainties surrounding the etiologic agent of TSEs, a definite diagnosis cannot be made by isolation of the infectious agent from tissues of an infected animal. Therefore, routine laboratory diagnosis relied originally on the identification of pathognomonic markers of the disease by histopathological examination of brain tissues. The most prominent pathological feature is a widespread vacuolation of neuronal cells giving brain tissue a sponge-like appearance, hence the name spongiform encephalopathy. Astrocytic gliosis is also regularly seen although it is more consistently seen in scrapie than in BSE. The extent of astrocytic gliosis in brain tissue can be assessed by immunohistochemical staining using antibodies to the astrocytic marker protein glial fibrillary acidic protein (GFAP). The third morphological feature, amyloid plaques, albeit not consistently seen in all TSEs, are composed of abnormal PrP (PrP^{Sc}) and exhibit the typical fluorescence birefringence of amyloid after staining with the dye Congo Red. During the BSE epidemic in the UK, investigations on brain lesions of cattle with BSE led to the identification of the medulla oblongata (at the level of the obex) as the most suitable diagnostic target site for histopathological examination and this method was used as reference diagnostic tool for the confirmation of a clinical suspect case of TSE.

Immunohistochemistry

With the identification of the disease-specific form of the PrP that accumulates in the brain of animals infected with TSE agents, antibodies to PrP were exploited to perform immunochemical staining of formalin-fixed, paraffin-embedded tissue sections. Studies on field cases of classical BSE and experimentally infected BSE comparing the lesion profile determined by histopathology and PrP^{Sc} deposits by immunohistochemistry, confirmed that the obex region of the medulla oblongata is the primary target site for the TSE agent in the brain. Because of its high sensitivity and specificity, immunohistochemistry for PrP^{Sc} has replaced histopathology as the

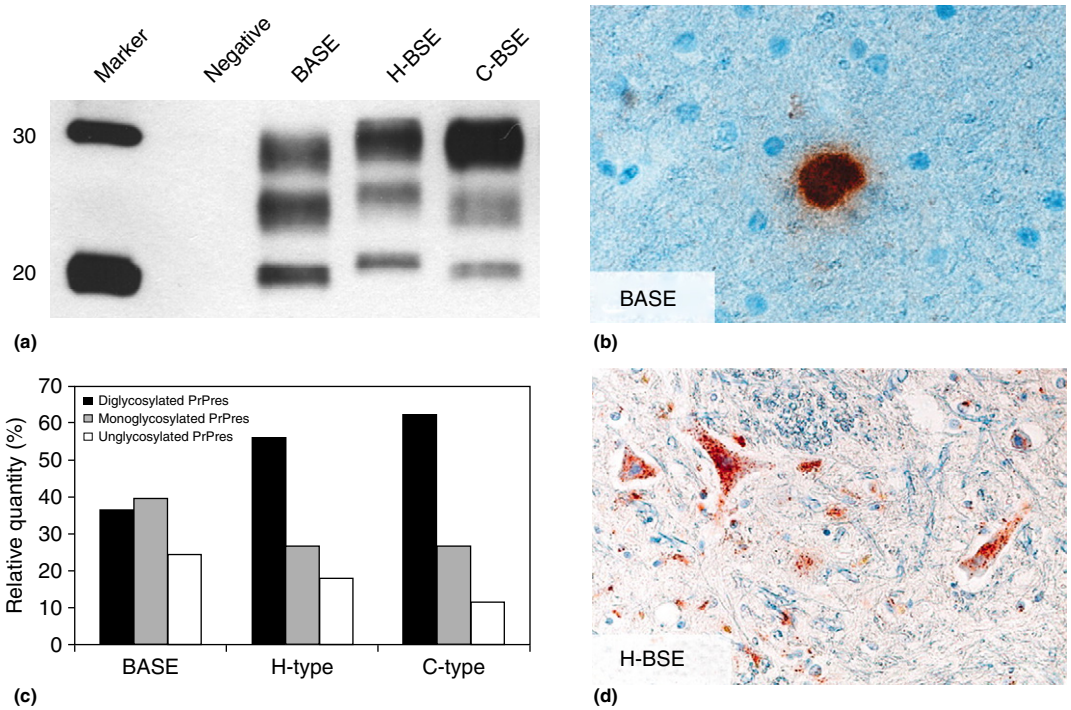

Figure 1 Discrimination of different types of bovine spongiform encephalopathy (BSE) by Western blot and immunohistochemistry. (a) Western blot showing the glycopattern of the two atypical BSE strains, BASE and H-BSE and the classical BSE (C-BSE) strain. In C-BSE cases the diglycosylated PrP^{Sc} band is the most prominent band and is often referred to as PrP27–30 because of its apparent molecular weight ranging from 27–30 kDa. BSE-negative sample served as control. Molecular masses of a protein marker are indicated on the left in KDa. (b) Quantitation of the relative intensities of the three PrP^{Sc} bands reveals that the diglycosylated band in the BASE strain is less prominent than in the H-BSE and C-BSE cases. (c) Immunohistochemistry showing amyloidotic PrP^{Sc} plaques stained with antibodies to PrP as a characteristic feature found in brains of BASE-affected cattle. (d) PrP^{Sc} deposition pattern in H-BSE (zebu [*Bos indicus*], olivary nuclei) resembles that in C-BSE. Reproduced from Seuberlich *et al.* (2010) A typical transmissible spongiform encephalopathies in ruminants: A challenge for disease surveillance and control. *Journal of Veterinary Diagnostic Investigation* 22: 823–842, with permission from Sage.

reference diagnostic method for TSEs and thus was adopted by regulatory authorities and reference laboratories as the standard method for confirmation of a suspect TSE case (Figure 1(b)). In addition, the PrP^{Sc} distribution pattern in various brain regions has become an important tool for the characterization of TSE strains.

Western Immunoblotting

Diagnosis of TSEs by Western immunoblotting is based on the presence of protease resistant PrP (PrP^{Sc}) which is pathognomonic for TSEs. In an unaffected animal PrP^{C} with an apparent molecular weight of 33–35 kDa is protease sensitive and completely digested following incubation with proteinase K. In TSE affected organisms PrP^{Sc} is partially protease resistant and digestion with proteinase K leads to the removal of the *N*-terminus leaving a protease resistant core fragment with an apparent molecular weight of 27–30 kDa (PrP27–30). Sample collection and homogenization is one crucial part of the diagnostic tests and influences the diagnostic sensitivity and specificity. Both forms of PrP are associated with membranous cellular elements and thus detergents are required during tissue homogenization to allow efficient solubilization of PrP. In addition, conditions for protease digestion need to be optimized in order to allow complete digestion of PrP^{C} but only removing the *N*-terminus of PrP^{Sc} thereby leaving intact the protease-resistant core, PrP27–30, for the subsequent detection by anti-PrP antibodies. A piece of tissue from the brain stem (obex region) is homogenized and treated with proteinase K. The proteins in the sample are resolved by denaturing polyacrylamide gel electrophoresis and transferred to a membrane. The protease resistant fragments of PrP are detected on the membrane using a PrP-specific antibody directed to a sequence in the protease-resistant core and visualized using an enzyme-coupled secondary antibody with the corresponding substrate detection system. The presence of a PrP-immunoreactive signal with the additional two criteria of a reduced molecular weight (due to digestion of the *N*-terminus of PrP^{Sc}) and a typical three-band pattern representing unglycosylated, monoglycosylated, and diglycosylated PrP^{Sc} forms result in a TSE-positive diagnosis. The main advantage of the Western immunoblotting technology compared to Enzyme-linked immunosorbent assay is its high specificity due to the three independent criteria used for diagnosis. The Western immunoblotting technology has been validated and approved by the International Office for Epizooties (OIE) as a method to confirm postmortem the diagnosis of suspect or clinical cases including confirmation of a positive result in a rapid screening test. Furthermore, the Western blot is the only

diagnostic laboratory method suited for the discrimination of different TSE strains either using different antibodies that recognize strain specific epitopes on PrP or by comparing the relative intensities of the three protein bands on the blots representing the unglycosylated, mono-, and diglycosylated form of PrP (Figure 1(a)).

ELISA

Several ELISA have been developed and commercialized as rapid screening tests for TSEs. Most of them rely on a tissue homogenization procedure followed by protease digestion to eliminate PrP^{C} from the sample and prepare the analyte PrP27–30 for detection by anti-PrP antibodies. Some ELISA tests make use of the different conformational properties of PrP^{C} and PrP^{Sc} and use PrP^{Sc}-specific binding reagents that allow capture of full-length PrP^{Sc} without proteolytic degradation of PrP^{C}. Detection occurs by sandwich ELISA using two monoclonal antibodies, one of them enzyme labeled. The digested homogenate is either directly incubated with the capture antibody immobilized on the microtitre plate, or alternatively incubated with the detection antibody and the mixture is then transferred to the microtitre plate that is coated with the capture antibody. Detection is colorimetric or based on chemiluminescence and results are analysed using validated cut-off settings. The main advantage of ELISA tests is simplicity, ease of use, and capability for full automation which allows high throughput of samples. The disadvantage of ELISA tests is the occasional false positives due to incomplete digestion of PrP^{C} or cross reactivities of the antibodies with other protein in the brain extract.

Lateral Flow Immunochromatography

Lateral flow immunochromatographic (LFI) assays or strip tests are essentially immunoassays adapted to operate along a single axis to suit the test strip format. The basic technology that underlies LFI assay was first described in 1960s, but it was not until 1988 that the first commercial application as home pregnancy tests was launched. Similar to ELISA tests, strip tests employ a tissue homogenate subjected to treatment with proteinase K followed by incubation with the conjugate consisting of a colored latex bead-labeled anti-PrP antibody in a microtitre format. The strip is inserted into the sample-conjugate reaction mixture and the sample then continues to migrate across the membrane until it reaches the capture zone where the immunocomplexes consisting of PrP27–30 bound to antibody residing on the latex bead are captured by the immobilized second monoclonal anti-PrP antibody sprayed as a line perpendicular to the long axis of a strip producing a colored line on the membrane. The sample then migrates further along the strip until it reaches the control zone, where excess conjugate will bind and produce a second colored line on the membrane. This control line indicates that the sample has migrated across the membrane as intended. Two clear lines on the membrane represent a positive result. A single line in the control zone is a negative result. The reading and result interpretation can be done either visually or automatically allowing a quantitative analysis using a flat-bed scanner, and dedicated software. To allow for high throughput testing, individual strips are arranged in a comb-shaped cartridge holding eight strips. The main advantage of LFI assays is their speed and ease of use with only minimal equipment needed which makes them superior to conventional ELISA tests.

Rapid BSE Tests as Screening Tools

Together with other measures to control and eradicate BSE , postmortem testing of healthy cattle over 30 months of age was introduced in Europe in 2001 and later also in Japan for all cattle over 21 months of age. Although testing for BSE and subsequent removal of infected animals from the food chain was important to regain consumer confidence, rapid BSE tests could only eliminate a proportion of all infected animals even though that part represents the animals containing the highest amount of infectivity. Experimental BSE infection studies have shown that all postmortem diagnostic tests can detect a BSE infected animal up to 6 months before onset of clinical signs when substantial levels of infectivity have already accumulated in nervous tissues.

The introduction of active BSE surveillance required the implementation of routine sampling procedures in the abattoir, the set-up of a logistics chain to send the samples to accredited laboratories, and the development and validation of rapid BSE screening tests for diagnosis using fresh brain tissue as sample matrix. The sampling of brain tissue in the slaughterhouse involves the removal of the medulla oblongata from the skull of slaughtered animals through the foramen magnum. This procedure is described in the latest edition of the 'Manual of standards for diagnostic tests and vaccines' of the OIE. The sample is transported to the laboratory and a subsample of the obex region is used for diagnostic analysis. Testing is performed by accredited laboratories and the test must be performed exactly as described in the manufacturer's instructions of use. If the result from the rapid screening test is negative, the animal carcass can be released from the abattoir. A positive or inconclusive result in the initial screening test needs to be confirmed by the National or European Reference Laboratory (EURL) using one of the approved confirmatory tests. If the initial positive test result is confirmed, the carcass is not to be used for human consumption and needs to be destroyed in accordance with the respective regulations.

The routine laboratory testing with rapid BSE tests in the EU is controlled and overseen by the EURL which organizes regular testing of proficiency sample panels for comparison of performance between testing laboratories. In addition, the test manufacturers have to comply with defined quality management requirements and each kit lot is undergoing a European batch release procedure which is unique in the field of veterinary diagnostics.

Validation of Rapid BSE Screening Tests

Since 2001, when compulsory active surveillance of healthy cattle over 30 months of age was introduced in the EU, rapid postmortem tests for BSE have been evaluated and approved

by the EU authorities. A new rapid BSE test is considered fit for purpose if the performance of the test meets the requirements defined in the 'Protocol for evaluation of new rapid BSE post mortem tests' published under the auspices of the EFSA. The protocol in principle states that each new test submitted by a manufacturer to the EU under a call for expression of interest will be subjected to a two stage evaluation procedure consisting of a laboratory evaluation and a field trial. In this evaluation a new test should perform not inferior to an already approved rapid BSE test. The whole evaluation exercise is supervised by the Institute of Reference Materials and Methods .

The hallmark of any diagnostic test is its diagnostic sensitivity (ability to identify infected reference samples as positive) and specificity (ability to identify uninfected reference samples as negative). This will determine the usefulness of a test in the field, i.e., how many true and false positives it will produce. The diagnostic sensitivity and specificity of BSE tests were evaluated by the EU commission using defined numbers of positive and negative samples from animals previously diagnosed for TSE with a reference method such as histopathology or immunohistochemistry. All rapid BSE tests approved for BSE surveillance have a diagnostic sensitivity of 100% and a diagnostic specificity of 99.3% or 100% (Table 1).

In addition, the evaluation protocol included an assessment of the detection limit using serial dilutions of a BSE-positive brain homogenate diluted in negative brain homogenates. Determination of the detection limit for the analyte PrP^{Sc} should give an indication on the test's capability to detect preclinical cases of BSE. In this evaluation exercise the lowest detection limits of the rapid tests ranged from a dilution of 1:30 up to at least 1:200 (Table 1). However, the analytical sensitivity may or may not correlate with the diagnostic sensitivity depending on the appearance and concentration of the analyte during the course of the disease. For this reason, slight variations in analytical sensitivity do not necessarily reflect differences in diagnostic sensitivity.

The rapid BSE tests were further evaluated in a field trial in order to determine their performance under normal routine conditions. This enabled a thorough assessment of parameters like robustness, applicability in different laboratories, expected rate of false initial reactives under high throughput field conditions, and necessary cut-off adjustment before market introduction. All tests showed a diagnostic specificity of 99.9% – 100% on tissue samples from healthy slaughtered cattle that were tested negative with an approved reference test. Similarly, all evaluated rapid tests showed a diagnostic sensitivity of 100% using a set of true positive samples that were tested positive using a reference test. In addition the tests were assessed for their performance on poor quality samples. This is important because field samples are often in a deteriorated state due to poor storage conditions of carcass samples over long periods of time. Such samples show extended autolysis and a robust diagnostic test has to give accurate results under such conditions. In this evaluation, one test had a specificity of 99.6% and all other tests showed a specificity of 100%. Table 1 shows an overview of the rapid BSE tests that are approved for BSE surveillance within the EU and are listed in Annex X Chapter C of the TSE Regulation (EC 999/2001).

Field Applications of Rapid BSE Tests

Between 2001 and 2010, approximately 10 million rapid BSE tests were performed in the EU per year and approximately 1 million per year in Japan within the compulsory rapid testing

of risk animals and slaughtered cattle. Routine statutory testing algorithm in the EU requires that each screening test-positive sample is retested by either a confirmatory test or a second screening test in order to confirm or reject the initial positive result. As confirmatory test either immunohistochemistry or an ultrasensitive Western blot procedure combined with enrichment of PrP^{Sc} by a centrifugation protocol are employed. Large scale field performance of three rapid BSE tests – Western blot, ELISA, and LFI – for the BSE surveillance program in Italy on more than 2.8 million samples from slaughtered animals resulted in the identification of 81 positive BSE cases. Both the Western immunoblotting test as well as the LFI test gave no false-positive results whereas the ELISA showed a false-positive rate of 0.94 per 100 000 negative samples tested. In the same study the rate of false-positives in fallen stock samples was recorded. In 200 000 fallen stock samples tested, the Western immunoblotting test showed no false-positive results while ELISA and LFI gave false-positives rates of 84.3 and 8.48 per 100 000 negative samples tested, respectively. Although all tests showed a similar high diagnostic sensitivity and specificity in the EU validation, ELISA and LFI based rapid tests tend to show increased rates of false positive results when used in routine testing compared to Western blot technology.

Diagnosis of Atypical BSE Cases

The introduction of mandatory active surveillance in the EU using rapid BSE tests allowed more systematic investigations into the circulating BSE disease phenotypes. Strain typing analysis of spongiform lesions and PrP^{Sc} distribution patterns in the brains of several hundreds of British BSE cases indicated that the epidemic was sustained by a single or major strain of TSE agent which was distinct from the many different strains of scrapie agent. These findings were confirmed by strain typing studies in mice. Nevertheless, given the magnitude of the epidemic in Britain, it seemed likely that a minor strain could have escaped recognition and that new strains of BSE would surface once the epidemic would decline further.

In 2004, the first atypical BSE strains exhibiting novel molecular and pathological phenotypes were identified in Italy, France, and Japan. These strains were detected among routinely diagnosed BSE cases in the active surveillance using rapid BSE tests. All atypical BSE cases were found in apparently healthy cattle with no clinical signs suggestive of BSE. Whereas the cases in Italy and France were found in old cattle, the Japanese case was the first BSE case confirmed in an animal less than 2 years old. Characterization of the atypical BSE cases was performed by strain typing using Western blot analysis of the protease-treated PrP^{Sc}. Classically, TSE strains have been characterized through inoculation of brain homogenates into a series of mouse lines. Distinct strains are then differentiated based on incubation time and lesion profile within the same mouse line. These are the most important criteria for differentiation of strains. More recently and with the availability of immunochemical diagnostic methods, a more detailed analysis was made possible based on glycosylation patterns of protease-treated PrP^{Sc}. On Western blots, proteinase K-treated PrP^{Sc} is resolved into three bands that correspond to the di-, mono-, and unglycosylated PrP. These bands can exhibit different mobility patterns, presumably reflecting different conformations of PrP^{Sc} associated with different prion strains. All classical BSE cases (C-BSE) that were analyzed showed the same PrP glycopattern with the highest intensity for the diglycosylated form of PrP (**Figure 1(b)**). The French animals presented with a higher apparent molecular mass of the unglycosylated PrP (**Figure 1(a)**) hence the cases were later designated H-BSE with 'H' referring to the higher molecular mass. The Italian cases showed a PrP^{Sc} type with predominance and a lower apparent molecular mass of the unglycosylated PrP which led to the designation L-BSE with 'L' for lower molecular mass. Further investigations on the pathology of the Italian atypical BSE cases by immunohistochemistry revealed a different distribution of PrP^{Sc} deposits and PrP-positive amyloid plaques, a feature which has not been described before for classical BSE (**Figure 1(c)**). These findings prompted the authors to name this disease BASE, for bovine amyloidotic spongiform encephalopathy. Worldwide, some 50 atypical cases of BSE have been described with all of them being diagnosed in animals between 8 and 20 years of age. In contrast most C-BSE cases fall into an age range of 5 – 6 years. Clearly, atypical BSE represents a different disease entity than C-BSE and this led to the notion that atypical BSE could arise spontaneously similar as sporadic prion diseases in humans. This is in agreement with the low prevalence of atypical BSE of 1 case per 3 million adult cattle. From a diagnostic perspective, all atypical BSE cases were identified in routine surveillance by approved rapid BSE tests, suggesting that these tests are capable to detect all forms of BSE although they were not evaluated for atypical BSE.

Conclusion

The history of BSE control and eradication is merely 20 years old but the changes that were brought about by the measures implemented to protect the global food supply and public health are unique among newly emerging zoonotic disease in livestock animals. Together with the ban on feeding ruminant derived meat and bone meal to ruminants and the removal of specified risk materials, monitoring programs using rapid BSE tests played an important role in the management of risks posed by the BSE epidemic. Although none of the currently used diagnostic test methods is able to detect the disease in a living animal or at an early stage of infection, routine active surveillance for BSE allowed removal of a significant proportion of infected cattle and therefore the majority of infectivity from the food chain.

Before being applied as routine tests for consumer protection, rapid BSE tests underwent rigorous validation by the competent authorities and, once marketed, were required to undergo quality assurance and quality control measures to an extent that is so far unseen in the field of veterinary diagnostics.

From a scientific perspective, the introduction of rapid BSE tests has led to the identification of atypical cases of BSE which seem to represent sporadic forms of BSE that were most likely present in the cattle population before the BSE epidemic

started in the UK. Although transmission studies in transgenic mice have shown that atypical BSE replicates at least as efficiently as C-BSE, it remains to be determined whether infectivity distribution in different tissues is also similar between the two disease entities. These uncertainties underscore the fact that continued surveillance and monitoring of BSE is crucial to minimize potential risks from atypical BSE cases and maintain consumer protection at a high level.

Glossary

Bovine spongiform encephalopathy A progressive, fatal neurodegenerative condition in cattle, also known as mad cow disease, caused by infection with a prion.
Cytokines Proteins synthesized and secreted by inflammatory leukocytes and some nonleukocytic cells that act as intercellular mediators and affect the immune response.
Guillain–Barré Syndrome A temporary immune-mediated neuropathy that may occur days or weeks after a viral infection, during the recovery stage, and presents with progressive muscle weakness and paralysis.
Integrins Heterodimeric transmembrane glycoproteins consisting of noncovalently linked α- and β-subunits, which mediate cell–cell or cell–matrix interactions and function in signal transduction.
Lysosome A membrane-enclosed low-pH intracellular organelle that contains hydrolytic enzymes, where components destined for breakdown are digested.
Microvilli Actin-rich microscopic cellular projections that are found on many types of epithelia and increase the cellular surface area.
Phagosome An intracellular vesicle that forms after the plasma membrane fuses around particles engulfed by phagocytosis, such as cells, tissue debris, or microorganisms.
Variant Creutzfeldt–Jakob disease A rare, progressive, fatal neurodegenerative condition in humans, causally linked to a prion that also caused BSE, characterized by the spongy degeneration of the brain.

Introduction

Foodborne illnesses represent a global medical and public health concern with an economic and social burden that is difficult to quantitate. One in four individuals in the US and approximately one in five individuals in England develop acute gastroenteric infections annually. For $>80\%$ of the foodborne infections, the causes remain unknown. Foodborne pathogens include bacteria, viruses, protozoa, microbial toxins, or chemicals that employ different pathogenesis strategies at various stages during their interaction with the host. These strategies include resistance to acidic conditions, disruption of the intestinal epithelial barrier, survival in vacuoles, escape from phagocytosis, inhibition of protein synthesis, actin-based motility, or manipulation of the immune response. In certain instances, studies of the host–pathogen interaction enabled the discovery and characterization of new cellular components with physiological roles. For example, research on *Listeria monocytogenes* ActA facilitated the discovery of the Arp2/3 family of eukaryotic actin-nucleating proteins. Another foodborne pathogen, *Campylobacter jejuni*, the main cause of bacterial diarrhea in European Union countries, was causally linked to the Guillain–Barré syndrome, a peripheral neuropathy that represents the most frequent cause of acute neuromuscular paralysis, and exemplified the first instance when molecular mimicry explained the pathogenesis of this condition. Insights into the virulence factors of foodborne pathogens will be

 doi:10.1016/B978-0-12-378612-8.00061-5

instrumental in designing and implementing prophylactic and therapeutic strategies to benefit global public health, and should be the focus of expanding research endeavors in the coming decades.

Resistance to Acidic Conditions

A key requirement, for many pathogens that colonize the gastrointestinal tract and cause disease, is their ability to survive acidic conditions. At pH levels between 1.5 and 2.5, the gastric acid is one of the harshest and most inhospitable environments in the human body, but several pathogens are able to survive these conditions and cause disease. The terms acid tolerance, acid resistance, and acid habituation have been used to describe the ability of certain microorganisms to survive acidic environments.

Certain pathogens survive in the gastric environment better than others. For example, studies on human volunteers revealed that 50–100 *Shigellae* are sufficient to cause dysentery in healthy adults, as compared to 10^8 organisms that are required in the case of other pathogens, such as *Vibrio cholerae*. At least in part, this is explained by the better ability of certain pathogens to survive the acidic conditions of the stomach.

Five acid response pathways that were described in *Escherichia coli*, AR1–AR5, protect bacteria in log or stationary phase growth conditions. AR1 operates in stationary phase cells growing under moderately acidic conditions, at pH ~ 5.5, requires the stationary phase alternative transcription factor RpoS and the cyclic adenosine monophosphate (cAMP) regulatory protein CRP, and is repressed by glucose. AR2–AR4 involve amino acid decarboxylase-based pathways – glutamate, arginine, and lysine decarboxylases for AR2, 3, and 4, respectively. AR2, the glutamate decarboxylase system, and the one that was most extensively studied, represents the major pathway allowing bacterial survival under extreme acidic conditions, such as at pH 2.5. In this system, two decarboxylases, GadA and GadB, use a cytoplasmic proton to convert glutamate to GABA and carbon dioxide, and an inner membrane antiporter, GadC, removes GABA from the cell in exchange for more glutamate. *Escherichia coli* acid resistance depends on the growth conditions and is present only during growth in rich media. In minimal media with glucose, the pathogen is not resistant to acid stress. AR5, an ornithine–putrescine antiporter encoded by the *potE* gene, was less extensively studied.

Salmonella has acid tolerance response mechanisms that protect under log or stationary phase conditions. Shifting the bacteria to extremely acidic pH requires a previous exposure to moderate acidity, but the pathogen can survive at pH 3 for several hours. One difference between *E. coli* and *Salmonella* is that in complex media, stationary phase *E. coli* is more resistant than *Salmonella* to low pH, and may survive at pH 2 for several hours. *Salmonella enterica* serovar Typhimurium has an arginine decarboxylase, AR3, which is induced under anoxic conditions, and a lysine decarboxylase, AR4. As opposed to the *E. coli* AR4 system, where *cadC*, which activates transcription of the *cadBA* operon that converts lysine into cadaverine and CO_2, is constitutively expressed, *cadC* in *S. enterica* AR4 is induced by low pH and lysine. *Salmonella* has two additional acid stress response pathways. One of them is induced in exponentially growing cells that undergo a transition from moderate to low pH (pH < 3) and involves > 60 acid shock proteins. The other system, which operates in stationary phase cells, involves 48 genes, of which only five overlap with the genes required during the log phase acid stress response.

Helicobacter pylori, a gram-negative microaerophilic pathogen linked to gastritis, and certain strains to gastric cancer, has a particularly strong ability to survive the acidic gastric environment due to urease, one of its most prominent proteins that is essential for colonizing the mucosa. Urease helps the pathogen hydrolyze urea into carbon dioxide and ammonia. Ammonia is converted to ammonium, which reacts with the carbon dioxide and forms bicarbonate, neutralizing the gastric acidity. *In vitro*, *H. pylori* can survive at pH 1 for several hours in the presence of urea. The urease operon has seven genes. *UreA* and *ureB* have structural roles, and *ureE–ureH* are required for inserting Ni^{2+} into the apoenzyme. *UreI* encodes a six-transmembrane-domain integral membrane protein and functions as a proton-gated channel that is activated at acidic pH, when it increases urea transport into the cytoplasm.

Listeria monocytogenes, a gram-positive facultative anaerobe, utilizes a glutamate decarboxylase system similar to the one in *E. coli*. The *gadA* and *gadB* genes encode two glutamate decarboxylases, and *gadC* encodes a glutamate-γ-aminobutyrate antiporter. In addition, a two-component signal transduction system, encoded by *lisRK*, is important for stationary-phase acid tolerance and *in vivo* virulence, and an F_0F_1 ATPase removes protons from the cytoplasm. This multisubunit complex has a cytoplasmic domain, F_1, with a catalytic role, and an integral membrane domain, F_0, which functions in proton translocation. Its role is to generate ATP aerobically when protons enter the cell, and hydrolyze ATP anaerobically, generating the proton motive force, when protons move out of the cell, an activity that can increase the intracellular pH when it becomes acidified.

Type III Secretion Systems

Many gram-negative bacteria have molecular injection devices known as type III secretion systems, which transport bacterial effector proteins across bacterial and host membranes into the host cells, where they perform specific virulence-related functions. Because the two cells establish direct contact, this process is also referred to as contact-dependent secretion.

Type III secretion was first described in 1994 in *Yersinia*, and over 20 systems were characterized to date in animal, plant, and insect pathogens. It enables pathogens that are extracellular or reside in phagosomes to inject bacterial proteins across the membranes, into the cytosol, where they hijack the eukaryotic cellular machinery, induce cytoskeletal changes, and/or initiate signal transduction pathways. The type III secretion apparatus, often referred to as a 'molecular syringe' or injectisome, represents a complex macromolecular machinery that spans the inner bacterial membrane, the periplasmic space, the peptidoglycan layer, the outer bacterial membrane, the extracellular

space, and the host cell membrane. Although type III secretion systems coexist in many pathogens with additional virulence factors, they represent a major virulence determinant. A simplified view depicts the injectisome as a basal body built of two sets of rings positioned within the inner and outer bacterial membranes, a needle-like structure extending 20–50 nm from the bacterial cell surface, through which the proteins travel, and the translocon, which is the pore formed by hydrophobic proteins inserted into the eukaryotic membrane. The injectisome is assembled in three steps. The basal body is formed first. This is followed by the assembly of the needle structure, from a single protein that is synthesized in the cytoplasm, secreted to the cell surface, and polymerized via its *C*-terminal amino acids. The 2–2.5-nm internal diameter of the needle allows effector proteins to travel in an unfolded state. Straight and hollow needle-like structures were visualized by electron microscopy in several pathogens, including *Salmonella*, *Shigella*, and *Yersinia*. In a third step, proteins that form the translocon, the pore-forming complex inserted into the host cell membrane, are secreted and localize to the target membrane. The components of type III secretion systems are tightly regulated at several levels.

Microorganisms that use different pathogenesis strategies and cause clinically distinct diseases often rely on very similar type III secretion systems as one of their major virulence mechanisms. For pathogens from the *Yersinia* genus, type III secretion is key to virulence. Before contacting a eukaryotic cell, *Yersinia* cells develop, on their surface, syringe-like structures made of ~25 proteins that form the Ysc injectisome. On encountering professional phagocytic cells, the pathogen upregulates a group of proteins known as *Yersinia* outer proteins (Yops) which orchestrate type III secretion. Two secreted proteins, YopB and YopD, are the translocators that become inserted into the host cell plasma membrane, and form a multimeric 500–700-kDa integral membrane complex. This process also requires a chaperone, LcrH in *Yersinia pseudotuberculosis* and SycD in *Yersinia enterocolitica*, and the pores allow the transport of effector proteins into the cytosol. Inside the eukaryotic cell, Yops perform specific functions. YopH, YopJ, YopE, YopT, YpkA, and YopM modulate the dynamics of the cytoskeleton and prevent the pathogen from being phagocytized. YopH, one of the most powerful tyrosine phosphatases known, dephosphorylates proteins from the focal adhesion complex, some of which are involved in adhesion during phagocytosis, and inhibits integrin signaling and phagocytosis. *Yersinia pseudotuberculosis* YopJ (YopP in *Y. enterocolitica*) is a cysteine protease that inhibits mitogen-activated protein kinase (MAPK) and nuclear factor kappa B (NF-κB) signaling pathways, promoting apoptosis in macrophages and suppressing the inflammatory response to the pathogen. In addition, YopJ/YopP is a promiscuous deubiquitinating enzyme that removes ubiquitin groups from key cellular proteins, such as IκB-α, negatively regulating signaling pathways. YopE, a Rho GTPase activating protein (GAP), inactivates Rho GTPases and causes the depolymerization of actin microfilaments, which enhances the ability of the pathogen to resist phagocytosis and inhibits the inflammatory response in the host. YopT, a cysteine protease, cleaves RhoA, Rac, and Cdc42 *N*-terminally from a prenylated cysteine, causing their inactivation by releasing them from the membrane, and subsequently disrupting the actin cytoskeleton. *Yersinia pseudotuberculosis* YpkA (YopO in *Y. enterocolitica*) inhibits nucleotide exchange by the Rac1 and RhoA GTPases, and disrupts the actin cytoskeleton. YopM, unique among the Yops due to its ability to traffic to the eukaryotic cell nucleus, and important for virulence *in vivo*, binds the ribosomal 6 kinase (RSK) family of proteins, a group of serine/threonine kinases involved in cell growth, motility, and survival. YopM binding to RSK causes sustained RSK activation by inhibiting dephosphorylation of the active, phosphorylated form of the protein, revealing a new strategy for pathogenesis, in which a bacterial virulence factor hyperphosphorylates and overactivates RSK family kinases.

Salmonellae provide an interesting example by being the only species identified to date that uses two different type III secretion systems encoded on different pathogenicity islands. After colonizing the small intestine, *Salmonella* invades nonphagocytic epithelial cells and gains access to the lymphatic tissue, a process mediated by a type III secretion system encoded on the SPI1 *Salmonella* pathogenicity island. SPI1, a ~40-kb chromosomal region located at centisome 63 on the chromosome, is the best characterized SPI from the five that exist in this bacterium. The virulence of SPI1 mutants is attenuated in animal models when the pathogen is administered orally, but not systemically, indicating that this pathogenicity island, thought to have been acquired earlier during evolution, might have had roles limited to intestinal colonization, and additional virulence factors, acquired later, enabled the pathogen to cause systemic disease. SPI1 is most important for crossing the intestinal barrier and for establishing intestinal inflammation. In addition to factors required to infect intestinal epithelial cells, *Salmonella* also encodes virulence factors needed for systemic infection. The second type III secretion system, encoded by the SPI2 pathogenicity island at centisome 31 on the chromosome, contains virulence factors needed for the systemic phase of the infection and for survival in macrophages. However, this division is not very sharp, as certain SPI1 components mediate intracellular effects, and certain SPI2 components are important during intestinal inflammation. SPI2 has been more difficult to study *in vitro*, particularly because genes from this pathogenicity island are expressed only after the pathogen enters host cells. Genes encoded in SPI3 and SPI4 are also required for the systemic stage of the disease, and SPI5 is required for inflammation and chloride secretion that are part of the enteric disease.

The *Shigella* type III secretion system represents a key virulence determinant encoded on a large, ~220-kb plasmid. *Shigella* uses membranous epithelial cells (M cells) to cross the intestinal epithelial layer, and invades epithelial cells through their basolateral surface. During entry, type III secretion allows the pathogen to form pores, made of the IpaB and IpaC proteins, two major invasins, in the cytoplasmic membrane of the target cells, and inject effector proteins into the cytosol. Additionally, the *C*-terminus of IpaC recruits and activates the Src tyrosine kinase, inducing actin polymerization. Enninga *et al.* visualized *Shigella* type III secretion in real time, and revealed that the process is activated on contact with the host cell. Approximately 50% of the IpaB and IpaC effectors were released within 24 s after contact. The *Shigella* type III

secretion system, known as Mxi–Spa, involves ~50 proteins, ~25 of which are effectors. Among these, three classes of effectors were described. Certain proteins are produced independently of type III secretion, others are positively controlled by the type III secretion system, and a third class contains proteins that are weakly expressed when type III secretion is not active, but their expression further increases on its activation.

An interesting example reveals that proteins encoded in the type III secretion system enable certain pathogens to initiate cytoskeletal changes in the host even before entering the cell. Enterohemorrhagic and enteropathogenic *E. coli* (EHEC and EPEC), major causes of diarrhea, subvert the actin cytoskeleton even before entering the host cell. EHEC and EPEC cause attaching and effacing (A/E) lesions, intestinal epithelial changes characterized by the loss of microvilli, the adherence of bacterial cells to the host cell membrane, and the formation of actin pedestals, which are raised actin-filament rich structures located under the bacterial attachment sites. Both pathogens harbor a ~35-kb chromosomal pathogenicity island called the locus of enterocyte effacement (LEE), which encodes proteins that are part of a type III secretion system and is sufficient to render a nonpathogenic *E. coli* strain capable of inducing A/E lesions, indicating that it contains all the genetic determinants required for this process. This region has a much lower G + C content than the rest of the *E. coli* chromosome (~38% vs. ~51%), suggesting that it was acquired from a foreign source. In the bacterial chromosome, LEE is located at the site that encodes selenocysteine transfer ribonucleic acid (tRNA), and this is also the location where several other pathogenicity islands, encoding other virulence genes, are inserted, including the ones from uropathogenic *E. coli*.

One of the proteins involved in A/E, translocated intimin receptor (Tir), formerly known as Hp90 (EspE in EPEC) is injected by the pathogen into the host cells to function as the receptor for intimin, a bacterial outer membrane protein. Tir is secreted in an unphosphorylated form, and becomes phosphorylated in the host, after insertion into the target cell membrane. Its *N*- and *C*-termini are in the host cell cytoplasm, where they interact with other molecules and participate in signaling, and an extracellular loop contains the intimin-binding domain. So far, this is the only system where the bacterium injects its own receptor into the host cell cytoplasm. Each Tir molecule has an extracellular antiparallel α-helix joined by a loop. Two α-helices from a Tir dimer establish a four-helix bundle that contacts two intimin molecules via the loops that join them. The Tir–intimin interaction leads to the intimate attachment of the bacterium to the eukaryotic cell and enhances the translocation of additional effector proteins. A distinct feature of Tir-based actin signaling in EPEC and EHEC is that the two pathogens use highly similar gene products, and generate morphologically similar pedestals, but employ different mechanisms to trigger actin polymerization. Kenny *et al.* demonstrated for the first time that EHEC O157:H7 Tir does not support the formation of actin pedestals when expressed in EPEC, and showed that actin signaling was defective, revealing that distinct signaling mechanisms operate in these two pathogens.

Flagellar Motility

For certain enteric pathogens, flagellar motility plays an essential role in the adaptation to various niches, and often represents an important virulence factor during gastrointestinal colonization. The flagellar motor, one of the most common and most studied motility structures in bacteria, is one of their largest molecular machines. Most studies that unveiled the genetics and biochemistry of the bacterial flagella were conducted in *E. coli* and *Salmonella typhimurium*. The flagellum consists of three elements: a basal body embedded in the cell wall, which anchors the flagellum to the bacterial cell envelope and contains the motor that powers flagellar movement; a flexible hook that smoothly transmits the torque generated by the motor to the filament; and a helical filament, 5–10 μm in length and 20 nm in diameter, containing thousands of copies of proteins called flagellins. More than 50 genes are required to encode the products involved in synthesizing the flagellar apparatus, in a complex and highly ordered process. These include structural proteins and proteins that fulfill nonstructural roles, such as secretion, assembly, and regulation. The basal body is synthesized first, followed by the hook and the filament. The flagella contain their own type III protein export machinery, and flagellar proteins travel through diffusion, in a partially or totally unfolded state, through a 2-nm-wide internal channel along the length of the flagellum, to be incorporated into the growing filament.

Helicobacter pylori and *C. jejuni* are two of the pathogens that rely on flagellar locomotion during the infection process. *Helicobacter pylori*, a gram-negative bacterium colonizing half of the world's population, is a major cause of chronic inflammation of the gastric mucosa, peptic ulcer, and gastric cancer, and in 1994 was classified by the World Health Organization as a class I carcinogen. *Campylobacter jejuni* is a leading cause of diarrheal disease worldwide. The two organisms reside within the mucus layer of the gastric and intestinal epithelium, respectively.

The involvement of flagellar motility in virulence was extensively studied for *H. pylori*, a noninvasive, highly motile pathogen that is propelled through a bundle of 4–7 flagella important for its chemotaxis toward urea. By using urease, another virulence factor, to hydrolyze urea and generate ammonia, the pathogen elevates the local pH and lowers the viscosity of the gastric mucus, facilitating its movement. The flagella are covered by a sheath, continuous with the bacterial outer membrane which is thought to protect it against the harsh gastric environment. The pathogen maintains its motility even under high viscosity conditions, when the motility of other bacteria is inhibited.

An interesting strategy, used by several microorganisms, is phase variation, the process of reversibly alternating between the expression of different flagellar antigens. In *C. jejuni*, both *flgS* and *flgR*, which encode a two-component regulatory system required for the expression of several flagellar genes, are targets of phase variation. Homo- or heteropolymeric nucleotide tracts in the two genes are involved in this process, and this represents, to date, the only known example when both regulators of a two-component system undergo phase variation. A unique mechanism for phase variation was described in *H. pylori*. *FliP*, the gene encoding a flagellar body protein,

contains a homopolymeric cytosine tract. As a result of slipped-strand mispairing, after the addition or deletion of a single nucleotide, *fliP* can be reversibly inactivated by the frameshift mutation that prematurely introduces a stop codon. This turns off flagellar assembly and the pathogen loses its motility.

In most *S. enterica* serovars, flagellar expression is biphasic. Only one of two flagellar antigens, FljB or FliC, can be expressed at any given time. This alternative expression is controlled by a site-specific deoxyribonucleic acid (DNA) recombinase that inverts a 996 base-pair chromosomal region, called the H segment, containing the promoter for the operon encoding *fljB* and *fljA*, which is a negative regulator of *fliC*. The significance of flagellar phase variation for *Salmonella* pathogenesis is not yet clear. Even though flagella are not essential for *Salmonella* virulence in a mouse model, they are important in other processes related to pathogenesis, such as in initiating a proinflammatory reaction.

In *L. monocytogenes*, flagellar motility, important for colonizing environmental surfaces and the host, is temperature dependent, and it is controlled by the reciprocal activities of the MogR repressor and the GmaR anti-repressor. MogR is constitutively expressed at all temperatures. The GmaR anti-repressor undergoes temperature-dependent conformational changes. Below 37 °C, GmaR binds and antagonizes MogR. At 37 °C, the GmaR–MogR complex is destabilized and releases MogR, which binds the promoters of flagellar motility genes, repressing their transcription and that of *gmaR*.

The energy for flagellar motility does not come from ATP, but from an ion motor source that converts electrochemical energy into mechanical energy. Although *H. pylori* and *E. coli* flagella are powered by a proton motive force, certain *Vibrio* species, such as *Vibrio parahaemolyticus*, which posses a dual flagellar system, use a sodium motive force for the single sheathed polar flagellum that propels the bacterium in liquid medium (swimming), and a proton motive force for the numerous unsheathed peritrichal flagella that allows translocation in viscous environments or over surfaces (swarming). The two types of flagella, powered by different energy sources, operate within the same bacterial cell, do not share structural components, and are regulated by a single CheY response regulator species, making this organism an interesting model to dissect the interface between flagellar biology and pathogenesis.

Manipulation of the Intestinal Barrier

Pathogens use several strategies to breach the intestinal barrier. Certain microorganisms, such as EHEC, attach to the intestinal epithelium but remain mostly extracellular during the infection. Other pathogens are intracellular, and developed two mechanisms to invade nonphagocytic cells, invasive zippering and triggering. In invasive zippering, a strategy used by *Listeria* and *Yersinia* species, bacterial molecules that mimic host cell ligands bind and activate host cell receptors, and the ligand–receptor interaction initiates a signaling cascade that reorganizes the actin cytoskeleton. After close apposition between the host and the bacterial cell, host cell membrane extensions form like a zipper around the bacterium, engulfing it. In invasive zippering, these cytoskeletal changes are not so dramatic, and usually disappear minutes after bacterial entry. In invasive triggering, used by *Salmonella* and *Shigella* species, bacteria bypass the need to bind cellular receptors and, instead, use type III secretion systems that deliver bacterial effectors into the host cell, where they regulate the actin cytoskeleton. In invasive triggering, cytoskeletal changes are much more extensive.

Intestinal epithelial cells have an apical and a basolateral membrane, each characterized by very distinct compositions and specific roles in maintaining epithelial integrity. Epithelial cells are attached to each other by three structures: tight junctions, adherens junctions, and desmosomes, and many pathogens developed strategies to target one or several of these components.

Disrupting the Mucus Layer

Certain pathogens produce virulence factors that disrupt the protective mucus layer, which forms a physical barrier between the intestinal tract content and the underlying gastrointestinal epithelium that it protects. MUC2 mucin, the major structural component of the mucus gel, is a high-molecular weight glycoprotein produced by the goblet cells in the colon and small intestine. Individual MUC2 subunits assemble into large polymers. Assembly starts in the endoplasmic reticulum, where MUC2 dimers are initially formed via the *C*-termini of individual molecules. After *O*-glycosylation in the Golgi apparatus, multimerization occurs late in the secretory pathway via disulfide bond-mediated trimerization of the *N*-termini. The extensive *O*-glycosylation prevents proteolytic cleavage by pancreatic digestive proteases. One example of a pathogen that disrupts the mucus layer is the protozoan parasite *Entamoeba histolytica*, the etiologic agent of human amebiasis, which is annually responsible for 50 million infections and 100 000 deaths worldwide and represents one of the most frequent causes of death from parasitic infections. Amebiasis is second only to malaria as the cause of mortality due to a protozoan parasite. In the early stages of the infection, *E. histolytica* uses cysteine proteases that depolymerize and disrupt the intestinal mucus gel by targeting poorly glycosylated, cysteine-rich regions in the *C*-terminus of MUC2. Additionally, the parasite releases glycosidases into the intestinal environment, degrading mucin oligosaccharides.

Attachment to the Apical Pole of Epithelial Cells

Colonization of the host is one of the most important early steps toward establishing an infection. One of the strategies employed by many bacteria is the use of adherence factors. Pili or fimbriae, one type of adherence factors that pathogens use, are 5–7-nm diameter, rigid, rod-shaped structures that help attachment to the host. As a result of their key roles in pathogenesis, pili also emerge as attractive vaccine candidates. Enterotoxigenic *E. coli*, the most important cause of traveler's diarrhea, and a leading cause of diarrhea in developing countries, produces several types of pili. Of these, the CS1 pili were the most extensively studied and the most commonly associated with the disease. Only four genes, which encode structural and assembly proteins, are required to produce CS1 pili. The CooA protein represents the major pilin subunit that

forms the body of the pilus. CooD, a protein localized to the tip of the pilus and required for adherence, is thought to initiate assembly, CooC is an outer membrane protein involved in transport, and CooB is a periplasmic chaperone-like protein that stabilizes the other three proteins.

In the first stage of the host–pathogen interaction, EPEC, an important cause of watery diarrhea, adheres to the apical pole of the small intestine epithelial cells by using bundle-forming pili (BFP). These rope-like intertwined filaments bundle together several microorganisms to form microcolonies, and mediate their interaction with *N*-acetyllactosamine glycan receptors on the host cell surface, two events collectively referred to as localized adherence. BFPs are encoded on the EPEC adherence factor plasmid, and their expression requires a cluster of 14 genes that are designated *bfpA–bfpL*, *bfpP*, and *bfpU*. *BfpA* encodes prebundlin, which is processed to bundlin, the major structural subunit of the pili, by two enzymes, BfpP, which cleaves the signal sequence, and DsbA, which catalyzes the formation of a disulfide bond in the periplasmic *C*-terminal region of the protein. Certain BFP mutants are impaired in their ability to cause disease, as shown in human volunteer studies. EHEC does not have BFP and infects the intestinal tract through the colon. BFPs can be extended and retracted by the bacterium. Both the formation of the pili and their capacity to retract, represent important virulence factors, and BfpD and BfpF are involved in the extension and retraction, respectively. The retraction, which closes the gap between the bacterial and the intestinal cells, ensures intimate adherence between the two, and promotes the translocation of bacterial effectors into the eukaryotic cell, contributing to the disruption of tight junctions and to the formation of actin-rich pedestals.

Counteracting Intestinal Epithelium Turnover

One of the innate defense strategies against pathogens is the rapid self-renewal, every 4–5 days, of the intestinal epithelial cells. Kim *et al*. recently described a new virulence tactic used by intestinal pathogens. *Shigella flexneri* OspE, a type III effector protein injected into cells, interacts with integrin-linked kinase, and the complex stabilizes integrin-containing adhesion sites, increasing the adherence of intestinal cells to the basal membrane, and decreasing their detachment. This strategy prevents the turnover of the infected intestinal epithelial cells. Iwai *et al*. provided *in vitro* and *in vivo* evidence that IpaB, a *Shigella* effector, after being injected into intestinal epithelial cells, binds Mad2L2, an inhibitor of the anaphase-promoting complex/cyclosome, and modulates the cell cycle progression of intestinal epithelial cells, slowing down the renewal of infected cells and allowing the pathogen to persist longer.

Disruption of Tight Junctions

Vibrio cholerae adheres to the brush border of the intestinal epithelium and secretes its main virulence factor, the heat-labile cholera enterotoxin, encoded by the *ctxAB* genes located on CTXϕ, the 6.9-kb filamentous bacteriophage integrated into chromosome I. Cholera enterotoxin is an AB5-type toxin. Its five identical B subunits form a homopentamer through interactions between β-sheets from adjacent monomers, and bind to intestinal cell receptors. The A subunit is proteolytically cleaved into two fragments, CT_{A1} and CT_{A2}, which remain linked by a disulfide bond. CT_{A1} harbors the enzymatic activity, and CT_{A2} inserts CT_{A1} into the B-subunit homopentamer. The interaction between CT_{A2} and the B-subunit homopentamer is noncovalent.

The receptor for the cholera toxin B subunit is the GM_1 ganglioside. The toxin reaches the endoplasmic reticulum and the cytoplasm via retrograde transport. Its intracellular target is adenylate cyclase, the enzyme that converts ATP into cAMP, one of the most important intracellular secondary messengers. The CT_{A1} fragment catalyzes the transfer of the adenosine diphosphate (ADP)-ribose moiety from nicotinamide adenine dinucleotide (NAD) to an arginine residue on the α-subunit of the G_S protein that activates adenylate cyclase, and increases intracellular cAMP levels in intestinal epithelial cells. This leads to protein phosphorylation and ion transport changes, including increased Cl^- secretion. The increased Cl^- secretion in crypt cells and the decreased coupled Na^+–Cl^- absorption in the villus cells cause the net movement of electrolytes into the lumen, with subsequent water loss and diarrhea. An interesting aspect about cholera toxin is that the GM_1 ganglioside, its cellular receptor, resides on the apical side of the intestinal epithelial cells, but the effector, adenylate cyclase, is on the basolateral side, and several models were proposed to explain how the signal is transduced between these two distinct cellular locations.

Vibrio cholerae harbors several additional toxins. A cytotoxin, hemagglutinin/protease, the first protease noticed in pathogenic vibrios, is a metalloprotease that degrades the extracellular domain of occludin and reorganizes ZO-1 from tight junctions, perturbing the barrier function of the intestinal epithelium. A virulence factor discovered in 1991, a $\sim$45-kDa outer membrane protein encoded by the cholera toxin bacteriophage CTXϕ and known as zonula occludens toxin (Zot), reversibly opens tight junctions. The biologically active domain responsible for its enterotoxic activity resides in a $\sim$12-kDa *C*-terminal fragment, which is cleaved off and secreted into the intestinal environment. After binding its receptor, Zot is internalized and activates phospholipase C, generating inositol trisphosphate and diacylglycerol. Protein kinase Cα, which is activated either directly by diacylglycerol, or indirectly through the release of Ca^{2+} via inositol trisphosphate, phosphorylates cellular proteins. One of the effects is G-actin polymerization into F-actin filaments, with the rearrangement of actin filaments. This leads to the displacement of other proteins, including ZO-1, from the tight junctions, and to the disassembly of the tight junctions, causing increased intestinal permeability.

Clostridium perfringens enterotoxin, a 35-kDa single-chain polypeptide with a *C*-terminal receptor-binding domain and an *N*-terminal toxicity domain, binds claudin, a tetratransmembrane component of the tight junctions that has two extracellular loops. Claudin is, so far, the only receptor identified for this toxin. From more than 24 proteins in the claudin family, only certain members are receptors for the *C. perfringens* enterotoxin. The second loop represents the toxin recognition site and, within this loop, the *C*-terminal 12 amino acids shape sensitivity to the toxin through an interaction that appears to be electrostatic. Several pathogenic *Shigella* serotypes are also able to remove claudin-1, down-regulate ZO-1,

and dephosphorylate occludin, disrupting tight junctions. One of the virulence strategies of *Giardia lamblia* involves disrupting ZO-1 from tight junctions in a myosin light chain kinase- and caspase-3-dependent manner, leading to increased epithelial permeability.

Another pathogen that manipulates tight junctions is rotavirus, a leading cause of severe diarrhea in infants and young children, which annually claims ~500 000 deaths worldwide. Rotavirus particles are made of three concentric protein layers. The inner layer surrounds the 11 segments of its double-stranded RNA, and is formed of three proteins: VP2, the main structural protein, and VP1 and VP3, which are embedded in this layer and are crucial for RNA replication. The middle layer protein is VP6. The outer layer has two major proteins, VP7 (protease cleaved or P protein), which forms the smooth surface of the virus, and VP4 (glycoprotein or G protein), which forms the spike-like projections. VP4, the main protein involved in the virus–host interaction, is cleaved by trypsin into two peptides, VP5 and VP8. VP8 displaces ZO-1, claudin-3, and occludin from the tight junctions, disrupting them in a reversible, time- and dose-dependent manner.

Disruption of Adherens Junctions

Listeria has developed a sophisticated array of virulence factors. The two most extensively characterized bacterial surface-associated proteins, internalins InlA and InlB, are important for invading host cells. Internalins have an *N*-terminus made of tandem repeats organized into a solenoid shape. Expression of InlA in noninvasive *Listeria* species makes the bacteria become invasive *in vitro*, and the protein appears to be important in human fetoplacental listeriosis. InlA is an 80-kDa protein that engages the most distal extracellular domain of E-cadherin, the adherens junction cell–cell adhesion molecule that, through its *N*-terminus, binds E-cadherin molecules from neighboring cells in a Ca^{2+}-dependent interaction. The three-dimensional structure of the InlA *N*-terminal domain bound to the *N*-terminal part of E-cadherin reveals that the InlA LRR domain wraps around the E-cadherin *N*-terminal domain in a geometry that is very different from the one established between E-cadherin molecules. This interaction is very specific and occurs only for human, but not for mouse E-cadherin, despite an 85% amino acid identity between the two proteins. The specificity is conferred by a single amino acid, at position 16 of E-cadherin, which is proline in the human protein and glutamic acid in the mouse and rat proteins. The replacement of glutamic acid with proline in the mouse E-cadherin confers it with the ability to bind InlA. The second bacterial surface protein, InlB, is a 67-kDa invasin that binds Met, a protein tyrosine kinase that is activated by the binding of hepatocyte growth factor (HGF). X-ray crystallography revealed that InlB does not compete with HGF for the same binding site on Met. The binding of InlA and InlB to their receptors triggers intracellular signaling cascades that result in cytoskeletal rearrangements and actin polymerization.

Using M Cells to Invade the Host

Membranous epithelial cells (M cells) from the intestinal mucosa are cells of epithelial origin that, in addition to their role in capturing antigens and presenting them to the immune system from the underlying lymphoid tissue, are exploited as an entry route by pathogens that are unable to enter epithelial cells or do so inefficiently. M cells have poorly organized brush borders, short and irregular microvilli, a thin layer of glycocalyx, high endocytotic activity, and few lysosomes, and these characteristics are exploited by several pathogens as they gain access to the intestinal epithelium. The hallmark of M cells is the presence, on their basolateral membrane, of invaginations that form pockets and provide a docking site for intraepithelial lymphocytes, greatly reducing the distance that antigens have to travel. This is instrumental in accomplishing one of their major functions, the uptake and transport of antigens from the intestinal lumen to the mucosal immune system.

Some pathogens preferentially, and others exclusively use M cells when invading the host. *Salmonella* crosses the intestinal epithelium through M cells, enterocytes, or dendritic cells, but M cells represent its major route of entry. On entry, the pathogen causes extensive ruffling, which results from apical membrane changes and the redistribution of actin filaments. Virulence factors encoded in the SPI1 pathogenicity island are important during epithelial cell invasion, and also appear to be important for M-cell invasion, but SPI1 mutants, although still capable of invading M cells, do not destroy the follicle-associated epithelium. Inside macrophages, the pathogen survives due to the second type III secretion system, encoded by SPI2.

After reaching the ileum, *Y. enterocolitica* and *Y. pseudotuberculosis* use invasin, a chromosomally encoded outer membrane protein, to bind $\beta 1$ integrins expressed on the apical side of the M cells. The pathogens not only exploit M cells to gain access to the host, but they can also use epithelial cells. *Yersinia* provides an example of structural mimicry at the molecular level, as invasin mimics the $\alpha 5\beta 1$ integrin-binding surface of fibronectin to manipulate the host signal transduction pathways during internalization. Despite tertiary fold and molecular surface differences between invasin and fibronectin, their integrin-contacting residues align almost perfectly, unveiling a strong similarity in the functional features. However, invasin binds integrin with a much higher affinity than fibronectin, with a two-order magnitude difference between the dissociation constants of the two complexes (K_d invasin $= 5 \times 10^{-9}$ M, K_d fibronectin $= 8 \times 10^{-7}$ M).

From the four *Shigella* species that cause human disease, *Shigella sonnei* and *S. flexneri* are most common in the US and developed countries, whereas *Shigella dysenteriae* and *Shigella boydii* are more frequent in developing countries. *Shigella flexneri*, the most intensively studied member of the species, invades M cells that overlie solitary lymphoid nodules in the colorectal mucosa. The pathogen crosses the cells in an intact endocytic vacuole and is delivered to the intraepithelial pockets of the M cells, where it is engulfed by macrophages and dendritic cells, but survives degradation by lysing the phagosomal membrane and by inducing apoptosis. Subsequently, *Shigella* enters epithelial cells through their basolateral surface and is surrounded initially by a membrane vacuole. After disrupting the vacuole, the bacterium replicates in the cytoplasm and induces actin polymerization at one of its poles, forming a 'comet tail' that depends on IcsA (VirG) and *N*-Wiscott–Aldrich syndrome protein (*N*-WASP) to help

it move intracellularly. Subsequently, the pathogen forms membrane-bound protrusions, most of them localized to focal adhesion sites, which fuse with the plasma membrane of the adjacent cell, forming pathogen-containing vesicles. In the new cell, the bacterium is transiently found in these double membrane-bound vacuoles, and it is released into the cytoplasm after disrupting their walls. This strategy helps the pathogen gain access to the cytoplasm of new cells without being exposed to the extracellular environment.

Survival within Vacuoles

Intracellular replication of the *Salmonellae* occurs in a membrane-bound compartment known as *Salmonella*-containing vacuole (SCV), a highly dynamic structure that the pathogen actively remodels to make it permissive for its growth. After internalization, bacteria are enclosed in these vacuoles and prevent their fusion with lysosomes, where they could be degraded, establishing a niche supportive of their replication. At the same time, growth within a vacuole presents the pathogen with several challenges, such as obtaining nutrients or escaping the vacuole to replicate and infect other cells.

Several bacterial proteins maintain the SCVs, which undergo early (<30-min postinfection), intermediate (30 min–5-h postinfection), and late (>5-h postinfection) stages of development during their life cycle. One of the early events in vacuole development is membrane remodeling. SopB, a protein encoded in the SPI1 pathogenicity island and translocated into the cell by type III secretion, is important for this process. SopB is a phosphoinositide phosphatase that hydrolyzes phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) to generate phosphatidylinositol 3-phosphate, and also decreases phosphatidylserine (PS) levels in the SCV membrane. By decreasing the levels of the negatively charged $PI(4,5)P_2$ and PS, SopB regulates the surface charge of SCVs and alters the recruitment of the Rabs, small GTPase proteins that regulate membrane trafficking. Preventing the recruitment of Rab23 and Rab35, which are important for phagosome maturation and the fusion between phagosomes and lysosomes, inhibits the SCV fusion with lysosomes, changing their fate.

As they mature, SCVs sequentially incorporate and lose endosomal components and move by dynein-dependent transport from their internalization sites toward a perinuclear position, adjacent to the microtubule-organizing center. Actin-based nonmuscle myosin II and dynein-microtubule-dependent movement, along with several SPI1- and SPI2-encoded effectors, appear to be important for this process.

SpiC, an effector protein secreted by the SPI1-encoded type III secretion system, interferes with vesicular trafficking and prevents SCV fusion with endosomes and lysosomes. SpiC binds and inactivates Hook3, a mammalian protein that links the Golgi complex to microtubules and is implicated in cellular trafficking. Additional SPI2-encoded gene products protect against nicotinamide adenine dinucleotide phosphate-dependent killing in macrophages, interfere with inducible nitric oxide synthase localization to the vacuole, and delay apoptosis, helping the intravacuolar replication of the pathogen.

During the late stages of vacuole development, membrane tubules form on their cytoplasmic surface and extend along microtubules toward the cell periphery. These structures, first described in 1993 by García-del Portillo *et al*. were called Sifs, for *Salmonella*-induced filaments. Among the best-studied proteins acting at this stage and required for Sif formation is SifA, an effector encoded in the *Salmonella* SPI2 pathogenicity island that impacts virulence by several mechanisms. One of these is through the maintenance of the *Salmonella*-containing vacuolar membrane. Bacteria harboring a $sifA^-$ mutation are not surrounded by a vacuolar membrane, replicate inefficiently in the cytoplasm, and exhibit decreased virulence in a mouse model. SifA was the first example of a bacterial protein that is responsible for maintaining a membrane-bound vacuole permissive for replication. The SifA *C*-terminal domain resembles a guanine nucleotide exchange factor and binds the guanosine diphosphate (GDP)-bound form of RhoA. This is thought to activate RhoA, which binds and activates SseJ, modifying the SCV membrane phospholipid composition. The *N*-terminal domain of SifA binds SifA and kinesin-interacting protein (SKIP), and the complex binds and activates kinesin-1, linking SCV to the intracellular tubular network. A *Salmonella* SPI1 effector, SptP, harbors a *C*-terminal domain with tyrosine phosphatase activity and dephosphorylates valosin-containing protein/p97, a mammalian protein involved in membrane fusion, and in this manner facilitates pathogen replication inside SCVs.

This tubular network is much more complex than initially envisioned, and involves several additional components, including sorting nexin tubules, *Salmonella*-induced secretory carrier membrane protein 3 tubules, and LAMP1 negative tubules. The complex tubular network involved in SCV maturation was mostly studied *in vitro*, and was not visualized yet *in vivo*, most likely because of technical limitations. This tubular network appears to be important for pathogen survival, replication, and virulence, as mutants are attenuated for pathogenicity in animal models.

Escape from the Phagosome

The ability of some pathogens to avoid phagocytic killing represents an important virulence strategy, and different pathogens developed different approaches to achieve this. Although *Salmonella* employs a strategy to survive inside macrophages by inhibiting the phagosome–lysosome fusion, and is able to replicate inside modified phagosomes, *Yersinia* developed an antiphagocytosis strategy by using the YopH protein tyrosine phosphatase, and *Shigella*, after entering macrophages, can disrupt the phagosome and subsequently multiply in the cytoplasm and kill macrophages by apoptosis within 2 h. A well-characterized system to escape the phagosome is the one used by *L. monocytogenes*. After entering the cell by receptor-mediated endocytosis, *Listeria* is found in primary phagocytic vacuoles, also known as phagosomes, for approximately 30 min. Normally, the phagosome undergoes a process of maturation, in which after gradual acidification it fuses with the lysosome that contains digestive enzymes, to form a phagolysosome where the pathogen is destroyed. *Listeria* is able to prevent this by escaping into the cytosol, where it replicates,

and can subsequently infect other cells. A pore-forming cytolysin, listeriolysin O (LLO), encoded by the *hly* gene, together with two type C phospholipases, phosphatidyl inositol-specific phospholipase C (PI-PLC), encoded by *plcA*, and phosphatidyl choline-specific phospholipase C (PC-PLC), encoded by *plcB*, are important in orchestrating the escape from the phagosomes. In 1990, it was shown that LLO is sufficient to allow the pathogen to escape from the phagosome. LLO, a member of the cholesterol-dependent cytolysins, binds membrane cholesterol as a monomer and establishes large multimers composed of up to 50 subunits. The oligomers extend transmembrane β-hairpins that penetrate the membrane and form 200–300-Å diameter pores, allowing macromolecules to leak from the affected cells. *Listeria* is the only known pathogen to secrete this type of toxin inside the cell, an aspect that opens significant challenges about how it is regulated to prevent cellular damage. LLO is controlled at several levels, including gene transcription and protein synthesis, activity, and degradation. LLO has an optimum activity under acidic conditions, at $pH < 6$, and it unfolds and aggregates at neutral pH. Its transcription is largely controlled by positive regulatory factor A (PrfA), which is a key virulence factor that represents a 'master switch,' as it orchestrates the transition between the saprophytic and the virulent, intracellular form of this pathogen. PrfA positively controls the expression of many virulence genes, including that of its own. A PrfA deletion mutant is 100 000 less virulent in a mouse model. PrfA is a 27-kDa symmetrical homodimer with an *N*-terminal β-barrel similar to the one found in cyclic nucleotide-binding domains that is connected, via a hinge, to a *C*-terminal helix-turn-helix motif. This *C*-terminal domain binds a 14 base-pair palindromic nucleotide sequence centered at position -41.5 in target promoters, known as the PrfA box. Ten genes that are directly regulated by PrfA form the core PrfA regulon, and include *hly*, *plcA*, *plcB*, *actA*, *inlA*, *inlB*, *inlC*, *mpl*, *hpt*, and *prfA*. At least 145 additional genes were predicted, based on microarray experiments and proteomics approaches, to be regulated by PrfA.

An interesting feature of PrfA is its posttranscriptional thermoregulation. *Listeria monocytogenes* key virulence genes are maximally expressed at 37 °C and are almost silent at 30 °C. At temperatures ≤ 30 °C, the *prfA* 5′-untranslated region forms a stable inhibitory secondary structure that masks the ribosome binding site and prevents access of the Shine–Dalgarno sequence to the ribosome. Under these circumstances, PrfA is not translated and virulence genes are not expressed. At 37 °C, which is the temperature in the human host, the leader transcript cannot form this secondary structure, PrfA is translated, and virulence genes are expressed.

LLO has a PEST-like sequence implicated in virulence and localization to the phagosome. Mutants lacking this sequence accumulate in the cytosol and eventually cause cell death. This indicates that, as an additional strategy, the pathogen might have developed a eukaryotic protein degradation signal to achieve a balance between vacuolar escape and avoiding damage to the host cell.

After replicating in the cytosol, the pathogen moves by using the actin cytoskeleton of the eukaryotic host, and when encountering the plasma membrane, it forms an invagination into the neighboring cell, where it is subsequently found in a double-membrane vacuole, also known as the secondary vacuole. In secondary vacuoles, as opposed to the primary vacuoles, the cytosolic face of the inner membrane is close to the bacterium. The pathogen escapes again, by using LLO and the two phospholipids, to initiate a new infection cycle. Compared to wild-type bacteria, which are free in the cytoplasm, *hly* mutants do not produce LLO and are unable to escape from vacuoles.

A similar pore-forming toxin, perfringolysin, is a nonessential virulence factor produced by *C. perfringens*, one of the most frequent causes of food poisoning in developed countries. This pathogen is a medical and public health concern for several reasons, including its very short generation time of ~ 10 min under optimal growth conditions, the wide distribution of its spores in nature and in the gastrointestinal tract of humans and animals, and its ability to produce > 15 toxins. One of these, perfringolysin O (PFO), oligomerizes and creates large pores in cholesterol-containing membranes. X-ray crystallography revealed that PFO is an elongated protein, organized into four domains, with a $\sim 40\%$ β-sheet content. The monomeric toxin is water soluble. A tryptophan-rich loop near its *C*-terminus recognizes the cholesterol-containing membrane and anchors the toxin to the membrane. Conformational changes in this domain are transmitted through the molecule to a more distant domain, which loses many of its contacts with the rest of the molecule, as it undergoes a conformational change in which six α-helices transition to form two transmembrane β-hairpins that span the membrane. Monomers initially oligomerize on the membrane surface into a prepore intermediate, which subsequently forms large homooligomeric complexes that create pores. This profound conformational change, along with the fact that each PFO monomer penetrates the membrane with two amphipathic β-hairpins that completely span the membrane bilayer, defines a new paradigm for the membrane insertion of a cytolytic toxin.

Actin-Based Movement and Actin Remodeling

Several pathogens developed strategies to manipulate the host actin cytoskeleton and promote their own motility during infection. This represents an important virulence strategy and, at the same time, provides an attractive therapeutic target. Pathogens that show actin-dependent movement were organized into two groups. Although some pathogens, such as *Listeria*, mimic nucleation-promoting factors, others, such as *Shigella* and EHEC, recruit nucleation-promoting factors to the bacterial cell surface.

After escape from the vacuole, on being released into the cytosol, *Listeria* uses the host cytoskeletal actin to move intra- and intercellularly. *Listeria monocytogenes* actin-assembly-inducing protein A (ActA) polymerizes actin and provides the force allowing the pathogen to move within the cell. *Listeria ivanovii*, primarily an animal pathogen, uses a related protein, IactA. Cameron *et al*. revealed that ActA is necessary and sufficient to move coated polystyrene beads in cytoplasmic extracts. The protein mimics the actin nucleation-promoting activity of eukaryotic host cell proteins from the WASP and WASP-family verprolin-homologous protein (WAVE) families. The WASP/WAVE family includes actin nucleation-promoting factors that activate the Arp2/3 complex, a highly conserved seven-member protein complex that in addition to Arp2 and

Arp3 contains five other proteins: p16, p20, p21, p34, and p40. This complex binds preexisting actin filaments and nucleates new filaments, and is found particularly in regions with increased actin dynamics.

The ActA protein has three distinct functional domains. ActA-*N*, its *N*-terminal region that is essential for motility, binds monomeric actin (G-actin) and together with other host proteins forms an Arp2/3-containing complex that nucleates actin, enhancing the formation of branched filaments. This basic region is similar to a *C*-terminal region from WASP family proteins. The 146-KKRRK-150 sequence within this region is important for intracellular motility, and mutation of the arginine residues abolishes motility. The central domain contains four consensus proline-rich motifs, and is important for shaping the velocity of movement. *Listeria monocytogenes* mutants lacking these central proline-rich domains produce actin tails that are shorter and move more slowly as compared to the wild-type strains. Each proline repeat is thought to contribute $\sim 2.5\ \mu m\ min^{-1}$ to the rate of the movement. This central domain recruits the focal adhesion protein vasodilator-stimulated phosphoprotein (VASP), which contains a proline-rich region that binds the G-actin-binding protein profillin and stimulates actin polymerization and actin tail formation. The ActA *C*-terminal hydrophobic domain is a membrane anchor that noncovalently links the protein to the cell wall. An interesting feature that distinguishes ActA from the eukaryotic proteins that it mimics is the absence of regions interacting with regulatory proteins. This ensures that pathogen-induced actin nucleation occurs constitutively and is not influenced by host regulatory factors. ActA played a fundamental role in discovering and understanding actin nucleation and dynamics by Arp2/3 in eukaryotes, and *L. monocytogenes* provides one example when studies on bacterial pathogenesis unveiled key physiological cellular processes in eukaryotes.

In contrast, *Shigella* uses IcsA, an outer membrane protein previously known as VirG, which does not share sequence homology with *Listeria* ActA and activates Arp2/3 via a different pathway. Although *Listeria* ActA mimics WASP/WAVE family proteins, *Shigella* IcsA binds directly, through its *N*-terminal glycine-rich repeats, to the actin nucleation-promoting factor *N*-WASP, recruiting it to the bacterial surface, and one of the prevailing models proposes that IcsA, as part of a ternary IcsA–*N*-WASP–Arp2/3 complex, mimics Cdc42-induced *N*-WASP activation, explaining also why *Shigella* actin-based motility is independent of the Rho-family GTPases.

Yarbrough *et al*. reported for the first time that *Vibrio* outer protein S (VopS), a *V. parahaemolyticus* type III secreted effector that causes cell rounding, covalently modifies a conserved threonine residue in the Rho, Rac, and Cdc42 Rho-family GTPases with adenosine 5′-monophosphate. This modification, known as AMPylation, prevents the interaction of these proteins with downstream effectors and actin assembly.

Other pathogens can subvert the actin cytoskeleton even without entering the cell. As previously mentioned, the A/E lesions caused by EHEC and EPEC are accompanied by actin accumulation in the host cell cytoplasm, directly beneath the adherent bacteria, forming pedestal-like structures that sometimes extend as much as 10 μm and anchor the pathogen to the host cell. The loss of microvilli on the intestinal epithelial cells during this process is thought to be a key factor leading to the infection-associated diarrhea. A/E is the result of enterocyte brush border degeneration and represents a unique ability of the pathogen to subvert the host cell actin cytoskeleton from the outside.

On the Tir–intimin interaction in EHEC (EspE–intimin interaction in EPEC), the Tir cytoplasmic domains interact with other host cell molecules and participate in signaling events. Despite similarities in initiating signaling, and despite highly similar gene products and morphologically similar pedestals, EHEC and EPEC use different mechanisms to trigger actin polymerization. One of the major differences between the Tir cytoplasmic domains in the two pathogens is phosphorylation of tyrosine 474 in the cytoplasmic tail of EPEC, but not EHEC. This allows the phosphotyrosine-dependent binding of Nck, a host adapter protein that recruits *N*-WASP and additional host proteins and initiates signaling cascades culminating with actin assembly and filament formation. This strategy is very similar to the one encountered in vaccinia virus, where a protein, A36R, becomes phosphorylated on tyrosine 112, and recruits Nck, indicating that two proteins from these two distinct pathogens employ very similar strategies to manipulate the host cytoskeleton. Both proteins activate WASP and the Arp2/3 complex, and generate actin tails in the vaccinia virus, and pedestals in EPEC and EHEC. In addition, EPEC can activate a less efficient, Nck-independent pathway that uses tyrosine 454, which is less efficiently phosphorylated, to activate *N*-WASP independently of tyrosine 474. Actin pedestal formation in EHEC does not require Nck and occurs through a process that involves additional bacterial proteins and was less extensively characterized. The EHEC Tir molecule lacks the Nck binding site and uses a tyrosine residue from an NPY458 motif within its *C*-terminal domain. This recruits the insulin receptor tyrosine kinase substrate and the insulin receptor substrate protein of 53 kDa, which subsequently recruit the Tir-cytoskeleton coupling protein, also known as $EspF_U$, a protein that has five and a half 47 amino acid repeats. A 17-residue motif within these repeats is sufficient to bind *N*-WASP. The ability of *N*-WASP to activate the Arp2/3 complex is normally regulated by an inhibitory intramolecular interaction between its GTPase binding domain and its *C*-terminal helical region. Cdc42 binding to the GTPase activation domain causes a conformational change that releases the *C*-terminus, enabling its interaction with the actin regulation machinery downstream. $EspF_U$ mimics this autoinhibitory *C*-terminal helix from *N*-WASP and binds the GTPase activation domain, activating the protein by competitively disrupting its autoinhibited state. This subsequently leads to actin polymerization.

Additional pathogens exploit the actin cytoskeleton for various purposes during the infection. At least six *Salmonella* effectors, *Salmonella* invasion protein A (SipA), *Salmonella* invasion protein C (SipC), *Salmonella* outer protein B (SopB), *Salmonella* outer protein E (SopE), *Salmonella* outer protein E2 (SopE2), and *Salmonella* protein tyrosine phosphatase (SptP), manipulate the actin cytoskeleton during invasion. The SipA, also called stringent starvation protein A (SspA), binds G-actin and reduces the critical actin concentration needed for polymerization, protects actin filaments from the

ADP/cofilin-directed depolymerization and from the severing activity of gelsolin, and cooperates with SipC to generate stable F-actin bundles by promoting actin nucleation. These cytoskeletal rearrangements help induce membrane ruffling to envelope and internalize the pathogen. SopE and SopE2 activate Cdc42. In addition, SopE activates the Rac1 Rho GTPase. The Rho family of GTPases, important regulators of the actin cytoskeleton, function as molecular switches that alternate between an active, GTP-bound and an inactive, GDP-bound conformation. During this transition, structural changes occur mainly in two regions, switch I and II, which in the presence of Mg^{2+} form a binding pocket that stabilizes the bound guanine nucleotide. A unique 166-GAGA-169 loop from SopE becomes inserted between Cdc42 switch I and II and induces conformational changes that distort the nucleotide-binding site, promoting nucleotide release. SopE represents the first example of a non-Dbl-like protein that is able to induce the release of a guanine nucleotide in a Rho-family protein. Activated Cdc42 and Rac1 recruit WASP and Scar/WAVE proteins, which activate Arp2/3 and cause actin polymerization and cytoskeletal rearrangements. A virulence factor produced by certain *Salmonella* strains, *Salmonella* plasmid virulence B, contains a *C*-terminal ADP-ribosylating motif and uses NAD as a substrate to covalently attach ADP to arginine 177 of G-actin. The C2 toxin from certain *Clostridium botulinum* strains also ADP-ribosylates the same arginine residue on G-actin. ADP-ribosylated G-actin binds to the barbed (fast growing) end of the F-actin filaments and acts as a capping protein, preventing actin polymerization and filament formation, and shifting the equilibrium toward monomeric G-actin. Another *Salmonella* SPI1 effector, SptP, harbors within its *N*-terminal domain an arginine finger motif 206-GPLRSLM-212, in which the arginine residue is conserved among all Rho GTPases. Through this region, SptP acts as a GAP for Cdc42 and Rac1, reversing the actin cytoskeletal changes caused by SopB, SopE, and SopE2, and restoring the cytoskeletal architecture in the host cell after the infection.

Inhibition of Ribosomes

Shigellae, gram-negative nonsporulating bacilli that belong to the family *Enterobacteriaceae*, cause bacterial dysentery, a disease transmitted by the fecal–oral route and characterized by abdominal cramps and bloody diarrhea with mucus. One of the toxins produced by *S. dysenteriae* serotype 1, and rarely by other *Shigella* species, is the Shiga toxin (Stx). The name comes from Kiyoshi Shiga, the Japanese microbiologist who in 1897 characterized for the first time the bacterial origin of dysentery. The Stx is nearly identical to members of the Stx1 and Stx2 families, produced by certain *E. coli* strains known as Stx-producing *E. coli* (STEC) or verocytotoxin-producing *E. coli*. Shiga toxin and *E. coli* Stx1 differ by only one amino acid in the catalytic A subunit. Stx2, the more potent of the two antigenic forms, is responsible for most instances of fatal human infections. Stx1 and Stx2, despite being approximately 56% identical at the amino acid sequence level, are immunologically distinct and, in addition, they do not target exactly the same cell types and tissues. Some isolates produce one of these toxins, whereas others produce both. Each of the two Shiga-like toxin families consists of multiple variants, and the toxin subtype determines the clinical course and the severity of the infection.

The X-ray crystals of both the *S. dysenteriae* and the *E. coli* toxins reveal an AB_5 structure, in which an ~32-kDa enzymatically active A subunit is noncovalently associated with five identical B subunits, ~7.7 kDa each, organized as a ring. The *C*-terminus of the A subunit is interdigitated into the central pore formed by the B-subunit pentameric ring.

The Shiga toxin cellular receptor is a neutral glycosphingolipid, globotriaosylceramide (Gb3), $\alpha Gal(1-4)\beta Gal(1-4)\beta Glc$-ceramide, also known as CD77, on which the toxin recognizes the terminal α-1,4 digalactose. This receptor also exists on renal endothelial glomerular cells, mesangial cells, and tubular epithelial cells, and cellular differences in its expression pattern are thought to explain the organ-specific pathology associated with the infection. The receptor is not present in the cattle gastrointestinal tract, which explains why cattle, which are a major EHEC reservoir, are asymptomatic. One Stx2 subtype, Stx2e, prefers to bind globotetraosylceramide (Gb4), $\beta GalNAc(1–3)$-$\alpha Gal(1–4)$-$\beta Gal(1–4)$-$\beta 1Glc$-ceramide, in which an additional *N*-terminal *N*-acetylgalactosamine is linked by a $\beta(1–3)$ linkage.

On binding its receptor, the Shiga toxin is internalized by clathrin-mediated endocytosis, in which clathrin-coated pits pinch off the plasma membrane and form sealed vesicles that contain toxin bound to the internal surface. The toxin is taken up into the cell even when clathrin-dependent endocytosis is inhibited, indicating that the clathrin pathway is not an absolute requirement for its uptake. The toxin subsequently undergoes retrograde transport through the secretory pathway to the endoplasmic reticulum. The Shiga toxin was, in fact, the first example of a molecule that is transported from the cell surface to the endoplasmic reticulum through the Golgi apparatus. Early during the endocytic pathway, the A subunit is cleaved at a *C*-terminal protease-sensitive loop, between arginine 251 and methionine 252, by membrane-associated furin, generating an ~27-kDa A1 fragment that is catalytically active and the A2–StxB complex. The A1 fragment remains associated with the complex via a disulfide bond between the A1 and A2 fragments, which is reduced in the endoplasmic reticulum. This releases the A1 fragment, which is translocated to the cytoplasm and performs the molecular damage that includes protein synthesis inhibition. The A1 fragment acts as an *N*-glycosidase, cleaving an adenine base at position 4324 in domain VI of the 60S eukaryotic ribosome 28S ribosomal RNA (rRNA) subunit. This property is shared with the plant toxin ricin. The cleavage prevents the formation of a critical stem-loop structure to which elongation factors should bind, preventing aminoacyl-tRNA binding and elongation, and inhibiting protein synthesis. The toxin was also shown to trigger apoptosis by multiple mechanisms, in several cell types.

The X-ray crystal structure of the Stx1 B pentamer in complex with an analog of its Gb3 trisaccharide receptor, solved at 2.8-Å resolution, was reported in 1998 and revealed that each B-subunit monomer has three distinct trisaccharide moiety binding sites. The 15 binding sites per pentamer account for the high binding affinity between this toxin and its receptor.

Although certain infected individuals remain asymptomatic, others develop the infection, and ~5–8% progress to a life-threatening extraintestinal complication that occurs when the toxin translocates through the intestinal epithelial barrier into the circulation. This complication, known as hemolytic–uremic syndrome (HUS), presents with the hemolytic anemia, thrombocytopenia, and acute renal failure triad, and represents the main cause of acute renal failure in children. HUS may occur even after the pathogen is no longer detectable in the stool. The STEC strains that cause hemorrhagic colitis and HUS are collectively known as EHEC. *Escherichia coli* O157:H7 is the main STEC serotype from >500 that were described in humans, and is most frequently associated with severe disease worldwide, causing an estimated 73 000 foodborne infections annually in the US. Shiga toxin can also be produced by other, non-O157 *E. coli* serotypes.

It is not known why certain individuals develop HUS whereas others do not, but children and the elderly are particularly susceptible. Children <10 years have a 10–15% risk of developing HUS after an *E. coli* O157:H7 infection. The risk of HUS depends on several factors. Some of these factors, such as serotype, inoculum size, and the presence of pathogenicity islands, are pathogen specific. Others, such as age, underlying immune conditions, genetic factors that shape the inflammatory response, and the use of antibiotics and antiemetic medication, are host specific. It was reported that individuals who developed HUS after a Shiga-like toxin-producing *E. coli* infection had higher levels of hydroxylated fatty acid in their red blood cell Gb3, a factor known to affect receptor conformation, and this pointed toward receptor molecular differences that could shape the infection. HUS mortality is currently <5%, but up to 50% of surviving patients may have long-term sequelae, including chronic renal failure and neurological complications.

One of the most important features of the Shiga toxin is its ability to damage vascular endothelial cells. The gastrointestinal tract, the kidneys, and the central nervous system are the most frequent locations affected in patients with HUS. From the intestinal lumen, the toxin is absorbed through the mucosa and enters the circulation; a paracellular pathway was also proposed to exist. Subsequently, it binds receptors on the endothelium and on cells from various organs, causing organ-specific pathology and symptoms. The Gb3 receptor is also present on the renal glomerular endothelial cells, which bind the toxin, resulting in vascular injury, fibrin deposition, thrombus formation, and renal failure. Additional effects of the toxins are cytokine synthesis and release, cytokine-stimulated activation of polymorphonuclear (PMN) leukocytes with the release of oxygen metabolites and endothelial injury, and apoptosis.

A more recently found activity of the Shiga toxin is its ability to stimulate the release of chemokines, cytokines, and adhesion molecules. An apparent paradox is that even though the Shiga toxins inhibit the ribosome and protein synthesis, at similar concentrations they also increase the level of several cytokines. In fact, it was shown that very small amounts of toxin, which have only minor effects on protein synthesis, exert a large impact on gene expression. This was explained by the fact that, at the same time as inhibiting the ribosome, the toxins activate the stress-activated protein kinases and upregulate the inflammatory response.

Another ribosome-inactivating toxin, ricin, is one of the most potent naturally occurring toxins, with as little as 500 μg being sufficient to kill an adult. Ricin is a heterodimeric protein produced by the castor bean plant *Ricinus communis*, made of two polypeptide chains, a 32-kDa A chain and a 36-kDa B chain that are covalently linked by a disulfide bond. The toxin is internalized by endocytosis, which not only occurs by clathrin-coated pits, but was also shown to occur when this pathway is blocked, indicating that other endocytic mechanisms are operational. Experiments with ricin provided the early indications supporting the existence of a clathrin-independent cellular endocytic pathway. After uptake, ricin is transported to the Golgi apparatus and the endoplasmic reticulum, from where the A chain is translocated to the ribosome. The A chain has deadenylase activity and irreversibly depurinates the 28S RNA ribosomal subunit, inhibiting protein synthesis. The B chain is a catalytically inactive lectin that binds β-D-galactopyranoside moieties on glycoprotein and glycolipid receptors with galactose residues, a characteristic that enables it to bind all over the eukaryotic cell surface. The mechanism of action of ricin was first reported in 1987, when investigators revealed that catalytic amounts of ricin modified one nucleotide, adenine A4324, in the 28S rRNA located adjacent to the α-sarcin site in the rat ribosome. A single ricin molecule is able to inactivate more than 1500 ribosomes per minute, a rate that exceeds the ability of the cell to manufacture new ribosomes. This, in addition to other characteristics, such as its stability and its resistance to proteolytic degradation, explains why one or a few molecules are sufficient to cause cell death.

Synaptic Inhibition

Clostridia produce the largest number of toxins among animal and human pathogenic bacteria. *Clostridium botulinum* is a gram-positive, rod-shaped, and spore-forming obligate anaerobe with worldwide distribution. This pathogen causes several types of botulism. Foodborne-, infant-, wound-, and adult intestinal toxemia botulism occur naturally, whereas inhalation- and iatrogenic botulism may result from the deliberate aerosolization and from the therapeutic or cosmetic injection of the toxin, respectively.

All these forms of the disease are potentially fatal and represent medical emergencies. The neurological symptoms of botulism often start with blurred vision and progress with descending bilateral flaccid paralysis, with respiratory and cardiac complications in severe cases. Foodborne botulism has a 5–10% fatality rate and occurs after the consumption of food contaminated with the toxin produced by bacteria growing under anaerobic conditions. This form of the disease is not caused by bacteria or spores themselves, but by the ingestion of preformed botulinum neurotoxin, and it is therefore considered to be an intoxication rather than an infection. The term botulism derived from *botulus*, the Latin word for sausage, and it was used in the eighteenth century central Europe to describe a highly fatal disease presenting with muscle paralysis and breathing difficulties that often occurred after eating blood sausage.

Infant botulism was described in the first year of life, and several studies suggested that the incompletely established intestinal microbial flora, which could compete with the pathogen, facilitates the infection. It classically presents with the clinical triad of bulbar palsy (slow or absent pupil responses), alertness, and the absence of fever. Some of the risk factors for infant botulism are residence in an area with high spore density, decreased intestinal motility, and the consumption of honey.

Botulinum neurotoxins are considered to be the deadliest toxins known to humans, with the median lethal dose of 1 ng kg^{-1} or less. The seven known serologically distinct toxins were designated A–G and differ by approximately 70% in their primary amino acid sequences. Of these, four serotypes, A, B, E, and F, cause human botulism. Botulinum neurotoxins act by irreversibly binding acetylcholine receptors at motor nerve terminations and neuromuscular junctions, inhibiting the release of neurotransmitter at peripheral cholinergic nervous system synapses. Each toxin is synthesized as a ~150-kDa inactive single-chain protein precursor that is cleaved into a ~50-kDa light chain, which is connected by a disulfide bond to a ~100-kDa heavy chain. The heavy chain ensures protein transport across the neuronal plasma membrane into the cytosol, and the light chain represents the active, catalytic moiety.

The toxin, called a 'marvel of protein design,' consists of three modules: an *N*-terminal catalytic domain that is formed by the light chain and a central translocation domain followed by a *C*-terminal receptor-binding domain, both formed by the heavy chain. The light-chain active site is partially occluded in the unreduced holotoxin by a translocation belt, which is a heavy chain loop wrapped around the light chain.

Botulinum neurotoxins bind to the presynaptic surface of motor neurons and are internalized by receptor-mediated endocytosis. In the acidic environment of the endosomes, the heavy chain undergoes a conformational change that helps it insert into the endosomal membrane to form a channel. The light chain is translocated through this channel and reaches the cytosol, where it acts as an endopeptidase. The catalytic center of the light chain contains a conserved zinc-binding HExxH motif, also found in many zinc proteases. Activation of the enzyme occurs when the disulfide bond connecting the heavy- and light chains is cleaved in the reducing environment of the cytosol. Botulinum neurotoxins introduce a single proteolytic cleavage in presynaptic proteins known as soluble NSF attachment protein receptors (SNARES), inhibiting the fusion of synaptic vesicles and the release of neurotransmitter into the synaptic cleft, and blocking neurotransmission. In the B, D, F, and G toxins, the light chain hydrolyzes a specific peptide bond in the synaptic vesicle protein synaptobrevin or vesicle associated membrane protein. In the A, C, and E toxins, a specific peptide bond in the presynaptic membrane protein synaptosome-associated protein of 25 kDa is hydrolyzed. In addition, the type C toxin cleaves a peptide bond in syntaxin, a presynaptic membrane protein.

N- and *O*-Glycosylation

Although relatively little is known about *C. jejuni* pathogenesis, one of the main bacterial causes of human gastroenteritis worldwide, its most important virulence determinants are the flagellum, the adherence to the intestinal mucosa, the ability to invade, and the production of toxins. The pathogen has a polar flagellum made of two *O*-glycosylated structural proteins, FlaA and FlaB, whose biogenesis is controlled by a two-component system comprising the FlgS sensor and the FlgR response regulator. A genetic locus containing ~50 genes is responsible for completing this posttranslational modification. Defects in *O*-linked glycosylation lead to decreased motility, adherence, and invasion. *O*-glycosylation occurs when glycan residues are attached to the hydroxyl oxygen of serine or threonine residues. In *C. jejuni* strain 81–176, each FlaA monomer, the major flagellar protein, has up to 19 serine or threonine residues that can become *O*-glycosylated with pseudaminic acid, a 9-carbon sugar that structurally resembles sialic acid, and with its acetamidino derivatives. As opposed to *N*-glycosylation, *O*-glycosylation is not sequence specific, but appears to be determined mainly by the protein tertiary structure, and exposed residues are mostly the ones that are modified. The residues that undergo *O*-glycosylation are, with one exception, in the flagellar regions in the primary sequence that are predicted to be surface exposed, and this process is necessary for flagellar assembly. The *O*-linked glycans represent up to 10% of the protein mass, making this one of the most extensively modified bacterial proteins described to date. *O*-linked glycosylation is important for flagellar assembly, bacterial colonization, and biofilm formation. In addition, several genes in the flagellar glycosylation locus contain homopolymeric tracts and undergo phase variation, a process that is important for adapting to the changing environmental conditions and for evading the host immune response. An *O*-linked glycosylation system was also described in *C. botulinum* flagellins.

Campylobacter jejuni is the pathogen in which another virulence factor, *N*-glycosylation, was described for the first time. This modification is required for attachment, invasion, and colonization in cell culture and in animal models of infection. Genetic approaches that block *N*-glycosylation render the bacterium significantly less pathogenic, and cause pleiotropic effects that include decreased virulence in human epithelial cell lines and reduced colonization in animal models. Proteins involved in *N*-glycosylation are encoded in a locus with 12 putative genes. During *N*-glycosylation, the oligosaccharyltransferase PglB, the key enzyme in the pathway, transfers en bloc a heptasaccharide to an asparagine residue from a consensus sequence, Asp/Glu-X_1-Asn-X_2-Ser/Thr, where X_1 and X_2 can be any amino acid except proline. More than 65 *C. jejuni* proteins are *N*-glycosylated, and more than 150 proteins are predicted, based on a sequence prediction of the acceptor consensus sequence, to undergo *N*-glycosylation.

Manipulation of the Host Immune Response

Campylobacter jejuni is the most frequent pathogen linked to the Guillain–Barré syndrome, a peripheral neuropathy that develops ~1–3 weeks after *Campylobacter* enteritis in approximately 1 in 1000 individuals. Guillain–Barré syndrome is an autoimmune condition characterized by limb weakness and areflexia, and represents one of the most frequent causes

of flaccid paralysis. At least four subtypes of the syndrome were described. Of these, the two major categories are acute motor axonal neuropathy, in which axons are the primary target and presents with pure motor involvement, and acute inflammatory demyelinating neuropathy, in which myelin is the primary target. *Campylobacter jejuni* infection was associated only with the acute motor axonal neuropathy. Another condition, Miller Fisher syndrome, characterized by ophthalmoplegia, ataxia, and areflexia, is thought to be a variant of the Guillain–Barré syndrome and was also associated with *C. jejuni* infection during the weeks preceding its onset.

Several animal and human studies found that the structural similarity between lipooligosaccharides from the outer membrane of the pathogen and gangliosides, a group of glycosphingolipids anchored to the external leaflet of the lipid bilayer by a ceramide moiety, could generate cross-reacting anti-ganglioside antibodies that are responsible for the autoimmune disease. In 1993, Yuki *et al*. revealed, for the first time, that a *C. jejuni* strain obtained from a patient with acute motor axonal neuropathy with immunoglobulin G against the GM1 ganglioside had the Gal β1-3 GalNAc β1-4 (NeuAc α2-3) Galβ oligosaccharide protruding from the lipooligosaccharide core. This oligosaccharide was identical with the tetrasaccharide present on the GM1 ganglioside. The authors confirmed the existence of molecular mimicry between *C. jejuni* lipopolysaccharide (LPS) and a terminal tetrasaccharide on the GM1 ganglioside, marking the first instance when mimicry between a pathogen isolated from a patient with Guillain–Barré syndrome and the nervous tissue was shown.

The mechanism that explains why certain individuals develop Guillain–Barré syndrome and others develop the Miller Fisher syndrome after *C. jejuni* enteritis was recently elucidated. Cst-II, the bacterial enzyme that transfers sialic acid to the lipooligosaccharide, exhibits a polymorphism. The amino acid at position 51 can be a threonine, in which case the enzyme has α-2,3-sialyltransferase activity and produces lipooligosaccharides that induce antibodies against GM1 and GD1a gangliosides, which exist on motor neurons that control the limbs. If position 51 is an asparagine, the enzyme exhibits both α-2,3- and α-2,8-sialyltransferase activity, and produces lipooligosaccharides that induce antibodies against GQ1b gangliosides, which exist mostly on oculomotor and primary sensory neurons. Thus, this polymorphism appears to determine the clinical course of the autoimmune condition subsequent to *C. jejuni* enteritis.

The current model proposes that during the *C. jejuni* infection, the pathogen produces GM1-like and GD1a-like lipooligosaccharides, which induce anti-GM1 and anti-GD1a antibodies. During the eradication of the infection, the antibodies that form against lipooligosaccharides also bind gangliosides in the nervous system, and initiate autoimmune injury. These findings reveal a new paradigm, in which a bacterial gene polymorphism shapes the clinical presentation of the postinfection autoimmune disease.

Several strategies to subvert the immune response were described for the *Yersinia* Yop proteins, and their ability to interfere with cytokine production and to inhibit phagocytosis is one of these. YopH, one of the most powerful tyrosine phosphatases known, inhibits signaling from the integrin receptor, and dephosphorylates proteins from the focal adhesion complex, some of which are involved in adhesion during phagocytosis, directly blocking phagocytosis. A conserved YopH cysteine residue, C403, is essential for catalytic activity, and a strain in which this residue is mutated can still be phagocytosed but it is not virulent in mice. YopH also inhibits lymphocyte proliferation. YopJ in *Y. pseudotuberculosis* (YopP in *Y. enterocolitica*) reduces tumor necrosis factor-α (TNF-α) and interleukin-8 release and suppresses the inflammatory response by inhibiting IKKβ, a kinase that phosphorylates the NF-κB inhibitor IκB. This inhibits IκB phosphorylation and degradation, preventing NF-κB translocation into the nucleus. Brodsky *et al*. identified a new effector, YopK, without known sequence homology to any protein to date, except proteins from pathogenic *Yersinia* species, and revealed that its intracellular domain interacts with the type III secretion translocon to prevent recognition of the type III secretion proteins by the host innate immune system. In this manner, YopK prevents assembly of the inflammasomes, key molecular complexes that are important for innate immunity and enhance bacterial survival in the host.

An additional strategy to manipulate the immune system exists in *S. flexneri*, which contains two functional copies of the *msbB* gene, one encoded on the chromosome (*msbB1*) and the other one on a virulence plasmid (*msbB2*). The products of these two genes produce a transferase that catalyzes the acyloxy-acylation of myristate at the 3′ position of glucosamine disaccharide on lipid A, a component of the bacterial LPS. This modification is required for the recognition of lipid A in the host. It was recently shown that both genes are required for the maximal acylation of lipid A, and a strain with both genes mutated showed defective TNF-α production in monocytes, decreased intestinal inflammation, and reduced invasion of the intestinal epithelium.

Another group of virulence factors that manipulate the immune system is illustrated by staphylococcal enterotoxins, one of the major causes of food poisoning worldwide, and the most common cause of food poisoning in the US. Staphylococcal enterotoxins are heat-stable toxins, an important characteristic in terms of food safety, and are resistant to inactivation by gastrointestinal proteases, such as pepsin. *Staphylococcus aureus* enterotoxins were first identified in 1959 and more than 20 members are currently known, types A and B being most frequently involved in food poisoning and the most extensively characterized. Less than 1 μg of toxin is sufficient to cause disease. In 1988, Evenson *et al*. reported an outbreak in a US school district where >850 students became ill after drinking 2% chocolate milk. Even though no bacteria were present in the chocolate milk, staphylococcal enterotoxin A was detected. On average, 11 ng of enterotoxin were found in one-half pint cartons. The attack rate was 31.5% among those who drank one carton and 44.4% among those who consumed three or more cartons.

In addition to being gastrointestinal toxins, staphylococcal enterotoxins act as superantigens, and stimulate nonspecific T-cell proliferation. The term 'superantigen' was coined in 1989 in Philippa Marrack's and John Kappler's research group, to describe a group of antigens that can stimulate T cells with very high potency. Unlike conventional antigens, which are processed into peptides in antigen-presenting cells, superantigens are not processed. Instead, they can

simultaneously bind the major histocompatibility complex (MHC) class II molecules on antigen-presenting cells and T-cell receptors on T cells, where they interact with the variable region of the receptor β-chain. The trimolecular complex that forms bypasses the process of antigen presentation, activates more lymphocytes than conventional antigens, and produces large amounts of cytokines. The resulting inflammatory cascade may overwhelm the immune response and lead to fever, shock, tissue and organ damage, and sometimes death. These manifestations, and the uncontrolled T-cell proliferation, sometimes occur at superantigen concentrations <0.1 pg ml^{-1}, and certain superantigens are able to stimulate T cells *in vitro* at 1 fg ml^{-1} (10^{-15} g ml^{-1}). Although most conventional antigens interact with very few naïve lymphocytes, usually activating one in 10^5–10^6 naïve T cells, superantigens interact with a large proportion of the lymphocytes, and may activate as many as one in five T cells. Enterotoxin A is the most potent T-cell stimulator from all staphylococcal enterotoxins.

The X-ray crystal structure of the staphylococcal enterotoxin type A, reported in 1995, reveals a 27-kDa monomer composed of two domains. One domain contains a β-barrel made of two β-sheets, and the second domain contains a β-grasp motif, which is a mixed β-sheet packed against a single α-helix. This β-grasp motif contains the major Zn^{2+} coordination site that is involved in MHC class II binding, and an additional MHC II binding site exists in the first domain. Mutational studies revealed that the two sites cooperate, a process that explains the high binding affinity of the toxin to MHC class II molecules. In both type A and type B enterotoxins, the two unequal domains are separated by a central shallow cavity that represents the T-cell receptor-binding site.

An additional strategy to manipulate the immune response is antigenic variation, and for foodborne pathogens, this is illustrated by intestinal parasites. *Giardia lamblia*, also known as *Giardia duodenalis* or *Giardia intestinalis*, is one of the most frequent human intestinal parasites, and one of the leading causes of parasitic diarrheal disease worldwide. An important strategy used by *Giardia* trophozoites to evade the vertebrate host humoral immune response is antigenic variation. This phenomenon is also observed in other pathogens, such as the ones causing malaria and syphilis. By varying its surface molecules and evading the immune response, the parasite is able to successfully perpetuate long-term infections. Antigenic variation in *Giardia*, unlike in other pathogens, does not occur by gene rearrangements or DNA sequence variation, but through epigenetic mechanisms that involve post-transcriptional silencing mediated by microRNAs. *Giardia* antigenic variation explains the ability of the parasite to cause persistent infection or multiple reinfections. Antigenic variation is mediated by the off/on switching of the *vsp* genes, a family of >190 genes that vary in size between 20 and 200 kDa and encode cysteine-rich surface proteins with conserved *C*-termini and variable *N*-termini that cover the entire surface of the parasite. Variant-specific surface proteins (VSPs) represent the main surface antigen of the parasite that is recognized by the host immune system. The parasite expresses only one VSP at any given time, but it can spontaneously switch to another type. Prucca *et al*. showed that most or all the *vsp* genes are transcribed, and the primary transcripts of all but one gene are subsequently degraded by an RNAi-like mechanism, which explains the expression of specific antigenic variants on the parasite surface. In addition to allowing the parasite to escape the immune system, antigenic variation also appears to facilitate survival in different intestinal environments.

Epigenetic Modifications

The DNA adenine methylase (Dam) system has been increasingly linked to virulence in several bacterial species. Dam methylates the position N6 of adenines in 5′-GATC-3′ sequences, and shapes several processes including DNA replication, chromosome segregation, gene transcription, transposition, and repair. Methylation of the adenine amino group alters DNA curvature and lowers the thermodynamic stability of the DNA, changing DNA–protein interactions. *Salmonella enterica*, *V. cholerae*, and *Y. pseudotuberculosis dam*$^-$ mutants are attenuated for virulence in animal models. In *S. enterica*, the Dam methylation system regulates genes involved in flagellar subunits. *Salmonella dam* mutants have reduced motility, decreased expression of the genes from the SPI1 pathogenicity islands, and in a mouse model, the LD_{50} (median lethal dose) of a *S. typhimurium dam* mutant administered orally was $\sim$10 000-fold higher than for the wild-type strain.

Another epigenetic modification linked to virulence, recently reported by Hamon *et al*. was that early during the infection, before entry into cells, secreted LLO dephosphorylates Ser^{10} on histone H3 and deacetylates histone H4, in a manner that is independent of its ability to form pores. These activities correlated with decreased transcription of key immunity genes in the host, providing a fascinating mechanism by which a bacterial pathogen can manipulate the epigenetic machinery in the host as a novel virulence strategy.

Neurotoxicity Caused by Insoluble Proteinaceous Aggregates

Recent advances in the study of transmissible spongiform encephalopathies challenged existing dogmas and revealed new concepts in disease transmission and pathogenesis. Prions are associated with a group of fatal, progressive neurodegenerative diseases that can be spontaneous, genetic, or infectious in origin. In humans, they include kuru, the sporadic, familial, iatrogenic, and variant forms of the Creutzfeldt–Jakob disease, the Gerstmann–Sträussler–Scheinker disease, and fatal insomnia. In animals, some of the examples of prion diseases are scrapie in sheep, transmissible mink encephalopathy in farmed mink, and bovine spongiform encephalopathy (BSE) in cattle.

One of the early insights into prion diseases came from the study of kuru, a fatal transmissible neurodegenerative condition that was first described among people of the Foré linguistic group in Papua New Guinea and started to be scientifically studied in 1957. The disease was causally linked to endocannibalistic practices, and most frequently occurred in women and children, who were the most likely to consume

the brain during these rituals. Initially, the pathogen was thought to be a slow virus. A challenging finding was that prions could be transmitted and could act as infectious agents in the absence of a nucleic acid genome. In addition, they were unusually resistant to treatments known to inactivate most bacteria and viruses, including formaldehyde, high temperatures, or treatment with UV. Subsequently, the 'protein-only hypothesis' was developed, asserting that nucleic acid is not required for transmission, and that the infectious agent is a proteinaceous particle that can self-propagate by recruiting and converting the normal, noninfectious host cellular prion protein (PrP) into aggregates.

Prion diseases recently reemerged in the public attention with the BSE outbreak that was reported first in the UK in April 1985 and subsequently in several countries in the mid-1980s, reaching its peak in 1992. The supplementation of cow feed with meat-and-bone meal, a high-protein nutritional supplement prepared from the offal of cattle, sheep, pigs, and chickens, was implicated in the outbreak. Even though this food type had been used before, retrospective studies revealed that a change in the organic extraction process, and particularly the abrogation of the organic solvent use, allowed prions, which can be inactivated by lipid solvents, to maintain their infectivity and cause disease. It was reported that, as the use of organic solvent became less profitable, the amounts that were used to prepare the meat-and-bone meals decreased progressively after the late 1970s, leading to meat-and-bone meals with higher lipid content, and in the early 1980s, most plants abandoned the use of organic solvents. This time period coincided with the first reports of BSE in the UK. It is thought that this change in the manufacturing process allowed scrapie from sheep to survive, and it was passed to the cattle through the feed. After the feeding of ruminant-derived proteins to cattle was banned in July 1988 in the UK, and subsequently throughout the EU, the incidence of the disease started to decline after approximately 5 years, a time that corresponded to the approximate BSE incubation period.

Several lines of evidence pointed toward BSE as the cause of a neurodegenerative human disease that became known as variant Creutzfeldt–Jakob Disease (vCJD), first reported in the UK in March 1996, and subsequently in other countries. Both the animal and the human epidemics attracted considerable attention, particularly because of the oral transmission, the causative relationship between the infectious agent involved in the cattle and the human outbreaks, and its resistance to conventional decontamination procedures.

The current view, supported by several lines of experimental evidence, is that the PrP exists in two conformations: a cellular isoform (PrP^{C}) that is properly folded, protease-sensitive, noninfectious, soluble in detergents, and rich in α-helices, and a scrapie-related disease-inducing isoform (PrP^{Sc}) that is aberrantly folded, infectious, protease resistant, insoluble in detergents, and rich in β-sheets. PrP^{Sc} has the propensity to aggregate into amyloid-like fibrils or plaques. PrP^{C} conversion to PrP^{Sc} is poorly understood, and is thought to occur spontaneously or be induced by mutations, but once PrP^{Sc} is formed, it can act as a template to recruit PrP^{C}, and as a catalyst to convert it into more PrP^{Sc}. The cellular synthesis of PrP^{C} replenishes the PrP^{Sc} pool. Prions are capable of self-propagation and nucleation. The initial conversion of a cellular protein to a prion is thought to occur rarely, but once it happens, the prion may bind protein molecules in the healthy configuration and catalyze their conversion.

An interesting observation revolves around a polymorphism described in *PRNP*, the gene on chromosome 20 that encodes the human PrP. Position 129 in this protein can be ATG and encode methionine, or GTG and encode valine. It was observed that homozygosity at this site predominates among individuals with sCJD, and all but one individual with vCJD carried the 129 MM genotype. Heterozygosity at this locus was reported in the recipient of a blood transfusion from a donor who subsequently developed vCJD. The transfusion recipient died 5 years later from a nonneurological condition, and protease-resistant PrP was detected in several tissues. Among Foré women, heterozygosity at the same locus was reported to confer survival advantage, and heterozygous individuals had a much later onset of the disease as compared to homozygous individuals. The association between homozygosity and disease is explained by the ability of homologous protein species to establish protein–protein interactions with greater efficiency, whereas in heterozygous individuals, subtle differences between the protein species could make these interactions more difficult.

An important concept regarding prion diseases is the existence of species barriers: prions isolated from one species are often less infectious when introduced into a different species. For example, a species barrier was shown when it was reported that the hamster protein does not cause disease in mice. This is explained, at least in part, by dissimilar sequences and structures between an infectious prion and the host PrP variant. This species barrier was abrogated when mice were genetically engineered to harbor the hamster *PRNP* gene and express the hamster PrP^{C} protein. Sometimes, the species barrier is unidirectional, for example, although hamster-derived prions did not cause disease in mice even after several years, mouse-derived PrP caused disease in hamsters after $\sim$378 days. Similarly, hamster PrP cannot seed human amyloid, and human PrP does not cause disease in hamsters. Nevertheless, the species-specific substitution of a single amino acid at a critical region was sufficient to change this seeding specificity, and to bypass the species barrier, making the protein acquire the seeding characteristics of the other species. As it is well known by now, vCJD emerged in humans after the BSE epidemic in cattle, showing that the species barrier is not absolute. An interesting model proposes that the species barrier might be shaped by interactions between the PrP and host PrP sequence variants, a concept that opens thought provoking questions and has far-reaching medical and public health implications.

CHARACTERISTICS OF FOODBORNE HAZARD AND DISEASES

Microbial Stress Response

CER Dodd, University of Nottingham, Loughborough, UK

Glossary

Chaperone A protein which has the role of helping other protein chains fold correctly into a functional form.

Enterobacteriaceae A family of Gammaproteobacteria which are Gram negative, catalase positive, oxidase negative, rod-shaped facultative anaerobes which are bile-salt tolerant and often inhabit the gastrointestinal tract. It includes the genera *Escherichia*, *Salmonella*, *Shigella*, *Yersinia*, *Klebsiella*, *Enterobacter* and *Erwinia*.

Exponential phase Phase of growth curve when cell numbers increase logarithmically; cells are actively growing and doubling their numbers periodically.

Facultative anaerobe A microbe which can grow with or without oxygen present but grows better when oxygen is present. Such organisms can switch their metabolism between oxidative and fermentative states.

Gram-negative bacteria Bacteria that have a thin layer of peptidoglycan in the cell wall and an outer lipopolysaccharide layer. These cells fail to retain the Gram stain.

Gram-positive bacteria Bacteria that have a cell wall with a thick peptidoglycan layer, which helps them to retain the Gram stain.

Humectant A substance that aids the retention of moisture; examples in foods are salt, sugar, glycerol. Their addition causes changes to osmotic pressure and water activity.

Probiotic Live microorganism that, when consumed in sufficient numbers, gives a health benefit to the host.

Sigma factor A variable subunit of RNA polymerase which is often responsible for allowing differential gene expression. Examples: sigmas also known as RpoS, the stationary phase sigma factor; σ^{32}, also known as RpoH, the heat-shock sigma factor.

Stationary phase Phase of a logarithmic growth curve when cell numbers plateau; cells such as *Escherichia coli* change their characteristics though changes in gene expression.

Water activity (a_w) The vapor pressure of a liquid divided by that of pure water at the same temperature. Effectively it measures the amount of available water; a_w for pure water is 1 and this decreases as the solute concentration increases.

Food-Related Stresses

Many foods present a stressful environment for microorganisms. This may occur naturally because of the properties of a food, for example, the acidity in fruits or be part of a food's design with regard to formulation, packaging, and storage conditions. Table 1 shows the factors which control microbial growth in foods: intrinsic factors are those inherent in the food formulation; extrinsic factors are those related to packaging and storage conditions; implicit factors are related to the natural microbial contaminants; and processing factors are those processes which are applied to foods and designed to control microbial growth. For each of these factors there is a varying tolerance amongst microorganisms. For example, the minimum water activity (a_w) for bacterial growth ranges from 0.97 for bacteria like *Pseudomonas* and *Clostridium botulinum* type E to 0.85 for *Staphylococcus aureus* with only specialist halophilic bacteria growing at a_w 0.75 and xerophilic molds down to 0.61. For other factors such as pH and temperature, organisms have an optimum condition under which they will grow and a range either side of this where they grow at a slower rate; an organism will become stressed outside of these extremes but, because of the variation in intrinsic tolerance between different organisms, the levels causing stress will vary. For example, both *Salmonella* and *Campylobacter* have a pH optimum at neutral. However, *Salmonella* will grow over a pH range of >4 and <9.1, while *Campylobacter* is much more acid sensitive with a range of pH >5.9 to <9. These ranges are in turn affected by the other factors present: if another factor in the environment is below optimum, for example, water activity, then this will not only reduce the level of growth of the organism but also may reduce the pH range over which it grows. This is the basis of the 'hurdle effect' which imposes a series of low-level stresses on the organism which together will prevent its growth.

Culture Production

The production of live bacteria for use in food production as starter cultures and as probiotics is a major industry. Where

Table 1 Factors controlling microbial growth in foods

Intrinsic factors
Water activity (a_w): concentration of humectant, for example, NaCl, sucrose, and glycerol
pH

Preservatives: for example, sulfite and nitrite
Natural antimicrobial components: for example, allicin, eugenol, and thymol
Nutrient supply
Food structure
Extrinsic factors
Temperature
Time (shelf life)
Gas atmosphere
Relative humidity
Implicit factors
Microflora composition
Microflora levels
Cell state
Spatial distribution
Processing factors
Heat
Freeze–thaw
Irradiation
Biocides

these are provided as dried powders or as frozen cultures the viability of the organisms may be compromised as the processes used in culture production can cause damage to the cells. Optimizing bacterial cellular recovery so that a high level of viable cells is provided is a major concern for the industry and an understanding of stress response in these organisms may be exploited to provide mechanisms by which stress response can be switched on before exposure to the stress, thus providing improved culture viability.

Bacterial Stress Response

Although all organisms have an intrinsic resistance level to different stress, they can show adaptations which allow them to grow outside of their normal range. In bacteria there are a number of adaptive responses which have been demonstrated: some are generic responses which allow adaptation to a range of stresses and some are stress-specific responses.

The Global Response Regulator: *rpoS*

When a population of cells of *Escherichia coli* is exposed to a sublethal stress such as moderate heat treatment (e.g., 56 °C), a proportion of the cells die but some will grow on culture media. The proportion of cells which can be recovered depends on a number of factors including the level of stress imposed, the nature of the recovery conditions, and the phase of growth in which the cells were when the stress was imposed. In particular, stationary phase cells show a greater tolerance to stress than exponentially growing ones. Such a response is seen in other facultative anaerobes such as *Salmonella* and *S. aureus* but not in strictly fermentative organisms such as *Streptococcus mutans*. *Campylobacter jejuni* does not mount this enhanced stress resistance stationary phase phenotype but shows a reduced resistance in stationary phase.

In *E. coli* and other Enterobacteriaceae, the entry into stationary phase of growth causes a series of cellular changes. In particular, cells show increased resistance to oxidative stress, near-ultra violet (UV) irradiation, thermal, acid, and osmotic stress and starvation. The increased expression of a central regulator of stationary phase genes, the sigma factor σ^s or RpoS, is responsible for these changes. Increased levels of the sigma factor lead to upregulation of a large series of genes and operons under its control, many of which create increased stress tolerance. Genes such as *tre*A (*osm*A) and *ots*AB, which are associated with trehalose metabolism, provide increased resistance to thermal and osmotic stress; genes for catalase hydroperoxidase, *kat*G and *kat*E, provide oxidative stress protection against hydrogen peroxide; there are also a series of genes involved in deoxyribonucleic acid (DNA) repair which give increased resistance to oxidative stress and near-UV light. Other changes such as a switch to anaerobiosis and the shortening of cell shape may also have a role in creating increased stress tolerance.

Although originally considered as a gene induced in stationary phase, *rpoS* is now seen as a global response regulon as a range of stress factors cause levels of the sigma factor to increase. These include osmotic stress caused by different humectants, starvation, temperature stress, and acid stress. Redox potential has also been shown to influence RpoS induction leading to increased stress resistance as have concentrations of nitrite >500 ppm, although these levels are above those allowed in the food industry. As such the use of sublethal levels of these stresses in foods and food processing present a particular problem. Exposure to sublethal levels of one stress will switch on resistance in the surviving cells to a whole host of other stresses via RpoS induction and will also induce expression of some virulence genes, for example, *spv* in *Salmonella*. Thus cells surviving one sublethal stress will be primed to survive subsequent different stresses and may be more virulent.

Specific Stress Responses

Acid Stress

Although microorganisms have a pH range over which they naturally grow, many organisms show the ability to adapt to low acidic conditions. The acid tolerance response (ATR) can be defined as the induced resistance to a normally lethal low pH challenge following growth or exposure at moderately low pH. This response has been extensively studied and was founded on the original study of Foster and Hall who showed that when exponential phase *Salmonella* Typhimurium bacteria grown at pH 7.6 were shifted to pH 5.8 for one doubling and then challenged with pH 3.3, they survived this normally lethal challenge. The response has been shown to be influenced by a whole range of factors (such as type of acid, the pH challenge used, and growth phase) and more than one molecular mechanism is in place with exponential phase ATR

and stationary phase ATR being different responses. The acid shock proteins (ASPs) which are induced influence a range of cellular metabolism and repair functions and different subsets of these are controlled by central response regulators including RpoS, OmpR, and Fur, as well as the two-component systems PhoPQ and OmpR/EnvZ, each of which regulate a subset of ASPs. Different ASPs are induced in the exponential and stationary phase responses (60 and 48 ASP, respectively having only 5 in common) and by the nature of the acid used (organic vs. inorganic). However, it must be remembered that other bacteria are also capable of mounting this response, for example, *E. coli* and *Listeria monocytogenes* although the precise cellular mechanisms by which this is achieved vary.

Of the many ATR proteins produced glutamate decarboxylase (*gad*) has been shown to be important for very low pH challenge. This enzyme converts glutamate γ-aminobutyric acid (GABA) and in doing so uses up a proton. GABA is then transported out of the cell by an induced antiporter in exchange for another glutamate. Interestingly, whereas *E. coli* and *Shigella* both contain this enzyme, *Salmonella* does not. Arginine decarboxylase, the product of the *adiA* gene, is a second system which provides resistance when arginine is present in the medium. The enzyme converts arginine to agmatine again after consuming a proton in the reaction.

The importance of acid resistance in food safety is that acid-adapted bacteria may then survive a later more extreme challenge. Hence, *Salmonella* surviving exposure to an intermediate pH in a food may then be more able to survive the acid challenge of the stomach. The rate at which a fermentation takes place could also be crucial as a slow rate of initial acid production could lead to acid adaptation and survival in the final product even which this achieves a presumed lethal pH. Moreover, the acid stress response of exponential phase cells has been shown to provide a cross-protective effect to other stresses such as heat shock, high osmolarity, oxidative stress, and DNA damage (although this does not occur reciprocally). The involvement of global regulars in ATR may be an explanation for this but this does mean that cells surviving acid stress will have increased tolerance to other usually hostile environments and not just low pH. From a more beneficial aspect, the acid stress response in probiotic species like *Bifidobacterium longum* has also been investigated with a view to increasing their ability to survive the stomach acid challenge.

Heat Shock

When cells are exposed to a sublethal increase in temperature or heat shock, a set of proteins called the heat shock proteins (hsps) is expressed. This response is ubiquitous in all cells but the precise nature of the genes induced and their regulation varies. Two examples will be used to illustrate this here: heat shock in the Gram-negative bacterium *E. coli* and in the Gram-positive bacterium *Bacillus subtilis*.

In *E. coli* approximately 20 hsps are temperature responsive showing a large increase in their rate of synthesis by 10- to 20-fold. This increase is regulated at the transcriptional level by sigma factor σ^{32} or *rpo*H; a second sigma factor σ^{E} (σ^{24}) has been shown to be important for the regulation of *rpo*H expression itself at high temperature ($>50\ ^{\circ}C$). However, hsps are not always induced only by heat and other stresses such as ethanol can also switch these on. Many of the functions the hsps affect are basic cellular functions such as DNA replication, ribonucleic acid (RNA) and protein synthesis, and cell division and some *rpo*H- regulated hsps are required at all temperatures. In fact, mutants of *rpoH* are compromised for growth, not growing above 20 °C. Therefore, although upregulated during heat shock, the functions of these proteins appear to be more fundamental to the cell. For example, the hsp GroEL increases from $<1\%$ to 20% of cellular protein when *E. coli* is moved from 30 to 46 °C.

Many hsps under σ^{32} control are chaperones whose function is to ensure correct folding of proteins in the cells. As one of the cellular responses to heat is for proteins to denature, chaperones allow correct refolding of these to take place. Typical of these are chaperone teams DnaK–DnaJ–GrpE and GroEL–GroES complexes which act cooperatively in protein folding and are involved in nascent chain folding as well as refolding of thermally damaged protein species.

Other hsps under σ^{32} control are proteases and these break down damaged proteins and thus regulate protein turnover. Typical of these are Lon and Clp proteases which are produced constitutively but are upregulated on heat shock. Their normal function may be to act to control regulator proteins as well as to degrade abnormal or damaged proteins.

In *B. subtilis* there are three classes of heat shock inducible genes. Class 1 are hsps which include GroESL and DnaK and the operons are controlled by a conserved region in the chromosome, controlling inverted repeat of chaperone expression (CIRCE), which is only induced by heat shock. Class 2 hsps are controlled by the alternative sigma factor σ^{B} which is a general stress sigma factor; class 2 heat shock genes are the largest group comprising >125 genes. These also respond to salt, ethanol, and starvation stress and stationary phase, and so are really general stress-response proteins (gsps). Class 3 hsps are independent of σ^{B} and CIRCE and are proteases including the *Clp* genes and Lon. The cellular control of these three systems is complex at the transcriptional/translational level.

Thus both Gram positives and Gram negatives respond to heat stress by producing chaperones to repair the damaged proteins and proteases to remove those that cannot be repaired. However, their cellular control of these is quite different and under complex regulatory systems.

Recent studies on heat shock in *Salmonella* have compared planktonic and immobilized cells. Immobilized cells may be considered to be more typical of what is found in foods where colonial microenvironments may develop. This study examined transcriptome differences in the response of *S.* Typhimurium to treatment at 45 °C for 30 min and showed that the pattern of expression of 538 genes was different if cells were immobilized or planktonic. In particular, invasion of Hela cells and virulence gene expression were two elements which showed differences in expression with immobilized cells in contrast to planktonic cells, showing an increased upregulation. This study demonstrates that understanding of a bacterium's response to stress is dependent on more than the stress alone and the whole of the environmental conditions under which the response is studied needs to be considered.

Cold Shock

Cold shock is induced when cells suffer a temperature downshift of 13 °C. Unlike heat shock it has a less damaging effect on cellular components and the main attribute is the loss of membrane fluidity, nonstabilization of secondary structures of nucleic acids and proteins and reduced function of ribosomes through the formation of RNA structures that cause these to stall and inhibit translation initiation. Like the response to heat shock, cold shock induces a series of proteins, the cold shock proteins (Csps), which are found widely in many organisms. The major Csp, CspA is sufficiently conserved in sequence that it has been suggested as an alternative taxonomic marker in Gram-positive and Gram-negative bacteria.

In the Gram-negative *E. coli*, two classes of Csps are induced. Class 1 shows a 10-fold or greater induction following cold shock. One of these is the CspA family, a structurally related group of proteins; although there are nine homologous proteins in CspA-I, only CspA, CspB, CspG, and CspI are induced on cold shock and these are nucleic acid chaperones. Of these CspA is expressed at the highest levels and its role is to bind to single-stranded RNA and function as an RNA chaperone to prevent secondary structure formation. CspB and CspG are believed to perform a similar role but may also act as DNA chaperones assisting in DNA replication. Other Csps in class I are CsdA, RbfA, and NusA, all of which are ribosome-associated proteins assisting in ribosome function, and polynucleotide phosphorylase, a ribonuclease which may be involved in mRNA degradation.

Class 2 Csps are all induced to a much lesser extent (<10 fold); three of these are bacterial translation initiation factor IF2, GyrA and H-NS. IF2 is again a ribosome-associated protein involved in translation and is required for efficient ribosome function at low temperatures. IF2 ensures that protein synthesis begins at the correct codon within a messenger RNA by mediating the binding of the initiation tRNA (fMet-tRNA) to the 30 S subunit.

In the Gram-positive *B. subtilis* the block in translation initiation also induces a series of ribosome-associated proteins which are functionally similar to those seen in *E. coli*; however many of these are parts of the standard translation system and are not cold specific.

Loss of membrane fluidity is a major factor which affects the functioning of the cell as transport and secretion systems are impaired. A change to lower temperatures results in a change in lipid composition to ensure that the liquid crystalline nature of the membrane is retained and to prevent the formation of a gel state. Fluidity in part is regulated by the ratio of unsaturated to saturated fatty acids present in membrane lipids. In aerobic bacteria this can occur by direct conversion of unsaturated to saturated states. In *Bacillus* this is through the action of the membrane-bound desaturase enzyme, *des*, the gene for which is cold inducible. In *E. coli* increased activity of the enzyme synthase II converts palmitic acid to cis-vaccenic acid. It is also reported that in *L. monocytogenes* the ratio of anteiso- to iso-branched fatty acids is dramatically changed after temperature downshift.

In *L. monocytogenes* which is a psychrotrophic bacterium (a mesophile which can grow at low temperatures) balanced growth at low temperatures has been called cold acclimation and proteins exhibiting increased synthesis during this period are called Caps. Five of the 12 Csps induced in *Listeria* are also Caps. This includes CspLa, the major Csp protein in *Listeria*. As well as this, an oligopeptide-binding protein, OppA, is required for low-temperature growth.

Osmotic Shock

Osmotic shock in bacteria occurs when they are placed in hypo- or hypertonic conditions and a range of humectants widely used in the food industry can induce this state. Most work has concentrated on the effect of NaCl as this is experienced naturally as well as in artificial conditions such as foods. With the exception of true halophiles, a salt concentration of approximately 1% is optimum for most organisms but some species are naturally halotolerant and will grow at high salt levels, for example, *S. aureus* and *L. monocytogenes* will grow in conditions of up to 10% salt.

In high osmolarity environments the cell needs to prevent water loss to the environment and this is achieved by the accumulation of compatible solutes in the cell. K^+ ion influx is a rapid initial response in *E. coli*, occurring via three different uptake systems. Following this in Gram-negative bacteria, glutamate is synthesized by two enzymes: glutamate dehydrogenase and glutamate synthase and accumulates quickly; this synthesis is dependent on K^+ ion as an initiator for synthesis. Following this, another compatible solute trehalose is synthesized by the *otsAB* operon. OtsA is a trehalose-6-phosphate synthase and OtsB is a trehalose-6-phosphate phosphatase. These genes are under RpoS control as already discussed and *rpoS* is induced in exponential phase by high osmolarity. Gram-positive bacteria show a similar response although proline generally replaces glutamine.

Many compounds found in animals and plants can act as osmoprotectants in bacteria. These include compounds such as betaine, choline, and carnitine. In the presence of these, cells will accumulate derivatives, for example, in *E. coli* choline is converted to betaine aldehyde and then to glycine betaine. The ProU permease in *E. coli* shows a higher affinity for betaine than for proline.

In many of the enteric bacteria, a change in several major outer membrane proteins occurs in high osmolarity. In particular, there is a switch in the expression of OmpC and OmpF. These are porin proteins which form pores in the membrane. The pore size of OmpC is smaller than that of OmpF and in high osmolarity, OmpC porin predominates, reducing the ingress of solutes. *ompR* is one of the regulatory genes for this system, another central regulatory system.

Oxidative Stress

Microorganisms grow under a range of atmospheric conditions from the strict aerobes which have an absolute requirement for oxygen to grow to facultative anaerobes that can grow with or without oxygen to strict anaerobes which are killed by oxygen presence. In respiratory organisms, the generation of oxygen radicals is potentially damaging to DNA, proteins, and lipids. A series of enzymes are responsible for the inactivation of these and these can also protect the organism from applied oxidative stress. Hydrogen peroxide is excreted as a waste product by many heterofermentative lactic

acid bacteria and may also be used in surface sterilization procedures. It can also be formed as a product of superoxide dismutase (SOD) which converts superoxide radicals to hydrogen peroxide and oxygen. Hydrogen peroxide is inactivated by catalase, the enzyme breaking it down into oxygen and water.

In *E. coli* there are two catalase genes, *katG* and *katE*, which are complexly regulated; *katE* expression is solely under *rpoS* regulation and hence its expression correlates with the levels of RpoS in the cell. *katG*, in contrast, is also part of another response regulon under the control of *oxyR*, another global response regulator, which is induced in response to oxidative stress. There is an interdependence of these regulators involved in *katG* expression. OxyR in turn regulates OxyS, a small RNA regulator which negatively regulates the levels of active RpoS in the cell. This is believed to be a fine-tuning mechanism to allow induction of only the oxidative stress genes which are under the control of both regulators (e.g., *katG*) and to avoid the full expression of the RpoS regulon under conditions of oxidative stress. Hence, cellular levels of catalase activity are regulated in a complex manner and different genes may be involved at different stages of growth. Another gene under OxyR control is alkyl hydroperoxide reductase (ahpC and ahpF), the function of which is probably in the detoxification of lipids and other hydroperoxides produced during oxidative stress.

In a number of studies examining the induction of genes involved in the stress response to a variety of stresses, induction of oxidative stress protection systems have been reported even when the organisms were not exposed to oxidative stress. Privalle and Fridovich showed that *E. coli* expresses SOD when exposed to heat stress, and Belkin *et al*. showed that catalase was induced following ethanol challenge. In *S. aureus* Armstrong-Buisseret *et al*. demonstrated that alkyl hydroperoxide reductase is induced when the organism was subjected to osmotic shock. Deficiencies in any of the protective mechanisms against oxidative stress lead to multiple stress sensitivity in bacterial cells, for example, *E. coli* deficient in SOD was reported to be sensitive to heat, as well as O^{2-}.

Dodd *et al*. advanced a theory suggesting that a major cause of damage in sublethally injured cells is intracellularly produced free radicals; this effect was termed the bacterial suicide response. The central tenet of this theory is that, when injured by any applied stress, actively growing cells produce a burst of free radicals which causes oxidative damage to the cell; this contributes to cellular injury and death. This response occurs regardless of the nature of the stress causing the injury and is generic in nature. Exponential phase cells, because of their greater metabolic flux, are more susceptible to the effect than stationary phase ones and hence incur greater damage in response to sublethal injury. The presence of a free radical burst on exposure to sublethal injury has been demonstrated by Aldsworth *et al*. (1998b).

Conclusion

From the work discussed in this article, it can be seen that the induction of resistances following a variety of environmental stresses can also lead to induction of other stress regulons and in particular, some of the central stress regulators like *rpoS* which coordinately induce a whole range of other resistances and indeed virulence genes. There are obvious disadvantages in this for the food industry. The move toward minimal processing to improve the quality of foods may mean that there is a greater risk of this occurring.

CHARACTERISTICS OF FOODBORNE HAZARD AND DISEASES

Sublethally Injured and Viable but Nonculturable Cells

BM Mackey, University of Reading, Reading, UK

Glossary

Microcosm Sealed chamber containing water from a natural source into which microorganisms are inoculated for survival studies.

Pre-enrichment An incubation step in a non or mildly-selective medium that allows cells to repair injury and multiply before being subcultured into a more selective medium.

Reactive oxygen-containing species Oxygen-containing compounds, ions, or free radicals that react directly with cell components causing damage or giving rise to reactive products. Examples include hydrogen peroxide, superoxide anion, hydroxyl free radical, and singlet oxygen.

Resuscitation Procedure in which sublethally injured or VBNC cells are incubated under appropriate conditions to allow repair of injury and/or recovery of culturability.

Selective medium A medium containing selective agents that when incubated under appropriate conditions suppresses growth of unwanted organisms, while allowing multiplication of the target group of organisms.

Introduction

Detecting and enumerating viable microorganisms forms an essential part of any strategy for ensuring the microbiological safety and quality of food. However organisms that have survived exposure to food processing treatments may suffer debilitating cellular injury that renders them unable to grow on the selective media used for their detection. Another class of organisms, those in the viable but nonculturable (VBNC) state, are believed to be viable but unable to grow on media that normally support their growth. Under suitable conditions, injured or VBNC cells can resuscitate and regain all their normal properties, including virulence. Understanding the properties of these organisms and how they may be recovered is therefore important in assessing risks to public health.

Properties of Sublethally Injured Cells

Injured cells display a diverse range of altered growth properties. These are summarized in Table 1, together with possible explanations for the altered phenotypes.

An example of the practical implications of sublethal injury when assessing the survival of *Escherichia coli* O157 under conditions simulating those in a fermented sausage is shown in Figure 1. When counts were made on Sorbitol MacConkey Agar (SMAC), it appeared that a 5-log reduction had been achieved by approximately 10 days storage, whereas enumeration on Tryptone Soya Agar (TSA) showed that this underestimated survival by a factor of approximately 10 000 and in fact viable organisms were still present after 30 days.

Resuscitation and Repair of Injury

Repair of injury in pure cultures can be demonstrated by the differential plating method, in which injured cells are incubated in a suitable liquid medium and samples removed at intervals for plating onto selective and nonselective agar media (Figure 2). The nonselective medium allows growth and enumeration of both injured and healthy cells, whereas the selective medium allows growth of uninjured cells only. During the extended lag period, repair takes place and cells regain their ability to grow on the selective medium. Multiplication ensues usually, soon after the repair of injury is complete.

Under optimum conditions, injury caused by chilling, freezing, freeze-drying, γ-radiation, or acid is normally repaired within 4–5 h and often within 1–2 h. Mild heat injury can be repaired in approximately 5 h, but cells with severe heat injury may require much longer times, up to 24 h in extreme cases. The severity of injury varies within injured populations and this is reflected in wide differences in lag times of individual cells. Such heterogeneity becomes relevant when examining samples likely to contain low numbers of pathogens.

Screening for the Presence or Absence of Pathogens

For pathogenic microorganisms that have a low infective dose such as *E. coli* O157, *Campylobacter jejuni*, and *Salmonella enterica* serovars, the presence or absence of the target organism is the main concern and prolonged pre-enrichment can be used, because multiplication after repair will not affect the result and will in fact increase the sensitivity of detection. With *Salmonella*, pre-enrichment in buffered peptone water or lactose broth has been

 doi:10.1016/B978-0-12-378612-8.00064-0

Table 1 Symptoms of sublethal injury

Symptom of injury	*Probable or possible cause of injury*
Sensitivity to ingredients of selective media: bile salts, dyes, and hydrophobic antibiotics	Loss of lipopolysaccharide from Gram-negative outer membrane or loss of gram-positive surface protein layer. Loss of transmembrane proton gradient and multidrug efflux pump activity
Sensitivity to lysozyme, bacteriocins, and large hydrophilic antibiotics	Transient physical disruption of Gram-negative outer membrane
Sensitivity to acid, alkali, osmotic stress, and some inorganic ions	Unknown. Possibly impairment of cytoplasmic membrane barrier properties toward cations and protons. Physical disruption of efflux or uptake systems involved in homeostasis. Depletion of cellular adenosine triphosphate or loss of proton motive force required for membrane transport systems
Sensitivity to exogenous oxidative stress	Inactivation of protective enzymes catalase, peroxidase, and superoxide dismutase Depletion of intracellular reductants or inactivation of thiol disulfide redox systems Increased permeability of membrane toward exogenous oxidants
Increased production of intracellular reactive oxygen species	Membrane perturbation leading to disorganization of electron chain components and increased likelihood of univalent reduction of oxygen by intermediates of the chain Imbalance in metabolism leading to increased metabolic production of hydrogen peroxide or superoxide Disruption of iron sulphur complexes, release of iron and production of hydroxyl free radical by Fenton reaction
Altered nutritional requirements for growth (real or apparent)	Enzyme inactivation (e.g., peptidases) Sensitivity to peroxide in rich media or requirement for reductants (minimal medium injury) Metabolic imbalance on nutritional upshift
Restricted temperature range for growth	Unknown. Possibly imbalance between repair and degradative processes
Loss of virulence	Unknown
Extended lag	Need to resynthesize damaged membranes, nucleic acids, ribosomes, etc

in use since the 1970s, but a wide range of other pre-enrichment broths have been approved by official bodies depending on the target organism and type of food being examined. Details of pre-enrichment media, appropriate for specific organisms, can be found in other chapters of this Encyclopedia and from official sources such as the International Organization for Standardization (ISO) or the Bacteriological Analytical Manual (BAM) of the US Food and Drug Administration (FDA).

Recommended pre-enrichment-incubation periods for presence–absence tests are generally around 16–24 h, although much shorter periods have often been advocated; especially with rapid methods employing nucleic acid-based endpoint detection systems. Short resuscitation steps are perfectly adequate for many types of food, but may give false-negative results if severely injured organisms are present. However, prolonged incubation in nonselective medium can lead to overgrowth by competitor organisms that suppress the growth of the target organisms. A compromise arrangement employed with *Campylobacter* spp. is to have a short and nonselective incubation period (e.g., 4 h), followed by the delayed addition of antibiotics, and/or an increase in the incubation temperature. This procedure allowed the detection of *Campylobacter* from bathing beaches, a difficult habitat from which to isolate pathogens. Delayed addition of selective ingredients can be accomplished by the use of timed-release capsules which, though effective, have not found wide use.

Enumeration Using the Most Probable Number Method

Enumeration of injured cells can be achieved by combining liquid resuscitation with the most probable number (MPN) approach. Following serial dilution of the sample, replicate volumes are inoculated from each dilution into separate tubes of nonselective medium to allow resuscitation, and this is followed after a suitable interval by subculture to a selective medium appropriate for the target organism. The number of positive replicates on or in a selective medium at each dilution is recorded and MPNs are estimated by reference to standard tables. The method depends only on the proportion of tubes showing growth, and is thus not affected by the extent of multiplication after repair. An example of this method is the multiple-tube MPN method for the enumeration of *E. coli* in water, in which resuscitation in minerals-modified glutamate medium is followed by incubation in bile salts and brilliant green-containing media. The MPN method is sensitive but labor intensive, and the precision is poor unless the number of replicate tubes per dilution is very large. Microwell plates have sometimes been used for greater convenience rather than tubes or bottles.

Enumeration Using Selective Agar Media

Baird–Parker selective agar for *Staphylococcus aureus* is unusual in that it supports good recovery of cells damaged by drying, freezing, or heating. There are few other examples of non-inhibitory selective media, so a resuscitation step is needed to allow recovery of injured cells before exposure to selective agar. Resuscitation in broth before plating on agar is unsatisfactory because cell multiplication in the broth may occur leading to an overestimate of viable numbers. If resuscitation is allowed to take place in cells immobilized on agar, then enumeration problems arising from multiplication after repair are circumvented. The thin agar layer method consist of pouring a layer of

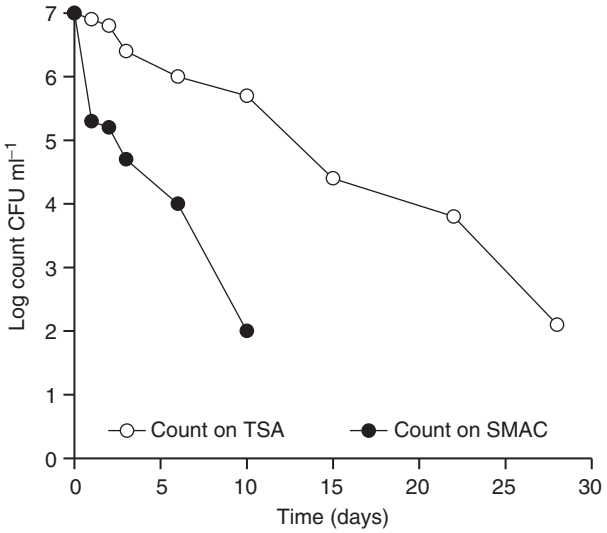

Figure 1 Sensitivity of sublethally injured *E. coli* O157 to selective media. Cells were inoculated into Tryptone Soya Broth containing 13.5% NaCl adjusted to pH 4.9 with lactic acid representing conditions found salami. Samples were removed at intervals for viable counting on TSA or SMAC. Reproduced from McCarthy J, Holbrook R, and Stephens PJ (1998) An improved direct plate method for the enumeration of stressed *Escherichia coli* O157:H7 from food. *Journal of Food Protection* 61: 1093–1097. © International Association for Food Protection, Des Moines, Iowa, USA.

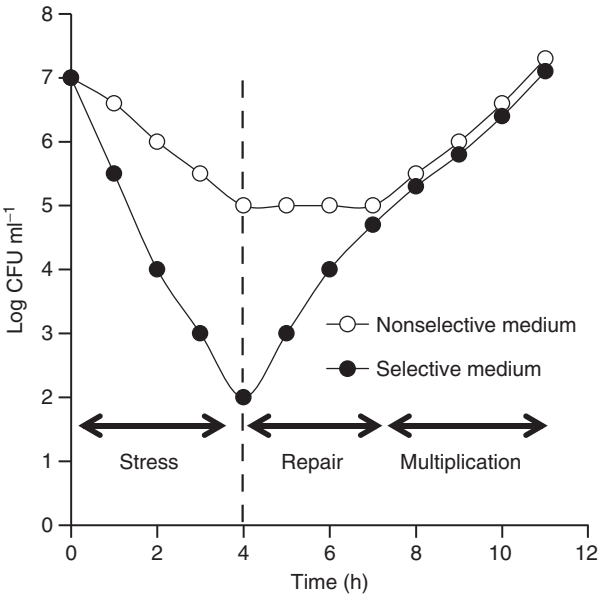

Figure 2 Development of sublethal injury and subsequent repair monitored using the differential plating method.

nonselective agar over a selective medium and allowing this to set immediately before spreading the sample (Figure 3(a)). Resuscitation takes place on the nonselective layer as selective agents diffuse into the upper layer to suppress the growth of competing bacterial species. A method that avoids having to pour agar immediately before spreading the sample consists of spreading samples on acetate or polycarbonate membranes, which are incubated on nonselective medium to allow injury repair before transferring the membranes to selective agar (Figure 3(b)). This method is in routine use for the enumeration of *E. coli* as indicator organisms.

Preventing Death of Injured Cells from Oxidative Stress During Recovery Procedures

Sensitivity to oxidative stress can exacerbate the inhibitory effects of selective media ingredients toward injured cells and can even prevent their growth on supposedly noninhibitory nutrient media. Avoidance of oxidative stress depends on minimizing the metabolic generation of damaging reactive oxygen-containing species (ROS) and/or by removing exogenous oxidants present in recovery media. During normal respiration, small amounts of the damaging superoxide anion or hydrogen peroxide are produced, but in healthy cells these are removed by the action of superoxide dismutase and catalase. The fine balance between the production and removal of ROS can be disturbed either by inactivation of protective enzymes or by an increased metabolic flux of peroxide or superoxide. This appears to happen in injured cells, although the mechanisms are not fully understood (Table 1).

Metabolically-generated oxidative stress can be avoided by allowing injured cells to resuscitate under anaerobic conditions. This has been shown to improve recovery of heat-injured cells of *E. coli* and *Listeria monocytogenes* substantially, sometimes by several orders of magnitude (Figure 4).

Resistance to aerobic incubation is recovered during the lag phase when cells are incubated anaerobically. It is important to note that this dramatic enhancement of the recovery of injured cells during anaerobic incubation in broth restores the ability to grow aerobically on nonselective nutrient media such as TSA. It is therefore highly relevant to laboratory studies with pure cultures designed to establish resistance to heat and other processes used in food preservation. It is also worth noting that aerobic incubation in static liquid medium causes less oxidative stress than incubation on the surface of an agar plate so that MPN counts in broth are much higher than plate counts on agar media of similar composition.

Exogenous oxidative stress can arise from the presence, in recovery media, of hydrogen peroxide, superoxide anion, organic peroxides, and other uncharacterized oxidants. These can be generated in nutritionally rich media by a range of processes including reactions between reducing sugars and phosphate during autoclaving and by subsequent photochemical oxidation of tryptophan, riboflavin, or peptones. Tests using low numbers of injured *Salmonella* cells have shown that the numbers of cells able to recover in commercially available nonselective broth media can vary by orders of magnitude. This was attributed to differences in the inhibitory properties of different peptone ingredients. Exogenous oxidative stress can be minimized by formulating media with noninhibitory peptones and by adding supplements that act as reducing agents or remove exogenous ROS. These include blood, charcoal, catalase, sodium pyruvate, sodium metabisulphite, and ferrous sulphate. For example, a blood-free charcoal cefoperazone deoxycholate (CCD) selective agar commonly used for *Campylobacter* spp.

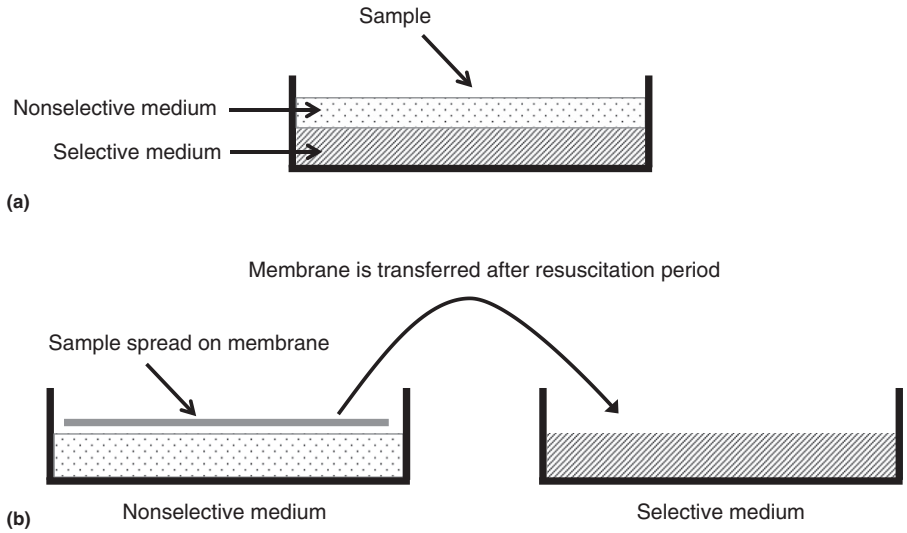

Figure 3 Solid medium repair. (a) Sample is spread on a thin layer of nonselective medium that has been overlaid on selective agar. (b) Sample is spread on membrane filter on nonselective agar. After incubating to allow repair of injury, membrane is transferred to selective agar.

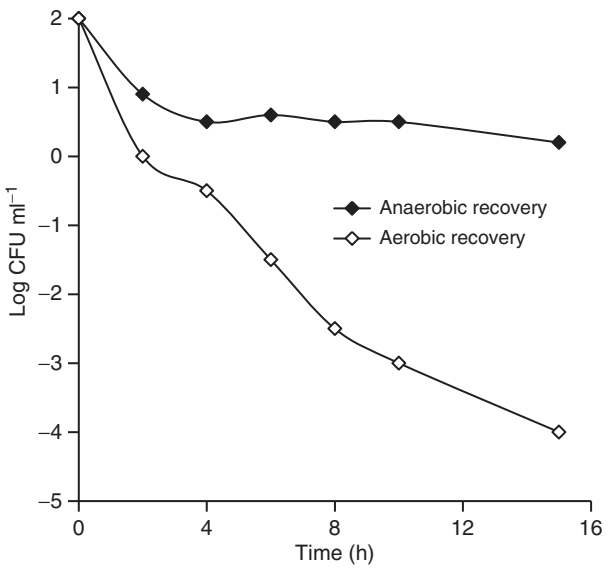

Figure 4 Effect of anaerobic incubation on recovery of heat-injured cells *E. coli* O157. Reproduced from George SM, Richardson LCC, Pol IE, and Peck MW (1998) Effect of oxygen concentration and redox potential on recovery of sublethally heat-damaged cells of *Escherichia coli* O157:H7, *Sal. enteritidis* and *Listeria monocytogenes*. *Journal of Applied Microbiology* 84: 903–909, with permission from Wiley.

contains a mixture of charcoal, sodium pyruvate, and ferrous sulphate, whereas sodium pyruvate is included in buffered *Listeria* enrichment broth and universal pre-enrichment broths specified in the BAM of the FDA.

Strictly anaerobic conditions can be achieved by working entirely within an anaerobic cabinet with pre-reduced media. More convenient methods for achieving anaerobiosis are available including the use of 'Oxyrase,' a proprietary crude membrane preparation from *E. coli* that scavenges oxygen with high affinity. The simple expedient of incorporating the reducing agent cysteine into recovery broth and sparging the headspace with nitrogen allowed the recovery of severely heat-injured *L. monocytogenes*. The use of semisolid media containing cysteine in screw-capped tubes achieved the same end. As a minimum precaution, when estimating viable numbers of stressed cells in pure culture studies, catalase or sodium pyruvate should be incorporated into nutrient nonselective agars, for example, when determining resistance to heat, high pressure acidity, and other preservation processes.

Viable but Nonculturable Cells

In recent years, there has been considerable interest and concern about possible safety problems posed by VBNC cells. These are physically intact and show metabolic activity of various sorts, but fail to multiply on nonselective media that normally support their growth. In many studies, the VBNC state has been induced by incubating cells at low temperature in natural water microcosms, but more acute stresses may induce nonculturability including aerosolization, freezing and thawing, and exposure to weak organic acids and biocides. *Vibrio vulnificus* can be induced to enter the VBNC state by growing in artificial seawater at 20–25 °C and then decreasing the temperature to approximately 4–5 °C. The cells change in shape from rods to cocci and rapidly become nonculturable, but retain metabolic activity.

A number of indicators of cellular integrity and metabolic activity have been used as indicators of viability when studying the VBNC state. One that is widely used is the BacLight Live–Dead kit, which stains cells with a mixture of the fluorescent dyes, SYTO-9 and propidium iodide. SYTO-9 is a membrane-permeant nucleic acid stain, which stains all cells and therefore gives the total cell count, whereas propidium iodide stains only cells with disrupted cytoplasmic membranes, which are scored as dead. Intact cells are counted as viable. Other methods are based on the detection of esterase activity, reduction of tetrazolium salts, membrane potential, induced enzyme synthesis, gene expression, and the presence of short-lived mRNA. The Kogure direct microscope count method depends on the

Table 2 Examples of treatments leading to an increase in culturability *in vitro*

Organism	*Inducer of VBNC state*	*Resuscitation treatment*
Vibrio vulnificus and *Vibrio parahaemolyticus*	Starvation at 5 °C in artificial seawater medium	Temperature upshift to 20–25 °C
Campylobacter jejuni	Anaerobic incubation	Incubation under microaerobic conditions with added spent medium
Salmonella enterica serovar Typhimurium	Starvation in river water 25 °C	Nutrient addition
Sa. enterica serovar Typhimurium	Prolonged incubation in water microcosm. Heating at 53 °C	Incubation in nutrient broth supplemented with Ferrioxamine E, Oxyrase or heat-stable enterobacterial autoinducer (AI)
Sa. enterica serovar Oranienberg	Incubation in 7% NaCl at 37 °C	Resuscitation promoting factor (Rpf)-like protein derived from *Salmonella* Typhimurium; product of *YeaZ* gene possibly a peptidase
Escherichia coli (clinical or food isolates)	Starvation in 0.9% and 4% saline at 4 °C	Minimal medium supplemented with methionine, glutamine, threonine, serine, and asparagine
E. coli O157	Sodium hypochlorite	Conditioned medium, Autoinducer AI-2
Micrococcus luteus, *Rhodococus rhodocrous*, *Mycobacterium tuberculosis*, and *Mycobacterium smegmatis*	Prolonged incubation in stationary phase	Incubation in liquid medium alone or with Rpf with muralytic activity
Staphylococcus aureus	Starvation at seawater at 4 °C	Temperature upshift to 22 °C

ability of cells to elongate in response to nutrients in the presence of an antibiotic that inhibits cell division.

Resuscitation of Viable but Nonculturable Cells

If one accepts the widely held view that a viable microbial cell is one that is capable of multiplying under suitable conditions, then definitive proof that putative VBNC cells are actually alive depends on applying a resuscitation treatment that restores culturability. A wide range of resuscitation treatments have been reported (Table 2).

When VBNC populations of *V. vulnificus* produced by starvation at low temperature are warmed to approximately 20 °C, there is a rapid increase in plate counts accompanied by a transformation of coccoid to vibrioid cell shape. This procedure has been criticized because it does not distinguish between resuscitation and multiplication of a few residual culturable cells present in the population. Nevertheless, some studies with *V. vulnificus* and other organisms have demonstrated resuscitation in samples in which the probability of residual culturable cells was vanishingly low. However resuscitation is often followed or accompanied by cell multiplication, so it is impossible to know by simply following the increase in colony counts and proportion of cells in the original population that were capable of resuscitation. Ambiguity can be avoided by using the MPN approach described in Section 'Enumeration Using the Most Probable Number Method'. Suspensions of bacteria containing VBNC cells are serially diluted in a liquid medium before applying the resuscitation treatment. The MPN after resuscitation can be compared with the plate count to give the proportion of VBNC cells in the population. Unfortunately most reported studies fail to use the MPN approach, so the size of the putative viable population relative to the total number of metabolically active cells is often unknown.

Virulence of Viable but Nonculturable Cells

Virulence of cells in the VBNC state has been tested with *Sal. enterica* serovar Typhimurium, *E. coli*, *L. monocytogenes*, *V. vulnificus*, *Vibrio cholerae*, *Legionella pneumophila*, *Ca. jejuni*, *Helicobacter pylori*, *Aeromonas salmonicida*, *Shigella dysenteriae*, and *Enterococus faecalis*. Infectivity has been measured in a variety of ways including injection into suckling mice, ligated rabbit ileal loops or embryonated eggs, colonization of chicks, and ability to cause symptoms in human volunteers. Unfortunately, the results have been variable and sometimes contradictory. Although several carefully designed studies demonstrated the potential of VBNC cells to cause disease, others found no such effect. This may perhaps be related to differences between strains, protocols, or the method of producing VBNC cells. One study with VBNC cells of *Ca. jejuni* generated by storage at 4 °C in artificial seawater found that cells could be resuscitated by passage though the mouse intestine for considerable time after the loss of culturability, but the capacity for resuscitation diminished progressively and was lost before the loss of metabolic activity measured as ability to reduce the fluorescent tetrazolium salt, 5-cyano-2,3-ditolyl tetrazolium chloride (CTC). Infectivity may thus be retained transiently after cells become unable to grow on agar plates.

Resistance of Viable but Nonculturable Cells

There have been a few reports that VBNC cells are more resistant to physical and chemical stress than culturable cells in accord with their supposed role in survival. *Vibrio parahaemolyticus* VBNC cells were more resistant to heating at 42 °C and 47 °C than exponential phase cells when viability after heating was assessed by the BacLight Live–Dead kit. *V. vulnificus* VBNC cells were similarly found to be somewhat more resistant to high hydrostatic pressure than exponential

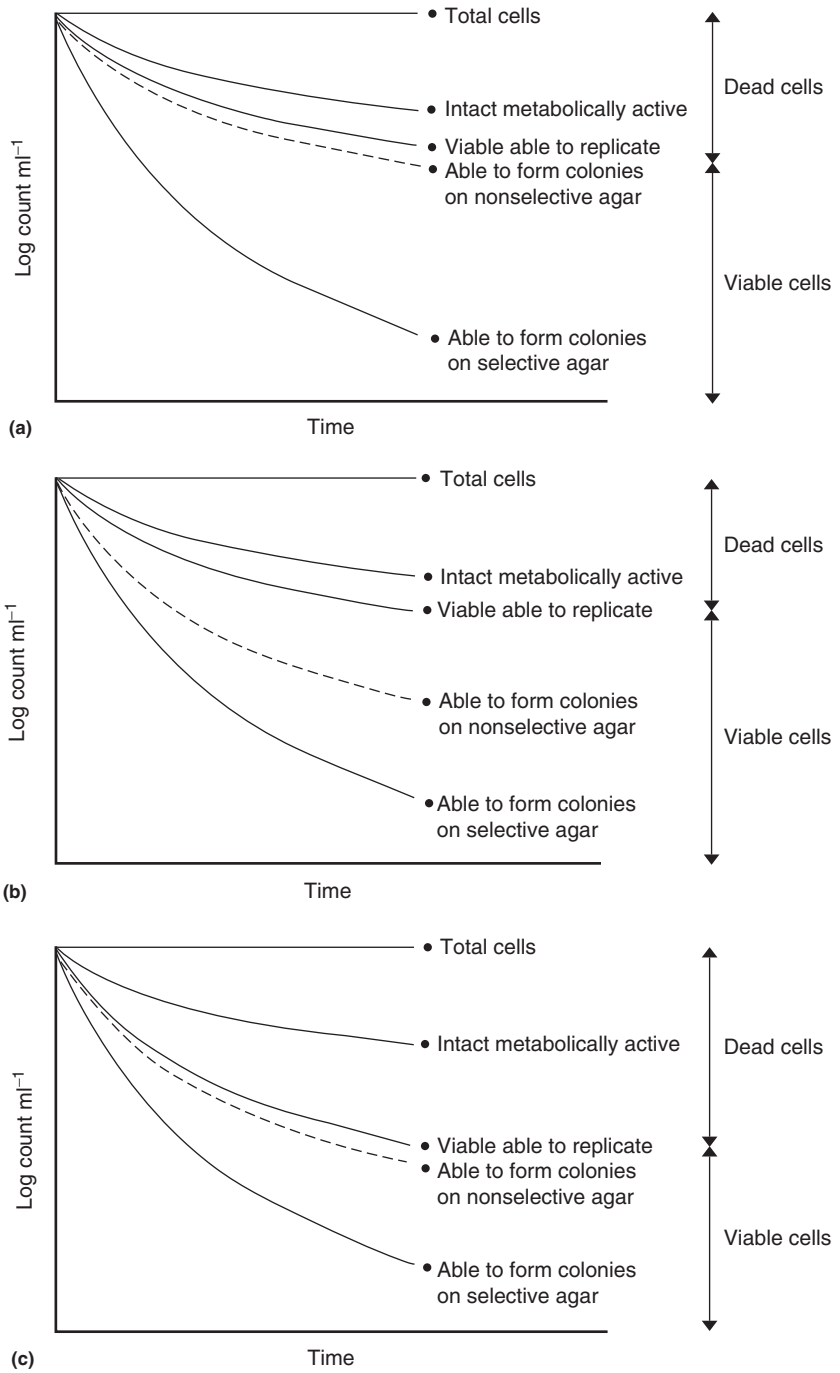

Figure 5 A general scheme for describing development of sublethal injury and entry into VBNC. (a) Loss of culturability occurs at a similar rate to loss of viability. (b) Loss of culturability occurs faster than loss of viability. (c) Loss of viability and culturability occurs much faster than loss of metabolic activity.

phase cells. *Ca. jejuni* cells, however, were more sensitive to a range of disinfectants but more resistant to chlorine. A problem with these and other similar studies is that the number of cells actually able to resuscitate after exposure was not determined. The susceptibility of *V. vulnificus* to sonication can be assessed directly by the microscopy of treated cells. This showed that the resistance of cold-incubated VBNC cells was initially similar to that of growing cells but increased to equal that of starved but culturable cells. Prolonged storage of *Mycobacterium smegmatis* leads to the formation of morphologically distinct ovoid dormant cells that do not form colonies on agar but can be resuscitated in liquid medium. Thermal resistance of starved cells was much higher than that of cells from a 24-h culture. Survival was assessed by colony counts so although VBNC ovoid cells were present in the aged suspension, the survivors must have been derived from

Table 3 Sublethal injury of bacterial spores

Treatment	*Symptom of injury*	*Possible cause or mechanism*
Heat	Better recovery on rich than minimal media	Reduced biosynthetic burden. Probably many different mechanisms
Heat	Recovery dependent on addition of starch or activated charcoal to recovery media	Sensitivity to unspecified inhibitors present in recovery media that are neutralized by additives
Heat	Requirement for non-nutrient germinants (lysozyme, calcium–dipicolinic acid)	Inactivation of germination system
Heat	Sensitivity to lysozyme	Damage to spore coat
Heat and radiation	Restricted temperature range for recovery	Inactivation/activation of germination systems having different temperature optima Damage to spore protoplast membrane leading to lysis on outgrowth at non-optimal temperatures
Heat, ionizing radiation, and oxidizing agents	Increased sensitivity to sodium chloride	Damage to spore protoplast membrane. Damage to metabolic enzymes and inability to generate adenosine triphosphate needed for biosynthesis of osmolytes
Heat	Sensitivity to nitrite (low concentrations)	Inhibition of germination systems
Heat	Increased sensitivity to organic acids	Unknown
Heat and oxidizing agents	Increased sensitivity to surface active compounds and certain antibiotics	Damage to spore protoplast membrane. Inactivation of detoxification mechanisms
Ionizing radiation	Decreased heat resistance	Damage to spore cortex and partial rehydration
Acid	Greatly reduced heat resistance	Loss of cations from spore cortex affecting level of spore hydration
Alkali and/or reducing agents	Sensitivity to iodine chloroform, ethanol, glutaraldehyde, and other disinfectants	Damage to spore coat

culturable cells. Based on the few studies so far available, there is no firm evidence that nonculturable cells are more resistant than cells that have mounted a starvation or stationary-phase stress response. There appear be no studies in which a stress treatment has been applied to a VBNC population, and the number of surviving viable cells has been assessed after exposure by using the MPN resuscitation approach.

Nature of the Viable but Nonculturable Condition

A commonly held view is that the VBNC state is an adaptive survival mechanism analogous to spore formation that results from a genetically regulated developmental process. An alternative view is that it is a transient phase in a degenerative process leading to cell death. Changes reported to be characteristic of entry into the VBNC state include a decrease in metabolic activity, a decrease in cell size and adoption of a more rounded or coccoid cell shape, an increase in cross-linking of cell wall peptidoglycan, and changes in membrane phospholipid composition. It remains difficult to identify changes that are uniquely related to the VBNC condition because somewhat similar changes occur in starved culturable cells.

Although the term VBNC is used as a blanket term, it is now clear that there is more than one cause for nonculturability. Evidence is now accumulating that in *V. vulnificus* and some other organisms, nonculturability is due to sensitivity to oxidative stress rather than being an adaptation for survival. Sensitivity to exogenous oxidants appears to be due to inactivation of catalase following cooling to 5 °C; and the addition of catalase or pyruvate to agar media restores culturability. Conversely, a mutant of *V. vulnificus* that remained culturable when exposed to artificial seawater at 4 °C was found to overexpress glutathione *S*-transferase and was more resistant to hydrogen peroxide. Similarly, mutational inactivation of catalase or superoxide dismutase in *Sta. aureus* made cells hypersensitive to becoming nonculturable in seawater at 4 °C and prevented resuscitation on raising the temperature to 22 °C. The resuscitation promoting effect of ferrioxamine on *E. coli* and *Sal. enterica* serovar Typhimurium may perhaps be related to its ability to chelate iron and prevent the production of superoxide anion via the Fenton reaction. The sensitivity to oxidative stress of this class of VBNC cells is thus identical to that of sublethally injured cells described in **Table 1**. The role of enterobacterial autoinducer in resuscitation remains unclear and organisms responding to this compound may perhaps represent a different class of VBNC cells.

The nonculturable state of *Micrococcus luteus* arises for different reasons. When grown in a minimal medium and maintained for several months in stationary phase *Mi. luteus* enters a state of very low metabolic activity, becomes smaller in size, and loses its ability to grow on agar plates unless first resuscitated in liquid medium. Resuscitation is considerably enhanced by the presence of other live cells, spent culture medium or, more specifically, by resuscitation promoting factor (Rpf) a 17-kDa protein with lysozyme-like activity secreted by active cells. The requirement for Rpf has been interpreted as a mechanism, wherein a few growing cells in the population can communicate to dormant ones that conditions are favorable for growth.

Loss of culturability at low temperature in vibrios can be prevented if the starvation response is first initiated at higher temperatures. Nonculturability may therefore represent a

symptom of debilitation rather than a positive survival response. An interpretation of the VBNC condition is shown in Figure 5. This proposes that culturability on selective or nonselective media, metabolic activity, and viability (ability to replicate under appropriate conditions) can decline at different relative rates during starvation or exposure to other stresses. In Figure 5(a), culturability and viability decline at similar rates during starvation as occurs in cells that have mounted a general stress response. In Figure 5(b), culturability declines much faster than either viability or metabolic activity as occurs in VBNC cells. In Figure 5(c), viability and culturability decline much faster than loss of membrane integrity and metabolic activity as would occur in ultraviolet-irradiated cells. This scheme sees loss of culturability as a transient state before loss of viability during which cells are intact and metabolically active and may retain virulence for a while albeit at a reduced level but require resuscitation before they can grow on agar plates.

Spore Injury

The pioneering studies of Esty and Meyer in the 1920s on the thermal destruction of *Clostridium botulinum* spores and subsequent work by others with *Bacillus* spp. revealed that recovery of heat-treated spores was markedly influenced by the composition of the medium, incubation temperature, and gas atmosphere. It was also discovered that heated spores became more sensitive to sodium chloride and other food preservatives. The spore is a dormant structure and injury is sometimes only detectable during germination or outgrowth. Table 3 gives examples of different manifestations and possible mechanisms of spore injury.

Severely damaged spores may require additives such as blood, charcoal, pea infusion, or starch for maximum recovery. Injured anaerobic spores may be very sensitive to gas atmosphere or redox potential though in some cases the simple expedient of pour plating and incubating anaerobically is adequate. The addition of bicarbonate to Reinforced Clostridial Agar has been shown to increase the recovery of heat-damaged spores of *Cl. botulinum*, *Clostridium sporogenes*, and *Clostridium. histolyticum*. Spore germination times often follow a log-normal or skewed log-normal distribution with some spores having very long lag times. In predictive modeling studies of survival and growth of spores under different conditions, it is advisable to make observations for 3–6 months to allow for delayed spore germination.

Conclusions

Practical resuscitation treatments are often a compromise between recovering all sublethally injured cells and avoiding overgrowth of competitors. With regard to VBNC cells, there is little evidence that nonculturability *per se* confers any enhanced resistance to environmental stress over that of cells that have mounted a general stationary-phase stress response. The dormant condition, however, can readily be understood as a mechanism for enhancing long-term survival and resistance to antibiotics that require active metabolism for their effect. Apart from *Mi. luteus* and related Actinobacteria nonculturability appears to be a consequence of debilitation rather than a survival mechanism.

It is generally accepted that safety is best ensured by the application of hazard analysis and critical control points (HACCP) rather than end-product testing. Provided that critical control points are effective, the presence of injured or VBNC cells in food is unlikely to impact directly on safety during food processing. However, failure to detect injured or VBNC organism may affect other aspects of safety management such as risk assessment, investigations of foodborne illness, and epidemiological studies. It is therefore important to apply recommended resuscitation procedures as appropriate and to continue research into the physiological basis of the not readily culturable state given that there may be several causes requiring different resuscitation measures.

CHARACTERISTICS OF FOODBORNE HAZARD AND DISEASES

Drug Resistant Pathogens

RA Stein, New York University School of Medicine, New York, NY, USA
M Chirilă, "Iuliu Haţieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania

Glossary

Antimicrobials Pharmaceutical compounds that kill microorganisms or slow their growth, and can be classified into antiviral, antibacterial, antifungal, or antiparasitic agents.

Avoparcin A glycopeptide antibiotic that shows cross-resistance with vancomycin and was used for growth promotion in animal farming in several European Union countries before being banned, starting with 1995.

Commensal microorganisms Microorganisms that coexist with the host without causing disease, and sometimes having beneficial effects.

Hemolytic–uremic syndrome A life-threatening medical condition characterized by hemolytic anemia, impaired blood clotting, and kidney failure, that is often preceded by infection with bacterial pathogens, mostly *Escherichia coli* O157:H7.

Horizontal gene transfer Also known as lateral gene transfer, it represents the transfer of genetic material between two microorganisms, in a process that often involves plasmids, and represents the primary cause of antimicrobial resistance.

Methicillin-resistant *Staphylococcus aureus* A pathogen that initially emerged in health care facilities (healthcare-associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA)) but subsequently was increasingly described in the community (community-associated MRSA (CA-MRSA)) and represents a clinical and public health challenge.

Multidrug-resistant pathogens Microorganisms resistant to more than one antimicrobial agent.

Vancomycin A naturally occurring glycopeptide antibiotic made by the soil bacterium *Amycolatopsis orientalis*, used in the prophylaxis and treatment of infections caused by Gram-positive bacteria.

Introduction

In an elegant experiment that administered healthy volunteers a regular diet for 21 days, followed by a sterile diet for 20 days, Corpet documented a drastic decrease in the percentage of ampicillin-, tetracycline-, and streptomycin-resistant lactose-fermenting microorganisms in the stool during the sterile diet period. This finding supported the view that most resistant enterobacterial strains could originate from food sources, and pointed toward the need to allocate enhanced attention to the presence and dynamics of antimicrobial resistance originating in food.

While in the 1950s an average grocery store in the US stored approximately 300 items, by the 1980s this number increased to approximately 25 000 and, in more recent years, it reached 50 000. The growing availability of fresh produce and the increasing use of antimicrobials for many applications other than human medicine, including agriculture, aquaculture, and animal farming, increased the likelihood that certain food products may harbor and transmit antimicrobial-resistant pathogens.

The dynamics of antibiotic-resistant pathogens in food products has two distinct dimensions. One of them involves the transmission of resistant bacterial pathogens from food products to animals or humans; the second one involves the circulation of antimicrobial resistance-conferring genetic determinants, which can be horizontally transferred from resistant to susceptible bacterial strains, sometimes between members of different genera, and often after very short contacts.

Surveillance programs represent one of the most significant initiatives to monitor foodborne pathogens and develop and implement interventions. One of the first national surveillance models, established in 1995 by the Danish Ministry of Food, Agriculture and Fisheries and the Danish Ministry of Health, was the Danish Integrated Antimicrobial Resistance Monitoring and Research Programme. In the US, the Foodborne Diseases Active Surveillance Network (FoodNet) was initiated in July 1995 as a collaboration between the US Centers for Disease Control and Prevention (CDC), the US Department of Agriculture (USDA), the US Food and Drug Administration (FDA), and selected state health departments. It initially included five sites in California, Connecticut, Georgia, Minnesota, and Oregon, and later incorporated Colorado, New Mexico, New York, Maryland, and Tennessee, covering approximately 15% of the US population. This program

 doi:10.1016/B978-0-12-378612-8.00065-2

conducts active surveillance and epidemiological studies to characterize the burden and temporal trends of foodborne illnesses, and proposes the development and implementation of initiatives to reduce their incidence. National surveillance of antimicrobial resistance in foodborne bacteria in the US started in 1996, with the establishment of the National Antimicrobial Resistance Monitoring System (NARMS), a collaborative effort of the FDA, CDC, and USDA.

Epidemiology of Major Foodborne Pathogens in Commercial Food

Staphylococcus aureus and MRSA

Staphylococcus aureus, identified in many commercial food products, was involved in several foodborne outbreaks. From an antimicrobial resistance perspective, methicillin-resistant *St. aureus* (MRSA) is the main concern. Recent studies from several countries reported the detection of MRSA in commercial food. In 2007, investigators from the Netherlands found MRSA in 2 (2.5%) of 79 commercial meat samples collected at supermarkets and butcher shops. One isolate, nontypable by *Sma*I digestion, was identical to isolates identified in pigs. In Japan, the first piece of evidence for MRSA in commercial raw chickens came in 2005, when the pathogen was detected in samples collected from retail locations in different prefectures. MRSA was detected in 5 (1.6%) of 318 meat samples collected between November 2007 and March 2009 in La Rioja, Spain. Two isolates were sequence type ST398, a new strain that is nontypable by *Sma*I pulsed-field gel electrophoresis, suggesting animal origin, and they were also resistant to tetracycline, an antibiotic widely employed in the pig industry. Six (3.75%) of the one hundered and sixty *St. aureus* strains collected between 2003 and 2005 from dairy products in Italy harbored *mecA*, the gene that confers methicillin resistance.

In 2009, the first survey on the prevalence and characteristics of MRSA isolated from retail meat in the US, which used samples randomly collected from several supermarket chains in Baton Rouge, Louisiana, reported the presence of MRSA in one beef and five pork samples. More recently, Waters *et al.* revealed that almost half the meat and poultry samples collected in grocery stores from five US cities harbored *St. aureus*, and over half of the isolates exhibited multidrug resistance, defined in the study as resistance to three or more classes of antimicrobials.

In 1995, Kluytmans *et al.* described an MRSA outbreak in the hematology unit of a hospital from the Netherlands, where 21 patients developed clinical disease and five died. Phenotyping and genotyping indicated that food contaminated by a dietary worker, who prepared the food and did not have direct contact with patients, was the most likely cause of septicemia in the first patient, and this marked the first documented instance of foodborne MRSA transmission. Twenty-one patients developed the infection, and five of them died. Jones *et al.* were the first to report gastrointestinal illness caused by community-acquired MRSA, when they showed that strains isolated from stool samples in three family members, a coleslaw sample that they ate, and a nasal swab from a food preparer in the convenience market where they purchased the food, were indistinguishable by pulsed-field gel electrophoresis.

Campylobacter Species

Campylobacter, one of the most frequent foodborne microorganisms, is the leading gastrointestinal pathogen in several countries. In the US, 95% of the estimated 1.4 million annual *Campylobacter* infections are caused by *Campylobacter jejuni* and 5% are caused by *Campylobacter coli*. Most infections are self-limited and do not require antibiotics.

An increasing incidence of antibiotic resistance was reported in recent years among *Campylobacter* strains isolated from food products and humans. While rarely reported in North America before 1992, fluoroquinolone-resistant *Campylobacter* was subsequently described with increasing frequency in animal carcasses and retail meat. In several countries, this coincided with the use of fluoroquinolones in animal food. In the US, after sarafloxacin and enrofloxacin were approved for animal feed in 1995 and 1996, respectively, an increasing prevalence of fluoroquinolone-resistant *Campylobacter* strains was reported in commercial food. A study conducted in the US found that approximately 20% of the *Campylobacter* isolates from chickens purchased in 1997 at supermarkets in the Minneapolis–St. Paul metropolitan area were fluoroquinolone-resistant. At the same time, fluoroquinolone resistance increased between 1992 and 1998 from ~1% to slightly more than 10% in *Campylobacter* strains isolated from humans. Another study reported that between 1995 and 2001, fluoroquinolone resistance among *C. jejuni* human isolates collected at several Philadelphia-area hospitals increased from ~21% to more than 40%, even though resistance to erythromycin for the same period remained low, under 5%. Similar trends were reported in other countries. More than 30% of the *C. jejuni* isolates from chickens in the Netherlands and France were resistant to nalidixic acid and ciprofloxacin, and resistance rates as high as 32% and 77% were found in Japan and Thailand, respectively.

In a population-based study conducted between 1998 and 1999, Kassenborg *et al.* reported that eating chicken or turkey at commercial food establishments increased approximately 10-fold the risk of a fluoroquinolone-resistant *Campylobacter* infection over the next 7 days. This pointed toward poultry being a major cause of fluoroquinolone-resistant *Campylobacter* infections in the US, a finding echoed by reports from other countries.

Miflin *et al.* examined the antibiotic resistance profile of *Campylobacter* species isolated on Australian broiler farms and noted, as the most salient feature, the lack of ciprofloxacin-resistant strains. The authors speculated that this observation could be explained by the fact that fluoroquinolones were never approved for poultry farming in Australia.

In 2000, the FDA proposed the withdrawal, and in 2005 withdrew its approval for the use of fluoroquinolones in live poultry. The first study to examine the temporal trends of resistance in two poultry producers that voluntarily stopped fluoroquinolone use in 2002 did not find a significant decrease in the prevalence of fluoroqinolone-resistant strains in

2004 and 2006. Despite several limitations, the study indicated that the ban might not have been sufficient by itself to reduce the prevalence of resistant strains, and suggested that additional interventions might be required.

Salmonella Species

Salmonella is one of the major foodborne pathogens worldwide, and in the US it is responsible for 800 000 to 4 million infections annually. Poultry and poultry products, eggs, vegetables, and fruits are some of the food products most frequently implicated. The most common resistance patterns in *Salmonella* are to antimicrobials often used in animal husbandry, and infections with resistant strains have higher morbidity and mortality than those caused by susceptible isolates.

Worldwide, *Salmonella* isolates of food origin show a remarkable variation in their antimicrobial resistance pattern. A 2009 study that collected *Salmonella* strains contaminating meat samples at markets and stores from Seoul, South Korea, reported that all 18 isolates were resistant to erythromycin, 22.2% were resistant to streptomycin, and 16.7% were resistant to tetracycline and chloramphenicol. Five isolates showed resistance to at least two antibiotics, and one was resistant to eight distinct antibiotics.

A study conducted in the wake of an almost 5-fold increase in the incidence of *Salmonella newport* infections reported to the Los Angeles County Health Department in May 1985 revealed that most strains were chloramphenicol-resistant and harbored an identical ~25-MDa plasmid. Epidemiological and microbiological analyses traced the pathogen to infected hamburgers, to the abattoirs where the animals were slaughtered, and to the ill dairy cows. The isolation of chloramphenicol-resistant strains on these dairy farms was associated with the local use of chloramphenicol. These findings indicated that food animals may be a major source of antimicrobial-resistant *Salmonella* infections in humans, and that antimicrobial use on farms contributes to these infections.

The NARMS revealed various trends, in time, for the incidence of resistance to specific antibiotics among foodborne microorganisms. For example, between 1997 and 2009, the prevalence of gentamicin-resistant *Salmonella* isolated from turkeys decreased from 21% to 15%. During the same interval, the prevalence of ceftriaxone-resistant isolates in chickens increased from 0.5% to almost 13%, and the prevalence of chloramphenicol-resistant isolates in cattle increased from 4% to 21%. Multidrug resistance, defined as resistance to five or more classes of antimicrobials, became more prevalent during the same period in isolates originating from several food sources – for example, it increased from 1.4% to ~8% in chicken and ~8% to 20% in cattle isolates.

Between August 1984 and March 1985, the largest *Salmonella* outbreak recorded in the US occurred in northern Illinois and was linked to 2% pasteurized milk originating from a single dairy plant. Its two waves caused >16 000 culture-confirmed infections, but the total number of cases is thought to have exceeded 168 000. The *Salmonella typhimurium* strain involved in this outbreak showed a very rare and unusual pattern of resistance to multiple antibiotics. The use, during the preceding months, of antimicrobials to which the pathogen was resistant, increased the risk of symptomatic infection approximately 5-fold during the outbreak and lowered the dose of pathogen needed to cause clinical disease.

In the 1990s, a new resistance pattern was reported in the US and Europe, with the emergence of a strain known as R-type ACSSuT or *Sa. typhimurium* DT104, resistant to five different antibiotics: ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. This multiresistant pathogen can acquire resistance to even more antimicrobials, opening further therapeutic challenges. In food animals, *Sa. typhimurium* DT104 was first reported in 1984 in the UK, initially in cattle and later in poultry and pigs. Subsequently, the pathogen disseminated throughout Europe and was first reported in the US in 1985. Occasionally, *Sa. typhimurium* DT104 was implicated in life-threatening human infections. For example, in 1998, a previously healthy woman died in Denmark from an infection caused by this strain, and the infection was traced to contaminated pork.

In June 1998, Mølbak *et al*. isolated an unusual quinolone-resistant and multidrug-resistant *Sa. typhimurium* DT104 strain from five patients, in one of whom the infection was fatal, and from pork at a slaughterhouse in Denmark. By using microbiological and epidemiological approaches, the authors demonstrated that quinolone-resistant bacteria could spread from food products to humans and cause therapeutically challenging infections.

Another relatively recent multiresistant *Salmonella* strain, Newport MDR-AmpC exhibits, in addition, resistance to amoxicillin/clavulanic acid and ceftiofur, and reduced susceptibility to ceftriaxone. Although no Newport MDR-AmpC strains were reported in 1996, they represented 1%, 22%, and 15% of the human isolates in 1998, 2002, and 2004, respectively. A population-based case-control study conducted at 8 FoodNet sites between 2002 and 2003 identified beef, eggs, and chicken as the most probable sources for contamination and revealed that infections were more likely after using antimicrobials to which the strain was resistant, during the 28 days preceding the diarrhea. Consumption of uncooked ground beef, or runny scrambled eggs or omelets prepared at home, during the 5 days preceding the onset of the disease, emerged particularly important risk factors for infections with multidrug-resistant strains.

Koningstein *et al*. identified human antibiotic use as a risk factor for resistant foodborne *Salmonella* infections. This heightened risk, present for at least 1 year subsequent to antibiotic treatment, was evident for several classes of antimicrobials, although its magnitude differed for specific compounds. In an analysis of 32 *Salmonella* outbreaks that occurred in the US between 1984 and 2002, Varma *et al*. found that more hospitalizations occurred during outbreaks with resistant than with susceptible bacterial isolates. Holmberg *et al*. examined 52 *Salmonella* outbreaks between 1971 and 1983, 17 of which were caused by resistant isolates, and reported that antimicrobial resistance is associated with an >20-fold higher fatality rate as compared to antimicrobial susceptibility. Furthermore, human outbreaks with antimicrobial-resistant *Salmonella* strains were shown to be more likely to have a food animal source than outbreaks caused by susceptible strains. Additional epidemiological studies found that individuals infected with resistant *Salmonella* strains

were more likely to have visited or resided on a farm before the infection than individuals with antibiotic-susceptible infections.

Raw milk consumption represents an additional source of antimicrobial-resistant salmonellosis. In the US, the interstate transportation of raw milk that is not destined for pasteurization was prohibited in 1987 and, as of 1995, 28 states permitted its intrastate sale to consumers. In a multidrug resistant *Salmonella* outbreak that occurred in New Mexico in 1983, 12 of the 19 individuals with available food histories ingested raw milk within the 2 weeks preceding the outbreak. Tacket *et al.* found a multiresistant strain in a 72-year-old woman who died in Arizona in 1983 from *Salmonella* enteritis after consuming raw milk, and also identified the pathogen in other individuals from the community who became ill, and in milk samples. Raw or inadequately pasteurized milk consumption was also implicated or suspected in 14 of the 23 *Campylobacter* enteritis outbreaks reported to the CDC between 1980 and 1982.

Data from the FoodNet surveillance network revealed that even though the incidence of Shiga toxin-producing *E. coli* (STEC) O157 infections declined in 2010, the incidence of *Salmonella* infections has not decreased significantly for over a decade, and *Salmonella* remained one of the most prevalent causes of foodborne bacterial infections. Preventing contamination during the slaughtering process, properly cooking the food, detecting and investigating outbreaks, and promptly recalling contaminated food, emerge as some of the most significant initiatives of global importance.

Escherichia coli

Escherichia coli represents the predominant facultative anaerobic bacterium from the gastrointestinal tract. It was causally linked to intestinal and extraintestinal infections, the second group including urinary tract infections, pneumonia, meningitis, and encephalitis. Based on their virulence characteristics, six major *E. coli* groups relevant for gastrointestinal disease were described: enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), diffusely adherent *E. coli* (DAEC), and STEC. EPEC is a frequent cause of watery or bloody diarrhea in infants, but also affects adults, and represents an important cause of traveler's diarrhea. ETEC, a pathogen that produces both heat-labile and heat-stable enterotoxins, is the leading cause of diarrhea in the developing world, the leading cause of traveler's diarrhea, and a frequent pathogen in children under 5 years old worldwide. It causes infections accompanied by watery diarrhea and cramps, but fever is generally low or absent. EIEC, a pathogen that resembles *Shigella* in its mechanisms of pathogenesis, penetrates intestinal epithelial cells and multiplies inside them, causing extensive tissue destruction. It is accompanied by severe diarrhea with blood and mucus, and high fever. EAEC, a pathogen that can attach to the intestinal epithelium in an aggregative manner, is mostly associated with persistent diarrhea in infants. DAEC, a less common cause of enteric disease, causes watery diarrhea, particularly in older children. STEC encodes toxins that are similar to the toxin produced by *Shigella dysenteriae*. Owing to its cytotoxic effects on Vero cells, which were first reported in 1977 by Jack Konowalchuk and colleagues, this pathogen also became known as verocytotoxigenic *E. coli* (VTEC). Stx1 and Stx2 are the two immunologically distinct primary types of toxins produced by STEC. Certain isolates produce only one of these toxins, others produce both, and a few produce multiple toxins, including several Stx2 variants. A STEC subgroup, which contains strains that attach to and efface the intestinal epithelial cells, a lesion known as attaching and effacing (A/E), is referred to as enterohemorrhagic *E. coli* (EHEC). This pathogen may cause infections that range from asymptomatic to life-threatening intestinal and extraintestinal disease, including the complication known as hemorrhagic colitis or hemolytic–uremic syndrome. STEC, EPEC, ETEC, and EAEC are the *E. coli* strains most frequently implicated in foodborne outbreaks.

Multiple lines of evidence indicate that *E. coli* strains, often resistant to one or several antimicrobials, are present in commercial food, and their ability to cause human disease represents a medical and public health concern. Extended-spectrum β-lactamase-producing *E. coli* strains in meat animals and retail meat were reported in Europe and in the US and, in addition, sulfonamide-, fluoroquinolone-, and aminoglycoside-resistant *E. coli* isolates in food animals were described in several countries. A survey that examined food products in retail markets from the Minneapolis–St. Paul area between 2001 and 2003 reported that, overall, 24% of the food samples harbored *E. coli*, and antimicrobial resistance was present in 27% of the miscellaneous food items, 85% of the beef and pork samples, and 94% of the poultry samples. Indirect evidence supported the on-farm origin of resistance in these bacteria. A 2011 study on meat samples collected over a three-year period from retail stores in Northern Greece reported ciprofloxacin resistance in 62% and 28% of the *E. coli* strains isolated from chicken and beef, respectively. A study that examined turkey samples from grocery stores in Ontario, Canada, between February 2003 and May 2004, found that 71% of the *E. coli* strains, 81% of the *Campylobacter* strains, and 49% of the *Salmonella* strains were resistant to one or more antimicrobials. Furthermore, 13% of the *Salmonella* isolates and 18% of the *E. coli* isolates showed resistance to five or more antimicrobials.

Genotypic and phylogenetic analyses of *E. coli* isolated from human volunteers in Minnesota and Wisconsin revealed that antimicrobial-resistant human isolates were more similar to isolates from poultry than to antimicrobial-susceptible isolates colonizing humans, pointing toward their probable origin in poultry reservoirs. The additional observation that drug-resistant and drug-susceptible isolates from poultry were highly similar to each other suggested that drug-resistant isolates originated in the sensitive ones, possibly under selective pressure from antimicrobials used on the farm. This finding mirrored previous observations from Europe, where resistant *E. coli* of human origin was found to be highly similar to resistant isolates detected in poultry.

STEC represents the most important group of emerging foodborne pathogens, and *E. coli* O157:H7, a member of this group, has emerged in recent decades as the etiologic agent of some of most challenging foodborne infections. Additionally, the incidence of non-O157 STEC infections was reported to

also be on the rise worldwide. In North America, STEC was first identified as a foodborne pathogen in 1982, in two *E. coli* O157:H7 outbreaks related to the consumption of undercooked ground beef, and infections caused by this pathogen subsequently became more frequent worldwide. Many outbreaks were initially linked to minced beef and, more recently, additional sources, including vegetables, fruits, milk, juices, and recreational water were implicated. The CDC estimates that more than 73 000 *E. coli* O157:H7 infections and more than 37 000 infections with non-O157 serotypes occur annually in the US, and 85% of these are spread by food and water. In addition to gastrointestinal manifestations, which are often self-limiting, one of the most frequent systemic complications caused by this pathogen, and a potentially fatal outcome of the infection, is the hemolytic–uremic syndrome, a medical emergency that predominantly affects children. Although early *E. coli* O157:H7 isolates were usually susceptible to most antibiotics active against Gram-negative microorganisms, the antibiotic resistance profile of this pathogen has drastically changed over time, and resistance was increasingly reported, particularly during the past two decades, and frequently attributed to multiple antibiotics. Although only 1% of the 200 *E. coli* O157:H7 isolates that were examined by the CDC between 1983 and 1985 were resistant to antibiotics, a 2004 study that examined 901 *E. coli* O157:H7 isolates, 663 from bovines at feedlots in the Midwestern US, and 238 from humans, representing outbreaks and sporadic infections, reported that almost 7% of the bovine isolates and more than 12% of the human isolates were resistant to at least one antibiotic.

In 2009, a molecular epidemiology study comparing cefoxitin-resistant *E. coli* isolated from cattle at four feedlots in southern Alberta with *E. coli* isolated concomitantly from infections affecting patients in Canadian hospitals revealed that similar multidrug resistance-conferring plasmids can be isolated from both sources. Some of the isolates shared more than 90% sequence similarity, as determined by deoxyribonucleic acid (DNA) fingerprinting. This finding underscores the need to focus on the therapeutic implications that accompany the transfer of resistant pathogens and resistance determinants across species.

Shigella Species

Shigella, the etiologic agent of bacillary dysentery, was discovered in 1897 by the Japanese bacteriologist Kiyoshi Shiga. The genus includes Gram-negative, facultatively anaerobic, nonmotile rods that were organized into four serogroups: *Sh. dysenteriae*, primarily associated with epidemics; *Shigella flexnerii*, most frequent in endemic areas; *Shigella boydii*, described in many outbreaks in Central and South America; and *Shigella sonnei*, commonly encountered in developed countries. One feature of the *Shigella* infections is the low infective dose. For example, less than 10 *Sh. dysenteriae* cells are sufficient to cause disease.

An increase in the incidence of antibiotic resistance was reported, over time, for many *Shigella* isolates worldwide. A study conducted between 1989 and 1990 in Germany reported that over 80% of 255 *Shigella* strains were resistant to at least one antibiotic. Ashkenazi *et al.* examined 3511 *Shigella* isolates collected between 1984 and 1992 in Israel and, over the study period, reported that resistance to trimethoprim–sulfamethoxazole increased from 59% to 92%, and that to ampicillin increased from 13% to 86%. *Shigella sonnei* showed a higher incidence of resistance to these antibiotics than *Sh. flexneri*. Another study that examined antimicrobial resistance trends in *Shigella* sp. collected between 1984 and 1989 in the Netherlands revealed that 23% of the 3313 isolates examined were resistant to trimethoprim–sulfamethoxazole and 30% were resistant to ampicillin. In recent years, multidrug-resistant *Shigella* isolates, including strains resistant to extended-spectrum cephalosporins, were described worldwide, and isolates resistant to fluoroquinolones and ciprofloxacin were documented in several countries.

One of the clinically relevant features of *Shigella* infections is their high communicability. In 1987, a shigellosis outbreak was recorded at a mass gathering held in a national forest from western North Carolina. The infections were caused by a *Sh. sonnei* strain resistant to ampicillin, tetracycline, and trimethoprim–sulfamethoxazole. After the gathering, the nationwide dispersal of the participants was linked to several outbreaks that occurred over the next 2 months in other communities.

Another challenge is the transmission of resistance determinants from *Shigella* to other bacterial species. Tauxe *et al.* reported the *in vivo* transfer of antimicrobial resistance during a small outbreak caused by a multiply drug-resistant *Sh. flexneri* isolate that occurred in 1983 on the Hopi Indian reservation. The plasmid conferring multiple drug-resistance, isolated from one patient affected during the outbreak, was identical to a plasmid that was isolated, 3 weeks before the onset of shigellosis, from an *E. coli* strain that caused urinary tract infection in the same patient.

Listeria monocytogenes

Bacteria that belong to the *Listeria* species increasingly emerge as significant foodborne pathogens. As listeriae are widely distributed in nature, human contact occurs frequently, but infections are relatively rare. Nevertheless, when human infections occur, their case-fatality rate can be as high as 30%, despite the availability of antimicrobial treatment. *Listeria monocytogenes* is the most frequent member of the species to infect humans, and in rare cases, *Listeria ivanovii*, primarily an animal pathogen, may also cause human disease. The ability to survive at refrigeration temperatures and to grow on minimal nutrients and in diverse environments, including soil, water, plants, and animals, are some of the features that make *Listeria* a particularly challenging pathogen.

The first time that *Listeria* transmission was attributed to food was in 1979 at a Boston hospital, when the involvement of vegetables was suspected. The possibility that this pathogen is transmitted by food was further strengthened in 1981, when an outbreak in Nova Scotia, Canada, which caused 41 infections and 18 deaths, was traced to contaminated coleslaw prepared from cabbage grown on a farm that used contaminated sheep manure as a fertilizer. This marked the first time when the involvement of *L. monocytogenes* in human foodborne infections was demonstrated.

Sporadic as well as epidemic *Listeria* infections are mainly transmitted by the foodborne route. Listeriosis saw a worldwide increase during recent years, and high mortality rates were reported particularly among pregnant women, immunocompromised individuals, the elderly, and the newborn, although the infection affects healthy people of all age groups. Besides gastrointestinal manifestations, listeriosis is also associated with extraintestinal complications such as meningitis, septicemia, and miscarriage. Particularly soft cheeses prepared from raw milk and ready-to-eat meat products pose heightened risk for susceptible individuals.

Several studies reported that *L. monocytogenes* isolates showing resistance to a wide range of antibiotics are present in food products. Samples collected between 1992 and 1993 from poultry slaughterhouses and from raw milk and cheese at markets in northwestern Spain revealed streptomycin-resistant *L. monocytogenes* and chloramphenicol-resistant *Listeria innocua* in the food samples, and tetracycline-resistant *L. innocua* in the poultry and poultry slaughterhouses. A study that examined *L. monocytogenes* in retail poultry in Porto, Portugal, identified the pathogen in 41% of 63 samples, and 73% of these were resistant to at least one antibiotic. Of 114 *L. monocytogenes* isolated between 2000 and 2002 from food products in Denmark, all showed high minimum inhibitory concentration (MIC) values for ceftiofur, but were fully susceptible to other antimicrobials, including ciprofloxacin, erythromycin, cotrimoxazole, and streptomycin. Studies on food samples, including ready-to-eat salads and milk and raw meat products collected in ten open-air markers from Thessaloniki, Greece, found *L. monocytogenes* in more than 14% of the 210 samples, with one strain exhibiting tetracycline resistance. Food and environmental samples collected between 1996 and 2006 in France found four *Listeria* isolates that were antibiotic-resistant, two to erythromycin and one each to tetracycline–minocycline and trimethoprim. A study that included isolates from food sources and food environments in Italy reported, in 2009, that almost 12% of the 126 isolates were resistant to at least one antibiotic, and one strain (0.8%) was resistant to five antibiotics. Isolates were most frequently resistant to clindamycin, but resistance to other antibiotics, including linezolid, ciprofloxacin, ampicillin, vancomycin, and tetracycline, was also found.

In the US, Prazak *et al*. reported that 95% of the 21 *L. monocytogenes* isolates collected in Texas from cabbage and several environmental and water samples were resistant to two or more antibiotics, and 85% were resistant to penicillin, marking the first time when penicillin-resistant *Listeria* was identified in human, environmental, or food samples. The first study to examine *L. monocytogenes* antimicrobial susceptibility on a dairy farm environment, conducted in Tennessee, reported that all 38 strains isolated from four farms exhibited resistance to at least one of 15 antimicrobials tested, and the overall resistance profile of the isolates covered a broad range of compounds. From the 167 *L. monocytogenes* isolates collected between 2002 and 2003 from raw chickens, ready-to-eat meat, and fresh produce from retail food in Florida and Washington, DC, 73% were resistant to sulfonamides, and more than 8% and almost 2% exhibited resistance to tetracycline and ciprofloxacin, respectively.

Relatively few studies have focused on antimicrobial resistance in *Listeria* species in a clinical setting. In France, Morvan *et al*. examined *L. monocytogenes* antimicrobial resistance in the largest clinical collection to date, and found that more than 1% of 4668 isolates collected between 1989 and 2007 were resistant to at least one clinically relevant antibiotic. An analysis of the temporal evolution of antimicrobial susceptibility in historical isolates collected between 1926, when the pathogen was first characterized, and 1988, reported no acquired resistance to 23 antibiotics, but the minimum inhibitory concentrations for several antibiotics increased subsequently, during the more recent time intervals. Even though the incidence of antimicrobial resistance in *L. monocytogenes* human isolates is currently low, the ubiquity of this bacterium, and the increasing incidence of antimicrobial resistance in animal and food isolates, open concerns about resistance among clinical isolates. This is compounded by the ability of listeriae to acquire resistance determinants from other species. Doucet-Populaire *et al*. reported that the Tn*1545* transposon, which confers resistance to kanamycin, tetracycline, and erythromycin, can be transferred *in vivo* between *Enterococcus faecalis* and *L. monocytogenes*, with an efficiency that is 10-fold higher in the presence of small concentrations of tetracycline.

Enterococcus Species

Enterococci are ubiquitous, Gram-positive bacteria found in many environments, including the soil, water, plants, animals, and the human intestinal flora. Certain enterococcal strains exhibit health-promoting characteristics, and are effective in managing childhood and antibiotic-associated diarrhea, whereas others found applications as dairy adjunct or starter cultures, thanks to their fermenting activity. However, enterococci are also among the most frequent nosocomial pathogens. Despite their presence in the food, enterococci have been associated with foodborne outbreaks in very few instances. Nevertheless, their use as probiotics has been controversial, particularly due to the recent emergence of antibiotic-resistant strains identified in clinical isolates worldwide that, in addition to causing disease, could transfer resistance determinants to other bacteria.

Di Labio *et al*. reported that 69%, 99%, and 68% of the *E. coli*, *Enterococcus*, and *Campylobacter* isolates collected from fecal samples collected between March and July 2006 from 500 randomly selected Swiss veal calves, originating from 129 farms, were resistant to at least one antibiotic, mostly compounds used in animal husbandry. Among *Enterococcus faecium* strains, 35% were resistant to quinupristin/dalfopristin, and almost 80% were resistant to nitrofurantoin.

Ampicillin, gentamycin, and vancomycin are among the most frequent antibiotics used to treat enterococcal infections, and this represents only one of the reasons why vancomycin-resistant enterococci (VRE) emerge as a particularly important medical and public health challenge. A VRE reservoir was established in animals by the use of avoparcin, a glycopeptide growth promoter antimicrobial analogous to and showing cross-resistance with vancomycin, which has been used in animal husbandry in many European countries since 1975, before being banned first in Denmark in 1995, Germany in 1996, and subsequently in other countries, culminating with a comprehensive ban by the European Commission in

1997. VRE were first recorded in 1987 in Europe, and within 10 years, the pathogen represented more than 25% of the enterococci associated with bloodstream infections in the US hospitals. Studies conducted in several European countries revealed that in the years following the avoparcin ban, the incidence of VRE in food products and that of human colonization with this pathogen decreased progressively. In Hungary, during the years after the avoparcin ban in 1998, in addition to a progressive annual decrease in the incidence of VRE strains colonizing food animals, a decrease in the vancomycin MIC values was also recorded. At the same time, in several countries, resistant strains were detected for several years after the avoparcin ban, indicating that antimicrobial resistance persists for a long time, even after the antibiotic use is discontinued.

Yersinia Species

Yersiniae have three medically important members: *Yersinia pestis*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis*. *Yersinia enterocolitica*, a significant foodborne pathogen, has been isolated from food products and several domestic and wild animals. Swine represent one of the most significant reservoirs. Several studies revealed a high genetic similarity between human and pig isolates. The ability to grow between 0 and 42 °C and at pH values between 4 and 10 enable this pathogen to survive and multiply in a broad range of refrigerated food products. *Yersinia enterocolitica* antibiotic resistance is dependent on the biogroup and shows broad geographic variations. A study conducted in Austria that examined meat samples from markers and slaughterhouses over a three-year period reported that one of 167 isolates, originating from chicken, was resistant to tetracycline, and the remaining ones were sensitive to several antibiotics tested. All *Y. enterocolitica* isolates harboring *ail*, a gene encoding an outer membrane protein required for attachment and for human virulence, that were collected in 2006 from pigs at an abattoir in Switzerland, exhibited resistance to at least one compound, most frequently ampicillin or erythromycin. The isolates were susceptible to many clinically relevant antibiotics. More than 93% of the *Y. enterocolitica* strains isolated in Switzerland between 2000 and 2003 from humans, retail pork, and pork feces were resistant to cephalothin, and more than 68% were resistant to amoxicillin/clavulanic acid. However, only 1% exhibited resistance to tetracycline, 3.6% were resistant to streptomycin, and all isolates were susceptible to several antibiotics including ciprofloxacin, gentamicin, kanamycin, and neomycin. A survey conducted between 2004 and 2007 that examined commercial food samples from retail stores in northwestern Greece found that *Y. enterocolitica* from pork samples showed resistance to broad-spectrum penicillins, cephalosporin, aminoglycosides, and ampicillin. In the US, Funk *et al*. reported that *Y. enterocolitica* isolated from the oral cavity of swine exhibited a high degree of resistance to sulfonamide, and variable resistance to oxytetracycline, two compounds frequently used in pig feeds. A survey of *ail*-positive *Y. enterocolitica* strains obtained in 2000 from pig fecal samples in the US reported that, even though the isolates were susceptible to 13 of 16 antimicrobials tested, all of them were resistant to ampicillin, more than 87% were resistant to cephalothin, and more than 27% to tetracycline.

Resistant Foodborne Pathogens may Cause Intestinal and Extraintestinal Disease

Extraintestinal pathogenic *E. coli* strains were linked to several types of infection, including sepsis, urinary tract infections, neonatal meningitis, and pneumonia. Multiple lines of experimental evidence reveal that bacteria from food products, in addition to their ability to cause gastroenteric infections, are causally linked to extraintestinal infections as well. Epidemiologic and molecular data traced resistant pathogens causing human urinary tract infections to food animals and food products, and these findings are supported by *in vivo* studies on animal models, which showed that strains isolated from food animals and products may case urinary tract infections in healthy animals. In 2006, investigators recovered extraintestinal pathogenic *E. coli* from retail chicken and turkey food samples collected in Georgia, Maryland, Oregon, and Tennessee. Most isolates belonged to the same phylogenetic group as virulent human strains, several of them were resistant to antimicrobials, and some of them carried genes associated with uropathogenic *E. coli*. A study conducted in Montréal, Canada, found *E. coli* isolates in retail chicken samples and other food sources that were genetically indistinguishable from or closely related to strains implicated in urinary tract infections, reinforcing previous observations that food may serve as a reservoir of extraintestinal *E. coli*. An isolate from retail chicken was indistinguishable by pulsed-field gel electrophoresis from a human clinical isolate, a finding that, even though it does not inform about directionality, indicates that transmission between meat products and humans had occurred, and opens intriguing public health questions. This isolate belonged to clonal group ST131, a worldwide pandemic clone that represents a newly characterized extraintestinal pathogenic *E. coli* isolated, in several countries, from food of animal origin, environmental samples, and healthy food animals. ST131 was for the first time reported as a human pathogen in 2008, is frequently resistant to multiple antibiotics, and isolates infecting humans, companion animals, and poultry often exhibit high genetic similarity.

Antibiotics and the Selection of Resistant Pathogens on Farms

The ability of antimicrobials used on farms to select for resistant bacteria has long been recognized. The Swann Committee Report, published in the UK in November 1969, which emphasized the dangers that antibiotics used in animal farming pose to animals and humans, proposed to carefully monitor antibiotic use in animals, and recommended that certain compounds, which are also prescribed in human medicine, should not be used as growth promoters.

In 1976, Levy *et al*. showed that the intestinal flora of chickens fed tetracycline-supplemented food contained, within a week, almost exclusively tetracycline-resistant bacteria, and within 5–6 months, more than 30% of the fecal

samples collected from individuals living on the farm contained a preponderance of tetracycline-resistant bacteria, as compared to less than 7% in the samples collected from neighbors. The authors suggested that tetracycline from the animal feed exerts selective pressure in individuals in contact with the feed and chickens. Marshall *et al*. demonstrated that resistant *E. coli* could spread from the bovine or porcine gut to other animals and humans on the farm, resulting in prolonged colonization. Importantly, this process occurred in the absence of antibiotic selection.

Holmberg *et al*. described a *Sa. newport* outbreak with a strain harboring a 38-kb R plasmid, and resistant to ampicillin, carbenicillin, and tetracycline, which in 1983 affected individuals from four midwestern states. In several patients, the symptoms appeared 24–48 h after starting antibiotic therapy for nondiarrheal conditions, and multiple lines of evidence indicated that they most likely had asymptomatic *Sa. newport* infections, and antibiotic use provided the selective pressure that allowed pathogen growth. Epidemiological and laboratory analyses of the plasmids from animal and human isolates revealed that the patients had been infected, before initiating antimicrobial therapy, from hamburgers that originated in beef cattle receiving subtherapeutic chlorotetracycline for growth promotion and disease prevention. These findings underscore the need for more prudent antimicrobial use in animals and humans.

Cohen and Tauxe reviewed several studies conducted on *Salmonella*, for which the molecular epidemiology of antimicrobial resistance was extensively studied, and found that strains of animal origin exhibited an antibiotic resistance profile that matched the antibiotics used in animal feed. Similar findings were reported by other investigators and, for several pathogens, multiple lines of evidence pointed toward a causal link between antimicrobials used in animal husbandry and resistance in bacteria from food animals, the farm environment, food products, and humans.

Antibiotics are generally agreed to represent the most important factor responsible for selecting resistant bacteria. Antimicrobial resistance, a global public health crisis, is fueled to a great extent, by the vast amounts of antibiotics used in human medicine and for many nonclinical applications, of which agriculture represents merely one example. Selection of resistance was recently shown to occur even at subtherapeutic antibiotic levels. Gullberg *et al*. revealed that antibiotic concentrations much below therapeutic levels, similar to the ones found in some aquatic and soil environments, are able to select for resistant bacteria. As the authors showed, the concentration range where resistant strains can be selected is much wider than previously thought and might need to include values that are several 100-fold below the minimal inhibitory concentration of susceptible strains.

Several authors pointed out that only a fraction of the antibiotics are correctly used for treating human bacterial infections. In addition to often being improperly prescribed, both in children and adults, for medical conditions that would not benefit from them, such as for viral infections, antibiotics are used in agriculture, aquaculture, and animal farming, in amounts that exceed, by far, their clinical use in humans. Estimating the amount of antibiotics used in agriculture and for food animals is challenging. The large amounts of antibiotics used in agriculture and animal husbandry serve three purposes. In addition to their prophylactic or therapeutic use, antibiotics can be continuously administered at subtherapeutic doses as growth promoters or to reduce the incidence of diseases associated with shipping stress. This latest application originates from the discovery that low, subtherapeutic doses of certain antimicrobials provide growth benefits that are distinct from the advantages associated with infection prophylaxis and therapy.

Approximately half of over 1 million tons of antibiotics released into the biosphere during the last 50 years are estimated to have been used for veterinary and agricultural purposes. An estimated 48% of the over 10 000 tons of antibiotics used in 1997 in the European Union and Switzerland were used in animals. One third of this served therapeutic and prophylactic purposes, and 15% was for growth promotion, with large country-to-country variations. Antibiotic growth additives were banned in the European Union in January 2006. In Chile, it was reported that over 100 metric tons of quinolones, 10 times more than the amount used in human medicine, are used annually for veterinary applications, most of it in aquaculture. Between 50% and 80% of the antibiotics produced in the US are used in agriculture. Approximately 70% of the antibiotics used in subtherapeutic concentrations in animals serve prophylactic purposes, and the remainder is used for growth promotion. The Institute of Medicine estimated that over half of the approximately 31 million pounds of antibiotics produced in 1985 were used in animals, for prophylaxis and growth promotion, and the Union of Concerned Scientists estimated that in 1999, 24.6 million pounds of antimicrobials were used in cattle, swine, and poultry, in the absence of disease, for nontherapeutic purposes.

The link between agricultural antibiotic use and resistant bacteria in animals and humans is illustrated by an example from Europe. Avoparcin, a growth promoter that was never approved in the US, was widely used in animal husbandry in Western Europe before being banned in the European Union in 1997. In 1994, $\sim$24 000 kg of active avoparcin were used as a food additive for animals in Denmark, as compared to 24-kg active vancomycin used for human therapy, and in Austria, over 62 000-kg avoparcin were used for animal husbandry annually between 1992 and 1996. Avoparcin exhibits cross-resistance with vancomycin and can facilitate the selection of vancomycin-resistant pathogens. Several authors found a causal relationship between avoparcin use in farming and the emergence of VRE. After avoparcin was discontinued in Germany in 1996, the incidence of VRE strains in poultry meat decreased, and VRE prevalence in the intestinal flora of healthy humans in the community decreased from 12% to 3% between 1994 and 1997. Studies conducted in several countries showed that resistant strains were still detected several years after the avoparcin ban, indicating that resistance may persist in food-producing animals long after an antimicrobial agent is discontinued.

Smith *et al*. pointed out that in the US, where avoparcin was never approved, the prevalence of VRE in the community is $<1\%$ and the presence of the bacterium is usually limited to individuals with a history of hospitalization, whereas its prevalence in the European Union during the late 1990s was between 2% and 12%. This underscores the additional impact

that antibiotic use for agricultural purposes exerts on the human population, as compared to its exclusive use for medical purposes. Based on this argument, the authors suggested that the agricultural use of antibiotics significantly and quantitatively contributes to antimicrobial resistance in the community. Reducing the agricultural use of antibiotics could, therefore, lower the prevalence of resistance in food animals and should also decrease the risk of contamination of commercial food.

Additional Routes to Contaminate the Food Chain

Resistant pathogens found in the food chain may originate not only from food animals, where they emerge under the selective pressure of antibiotics on the farm, but also from individuals who, after becoming colonized, either on the farm or in other locations, such as hospitals, contaminate the food animals, by a process known as reverse zoonotic transmission, or directly contaminate the food products.

Studies conducted in several countries reveal that farm workers and their families are at higher risk for contamination with resistant pathogens. Voss *et al*. provided the first observation linking pig farming to human MRSA colonization, when they reported an over 760-fold higher colonization risk in Dutch farmers as compared to patients admitted to Dutch hospitals. A cross-sectional study on nasal swabs collected between October 2007 and March 2008 from veal calves, farmers, their family members, and farm employees in the Netherlands, found more frequent MRSA ST398 carriage among calves receiving antibiotic treatment and among individuals living and working on farms. The first study that examined MRSA in swine and swine workers from the US reported an overall prevalence of 49% in swine and 45% in employees at two production facilities from Iowa and Illinois, and the first study conducted in China found MRSA in 11% of the swine and in 15% of the farm workers examined. All 60 strains isolated in this study were resistant to cefoxitin, ciprofloxacin, clindamycin, and tetracycline. Price *et al*. found that poultry workers in the US have a 32-fold higher risk for colonization with gentamicin-resistant *E. coli* than individuals in the community, and underscored the need to consider occupational exposure as a route that enables the entry of resistant pathogens into the community.

Although many studies documented the zoonotic transmission of pathogens from farm animals to humans, an additional, somewhat less extensively studied concept is the reverse zoonotic transmission of antimicrobial-resistant pathogens from humans to animals. In the first known human-to-dog MRSA transmission documented in the Netherlands, van Duijkeren *et al*. found the pathogen in the nose of a healthy dog whose owner became colonized while working in a nursing home. Lefebvre and Weese reported that pet dogs became contaminated with MRSA and *Clostridium difficile* during visits to health care facilities, and Ocepek *et al*. provided the first molecular epidemiologic evidence for *Mycobacterium tuberculosis* transmission from humans to cattle.

Individuals colonized with resistant pathogens may also directly contaminate food products, as demonstrated by Kluytmans *et al*., who reported the case of a hospital dietary worker thought to have contaminated food with MRSA, initiating an outbreak that affected multiple patients and health care workers and caused several deaths.

Resistant pathogens may gain access to humans and food animals by additional routes, which have been less extensively studied, but should receive enhanced attention. Chapin *et al*. found high concentrations of multidrug-resistant enterococci, coagulase-negative staphylococci, and viridans group streptococci in the air of a concentrated swine feeding operation in the US, and 98% of the bacterial isolates showed resistance to at least two antimicrobials used in swine husbandry. Some of the alarming findings from this study were the presence of bacteria resistant to clindamycin and virginiamycin. This latter compound, a swine growth promoter, is an analog of quinupristin/dalfopristin, an antibiotic of last resort for treating certain multidrug-resistant Gram-positive infections in humans. Gibbs *et al*. tested the distance that antibiotic-resistant microorganisms can travel by aerosols from a confined swine animal-feeding facility in the midwestern US, and reported that resistant *St. aureus*, the most frequent organism identified, could be recovered up to 150-m downwind from the facility. In the first study to characterize the presence of resistance genes to a major class of antibiotics in natural groundwater as a result of animal agriculture, Chee-Sanford *et al*. reported that tetracycline resistance determinants were present as far as 250-m downstream from waste lagoons and groundwater underlying swine farms. Illustrating an additional route allowing antibiotic-resistant pathogens access to the food chain, Kumar *et al*. reported that chlorotetracycline from animal manure used for fertilization can be detected in corn, green onions, and cabbage, in amounts that are small but increase with increasing amounts of antibiotic in the manure. Other authors also detected antibiotics originating in manure in different plants, and emphasized that the dangers of soilborne antibiotic resistance in humans have been underestimated.

Resistant Bacteria in the Kitchen and the Potential for Cross-Contamination

Although cooking destroys certain pathogens from food, they pose significant threats under several circumstances, such as the consumption of raw food. Cross-contamination of utensils, clothes, fingers, and kitchen surfaces during food preparation also poses substantial dangers. Although many studies examined antimicrobial-susceptible pathogens, the results are relevant for resistant pathogens as well. Kusumaningrum *et al*. reported that the *St. aureus* transfer rate from artificially contaminated sponges to stainless steel surfaces immediately after contamination was approximately 40%, and some bacteria remained on sponges after the transfer, enabling additional cross-contamination. High percentages of *St. aureus* were recovered from dry stainless steel surfaces at room temperature, exceeding the recovery of other organisms tested, such as *Salmonella enteritidis*, *Bacillus cereus* spores, or *C. jejuni*. On dry stainless steel surfaces, *St. aureus* was detected for at least 96 h when contamination was moderate (10^5 CFU/100 cm^2) or high (10^7 CFU/100 cm^2), revealing its ability to survive and cross-contaminate other surfaces. Scott and Bloomfield

reported that significant numbers of *St. aureus* survive on laminated surfaces and cloths, from where the pathogen may be transferred to fingertips or inanimate surfaces even after a brief contact, posing an infection hazard after contact with food. In a study that examined the secondary dissemination of pathogens from contaminated food in the kitchen environment, Gorman *et al*. revealed the ability of *St. aureus*-contaminated chickens to cross-contaminate multiple sites, including preparers' hands, refrigerator and oven handles, counter-tops, and draining boards.

Interactions Between Ecosystems: The Farm and Beyond

Genes encoding antimicrobial resistance can spread between microorganisms more easily than previously thought, by horizontal transfer. This mechanism occurs more frequently than mutations, and allows the transfer of resistance-encoding genetic elements between plasmids, chromosomes, or plasmids and chromosomes, causing susceptible isolates to become resistant. The horizontal transfer of resistance between different *E. coli* strains, sometimes between strains colonizing animals and humans, together with reports of antimicrobial resistance in *E. coli* colonizing healthy individuals, underscore the need to focus on commensal bacteria as a potential reservoir of resistance for pathogenic strains. Several studies described the transfer of antimicrobial resistance between *E. coli* strains colonizing the intestinal flora. Trobos *et al*. revealed that *sul2*, the gene encoding sulfonamide resistance, can be transferred between different *E. coli* strains residing in the human intestine, and showed that this process may occur concomitantly for multiple antibiotic resistance genes. Resistance can also be transferred from *E. coli* to other pathogens such as *Enterobacter*, *Salmonella*, and *Pseudomonas*. McMahon *et al*. documented the transfer of antibiotic resistance genes between *Sa. typhimurium* DT104 and *E. coli* K12 in broth, milk, and ground meat, at temperatures commonly encountered during food processing and distribution. Ampicillin-resistance genes were transferred at temperatures as low as 15 °C. The horizontal transfer of genetic resistance in food products becomes even more relevant if we consider the report of Sørensen *et al*. who found that glycopeptide- and streptogramin-resistant enterococci of chicken and pork origin, ingested by healthy volunteers, may be detected in the stool for up to 14 days, demonstrating their ability to survive in the gastric and intestinal environment, where resistance genes could be transferred to other bacteria from the intestinal microbiota.

In addition to impacting the local farm environment, antibiotic-resistant strains that emerge on the farm also exert a global impact as a result of the interconnectedness between the various compartments of the ecosystem. In this context, understanding the circulation of pathogens within and between farms becomes an important facet of public health initiatives. Davis and Wray showed that mice infected experimentally with *Sa. enteritidis* shed the pathogen, infecting chickens coming into contact with their droppings. Van de Giessen *et al*. found MRSA-infected rats on three of five pig farms that they examined in early 2008 in southern Netherlands and northern Belgium. The authors emphasized the fundamental role that rats play in disseminating this, and possibly other microorganisms, within and between farms, and underscored the need to incorporate this finding into strategies designed to control the spread of pathogens. In Libya, Rahuma *et al*. reported that significantly more houseflies isolated from hospitals harbored antibiotic-resistant bacteria than flies isolated in the streets, and two flies originating from hospitals tested positive for MRSA, whereas Bouamamaa *et al*. found antibiotic-resistant bacteria, including MRSA, in cockroaches and houseflies collected from residential areas in Tangier, Morocco. Wang *et al*. found identical pulsed-field gel electrophoresis profiles in several multidrug resistant *Salmonella* isolates recovered from swine stool and flies on multiple farms from northwestern Taiwan, reinforcing the idea that flies can serve as vectors for antimicrobial-resistant *Salmonella*. Chaslus-Dancla *et al*. found that gentamycin- and apramycin-resistant *E. coli* and *Salmonella* strains isolated from cattle and hospitalized patients in France and Belgium harbored the same antibiotic resistance-conferring plasmid, indicating that plasmid transfer occurred between bacteria infecting animals and humans.

The importance of focusing on the global, ecological perspective of antimicrobial resistance is illustrated by integrated fish farming, a widespread practice throughout Southeast Asia that involves recycling excreta from human and agricultural sources to feed fish in fishponds, where the resulting nutrients support aquatic photosynthetic organisms. Petersen *et al*. examined an integrated chicken-fish farm for 2 months after fish production started and reported that, over time, significantly more bacteria isolated from water-sediment samples became resistant to several antimicrobials. Rhodes *et al*. provided direct evidence that tetracycline-encoding plasmids, previously associated only with fish farms, disseminated between *Aeromonas* and *E. coli* species and between the aquaculture and human environments in at least four countries: Norway, England, Germany, and Scotland. The authors proposed that instead of viewing the fish farm and hospital as two separate components of the environment, they should instead be envisioned as one interactive compartment that facilitates the free exchange of genetic information.

The flow of antibiotic resistance in nature is further illustrated by the identification of antibiotic-resistant pathogens in populations where their presence cannot be simply explained by exposure to the antibiotic. Bartoloni *et al*. showed that in a remote rural Bolivian community of Guaraní Indians located at an altitude of 1700 m, despite minimal antibiotic use and limited exchange with other communities, 67% of the inhabitants that they examined carried fecal *E. coli* with acquired resistance to over one antibiotic. Gilliver *et al*. reported widespread antibiotic resistance in wild rodents previously unexposed to antibiotics, and Sjölund *et al*. showed that eight *E. coli* isolates obtained from Arctic birds were resistant to more than one antibiotic, with four of them resistant to four or more compounds that were tested. A multiresistance pattern that the authors observed was similar to one that is commonly seen in clinical isolates.

To better reflect the circulation of antibiotic resistance between different compartments of the ecosystem, D'Costa

et al. proposed the concept of antibiotic resistome, which encompasses the totality of antimicrobial resistance determinants across the globe, and incorporates not only resistance determinants directly relevant to the clinic but also the ones encountered in bacteria from other ecosystems, including those from nonpathogenic microorganisms such as soil bacteria.

These examples illustrate the need to employ a complex, interdisciplinary framework when exploring antimicrobial resistance in the food chain and implementing effective public health interventions. To reflect the ability of microbial pathogens from the farm environment to infect animals, humans, and the food chain at various stages and by various routes, this perspective should incorporate multiple facets. These include the ability of antimicrobials to select for resistant bacteria in food animals, farm workers, and the farm environment; the zoonotic and reverse zoonotic transmission of pathogens; cross-contamination in the kitchen environment; and the transfer of bacterial resistance across distinct compartments of the ecosystems.

CHARACTERISTICS OF FOODBORNE HAZARD AND DISEASES

Cost of Foodborne Diseases

JC Buzby, Economic Research Service of the US Department of Agriculture, Washington, DC, USA

Glossary

Contingent valuation method The use of surveys of individuals to elicit their preferences, measured in monetary terms, for a specified improvement in their health outcomes. It circumvents the absence of markets for health outcomes by presenting survey respondents with hypothetical markets in which they are asked their willingness to pay (WTP) for the improvement in question.

Cost-of-illness (COI) method An approach used to estimate the societal costs of a particular illness or injury in a given time frame (such as a 1-year period). The approach typically focuses on two main types of societal costs associated with the particular illness or injury: medical costs and costs of lost productivity due to morbidity or premature mortality.

Disability-adjusted life years (DALYs) method This method makes time a common metric for death and disability by combining the years of life lost due to premature death (YLL) and the years lived with disability (YLD) for varying degrees of severity.

Health-adjusted life years (HALYs) method The HALYs method measures the years of full health lost because of living with morbidity. Within this group, two popular methods are quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs). QALYs assign values to health outcomes on a 0 to 1 scale, with 0 indicating death and 1 indicating perfect health. DALYs have the reverse 0 to 1 scale. This means that food safety interventions would aim to maximize QALYs and minimize DALYs.

Hedonic wage studies Statistical analyses that estimate the effect of intrinsic job characteristics, such as health risks, fringe benefits, or autonomy, on wages. It is a method to estimate the risk premium.

Human capital approach A method for estimating the impact of an individual's illness or premature death on society by measuring the discounted value of his/her productivity loss (labor earnings) due to morbidity or premature mortality.

Premature death/premature mortality A preventable death that occurs before the average life expectancy for an individual's subpopulation.

Productivity loss The monetary value of output that would have been produced in the absence of an illness, disability, injury, morbidity, or premature mortality.

Value of statistical life The value of a statistical life (VSL) is the conventional way to summarize the value of small risk reductions in mortality. These estimates are not meant to be applied to the value of saving any particular person's life.

Willingness to pay (WTP) A measure of the monetary value an individual would place on reducing the risk of death or illness. It is the maximum dollar amount the individual would be willing to pay in a given hypothetical risk-reducing situation.

Introduction

This article discusses the economic costs and burden of foodborne disease and why their estimation is important. Here, we define burden as the prevalence and incidence of morbidity, disability, and mortality associated with acute and chronic manifestations of foodborne diseases. Estimation challenges are briefly discussed followed by an overview of the methods used to estimate foodborne disease costs. The article shows the US situation for Shiga toxin-producing *Escherichia coli* as an example, though some international examples are also provided. The article concludes with a look at future directions.

Individual, Industry, and Public Sector Costs of Foodborne Disease

Societal costs of foodborne disease are incurred by three main groups: individuals/households, the food industry, and the public sector. Taken as a whole, the costs of foodborne disease pose an economic burden on society, particularly in developing countries where the costs to prevent or treat foodborne disease can strain already limited federal and household resources. Persistent problems with foodborne pathogens within a country's food supply can also hinder food exports, which in turn can ultimately affect a country's agricultural revenue. Developing countries have the potential to

 doi:10.1016/B978-0-12-378612-8.00068-8

be relatively hit harder by a food safety problem that adversely affects their food exports, compared to developed countries. This is because food exports from developing countries may account for a proportionally larger share of their total export revenue.

When researchers estimate the economic costs or burden of foodborne disease, they often include only a handful of the costs illustrated in Table 1. More easily measurable costs, such as some of the medical costs, costs of lost income (typically called productivity loss), and premature death are frequently included in these analyses. Most types of costs are excluded due to data limitations and lack of suitable analytical techniques, meaning that societal costs may be underestimated. The impact on industry members can be sizeable, particularly when large recalls or product liability suits are involved.

Why is it Important to Estimate the Costs and Burden of Foodborne Disease?

The estimated economic costs and burden of one or more foodborne diseases on a nation, other population subgroups, or the world can be used in three main ways, to:

1. Evaluate the economic costs or burden of a broader group of foodborne diseases.
2. Serve as input for analyses needed in policymaking, such as for a proposed food safety rule. In the US, cost-of-illness (COI) estimates for foodborne disease have been used in food safety rulemaking by several agencies. For example, cost estimates for several foodborne diseases in the US were used to estimate the benefits of the Hazard Analysis Critical Control Points (HACCP)/pathogen reduction rule for federally inspected meat and poultry slaughter and processing plants in the official regulatory impact analysis. In general, a benefit–cost analysis weighs the pros (i.e., benefits) and cons (i.e., costs) of a proposed regulation against a baseline (i.e., without the regulation). The benefits of some regulations are the costs of foodborne disease avoided or prevented because of the rule.
3. Aid comparisons and other analyses, such as to compare/rank estimated costs for different foodborne diseases or compare benefits and costs of alternative pathogen-prevention and control rules, programs, and strategies to determine the most cost-effective interventions so that resources are appropriately allocated (e.g., cost-effectiveness analysis).

Estimation Challenges for Foodborne Disease

In 2009, Buzby and Roberts identified epidemiological and methodological challenges that hinder the estimation of the economic costs and burden of foodborne disease. Figure 1 provides a simple schematic of a subset of these challenges.

Epidemiological Challenges

Four epidemiological challenges relevant here are:

1. Estimating the annual number of illnesses caused by a particular pathogen.

   Data limitations hinder the estimation of the annual number of foodborne illnesses caused by each pathogen. In short, many events must occur for an ill person to be identified as a laboratory-confirmed case of foodborne disease in the US and for the disease to be recorded in a national database – the ill individual must seek medical care, a specimen must be obtained, the laboratory must test for the particular foodborne disease that caused the illness, and the laboratory must confirm the causative agent and report the case to public health surveillance. This sequence of events does not occur in most instances, partly because most people with a foodborne illness do not seek medical care.

   In the US, one major source of data on foodborne diseases is the Foodborne Diseases Active Surveillance Network (FoodNet), which is a collaborative project of the Centers for Disease Control and Prevention (CDC), 10 Emerging Infections Program sites in different states, the US Department of Agriculture (USDA), and the Food and Drug Administration (FDA). FoodNet consists of active surveillance and related epidemiologic studies for foodborne diseases in the US. Using FoodNet data and other sources of information, the total number of foodborne disease cases in the US is estimated to be 76 million annually, according to a seminal article by Mead *et al.* in 1999. This article also estimated that unknown agents accounted for roughly 81% of all foodborne illnesses in the US and 64% of the associated deaths. Data limitations are particularly glaring for unknown agents, yet total costs will be underestimated if they are not included in the analysis.
2. Attributing foodborne disease to particular foods.

   A second epidemiological challenge is that there is limited data on the share of particular illnesses attributed to specific foods. This information is critical in economic analyses that estimate the number of foodborne disease cases which might be prevented by a proposed regulation. For example, the previously mentioned official regulatory impact analysis of the HACCP program for federally inspected meat and poultry plants included assumptions about what portion of selected foodborne diseases (e.g., campylobacteriosis, salmonellosis, and listeriosis) were due to meat and poultry. Internationally, food attribution data and approaches to obtain estimates of the share of foodborne illnesses attributed to specific foods include analysis of outbreak data, expert judgment, microbial subtyping and source tracking methods, case-control studies, among others.
3. Estimating acute illness outcome severity.

   Thorough economic evaluations of foodborne disease require information on illness severity, duration, and outcomes, which range from regaining full health to premature death. Yet, outcome distributions are limited for most pathogens. In the US, FoodNet collects information on three illness severities (illnesses, hospitalizations, and

Table 1 Costs to society from foodborne disease

Costs to individuals and households[a]	*Industry costs*[b]	*Regulatory and public health sector costs for foodborne pathogens*
Human illness costs:	*Costs of animal production:*	*Disease surveillance costs to:*
Medical costs:	Morbidity and mortality of animals on farms	Monitor incidence/severity of foodborne disease
Physician visits	Reduced growth rate/feed efficiency and increased time to market	Monitor pathogen incidence in the food chain
Laboratory costs	Costs contaminated animal disposal (e.g., farm and slaughterhouse)	Develop integrated database from farm to table
Hospitalization or nursing home	Increased trimming or reworking at slaughter and processing plants	
Drugs and other medications	Illness among workers due to handling contaminated animals/products	*Research to:*
Ambulance or other travel costs	Increased meat product spoilage due to pathogen contamination	Identify new foodborne pathogens for acute and chronic illnesses
Income or productivity loss for:		Identify high-risk products
Ill person or person dying	*Control costs for pathogens at all links in the food chain:*	Identify high-risk production and consumption practices
Caregiver for ill person	New farm practices (age-segregated housing, sterilized feed, etc.)	Identify which consumers are at high risk for which pathogens
Other illness costs:	Altered animal transport and marketing patterns (animal identification)	Develop cheaper and faster pathogen tests
Travel costs to visit ill person	New slaughterhouse procedures (hide wash, carcass sterilizing)	Risk assessment modeling for all links in the food chain
Vocational/physical rehabilitation	Altered product transport (increased use of time/temperature indicators)	
Child-care costs	New wholesale/retail practices (pathogen tests, employee training)	*Outbreak costs:*
Special educational programs	Risk assessment modeling by industry for all links in the food chain	Outbreak investigation costs
Institutional care	Price incentives for pathogen-reduced product at each food chain link	Testing to contain an outbreak
Lost leisure time	New processing procedures (pathogen tests, contract purchasing requirements)	Legal suits to enforce regulations that may have been violated[c]
Home modifications		Cleanup costs
Psychological costs:	*Outbreak costs:*	*Other considerations:*
Pain, other psychological suffering	Herd slaughter/product recall	Distributional effects in different regions, industries, etc.
Risk aversion	Plant closings and cleanup	Equity considerations, such as special concern for children
	Regulatory fines	Impact on food exports
Averting behavior costs:	Product liability suits from consumers and other firms	Impact on agricultural revenue
Extra cleaning/cooking time costs	Reduced product demand because of outbreak:	
Extra cost of refrigerator, freezer, etc.	Generic animal product – all firms affected	
Flavor change from traditional recipes	Reduction for specific firm at wholesale or retail level	
Increased cost to buy safer foods	Increased advertising or consumer assurances following outbreak	
Altruism (willingness to pay for others to avoid illness)		

[a]Willingness-to-pay estimates for reducing risks of foodborne disease is a comprehensive estimate of all these categories (assuming that the individuals have included employer-funded sick leave and medical programs in their estimates) and the estimate covers reduced risks for everyone – those who will become ill as well as those who will not.

[b]Some industry costs may fall with better pathogen control, such as reduced product spoilage. Possible increases in product shelf-life may permit shipment to more distant markets or lower shipment costs to nearby markets.

[c]In adding up costs, care must be taken to assure that product liability costs to firms are not already counted in the estimated pain and suffering cost to individuals. However, the legal and court expenses incurred by all parties are societal costs.

premature deaths) but it covers less than a dozen (i.e., *Campylobacter*, *Cryptosporidium*, *Cyclospora*, *Listeria monocytogenes*, STEC O157, STEC non-O157, *Salmonella*, *Shigella*, *Vibrio*, and *Yersinia enterocolitica*) of the more than 200 microbial agents that cause foodborne disease.

4. Estimating chronic complications.

   Many foodborne pathogens cause one or more chronic complications that can have lifetime health consequences or cause premature death (e.g., paralysis, kidney failure, irritable bowel syndrome). Some, like reactive arthritis, are autoimmune diseases caused in response to infections by certain foodborne bacterial pathogens. Obtaining data and information to estimate the costs and burden of these complications is challenging, yet their inclusion in cost studies is important because they can result in high average and total costs relative to acute manifestations.

Methodological Challenges

The main methodological challenges that hinder the estimation of the economic costs and burden of foodborne disease include:

1. Selecting the method.

   Selecting which method to use for the analysis to estimate the impact of foodborne disease is the first methodological challenge. If the resulting estimates are going to be used in an economic analysis of proposed Federal food safety rule, this choice is particularly important. In general, the analysis' goal usually determines which method is used. The main options include monetary (e.g., COI and willingness to pay (WTP)) and non-monetary methods (e.g., versions of the health-adjusted life years (HALYs) method). The Valuation Methods section discusses these in detail. Economic theory suggests that the WTP method should be used to estimate the benefits of a regulation if the goal of these estimates is their use in a benefit–cost analysis of a potential food safety regulation to see if the regulation is worthwhile to implement. This method can best reflect individual risk preferences. The 2003 US Office of Management and Budget recommends the WTP approach to value-anticipated reductions in the risk of premature deaths which could arise from implementing a proposed regulation.

   The COI method may be the better approach if the goal is to estimate foodborne disease costs and have a detailed breakdown of the cost components. For example, this method is valuable when estimating the monetary value of the benefits of implementing a regulation that reduces foodborne disease risks. Monetizing both the major benefits and costs is usually preferred in the US rulemaking. When monetization is not possible due to ethical issues, analytical limitations, and other factors, non-monetary methods are used.

2. Selecting the point or dollar estimate(s) of the value of statistical life.

   Perhaps the most crucial methodological challenge in a cost or burden analysis is selecting the dollar or point estimate(s) of the value of a statistical life (VSL) for premature deaths. The valuation of premature deaths can be by far the largest component of total estimated costs. For example, USDA's Economic Research Service (ERS) estimates suggest that premature deaths accounted for more than 88% of total costs for *Salmonella* and 90% of total annual costs for Shiga toxin-producing *E. coli* O157 (STEC O157) in 2008 dollars. Over the past decade or so, many of the VSL estimates in analyses that support US federal rulemaking have centered around $5 million per statistical life, updated to current dollars. This value is the midpoint of amounts found in a review of labor market studies.

   How economists value premature deaths is evolving over time. Different parts of the US Federal government have historically used different WTP estimates of the VSL. The choice matters when analyzing a proposed food safety rule because final estimates can vary widely, depending on the assumptions used. That is, whether or not a regulation is put into effect could conceivably be on the line. Sensitivity analysis using different VSL scenarios are helpful when there is uncertainty about which estimates are appropriate.

3. Deciding whether or not to adjust for age or preexisting health status.

   A third methodological challenge is the decision whether the VSL estimate in an analysis should be adjusted for age or preexisting health status. Adjusting for age means that WTP for mortality risk reductions are calculated on the expected remaining years of life lost due to the premature death (i.e., the elderly could forego a few years of their remaining lifespan whereas younger individuals could forego many decades of life). As an example of an adjustment for a preexisting health status, an analysis could account for the elderly being more likely than younger individuals to have a co-morbidity that affects their ability to respond, thus potentially making them more susceptible to foodborne illness. Estimated total costs could vary widely if these adjustments are made. Many of these adjustments are controversial. Analysts for the US Environmental Protection Agency are now directed to not include age adjustments.

4. Estimating the anticipated impact of a proposed rule.

   An integral part of an economic analysis for a proposed food safety rule is estimates of the anticipated number of foodborne disease cases and deaths that would be prevented if the rule is implemented. Predicting what might happen in the future is a challenge. Therefore, sensitivity analyses may be used to cover the plausible range of preventable cases. Epidemiologists and risk assessors are often relied on for this technical information.

Valuation Methods

Monetary Methods

Cost-of-Illness Method

Table 2 summarizes the three main methods for estimating the costs and burden of foodborne disease and, in turn, for valuing

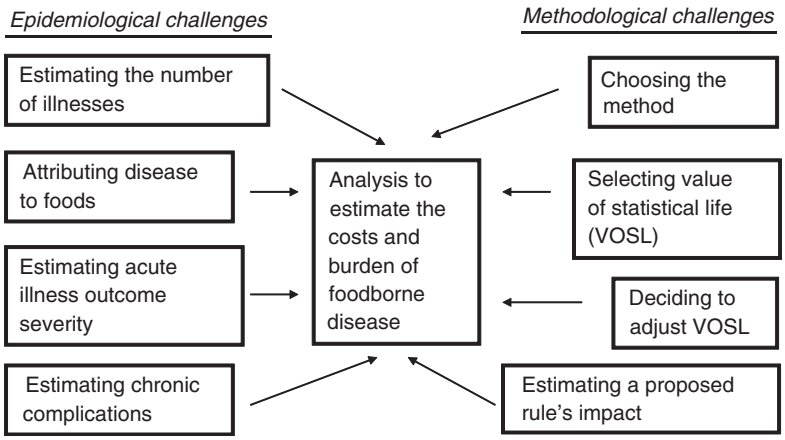

Figure 1 Epidemiological and methodological challenges to estimate the costs and burden of foodborne disease.

the benefits of proposed food safety policies. One main monetary method is the COI method, which estimates the dollars spent on medical costs and the value of lost productivity, such as the wages foregone because of a foodborne disease.

In general, a COI analysis traditionally starts with an estimate of the annual number of cases for a particular disease from all sources, foodborne and other, and then divides this number into severity groups. For example, Figure 2 presents the schematic of a COI study by USDA's ERS on Shiga toxin-producing *E. coli* (STEC O157). The initial acute illness is subdivided into two categories: those who did not visit a physician and survived and those who visited a physician. Some of those who visited a physician were hospitalized and these hospitalizations were divided into subgroups by outcome severity. Some developed hemolytic uremic syndrome (HUS), which is characterized by kidney and neurological failure, and some of these HUS cases also developed end-stage renal disease (ESRD), a chronic condition that results in reduced life expectancy. Those who died prematurely because of their illness are in additional subgroups.

For each severity group identified in a COI analysis for a particular disease, total annual costs are estimated. This entails obtaining appropriate data and calculating the corresponding medical costs, lost productivity costs, value of premature deaths, and other illness-specific costs, such as special education and residential care. In general, medical costs include physician and hospital services, supplies, medications, and special procedures sometimes required for chronic complications (e.g., dialysis for ESRD). Hospitalizations tend to swamp total medical costs.

Productivity loss typically measures the decline in work because workers were ill with a disease and missed work, performed poorly at work, regained only a portion of their preillness productivity, switched to less demanding and lower paying jobs, or were unable ever to return to work, such as from dying prematurely. Productivity losses for those who missed some work but later resumed work are usually calculated differently from those who died or were unable to return to work. The human capital approach is often used for temporary interruptions of work. In essence, this approach uses the present value of the future earnings foregone because of the illness. This productivity loss may be calculated as the product of time lost from work and the corresponding average daily wage rate. Productivity losses for those who died or were unable to return to work can be calculated in several ways, including using a VSL estimate. The total cost of lost productivity and premature deaths is the sum of all costs for all individuals affected, primarily the patients and, in the case of ill children, their parents or paid caretakers. In a COI analysis, subsequent steps often identify what portion of total costs is attributable to foodborne sources. The resulting data may be included in a larger analysis that estimates what portion of cases and deaths would potentially be averted by a proposed regulation.

Willingness-to-Pay Approach

The WTP approach is a second monetary method. It measures the dollars individuals are willing to pay for a reduced risk of encountering a certain health hazard. WTP estimates are often the result of contingent valuation studies, or hedonic wage or labor market studies, which evaluate the small statistical risk of premature death and the increase in wages to compensate for taking this risk (i.e., risk premium). As previously mentioned, the WTP approach is theoretically superior to other approaches and the US Office of Management and Budget 2003 states that it is the preferred approach when valuing reductions in fatality risks that are expected by implementing a proposed regulation. However, it does have some disadvantages as outlined in Table 2 and as a result, some analysts prefer non-monetary methods.

Non-Monetary Methods

Non-monetary methods provide estimates that are not in a monetary unit of measurement (e.g., healthy-time equivalents instead of dollars). They often deal with the health-related quality of life. That is, they convert adverse health outcomes from an illness that compromise both lifespan and functional ability into a common unit of measurement. An umbrella group of non-monetary methods is the HALYs method, which measures the years of full health lost because of living with morbidity. Within this group, two popular methods are quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs). QALYs assign values to health outcomes on a 0

Table 2 Methods to estimate the costs and burden of foodborne diseases

Method	*Advantages*	*Disadvantages*
The *cost-of-illness (COI) method* is an monetary accounting or tally of the annual dollars spent on: ● Medical costs (e.g., physician and hospital services, supplies, medications, medical procedures, transportation to health care, relocation expenses, special education, residential care). ● Lost productivity and other costs like the dollars of employment compensation that was foregone as a result of morbidity or mortality (e.g., lost productivity because workers were ill and either missed work, performed poorly at work, were unable ever to return to work, or died prematurely).	● Provides easy to understand monetary measure of foodborne disease costs or the benefits of a program that reduces foodborne disease. ● Represents real costs to society.	● Estimates may be influenced by income, education, and other factors. ● Intricate disease coding and insurance arrangements can complicate estimation of medical expenses. ● Estimating lost productivity costs may also be difficult because of the various forms of compensation available to employees and because large sections of the population under study may not be in the workforce. ● Provides a partial estimate of economic costs as it excludes more difficult to measure costs to individual/households, industry and the regulatory/public health sector and excludes the vast majority of chronic complications associated with foodborne disease. Therefore, estimates may underestimate the actual benefits of a proposed food safety policy.
Willingness-to-pay (WTP) is a monetary method that estimates the money that individuals are willing to pay to reduce their probability of encountering a health hazard. WTP estimates are often the result of labor market studies, which evaluate the small statistical risk of premature death and the increase in wages to compensate for taking this risk.	● Reflects individual preferences for risk reduction. ● Theoretically superior measure. ● Includes valuation of pain and suffering, lost leisure time, and other costs.	● Estimates are sensitive to the study populations, type of risk, and level of risk so they may not be applicable if used in a different study. ● May not be practical to have a study focused on the risk being evaluated. ● Has some measurement difficulties, especially for nonfatal outcomes.
Non-monetary methods Non-monetary methods look at health-related quality of life, such as in healthy-time equivalents, and are useful in cost-effectiveness analyses. Health-adjusted life years (HALYs) is an umbrella group of non-monetary methods that measure the years of full health lost because of living with a morbidity. Two methods within this group are quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs). Some analyses monetize the estimates in a separate step. For example, the US Food and Drug Administration has been monetizing QALYs in their benefit–cost analyses. *DALYs*. According to WHO, 'the DALY measure combines the years of life lost due to premature death (YLL) and the years lived with disability (YLD) for varying degrees of severity, making time itself a common metric for death and disability. One DALY is a health measure, equating to one year of healthy life lost.' (WHO, 2006)	DALYs are: ● An internally consistent common metric. ● Can develop and incorporate downstream effects on agricultural, social, and trade costs that are traditionally missing from a cost or global burden analysis. ● Can segregate comorbidity (i.e., where several pathologies coexist, and contribute and compete for the cause of death). ● Uses the same value of a human life in rich and poor countries and also levels the playing field between acute and chronic disease because it takes into account the duration of the syndrome and its severity.	● Poorly represents some social costs (e.g., reduced production and trade of cattle because of a food safety issue). ● Still requires subjective value judgments on how to weight or discount for age of onset, disability weights, and future losses.

to 1 scale, with 0 indicating death and 1 indicating perfect health. DALYs have the reverse 0 to 1 scale. This means that food safety interventions would aim to maximize QALYs and minimize DALYs. Estimates from these methods are useful in cost-effective analyses. Some analyses convert the estimates to dollars in a separate step by using a dollar value per HALY, QALY, or DALY conversion factor. For example, the US FDA monetizes QALYs in some of their benefit–cost analyses.

Disability-Adjusted Life Years

According to the World Health Organization (WHO), the DALY measure makes time a common metric for death and disability by combining the years of life lost due to premature death (YLL) and the years lived with disability (YLD) for varying degrees of severity. In essence, one DALY equates to 1 year of healthy life lost. DALYs are the WHO's preferred disease-burden measure. Importantly, DALYs use the same value of a human

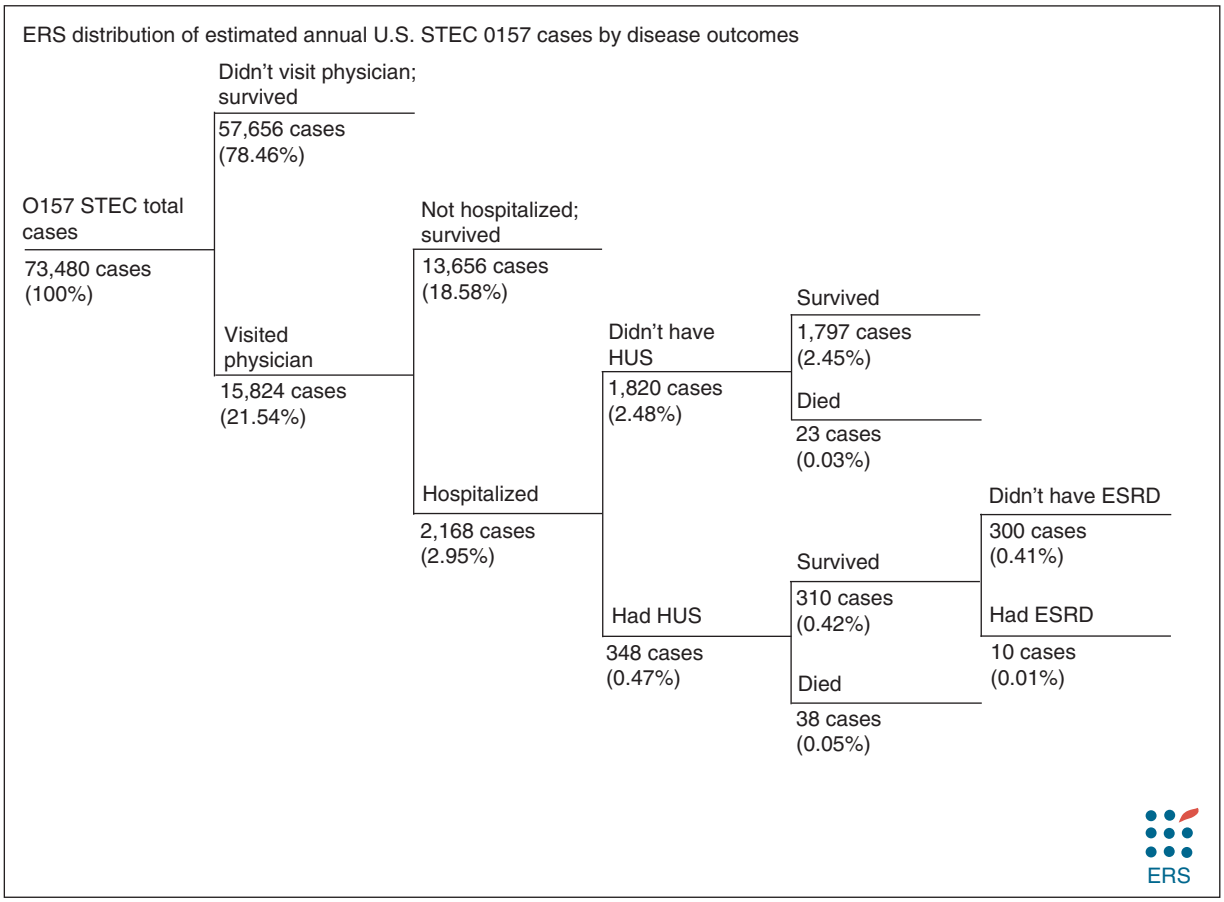

Figure 2 ERS distribution of estimated annual US STEC O157 cases by disease outcomes. *Source*: USDA/Economic Research Service.

life in rich and poor countries and they also level the playing field between acute and chronic disease because they take into account the duration of the syndrome and its severity. The DALY approach is an internally consistent common metric that can segregate co-morbidity (i.e., where several pathologies co-exist, and contribute and compete for the cause of death).

Examples of the Economic Costs and Burden of Foodborne Disease

In the 1980s, the ERS began to conduct some of the earliest studies on the economic costs of foodborne illness in the US. Initially, these analyses incorporated the limited information then available about the incidence of foodborne illness and used the COI method. ERS has continued to update and expand these analyses using improved estimation methods and better data. In 2003, ERS introduced their web-based Foodborne Illness Cost Calculator, which provides information on the assumptions behind foodborne illness cost estimates for *Salmonella* and Shiga toxin-producing *E. coli* O157 (STEC O157). Data users can make their own assumptions in this calculator and calculate their own cost estimates. The calculator uses the COI method for nonfatal illnesses and WTP point or dollar estimates for premature deaths.

ERS, in collaboration with CDC's FoodNet, developed the total cost estimate for STEC O157 in 2005, using a case-control study of STEC O157 patients and FoodNet surveillance data. Table 3 illustrates how estimated costs per case vary by severity level. Estimates include costs for complications that can arise from STEC O157 disease: acute illness costs arising from hemorrhagic colitis (HC, a clinical syndrome manifested by bloody inflammation of the colon), and chronic illness costs for HUS, with and without ESRD. Total costs include medical costs for kidney dialysis and transplants, the value of time lost from work due to nonfatal illness, and the value of premature death, but exclude other potential costs, such as for special education and pain and suffering. This collaboration did not estimate foodborne disease cost because of the lack of a widely-accepted estimate of the percentage of STEC O157 cases that are foodborne. Table 3 assumes two different estimates of the percentage of cases that are foodborne to illustrate how total costs may change with this final assumption, thus emphasizing the importance and need for quality data. Solely for illustrative purposes, this table assumes Mead *et al.*'s estimate from 1999 that 85% of STEC O157 cases are from foodborne transmission, and also assumes the arbitrary number of half of this amount (42.5%). Estimated annual costs of foodborne STEC O157 in the US in 2008 totaled $203.2 million under the 42.5% assumption and $406.4 million under the 85% assumption. One can easily imagine from this simplistic example how costs of foodborne STEC O157 could vary greatly, depending on the assumption of the percent due to foodborne transmission and how this

Table 3 Estimated STEC O157 costs in the US, from all sources and foodborne sources, 2008 Dollars

Severity level	*Total cases*	*Total costs*	*Average cost/case*	*Foodborne*			
				Assuming 42.5% FB		*Assuming 85% FB*	
				Cases	*Costs*	*Cases*	*Costs*
	Number	*Million Dollars*	*Dollars*	*Number*	*Million Dollars*	*Number*	*Million Dollars*
Not hospitalized							
Didn't visit physician; survived	57 656	1.7	30	24 504	0.7	49 008	1.4
Visited physician; survived	13 656	7.4	540	5804	3.1	11 608	6.3
Hospitalized							
Didn't have HUS; survived	1797	13.2	7351	764	5.6	1527	11.2
Had HUS but not ESRD; survived	300	12.4	41 188	128	5.3	255	10.5
Had HUS and ESRD; survived	10	60.9	6 094 462	4	25.9	9	51.8
Didn't have HUS; died	23	107.6	4 680 193	10	45.7	20	91.5
Had HUS; died	38	274.8	7 232 443	16	116.8	32	233.6

Source: Total cases, total costs, and average costs estimates are from the Economic Research Service, http://www.ers.usda.gov/data/foodborneillness/ecoli_Intro.asp (accessed December 2009). For illustrative purposes only, foodborne (FB) cases and costs assume 85% of total cases are foodborne (Mead *et al*., 1999) and arbitrarily half of that amount (42.5%). *Note*: HUS is characterized by red blood-cell destruction, kidney failure, and neurological complications, such as seizures and strokes. Although these figures are for STEC O157 illnesses from all sources, average foodborne illness costs are usually considered to be the same as costs for those illnesses from non-foodborne sources. Columns may not total due to rounding.

Table 4 Sample of estimated costs and burden of foodborne disease

Method	*Author (year of study/method)*	*Foodborne disease*	*Estimated costs*	*Country*
COI	Buzby and Roberts (1997)	Six bacteria, one parasite	$6.5–34.9 billion	US
COI	Roberts and Upton (2000)	STEC O157:H7 outbreak	£11 930 347	UK
DALY	Havelaar *et al.* (2000)	*Campylobacter* sp.	1400 DALY per case	Netherlands
COI	Scott *et al.* (2000)	All foodborne disease	$55.1 million	New Zealand
COI	Lindqvist *et al.* (2001)	Foodborne disease	$123 million	Sweden
COI	Abe *et al.* (2002)	STEC O157:H7 outbreak	¥82 686 000	Japan
COI	Frenzen *et al.* (2005)	STEC O157 (all sources)	$344 million	US
COI	Abelson *et al.* (2006)	All foodborne disease	AU$1249 million	Australia
WTP	Roberts (2007)	All foodborne disease	$1.4 trillion	US
DALY/COI	Haagsma *et al.* (2009)	Select foodborne diseases and irritable bowel syndrome	3757.9 DALY, €65.4 million	Netherlands

might affect a regulatory cost–benefit analysis, particularly if total costs were roughly equal to total benefits. In essence, one weak estimate, if used, can cloud an otherwise well-supported analysis.

Internationally, several studies have estimated the economic costs and burden of foodborne disease. Table 4 provides a small sample that used the COI, DALY, and WTP methods in developed countries. As with the US studies, the international studies' methodology and comprehensiveness have developed over time, with early studies focusing on one or more foodborne diseases. Similar studies have not been conducted in developing countries, largely due to data and resource limitations. However, there are some estimates of selected foodborne and diarrheal diseases and discussions of potential societal costs.

Looking Ahead

The global burden of foodborne disease is unknown. Current national estimates of the costs and burden of foodborne disease may significantly underestimate true values due to incomplete coverage of: (1) the breadth of acute and chronic manifestations of foodborne diseases, (2) the array of associated costs outlined in Table 1, and (3) the unknown pathogens that cause foodborne disease. As a result, economic analyses for policymaking that use these costs or burden estimates will be similarly restricted. Less comprehensive estimates of the costs and burden of foodborne disease could potentially mean that some regulations may not be put in place that would otherwise be adopted, had all foodborne disease costs and burden been accounted for. This also means that funding for public health may be less than what would be justified had total foodborne disease costs been more comprehensive. Additionally, incomplete accounting may mean reduced priority of foodborne disease at the international level.

In 2006, the WHO launched an initiative to estimate the global burden of foodborne disease. This initiative ultimately aims to express the impact of each disease in DALYs – and this reflects the growing trend toward using non-monetary estimation measures. Other trends include increasing dialog and analysis about the merits, pitfalls, and different outcomes from adjusting VSL for age and other factors. For example,

CDC–ERS collaboration is currently estimating the annual cost of premature deaths from foodborne disease using updated death estimates in an analysis, with and without adjustments for age. ERS is also in the process of expanding its cost calculator to incorporate additional foodborne diseases and newly released data from CDC.

For these and other analyses that estimate the economic costs and burden of foodborne disease, the ultimate challenge boils down to obtaining appropriate and reliable data for the various components of the analyses and to develop appropriate methodologies that can best use the limited data and information currently available. Better data could enhance understanding of foodborne disease and help support the need for effective food safety regulations, practices to reduce foodborne disease, and funding for public health to prevent and treat foodborne disease. Globally, foodborne disease will become increasingly important to prevent as, among other factors, the amount of internationally traded food increases and advances in transportation and subsequent decreases in average price per trip allow more people to travel worldwide, potentially increasing the spread of disease, including foodborne diseases.

Introduction

The International Classification of Diseases (ICD) allows to categorize diseases, health-related conditions, and external causes of disease and injury in order to be able to compile useful statistics in mortality and morbidity. ICD has evolved over the past 150 years from an International List of Causes of Death to a comprehensive classification system for use in mortality, morbidity, case mix, quality, and patient safety. The ICD has become the international standard diagnostic classification for all general epidemiological and many health management purposes. These include the analysis of the general health situation of population groups and the monitoring of the incidence and prevalence of diseases and other health problems in relation to other variables, such as the characteristics and circumstances of the individuals affected. In this process, ICD has become the tool to allocate the majority of the global health resources. Users nowadays include physicians, nurses, other providers, researchers, health information managers and coders, health information technology workers, policy makers, insurers, and patient organizations. More specifically, its uses include:

- national and international health statistics (mortality and morbidity);
- epidemiology, surveillance, and monitoring;
- individual patient records and electronic health records;
- reimbursement and health system financing;
- reference for treatment guidelines, scientific literature, and research; and
- quality assessment at the level of individual cases up to assessment of health system outcomes and monitoring.

ICD is one core classification of a set of international classifications, the World Health Organization Family of International Classifications (WHO-FIC), that is designed to cover all domains of health. In addition to ICD, it includes core classifications for functioning, disability and health, and health interventions. A set of derived classifications, ICD-O, cover additional detail necessary for special disciplines. Related classifications, such as the anatomical therapeutic chemical (ATC)/defined daily dose (DDD) for drugs, complement the core classification for specific domains.

ICD-10 can be looked up online in English and French at WHO and accessed in other languages through the relevant national institutions and WHO-FIC Collaborating Centres. Overall, ICD-10 is available in 42 languages.

The revision process toward ICD-11 started in 2007, to be ready for publication by 2015. ICD-11 will be scientifically up-to-date and will be designed to provide the necessary detail and functionality to be useful in above-mentioned use cases and for use in electronic environment. An open, Internet-based mechanism allows for broad participation in the process.

ICD is used in various settings with different levels of resolution ranging from a set of 100 to 10 000 codes.

History

The history of the systematic statistical classification of diseases dates back to the nineteenth century. Groundwork was done by early medical statisticians, such as William Farr (1807–83) and Jacques Bertillon (1851–1922). The French government convened the first International Conference for the revision of the Bertillon or International List of Causes of Death in August 1900. The next conference was held in 1909, and the French government called for succeeding conferences in 1920, 1929, and 1938. With the sixth revision of the ICD in 1948, WHO became the custodian of the ICD. The ICD-6 extended the scope of the classification to nonfatal diseases, and WHO has continued to be responsible for periodic revisions of the classification. With a need to create comparability at the international level in public health as well as in clinical research, more and more clinical concepts have been introduced.

Content

The ICD can be used to classify diseases and other health problems recorded on many types of health and vital records. Its original use was to classify causes of mortality as recorded at the registration of death. Later, its scope was extended to include diagnoses in morbidity. The ICD is primarily designed for the classification of diseases and injuries with a formal diagnosis. In addition, the ICD provides for a wide variety of signs, symptoms, abnormal findings, complaints, conditions, and social circumstances, which are the problems or reasons for coming into contact with health services that stand in place of a diagnosis on health-related records. Most of these

categories can be found in Chapters XVIII and XXI of ICD-10. However, most other chapters also include such categories.

Structure

The ICD-10 consists of three volumes, and all three volumes are necessary for correct coding. This section provides an overview of the structure of ICD and how to use it. Before coding with ICD-10 and before interpreting ICD-coded information, users need to study the detailed descriptions in Sections 2.4–3.3 of ICD-10, Volume 2, and undergo some training with the electronic ICD-10 self-learning course.

Volume 1 contains the tabular list, as well as some definitions and a copy of the international agreement about reporting health information, the WHO nomenclature regulations. Volume 2 is a manual with extensive description of the classification and methods for use in mortality and morbidity, including short lists. Volume 3 is the alphabetical index. It contains separate indices for diseases, external causes, and drugs/substances.

The basic ICD is a single coded list of three-character categories, each of which can be further subdivided into 10 four-character subcategories. The three-character categories are grouped into blocks and chapters. The full meaning of a specific category is conveyed by its place in a chapter, block, its title, inclusions and exclusions, and other notes at any level of the hierarchical structure. Essentially in Chapter V, 'Mental and Behavioural Disorders,' definitions indicate the meaning of categories.

For coding, a term is looked up in the index. The index points to a category. The category is verified in Volume 1 taking into account information given in the context of chapters, blocks, categories, and Volume 2.

Chapters

ICD-10 is divided into 21 chapters. Chapters I–XVII relate to diseases and other morbid conditions and Chapter XIX relates to injuries, poisoning, and certain other consequences of external causes. The remaining chapters complete the range of subject-matter nowadays included in diagnostic data. Chapter XVIII covers symptoms, signs, and abnormal clinical and laboratory findings, not classified elsewhere. Chapter XX, 'External Causes of Morbidity and Mortality,' was traditionally used to classify causes of injury and poisoning, but, since the ninth revision, has also provided for any recorded external cause of diseases and other morbid conditions. Finally, Chapter XXI, 'Factors Influencing Health Status and Contact with Health Services,' is intended for the classification of data explaining the reason for contact with health care services of a person not currently sick, or the circumstances in which the patient is receiving care at that particular time or otherwise having some bearing on that person's care.

Blocks

The chapters are subdivided into homogeneous 'blocks' of three-character categories. Within each block, some of the three-character categories are for single conditions, selected because of their frequency, severity, or susceptibility to public health intervention, whereas others are for groups of diseases with some common characteristic. There is usually provision for 'other' conditions to be classified, allowing many different but rarer conditions to be coded. Usually at the end of blocks and chapters, special categories with the postfix 'unspecified' allow coding of cases where the reported detail does not allow assignment to more specific categories.

Categories

Most of the three-character categories are subdivided into four-character subcategories. This serves to identify, for example, different sites or varieties if the three-character category is for a single disease, or individual diseases if the three-character category is for a group of conditions. When the same fourth-character subdivisions apply to a range of three-character categories, they are listed only once, i.e., at the start of the range. A note at each of the relevant categories indicates where the details are to be found.

For Chapters XIII, 'Diseases of the Musculoskeletal System,' and XIX, 'Injury, Poisoning and Certain Other Consequences of External Causes,' supplementary subdivisions for use at the fifth or subsequent character level are proposed.

More Codes per Condition

With ICD-10, diagnostic statements can be coded in more detail using more than one code. The dagger–asterisk system is suitable for cases where a manifestation of a disease is a clinical problem in its own right and needs to be identified in addition to the underlying disease. The primary code is for the underlying disease and is marked with a dagger (†); an optional additional code for the manifestation is marked with an asterisk (*). Other multiple coding systems allow adding the infecting organism, functional activity of tumors, histopathological type of a tumor, or information about toxic agents and causal mechanisms.

Maintenance

Since the publication of ICD-10 in 1992, an updating mechanism allows yearly updates and major revisions every 3 years. Issues that arise in mortality and morbidity use of ICD are reported to WHO-FIC Collaborating Centres, or directly on an online platform. An international consensus process identifies solutions in consultation with classification and scientific experts and makes recommendations for updates to ICD-10.

Implementation

ICD-10 has been implemented in the majority of WHO Member States as the standard for coding diseases in mortality and/or morbidity (statistics, reimbursement, resource allocation, administration, treatment, and research), and ICD is in the process of being implemented in many other Member States. For example, the ICD is used in systematic full

mortality registration in more than 117 countries. However, implementation is not easily defined, because it gives no indication of the level of use of ICD-10 within the whole health sector. For example, a government might decide to implement ICD-10 for coding mortality; however, this represents only a fraction of the use of ICD-10 within a health system, and use in morbidity may relate only to pilot projects or specific diseases. If a country has fully implemented ICD-10 at a national level, this would mean that it has mandated the use of ICD-10 for coding mortality and morbidity across the whole health sector, as in the UK, South Africa, and many other countries. This means that all health care providers (or the appropriate allied personnel) will be required to code every death and every patient discharge, thus using ICD-10 for death registration, claims, and reimbursement purposes.

Modifications and Adaptations

Although some countries found ICD sufficient for clinical reporting, many others felt that it did not provide adequate detail for clinical and administrative uses. As a result, clinical modifications of ICD were developed, as was done for Australia (ICD-10-AM), Germany (ICD-10-GM), or Canada (ICD-10-CA). The USA uses a clinical modification based on ICD-9, the ICD-9-CM. It is used in several other countries that have adopted the US health sector reimbursement system. Recently, the process has been initiated to migrate to a more recent revision of ICD.

ICD and Foodborne Diseases (FBDs)

Traditionally, the term FBD was used for illnesses caused by microorganisms. However, in order to address the full scope of causative agents – of bacterial, viral, parasitic, or chemical nature – and acute and chronic health consequences, the term FBD is used now in a much more general, all-encompassing sense. It also includes foodborne zoonoses.

FBDs are commonly transmitted through ingested food. They comprise a broad group of illnesses caused by enteric pathogens, parasites, chemical contaminants, and biotoxins.

FBDs are an important cause of morbidity and mortality worldwide. They are most commonly associated with self-limiting diarrhea or vomiting. Foodborne contaminants can also contribute to a number of noncommunicable diseases, such as cancer and cardiovascular diseases; however, the contribution of unsafe food to these diseases is often not understood or quantified. Hundreds of different FBDs exist – some have been known for centuries, whereas others have only recently emerged. Standardization in reporting and coding is essential to learn more about the global burden and cost of unsafe food, and allocate adequate resources for FBD control efforts. To provide the necessary evidence base, WHO has started the initiative to estimate the global burden of FBDs.

ICD allows for coding FBDs. In some instances, there are specific categories; in other instances, foodborne conditions are grouped with conditions of other origin. For animal poisons and chemical contaminants, using two codes allows to specify the disease and the relevant group of substances.

The achievable detail in analysis and conclusion depends largely on the quality of reporting. Only fully formulated diagnoses allow correct coding and resulting conclusions, for example, Hepatitis or Hepatitis A.

When analyzing ICD-coded data for FBDs, aspects like attributable fractions, impact of rules for selection of the underlying cause of death, and health system-induced differences in frequencies of encounter or hospitalization need to be taken into account.

ICD has in Chapter I categories for intestinal infectious diseases (and poisoning by related toxins), like salmonellosis or cholera, as well as other FBDs like listeriosis, or hepatitis A, and parasites. The organ system-specific chapters include in many instances conditions that can be foodborne, as for ulcers, or toxic gastroenteritis and colitis. In such instances, the relevant substances (and intent) are identified by adding a code from Chapter XX. The Volume 3, Index to Diseases and Nature of Injury and the Table of Drugs and Chemicals will help the users in finding these conditions in the tabular list (provided in Volume 1). Categories for specific foodborne infections and parasitic diseases are provided in Chapter I and for food poisoning in Chapter XIX. For deaths from food poisoning, appropriate categories are provided in Chapter XX. A new notion of FBDs included lifestyle-related nutrition resulting in obesity and different metabolic syndromes. ICD has categories for such cases, although counting such cases in the group of FBDs is a matter of discussion in the upcoming years.

Examples

Conditions	*ICD-10*
Most infectious diseases	Chapter I
Other possible foodborne conditions	Chapters II–XVIII
Substance toxic effects (injury in general organ specific, as ulcers, are usually located in other chapters)	T36–T65 (Chapter XIX)
Substance toxic effects (intent, mechanism substance)	(Chapter XX)
Accidental (and unknown intent)	X40–X49
Intentional	X60–X69
Assault	X85–X90
Undetermined intent (after an inquiry has been conducted)	Y10–Y19

The table above gives a hint as to where the conditions and agents might be found in ICD. The table does neither indicate that all codes of a given range are relevant to food safety, nor is the list exhaustive. Relevant conditions need to be looked up individually, consulting first the index (in Volume 3) and then verifying the code in the tabular list (in Volume 1). Search terms could include, for example, poisoning and intoxication, or the specific disease, infectious agent or contaminant of interest. Particular attention needs to be given to ICD-10 rules related to coding of perinatal or maternal conditions.

ICD-11

ICD has a broad range of use cases and users. It needs to be suitable for use cases such as mortality, morbidity, case mix, quality, and patient safety, and for use in primary care, secondary

care, and research. Linkages to terminology systems like SNOMED CT® (Systematized Nomenclature of Medicine – Clinical Terms) and alignment and integration with other members of the WHO-FIC have been built into ensure that ICD is the gold standard for defining 'diseases and health conditions' and reporting them, and that ICD is the foundation for global health statistics and captures what health providers are seeing in practice and organizes the health information so that it can be shared – between practitioners, between countries, and over the above-mentioned time. ICD-11 therefore is designed as an information framework that contains a fully specified set of health-relevant concepts and their attributes and relationships. ICD-11 ensures consistency with traditional use cases of earlier ICD versions, because change history is integrated. The revision process toward ICD-11 started in 2007, to be ready for publication by 2015.

Timeline

- May 2011: Open ICD-11 Alpha to the public.
- May 2012: Open ICD-11 Beta to the public.
- May 2015: Present the ICD-11 to the World Health Assembly.

Most important innovation in this revision process is to make use of information technology to enable experts and stakeholders to work collaboratively on a 'Wikipedia-like' joint authoring platform. From the beta phase onward, the platform is open to public for providing their comments, submitting proposals, and taking part in field trials. To assure the quality of the input, however, the ICD-11 Platform differs from the Wikipedia, in that (1) the input is structured and demands scientific references and (2) it is peer reviewed.

New features of ICD-11 include:

1. Collaborative web-based editing.
2. Free access – as an international public good ICD-11 will be freely accessible.
3. Multiple languages – ICD-11 is already produced in multiple languages during the beta phase.
4. Definitions and detailed content – each disease will be operationally defined to avoid ambiguity.
5. Ready electronic health record – ICD-11 will conform to IT standards to link to terminologies and ontologies.

Daily edits to ICD-11 will be continuously made over the next 3 years, and will be made visible online simultaneously. All of the stakeholders that have a vested interest in the product should participate so that ICD best meets the needs of the users, and the classification is fit for purpose. With more input, the tool will better capture the advances in health sciences and give us a more accurate global picture of what is happening in the field of health and medicine.

In relation to FBDs, the information contained in ICD-10 will continue to exist. New ones may be added depending on the input and scientific evidence provided by the experts. Historical crosswalks are built into ICD-11. The possibility of continuity and comparison over time is implemented.

More details on ICD-11, videos, and access to the online browser, for viewing and participating to work on ICD-11 are available at www.who.int/classifications/icd/revision

Conclusion

ICD is the international standard for categorizing and reporting diseases, health-related conditions, and external causes of disease and injury. Use of ICD in food safety will allow compiling international statistics that are comparable internationally, with the ICD-coded data coming from sources, causes of death, or hospital statistics.

An essential prerequisite for every data collection is accurate reporting at the start of the information chain. The documentation should always include a fully specified diagnostic term, for example, hepatitis A or hepatitis E (and not just hepatitis). This allows for proper interpretation of the information and accurate categorization of the case.

ICD coding of FBDs requires some training. An ICD-10 self-learning course can be accessed online or downloaded for use on a local computer.

ICD is accessible online, which includes the ICD-10 and the ICD-11 (which is under development).

Online resources inform users on ways to contribute to the continuous improvement of ICD.

FOODBORNE DISEASES

Contents

Overview of Biological Hazards and Foodborne Diseases

ECD Todd, Ewen Todd Consulting LLC, Okemos, MI, USA

Glossary

Cysticercosis Infection caused by the tapeworm, *Taenia*; the infection occurs when the tapeworm larvae enter the body and form cysticerci: these resemble cysts whose walls are retracted in one place to form heads; each head has suckers and sometimes hooks. The cysticercus develops from an oncosphere in any organ (frequently in muscles, brain, and eye) of its intermediate host, such as swine and cattle. After entering the definitive human host, the cysticercus protrudes from the cyst and the larva is transformed into an adult worm.

Endemic disease A disease occurring within a particular area.

Enterotoxin A toxin produced by a microorganism specific for the cells of the intestinal mucosa and causing vomiting and/or diarrhea.

Epidemic Outbreak of disease that affects a much greater number of people than is usual for the locality or that spreads to regions where it is ordinarily not present.

Hemolytic-uremic syndrome A disorder that usually occurs when an infection, for example, from *Escherichia coli* O157H7, in the digestive system produces toxic substances that destroy red blood cells, causing kidney injury.

Immunocompromised Having a weakened or impaired immune system.

Mastitis Inflammation of an animal's udder, usually as a result of bacterial infection.

Oocyst A fertilized gamete of parasitic sporozoans that is enclosed in a thick wall resistant to the environment.

Pandemic Worldwide epidemic, a global disease outbreak.

Plasmapheresis A process in which blood taken from a patient is treated to extract the cells and corpuscles, which are then added to another fluid and returned to the patient's body.

Retinochoroiditis Inflammation of the retina and choroid (a brownish membrane between the retina and the white of the eye).

Septicemia Illness with toxicity due to invasion of the bloodstream by virulent bacteria coming from a local seat of infection (also known as blood poisoning).

Sequela A disease or disorder that is caused by a preceding disease or injury in the same individual.

Thrombotic thrombocytopenic purpura Blood disorder that causes blood clots to form in small blood vessels around the body, and leads to a low platelet counts; these clots composed of platelets can block blood flow to the brain, leading to bleeding under the skin forming purple-colored spots called purpura.

Toxicoinfection Type of foodborne illness that occurs due to ingestion of a bacterium that produces toxins within the gut, which are absorbed to produce gastrointestinal symptoms.

Zoonotic disease An infectious disease that can be transmitted from wild and domestic animals to humans.

Introduction

Foodborne diseases can be both acute and chronic, and stem from three sources: biological, chemical, and physical. Bacteria, viruses, and parasites, are the main biological hazards causing acute foodborne diseases. Certain biological toxins can also be considered as causing acute effects, such as most seafood toxins, and these are discussed separately in another overview on chemical hazards. Acute can be defined as an incubation period between ingestion and an adverse effect of a determined time, usually from hours up to months, resulting from a single exposure. The impact of these agents results in toxins absorbed by the gastrointestinal tract or in infections produced in the intestines, but can subsequently affect other parts of the body. The whole human population is exposed to these types of agents, but more frequently where there is poor sanitation and lack of temperature control of food, as it occurs in many parts of the developing world. In developing countries and city slums, exposure to such agents on a continual basis may result in chronic diarrhea, which can be fatal for infants and young children. Foodborne bacterial agents include the following: *Bacillus cereus*, *Campylobacter*, *Clostridium perfringens*; different types of pathogenic *Escherichia coli*, *Salmonella*, *Shigella*, *Staphylococcus aureus*; and various types of vibrios, especially *Vibrio cholerae* and *Vibrio parahaemolyticus.* Less well investigated are illnesses caused by enteric viruses, such as hepatitis A and E viruses, caliciviruses, for example, norovirus (NoV), rotavirus, and possibly adenoviruses and astroviruses. More than 70 species of protozoan and helminth parasites can affect humans who consume contaminated food and water; most of these infections occur because of poverty, limited available sanitation, and improper food storage and preparation habits. Those most often investigated include the protozoa: *Cryptosporidium*, *Cyclospora*, *Toxoplasma*, *Entamoeba*, and *Giardia* and helminths: *Clonorchis*, *Echinococcus*, *Fasciola*, *Opisthorchis*, *Paragonimus*, *Taenia*, and *Trichinella.* Diagnostic and detection methods are routinely available only for a few parasites in food and water, mainly those that occur in industrialized countries, for example, *Cryptosporidium*, *Giardia*, *Toxoplasma*, *Anisakis*, *Trichinella*, and *Taenia.*

Epidemics and Pandemics

The major etiological agents that account for the estimated 1.5 million gastrointestinal deaths each year are enterotoxigenic *E. coli* (ETEC), rotavirus, *V. cholerae*, and *Shigella* spp.; all are known to be endemic in the vast majority of developing countries. Whereas *V. cholerae*, *Shigella*, and rotavirus can be detected by standard assays, ETEC is more difficult to recognize, and therefore is often not appreciated as being a major cause of either infantile diarrhea or of cholera-like disease in all age groups. It also causes traveler's diarrhea in visitors to endemic areas. In fact, ETEC is the most important pathogen of these four pathogens for diarrhea in infants, children, and adults, accounting for 280 million episodes and more than 400 000 deaths annually.

In the historical past, long-lasting plagues and pandemics of infectious disease agents were regularly documented. The latest of these, the seventh cholera pandemic of *V. cholerae* O1, has been the most thoroughly investigated, and has been shown to be transmitted by many related strains through water and food. It began in 1961 in Indonesia, and by 1966, it had affected most of Asia. Cholera incidence then decreased slightly until 1971, when an upsurge was observed in Africa and Europe, which had been free of cholera for >100 years. Cholera rates remained relatively low during the 1980s, with the disease confined to Asia and Africa. However, two major cholera outbreaks appeared in the 1990s: first, a resurgence of cholera in Africa and second, outbreaks starting in Peru that became the first cholera epidemic in Latin America since 1895. The cholera epidemic in Latin America was originally suspected to have come from Asia through the discharge of contaminated ballast water into Peruvian ports, but the isolates from Latin America were closely related to isolates found in Africa in the 1970s and 1990s, indicating that the strain that caused the epidemic in Latin America came from Africa rather than Asia. In addition, a novel serotype, O139, caused major outbreaks on the Indian subcontinent in 1992, and was later shown to be a variant of the seventh pandemic clone; in fact, 9 of the 12 O139 strains actually arose from the O1 precursor strain and were present in seventh pandemic isolates as early as 1979. In 2005, 56 countries had officially notified World Health Organization (WHO) of cholera cases for a total of 131 943 cases and 2272 deaths. The actual number of cases is probably much higher because of poor surveillance systems and frequent underreporting. Food, as well as water, is frequently implicated in the transmission of cholera, and the reporting of cholera resulted in trade embargoes and lost tourism income in many affected countries. Fecally contaminated water may be the main source but increasingly foods have been implicated. Foods are likely to be fecally contaminated during preparation, particularly those associated with water such as fish and shellfish or handled by infected food workers in an unhygienic environment. WHO estimates that the officially reported cases represent only approximately 5–10% of actual cases worldwide. Many of the *V. cholerae* groups/genotypes spread easily and widely to multiple countries or regions. This finding suggests that cholera epidemics or upsurges, which often occurred at the same time in many countries, are caused by the spread of newly arisen genotypes. Additionally, a genotype can also persist for long periods in an endemic region, as was demonstrated in Southeast Asia and Africa. Detailed analysis of how specific diseases are spread may be useful to monitor and control future potential pandemics.

The Burden of Foodborne Disease

With today's improvement in standards of personal hygiene and basic sanitation, safe water supplies, effective vaccination programs, food control infrastructure, and the wide application of newer food processing technologies and hazard analysis and critical control point (HACCP), many foodborne and waterborne diseases (e.g., poliomyelitis, brucellosis, cholera, scarlet fever, typhoid, and paratyphoid fevers) have been either eliminated or considerably reduced in industrialized countries. Nevertheless, most countries experienced important increases in several other foodborne diseases.

Zoonoses are particularly difficult to eradicate or even control because of an ever-present reservoir; these include both domestic and wild animal populations. In most developing countries, foodborne and waterborne zoonotic diseases have been so poorly investigated that even the crude burden of illness cannot be estimated with any degree of certainty. Although the situation regarding foodborne diseases is most serious in developing countries, industrialized countries have experienced a succession of well-publicized outbreaks, which have led to better estimates of foodborne disease cases in recent years. The annual estimates are 2.37 million cases of foodborne gastroenteritis in the UK, 5.4 million cases in Australia, and 11–13 million in Canada. The equivalent number for the USA (48 million; range 28.7–71.1 million in 2011) indicates there is considerable uncertainty in determining such estimates. The above data indicate that from 1 in 3 to 1 in 26 are ill from foodborne disease every year.

Bacteria

B. cereus

Bacillus cereus causes two types of mild foodborne illnesses. The emetic type is characterized mostly by nausea and vomiting and some abdominal cramps occurring 1–6 h after ingesting the food containing a heat-stable emetic toxin, similar in effect to staphylococcal food poisoning but typically milder. The other type is the diarrheal form which causes abdominal cramps and diarrhea after an incubation period of 8–16 h; the effect is similar to *Clostridium perfringens* toxicoinfections. This type produces a heat-labile diarrheagenic enterotoxin and/or a hemolytic enterotoxin, which cause intestinal fluid secretion. The symptoms of those experiencing either type of illness typically resolve themselves within 24 h. *Bacillus cereus* is commonly found in soil, crops, and dust, and therefore spores are frequently present in many foods. However, the spores themselves can be ingested without adverse effects; it requires their germination and toxin production in food to cause the above-mentioned symptoms. The emetic type is most often associated with rice dishes that have been cooked and then held at warm temperatures for several hours, such as fried rice. The diarrheal form is more associated with vegetable dishes or puddings containing cereal products that have been cooked and stored. However, both types of *Bacillus* spores may be present in the same food (or one strain can produce both types of toxin), and a mixture of incubation periods and symptoms may occur, and less typical foods like cooked poultry dishes may also be vehicles. Spices may be overlooked as a source of spores. Generally, illnesses from *B. cereus* (and other *Bacillus* species) are overlooked and rarely reported and they may be much more frequent than currently documented. Thus, there may be foods that may be important vehicles for which there is no record. Since most recognized cases have been confined to developed countries, the extent of *B. cereus* intoxications in much of the world remains unknown.

Campylobacter

Campylobacter jejuni is a major cause of bacterial diarrheal illness in the USA and in many other countries, with an estimated 845 000 foodborne cases per year in the USA alone, third in the number of estimated bacterial foodborne disease cases after *Salmonella* and *Clostridium perfringens*. Part of the reason for the high numbers is the low infective dose. However, this foodborne illness occurs mainly as sporadic cases and not as common-source outbreaks. Most cases of diarrhea, vomiting, fever, and abdominal cramping usually appear within 2–5 days of exposure and resolve within days, but one sequela of concern is Guillain–Barré syndrome (GBS) which is discussed under Section Autoimmune Sequelae to Gastrointestinal Infections, *Campylobacter* grows optimally at 42 °C under low oxygen concentrations, such as would be found in the intestines of warm-blooded birds and mammals. Thus, one of the most frequent sources of *Campylobacter* for consumers is raw meat and poultry, particularly the latter. A large proportion of chicken and turkey carcasses entering the kitchen contain this pathogen in higher numbers than *Salmonella*. Most *Campylobacter* organisms originate in poultry flocks. For instance, an European Union (EU) study shows it is approximately 30 times more likely that a *Campylobacter*-colonized broiler flock will yield positive carcasses for *Campylobacter*, compared with a noncolonized flock. Risks for contamination increase with the age of the slaughtered broilers and time of year. The handling, preparation, and consumption of broiler meat may directly account for 20–30% of human cases of campylobacteriosis in the EU. Outbreaks are not only associated with poultry but also with unpasteurized milk, cheese made from unpasteurized milk, undercooked beef, pork, lamb, shellfish, lettuce, and water, with many of these infections caused by cross-contamination in the kitchen, for example, from raw poultry to cooked poultry or salads or other ready-to-eat foods. Poultry growers have yet to significantly reduce infections in chicks because of their close contact and access to fecally contaminated drinking water. Thorough cooking of raw meats and poultry, avoidance of preparation practices that encourage cross-contamination, and proper hand washing will all reduce the risk of consumer infections.

Clostridium botulinum

Clostridium botulinum is a Gram-positive, rod-shaped anaerobic spore-former that produces oval endospores commonly found in soil, and marine, brackish, and freshwater sediments. Most spores are sufficiently heat resistant that the canning industry stipulated many decades ago that commercial canning for low-acid canned foods (e.g., foods having a pH >4.6) must be subjected to a 12-D log reduction heating step to ensure there are no surviving spores that could germinate and outgrow to flourish in the anaerobic environment. Although fairly frequent in the past, outbreaks involving commercial canned products (cans/tins and jars) are rare today. However, as recently as in 2007, eight cases of botulism were reported in US residents who had eaten commercially prepared hot dog chili sauce. In this outbreak, the spores apparently survived the retorting process through a processing failure. However, it is not the spores or organism themselves that are the concern but the neurotoxin(s) which are produced and ingested with the food. Seven different toxins (A–G) can be produced but

the most common affecting humans are A, B, and E. On ingestion the toxins can manifest themselves in several different types of symptoms from diarrhea to constipation, but the main effect is flaccid muscular paralysis that can cause respiratory failure, and eventual death. Some specific symptoms are double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, or muscle weakness. Symptoms generally begin 18–36 h after eating a contaminated food, but they can occur as early as 6 h or as late as 10 days. If untreated, the whole body may become paralyzed affecting the face, arms, breathing muscles, trunk, back, and legs. All Type A and some Type B strains are proteolytic with the food often spoiling with strong odors making it less likely to be consumed; whereas some Type B and all Type E strains are nonproteolytic and will not spoil the food. Infant botulism is an unusual syndrome affecting only very young children suspected of eating honey or other sweeteners, but the source of spores in such illnesses is rarely determined. Spores present in the low-oxygen, low-acid digestive system of an infant can outgrow and produce toxins. As soon as infants begin eating solid food, there are changes to the microbial flora of the bowel that start to inhibit growth of the bacterium. Types A and B *Clostridium botulinum* are frequently found in soil samples in North America and other continents. Type E is much more likely to be found in marine or estuarine sediments, fish, and marine mammal intestines. In Alaska, Arctic Canada, and northern Russia, the Eskimo/Inuit have traditional 'fermented' seal or whale fins or other parts stored outdoors with blubber. Improper storage conditions may allow spores that are frequently present to germinate and outgrow in the partly anaerobic environment. Although outbreaks are relatively few today, foodborne botulism remains a serious threat and may be caused by products distributed internationally. In Finland, botulism is rare and most domestic cases have been associated with fish products caused by *Clostridium botulinum* Type E toxin. In 2009, two cases of foodborne botulism were detected among French tourists who purchased fish from Finland, which was stored inappropriately and consumed after having returned home. In 2006, two persons in Finland were diagnosed with botulism after having eaten vacuum-packed smoked whitefish. Previously in Italy, conserved olives have also been implicated as a vehicle for foodborne botulism. There were three outbreaks in three different countries in Europe in 2011, all in a similar time frame (September–November). The foods involved were korma sauce (curry with yogurt, onions, and ground almonds, spices, and nuts); olive tapenades (chopped olives, capers, anchovies, and olive oil); and olives stuffed with almonds, all in glass jars. Improper processing was determined as the likely cause in two of these outbreaks. Fewer serious cases and deaths are now reported, perhaps due to better education in food preparation, more rapid medical care with antitoxin readily available for cases, and a younger generation with more Western food tastes and avoiding such foods that are an acquired taste. In North America, some British Columbian and Alaskan tribes still prepare 'fermented' salmon eggs ('stink eggs'), which have the same risks but few outbreaks have been recorded recently. Type E strains have also been associated with partially preserved uneviscerated fish with a few recorded outbreaks mainly in consumers of Middle Eastern origin. The risk for most consumers, however, is not exotic foods but home-canned vegetables, where the pressure cooking has not been sufficient to destroy the spores. Botulism is also occasionally associated with certain strains of *Clostridium baratii*, *Clostridium butyricum*, and *Clostridium novyi*.

Clostridium perfringens

Clostridium perfringens (formerly known as *Clostridium welchii*) is a Gram-positive, rod-shaped, anaerobic, spore-forming bacterium found as a normal component of soil, decaying vegetation, marine sediment, and the intestinal tract of animals including humans. Thus, it is present in areas subject to human or animal fecal pollution, and has sometimes been used as an indicator of fecal contamination of water and food facilities. Type A *Clostridium perfringens* is a frequent cause of foodborne illness in many countries, including the UK and the USA. It is the second most frequent cause of bacterial foodborne outbreaks in recent estimates for the USA. This strain possesses a chromosomal enterotoxin (*cpe*) gene and vegetative cells are relatively heat-resistant compared with other *Clostridium perfringens* strains. Symptoms of abdominal cramps and diarrhea begin 8–22 h after consumption of foods containing large numbers ($>10^8$) of vegetative *Clostridium perfringens* cells capable of producing an enterotoxin, during sporulation in the gut. This is a type of a toxicoinfection. *Clostridium perfringens*-associated illness is normally mild with a duration of <24 h but some symptoms may persist occasionally for 1 or 2 weeks, and deaths only rarely occur as a result of dehydration and other complications in elderly persons. Most illnesses occur after cooked soups or stews have been left too long at ambient temperatures or in too large quantities in coolers that would allow spores naturally present to germinate and produce vegetative cells. The cooking stimulates spore germination and once the temperature has dropped below 50 °C, the vegetative cells can multiply rapidly, growing to large numbers, especially in high protein foods. Because *Clostridium perfringens* can double in number every 7–10 min under optimal temperature (43–45 °C) and nutrient conditions after spore germination, even low numbers of spores can increase to illness-causing levels in a few hours. Thus, outbreaks are most frequently associated with catering companies and others who prepare and then improperly store large quantities of food; social events at churches or large family gatherings are also occasions where meat or poultry dishes may become vehicles for growth of the pathogen. If such stews, soups, gravies, roasts, and other meat or poultry products are served hot or are rapidly cooled before reheating and serving, the risk of *Clostridium perfringens* food poisoning is much reduced.

A more serious but rare illness, however, is caused by ingesting food contaminated with large numbers of Type C *Clostridium perfringens* strains, resulting in infection and necrosis of the intestines and subsequent septicemia. This illness is known as enteritis necroticans or pigbel disease in developing countries, particularly Papua New Guinea, but was also documented in post-Second World War Germany (where it was called Darmbrand). The main reason for the development of the disease is protein deprivation because of

starvation, episodic meat feasting (mainly pork), and staple diets containing trypsin inhibitors, such as sweet potatoes, combined with poor food hygiene. The enterotoxin is normally destroyed by trypsin protease, but production of this enzyme is inhibited if there is lack of protein synthesis. Consumption of spores alone has typically no adverse consequences for foodborne illness. However, *Clostridium perfringens* and other Clostridia can also cause gas gangrene in damaged tissue without medical aid, such as which occurs during military conflicts where spores from the soil can be trapped deep into body tissue where partially anaerobic conditions are present. If the pathogen can multiply in the tissue, it can spread rapidly to other parts of the damaged limb, and cause a systemic infection resulting in death. Interestingly, one reason for embalming dead bodies is to prevent the action of *Clostridium perfringens* from producing tissue gas, resulting from spores germinating and outgrowing into the increasingly anaerobic conditions of the corpse. Strangely, *Clostridium perfringens* has an apparent beneficial use. It is believed to be one of the starter culture components used as the leavening agent in artisanal salt-rising bread. This bread is rarely made today but has been reported to be made in Scotland and Ireland and by immigrants to Canada and the USA centuries ago. Salt-rising bread is different from other breads because yeast does not play any part in the fermentation process. It is thought that the salt used in the starter suppresses any yeast growth and provides an environment to allow naturally present *Clostridium perfringens* and other microorganisms to produce gas and a flavor different from that produced by yeast and lactobacilli (or baking soda). However, the ferment has not been scientifically investigated to understand its beneficial qualities.

Other clostridia apart from *Clostridium botulinum* may occasionally be implicated in foodborne illness but the one of current interest is *Clostridium difficile*, most commonly linked to hospital-acquired infections. These can be chronic and life threatening in humans and hard to eliminate from already-ill patients. *Clostridium difficile* is recognized as both a gut colonizer and cause of diarrhea in food animals, including cattle and poultry. *Clostridium difficile* epidemic infections also occur in piglets. Because *Clostridium difficile* has been isolated from retail foods intended for human consumption in the USA, Canada, and Europe and from meat products intended for consumption by pets, this may be a future concern for contamination of the food supply. At present, there are no analytical methods for testing foods for this pathogen, but these and standards may eventually have to be established to reduce the risk of infections though foods.

E. coli O157:H7 and Other Pathogenic *E. coli*

Escherichia coli O157:H7 was first recognized as a pathogen in 1982 as a result of an outbreak involving hamburgers in two US states. The organism was found to produce a toxin that is capable of damaging the kidneys (hemolytic-uremic syndrome (HUS)) and affecting the central nervous system (CNS) (thrombotic thrombocytopenic purpura (TTP)), often preceded by bloody diarrhea (hemorrhagic colitis (HC)). The toxin has been called both a verocytotoxin (affecting the vero kidney cells of the green monkey) and a Shiga-like toxin (similar to a toxin produced by *Shigella*). In fact, there are a number of similar toxins that make up the verotoxin/Shiga toxin category. This division of nomenclature remains today with both terms verotoxin-producing *E. coli* (VTEC) and Shiga toxin-producing *E. coli* (STEC) being used to describe the same group of organisms. Other virulence factors that may be necessary for severe infections are an attaching and effacing protein (adhesin/intimin) and a hemolysin. An earlier outbreak in Canada with one death in 1980 was likely caused by the same organism after apple cider (unfermented squeezed apple juice) was consumed at a farmer's market. Verotoxin was found in the intestines of the dead youth but VTEC were not successfully isolated. Outbreaks from apple cider have since been occasionally reported in Canada and the USA. In fact, outbreaks of *E. coli* O157:H7 and similar organisms producing verotoxin/Shiga toxin have occurred in many countries outside North America including Australia, Japan, the UK, and many other European countries. It is interesting that the more northerly countries seem to have the higher case rates, for example, Canada, Scotland, and Scandinavian countries. This may relate to farm practices for cattle and sheep that are the main reservoirs for the pathogen. Supershedders (animals that excrete large numbers of the pathogen in their feces) may be a major transmission factor in the field or feedlot and during and after transportation to the slaughterhouse.

In 1993, a major outbreak of *E. coli* O157:H7 infection affected approximately 500 people in four northwestern US states. Many children developed HUS, and four died as a result. This episode forced the US government to declare that *E. coli* O157:H7 was an adulterant in ground beef (and later in nonintact beef). Another large outbreak caused by this pathogen occurred in Africa in 1992, affecting probably thousands of people, with an undocumented number of cases of HUS; drinking water and cooked maize were the identified vehicles of transmission. In 1996, in an outbreak of *E. coli* O157:H7 in Japan, 6309 schoolchildren and 92 school staff members were affected, with two deaths; the epidemiological investigation identified fresh radish sprouts (kaiware-daikon) as the probable cause. This was the largest outbreak ever recorded from this pathogen. However, subsequently two very large and well-publicized outbreaks occurred in Scotland in 1996–97 (400 ill with 20 deaths of elderly persons) and Wales in 2005 (>170 schoolchildren and others, and 1 child died). Both were caused by butchers who managed catering businesses and also worked with slaughtered animals. The outbreaks were traced to contaminated meat dishes that were delivered to residences and schools. Another well-published outbreak originated from Californian bagged fresh spinach in 2006, with 205 confirmed cases of illness and 3 deaths. The ultimate source was not determined but upstream cattle, feral pigs, and irrigation water may have been involved in field contamination, and the washing and disinfection processes for the spinach were insufficient to prevent *E. coli* O157:H7 from entering the bags. This was one of the three leafy green outbreaks caused by *E. coli* and other pathogens in 2006 involving leafy greens, mainly lettuce, over the previous decade. The leafy greens industry is assessing how to minimize risks to avoid similar problems. Other outbreaks have been linked to

contaminated unpasteurized milk, alfalfa sprouts, salami, recreational water, and contact with infected live animals.

VTEC/STEC that are not of the O157:H7 serotype also pose a risk to human health. Several of these have caused outbreaks (O26, O103, O104, O111 O126, O145, and O157:NM), whereas many more have been reported as causes of sporadic illness. In Europe, infections by non-O157 VTEC/STEC, caused by 37 different O serogroups, are more common than those by O157:H7 strains. In the USA, though outbreaks associated with STEC of serotypes other than O157:H7 are rare, they account for approximately 30% of STEC illness reported to the Centers for Disease Control and Prevention. In 2011, the US Department of Agriculture announced that an additional six serotypes of STEC (O26, O45, O103, O111, O121, and O145) would be considered to be adulterants in nonintact raw beef products. Once implemented, it is likely that decision will have an impact on the meat and other food industries, with the potential for increasing the number of recalls. Industry is concerned that testing for more pathogens that may be controlled by the same means as for *E. coli* O157 may be an unnecessary burden.

Apart from VTEC/STEC, there are other enteric *E. coli* pathogens that have been implicated in foodborne outbreaks traced to fecally contaminated food or water, and also through person-to-person contact. These *E. coli* strains have been classified into four major groups based on their virulence mechanisms: ETEC; enteropathogenic *E. coli* (EPEC); enteroinvasive *E. coli* (EIEC); and enteroaggregative *E. coli* (EAEC). Though considered less significant than VTEC/STEC in the developed world, these pathogens are a major cause of infant mortality in regions with poor sanitation and untreated water supply. ETEC is a frequent cause of traveler's diarrhea in people from industrialized nations during visits to developing countries. Infected infants and children in developing countries suffer from dehydrating diarrhea and create a reservoir of the pathogen in these communities. Both heat-labile and heat-stable enterotoxins are produced when these organisms proliferate in the small intestine to induce watery diarrhea similar to cholera. EPEC and EIEC are most common among young children in the developing world. EIEC is very similar to *Shigella* and has a low infectious dose; infections are endemic in developing countries. EAEC is increasingly recognized as a cause of persistent diarrhea in children and adults in developing countries and is also a cause of chronic diarrhea among immunocompromised persons, such as those infected with the human immunodeficiency virus (HIV). Typically, EAEC strains originate only from human sources. However, an EAEC strain of the serotype O104:H4, possessing the genes for a verotoxin, was responsible for an outbreak in Germany in 2011 that involved approximately 4000 cases of illness and caused 50 deaths. This indicates that pathogenic *E. coli* strains have the ability to exchange genetic material between pathogens from different sources, a concern for future prevention and control measures.

A widespread related opportunistic pathogen, *Cronobacter* (formerly *Enterobacter*) *sakazakii* can cause bacteremia, meningitis, and necrotizing enterocolitis. The main concern is for infants consuming powdered infant formula with some strains able to survive in a desiccated state for more than 2 years.

Listeria monocytogenes

Surveillance of listeriosis has until recently been restricted to developed countries, with most incidence rates by country ranging from 0.3 to 0.5 per 100 000, irrespective of the regulatory system and industry control programs that have been in place. *Listeria monocytogenes* can no longer be called an emerging pathogen as foodborne outbreaks have been documented since 1981, and we already know much about the pathogen and its means of transmission. The incubation period may range from a few days to 2 months before flu-like symptoms progressing to more serious conditions such as meningitis and stillbirths, and usually those infected are hospitalized. Those who are highly immunocompromised are at greatest risk of infection and death, for example, the elderly, fetuses, acquired immunodeficiency syndrome (AIDS), and organ transplant patients. Ready-to-eat foods, such as meat, poultry, and dairy products, are the main vehicles documented in outbreak investigations, particularly deli meats and soft cheeses. These products have been most frequently implicated, but other foods including fresh-cut fruits and vegetables may also be transmission vehicles. Large outbreaks have mostly occurred through consumption of deli meats as cold cuts or in sandwiches, and linked to errors in food-processing plants, such as lack of proper sanitation of contaminated slicing machines, followed by opportunities for growth of the pathogen. Because the organism can grow at cold temperatures and can persist in damp environments, home refrigerators may be both reservoirs for cross-contamination and incubators for the slow growth of the pathogen. Because *Listeria* is ubiquitous in the environment, it is understandable that infrequently sanitized refrigerators can be continual sources of contamination if the opportunities for cross-contamination arise. One major concern in the USA is the illegal sale of raw-milk Hispanic cheeses which may contain several pathogens including *Salmonella*, *Brucella*, and *Mycobacterium*, as well as *Listeria*. In addition to outbreak investigations, case–control studies, risk assessments, food attribution studies, and expert elicitation, can help focus on areas of greatest risk for prevention and control measures throughout the food chain. Many governments have strict control policies for this organism in food because of its high mortality rate, with either a tolerance of no more than 100 cfu g^{-1} or no detection at all in the sample taken (usually 25 g). Recalls are relatively common for ready-to-eat food, especially if the zero tolerance policy is in place. Food processors are encouraged to determine if their foods permit the growth of the pathogen or not, and if so limit the opportunities for its growth by adding organic acids, freezing, or destroy any surviving organisms through postpackaging pasteurization. Despite industry awareness and government regulations and controls, the USA has not managed to achieve the Healthy People 2010 goal of 0.25 cases per 100 000 population (this was 0.34 in 2009), and outbreaks continue to occur. In the USA, food processors are encouraged to determine if their foods permit the growth of the pathogen or not, and if so limit the opportunities for its growth by adding organic acids, freezing, or destroy any surviving organisms through postpackaging pasteurization including high pressure. This was not the policy in Canada in 2008, when a large outbreak in Canada resulted in 58 cases and 22 deaths

(38% mortality rate), mainly affecting elderly persons after they ate commercially packaged deli meats. The cause was both improperly cleaned and sanitized large commercial slicing machines that had been contaminated over a period of time, and also poor oversight by the Canadian Food Inspection Agency, the Public Health Agency of Canada, and Health Canada, indicted in a special investigative report by the Government of Canada. Serious illnesses and death from listeriosis continue to be reported. In 2010, chopped celery was the source of a *Listeria* outbreak among 10 Texas residents, 5 of whom died. The 2011 Colorado cantaloupe outbreak with 30 deaths led to a congressional investigation that indicated that condensation from cooling systems drained directly onto the floor; poor drainage resulted in water pooling around the food processing equipment; inappropriate food processing equipment was difficult to clean; no antimicrobial solution was used to wash the cantaloupes; and there was no means to remove field heat from the cantaloupes before they were placed into cold storage. Another issue was that third-party auditors did not identify any major problems in the previous months. However, most risks involving *L. monocytogenes* of ready-to-eat food, particularly deli meats occur more at retail than at processing; the exposed public is likely to be much less and some small outbreaks may not be detected.

Mycobacterium avium Subspecies *paratuberculosis* (MAP)

Johne's disease, or paratuberculosis, is a chronic intestinal infection in ruminant animals believed to be caused by MAP. The usually fatal and slowly developing infectious disease is characterized by chronic intestinal inflammation, reduction of milk yield, wasting syndrome with loss of weight, muscle atrophy, fatigue, and weakness (cachexia), and in some species diarrhea, after a long preclinical phase. Treatment is ineffective and economically impracticable, which forces the farmer to cull these animals prematurely. Detection methods include serological testing, and culture followed by molecular typing of the isolated strains. The infection primarily affects domestic and free-ranging ruminants (cattle, sheep, goats, deer, elk, and bison), but has also been reported in primates, rabbits, stoats, foxes and other nonruminant wildlife. Wildlife reservoirs contribute to the persistence and spread of infection, which is widespread in domestic animals in Europe, North America, Australia, and other parts of the world. Because the pathogen can also exist subclinically in these animals for years without necessarily causing clinical disease, not only is the disease underreported but also these animals represent a reservoir for other animals as well. For instance, bovine herd prevalence has been reported from 7% to 55% in Europe and 9–22% in Australian dairy cattle. In the USA, 34% of lymph nodes and 80% of hide coats of culled beef and dairy cattle were positive for MAP as detected by polymerase chain reaction, but the rate was under 1% in the final processed carcasses. However, true animal prevalence is difficult to compare across studies as only a very few of them adjusted prevalence for factors such as test sensitivity and specificity. Even if animals do not die, there is economic loss because of premature culling and increased veterinary costs. Subclinically infected cows secrete *M. paratuberculosis* in their milk. MAP may also enter the milk by fecal contamination in the milking parlor, and one of the concerns is that it may survive commercial pasteurization as it is more thermotolerant than *Mycobacterium bovis*. It has been cultured from 2% to 3% of retail pasteurized milk units in the UK and the USA, and in the Czech Republic, it has been found in raw milk from fecal culture-positive cows (10–20% of animals), and 1.6% of commercially pasteurized retail milk. Because the population is exposed to this pathogen through the consumption of milk and meat from infected animals, it has been postulated that this organism may be a cause of, or at least a contributor to, Crohn's disease, a chronic inflammatory condition of the human intestine. Other possible routes of human exposure to MAP are dairy products, infant formula, vegetables, fruits, and contaminated water supplies. However, presently, the role of MAP in Crohn's disease is still debated and there is no consensus within the scientific community. Nevertheless, *M. paratuberculosis* is a pathogen of concern, with subclinically infected dairy cows being a major source of the pathogen. The fact that the milk containing MAP has been pasteurized to the required national and EU standards means that humans are likely being exposed to low levels of this chronic enteric pathogen on a regular basis.

Salmonella

The family Enterobacteriaceae, including the closely related genera *Cronobacter*, *Escherichia*, *Salmonella*, *Shigella*, and *Yersinia*, is responsible for most foodborne illnesses. Of these, *Salmonella* is the most widespread in the environment with over 2800 serovars now recognized. The ones most frequently associated with foodborne outbreaks are *Salmonella enterica* subspecies *enterica* with serovars such as Enteritidis, Montevideo, and Typhimurium (typically written *Salmonella* Enteritidis, etc.). In countries where enteric notifiable diseases and foodborne disease outbreak surveillance statistics are recorded, salmonellosis typically ranks first or second in terms of outbreaks and case numbers in most countries. In the USA, there are estimated 644 786–1 679 667 foodborne cases each year and 378 deaths. Symptoms of salmonellosis are typically moderate with gastroenteritis lasting several days, but sequelae can follow an infection, and *Salmonella* is the largest cause of foodborne disease-related deaths in the USA. Part of this is because the pathogen can persist in different environmental niches that range from wet to very dry and in highly nutritious foods to powders. A wide range of foods, including raw meats, poultry, eggs, milk and dairy products, fish, shrimp, frog legs, tomatoes, cantaloupes, leafy greens, yeast, coconut, sauces and salad dressings, cake mixes, cream-filled desserts and toppings, dried gelatin, peanut butter, cocoa, chocolate, tahini, and other foods have been identified as being contaminated with *Salmonella* spp., and, subsequently, serving as vehicles for the transmission of this pathogen in outbreaks. Where the organism is protected from stomach acids, such as in cheese, chocolate, or hamburger, the infectious dose can be quite low (1–100 cfu). As a result of industrialization, large-scale centralized production, and an increasing export market, large outbreaks have been reported. Recent examples of large outbreaks in the USA and Canada include *Sa.* Enteritidis in mung beans in 2005 (648 cases);

Salmonella Tennessee in peanut butter in 2006 (>600, two deaths); *Salmonella* I 4,[5],12:i:– (no serovar name) in pot pies in 2007 (425 cases); *Salmonella* Saintpaul in tomatoes/peppers in 2008 (1438 cases); *Salmonella* Typhimurium in peanut butter and peanut butter products (>3900 were recalled) in 2008–09 (691 cases, 9 deaths); *Salmonella* Montevideo in meat with pepper in 2009–10 (272 cases); and *Sa*. Enteritidis in shell eggs in 2010 (1500 cases and 550 million eggs recalled).

Eggs were also a key vehicle for *Salmonella* outbreaks in Europe, both as the main ingredient and in buffets and inadequately heated bakery items, as well as through contaminated pork products. Some of these were reported from only one country, as 225 cases (62 hospitalized) of *Sa*. Typhimurium from hard cheese in the Netherlands in 2007; 42 cases of *Salmonella* Kedougou from infant formula in Spain; and 53 cases of *Salmonella* 4, 12:i from dried pork sausage in France in 2008. However, in the EU community food items are regularly shipped across borders, and multinational outbreaks are also frequent. From 2001 to 2005, four outbreaks of salmonellosis (*Salmonella* Newport and *Sa*. Typhimurium) in the UK were traced to lettuce but the source of contamination was never conclusively identified because of the complex distribution system. In Finland, in 2005, however, 60 *Sa*. Typhimurium cases were linked to lettuce from a supplier in Spain. An outbreak occurred from chocolate in 2001–02 with 439 cases, not only in Germany but also in 6 other countries; *Salmonella* Oranienberg was found in 5% of 381 chocolates tested at levels of 1.1–2.8 MPN g^{-P}. In 2005, the largest outbreak documented in Spain occurred when precooked chicken contaminated with *Salmonella* Hadar infected 2883 persons; residents in four other EU countries were also affected. In 2007, 55 persons in England/Wales and a further 19 in 5 other countries were infected with *Salmonella* Senftenberg from fresh basil imported from Israel. Also, in 2007, a *Salmonella* Weltevreden outbreak was documented involving 45 persons in Norway, Denmark, and Finland from alfalfa seeds originating in the Netherlands and possibly Italy. In 2008, an outbreak occurred in Norway, Sweden, and Denmark with 37 cases and 4 deaths from *Sa*. Typhimurium in raw Danish pork products. Also in 2008, a similar *Sa*. Typhimurium outbreak, but involving two separate strains, occurred in Switzerland where approximately 150 persons were affected after eating pork, typically barbecued. One strain was more associated with cases from Denmark and France than with Switzerland based on molecular typing, thus indicating that the strain isolated from pork samples was not persistent in the factory but was introduced by pork imported from other European countries. Today, with the use of more sophisticated molecular strain identification systems, it is now possible to link human and food isolates across different countries. This has been facilitated through PulseNet using pulsed-field gel electrophoresis (PFGE) patterns shared on the Web.

In many *Salmonella* outbreaks multiple strains may be present, but typically only the dominant strain is recorded in most reports. An example of this occurred in September 2001, where an outbreak in Australia from imported peanuts resulted in a wider investigation in Canada, England/Wales, and Scotland. Patients infected with *Salmonella* serotypes known to be isolated from peanuts and reported to surveillance systems were interviewed to determine exposure histories, and PFGE patterns of *Salmonella* isolates were shared electronically among laboratories. From this there were 97 cases of *Salmonella* Stanley and 12 cases of *Sa*. Newport infection; one family in Canada had separate members infected with *Sa*. Stanley, *Sa*. Newport, and *Salmonella* Kottbus. Mainly persons of Asian ethnicity were affected: 66% of patients in Australia, 90% in England/Wales and Scotland, and 79% in Canada. This was because dry-flavored Asian-style peanuts were typically consumed by persons of Asian origin. Laboratories isolated *Sa*. Stanley, *Sa*. Newport, *Sa*. Kottbus, *Salmonella* Lexington, and *Salmonella* Unnamed from Brand X peanuts, and isolates of *Sa*. Stanley from peanuts and human patients were indistinguishable by PFGE. The concentration of *Salmonella* was generally very low, ranging from <0.03 to 2 MPN g^{-1} of peanuts in the shell. This international outbreak was detected because of rapid sharing of electronic deoxyribonucleic acid PFGE images.

Despite government vigilance and industry prevention and control procedures, *Salmonella* outbreaks remain a major issue for all countries, and with global trade, a wide variety of serovars exist to contaminate many different types of foods to cause illnesses all around the world. It is heartening to discover, however, that adherence to HACCP principles, at least in the US broiler industry, is now linked to fewer salmonellosis cases.

Shigella

There are four *Shigella* species that can be transmitted by food (as well as by water): *Shigella dysenteriae*, *Shigella sonnei*, *Shigella flexneri*, and *Shigella boydii*. *Shigella dysenteriae* Type 1 is primarily associated with serious life-threatening dysentery in epidemics (fatality rate 5–15%), and is mostly encountered in developing countries. A major virulence factor produced by *Sh. dysenteriae* is Shiga toxin (Stx), similar to the Shiga-like toxins produced by STEC/VTEC. *Shigella flexneri* predominates in areas of endemic infection, mainly in developing countries. More outbreaks of *Sh. boydii* occur in Central and South America than elsewhere. *Shigella sonnei* has been implicated in more foodborne outbreaks in developed countries than any other species. Outbreaks have been most often associated with food, water, and child care centers. However, most cases are sporadic and of unknown origin; in the USA, sporadic shigellosis is most likely to occur among young children and Hispanics. Common exposures include international travel and contact with ill persons or child care. Based on the many outbreaks identified, drinking untreated water, or recreational exposure to water, and eating ready-to-eat vegetables washed with untreated water remain important sources for the pathogen; more than one-third of US shigellosis cases could be foodborne. *Shigella* has been isolated a wide range of foods including potato salad, ground beef, bean dip, raw oysters, fish, and raw vegetables. Ready-to-eat foods are most commonly contaminated with *Shigella* by an infected food handler who practices poor personal hygiene, or products harvested from sewage-polluted areas. *Shigella* is salt tolerant, and can survive in many types of ready-to-eat foods including fruits and vegetables, and those subject to modified atmosphere or

vacuum packaging. Cold temperature storage increases their chances for survival. Outbreaks have implicated the following foods as vehicles: tossed salad, potato salad, tofu salad, pasta salad, bean salad, bean dip, shredded and iceberg lettuce, parsley, watermelon, fresh pasteurized milk, cheese, and oysters, mostly caused by *Sh. sonnei*. In one *Sh. sonnei* lettuce outbreak in Texas in 1986, an infected food worker at a lettuce-shredding facility likely infected 347 persons across two counties. In 1988, 240 passengers and also flight crew on 13 national and international flights originating in Minneapolis were infected with *Sh. sonnei* after eating cold items prepared by an airline flight catering kitchen. In 2005, in Bangkok, Thailand, 103 schoolchildren suffered from *Sh. sonnei* shigellosis (and possibly also salmonellosis) whose origins were likely a mixed chicken and rice dish served for lunch on 1 day. In 2009, in Sweden, there was an unusual outbreak of *Sh. dysenteriae* Type 2 infections involving 47 cases. The contaminated vehicle was sugar snaps imported from Kenya. Outbreaks in Norway and Denmark were also linked to the snaps. Trace back of the implicated sugar snaps showed that several import companies and distributers were involved, and the international certification and quality standards were questioned as to their utility in preventing such contaminated product from reaching consumers.

St. aureus

Staphylococcus aureus has been recognized as a cause of foodborne illness since the 1940s, mainly through ready-to-eat foods contaminated by the pathogen from the human skin or nasopharynx. Typically, *St. aureus* will grow to numbers in excess of 500 000 cfu g^{-1} and produce heat-resistant enterotoxins which cause nausea, vomiting, abdominal cramps, and diarrhea within a few hours of ingestion. Cream-filled bakery products displayed unrefrigerated in shop windows were a major vehicle for this pathogen allowing rapid growth in the filling where the high sugar content may inhibit growth of other organisms leading to rapid growth and enterotoxin production. This is less likely today with the use of more synthetic creams and better temperature control of the storage areas. Cooked poultry, egg, and seafood products have also been frequently implicated where worker contamination followed by storage at improper temperatures before consumption has occurred. Less frequent foods are fermented meats and cheese where the starter culture has been contaminated and the fermentation does not proceed rapidly. In South America, soft white cheese is frequently eaten and has been implicated in many outbreaks because of the use of raw milk from mastitic animals, manipulation by asymptomatic workers, and the use of unhygienic production and improper storage practices. Another occasional vehicle leading to outbreaks is dry pasta where the dough is typically extruded at warm temperatures on equipment that is difficult to clean, permitting growth of *St. aureus* and subsequent toxin production. The organism which competes poorly with other microorganisms can grow rapidly in ready-to-eat processed foods such as ham to produce one or more heat-resistant toxins. Generally, in most developed countries, illnesses from *St. aureus* intoxication have been declining. Part of the reason may be that it is not considered a major pathogen and is not looked for in many surveillance programs, and therefore may be underreported. One large outbreak in Brazil in 1998 with 4000 cases and 16 deaths, however, indicates that this is a pathogen not to be ignored. Methicillin-resistant *St. aureus* is an important hospital-acquired infection but has not yet been linked to foodborne outbreaks.

V. cholerae

Cholera is a severe infection caused by *V. cholerae*, which primarily affects the small intestine. The main symptoms include profuse watery diarrhea and vomiting. Transmission is primarily through contaminated drinking water or food. Severe diarrhea and vomiting can lead to rapid dehydration and electrolyte loss, which can result in death if rehydration with salts is not available. Cholera is a major cause of illness and death in the world, and seven pandemics have been documented since the early 1800s, with the latest major event in the early 1990s in South America. Despite our greater awareness of the disease today, and its means of spread, cholera shows no signs of diminishing, and in fact, new strains are encountered on a regular basis. *Vibrio cholerae* O1, the causative agent of epidemic cholera, has two biotypes (classical and El Tor). However, three variants of the El Tor biotype have been described after 2000 in Bangladesh, India, Vietnam, and Mozambique; hybrid vibrios have also been described in other regions of Asia and Africa. Also, *V. cholerae* O139 first identified in 1992, continues to cause outbreaks in India. Many of these strains are resistant to drugs such as trimethoprim, sulfamethoxazole, and streptomycin. Thus, this pathogen is generating different genetic recombinants, which may change the epidemiological role of the disease. Many large outbreaks have been reported in different regions of the world between 2000 and 2010, for example, in 2000, there were 140 000 cases around the world but mainly in Africa; outbreaks in India in 2007 and in Iraq in 2007 and 2008, with thousands of cases (lack of potable drinking water being one of the factors); Vietnam, Congo, Zimbabwe in 2008; South Africa in 2009; and Nigeria in 2010 (the Nigerian outbreak was blamed on heavy seasonal rainfall and poor sanitation). The epidemic in Zimbabwe lasted 9 months and spread to Botswana, Malawi, Mozambique, South Africa, Zambia, and other sub-Saharan African countries. By January 2010, there had been at least 98 000 reported cases and 4200 deaths making it the deadliest African cholera outbreak in the past 15 years. The Zimbabwean government declared the outbreak a national emergency and requested international aid. The epidemic had an unusually high fatality rate because Zimbabweans were seriously weakened by hunger, HIV, and AIDS. A major contributing factor to the severity of the outbreak was the collapse of Zimbabwe's public health system. In Malawi, 104 deaths were recorded, making it the worst outbreak since 2001–02 when 960 people died. Starting in 2006 and continuing to this day, cholera spread to many parts of Haiti and other countries. It likely originated from a peacekeeper encampment upstream of the first case, and perhaps could have been controlled earlier but neither the local or international agencies had surveillance and medical care facilities in place soon enough

because of other priorities. *Vibrio cholerae* non-O1 (nonepidemic) naturally occurs in the Gulf of Mexico causing most US cases from contaminated shellfish but the disease is relatively mild.

Vibrio parahaemolyticus

Vibrio parahaemolyticus was first isolated in 1950 from clinical samples and dried sardines during an outbreak of gastroenteritis in Osaka, Japan. Its pathogenicity is correlated with the production of a thermostable direct hemolysin, known as the Kanagawa phenomenon. Since the 1950s, *V. parahaemolyticus* infections have increased globally; they are usually associated with eating raw, improperly cooked, or cooked, recontaminated fish and shellfish. *Vibrio parahaemolyticus* is the leading cause of seafood-associated gastroenteritis in the USA, and typically associated with the consumption of raw oysters gathered from warm-water estuaries. A correlation exists between the probability of infection and warmer months of the year. Improper refrigeration will allow the proliferation of this organism in seafood, increasing the possibility of infection. The largest culture-confirmed outbreak in North America occurred during the summer of 1997 when 209 people became infected (one death) after eating contaminated raw oysters harvested from California, Oregon, Washington, and British Columbia. A more recent *V. parahaemolyticus* outbreak in 2005 with 22 cases occurred in Alaskan cruise ship passengers after they ate Prince William Sound oysters, extending by 1000 km, the northernmost documented source of oysters that previously had caused *V. parahaemolyticus* illnesses. All oysters associated with the outbreak were harvested when mean daily water temperatures exceeded 15 °C. Since 1997, mean water temperatures in July and August at the implicated oyster farm increased 0.21 °C per year; and in 2004, the mean daily water temperatures in July and August at the shellfish farm did not drop below 15 °C.

Vibrio parahaemolyticus causes approximately half of the foodborne outbreaks in some Asian countries, and is the leading cause of foodborne disease outbreaks in Taiwan with most infections from the O3:K6 strain. This strain also accounted for the majority of diarrhea cases in patients in Calcutta, India, between September 1996 and April 1997. Pandemic O3:K6 clone of *V. parahaemolyticus* appeared in Asia around 1996. Since its emergence, it has accounted for most *V. parahaemolyticus* infections in Asia. It then spread to the USA in 1998, and Spain and Chile in 2004, where it has caused hundreds of infections, resulting in the first *V. parahaemolyticus* pandemic in history. This serotype may have a lower infectious dose than other pathogenic *V. parahaemolyticus* strains, accounting for its apparent virulence. *Vibrio parahaemolyticus* has always been a major pathogen documented in Japan because much of the population loves seafood. However, illnesses are usually restricted to relatively small-scale outbreaks involving fewer than 10 cases. From 1996 to 1998, there were 1710 incidents, including 496 outbreaks, with 24 373 cases of *V. parahaemolyticus* reported. The number of foodborne cases of *V. parahaemolyticus* in Japan doubled in 1998 as compared to 1997 and exceeded the number of *Salmonella* cases. Similar to the 1994–95 period, outbreaks were more prevalent in the summer with a peak in August and relatively few outbreaks occurred during winter months. Boiled crabs caused one large-scale outbreak, involving 691 cases. In 1997, the incidence increased to 568 outbreaks and sporadic reports, with 6786 cases, and in 1998, there were 850 outbreaks and sporadic reports. The increased incidence during 1997–98 has been attributed to an increased incidence of serovar O3:K6. However, since the high of 667 outbreaks and 9396 cases in 1999 when *Salmonella* and *V. parahaemolyticus* were the main causes of the food poisoning, the incidence of *V. parahaemolyticus* has decreased dramatically to 17 outbreaks and 168 cases in 2008. An extended outbreak in northern Chile in 1997–98 was associated with consumption of shellfish and the exceptionally warm seawater caused by 'El Nino' may have favored the growth of the *Vibrio*. This was the first report of *V. parahaemolyticus* causing an outbreak in Chile. An outbreak in Vietnam with over 500 cases from 1997 to 1999 was associated with fresh seafood eaten by persons of high socioeconomic status. i.e., those who could afford to eat this delicacy.

In Europe, illnesses from *V. parahaemolyticus* have been rare and surveillance programs limited. However, in July 2004, a *V. parahaemolyticus* outbreak with 80 illnesses occurred among guests at several weddings after eating boiled crabs at the same restaurant in Coruna, Spain. *Vibrio parahaemolyticus* O3:K6 was isolated from stool samples. Live crabs were imported to Spain from the UK, processed under unhygienic conditions, and stored at room temperature for several hours before they were eaten. The emergence of this virulent serotype in Europe is a public health concern and emphasizes the need to include *V. parahaemolyticus* in microbiological surveillance and control programs for shellfish-harvesting areas and ready-to-eat seafood. Disease outbreaks caused by *V. parahaemolyticus* in Puerto Montt, Chile, began in 2004 and peaked in 2005 at 3600 clinical cases. Until 2006, every analyzed case was caused by the serovar O3:K6 pandemic strain. In the summer of 2007, only 475 cases were reported and this decrease was attributed to a change in serotype of many pandemic isolates to O3:K59 and the emergence of new clinical strains. There was evidence that pathogenicity-related genes were laterally transferred from the pandemic strain to one of the different *V. parahaemolyticus* groups comprising the diverse and shifting bacterial population in shellfish in this region. Other *Vibrio* species are also important marine and brackish water-related pathogens, particularly *Vibrio vulnificus*, which can cause severe wound infections and death. Symptoms are vomiting, diarrhea, abdominal pain, and a blistering dermatitis, which can lead to septicemia. With changing weather patterns and warming of seawater, we can expect more *Vibrio* infections and outbreaks in future.

Yersinia and Related Pathogens

Yersinia enterocolitica and *Yersinia pseudotuberculosis* have often been isolated from such animals as pigs, birds, beavers, cats, and dogs. Only *Y. enterocolitica* has been detected in environmental and food sources, such as ponds, lakes, meat, ice cream, and milk. Most isolates are not pathogenic; the exceptions are serotypes O:3, O:5,27, O:8, and O:9, which tend

to show different geographical distributions. These virulent strains most commonly found in pigs and raw milk can cause yersiniosis, characterized by gastroenteritis with diarrhea and/or vomiting, fever, and abdominal pain. The symptoms can be sufficiently painful that appendicitis is thought to be the cause and in many infected persons the appendix has been mistakenly removed. Both *Y. enterocolitica* and *Y. pseudotuberculosis* have been associated with reactive arthritis, at a frequency of 2–3%, which may occur even in the absence of frank symptoms. *Yersinia enterocolitica* has been transmitted through contaminated unpasteurized milk and milk products, raw pork, tofu, meats, oysters, and fish. Outbreaks have been associated with raw vegetables; the surface of vegetables can become contaminated with pathogenic microorganisms through contact with soil, irrigation water, fertilizers, equipment, humans, and animals. Another feature of *Yersinia* spp. is that they can grow at refrigerated temperatures. If product is contaminated during manufacture or preparation, subsequent refrigeration can increase the pathogen load. The food most frequently associated with *Y. enterocolitica* outbreaks and sporadic cases is pork. In Scandinavia, *Yersinia* infections are more frequently reported than in most other countries, and this may reflect a high proportion of meat being pork in these countries. For instance, in Norway, yersiniosis is the third most commonly reported cause of acute enteritis after campylobacteriosis and salmonellosis. One outbreak of *Y. enterocolitica* in 2007 was attributed to 11 persons eating a traditional Norwegian Christmas pork dish, brawn, which was probably undercooked. Small outbreaks have also occurred as when children were exposed to raw pork during the making of chitterlings from pork intestines, a traditional winter holiday food in certain US black families (soul food). *Yersinia enterocolitica* is transferred from raw chitterlings to infants, particularly to bottle-fed infants, through contact with the hands of the food preparers, and less frequently by direct chewing of the prepared intestines. However, such pork dishes from intestines are common in many countries with similar risks of infection.

Till date, no foodborne outbreaks caused by *Y. pseudotuberculosis* have been reported in the USA, but human infections transmitted via contaminated water and foods have been reported in Japan, Canada, and Europe. At least four outbreaks involving carrots contaminated with *Y. pseudotuberculosis* occurred in Finland in recent years; these mainly affected schoolchildren. The carrots had been stored over winter and a few had spoiled allowing the pathogen to grow. Over a 2-month period in 1998 in British Columbia, Canada, 74 cases of *Y. pseudotuberculosis* were associated with consumption of homogenized milk but no processing, handling, or storage errors were identified during the outbreak investigation. Outbreaks of *Y. pseudotuberculosis* linked to fresh produce have been detected repeatedly in Finland. From 1997 to 2006, there were nine outbreaks documented, including one with carrots as a vehicle where it was shown that shrews were the environmental source of the *Yersinia* either during harvesting or over the winter storage period. Kawasaki disease in Japan, characterized by fever, rash, conjunctival infection, cervical lymphadenitis, inflammation of the lips and oral cavity, and erythema and edema of the hands and feet, has been linked to *Y. pseudotuberculosis* infections but the etiology is not well established. *Yersinia pestis*, the plague *Bacillus* or *Francisella tularensis*, causing tularemia, have not been implicated directly in foodborne illness, but hunters and those in the endemic areas may contract these diseases from handling dead or alive infected animals, particularly from skinning rodents, or from flea and deerfly bites.

Viruses

Avian Influenza (AI) and Other Respiratory Viral Diseases

Viral diseases causing influenza and other respiratory problems were prominent in the 2000–09 decade. These attracted considerable attention because of their high numbers of cases, the speed with which the diseases traveled around the world, and the unacceptable fatality rates. None of these was transmitted directly through food, though food animals were involved. However, because viruses rapidly mutate, there is a growing concern that a major zoonotic viral disease can occur that will involve domestic food animals and then be transmitted rapidly person to person. Unfortunately, there is no simple methodology available to isolate and identify viruses in outbreaks and some are not culturable, all of which has limited understanding of the extent of foodborne outbreaks caused by these agents.

AI (or bird flu) is transmitted by the highly pathogenic influenza A virus subtype H5N1 virus. It was first identified in 1987, which subsequently led to global spread in 2003 with the deaths of millions of ducks, geese, and chickens in more than 50 countries, but mainly in Southeast Asia where small flocks of poultry are widely owned on small farms and even in households. A major concern was that it would spread through wild bird populations, especially ducks and geese that migrate long distances. In fact, there was some evidence for this; a few flocks were infected, but did not seem to be a major factor in causing a pandemic. There was no evidence that poultry meat could spread AI to the human population. In periodic outbreaks, infected birds are destroyed to regain public confidence in the poultry products and to revoke bans placed on exported products by other countries. AI has claimed at least 200 human lives in Asia, Turkey, Romania, and Russia. The main concern is that the AI virus could mutate to pass directly from person-to-person rather than from poultry-to-person. The H5N1 virus kills up to 60% of the persons it infects, but most infections occur after direct contact with an infected bird and the disease does not appear to spread well between humans. As long as human-to-human transmission remains rare, the virus cannot cause an influenza pandemic. However, if the virus can be first adapted to pigs, it then could develop the ability to spread among humans. Since 2007, in Indonesia, AI outbreaks have diminished in poultry and in people but pigs are still carrying signs of recent infection. This may mean the virus is still evolving and could eventually spread rapidly through pigs and become another version of the 2009 'swine flu' pandemic. This was a respiratory infection caused by the swine influenza A (H1N1), and contained genetic material from human, swine, and avian flu viruses. Occasionally, pigs transmit influenza viruses to people, mainly hog farm workers and veterinarians. However,

H1N1 flu spread quickly and easily around the world, and in June 2009, the WHO declared H1N1 influenza a global pandemic. However, like AI, H1N1 cannot be transmitted through swine or poultry meat or any other food.

Severe acute respiratory syndrome (SARS) is a respiratory illness caused by a virus. SARS was first reported in Asia in November 2002. It spread worldwide over several months before the outbreak ended in July 2003, with 8096 known infected cases and 774 confirmed human deaths (a case-fatality rate of nearly 10%). The severe illness was marked initially by systemic symptoms of muscle pain, headache, and fever, followed in 2–10 days by the onset of respiratory symptoms. The virus was later isolated from wild animals (palm civet, raccoon dogs, ferret badgers, cats, and bats) which were asymptomatic; the palm civets were sold as food in local markets in Guangdong, China. Because it was thought that the SARS virus crossed the species barrier from palm civet to humans, more than 10 000 of these animals were destroyed in Guangdong Province, alone. In 2005, an almost identical SARS-like coronavirus was found in Chinese bats. It was eventually deduced that the SARS virus originated in bats and spread to humans either directly, or through animals held in Chinese markets; bats are considered the natural reservoir of SARS-like coronaviruses.

Hepatitis A and E Viruses

Hepatitis A is one of five human hepatitis viruses that primarily infect the liver and cause illness, and is widespread throughout the world. However, it is declining in countries with adequate potable water and sewage disposal systems. Hepatitis A is one of the few foodborne diseases, i.e., vaccine treatable. The hepatitis A virus (HAV) is transmitted by food and water contaminated with sewage or even urine. Unlike hepatitis B and C, hepatitis A does not develop into potentially fatal chronic hepatitis or cirrhosis; however, HAV infections can still lead to acute liver failure and death (fulminant hepatitis A). Fresh produce contaminated during cultivation, harvesting, processing, and distribution has been a source of hepatitis A. In the USA and other countries, there have been outbreaks associated with frozen strawberries, blueberries, fresh green onions, and lettuce. Restaurant- or caterer-associated outbreaks typically involve an infected food worker who contaminates the food during extensive handling and preparation. Because the incubation period from infection to detectable symptoms can be ≥ 2 weeks, these infected workers can be asymptomatic excreters for many days or weeks before being identified and removed from preparing and serving food. Shellfish contaminated through polluted water are also an ongoing source of infections; the largest one occurred in Shanghai in 1987 and 1988 when 292 000 persons (with 32 fatalities) were reported in 2 months. These infections were acquired after clams were eaten. These were harvested by boats operating under unsanitary conditions, and from waters containing untreated sewage effluent in previously unharvested clam beds. The contaminated clams were then transported to Shanghai distributors. Clams like other shellfish are filter feeders that can concentrate ingested particles including HAV to cause infections after their ingestion. Steaming of clams was found to be insufficient to kill the virus, although those who ate raw clams were more likely to be infected than those who consumed cooked clams.

Like hepatitis A, hepatitis E is a disease transmitted between persons via the fecal–oral route, but less is known of the disease transmission. Hepatitis E virus (HEV) may be mainly acquired through water but may originate from animal sources. Domestic animals have been reported as a reservoir for HEV, with some surveys showing infection rates exceeding 95% among domestic pigs. Transmission after consumption of wild boar meat and uncooked deer meat has been reported as well. The rate of transmission to humans by this route and the public health importance of HEV, however, is still unclear. While most often developing into an acute, self-limiting disease, HEV can proceed into a fulminant form in 1–2% of those infected, and up to 20% in infected pregnant women. There is no effective treatment and the only action that can be taken is to relieve the symptoms through rehydration and patient care. When the disease has run its course, HEV is no longer detectable and the liver recovers its regular function. Major outbreaks have occurred in New Delhi, India (30 000 cases in 1955–56); Burma (20 000 cases in 1976–77); Kashmir, India (52 000 cases in 1978); Kanpur, India (79 000 cases in 1991); and China (100 000 cases between 1986 and 1988). More recent outbreaks occurred in 2004, one in Chad with 1442 reported cases and 46 deaths and another in Sudan with 6861 cases and 87 deaths. A larger outbreak occurred in northern Uganda during 2007 and 2008 with 7000 infected and 121 deaths. As these outbreaks demonstrate, HEV often becomes established in camps with displaced persons where sanitation is poor. Specific factors that have been identified with the disease include lack of covers on latrines in the camps; poor hygiene in homes; and lack of routine hand washing with soap before eating or after using the toilet; infections may also occur from eating the raw meat of a contaminated animal. Control measures include improving sanitation and providing adequate supplies of potable water at camps. However, increasingly, HEV is being seen in developed nations with reports of cases in the UK, USA, and Japan. In 2008, one small outbreak occurred with UK passengers on a cruise ship where consuming shellfish and drinking alcohol were risk factors (possibly with contaminated ice), indicating a common-source foodborne outbreak.

NoV

NoVs are a group of related, single-stranded ribonucleic acid, nonenveloped viruses that cause acute gastroenteritis in humans. NoV is the official genus name for the group of viruses previously described as 'Norwalk-like viruses' or small round structured viruses because of their morphological features. NoVs are part of the larger *Caliciviridae* family, which also includes the genus *Sapovirus*, formerly described as 'Sapporo-like viruses', which also cause gastroenteritis in humans. There are five NoV genogroups of which three (GI, GII, and GIV) cause human infections; variants of the GII.4 genotype have been the most common cause of NoV outbreaks. The incubation period is typically 24–48 h and the disease is characterized by acute-onset vomiting (projectile vomiting)

and watery diarrhea. Recovery is usually within 72 h. A major means of transmission is through aerosolization of vomitus, but the fecal–oral route is probably the most frequently encountered, either by consumption of fecally contaminated food or water, or by direct person-to-person spread. As the minimal infectious dose is 10 or fewer particles, one infected person can contaminate a large area and extensive outbreaks have been reported. In the USA and probably many other countries, more foodborne disease outbreaks are caused by NoV than any other pathogen, but the extent is hard to estimate because NoV infections are also transmitted by nonfood means. Asymptomatic infections are common and may play an important role in outbreaks caused by food workers. Also, infected persons can continue to excrete the virus for weeks after they have recovered. The most frequent vehicles in NoV outbreaks include lettuce, cold cuts, hors d'oeuvres, and multiingredient ready-to-eat products where there is much handling and no further cooking step. NoVs are relatively resistant to environmental stress, and are able to survive freezing, some cooking temperatures as high as 60 °C, including after being steamed in shellfish. NoV can survive in up to 10 ppm chlorine, but chlorine-based disinfectant compounds are better for disinfecting contaminated vomitus- or diarrhea-contaminated areas than quaternary ammonium compounds or vacuum cleaners which can actually create an aerosol of infectious particles. Contamination of foods by NoV can be lessened when persons suffering from gastroenteritis avoid preparing or serving food, by frequent hand washing with disinfectants (alcohol-based hand rubs are insufficient), appropriate use of gloves, and by discarding any food that is in the same area where someone has vomited.

Rotavirus

Rotavirus is the most common cause of severe watery diarrhea, typically preceded by vomiting, among infants and young children, and is one of several viruses that are attributed to 'stomach flu'. Infections are very common, and, with each infection, immunity develops, to make subsequent infections less severe, and adults are rarely affected. Dehydration is more common in rotavirus infection than in infections caused by most bacterial pathogens, and is the most common cause of death related to rotavirus infection in young children. As with other enteric viruses, rotavirus is transmitted by the fecal–oral route. The ease of transmission through a population is illustrated by the fact that the feces of an infected individual can contain more than 10^{10-12} infectious particles, and the infectious dose is only 10–100 of these particles. Rotaviruses are stable in the environment, and it is difficult to completely sanitize contaminated areas. Outbreaks of rotavirus diarrhea are common among hospitalized infants, young children attending day care centers, and elderly people in nursing homes. Apart from person-to-person spread, water is one known source of the virus, and there have been waterborne outbreaks documented. Food is thought to play a minor role in its transmission, probably $<1\%$ of cases. In the USA, it is estimated that NoV accounts for approximately 97% of the virus-caused foodborne outbreaks, with the remainder attributed to hepatitis A and rotavirus. However, a few foodborne rotavirus outbreaks have been described in Japan, the UK, and the USA. One outbreak lasting 4 days occurred in an English boarding school in 1994, and was associated with students eating chicken tikka masala (the median incubation period was 35 h). In 2000, 85 college students in the District of Columbia became ill over a 16-day period after eating sandwiches and deli meats prepared on campus. Some of the preparation staff were carriers. In both the Japanese outbreak from restaurant-prepared food and the above-described campus one, adults (patrons and cooks, respectively) were infected with frank symptoms, which would not have been expected from previous rotavirus studies, as adults are supposed to develop complete immunity. Increased strain virulence may have been a factor.

Other Viruses

In the past, poliovirus was one of the disease scourges of persons living under unsanitary conditions particularly in cities causing paralysis and premature death, but vaccination has largely eliminated the disease except in a few areas of Asia. Astroviruses are spread by the oral–fecal routes and are probably foodborne from time to time. Many other viruses are likely to be recognized at least as occasionally foodborne but the epidemiology has not yet been demonstrated.

Parasites

Protozoans

Cryptosporidium

Cryptosporidium species affect different species of mammals and birds. Young animals are those most susceptible to infection. Human cryptosporidiosis is predominantly caused by *Cryptosporidium hominis* and *Cryptosporidium parvum*, which differ in host range; the former infects mostly humans under natural conditions, and the latter infects both humans and many farm animals, such as cattle, sheep, and goats. The main symptoms are watery diarrhea lasting 2–4 days and most people recover quickly, but diarrhea can be prolonged lasting 1–4 weeks, such as in child care centers. In such centers, the spread of infection is highest among young children who are not toilet-trained and their caregivers (those who change diapers). Immunocompromised persons, especially AIDS patients, are at greatest risk for life-threatening conditions, particularly if the cryptosporidiosis develops into a pulmonary form. The infective dose is <10 oocysts. Oocysts are very resistant to normal decontamination procedures, and there is no universally recommended drug for the treatment of the disease, but nitazoxanide is now approved in the USA for diarrhea caused by *Cryptosporidium*. The infective oocyst stage of the organism shed in feces is resistant to most chemical disinfectants, like bleach, but is susceptible to drying and ultraviolet light. Hydrogen peroxide seems to work best. Outbreaks have occurred from infected food workers preparing ready-to-eat foods, and from environmental sources such apple cider from apples contaminated by animal feces or the processing water, and salad items. In 2008, a relatively large outbreak occurred in Finland among

government employees eating at the same canteen; 72 of them experienced mild gastrointestinal symptoms, mainly diarrhea after eating meals with mixed salad items shipped from Sweden.

There have also been instances of illness related to oocyst survival in milk because of improper pasteurization. Shellfish in polluted waters have been found to contain the oocysts but no outbreaks from consumption of these have been reported. Waterborne outbreaks are the most frequent in communities where there is no filtration system for the potable water supply, and these can sometimes affect thousands of people. For instance, in Milwaukee, Wisconsin in 1993, *Cryptosporidium* oocysts passed through the filtration system of one of the city's water-treatment plants, and in a 2-week period, 403 000 of the estimated 1.61 million residents became ill with stomach cramps, fever, diarrhea, and dehydration caused by the pathogen; there were 54 deaths attributed to this outbreak, mostly among the elderly and immunocompromised persons, such as AIDS patients. In 2000, three separate drinking water-associated cryptosporidiosis outbreaks occurred in Northern Ireland, each with over 100 cases. One outbreak was caused by the bovine genotype, and two were caused by the human genotype; subgenotyping analyses indicate that two predominant subgenotypes were associated with these outbreaks and had been circulating in the community, probably *Cr. parvum* and *Cr. hominis*, respectively.

Cyclospora

The coccidian parasite *Cyclospora cayetanensis* causes protracted diarrhea in humans, and was first identified among expatriates and travelers in Haiti, Guatemala, Nepal, and Peru, where infections are endemic. Since then, *Cyclospora* has been considered a cause of traveler's diarrhea, linked to consumption of untreated water, lack of adequate sanitation, and soil contact with young children. Asymptomatic carriers have also been identified. One waterborne outbreak occurred in the USA in 1990 where bird feces in a water storage tank might have been the source of the parasite. In the mid-1990s, the first foodborne outbreaks were recognized, when illnesses in both Canada and the USA were associated with raspberries and possibly blackberries imported from Guatemala, likely contaminated during spraying of pesticides. Later, mesclun lettuce and basil were identified as vehicles in other outbreaks, most likely from product imported from Mexico and South America. In 2009, 160 passengers and crew were infected by the parasite after the ship had called in at various ports in South America; no specific vehicle was determined but raw fruits or vegetables brought aboard were suspected. There are no known animal hosts for this pathogen and so human source contamination must be sought during an investigation. In developing countries, transmission most likely occurs through sewage-contaminated water that is sometimes used in the fresh produce industry for irrigation or pesticide application. Unfortunately, the oocysts are relatively resistant to chlorine which makes control difficult.

Toxoplasma

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. The parasite infects most genera of warm-blooded animals, including humans, but felines represent the only definitive hosts which shed the infective oocysts, with the domestic cat being the animal of greatest risk for humans. *Toxoplasma gondii* is a major cause of abortion and problems with fertility in livestock, especially among ewes, and therefore a significant cause of economic loss in livestock farming. In humans, during the first few weeks postexposure, the infection typically causes a mild flu-like illness or no illness. Thereafter, the parasite rarely causes any symptoms in otherwise healthy adults. However, those with an inadequate immune system, such as AIDS patients, may become seriously ill, and die. The parasite can cause encephalitis and neurological diseases, and can affect the heart, liver, ears, and eyes (chorioretinitis). Transplacental infections with *To. gondii* may occur in some 45% of seroconverted pregnant women. In 10–20% of non-fatal cases, the infants may suffer from damage to the CNS and retinochoroiditis, leading to blindness. It is believed that infected but asymptomatic infants may also develop some sequelae later in life, most commonly retinochoroiditis. It is estimated that, worldwide, in approximately 3 out of every 1000 pregnancies the fetus/infant is affected by toxoplasmosis. In the USA, toxoplasmosis is estimated to be one of the most costly foodborne diseases because of the high lifetime cost of care for surviving but impaired infected fetuses. Unfortunately, there is no completely effective treatment for humans or animals, although pyrimethamine/sulfadiazine are commonly used.

Up to one-third of the world's human population is estimated to carry a current or previous *Toxoplasma* infection. For instance, the seroprevalence in the USA was 10.8% from 1999 to 2004. Interestingly, 60% of the Inuit of Nunavik (northern Quebec) were seropositive for *To. gondii*. In multivariate analyses, risk factors for seropositivity included increasing age, gender (women > men), lower level of education, consumption of potentially contaminated water, frequent cleaning of water reservoirs, and consumption of seal meat and feathered game. In Doha, Qatar in 2008, approximately 30% of the population was affected where there was a high feral cat population (> 2 million), with the vast majority of the cats living on the streets, scavenging garbage as well as feeding on the rodents near homes and restaurants. The immunoglobulin M (IgM) serological information showed ongoing and repeated exposure to *To. gondii* for all age groups except infants. However, although cats are often blamed for spreading toxoplasmosis (such as children playing in sandboxes where cats have excreted), fecal contamination of hands and consumption of raw or undercooked meat containing tissue cysts are more significant risk factors for human infections. For instance, the seroprevalence in pigs in Guangdong Province, China, in 2008–09 was alarmingly high at 58% in one city region. These results indicate that *To. gondii* infection is a significant health problem in pigs, and pork from these animals represents a public health concern in southern China. This compares with a 2005 USA study where the seroprevalence for pigs was 2.6%, with a herd prevalence of 21.6%, and a mean within-herd prevalence of 2.7%. Analysis of swine management practices indicated that rodent control methods and carcass disposal methods were associated with differences in the number of *To. gondii*-positive samples on the farm.

Entamoeba

Entamoeba histolytica is an anaerobic parasitic protozoan that affects primates. *Entamoeba histolytica* is estimated to infect approximately 50 million people worldwide although there can be many asymptomatic cases. Symptoms can include fulminating dysentery, bloody diarrhea, weight loss, fatigue, and abdominal pain. The ameba can penetrate the intestinal wall and reach the bloodstream and internal body organs, such as the liver, spleen, lungs, and even the heart and brain. There is approximately 1–3% mortality rate in those with overt symptoms. A closely related species, *Entamoeba dispar*, is considered to be nonpathogenic but these species are hard to distinguish morphologically. The cysts are transmitted through consumption of contaminated water or food, such as salads, fruits, or vegetables that have been washed in water containing the cysts; handling objects that have been in contact with contaminated soil or animal feces, and by anal sex. More cases occur in the rainy season than in the dry season. One cyst may be enough to initiate an infection with an incubation period of 2–4 weeks. Although water is the primary vehicle for infection, raw fruits and vegetables may also be contaminated, and normal chlorination treatment for potable water is not effective in destroying the cyst. The most dramatic incident in the USA was the Chicago World's Fair outbreak in 1933 caused by contaminated drinking water. There were 1000 cases and 58 deaths; defective plumbing allowed sewage to contaminate the drinking water. More recently, food workers are suspected of causing a few sporadic infections, but there has been no single large outbreak in industrialized countries. Because asymptomatic persons can excrete large numbers of the protozoan, food workers who have recently returned from endemic areas should be cautioned to follow exemplary hand hygiene, especially when preparing ready-to-eat foods.

Giardia duodenalis *(syn.* Giardia lamblia, Giardia intestinalis*)*

Giardia duodenalis is present in many species of wild mammals, as well as in livestock and companion animals (dogs and cats). Thus, consuming water from an apparently pristine wilderness can contain this parasite and cause diarrhea ('beaver fever'), unless it has first been filtered or boiled. Also, up to 30% of dogs can be affected with diarrhea that can become a source of human infection. Giardiasis is widely distributed throughout the world and may be in both symptomatic and asymptomatic forms at a low prevalence level in the population. Symptoms may include diarrhea, gas or flatulence, greasy stools that tend to float, stomach or abdominal cramps, and occasional nausea. Giardiasis may be expressed as diarrhea within 1 week of ingesting the environmental-resistant cyst. Normally illness lasts for 1–2 weeks, but there are cases of chronic infections lasting months to years. The infectious dose is very low; perhaps even one cyst is sufficient to initiate an infection. Giardiasis is more prevalent in children than in adults, possibly because many individuals seem to have a lasting immunity after infection. However, some adults develop a chronic condition, which is difficult to treat. Infants and other children in child care centers and patients with AIDS are the most vulnerable to infections. Foodborne outbreaks from this parasite are relatively infrequently reported but small episodes may occur but are not typically investigated. In 1979, 29 school employees that ate home-canned salmon developed giardiasis. The wife of the school employee who brought the food had an asymptomatic *Giardia*-infected grandson, whom she diapered before handling the salmon; her subsequent washing was insufficient to remove all the cysts from her hands. In 1985, in Connecticut, 13 persons at a picnic later suffered from giardiasis after eating a noodle salad dish, which was made by the hostess. Either she or her asymptomatic children were the source of the infection. In New Jersey, in 1986, a similar outbreak occurred in which 9 individuals within a family of 25 developed symptoms after consuming a home-prepared fruit salad. The salad preparer had a diapered child and a pet rabbit at home, both later found to be positive for *G. lamblia*. The preparer had clearly come in contact with the parasite after diapering the child and/or cleaning up the rabbit cage. In 1998, 22 members of a church youth group in New Mexico suffered from giardiasis with taco ingredients being the most likely vehicle; the source was either contaminated municipal water or one of the parent preparers. In 2005, over a 3-month period, in California, 41 users of exercise equipment in a gym were identified as *Giardia* cases. There were 12 confirmed cases and 29 other persons with symptoms but no detectable cysts in their stools. The most likely source was the gym water dispenser. The dispenser spigot required substantial hand manipulation to use. Thus, contaminated hands could easily come in contact with the spout, which would be a viable environment for the *Giardia*. Those infected may have been a continuing source, because many continued to work out at the gym despite their symptoms.

Helminths

Most helminth infections fall under the term neglected tropical diseases (NTDs), as they are not reportable, but affect large segments of the world's population, mainly the poor and the hard-to-reach population groups where there is lack of access to health care. NTDs represent the fourth most important group of communicable diseases worldwide, behind lower respiratory infections, HIV/AIDS, and diarrheal diseases. Most of these diseases will often result in debilitating complications, contributing to malnutrition, disabilities, anemia, and stunted growth and cognitive development in children. It is estimated that more than 1.2 billion people could be infected with soil-transmitted helminths and/or schistosomes in the Asia-Pacific Region alone. A number of helminth parasites are transmitted to humans through foods. These include the nematodes *Trichinella*, *Anisakis*, and *Ascaris*; the tapeworms *Taenia*, *Echinococcus*, and *Diphyllobothrium*; and the trematodes *Fasciola*, *Clonorchis*, *Opisthorchis*, and *Paragonimus*. Ascariasis alone affects approximately 10–25% of the world's population, although most of those infected have mild or no symptoms. Severe *Ascaris* infections cause approximately 60 000 deaths each year, mainly in children. Eating uncooked food grown in contaminated soil or irrigated with inadequately treated wastewater is a frequent source of infection. *Anisakis simplex* (herring worm) and *Diphyllobothrium latum* (fish tapeworm) are associated with marine and freshwater

fish, respectively. They can be found in the gut or in other tissue. Most *Anisakis* infections occur in Japan where fish are more likely to be eaten raw, and they may have to be removed surgically from the stomach if pain like appendicitis or a gastric ulcer persists. Many of these helminths affect widespread populations in Asia and Africa and even if they are treated, diseased individuals can be reinfected in endemic regions transmitted through the fecal–oral route.

Trichinella

The nematode *Trichinella spiralis*, and other related *Trichinella* species, are acquired through the consumption of raw and undercooked meat containing encysted larvae. The initial symptoms of trichinellosis include diarrhea, abdominal pain, and vomiting, followed later by facial edema, conjunctivitis, fever, and myalgias. Occasional life-threatening manifestations include myocarditis, and CNS involvement. *Trichinella* species can infect swine, horses, foxes, wolves, bears, walrus, skunk, raccoons, rats, and other small mammals, as well as humans. Humans are most likely to be infected by *Tr. spiralis*, *Trichinella nativa*, or *Trichinella britovi*. The cold-adapted species, *Tr. nativa*, found in Arctic mammals is more resistant to freezing; the most frequent strain in bears is *Trichinella murrelli*. Although humans likely were exposed to *Trichinella* spp. long before the domestication of the pig, this host has been the most frequent source of infection in the past few thousand years. Foxes, wolves, and bears have the highest infection rates, but small mammals such as skunks, raccoons, and rats provide the highest risk of infecting the domestic pig. Domestic swine can be exposed to the parasite by the following three ways: (1) feeding on animal tissues containing *Trichinella* cysts; (2) exposure to infected rodents or other infected wildlife; and (3) cannibalism within an infected herd. Vigorous meat inspection programs have effectively lowered prevalence rates among domestic animals by controlling these transmission routes. Today, in the USA, safe cooking temperatures for pork can be as low as 145 °F, as long as the meat is let rest for a full 3 min before carving and serving. Horse, wild boar, and bear may be infected, and meat from these if eaten raw or undercooked, occasionally causes small outbreaks, but the population exposed to these is small. However, human trichinellosis is regularly reported in Poland, with 35 outbreaks and 702 cases being reported from 2002 to 2007. The primary source of human infection today has changed from pork to wild boar meat because of stringent control of commercial pork operations. Escaped raccoon dogs (prevalence of 4%) have expanded in both Poland, and Germany and pose a risk to hunters and domestic pigs kept on backyard farms. Wild (feral) pigs are also expanding in the USA, and because the hunting of these animals is encouraged they may represent a source of infection in humans.

Taenia

Approximately 50 million people worldwide are infected by either the beef tapeworm, *Taenia saginata*, or the pork tapeworm, *Taenia solium*. Adult tapeworms develop in the small intestine when meat contaminated with larval cysticerci is consumed raw or poorly cooked. Whereas infections with adult tapeworms are not generally severe, infection with some larval stages can result in life-threatening conditions. When eggs of the pork tapeworm, *Ta. solium*, are ingested they develop into larval cysticerci which migrate to various sites in the body including the brain, in which case the condition is called neurocysticercosis (60–90% of *Ta. solium* taeniasis cases), and can be fatal. These infections are most often found in rural, developing countries with poor hygiene where pigs are allowed to roam freely and eat human feces. This allows the tapeworm cycle of infection to be completed and taeniasis becomes endemic in these regions. For instance, because pork is a staple meat in many provinces in China, cysticercosis is highly endemic, with >1 million cases annually; those affected are mainly ethnic minority groups preferring to eat raw pork; it is also associated with an increase in tourism and the promotion of 'ethnic' dishes to attract customers. In some regions of Mexico, prevalence is 3.6% of the general population. This compares with approximately 1000 cases in the USA where most cases are immigrants from Latin America. Approximately 50 000 people die each year from cysticercosis. However, there is limited information on the epidemiological profile of foodborne cestodes and trematodes (which are discussed in the next section), and infections from these are likely to be underestimated.

Trematodes

Approximately 6000 trematode species ('flukes') have been described, but only a few are important human parasites. Infection of humans occurs through the consumption of contaminated freshwater fish, frogs, shellfish, snails, tadpoles, snakes, water plants (e.g., watercress), and other aquatic products eaten raw or insufficiently cooked. Raw, pickled, or undercooked fish and other aquatic products are prepared in various ways. Such dishes have been extant for hundreds of years with high cultural, ethnic, and nutritional significance, making it difficult for many people to change to safer food habits. Examples of typical traditional preparations include raw crab meat spiced with soy sauce in the Republic of Korea (South Korea), raw grass carp dishes in China, and fresh uncooked small- or medium-sized fish, moderately or extensively fermented in Thailand and Laos. In the 1990s, an estimated 750 million people were at risk of infections with foodborne trematodes (>10% of the world's population), which comprise liver flukes (*Clonorchis sinensis*, *Fasciola gigantica*, *Fasciola hepatica*, *Opisthorchis felineus*, and *Opisthorchis viverrini*), lung flukes (*Paragonimus* spp.), and intestinal flukes (e.g., *Echinostoma* spp., *Fasciolopsis buski*, and the heterophyids). More recent estimates are staggering despite medical advances; the at-risk populations for clonorchiasis, paragonimiasis, fascioliasis, and opisthorchiasis are 601, 293, 91, and 80 million, respectively. The global estimate for the number of people infected with *Clonorchis sinensis* is 35 million; mostly in China, for *Paragonimus* spp. >20 million; for *O. viverrini* 10 million infections with 8 million in Thailand and 2 million in the Laos; for *O. felineus* 1.2 million; and for *Fasciola* species 2.4–17 million; whereas for several species of liver fluke 40–50 million. The annual mortality rate is probably much higher than the estimated 10 000. *Clonorchis sinensis* is endemic in China, South Korea, Taiwan, and Vietnam. *Opisthorchis viverrini* is prevalent in Cambodia, Laos, Thailand, and Vietnam,

O. felineus is endemic in the former Soviet Union, Kazakhstan, and the Ukraine. *Fasciola hepatica* is endemic on all continents but is of most concern in mountainous regions in South America, Cuba, Iran, Egypt, and Western Europe, with infections from *F. gigantica* being restricted to Africa and Asia. *Paragonimus* infections occur mainly in tropical and subtropical areas of East and South Asia and sub-Saharan Africa. Intestinal fluke infections from *Echinostoma* spp. occur in China, India, Indonesia, Japan, Malaysia, Russia, South Korea, the Philippines, and Thailand. *Fasciolopsis buski* is endemic to Bangladesh, China, India, Indonesia, Laos, Malaysia, Taiwan, Thailand, and Vietnam. *Heterophyes heterophyes* infections are reported from Egypt, Greece, Iran, Italy, Japan, South Korea, Sudan, Tunisia, and Turkey. The most commonly found intestinal fluke infection in China, South Korea, and Taiwan is *Metagonimus yokogawai*.

Clonorchiasis in China is endemic in several regions, and it is estimated that 15 million Chinese are infected with *Clonorchis sinensis*, with numbers tripling over the past decade. Individuals can become infected through consumption of raw freshwater fish (more men than women), handling freshwater fish and not washing, and water contaminated with infected feces, for example, where privies are built adjacent to fish ponds. This increase is partly attributable to rural residents who move to urban centers where raw fish consumption is more fashionable. The disease may decline in time where people are more inclined to eat more of raw, large aquaculture-raised fish (which do not harbor metacercaria) as well as a disinclination to eat fish from rivers polluted with industrial waste. In South Korea, eating raw vegetables and aquatic species are a valued part of many culinary traditions, and the soil may be contaminated through night soil (human fecal waste used as fertilizer) or polluted water. In Japan, foodborne trematode infections are most common in rural areas, where traditional food habits are more preserved and raw freshwater fishes and game meat are also incorporated into the diet. Owing to general unawareness of foodborne parasitic zoonoses, the cysts caused by many trematode infections (such as paragonimiasis and fascioliasis) are often mistaken for cancers, and examination for these false carcinomas results in large economic losses. There is currently no legislative system applied to these types of infections, and both increased surveillance for and awareness of these is needed. In Laos, it is estimated that 1 744 000 individuals are infected with opisthorchiasis throughout the country, with practically the whole population at risk (4 360 000). A campaign in 2008 delivered praziquantel in one Laotian province, targeting children and adults to control both opisthorchiasis and schistosomiasis. However, reinfection can occur rapidly following treatment when there are no supportive control measures in place, such as stressing the importance of thoroughly cooking all aquatic products and boiling water before consumption. Agricultural reform may increase risk factors, as demonstrated when fascioliasis emerged after irrigation systems had been built in Egypt and Peru. However, environmental change can reduce the risk of infections. In Henan province, China, low prevalences of paragonimiasis were found for two villages, where gold mining had contaminated streams and killed crabs, the second intermediate host of paragonimiasis. Pesticide use in rice paddies and farms can be effective in causing the death of the first and second intermediate aquatic hosts in China and South Korea. Unfortunately, although these reduce infections, the risk of chronic disease through inappropriate chemical action may increase. Foodborne trematodiases are being more frequently diagnosed in developed countries due to increasing travel patterns and consumption of exotic foods, and it is probable that climate change will favor conditions for human fascioliasis in newer regions, as air temperature and rainfall are crucial for the fluke to flourish. One area of concern is the rapid development of aquaculture. In well-controlled operations, the risk of infection is lower than in wild-caught fish. However, in Vietnam, metacercariae have been found in cultured fish or waste-fed ponds, with up to 50% of the fish infected with foodborne trematodes. The implementation of HACCP systems should be encouraged, as has been done for farming carp, where these have prevented *O. viverrini* from entering the ponds by monitoring the water supply, fish feed, and pond conditions, and control measures taken to address each deviation. Also, if cold storage is available for aquatic products, any metacercariae present will be killed.

Transmissible Spongiform Encephalopathies (TSEs) Including Bovine Spongiform Encephalopathy (BSE)

TSEs are a group of progressive conditions that affect the brain and CNS of certain animals, including humans. TSEs are unique diseases in that their etiology may be genetic, sporadic, or infectious via ingestion of infected foodstuffs and via iatrogenic (therapeutic action) means. TSEs cannot be transmitted through the air or through touching or most other forms of casual contact, but through contact with infected tissue, body fluids, or contaminated medical instruments, eating infected tissue, transfusion, or transplantation. Normal sterilization procedures such as boiling or irradiating materials fail to render the agents noninfective. For BSE, the best studied of the TSEs, misfolded or contorted prion proteins carry the disease between animals and cause a deterioration of the brain, characterized by the appearance of vacuoles, or clear holes in brain neurons, that give the infected brain its spongiform appearance. BSE in cattle was initially recognized in the UK in 1986, but the cause was not immediately identified, and BSE was subsequently reported in other European countries, with more than 1000 reported cases in 1992, and by 2000, the total number of infected cattle had increased to 180 000. Smaller numbers of cases were reported from Japan, Canada, and the USA, but all were traced back to affected animals in Europe. BSE – a lethal CNS disease specifically targeting cattle produces changes in temperament, such as nervousness or aggression; abnormal posture; lack of coordination and difficulty in rising ('downers'); decreased milk production; or loss of body condition despite continued appetite. The incubation period ranges from 2 to 8 years. Following the onset of clinical signs, the animal's condition deteriorates until death ensues or the animal is euthanized. This usually occurs within 2 weeks to 6 months. Most cases in the UK affected dairy cows between 3 and 6 years of age. The primary means of transmission of BSE to cattle was by eating feed contaminated with rendered material, for example, spinal cord, from BSE-infected cattle; this practice is banned today, as there is no guarantee that the feed will be

free of spinal cord tissue. There is also a possibility that in rare cases, mother-to-offspring transmission may occur, but this is unconfirmed. There is no evidence that BSE is transmitted directly from animal-to-animal. There have been a total of more than 188 000 cases of BSE documented from 30 countries since 1986, and it is possible more will be identified, although control measures of culling infected animals and their progeny has reduced the pool of infected animals considerably. More than 4.4 million cattle were slaughtered during the eradication program in the UK alone. The origin of the infectious BSE prion has not been determined; it was assumed to be a recent phenomenon, but interestingly cases of a disease with similar characteristics were documented by Publius Flavius Vegetius Renatus in the fourth and fifth century AD in the western Roman Empire.

In sheep and goats, scrapie has been documented for many years (infected animals scrape themselves because of itchy skin); this is a fatal, degenerative disease that affects the nervous systems. European Food Safety Authority (EFSA) has stated that sheep and goat milk and derived products are unlikely to present any risk of TSE contamination if the milk comes from healthy animals. EFSA also considers the risk from eating sheep and goat meat to be low, due to the BSE measures currently in place. However, out of fear of BSE-related illnesses, many European countries banned some traditional sheep or goat products made without removing the spinal cord, such as smalahove (Norwegian origin delicacy of smoked sheep's head at Christmas) and smokie (West African origin of blowtorching the fleece off the unskinned carcass of an old sheep or goat).

Chronic wasting disease (CWD) of deer, elk, and moose in western and mid-western USA and Canada, which may be mainly transmitted through saliva, appears to be spreading eastwards. Although there is no proven link between affected cervids and human TSE, hunters should avoid eating tissues (e.g., brain, spinal cord, eyes, spleen, tonsils, and lymph nodes) from animals taken from areas where CWD has been identified. There is also a transmissible mink encephalopathy. There are probably more TSEs to be diagnosed in animals.

Human prion diseases are rare and include classic Creutzfeldt–Jakob disease (CJD; a dementia), Gerstmann–Sträussler–Scheinker syndrome (a dementia), fatal familial insomnia (hallucinations and dementia), Alpers' syndrome (intractable seizures in infants), and kuru (ritual eating of the body and brains of dead relatives leading to a loss of coordinated muscle movements). In CJD, defective protein can be transmitted by contaminated harvested human growth hormone products, immunoglobulins, corneal grafts, dural grafts ,or electrode implants (acquired or iatrogenic form); it can also be inherited (hereditary or familial form). In 1996, a possible link between consumption of BSE-infected meat and the development of a new variant CJD (vCJD) in human cases was postulated, with the prion identified as the causative agent. Approximately 275 people worldwide have been infected with vCJD, but mainly in the UK, and most of these have already died. It is believed that they became infected by eating products from BSE-infected animals. The finding of a second BSE prion (different protein shape contortion) in 2004 raises the possibility that transmission of BSE to humans has been underestimated, because some of the individuals diagnosed with spontaneous or sporadic CJD may have actually contracted the disease from contaminated beef. The BSE crisis caused economic loss for countries that declared they had BSE in their herds even at small numbers; that included the USA, which could not sell beef to Japan for many years. However, the USA permitted cattle from Canada to continue to be exported to the USA because the beef industries were already well integrated after both countries had reported cases, and they both had control strategies in place. It is interesting that although the risk of contracting vCJD, even in the UK, is very low, for example, 1 case per 10 billion servings of beef and beef products, the horror of a progressive dementia-like disease has created huge economic barriers to previously well-established beef trading arrangements. It is unlikely that BSE can be eradicated for several more years to come, as new cases are still reported in cattle worldwide. An interesting new development is that the eyes of sheep in the early stages of scrapie glow when a beam of light is shone on the retina. This finding could develop into an early diagnostic tool for detecting cattle with BSE, rather than requiring dissection of the brain tissue at death or slaughter. Noticing the symptoms early may help prevent infected meat from getting into the food supply. It is, therefore, crucial for animal health authorities to establish and/or maintain effective BSE surveillance and control programs, such as the one just mentioned. All these more recent developments are an indication that TSEs, including BSE and vCJD, are likely to occupy the veterinary and public health/food safety authorities for many more years to come.

Chronic Effects of Foodborne Disease Infections

Most foodborne illnesses result in acute symptoms including diarrhea, vomiting, abdominal pain, cramps, and sometimes fever and jaundice, and are self-limiting. The majority of these cases recover within a few days to a few weeks with no lasting effects. However, for some pathogens and some infected individuals illnesses can last much longer and may have life-shortening outcomes. If the disease becomes systemic and affects the bloodstream and one or more organs, without rapid and appropriate medical intervention, the patient may either die or have a long recovery period.

Life-Threatening and Chronic Infections

Those foodborne diseases deemed to be most severe include brucellosis, listeriosis, typhoid fever, and botulism, although none are common in the developed world. However, the health consequences of these when they occur can be serious and life threatening. Many parasitic diseases also fit this picture of a long-lasting chronic condition with severe effects. Those most vulnerable are the very young, very old, those already ill, and pregnant women, all of whom may have underlying health conditions or lower immunity than healthy adults. For example, in pregnant women listeriosis can lead to abortion, stillbirth, or malformation of the fetus, and the overall fatality rate is approximately 30%. Also, those who are malnourished due to inadequate food production are at greater risk of severe infections. These conditions may follow

adverse climatic conditions, such as flooding, drought, or extended high ambient temperatures, and the only available nutritious food may be spoiled or in short supply. Also, repeated episodes of foodborne diseases over a period of time can lead to malnutrition, with serious impact on the growth and the immune system of infants and children. An infant whose resistance is suppressed becomes more vulnerable to other diseases (including respiratory tract infections) and is subsequently caught in a vicious cycle of malnutrition and infection, and many do not survive under these conditions. Gastrointestinal infections can be followed by invasion of the bloodstream or organs, and systemic infections can be very serious indeed if they cannot be treated quickly by antimicrobial drugs. Although some *L. monocytogenes* infections are mild (gastrointestinal form or with a flu-like syndrome) and can occur without seeking medical aid, they can lead to life-threatening complications, such as septicemia, meningitis, encephalitis, osteomyelitis, and endocarditis. Early in pregnancy, a *Listeria* infection may lead to miscarriage, even if the mother is only mildly ill. Later in pregnancy, such an infection may lead to stillbirth, premature birth, or a potentially fatal infection in the baby after birth. Infants who survive a *Listeria* infection may experience long-term neurological damage and delayed development. Adults aged over 60 years can also be seriously affected by listeriosis, and death rates may be as high as 10–20% for this age group.

Enterohemorrhagic *E. coli* (EHEC) strains, which include *E. coli* O157:H7, produce verotoxin/Shiga toxin that can cause diarrhea, ranging from mild and nonbloody to stools that are virtually all blood but contain no fecal leukocytes. Complications of EHEC infection can include HUS and TTP. These are sometimes called sequelae but are really a continuation of the virulence factors of the *E. coli*, for example, it takes time for kidney damage to be apparent compared with HC and bloody diarrhea. HUS is characterized by the acute onset of microangiopathic hemolytic anemia (loss of blood through small blood vessels), renal injury, and low platelet count. TTP also is characterized by these features but can include CNS involvement and fever and may have a more gradual onset. Most cases of HUS occur after acute diarrhea, often bloody. Antibiotic treatment of *E. coli* O157:H7 colitis may, in fact, stimulate further verotoxin/Shiga toxin production. This will increase the risk of HUS, which is a potential life-threatening condition and can induce hypertension, proteinuria, and chronic renal failure in 5% of affected patients. After exposure to VTEC/STEC, 38–61% of individuals develop HC and 3–9% (in sporadic infections) to 20% (in outbreaks) progress to overt HUS. The overall incidence of HUS is estimated to be 2.1 cases per 100 000 persons per year, with a peak incidence in children who are younger than 5 years (6.1 per 100 000 per year), and the lowest rate in adults who are 50–59 years of age (0.5 per 100 000 per year). A Canadian prospective study showed an annual incidence of 1.11 cases of diarrhea-associated HUS per 100 000 children under the age of 16 years. The provinces of Ontario, Quebec, and Alberta, respectively, accounted for 40%, 31%, and 18% of the cases. The mortality rate was 4%, and 34% for children who underwent dialysis for a median of 12 days (range 2–60 days). Individuals in countries where rare or undercooked beef is commonly consumed are at greater risk for HUS following *E. coli* infections. There are approximately 400 new cases of HUS per year in Argentina, the country with the highest incidence in the world. In the acute phase, mortality in children is 2–4%.

HUS has been associated with *E. coli* O157:H7 outbreaks in nursing homes, child care centers, and schools. Major vehicles of infection include ground beef, unpasteurized milk and juice, sprouts, leafy greens, and salami. Waterborne transmission occurs through swimming in contaminated lakes or pools, or through contaminated water. Because low numbers of organisms can cause infection, EHEC is easily transmitted from person-to-person and has been difficult to control in child care centers. From 1982 to 2002 in the USA, the HUS case rate was significantly higher among ground beef-associated outbreaks compared with all other foodborne outbreaks (5.5 vs. 2.5). In the large multistate hamburger outbreak of 1992–93, there were 589 cases of which 41 (7%) developed HUS. In more recent outbreak scenarios, HUS occurs in a higher proportion of cases. One example is the *E. coli* O157:H7 spinach outbreak of 2006 where 205 cases were reported in many states and Canada; 103 were hospitalized, 31 developed HUS (30.1%), and 3 died. The percentage of case patients in whom HUS developed (29%) was high compared to previous *E. coli* O157:H7 outbreaks (15–20%). This finding is consistent with studies that associate *E. coli* expressing Shiga toxin 2 with a higher incidence of HUS. HUS is reported not only from outbreaks caused by O157 serotype but also other VTEC/STEC serotype events as well. In an outbreak in Belgium in 2007, O145 and *E. coli* O26 infections occurred among consumers of ice cream produced at a farm. Five children, ranging in age from 2 to 11 years, developed HUS, and seven other coexposed persons contracted severe diarrhea. In three of the five HUS cases, VTEC O145 infections were laboratory confirmed, one in association with VTEC O26. Identical isolates of *E. coli* O145 and O26 were detected in fecal samples of patients and in ice cream leftovers from one of the birthday parties, and on the farm. The ice cream was made from pasteurized milk and was most likely contaminated by a food worker. A secondary consequence of HUS and kidney dialysis is the risk of diabetes, either shortly after HUS is diagnosed or many years later. The toxin can damage the insulin-producing cells in the pancreas and cause an insulin deficiency.

Infections caused by *V. vulnificus* may present as fulminate septicemia, decreased blood pressure (septic shock), often complicated with necrotizing cutaneous lesions. Wound infections can also cause septicemia. The case-fatality rate for patients with preexisting liver disease is more than 50%. Antibiotic therapy is usually successful in limited systemic infections, but the high mortality associated with this septicemia suggests susceptible individuals should be forewarned about eating raw shellfish.

Anthrax most commonly occurs in animals such as pigs, cattle, horses, and goats, but it can also infect people through skin contact with the spores (cutaneous anthrax), by inhaling the spores (pulmonary anthrax), or by eating meat that contains the spores (intestinal anthrax). Symptoms of intestinal anthrax appear in approximately 1–7 days, with severe abdominal pain, nausea, vomiting, severe diarrhea, and bleeding from the gastrointestinal tract (stomach and intestines). If the symptoms are not treated quickly, septicemia may follow with

possibly meningitis and pneumonia. Intestinal anthrax has a fatality rate of 25–60%. Certain regions of the world (South and Central America, Southern and Eastern Europe, Asia, Africa, the Caribbean, and the Middle East) report more anthrax in animals than others. For instance, an outbreak of anthrax killed at least 1500 wild game animals in nature preserves in southeastern Zimbabwe in 2009, and at least 83 hippopotamuses in a popular Ugandan game park in 2010. Natural anthrax is endemic in these and many other countries, including Canada and the USA, where the spores can live for decades in dry soil and be ingested by animals ruminating for remnants of vegetation in the driest months. Most human foodborne anthrax cases come from persons scavenging carcasses of animals that have died of anthrax such as described above with the meat consumed either raw or after minimal cooking. In 2010, an outbreak of anthrax in Bangladesh among hundreds of cows infected more than 500 people. The disease spread due to the slaughtering of infected cows from which the meat was sold and consumed. Vaccination of cattle was being carried out to contain the outbreak.

Brucellosis is an important zoonosis and a significant cause of reproductive losses in animals. In domestic livestock, it is caused by *Brucella abortus* (cattle), *Brucella melitensis* or *Brucella ovis* (sheep and goats), and *Brucella suis* (pigs). In humans, brucellosis causes undulant fever and other serious, debilitating, and sometimes chronic infections. Most cases are caused by occupational exposure to infected animals or the ingestion of unpasteurized dairy products. In the USA, *B. suis* has been eliminated from commercial pigs and *B. abortus* has nearly been eradicated from domesticated ruminants. In many patients, the symptoms last for 2–4 weeks and are followed by spontaneous recovery. Others develop an intermittent fever and other persistent symptoms that typically wax and wane at 2- to 14-day intervals. Most people with this undulant form recover completely in 3–12 months. A few patients become chronically ill.

For persons infected with *T. solium*, the pork tapeworm, after eating infected pork that has been undercooked, nearly 250 000 ova are passed daily from human feces to the environment. Cysticercosis is a systemic infection that results from ingesting the eggs of *Taenia*. The eggs are usually found in fecally contaminated water or food. Other possible routes are through autoinfection as a result of the entry of eggs into the stomach by retroperistalsis (reverse peristalsis) or as a result of accidental ingestion of eggs from the host's own fecally contaminated hands. Humans, in this case, are intermediate hosts. Ova are digested in the stomach and release oncospheres that penetrate the intestinal wall to reach the bloodstream. These oncospheres develop into cysticerci in any organ but are common in brain, subcutaneous tissue, or the eyes. The cysticerci become mature and viable approximately 2 months after egg ingestion, and can persist for more than 10 years without any apparent symptoms. Although most brain infections remain asymptomatic, much later, intense inflammation is provoked around the degenerating and calcified cyst, and can result in persistent headaches, seizures, and altered mental status (neurocysticercosis). Cysticercosis is highly endemic in Central and South America, and some parts of Africa and Asia. In Latin America, an estimated 75 million persons live in endemic areas and 400 000 people have symptomatic disease. In the USA, the disease is found in immigrants from Mexico, Central and South America.

Cholangiohepatitis, or recurrent pyogenic cholangitis (RPC), is characterized by a recurrent syndrome of bacterial cholangitis that occurs in association with intrahepatic pigment stones and intrahepatic biliary obstruction. Infection in the biliary system from the parasitic nematode, *Ascaris lumbricoides*, or from trematodes, such as liver flukes *Clonorchis sinensis* and *O. viverrini*, often results in significant epithelial damage. These flukes reside in the peripheral small bile ducts of the liver and produce chronic inflammation of the bile duct, bile duct dilatation, mechanical obstruction, and bile duct wall thickening. Coliforms may then result in portal bacteremia by bacterial translocation as a result of this epithelial damage. Repeated portal bacteremia may cause biliary stasis, obstruction, and stone formation from deficient glucuronidation as a consequence of extreme malnutrition, which consequently creates conditions for RPC. These flukes also are potentially carcinogenic to humans. Human infection of *F. hepatica* allow the flukes to migrate in the liver (hepatic phase) and reside in the bile ducts (biliary phase). In areas of endemic infection, more clonorchiasis cases are now diagnosed incidentally during radiological examinations and there is increasing evidence for links between clonorchiasis and cholangiocarcinoma, especially where there is chronic infection.

Autoimmune Sequelae to Gastrointestinal Infections

Infections from enteric bacteria may give rise to a number of chronic joint diseases which include reactive arthritis, Reiter's syndrome, and ankylosing spondylitis. It is the elevated antibody levels to these organisms generated during the infection that lead to these sequelae. Case reports and outbreak investigations have demonstrated an association between reactive arthritis and infection with *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* species with a frequency of reactive arthritis ranging from 1% to 21%. Symptoms commonly begin approximately 7–30 days after an intestinal illness. The knees and ankles are often affected but also other joints. The duration of symptoms varies considerably but, in most individuals, they subside in less than 6 months. However, some individuals may take in excess of 1 year to recover fully, and a significant portion of affected persons suffer persistent or relapsing illnesses. In addition to environmental factors, a human leukocyte antigen (HLA)-B27 genotype is a predisposing factor in over two-thirds of patients with reactive arthritis. Unfortunately, the use of antibiotics in these patients has not been shown to be effective. Initial treatment consists of high doses of potent nonsteroidal anti-inflammatory drugs.

Some large outbreaks have been followed up to identify cases with prolonged arthritis.

In 1984, in Ontario, Canada, an outbreak of *Sa*. Typhimurium occurred among police officers who were serving as security guards on routes during a papal visit; they had eaten meat sandwiches provided by a caterer when they were on duty. Of the 1608 police officers involved, 432 experienced acute gastroenteritis. Within 3 months following the outbreak, 27 (6.4%) of these officers had developed acute arthritis,

which resolved in 9 of them over the next 4 months. The remaining 18 officers had recurrent symptoms or developed reactive arthritis on reevaluation 5 years later. Four were so incapacitated they had to change their employment. Both HLA-B27 and HLA cross-reactive group antigens were risk factors for the arthritis. In 2000, a large waterborne outbreak occurred in Walkerton, Ontario, with over 2300 people suffering from acute gastroenteritis caused by *E. coli* O157:H7 and *Campylobacter*; there were 27 cases of HUS and 6 deaths. After a followup study 4.5 years after the outbreak with most of the Walkerton population participating but excluding those with a known history of arthritis, arthritic conditions were reported in 15.7% of participants who had been asymptomatic during the outbreak, and in 17.6% and 21.6% of those who had moderate and severe symptoms of acute gastroenteritis, respectively. Compared with the asymptomatic participants, those with moderate and severe symptoms of gastroenteritis had an adjusted relative risk of arthritis of 1.19 and 1.33, respectively. No association was observed between gastroenteritis and the subsequent risk of prescription medication for arthritis. In nonoutbreak cases involving persons aged >1 year with culture-confirmed *Campylobacter*, *E. coli* O157, *Salmonella*, *Shigella*, and *Yersinia* infections in two US states between 2002 and 2004, 4468 were interviewed within 8 weeks of specimen collection. Of these, 575 (13%) developed possible reactive arthritis; incidence was highest following *Campylobacter* (2.1/100 000) and *Salmonella* (1.4/100 000) infections. Risk was greater for females, adults, and subjects with severe acute illness, for example, fever, chills, headache, and persistent diarrhea. Risk was not associated with antibiotic use or HLA-B27. A total of 54 (66%) of 82 subjects examined had confirmed reactive arthritis. Enthesitis (inflammation of the ligamentous attachments to the bone) was the most frequent finding; arthritis was less common. Complications of *Campylobacter* infections apart from GBS are rare, but the infections may be followed by the development of reactive arthritis. In 2002–03, Danish researchers surveyed 1339 patients with *Campylobacter* infections, and 171 (19.9%) reported joint pain. Interestingly, complaints of joint pain were not associated with duration of diarrhea, and the prevalence of HLA-B27 antigen was 11.6% in patients with joint pain compared with 6.5% in patients with gastroenteritis only. In another study in Finland, 7% developed *Campylobacter*-triggered reactive arthritis; HLA-B27 was positive in 14% of reactive arthritis patients. In Scandinavia, where *Yersinia* infections are relatively common, *Y. pseudotuberculosis* serotype O:3 infection is frequently associated with reactive arthritis and the clinical picture is severe.

GBS is the most common cause of acute flaccid paralysis. GBS is an autoimmune disorder of the peripheral nervous system characterized by weakness and numbness in the extremities, evolving over a period of several days or weeks; it can eventually paralyze the entire body. Typically, an ascending paralysis occurs, with weakness in the legs spreading to the upper limbs and the face along with complete loss of deep tendon reflexes. Muscles may become so weak that patients need to be put on a ventilator, to allow proper breathing, or be fed through a tube into the stomach because swallowing is not possible. Symptoms are often worst during the first 2 or 3 weeks. With prompt treatment by plasmapheresis or intravenous immunoglobulins and supportive care, the majority of patients regain full functional capacity, but even without any treatment most people eventually recover completely. However, in some cases, the effects are seemingly permanent and can cause premature death; 3–10% of patients die and 20% are still unable to walk after 6 months, and many have pain and fatigue that can persist for months or years. GBS is typically preceded by a *Campylobacter* infection. Basically, the body's immune system reacting to the infection attacks the myelin sheaths protecting the nerves, and this interferes with the way that nerves send signals between the body and brain. *Campylobacter* is associated with several pathological types of GBS, including the demyelinating (acute inflammatory demyelinating polyneuropathy) and axonal (acute motor axonal neuropathy) forms. Different strains of *Campylobacter* as well as host factors likely play an important role in determining who develops GBS as well as the nerve targets for the host immune attack of peripheral nerves. GBS is unlike other disorders such as multiple sclerosis and Lou Gehrig's disease, and does not generally cause nerve damage to the brain or spinal cord. Although GBS cases have occurred following *Campylobacter* outbreaks from raw milk and water, most diagnosed *Campylobacter* cases are sporadic with no known vehicle association. So, the burden of GBS relating to campylobacteriosis has relied on a few extensive epidemiological investigations. For instance, a Swedish study with patient data from 1987 to 1995 showed that the risk of developing GBS during the 2 months following a symptomatic episode of *Ca. jejuni* infection (30.4 per 100 000) was approximately 100 times higher than the risk in the general population. (0.3 per 100 000). A similar study in the UK from 1991 to 2001 indicated that the incidence of GBS in a cohort of patients presenting with *Campylobacter* enteritis (11.7 per 100 000) was 77 times greater than that in the general population (<0.2 per 100 000).

Glossary

Dose–response assessment The determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response).

Exposure assessment The qualitative and/or quantitative evaluation of the likely intake of biological, chemical, and physical agents via food as well as exposures from other sources if relevant.

Food additive Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include 'contaminants' or substances added to food for maintaining or improving nutritional qualities.

Hazard A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.

Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents which may be present in food. For chemical agents, a dose–response assessment should be performed. For biological or physical agents, a dose–response assessment should be performed if the data are obtainable.

Pesticide Any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production, storage, transport, distribution and processing of food, agricultural commodities, or animal feeds or which may be administered to animals for the control of ectoparasites. The term includes substances intended for use as a plant growth regulator, defoliant, desiccant, fruit-thinning agent, or sprouting inhibitor and substances applied to crops either before or after harvest to protect the commodity from deterioration during storage and transport. The term normally excludes fertilizers, plant and animal nutrients, food additives, and animal drugs.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Risk analysis A process consisting of three components: risk assessment, risk management, and risk communication.

Risk assessment A scientifically based process consisting of the following steps: (1) hazard identification, (2) hazard characterization, (3) exposure assessment, and (4) risk characterization.

Veterinary drug Any substance applied or administered to any food-producing animal, such as meat- or milk-producing animals, poultry, fish, or bees, whether used for therapeutic, prophylactic, or diagnostic purposes or for the modification of physiological functions or behavior.

Introduction

This overview will cover chemical and physical hazards that may be present in food. It will also cover some miscellaneous hazards that pose risks through novel mechanisms. Chemicals present the largest group of hazards, because, in principle, all chemical compounds in existence in the natural world would be included as they all possess a degree of acute toxicity. In addition to these, hundreds of thousands of totally new chemicals have been synthesized, some of which are manufactured in large quantities. In reducing this universe of possibilities to a practical size, this overview will focus only on chemicals that are likely to be present in food. These include chemicals intentionally added to food (food additive, veterinary drugs, and pesticides) and those contaminants, which are known to pose potential health risks. Such contaminants represent a broad array of chemicals from organic to inorganic, from natural to man-made, from those known in antiquity to those discovered within the past decade. Also discussed are physical hazards that pose risks of injury, such as cutting or choking. Finally, short discussions of other categories of hazards are provided, including radiological and nutritional hazards.

Chemical Hazards

Unlike microbiological agents, which were only recognized as disease agents in the mid-1800s, the chemicals have long been known to cause illness and in some instances, death. Early hunter and gatherers were aware of poisonous plants and animals and some even devised methods to remove the toxic agent. In the first rational approach to chemicals, around 1450, the Swiss physician and alchemist Paracelsus elucidated his famous principle that states, "All things are poison, and nothing is without poison; only the dose permits something not to be poisonous." Or, more concisely, 'The dose makes the poison.' His insight earned him the recognition as the father of toxicology, but his work also laid the foundation for modern pharmaceutical science. Whereas every chemical poses some potential for causing acute toxicity, the potency, and nature of the adverse effect of chemicals vary markedly. For the vast majority of chemicals in the natural world, human exposures are far below levels that may cause any harm.

Although inhalation and dermal absorption can be important routes of exposure in some situations, ingestion of chemicals through food and drinking water is the most common route of chemical exposure for most populations. However, inhalation and dermal exposures as well as the ingestion of soil should be considered when such exposures might be significant, such as occupational exposure or proximity to an industrial pollution source.

Chemicals with Rapid Onset of Symptoms

Ingestion of a chemical in food may give rise to adverse effects rapidly, i.e., within hours or days (often referred to as poisons) or after some delay, i.e., months or years (chronic toxicants). When the onset of an adverse effect is short, the disease is commonly referred to as a 'food poisoning' or more properly, acute foodborne intoxication. Whereas inorganic chemicals, such as arsenic and mercury, often come to mind, the most toxic chemicals are those of biological origin. For example, botulinal neurotoxin is lethal at 1 ng per kg bodyweight and ricin is lethal at 10 μg per kg bodyweight. It might also be said that biotoxins are responsible for most of the cases of acute foodborne intoxications. For example, intoxications caused by the preformed toxins of *Staphylococcus aureus* and *Bacillus cereus* are common foodborne diseases in many countries. Note, however, that *S. aureus* and *B. cereus* are handled as biological hazards because prevention and control measures are focused on the organisms rather than on their toxins. In most cases, however, biotoxins, including those produced by plants and other organisms, are classified as chemical hazards.

Acute foodborne intoxications have been commonly reported throughout history. For example, ergot poisoning was common during the Middle Ages in Europe where it was called St. Anthony's Fire, because the toxin causes the extremities to atrophy, which feels like burning. The toxin is produced by the fungus *Claviceps purpurea* that grows on grain, and particularly rye. It was made famous because it is the precursor for the hallucinogenic drug lysergic acid diethylamide. Outbreaks were reported in Russia and England in the 1920s with the last documented outbreak of ergot poisoning in 1951 in France after a baker used contaminated rye flour to make bread resulting in 4 deaths and 200 cases of illness, some with permanent dementia. An intoxication of much greater impact occurred in Spain in 1981–82 when some 1000 people died and 25 000 were disabled, many permanently, after consuming an adulterated cooking oil that was sold door-to-door. Even today, acute outbreaks involving the misuse of organophosphate and carbamate pesticides are periodically reported. In addition, poisoning incidents caused by the intentional contamination of food have occurred, usually motivated by economic gain (adulteration) coupled with ignorance. Mass food poisonings perpetrated by terrorists and other disgruntled persons have also occurred and remain serious concerns. Although mentioned here in the context of chemicals, it should be noted that these concerns extend to other types of hazards, including biological and physical agents.

Following Paracelsus' principle, all chemicals possess the potential to cause acute toxicity and disease. This inherent toxic property or potency varies by several orders of magnitude. The most potent toxins are usually in the category of fast poisons and only small doses required to produce adverse effects. One measure of toxic potency is the lethal dose 50 (LD 50), which is the amount of a chemical that causes death in 50% of the animals treated, and is expressed on mg per kg bodyweight basis. However straightforward the experiment might appear, death is not a clear universal endpoint, but rather the result of one or more underlying adverse health effects. For example, different chemicals are known to exert their main toxic effects on different target organs. Furthermore, some adverse effects may be reversible, whereas others may be irreversible resulting in delayed injury and disease. Consequently, the LD 50 is only a crude measure of toxicity and other tests, including *in vitro* tests, may be more useful. In this regard, it has been recognized that certain pesticides might manifest acute intoxications in the dose ranges that can in exceptional cases be found on food. To evaluate this potential, risk assessors have developed the acute reference dose (ARfD) as a metric for assessing the health risk of short-term, high-level exposures to pesticide residues on food. However, the approach can be used for contaminants and other chemicals as well. The ARfD is the amount of a chemical that can be ingested within 24 h or less without any adverse effect, expressed on mg per kg bodyweight per day basis. *In vivo* and *in vitro* testing requirements have been developed. It should be noted, however, that chemicals often have more than one adverse effect and that, in principle, the need to establish an ARfD should be assessed for each effect. Another important distinction is the exposure assessment to the chemical that has to be performed to take into account high consumers, usually those in the 97.5th percentile. Similarly, residue concentrations used to determine exposure should also reflect the higher range of residue distributions.

Finally, the topic of food allergies should be mentioned under 'fast poisons' because often the reaction to an allergen is rapid. Chemical components, especially proteins, of many common foods, for example, eggs, milk, fish, shellfish, nuts, legumes, and cereals, may give rise to allergic reactions in many individuals. For those that are sensitive, the immune response to even the minutest exposure may produce life-threatening anaphylactic shock. Owing to the broad range of individual

sensitivities, a safe level cannot be established; therefore labeling of processed food to warn sensitive consumers has been widely adopted. In regard to the use of new biotechnology, the possible introduction of allergenic proteins is explicitly addressed during the safety review process.

Chemicals with Delayed Onset of Symptoms

The natural response to the presence of overt poisons in the food supply resulted in the banning of acutely toxic chemicals from the food supply. However, such lists were not without controversy. In the US, boric acid was banned for use in food in the early 1900s. However, a major debate erupted over the possible banning of sodium benzoate, a preservative that is still widely used today. Whereas such negative lists have their place and are still maintained in many countries, a more proactive precautionary approach was developed using a positive list of permitted chemicals as the basis for assuring that chemicals added to food were safe. During this time, however, safety largely meant the absence of acute effects. The possible delayed effects from long-term low-level exposure were not generally considered. Beginning in the 1960s, concern for chemicals in food started to focus on the health risks posed by such chronic exposures. Diseases, especially cancer, that might be caused by low-level exposure to a chemical, were perceived by the public as particularly insidious, because they could not be detected with the senses and adverse effects might not be manifested for months, years, or even decades later. Given this time gap, public health authorities were in the difficult position of trying to retrospectively establish clear links between exposure to a chemical and a disease outcome. This was further complicated because it is often difficult to exclude other concurrent sources of exposure such as those from air and water.

In view of these difficulties, laboratory animals were used as surrogates for human exposure, although not without its own limitations and controversy. In most developed countries today, before any chemical may be used in food, subchronic (usually 90 days studies) and often chronic studies (usually lifetime studies in rats and mice) as well as certain specialized studies, such as developmental studies, are required. Based on a review of all available toxicological data from animal and human studies, the maximum amount of a chemical that has no demonstrable adverse health effect is estimated, which is referred to as the no-observed-adverse-effect level (NOAEL). Because of the uncertainty in extrapolating from animals to human and variability in the human population, a safety/uncertainty factor of 100 is used to determine the acceptable daily intake (ADI) for the food chemical, which is the amount that can be consumed daily over a lifetime with no appreciable risk to health. These studies have mostly been supported by the food industry, which was required to obtain approval from food safety authorities before these chemicals could be marketed. The ADI has been the 'gold standard' for safety, applied to food additives, pesticides, and veterinary drugs and has served to protect public health for over the past 50 years. During the past decades, a lot of scientific advances and improvements to the ADI process have been undertaken by applying more dose–response modeling to determine a benchmark dose (BMD) to refine the NOAEL approach and to use the data-driven safety/uncertainty factors instead of the 100-fold default.

However, the determination of safety levels for chemical contaminants, which are naturally present or inadvertently find their way into food, have been the responsibility of governments. Besides toxicological information from experimental animal studies, contaminants that are present in the food supply may be subject to epidemiological studies to elucidate their adverse effects on health and take their toxic potencies into account. For example, the potency of aflatoxin B_1 to induce heptocellular carcinoma in human has been derived from long-term population studies in China. However, for most chemical contaminants, the evidence base is less than adequate and consequently, the health reference value used is the PTWI, in which 'P' means provisional because the value is subject to revision with new data, 'T' means tolerable because safety margins are often less than 100-fold used for food additives, 'W' stands for weekly in recognition that a contaminant may accumulate in the body, and 'I' stands for intake, which used here is equivalent to the term 'exposure,' which is the preferred risk assessment terminology. Depending on the half-life of the contaminant in the body, similar health guidance values for daily or monthly intake can also be established, such as the provisional tolerable daily intake (PTDI) and provisional tolerable monthly intake (PTMI), respectively.

For some contaminants where NOAELs cannot be established, another risk assessment approach has been developed. This relies on dose–response modeling to establish a BMD at lower confidence limit (BMDL), which is then compared to the estimated human exposure. The ratio of the BMDL to the estimated exposure is called the margin of exposure (MOE) and has been used for the risk assessment of several genotoxic carcinogens, such as acrylamide, polycyclic aromatic hydrocarbons (PAHs), ethyl carbamate, and arsenic, as well as the neurotoxin lead.

In the following sections, some of the major classes of chemicals with safety implications in food are briefly reviewed, with more detailed discussions appearing in the relevant articles in other parts of this Encyclopedia.

Food Additives

A food additive is a chemical added directly to food to improve their quality, safety, sensory qualities, and certain other properties. Another type of food additive (indirect) is incidentally added to food as a result of their use in other applications, such as lubricants for food- processing machinery and boiler water additives to reduce scaling. Food additives may be natural or synthetic, but are otherwise subject to a demonstration of safety before they can be used. Some of these, by virtue of their long history of use in food or their low inherent toxicity, are generally recognized as safe and are exempt from testing. However, excessive consumption of some traditional preservatives, such as salt, nitrites, and smoke curing, are now considered to be risk factors for certain diseases, such as hypertension and cancer.

Food additives are more specifically defined by the *Codex Alimentarius* as "any substance not normally consumed as a

food in itself and not normally used as a characteristic ingredient of food whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport, or storage of such food results, or may be reasonably expected to result in it or its by-products becoming directly or indirectly a component of such foods.'' Some additives have been used for centuries, such as vinegar, salt, or sulfur dioxide for preservation purposes. Curing or smoking of meats also has a long history of use. However, in the twentieth century many more additives were developed and used for such uses as preservatives, flavor enhancers, anticaking and antifoaming agents, antioxidants, bulking agents, food coloring, emulsifiers, humectants, propellants, stabilizers, gelling agents, and sweeteners.

Before they can be approved for use today, all food additives must have a demonstrated useful purpose and undergo a rigorous scientific safety evaluation by appropriate national authorities such as the European Food Safety Authority (EFSA), US Food and Drug Administration, and Health Canada. At an international level the Joint FAO/WHO Expert Committee on Food Additives (JECFA) has been evaluating the safety of food additives since 1956. It should be noted, however, that as new data becomes available, a reevaluation of a food additive might be warranted as in the case of certain colors. In addition, consumer reports of adverse reactions might also trigger a reevaluation, for example, in the case of monosodium glutamate.

The illegal use of banned or unapproved substances used as additives, such as boric acid and certain textile dyes, continues to be a problem in many developing countries. In some cases, the use of unapproved substance in a product that is in turn used as an ingredient in other food may result in global recalls, as was the case of the adulteration of chili peppers with the unapproved textile dye Sudan Red 1, which resulted in the recall of hundreds of food products.

Veterinary Drug Residues

Veterinary pharmaceuticals have been a key element in increasing the production of animal-derived foods. These are administered to animals to prevent and treat infections, promote growth, or otherwise improve animal health, particularly for those animals that are in close contact over long periods of time. These animals tend to be stressed and are more at risk for communicable diseases. When these compounds are administered to food-producing animals, residues may be present in milk, eggs, or other edible tissues. Unless they are degraded to endogenous chemicals, most of these drug residues are of potential toxicological concern and their presence in food products may produce pharmacological or other effects in consumers. Consequently, veterinary pharmaceuticals used in food-producing animals must undergo not only testing similar to food additives mentioned above but also include studies in the target animal, such as metabolism and elimination studies, often using radiolabeled drug. Once a safe level of the drug and its residues in food is established, unsafe residue levels are avoided by using prescribed treatment protocols, especially allowing sufficient time after treatment for the compounds to be depleted from the animal, i.e., withdrawal period to the established maximum residue limit (MRL).

The use of antibiotics to promote weight gain and to improve feed efficiency has been shown to contribute to problems with an increase in antibiotic-resistant microorganisms. Therefore there is an increasing trend by more and more countries to not approve this specific use for antibiotics that are important for human medicine. Another issue that has raised trade problems is the use of growth and other hormones. These are widely used in some parts of the world, especially in ruminants, to increase muscle tissue, i.e., faster and leaner growth. Another controversial drug is recombinant bovine somatotropin (rBST) hormone, which is made using new biotechnology methods. The hormone is capable of increasing milk production by 10–40% as it does not require 'freshening' the cow through pregnancy. JECFA has confirmed the safety of several anabolics, such as 17β-estradiol, trenbolone, melengestrol, and zeranol, and the protein hormone rBST, and concluded that, under good agricultural and veterinary practices, such substances do not present an appreciable risk to the consumer. A number of countries and notably the European Union still oppose their use in food-producing animals because of alleged human and animal health concerns.

As with food additives, illegal and uncontrolled treatment of food animals with veterinary drugs present is periodically detected. Examples are nitrofurans in poultry and egg powder, chloramphenicol in shrimps and honey, malachite green in salmon and other aquaculture fish, and clenbuterol in pork and other meat. In some countries, the use of clenbuterol in pigs and other food animals to keep their meat lean is widespread and occasional illnesses associated with the consumption of treated meat have been reported. Continued monitoring is therefore necessary to ensure that only approved veterinary drugs are used and that permitted doses and withdrawal periods are observed.

Pesticide Residues

The term pesticide includes insecticides, fungicides, rodenticides, insect repellants, herbicides, antimicrobials, and plant hormones. However, most food safety concerns are directed toward those chemicals, which are designed to prevent, destroy, repel, or reduce insects on food crops, as well as on food-producing animals. More recently, the use of certain herbicides in connection with genetically modified food crops has raised food safety concerns. Many countries have agencies other than health responsible for the approval of pesticides, such as the Environmental Protection Agency in the US, the Pest Management Regulatory Agency in Canada, and the Pesticides and Veterinary Medicines Authority in Australia. At the international level, the evaluation of pesticides is carried out by the Joint FAO/WHO Expert Meeting on Pesticide Residues (JMPR). Before a proposed pesticide can be marketed and used, it is evaluated to ensure that it will not harm human health. Pesticides that pass this evaluation are subject to good agricultural practices, usually including observance of withdrawal periods after application. This is intended to allow residues to deplete to the established maximum residue limit (MRL), which is set for each treated food commodity. If residues are found above that level, the commodity could be subject to

seizure by the government. In setting such limits, there must be a safety finding that the pesticide can be used with reasonable certainty of no harm by considering the toxicity of the pesticide and its breakdown products; how much of the pesticide is applied and how often; and how much of the pesticide residue remains in or on food by the time it is marketed and prepared. Typically, MRLs apply equally to domestic and imported food but many countries will now use the Codex MRL for an imported food in cases where the Codex MRL is higher than the national MRL.

The reported effects of pesticides range from mild and reversible effects to immunotoxicity, teratogenicity, carcinogenicity, and acute fatal poisoning. Some pesticides have raised consumer concerns because of their adverse impact on the environment. For example, the organochlorine compounds, like DDT, aldrin, heptachlor, and others, were widely used in agriculture resulting in a disastrous bioaccumulation in birds (see Rachel Carson's 'Silent Spring') as well as posing threats to other life forms on the planet, including humans. With increased government scrutiny covering both approval and monitoring, the health risks from pesticide residues in food now appear minimal. Routine monitoring of commodities for compliance with MRLs, mainly in developed countries, has indicated a low frequency of exceedences. For example, in 2007, the EFSA found that 96% of the 74 000 samples of almost 350 different food types complied with legal MRLs. In many developed countries, total diet studies have shown that virtually all pesticide residue exposures are well within safe levels.

In a number of situations, however, foods have been found to contain high levels of pesticide residues, for example, when the crops had been harvested too soon after the application of pesticides or when excessive amounts of pesticides had been applied through ignorance or incompetence. Sometimes food has been contaminated because of accidental contact with pesticides during storage or transport. Indirect information suggests that consumers in developing countries may be frequently exposed to higher than approved levels of pesticides in their diets. For example, the large number of acute poisonings among agricultural workers implies a poor knowledge of the handling and application of pesticides. Limited monitoring of data on food imported from developing countries indicate that these foods are sometimes highly contaminated. In addition, biomonitoring of organochlorine pesticide residues in breast milk in developing countries provides further evidence of significant cumulative exposure to these chemicals. However, it should be noted that although DDT is banned in all countries for agricultural use, in many tropical locations, DDT is still legally used for indoor spraying of houses to control malaria.

Although organochlorine pesticides were banned because of their environmental persistence, the use of cholinesterase-inhibiting pesticides (organophosphates and carbamates) expanded significantly. Although their rapid degradation reduced their long-term risk, the acute risk to farm workers and consumers has raised new issues, which are now being addressed. Most of these compounds, as expected, have relatively low ARfDs, which means that excessive residues may pose imminent risks to health. In addition, the regulation of such pesticides on an individual basis ignored the possibility of multiple residues occurring on the same commodity, which has been detected in monitoring programs. Therefore, the methodology for cumulative hazard characterization and exposure assessment is under development. At the same time, the possibility of aggregate exposure has also been raised because many of these pesticides are also used at home for pest control.

Environmental Contaminants

Heavy Metals

Heavy metals are stable elements that are slowly metabolized by the body and therefore tend to bioaccumulate. Most of these metals do not have any basic function in the body but can be highly toxic. If the heavy metals accumulate in the body tissues faster than the body's detoxification processes, a gradual build-up of these occur to block essential enzymatic reactions. These metals include lead, mercury, arsenic, and cadmium. Metals are released into the environment by both natural and anthropogenic sources. Most are released into the environment by mining and industrial processing. These toxic metals may leach into underground waters, moving along water pathways and eventually depositing in aquifers, or accumulate in surface waters resulting in water and subsequently soil pollution.

Lead

Although children have been exposed to lead from the ingestion of soil, i.e., pica, the main exposure of the general population is through food and drinking water. Lead affects the hematopoetic, nervous, and renal systems. It has been shown to reduce mental development in children in a dose-related manner with no defined threshold. When lead pipes or lead-soldered water storage tanks are used, the lead exposure from such water may be appreciable. Similarly, processed food and beverages may be contaminated by lead in pipes or other equipment. Food packed in lead-soldered cans may also contain significant amounts of lead and such cans can still be found in some developing countries. During recent years, many countries, especially the industrialized ones, have initiated efforts to reduce lead in drinking water systems and food equipment and containers and these efforts have led to a significant decrease in lead exposure. The elimination of lead-containing additives in gasoline also resulted in the elimination of lead contamination of foods grown along the motorways as well as reducing airborne exposure. Lead may also be found in leaded crystal glassware and some highly colored ceramic or old ceramic dishes. Spices occasionally have been implicated as lead sources, and lead is sometimes added to certain ethnic foods or food supplements to impart a yellow or orange color, a sweet taste, or to increase the weight of the product.

Mercury

Although there are several natural sources of mercury including volcanoes and leaching from rocks, most mercury is anthropogenic in origin, arising from industrial processes like coal burning for power generation, gold mining, alkali and metal processing, and in the past, production of pulp and paper. Mercury is converted to the more toxic methylmercury

through bacterial action, where it is taken up by small aquatic plant and animal species. It bioaccumulates by binding to protein and is biomagnified up the food chain. Although fish are the most common dietary source of mercury (mainly as methylmercury), food containing high fructose corn syrup (HFCS) is another possible source if the HFCS was made using caustic soda containing traces of mercury.

Methylmercury, the most toxic form of mercury, has been shown to have serious effects on the nervous system, which in severe cases, is irreversible. The fetus, infants, and young children are particularly sensitive. The most well-known incident of methylmercury intoxication occurred in the Minamata Bay, Japan, in the late 1950s and was caused by the industrial discharge of mercury-containing compounds. These were subsequently taken up by fish and shellfish and consumed by the local population. In general, fish are usually the major dietary source of methylmercury although certain marine mammals, such as dolphins and whales, can also contain high levels. Therefore, several countries have recommended that pregnant women choose fish that are low in methylmercury, but high in omega fatty acids, such as sardines and salmon.

Arsenic

Arsenic is a potent toxin, which interacts with many essential biomolecules in the body, including deoxyribonucleic acid. Over 137 million people in more than 70 countries are probably affected by arsenic poisoning of drinking water with at least 20 incidents of groundwater arsenic contamination being reported from all over the world. Four major incidents were reported in Asia, including locations in Thailand and China. However, the construction of shallow wells tapping into contaminated groundwater in Bangladesh caused the largest poisoning of a population in history, with 35–77 million people exposed. However, arsenic in groundwater is not confined to the developing regions; groundwater in many parts of the US and Europe contains relatively high levels of arsenic.

Away from areas with significantly contaminated drinking water, food is the major source of arsenic. Arsenic and its compounds are often found in food, as they are absorbed from the soil by plants, such as rice, wheat, and oats. In most cases, arsenic is in the form of organic arsenic, which has been estimated to be some 500 times less toxic than the inorganic form. Limited data indicate that approximately 25% of the arsenic present in food is inorganic, but this depends highly on the type of food ingested. Inorganic arsenic levels in fish and shellfish are low ($<1\%$). Foodstuffs such as meat, poultry, dairy products, and cereals can contain higher levels of inorganic arsenic. In cereals, arsenic is concentrated in the bran and consequently, certain whole grain foods, including complementary food for infants may contain arsenic. The tolerable daily intake for inorganic arsenic set by the JECFA at 2 μg per kg bodyweight was withdrawn earlier in 2011 amid growing evidence that arsenic can cause cancer even at low levels.

Cadmium

Cadmium occurs naturally and is often present in volcanic soils. Some soils have been contaminated with cadmium through the use of bird guano as fertilizers. Cadmium also occurs as an industrial pollutant, which is released into the air from waste sites and incinerators and through effluents from industrial processes. Inappropriate disposal of cadmium-containing batteries is now a major source of contamination in developed countries. Cigarette smoking is the single most important source of human exposure for the general population. The first case of mass cadmium poisoning was documented in Japan in the1950s, caused by contaminated rice that was irrigated with water contaminated with effluent-containing cadmium. The disease was known as Itai-itai disease (literally, ouch-ouch disease) because of the severe pain in the joints and the spine that it produces. More typically, chronic low-level exposure to cadmium is associated with renal failure because cadmium can accumulate in the kidney over a lifetime. Whereas molluscs and especially oysters contain the highest levels of cadmium, consumption of grains results in the highest exposure because of the larger amounts consumed. Present estimated mean dietary intakes of cadmium for most populations are within its PTWI, but some high-percentile consumers may exceed this limit.

Other Metals

There are many other metals that may be of concern at high levels but are less likely to be associated with food exposure to cause chronic illness. These include aluminum, antimony, bismuth, cerium, chromium, cobalt, copper, gallium, gold, iron, manganese, nickel, platinum, silver, tellurium, thallium, tin, uranium, vanadium, and zinc. Metal toxicity can result in reduced mental and central nervous system function; lower energy levels; damage to organs including kidneys, liver, and lungs; and degenerative diseases that mimic Alzheimer's disease, Parkinson's disease, muscular dystrophy, and multiple sclerosis. Of these, aluminum is perhaps of greatest concern because recent toxicity studies have indicated that aluminum is much more toxic than previously thought. Note that some metals listed above, such as iron, manganese, and zinc, have, at low levels, essential biological functions.

Polychlorinated Biphenyls (PCBs)

PCBs are a group of anthropogenic chemicals with 209 congeners first manufactured in the 1920s, and are now banned worldwide because they are hazardous, persistent, and bioaccumulative chemicals. Classified as persistent organic pollutants (POPs), PCBs are included in the Stockholm Convention on POPs that was adopted to eliminate the production and emission of these and related chemicals. Most commercial mixtures are clear, viscous liquids with high boiling points and high dielectric constants. They were used widely as coolants in transformers and capacitors, as heat exchange fluids, and as flame-retardants as well as other uses. Discharges from industrial operation over many years have occurred in several countries including, former Czechoslovakia, Japan, and the USA. Although no longer produced, sources today include old or fluorescent lighting transformers, electrical devices, and appliances containing PCB capacitors. Because high-temperature incineration is expensive, PCBs have often been illegally dumped into the environment, where they accumulate in the food chain (fish, mammals, and birds) due to their persistent nature.

The major source of human exposure is through the diet. The major dietary sources of PCBs are the fatty fish and foods of animal origin. PCBs may be stored unchanged for years or even decades, mainly in the fat and liver. PCBs have been shown to adversely affect neurological development including cognitive function in children. Information on the acute effects of PCBs in humans was obtained from two large-scale incidents that occurred in Japan (1968) and Taiwan (1979). Common symptoms included dermal and eye lesions, irregular menstrual cycles, a lowered immune response, fatigue, headache, and cough; there were also reports of children with poor cognitive development.

From 1998 to 2001, three incidents involving PCB/dioxin contamination of animal feed occurred in Belgium and one incident occurred in Ireland in 2008. The most serious one occurred in 1999 in Belgium when oil from a discarded transformer was unknowingly used in the formulation of approximately 500 t of animal feed, which resulted in the contamination of poultry, eggs, pork, milk, and beef. The contamination was only noticed after chickens started dying; the true human exposure from this incident is uncertain. However, the health, political, and economic consequences of this and other incidents have targeted PCBs and dioxins as priorities for intensive feed and food monitoring.

Polybrominated Biphenyls (PBBs)

Similar to PCBs, PBBs are biphenyls variously substituted with bromine atom instead of chlorine. PBBs were manufactured for use as fire retardants but now, are limited in use to electrical and electronic products sold in the European Union. One major incident occurred in the USA in 1973 when several thousand pounds of retardant were accidentally mixed with livestock feed that was distributed to farms in Michigan, USA. Some 1.5 million chickens, 30 000 cattle, 6000 pigs, and 1500 sheep consumed the contaminated feed before the error was discovered. Epidemiological studies of people who lived on the quarantined farms; people who received food from these farms; and workers engaged in PBB manufacture revealed various potential adverse effects, but the only consistent effect across the various groups appeared to be acne.

Dioxins

The name dioxin applies to a family of structurally and chemically related dibenzodioxins and dibenzofurans, which are mainly by-products of industrial processes and waste incineration. Dioxins are found at low levels throughout the world in many foods, but especially dairy products, meat, fish, and shellfish. Over 90% of human exposure to dioxins is through food. Major incidents involving elevated levels of dioxins in animal-derived foods have occurred in Belgium, USA, and Ireland. In the case of the USA incident, the source of the dioxins was a type of natural clay used as a binding agent in the formulation of animal feed. Acute effects of exposure to high levels of dioxins include a skin disease (chloracne) and altered liver function. Long-term exposure is linked to impairment of the immune system, the developing nervous system, the endocrine system, reproductive functions, and cancer. Levels of exposure to dioxins in several countries are estimated to be only slightly below World Health Organization-recommended PTMI, which is currently 70 pg per kg bodyweight per month. Data from a number of industrialized countries indicate that the trend in exposure is downward as source-directed measures have reduced environmental emissions. However, it should also be noted that chemicals that have the capacity to be endocrine disruptors may exert their effects through synergistic or antagonistic mechanisms so that the cumulative exposure to such chemicals is the subject of intense scientific debate.

Processing Contaminants

Processing contaminants are undesirable compounds, which are formed in, or appear on, food during treatment or processing, including preparation at home. Perhaps the most deadly is botulinal neurotoxin that is produced by *Clostridium botulinum* under anaerobic conditions, such as in canned food with low acid content that is improperly processed. Although rare, the outcome is almost always fatal and unusually detailed regulations have been promulgated to ensure the safety of such products. Other types of foods and processing methods can also give rise to chemical hazards. For example, grilling of meat on the barbeque can produce polycyclic aromatic hydrocarbons, which include a large group of substances typically found in soot. They exhibit varying degrees of toxicity, including carcinogenicity. Similarly, high-temperature cooking, as in frying, can enhance the formation of nitrosamines, especially in nitrite-cured meat, such as bacon. Nitrosamine may be responsible for thousands of cases of colon and gastric cancer per year globally. Nitrosamines are found in many foodstuffs, especially beer, fish, and fish by-products, and also in meat and cheese products preserved with nitrite pickling salt. Other processing contaminants include chloropropanols, which arise from multiple sources through different and complex pathways. They were initially associated with acid-hydrolyzed vegetable proteins and in particular, soy sauce. However, low levels of chloropropanols can also be formed in other foods that have been subjected to heat treatment such as baking, roasting, grilling, or under certain storage conditions. They can thus be present in cereal-based products such as pastries, biscuits, crackers, bread, as well as meat products, for example, burgers. Ethyl carbamate (urethane) has been used in the past for industrial, medical, and veterinary purposes, but present evidence has established its genotoxicity and carcinogenicity. It is produced during the fermentation process, with the highest levels found in stone-fruit brandies. One of the most recently identified processing contaminants is acrylamide, which was shown to be present in carbohydrate-rich foods that undergo heat treatment, such as baking or frying. It is a potent carcinogen and is found at high levels in commonly consumed foods. The formation of acrylamide derives from the Maillard reaction, which gives food its taste, aroma, and color, normally when foods are heated $>120\ ^{\circ}C$. The food industry and academia are working to reduce the level of acrylamide in food because it is perhaps the most serious health risk posed by any processing contaminant. Furan is another processing contaminant that has also been recently identified in foods, such as canned or jarred foods like soups, sauces, and baby foods. It probably originates when amino acids or sugars are

broken down during cooking. Its formation may also be linked to the presence of vitamin C and polyunsaturated fatty acids during cooking, bottling, or canning food products.

Biological Toxins

Mycotoxins

Mycotoxins are a group of toxic secondary metabolites of microscopic fungi (molds), which can cause a range of serious adverse effects in humans and animals. They have been of a growing national and international concern since the 1970s. Animal studies have shown that besides serious acute effects, mycotoxins are capable of causing carcinogenic, mutagenic, and teratogenic effects. Several hundred mycotoxins have been identified. Aflatoxin is the most well-known and important mycotoxin from an economic point of view. As fungi-producing aflatoxins prefer high humidity and temperatures, crops such as maize and groundnuts grown in tropical and subtropical regions are more prone to contamination. Epidemiological studies suggest that aflatoxins and hepatitis B virus are cocarcinogens and the probability of liver cancer is higher in areas where both aflatoxins contamination and hepatitis B are prevalent. Aflatoxins are found in peanuts, maize, tree nuts, and some dried fruits such as figs. Besides adverse weather conditions (both too wet and dry), postharvest handling plays an important role in the growth of molds such as aflotoxin.

Other mycotoxins of concern include ergot alkaloids, ochratoxin A, patulin, fumonisin B, and the trichothecenes. JECFA has established very low provisional tolerable intakes for ochratoxin A, patulin, fumonisin B, and some of the trichothecenes, such as deoxynivalenol and fumonisin B1. In view of their presence in many foods and their stability during processing, mycotoxins must be considered a major public health concern. Currently, over 100 countries have regulations regarding mycotoxins in the feed industry, in which 13 mycotoxins or groups of mycotoxins are of concern. The Codex Alimentarius Commission has also recommended maximum limits for a number of mycotoxins.

Marine Biotoxins

Harmful algal blooms (HABs) periodically kill fish or disrupt food sources for fish and shellfish. When HABs are not detected, seafood taken from such waters may be harmful for human health. HABs can cover huge areas, often stimulated by the right combination of temperature, salinity, nutrient, sunlight, and tidal conditions. When they discolor the water, they are typically called 'red tides.' Sometimes HABs can be highly localized as in the case of coral reefs where reef damage due to storms or construction can disrupt the marine ecology. Human intoxications by planktonic biotoxins result from the consumption of contaminated seafood, such as shellfish and fish. Marine biotoxins are produced by various species of dinoflagellates under certain conditions. Shellfish, which are filter feeders, accumulate the biotoxins without adverse effects and without any apparent organoleptic changes. Different types of intoxications have been described based on their major symptoms, including paralytic shellfish poisoning, diarrheic shellfish poisoning, neurotoxic shellfish poisoning, amnesic shellfish poisoning, and azaspiracid poisoning. Recent warming of the world's oceans has altered the distribution and range of dinoflagellates that make these toxins, introducing the problem to previously unaffected areas.

Another type of marine biotoxins is ciguatoxin, which causes ciguatera fish poisoning. Ciguatoxin is a neurotoxin, which can produce symptoms lasting for several weeks, months, or years. It is serious disease with a case/fatality rate that may range up to 4.5%. Ciguatera has been associated with the consumption of a variety of tropical and subtropical fish, mainly coral fish, feeding on toxin-producing dinoflagellates, or predatory fish consuming such coral fish. It should also be noted that certain fish species use biotoxins for their protection and can present risks to the consumer if consumed inadvertently or intentionally without proper handling, for example, puffer fish.

A lesser known group of biotoxins are derived from certain cyanobacteria (blue-green algae) in brackish or freshwater. These bacteria produce cyanotoxins, which are some of the most powerful natural poisons known. Although not normally affecting the commercial fisheries, exposure to these toxins has occurred through drinking water and occupational and recreational contact.

Plant Toxicants

Edible plants containing toxic substances are important causes of disease in many areas of the world. Cassava (manioc), which is a major source of carbohydrates in the world, contains a high level of toxic cyanogenic glucosides, which must be removed before consumption. Improper preparation of cassava is associated with a neurological disease (konzo), which is due to the presence of residual cyanide. Many food plants possess toxic parts, are toxic unless processed, or are toxic at certain stages of their life cycle. Most of these are not major contributors to human illness because of traditional society's prior knowledge of their preparation. These include apple, cherry, peach, plum, and almond seeds and leaves (cyanogenic glycosides); potato (solanine); tomato leaves and unripe fruit (tomatine); rhubarb leaves (oxalic acid); and various beans (lectin phytohemogglutenin). When such foods are introduced into countries with no previous knowledge of their preparation or when novels foods with no history of use are introduced, toxic exposures may result.

In some cases, poisonous plants that resemble or that cohabitate with edible plants are also potential hazards. In Europe, misidentification of toxic mushrooms is by far the leading cause of illness and death in this category. Seeds of plants producing pyrrolizidine alkaloids have accidentally contaminated wheat and millet, leading to acute and chronic liver disease. In some situations, populations facing extreme food shortages have eaten seeds (e.g., *Lathyrus sativus*), known to be toxic, out of hunger.

Biogenic Amines

Biogenic amines are decarboxylation products of amino acids and are formed during fermentation (e.g., cheese ripening and wine fermentation) and decomposition of protein, usually fish. These biogenic amines include histamine, tyramine,

cadaverine, putrecine, and related metabolites. Histamine fish poisoning (or scombroid poisoning) is a type of food poisoning caused by elevated levels of histamine being present in the fish such as tuna, sardines, mackerel, swordfish, and marlin. Naturally occurring bacteria in fish produce an enzyme, which converts histidine in the fish to histamine. Symptoms appear very quickly after eating the fish (usually within 30 min to a few hours) and include a peppery taste sensation, tingling of the mouth and lips, a skin rash, headaches, dizziness, and itching of the skin. Symptoms usually last for 4–6 h and rarely exceed 1 day, but can be readily treated with antihistamines. Poisoning caused by biogenic amines in other foods such as cheese, red wine, and sauerkraut are reported only sporadically.

Packaging Contaminants

The packaging of food is intended to protect the product from various hazards in the environment and to avoid formation of microbiological hazards, but occasionally, packaging can inadvertently introduce contaminants into food. Normally such materials undergo testing for extractables to determine the potential for the migration of packaging material components. In some cases, food safety issues are raised after the packaging material is in wide use. For example, bisphenol A is an industrial chemical used to make a hard, clear plastic known as polycarbonate, which is used in many consumer products, including reusable water bottles and baby bottles. It is also used in epoxy resins, which act as a protective lining on the inside of metal-based food and beverage cans. Although the exposure of the general public is very low, the greatest concern has been for newborns and infants because bisphenol A is a potential hormone disruptor, which is associated with increased risks for changes in behaviors and adverse effects on sperm. In another example involving exposure of infants, the carcinogenic substance semicarbazide was found in gaskets in baby food jars at low levels of contamination resulting in reformulation of the gaskets by the food industry.

Physical Hazards

A physical hazard is any extraneous object or foreign matter in a food item, which may cause illness or injury to a person consuming the product. Some of these agents cause cuts (glass shards, needles, and metal shavings), choking (jewelry, wood splinters, and gel capsules), and broken teeth (stones, nuts, and bolts). Complaints of physical hazards outweigh those of other issues because they are readily detected. Sometimes, foreign bodies, even though not a hazard per se, may result in psychological trauma (insects, mice, or their parts). Control methods include raw material inspection and specification, vendor certification and letters of guarantees, optical and magnetic detectors, X-ray technology to detect solid objects, effective pest control in the facility, preventative equipment maintenance and proper sanitation procedures, and employee education. Another risk is the possibility of choking on food products, particularly by infants and children. These occur frequently enough to cause concern but are not typically recorded as foodborne disease incidents. The risk of choking is related not only to the size and shape of the food item (e.g., baby biscuits, small sausages, and candies) but also to the consistency of the food, such as in the case of jelly sweets containing Konjac flour. Finally, it should also be mentioned that nanoparticles are also a type of physical hazard because their potential adverse health risks arise from their very small size and possibly their shape. However, for the purpose of this Encyclopedia, these are covered under food technologies.

Miscellaneous Hazards

Radiological Hazards

Unlike chemical hazards, radionuclides are dangerous because they emit particles that have sufficient energy (or that can liberate sufficient energy) to remove an electron from a neighboring molecule to produce free radicals. Such chemical species are highly reactive and are responsible for most of the adverse health effects associated with ionizing radiation. Radiological hazards that have been of concern include strontium-90, iodine-131, cesium-137, and various isotopes of plutonium. Note that plutonium also is a highly toxic chemical. The long-term health effects associated with radionuclides include cancer, teratogenic effects, and genetic mutations.

People are exposed daily to a wide range of naturally occurring radioisotopes of chemical elements. This background radiation is unavoidable and considered to be one of the inherent risks in life. However, consumers' concern for radionuclides derived from nuclear testing has created a climate of fear of an all-out nuclear war. In 1979, this was heightened by the nuclear reactor accident at the Three Mile Island in the USA, which occurred in spite of government's assurances that such accidents would only happen once in 10 000 years of operation. After the Chernobyl nuclear plant went critical in 1986, large parts of the Ukraine and numerous locals in Western Europe were contaminated by radionuclides with long half-lives, such as cesium-137. This resulted in the widespread contamination of food and subsequent trade restrictions. Following the Chernobyl event, Codex established guideline levels for radionuclide in food following the accidental nuclear release for use in international trade. Although the health risks from radionuclides in food appear to be low, most countries continued to employ a precautionary approach and only accepted food that was within previous background levels.

Although operational risks appear to have been reduced over the past 20 years, natural calamities remain potential threats to nuclear facilities. As a result of the unprecedented earthquake and tsunami in March 2011 that hit Fukushima, Japan, several nuclear reactors at the site released massive amounts of radioactive material into the environment. Radionuclides subsequently were found in a range of foods, including spinach, tea leaves, milk, cattle meat, and seafood. This points to the need for preparedness to maintain the sampling and analytical capabilities to respond to emergencies.

Nutritional Hazards

A nutrient is a chemical that an organism needs to live and grow. However, no single food commodity can supply all of our nutritional requirements. Therefore, the quantity and

quality of various foods in the diet are critical for sustaining and protecting health. Among the essential macronutrients, amino acids are considered the building blocks of the body, carbohydrates provide the bulk of the energy for functioning, and essential fatty acids are needed for metabolism. Certain trace elements are also nutritionally essential in small quantities for proper human growth and metabolism. These include iron, cobalt, chromium, copper, iodine, manganese, selenium, zinc, and molybdenum. In addition, vitamins such as thiamin, niacin, riboflavin, folate, vitamins C and D are essential organic chemicals that cannot be synthesized in the body and therefore must be obtained from the diet.

As with all chemicals, nutrients may pose risks if present in excessive amounts (Paracelsus). However, because they are essential for health, the optimum intake of an essential nutrient is neither too low to cause a nutritional deficiency nor too high to cause an adverse health effect. For macronutrients, such as proteins, carbohydrates, and fats, examples of both under and over nutrition exist, sometimes in the same country or same city. However, micronutrients are largely a problem of insufficient intakes. Micronutrient malnutrition is a term commonly used to refer to vitamin and mineral nutritional deficiency diseases. Diets, which lack adequate amounts of essential vitamins and minerals lead to such diseases. Vitamin A deficiency (blindness and susceptibility to infectious diseases), iron deficiency anemia (mental and physical retardation as well as fatigue), and iodine deficiency disorders (goiter, mental and physical impairment, as well as birth defects) are among the most common forms of micronutrient malnutrition. These deficiency diseases cause illnesses and deaths of millions of people every year, particularly in the developing world and particularly among children. Supplementing traditional diets with vegetables, fruits, fish, and meat will diminish the adverse effects of micronutrient malnutrition. Adding iodine to salt is considered to be the most common and cost-effective method of preventing iodine deficiency and in many countries, vitamin A is added to milk. In these cases, the application of food safety management tools, such as hazard analysis and critical control point, are needed to ensure that the products are fortified to prescribed levels.

Although micronutrients are mainly a problem of insufficient intake, it should be noted that the margins between safety and toxicity may be relatively small and exposure to levels significantly above the recommended daily intakes may cause disease.

Infants that rely on infant formula as their sole food source are particularly at risk to nutritional hazards. For example, if the formula is manufactured in such a way that it fails to add an essential nutrient, infants may be harmed. In the USA, the omission of sodium chloride from infant formula resulted in irreversible brain damage in infants. In a more recent case in 2003, thiamine (vitamin B_1) was omitted from the infant formula, and a reported 12 infants suffered neurological damage and two of them died.

Adulterants

Economic fraud in food was a common phenomenon throughout history. Laws relating to the purity and identity of food were adopted by most ancient societies. The practice of adulterating foods in order to deceive the purchaser as to their identity, quality, or other properties continues to the present day. Whereas some of these practices only harm the consumer economically, sometimes the adulteration causes injury, disease, or even death. For example, the addition of stones to add weight presents a physical hazard. A recent example causing serious harm was the addition of melamine to diluted milk in China, to give the impression of higher protein content. This incident involved an estimated 300 000 infants and caused the deaths of 6 and the hospitalization of 860. The large recalls of the contaminated products eroded consumer confidence in the safety of the food supply.

At times adulteration is carried out for purposes of extortion or to settle political or personal grievances. Adulteration of food may occur at any stage of the food production system and with a long list of potential adulterants, including physical objects, like glass shards. The modification of a product at the retail level to make it harmful to the consumer is referred to as tampering. This threat has prompted manufacturers to make products that are either difficult to modify or at least difficult to modify without alerting the consumer that the product has been tampered with.

In some cases, people with politically motivated agendas have adulterated food with chemical hazards and other agents. Terrorist threats to food have resulted in various preventive measures by the food industry and both industry and governments have developed programs to detect and respond to such threats, including tracing and recall systems. Because of the criminal nature of these threats, these programs are referred to as food defense and are headed by police or other security agencies.

Overview of Emerging Food Technologies

ECD Todd, Ewen Todd Consulting LLC, Okemos, MI, USA

Glossary

Animal cloning The production of progeny from a single parent by reproductive cloning using somatic cell nuclear transfer to create animals that are genetically identical.

Food irradiation A process of sterilizing food with a specific dosage of ionizing radiation (gamma rays, electron beams or X-rays) to destroy microorganisms or insects that might be present and to retard enzymic action such as inhibiting sprouting of vegetables and delaying ripening of fruit.

Genetically modified organism A genetically modified organism (GMO) or genetically engineered organism (GEO) is an organism whose genetic material has been altered using genetic engineering techniques.

High pressure processing (HPP) A cold pasteurization technique by which products, already sealed in final packages, are introduced into a vessel and subjected to a high level of isostatic pressure leading to the inactivation of vegetative microorganisms and enzymes in the food and extending its shelf life. Also called high hydrostatic pressure processing, Pascalization and bridgmanization.

Membrane filtration (MF) The process of separating suspended particles from a fluid through a porous material through which the fluid can pass while the suspended particles are retained. In food microbiology a filter, typically made of cellulose acetate, with pores of various maximum diameters is used to retain certain or all bacteria or viruses on the filter.

Microwave technology Electromagnetic radiation in the microwave spectrum (wavelength between that of infrared and short waves) causing polarized molecules in the food to rotate and build up thermal energy in a process known as dielectric heating.

Modified atmosphere packaging (MAP) A technique used for prolonging the shelf-life period of fresh or minimally processed food by decreasing the oxygen and increasing carbon dioxide and/or nitrogen gases in the atmosphere of a sealed container.

Nanotechnology The manipulation or materials at the nano level.

Pulsed electric field pasteurization (PEF) Application of very rapid pulses of high voltage to foods placed between two electrodes with minimum of heat causing loss of cellular contents of microorganisms present in liquid and semi-liquid food products.

Pulsed light (PL) or Pulsed light technology (PLT) The use of very short bursts of high-intensity white light, at roughly 20 000 times the brightness of the sun to destroy cell membranes of microbes with minimal effect on food quality.

Sous vide A method of cooking food sealed in airtight plastic bags (vacuum pack) in a water bath for longer than normal cooking times, up to 72 hours, at an accurately regulated temperature much lower than normally used for cooking, typically around 55 °C (131 °F) to 60 °C (140 °F) for meats and higher for vegetables. The intention is to cook the item evenly from inside to outside. It is then often rapidly chilled for storage at refrigeration temperatures and reheated at the time of service.

Introduction

New food technologies are continually being developed for both the food industry and consumers, and over the years have served to improve the food supply. At the farm level, these technologies are making crops and food animals more productive and healthier by reducing the likelihood and impact of disease. Some of these technologies have been the basis for the so-called the 'Green Revolution,' which has been essential in feeding the world's growing population. But food preservation technologies have been critical for human survival from the earliest civilizations, when foods had to be preserved between seasons when supplies were not available. When foods have been processed by using traditional methods (such as, drying, salting, smoking, fermenting, etc.), there has been little concern by the public about the safety of these products. These traditional methods were developed before the advent of refrigeration to prevent bacterial growth though control of water activity to avoid both spoilage and foodborne illness. However, present day a closer examination of some of these processes has found chemical hazards were inadvertently produced, such as the contamination of smoked foods with polycyclic aromatic hydrocarbons. Other processes, for example, salting, are now known to pose health risks, such as hypertension.

With the modern scientific tools, food science and technologists from government, academia, and industry have been constantly inventing more efficient processing procedures to reduce waste and promote safer, healthier foods. Specific innovators have been the military to ensure the troops have safe, nutritious, and agreeable foods in the field. Industry has also been involved in the development of new food products for the market. In developed countries, these emerging food technologies are subject to an evaluation process to ensure that the derived products are safe. Part of this evaluation must address the unforeseeable effects that might be posed by new technologies, including foods with no or limited food consumption history. In addition, animal health and environmental risks are assessed. As with other emerging technologies, potential trade barriers, and economic loss might arise if one jurisdiction approves the technology whereas another does not.

Risk managers also have to be cognizant of unfounded fears by consumers about new technologies and the need for special efforts to communicate the real risks, if any, versus the potential benefits. Whereas consumers may be wary of some new technologies such as genetically modified (GM) foods, they have embraced other food technologies without fully appreciating their potential risks and/or their role in their safe use. For example, microwave oven cooking was widely adopted by consumers without a full understanding of the required power (wattage) requirements for foods, problems with uneven heating of food, and the risk of pathogen survival. Risk communication as well as consumer education is essential for consumers so that they can understand and use these new technologies to produce safe as well as wholesome and nutritious food.

Technical terminology also has evolved over time. Pasteurization present day is more than a heating process. The broader definition is 'any process, treatment, or combination thereof, that is applied to food to reduce the most microorganism(s) of public health significance to a level that is not likely to present a public health risk under normal conditions of distribution and storage.' This leaves open processes like high-pressure, irradiation, microwave cooking, ohmic heating, pulsed electric field, pulsed light (PL), and *sous vide* (discussed later in this Introduction) to be considered as pasteurized.

Undoubtedly, other food technologies, such as nanotechnology, will emerge in the future through research and scientific developments and a discussion of their perceived benefits and risks will engage risk assessors and managers as well as civil society, because ultimately food is everyone's business. Some of the food technologies that have raised real or perceived safety concerns are presented briefly below. Some of these are also discussed in more detail in the specific articles.

Genetically Modified Organisms

By genetic engineering through the insertion or deletion of genes, new organisms with recombinant deoxynucleic acid (DNA) can be produced, which are referred to as genetically modified organisms (GMOs). Foods derived from GMOs are called GM foods and were first put on the market in the mid-1990s. The advantage of most GM crops is their ability to be resistant to specific herbicides or certain plant pests and pathogens. Present day, the potential of this technology can also be used to improve other aspects of the food supply. For instance, enhanced vitamin production is a feature of GM rice, the so-called 'golden rice' that produces β-carotene. Some of GM crops are successfully marketed worldwide, such as soybean, corn, rapeseed, and cotton. In contrast, one early product, a tomato with retarded postharvest fruit softening was taken off the market because of competition from a conventionally bred, long shelf life variety. Various GMOs are also routinely used as sources of enzymes for the manufacture of processed foods, with functions such as preventing clotting of milk protein during cheese making, improving juice clarity, and converting starch to sugars.

The development and sale of GM foods has been challenged on safety, economic, and environmental grounds. Evaluation of GM foods for human food safety requires a demonstration of substantive equivalence in nutrition compared to its unmodified counterpart. In addition, special studies are required to demonstrate that the GM food contains no new proteins (or increased level of a known protein) capable of causing allergenic reactions. In this regard, two GM products failed initial safety testing because of possible allergic reactions and were discontinued. To date no adverse health effects caused by GM products approved for sale have been documented.

However, environmental concerns and labeling remain major issues for marketing GM foods. Opponents of GM foods are demanding more rigorous environmental testing before any approvals are granted. Whereas public knowledge of GMO technology and GM foods is generally low, consumer acceptance of the technology is highly variable. In Canada, China, and the USA, many GM foods are on the market and no special labeling is required. However, the European Union (EU), Japan, Malaysia, Australia, and other countries have taken a cautious approach to GM food and have established labeling and traceability requirements for GMOs and their derived food products. These requirements dictate a physical separation of GMOs and nonGMOs throughout the whole supply chain. At the production and raw commodity level, this requires a certification scheme; this becomes more complicated for GM ingredients, especially those which are otherwise indistinguishable from their nonGM counterparts, such a vegetable oils. In some cases, conventionally grown crops and food made from them may contain a small amount of GMOs due to cross-pollination. Current analytical methods are capable of detecting approximately 1% of GM food in a mixture and this is used as the *de facto* limit in most legislation. Therefore, if a product is found to contain more than 1% GMO, it is considered to be mislabeled, and subject to regulatory action, even if it poses no safety concern. Another potential problem in labeling GM food is that it could, in principle, be applied at the foodservice level. As with the term 'organic,' some businesses may try to use 'nonGM' as a marketing advantage and thus further contribute to the unfounded fear of consumers to GM foods. GM animals have also been developed, although none is currently on the market. In September 2010, the United States Food and Drug

Administration (FDA) stated it was willing to consider approval of GM salmon, which grow twice as fast as native species because of the insertion of a gene to produce a growth hormone. The growth hormone shortens the time it takes to grow a mature salmon, and therefore will make salmon more plentiful and cheaper for the public. There are concerns, however, that GM fish might escape from growing pens and then breed with native fish, possibly causing catastrophic effects on the life cycle of wild fish, especially for GM salmon to outcompete the wild salmon population for limited food sources.

Particular issues stand out involving GMO hormone production in cattle because of long-term trade disputes and consumer unease. Bovine somatotropin (bST) hormone is a protein hormone naturally found in the pituitary gland of cattle and which is produced to initiate lactation in cows after giving birth. If bST is injected into nonlactating cows, milk production is induced without the need for a long gestation period. It can also be administered to lactating cows, increasing milk production significantly (10–25%). In the past few decades, a GM source of bST has been developed in the USA. Through recombinant DNA technology, a GM *Escherichia coli* bacterium is used to produce large amounts of the hormone, which is called recombinant bST (rbST). The USA is the only developed nation to permit cows to be given rbST and approximately 20% of herds use the hormone. Although the EU countries do not permit the use of rbST, milk produced using the technology may be imported and sold without labeling. There are various arguments against rbST use from uncertainty about its safety to consumers over a lifetime, economic reasons (too much milk may lower the price, and consumer reluctance to purchase such rbST milk or products made with the milk), to animal health (increase in the risk of clinical mastitis, a reduction in fertility, and an increased risk of animals developing lameness). The Codex Alimentarius Commission has not been able to achieve a consensus on the approval of rbST, especially as Canada and the EU have banned its use for animal health reasons.

Through the use of GM microorganisms, the production of hormones, enzymes, and other natural substances can be enhanced by changing genetic codes to produce the desired substances in much greater quantities and also to prevent the normal switch off signal from being activated to allow for continuous culture in fermenters. Where the desired product is only produced naturally by microorganisms that are difficult to grow in culture, the specific gene can be inserted into another microorganism (a bacterium, yeast, or fungus) that is easier to culture. Because the final product is highly purified, like a specific enzyme, there is no altered DNA or other substances to be concerned about in the product. Because the GMOs are contained in the fermentation vessel, there is also no release into the environment, and thus regulatory oversight is less stringent. GM microorganisms are used to produce vitamins, food additives, and processing agents for the food industry. Examples are: vitamins B_2 and C; xanthan thickeners; citric acid acidity regulators; amino acids, such as glutamate to improve flavor; and enzymes used in the production of cheeses, baked goods, fermented beverages, and glucose.

Apart from vaccines, the approved use of any GM bacteria or viruses present day (called genetically engineered microorganisms (GEMs) has been limited. In agricultural research experiments, such bacteria have been incorporated into soil to facilitate crop growth by fixing nitrogen and applied directly onto crops to kill pests by using a modified form of *Bacillus thuringiensis*. Another possible agricultural use of GEMs is the development of ice-minus bacteria (a modified *Pseudomonas syringae,* commonly found in vegetation) that can delay ice formation and death of the plants during freezing temperatures. Some monosodium glutamate and aspartame is industrially produced using fermentation by GM bacteria. However, relatively few specific GM microorganisms have been developed for the food industry itself to date, but it is likely that their use will be considered more in the future.

Animal cloning

Although animal clones used for food have not yet been commercialized, their potential future exploitation needs to be addressed. An animal clone is a genetic copy of a donor animal, which is intended to be used as breeding animals to introduce desirable traits into herds more rapidly than would be possible using conventional breeding. There is no genetic engineering in the process of cloning animals, just producing offspring identical to the parent. The US FDA concluded in 2008 that meat and milk from clones of cattle, swine, and goats, and the offspring of the clones, are as safe to eat as food from conventionally bred animals. Currently cloned animals are rare and costly to produce and they are unlikely to enter the food chain. It is their offspring, even in the future, that are most likely to be used for producing milk and meat, whereas the original clones themselves are reserved for breeding. Australia and New Zealand, Canada, and Japan are considering whether there is a need to regulate food from cloned animals and their offspring. The EU is considering banning any progeny of cloned animals from entering the food chain. Policies in most countries have not yet been formulated, and although there may be some initial concerns over unnatural breeding, the offspring of cloned animals are eventually likely to be treated as any other animal by meat and milk producers and retailers in most countries where cloning occurs, and their products will be sold to the public unlabeled. However, if the public raises sufficient concerns, their use in food would likely be inhibited.

High-Pressure Processing

High-pressure processing or high hydrostatic pressure processing (HPP), sometimes called pascalization, is a method of preserving, in which a product is processed under very high-pressure, leading to the inactivation of vegetative microorganisms and some enzymes in the food. Food products are sealed in flexible containers (usually a pouch or plastic bottle) and loaded into a high-pressure chamber filled with a pressure-transmitting (hydraulic) fluid, often water. High-pressure pumps are used to create pressures, constantly or

intermittently, up to 700 MPa (100 000 psi). Pressure is applied for usually 3–5 min. The application of HPP on a food product will kill mostly vegetative microorganisms; spores are typically not affected and other treatment, like use of acids, may have to be used if survivors create a potential spoilage or safety issue. HPP works especially well on acidic foods, such as juices, fruits, and yogurts, because pressure-tolerant spores will not germinate in low pH foods. However, HPP works equally well for some solid products, such as fish, shellfish, ready-to-eat (RTE) meats, salad dressing, salsas, rice cakes, and guacamole. The food itself is not affected but proteins are denatured causing death of microorganisms. However, because HPP can affect muscle tissues by increasing the rate of lipid oxidation, an off-flavor may occur in meat products. Although the technology may appear less applicable for dry solids, or foods with air pockets because of potential damage, it has been used successfully for strawberries and bread. Where there are air pockets, the process is designed for the compressed air to be dissolved in water or incorporated into the solid food, and then released slowly after the cessation of the pressure step. In 2008, the United States Department of Agriculture approved HPP as an intervention method for *Listeria monocytogenes* in prepacked RTE meat products, and is being used by at least one major US deli meat manufacturer. HPP is being used in the USA, Europe, and Japan on a select variety of high-value foods either to extend shelf life or to improve food safety. One application is to destroy any bacterial pathogens and spoilage organisms present when HPP is used to shuck raw oysters and clams. Destruction of enteric viruses, such as norovirus, cannot be guaranteed through HPP technology. However, demand for HPP foods is expected to grow in the future.

The pressure assisted thermal sterilization process has been used for the application in the production of sterilized prepackaged low acid foods. The packaged foods are immersed in hot water under pressure and preheated with microwaves at a frequency of 915 MHz; this frequency achieves higher penetration depth and more uniform heating than at other oven frequencies. This combination eliminates pathogens and spoilage organisms in less than 10 min to produce a high quality and safe product. Microwaving is just one process that can be used for preheating to make high-pressure treatment more effective so that rapid sterilization is possible; the pressure itself causes adiabatic heating. One example would be preheating a product to approximately 90 °C followed by pressurization; in a very short time there would be homogeneous heating to approximately 120 °C.

Modified Atmosphere Packaging

Modified atmosphere packaging (MAP) is one of the most important techniques used to achieve safety in fresh cut fruits and other products. This can also prolong their shelf life, as an alternative to ultraviolet (UV) light, infrared radiation, irradiation, and high-pressure. Fresh fruit continues to respire, consuming oxygen and producing carbon dioxide and water vapor, and high carbon dioxide and low oxygen levels reduce the respiration rate. Very successful applications of MAP are reported for fresh cut pineapple, apples, kiwifruit, honeydew, bananas, and mangoes. Unfortunately, although low O_2 atmospheres inhibit the growth of aerobic spoilage microorganisms, some pathogens such as *L. monocytogenes* and *E. coli* O157 are not affected and growth may even be stimulated, depending on the type of product packaged with added gases. Therefore, for safety reasons any MAP use has to be supplemented by other 'hurdles' to prevent pathogen survival and growth.

Food Irradiation

The irradiation of food is the process of exposing food to ionizing radiation to destroy nonsporing pathogens and spoilage microorganisms. With regard to insects and parasites, food irradiation acts by randomly damaging DNA so that these organisms do not survive or reproduce. In addition, root crops, such as potatoes and onions, are inhibited from sprouting. Generally, the shelf lives of irradiated fruits and vegetables are extended. Other uses include delaying fruit ripening, increasing juice yield, and improving rehydration. High-dose irradiation has been used to sterilize food.

Food can be irradiated using gamma radiation, X-rays, or high-energy electron beams. Food irradiation using gamma radiation is the preferred method by most processors because its deeper penetration enables treatment of industrial-size pallets, which reduces the need for repackaging and handling. Facilities using cobalt-60 have had excellent safety records and have been in operation for many years for other applications, such as sterilization of medical supplies, but they require high maintenance. In addition to good penetration, X-rays generated by machines have the added benefit of being an electronic source that can be switched off when not in use. However, X-ray systems require much more electrical energy than the other systems. Machine generated electron irradiation uses less energy than the other systems, and also may be turned off. Electrons are particulate radiation and thus do not penetrate beyond approximately 10 cm, depending on product density. However, this is also an advantage as it requires less concrete shields to protect workers and the environment from radiation exposure.

The early safety investigations were driven by the perception that irradiation of food would produce 'unique radiolytic products.' However, to date, the only ones of possible concern are cyclobutanones arising from irradiation of beef fat (2-alkylcyclobutanones (ACBs) and 2-dodecylcyclobutanones (DCBs)). Food irradiation is perhaps the most studied food process ever developed and Codex has adopted the General Standard for Irradiated Food that permits the use of any dose level subject only to Good Manufacturing Practice. Food irradiation has been approved in many countries for more than 30 products, particularly spices, onions, and potatoes, with an estimated 500 000 metric tonnes treated annually worldwide. Independent scientific committees in Denmark, Sweden, the UK, Canada, and the World Health Organization have endorsed the safety of irradiated food. The EU Scientific Committee for Food has also cleared irradiation treatment for dried aromatic herbs, spices, and vegetable seasonings, but the EU still requires a food by food approval process for other foods. Codex requires that any irradiated

product must be labeled with the word 'irradiated' with or without the 'Radura' symbol;

This labeling policy excludes spices or herbs used as ingredients in another nonirradiated product, such as sausage, in part, because no practical analytical methods exist to detect irradiated foods at that level. For the microbial disinfection of spices, the FDA has established that the maximum irradiation dose should not exceed 30 kGy. Labeling is another issue where consumers may want to know what the decontamination process was used. After the 2006 *E. coli* spinach outbreak, the FDA published a final rule that allows the use of irradiation for fresh iceberg lettuce and fresh spinach in 2008; this decontamination technology is not yet being used by the leafy green industry in the USA, where there is more reliance on product testing at the field and decontamination in the wash system before bagging. Pasteurization of in shell eggs is achieved through heated waterbaths but also has the potential for irradiation decontamination. Irradiation of seafood has the potential to extend the shelf life of fish under refrigeration and improve the quality of quick frozen shrimp, elimination of pathogens including vibrios and hepatitis A virus from raw oysters, and improve the hygiene of fish feed. The extension of shelf life due to irradiation depends on several factors, including initial quality of fish, irradiation dose, packaging conditions, and storage temperature. Irradiation should be considered as only one of several 'hurdles' impacting the growth and survival of pathogens which could include cooking, low temperature, water activity, pH, redox potential, and chemical preservatives.

Concerns have been expressed by some consumer groups that irradiation could disguise poor sanitation and food handling practices that could lead to unnecessary fecal contamination. In contrast, some consumer organizations support food irradiation as a means of eliminating bacteria from processed meat and poultry, particularly *E. coli* O157. As almost all cultures have dishes prepared with raw or partially cooked meat, the use of irradiation can make a major public health contribution to safer food. In developing countries, the technology may be useful to extend food supplies and reduce wastage, such as treating bulk foods at ports and using mobile irradiators to prevent onions and potatoes from sprouting. However, the future of irradiation worldwide remains uncertain with very limited use present day because of the lack of consumer acceptance.

Membrane Filtration

Membrane filtration (MF) allows separation of particles from a fluid and if desired, to concentrate those particles. The particles are separated on the basis of their size and shape with the use of pressure and specially designed membranes with different pore sizes. There are different MF methods in order of increasing pore size, i.e., reverse osmosis, nanofiltration, ultrafiltration, and microfiltration. Reverse osmosis is primarily used for water purification. MF is used for clarification, concentration, separation of components, desalting, and purification of a variety of beverages. Reverse osmosis filtration is based on a very dense membrane that rejects virtually all food components except water. This is possible due to a very high system pressure. For instance, liquids can be concentrated to those with higher solids levels. One reason for this concentration is economic to reduce transportation costs. Microfiltration is also applied to improving the food safety of products in order to avoid damaging heat treatment. Some examples of such products are fruit and vegetable juices, nonalcoholic beers, wines and ciders, ice cream, butter, cheeses, fermented milks, skimmed or low-lactose dairy products. Certainly, the dairy industry has been one of the major beneficiaries of this new technology. Pasteurization and sterilization developed to improve the safety and keeping quality of the milk can affect its taste and aroma. Microfiltration with polymeric or ceramic MF membranes is an alternative process to remove pathogenic microorganisms whilst preserving the taste and increasing its shelf life. Ultrafiltration of milk was first used in France for production of Camembert and Brie cheeses, and is used present day for any high-moisture cheese, for example, feta and ricotta. The filtration process is controlled to give the correct amount of fat, protein, and final moisture to which rennet is added. The carbohydrates, soluble vitamins, and minerals normally lost in the whey are now retained. There is no draining or drying, and what is left after the filtration process can be sold as whey protein. All this means that there is less milk required to make the same volume of cheese. Although the cheeses have higher nutritional value at a better price, there are some complaints that the cheese has lost some of its flavor and taste, and its keeping quality is reduced. This filtration will also remove any possible pathogenic microorganisms from the cheeses. However, proponents of raw milk (unpasteurized straight from the cow) do not seem to want to consider this option to reduce their chances of enteric infections even if the dairy farmer could afford the equipment.

Ohmic Heat Processing

Ohmic heating is also known as electrical resistance heating, direct resistance heating, Joule heating, or electro heating, and may be used for a variety of applications in the food industry. This is a thermal processing method where alternating electrical currents are passed through the food which acts as electrical resistance, and the electrical energy is dissipated into heat to give rapid and uniform heating throughout the product. In ohmic heating, heat energy occurs from within foods; unlike microwave heating, it is not reliant on transfer of energy by water particles, and therefore it is an important development for the efficient heating of low water, low particulate foods. Thus, ohmic heating is different from conventional heating where liquids heat faster than solids. With ohmic heating, solids can heat faster than liquids because the heating rate is a function of particle-shape and orientation to

the applied electric field. Therefore, process parameters for ohmic heating depend on food characteristics. Ohmic heating volumetrically heats the entire mass of the food material, thus the resulting product has a far greater quality than, say, food that has been canned. It is possible to cook large particulate foods (up to 2.5 cm) that would be difficult to process using conventional heat exchangers. Juices can be treated to inactivate enzymes without affecting the flavor. Liquid egg can be ohmically heated rapidly without coagulating it. Like thermal processing, ohmic heating inactivates microorganisms by heat. Ohmic heat processing is commercially used in Europe, Japan, and North America for pasteurizing liquid foods containing large particulates, such as soups, stews, whole and diced fruit, and fruit slices in sirups and sauces, fruit juices and heat sensitive liquids, and some prepared meals. One emerging environmentally friendly application of ohmic heating is fruit peeling, which may greatly reduce the use of lye that is now used in such operations. The shelf life of ohmically processed foods is comparable with that of canned and sterile, aseptically processed products.

Pulsed Electric Field Pasteurization

In pulsed electric field pasteurization (PEF), a liquid or semiliquid product is placed between two electrodes and a pulsed electric field is applied. This process involves applying repeated short pulses of a high-voltage electric field, for example, 10–80 kV cm^{-1}, to a fluid pumped between two electrodes. The effect is to enlarge the pores on the plant or animal cell membranes, lysing the cells. There is, however, no substantial temperature rise to kill pathogens. It would require $>30\,000$ V to cause the death of bacterial, yeast, and fungal cells, but it is still not known whether viruses or spores can be inactivated. The formation of large, permanent pores in cellular tissues helps improve juice yield, increase concentrations of functional components, and enhance the characteristics of dried produce. PEF is mostly used in refrigerated or ambient products, and because it is applied for just ≤ 1 s, it does not result in heating of the product. It is for this reason that it has nutritional advantages over more traditional thermal processes which degrade heat sensitive nutrients. However, most enzymes are not affected by PEF that can cause deterioration in the juice under ambient conditions and the treated products have to be refrigerated to preserve their organoleptic quality. Application of PEF technology has been successfully demonstrated for the pasteurization of foods such as juices, milk, yogurt, soups, and liquid eggs. Application of PEF processing is restricted to food products with no air bubbles and with low electrical conductivity. Any gas bubbles trapped in the liquid during extraction can allow electric arcing between the electrodes causing the potential formation of carcinogens. PEF can be used as continuous process, but after processing the products have to be packaged hygienically and kept cool during storage. PEF has not yet been used in Europe on industrial scale and has only been used in the USA in a very limited capacity for orange juice. PEF, however, does have the considerable large-scale potential for improving quality and taste of pasteurized foods compared with traditional preservation techniques.

Pulsed Light

PL or intense light pulses is a method of food preservation that involves the use of intense and short-duration pulses of broad-spectrum 'white light,' i.e., 20% UV, 50% visible, and 30% infrared, with an intensity claimed to be 20 000 times that of the sun at the earth's surface. The material to be treated is exposed to a least 1 pulse of light having an energy density in the range of approximately 0.01–50 J cm^2 at the surface. A wavelength distribution such that at least 70% of the electromagnetic energy is within the range from 170 to 2600 nm is used. Accumulating electrical energy in an energy storage capacitor over relatively long times (a fraction of a second) and releasing this storage energy to do work in a much shorter time (millionths or thousandths of a second) magnifies the power applied. The result is a very high-power during the duty cycle, with the expenditure of only moderate power consumption. Shorter wavelengths in the UV range of 200–320 nm are more efficient inactivation agents than the longer wavelengths, due to their higher energy levels. Because DNA is a target molecule for these UV wavelengths, it is thought that the primary cause of killing microorganisms is through DNA structural changes. For most pasteurization applications, a few flashes applied in a fraction of a second provide a high level of microbial inactivation, i.e., at least 1 pulse of light (typically 1–20 flashes per second with a duration range from 1 μs to 0.1 s. Light pulses may be used to reduce or eliminate the need for chemical disinfectants and preservatives. This technique is ideal for surface decontamination of packaging materials, transparent pharmaceutical products, and works best on smooth, dust-free surfaces. It has also led to significant surface reductions in microorganisms and extend the shelf life of meat, fish, produce, and bakery products. It can inactivate molds in a variety of baked goods and shrimp treated with PL and stored under refrigeration for 7 days remained edible, unlike the untreated shrimp. Both *Salmonella* in chicken and *Listeria innocua* in hotdogs were both reduced 100 fold after PL treatment. Other undesirable organisms such as *E. coli*, *Staphylococcus aureus*, *Bacillus subtilis*, and *Saccharomyces cerevisiae* have been inactivated by using 1–35 pulses of light with an intensity ranging from 1 to 2 J cm^{-2}. Treatments have shown that reduction of microorganisms is proportional to treatment time, but this is inversely proportional both to the sample's distance from the lamp source and to the treatment depth. This technology could be a solution to bagged leafy greens that caused outbreaks in the past. These have a risk of pathogens such as *E. coli* O157:H7 being present in low numbers in bags. However, PL treatment alone does not increase shelf life in spite of the reduction in the initial microbial load. PL may have to be used in combination with other decontamination strategies to create a 'hurdle' technology. PL has considerable potential to be implemented in the food industry. However, technological problems need to be solved in order to avoid food overheating as well as to achieve better penetration and treatment homogeneity. In addition, a more extensive research is needed to understand how PL affects quality food attributes, for example, possible undesirable side effects are lipid oxidation, vitamin inactivation, formation of toxic products, and discoloration.

Microwave Technology

Microwave ovens are now one of the most frequently used appliances in domestic and commercial kitchens, at least in the developed world. They save time by heating up foods relatively quickly with little loss of quality, especially for vegetables. For many people, these ovens are mainly used to heat drinks and packaged convenience foods. The power source is the magnetron which converts electric power into very short radio waves. At a frequency of approximately 2450 MHz, the wave energy is readily absorbed by water, fats, and sugars, and through very fast vibration (2.5 billion times per second) the high temperatures generated heat the food. The water molecules have polarity and are spun at the frequency of the electric field to absorb the energy converted to heat. Normally, food is cooked or reheated on full power; for lower power levels, such as defrosting or cooking large cuts of meat, the magnetron cycles are on and off. The higher the power of a microwave oven, the faster it will cook food. Also, over time the magnetron losses capacity. Many home food preparers do not know the current power (wattage) of their ovens and estimate cooking time by experience. So it is important for them to know the power of the oven when using cooking directions from various sources for food safety. A 'Time-to-Boil Test' (heating two cups of ice cold water to a boil) can estimate the microwave oven power, for example, 2 min at high power ($\geq$1000 W) and 3–4 min at low power (300–500 W). Also, because the waves do not reach the food in a consistent way, microwave ovens can cook unevenly and leave less heated areas ('cold spots') where pathogens may survive. Few persons use a food thermometer to test food in several locations to ensure it has reached the recommended safe temperature before it is eaten, although probes tend to be used for large pieces of food cooked over long periods of time. This is important because microwaves penetrate the food only to a depth of 2.5–4 cm. In thicker pieces of food, the microwaves do not reach any deeper, and the center is cooked by conduction of heat from the outer areas of the food into the middle. The uneven cooking brought about by this uncertain food penetration by the waves and lack of consistency in heating by the intrinsic microwave oven process means that temperature measurement for cooking or reheating potentially hazardous foods is critical. Covering a food dish with a lid or plastic wrap will allow the moist heat and steam that is created to ensure more uniform cooking and help destroy any microorganisms present. Sensor heating buttons in more modern microwave ovens may give some reasonable degree of effective cooking but cannot be relied to destroy pathogens alone. After the oven is turned off, it is typically recommended for domestic cooking that the food stand for some minutes to equilibrate the heat throughout the food by conduction to avoid hot and cold spots; this is often called standing time. The more risky practices that require careful temperature measurement are cooking whole stuffed poultry and large roasts, deep dish pizzas, defrosting large pieces of frozen food, warming of food rather than cooking it, home canning in jars. There is also the danger of a superheated cup of liquid erupting violently when it is removed from a microwave oven and scalding the hands. There is little cause for concern about excess microwaves leaking from ovens unless the door hinges, latch, or seals are damaged. Microwave ovens are also typically present in hotels, ski condos, beach houses, and time-shares, and are frequently used by the temporary occupants without knowledge of the power (the wattage and voltage are typically labeled in ovens but are rarely consulted by users). A few outbreaks have been associated with microwaved food.

Consumers present day are so used to eating convenient microwavable RTE fresh or frozen foods at home or work that they rarely read the instructions except for heating times. For these, the purpose of the ovens is simply to warm the food up to palatability. Unfortunately, there are also not-ready-to-eat (NRTE) foods in the market with a similar appearance, and these pose one of the biggest concerns to safe microwaving. If these are not cooked properly, pathogens like *Salmonella* may survive, and frozen NRTE microwavable meals have been reported as vehicles in salmonellosis outbreaks. In one large outbreak involving packaged pot pies, only 29% of patients interviewed reported knowing the power of their home microwave ovens, and 68% did not let pies stand the full recommended time after microwaving, as stated above to allow more even dispersion of the heat in the product and reduce the likelihood of cold spots that could allow survival of pathogens like *Salmonella*. Furthermore, 19% cooked more than one pie simultaneously, indicating that they did not follow microwaving instructions. This outbreak led companies to start making clearer microwaving instructions on their packages and what foods were RTE (warming only necessary) and what were NRTE (cooking sufficient to kill any pathogens). A better understanding of oven power would also help consumers follow manufacturer's instructions better. Unfortunately in 2010, another multistate outbreak was documented, this time from cheesy chicken and rice single serve frozen entrées where insufficient home microwaving was likely an important factor in causing the illnesses. From the above information it is quite possible that many outbreaks have occurred from NRTE convenience foods around the world, but without modern molecular tracing methods, they would not be identified.

In addition to domestic ovens, microwave heating is also used commercially for applications like thawing, drying, and preservation, as well as heating and cooking. Small offices, mini cafes, pastry shops, and many fast food restaurants all keep microwaves to provide hot food to clients. One reason for their popularity is that many models heat approximately 45 times faster than conventional cooking methods. Larger commercial ovens use two magnetrons for quicker and more efficient results (1000–2000 W compared with 600–900 W for domestic ovens). Large capacity microwaves, typically used in restaurants, can have a capacity of up to nearly 16 gallons (60 l), with a variety of cooking preparations.

Sous Vide

One recent particular approach to pasteurization with minimum heat is *sous vide* cooking. This has been promoted as method improving the quality of the final product by using lower cooking temperatures. This is achieved by placing the food in airtight plastic bags, preferably with as much air removed from the bags as possible, in a water bath for many

hours to allow gradual even penetration of the product to retain juices and not be overcooked. To be successful in this methodology, accurate temperature measurement is required. The time of cooking will vary with the type and size of the item in the bags. Most time-frames are up to 12 h. However, as large cuts of meat may take up to 72 h, one safety concern is the risk of germination and outgrowth of *Clostridium botulinum* spores and other anaerobes; water bath temperatures should be high enough ($\geq 55\ ^{\circ}C/\geq 131\ ^{\circ}F$) to prevent this from happening. In addition, unless food is to be consumed right away, any food, particularly *sous vide* products with minimum processing conditions, has to be chilled rapidly after cooking to reduce the opportunities for surviving bacteria to multiply.

Nanotechnology

Nanotechnology is a field of science applied to materials 1–100 nm (nm) in size for many different applications, such as electronics, pharmaceutics, cosmetics, medical devices, and textiles. Nanomaterials are very small, for example, the DNA molecule is approximately 2.5 nm wide, and may exhibit different physical and chemical properties compared with the same substances at a normal scale, such as increased chemical reactivity because of the greater surface area. Nanoparticles naturally occur in emulsions of air, food, and water and with no known adverse effects. However, industry is now looking at possible applications in the field of food science and technology including applications in food production, processing, functional foods, and packaging. Preliminary research has indicated there could be benefits for food ingredients, such as to alter the taste, texture, and nutrition of a product. Present day, the food sector is making significant investments in the application of nanotechnology to food production, although there is no substantial commercial application currently underway. Adding specifically labeled nanoparticles to foods can allow identification of these throughout the food chain and may in the future be a contribution to better traceability of foods and their ingredients and speedup recalls.

Materials with structural features at between 1 and 100 nm have been shown to have different properties when compared with their conventional, much larger counterparts. Examples of potential applications of these properties include delivering pesticides to plants more effectively, preventing (or retarding) microbial spoilage of food through packaging materials, modifying a food's texture and taste as a new food additive, and increasing bioavailability of vitamins and minerals. Specifically, 'smart' food packaging is an area where nanotechnology may offer better protection of the products by absorbing oxygen and moisture or by resisting heat, light, and mechanical damage. Another use might be to detect freshness of a food through embedded nanosensors in packaging that can detect minute quantities of chemicals such as those released when a food starts to spoil. Current examples of nanoenhanced food contact materials are polyethylene terephthalate beer bottles with a nanoclay gas barrier and polypropylene food containers with nanosilver for antimicrobial protection. Because the nanomaterials do not become a component of food, these applications may be less of a concern from a human safety standpoint, but environmental concerns would need to be addressed, and they would still have to be approved.

In food formulation, nanoencapsulation is being studied to allow a controlled delivery system for food ingredients and additives in processed food. This can be used to mask unpleasant flavors and protect ingredients from degradation. Existing organic materials that exist in nano form include vitamins, antioxidants, colors, flavors, and preservatives. Visions for the future include low-sodium foods that still taste salty because of nanointeractions with the tongue, and nutrient delivery systems that use nanotechnology to deliver micronutrients or other functional components. Potential applications include foods that can release an appropriate amount of calcium in consumers with osteoporosis, or those with 'smart filters' that trap molecules that might cause allergic reactions.

There are potential health risks, which have not yet been properly evaluated. For example, some nanomaterials are able to cross the blood–brain barrier. The assessment of potentially hazardous characteristics in new products will require a basic understanding of how these materials are handled by the body. In addition, another major challenge is the ability to detect and measure these materials. Because size is the intrinsic difference, traditional analytical methods cannot be used to quantify (i.e., count) nanomaterials. The manufacturing of nanomaterials does not produce a single entity, but rather a range of entities with different sizes and often different shapes. Such analytical challenges make it difficult to investigate the interaction and stability of nanomaterials in food and feed, in the gastrointestinal tract, and metabolism in biological tissues. Therefore, developing and validating sensitive methods to detect, characterize, and quantify nanomaterials in food and animals, including humans, are priorities for research. Another issue is the attitude of the potential consumer toward the application of nanotechnology in food and agriculture trying to weigh the benefits and risks with limited information.

Conclusion

New food technologies will continually evolve over time, and some of these will be adopted by the food industry and accepted by consumers. Not all of those that are scientifically safe and technically sound are economically feasible. New technologies are driven by a variety of stakeholders. Industry tends not to change unless there are economic advantages in doing so, or new regulations force a change. Both the industry innovators and the consumers have to be comfortable with what these technologies can and cannot provide before any marketing is done or the product is put up for sale. Some technologies will not be accepted by consumers even if the technology will make food safer that its unprocessed counterpart, food irradiation being a good example. Well-performed field trials should be conducted to prove that there is a benefit in safer or better quality food to be offered for sale. In addition, there should be an educational phase to alert the consumer of what to expect and what the consumers' responsibilities are. This information exchange has to be

tailored to the concerns and social issues of the day and to the knowledge level of consumers. Recent food scares may reduce the chances of consumer acceptance so that consumer education is essential. Politicians and policy makers are responsible for balancing the societal benefits offered by new food technologies with the assurance of safety that most consumers would consider reasonable and prudent. Ultimately, no new technology can be introduced without the confidence of the consumer in the safety of the food supply. The consumer has also to be sufficiently knowledgeable about the processes they control such as microwave cooking and what relevant safety information labels convey. For instance, as wattage is required for the correct microwave heating of food it is important to raise awareness of consumers on this matter and provide them the necessary information in language they can act upon; some labels on food packages present day give different cooking instructions for high- and low-power microwaves. Thus, risk assessment and risk communication approaches have to be well-researched with the understanding that consumers should have choices based not only on preference, but also on real safety concerns. What was made clear in the pot pie outbreak was the lack of clear communication by the processor to the consumer for cooking instructions. However, messages have not only to be understandable, but also acceptable to the majority of consumers. The broad policy communications are also important relating to the acceptance of new technologies; these are the responsibility of both industry and government. Poor understanding of GM and hormone issues by consumers was partly due to a lack of transparency by the innovators. When these are addressed, new technologies play an important part of the future in providing an abundant, safe, nutritious, and convenient food supply. Finally, it should be mentioned that in developing countries, 'new' technologies may include something as simple as refrigerators. In that case, education for their proper use, for example, safe storage times, and temperatures, cross-contamination, etc. will be essential for protecting public health.

FOODBORNE DISEASES

Prevalence of Foodborne Diseases in Africa

L Anelich, Anelich Consulting, Brooklyn, South Africa

Glossary

Decompensation The failure of an organ (especially the liver or heart) to compensate for the functional overload resulting from disease.

Enterosorption Adsorption of substances from the gastrointestinal tract onto an orally administered sorbent medium like activated charcoal.

Hazard Analysis and Critical Control Point System (HACCP) It is a system which identifies, evaluates, and controls hazards which are significant for food safety.

Helminth Parasitic worm; a fluke, tapeworm, or nematode.

Hepatoxicity A condition where liver injury has been caused by chemicals.

Immunocompromised Having an impaired immune system.

Mycotoxins Toxic secondary metabolites produced by toxigenic fungi that contaminate various agricultural commodities either before harvest or under postharvest conditions.

Polyparasitism Infection with more than one parasite simultaneously.

Zoonosis A disease that can be transmitted to humans from animals.

Introduction

Millions of people around the world become ill from food- and waterborne disease. Of these, an estimated three million people die every year with 700 000 estimated deaths occurring in Africa due to diarrhea alone, associated with contaminated food and water. Occurrence of such disease can easily escalate to a food safety emergency situation, which can adversely impact national economies and livelihoods through reduced availability of food for domestic consumption, closure of export markets, and/or the high cost of addressing the effects of the threat. Although cases of foodborne illness occur daily in all countries, there is a severe underreporting of such diseases, particularly in developing countries, including Africa. Consequently, the true prevalence of foodborne disease in Africa and the rest of the world is unknown.

Beyond its macroeconomic effects, foodborne diseases impede development at the country level. Without concerted action to estimate and reduce the burden of foodborne diseases, international efforts to achieve the Millennium Development Goals (MDG), particularly those goals relating to children and the poor, will be jeopardized.

Africa – the Scenario

Africa is a continent consisting of 54 countries, each with diverse cultures, religions, languages, and traditions. Owing to the size and geographical positioning of Africa, a number of different climates exist, which largely determine the types of crops and livestock that can be farmed in the different regions. The level of sophistication of the agricultural sector in Africa also differs, with well-established commercial farming and export markets on the one hand and reliance on subsistence farming, on the other. Similarly, well to poorly developed potable water and sanitation systems exist, often within the same country.

Huge food losses are experienced in many parts of Africa due to lack of infrastructure for transportation to markets, either by rail or road, lack of appropriate storage facilities, particularly refrigeration and freezing, inappropriate storage practices, and lack of applicable technologies for processing foods to extend shelf life. These factors drive the need to import basic commodities such as wheat, maize, and other grains, an unaffordable practice for the least developed, poorer countries. Natural disasters aside, exposed populations experience hunger as a result of these combined factors. The need to fill their bellies overrides food safety considerations, leading often to the consumption of contaminated food, simply because none other is available. The latter is particularly true for grains and nuts contaminated with mycotoxins.

In most countries in the region, the surveillance infrastructure for foodborne diseases is weak or nonexistent. With the exception of cholera (which is subject to the World Health Organization (WHO) International Health Regulations), there is no obligation to report foodborne disease internationally, and only a few countries in the region require national reporting of foodborne disease incidents. Where such reporting is required, the systems in place may be weak and not able to fully address the incidents. Consequently, data from Africa are scarce and where available, reflects situations in certain countries only, which may not be relevant to other regions at different levels of development. This absence of data impedes understanding of the importance of the burden of foodborne

 doi:10.1016/B978-0-12-378612-8.00072-X

disease on public health and prevents the development of risk-based solutions to its management, including informing policy makers how best to allocate resources for appropriate foodborne disease control.

Food safety is not regarded a priority among most, if not all African governments, particularly for domestic populations, and is often seen as separate from public health. The harsh reality is that Africa experiences many other challenges, which take priority in many instances. In 2012, 90% of malaria-related deaths occurred in Africa, numbering almost 600 000. Primary health care, provision of education, treatment of human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), supporting undernourished people, and enhancing food security are all important issues for Africa, requiring considerable spend, placing beleaguered budgets under pressure. According to the Food and Agriculture Organization (FAO, 2010), of the 925 million undernourished people in the world in 2010, Sub-Saharan Africa (SSA) had the highest proportion at 30%, which translates into 239 million people. With respect to HIV/AIDS (Note that HIV is not considered as a foodborne pathogen. However, it is relevant to food safety, as it can potentially be transmitted through breast milk. Also, HIV infections create vulnerability to other foodborne infections.), SSA remains the most heavily affected region, with an estimated 23.5 million infected people in 2011, representing 69% of the global HIV burden. In addition, 92% of pregnant women living with HIV/AIDS and 90% of children who acquired HIV in 2011 are found in SSA (UNAIDS, 2012). It is also a well-known fact that food- and waterborne diseases have a far more severe impact on immunocompromised persons and children under the age of 5 years and negatively affects food security status. The number of HIV-infected people together with the undernourished totals an approximate 263 million immunocompromised people in SSA. Considering that Africa has just over 1 billion people, this figure represents approximately 26% (more than one quarter) of the continent's population. Importantly, this number excludes the millions of children under the age of 5 years. Therefore, a significantly higher number than 26% are at risk of contracting food- and waterborne diseases with more severe consequences, placing a heavy burden on health systems and the economy of the country. Food and water safety therefore have a direct impact on human health and can no longer be ignored or viewed separately from matters of public health. African governments should better coordinate agriculture and public health policies and strategies and inclusion of food and water safety should form an essential part of this approach. Besides the positive impact this will have overall, it will result in more effective allocation and use of already scarce resources.

Food- and waterborne diseases can be due to a range of enteric bacteria, viruses, parasites, toxins, and chemical agents. Most food- and waterborne diseases in Africa are due to poor sanitation, poor personal hygiene, poor hygiene and storage practices, lack of education and awareness, lack of potable water, and inadequate infrastructure to support the provision of nutritious, safe food and water. This article discusses selected food- and waterborne microbiological, chemical, and phytotoxic hazards affecting the African region. It also includes an overview of the safety of street food vending as well as proposing potential solutions to the food and water safety issues facing Africa.

Bacteria

Pathogenic bacteria are one of the major causative agents of food- and waterborne diseases in Africa. Cholera is the most well known, mainly because it is obligatory to report it internationally according to WHO International Health Regulations, and so is discussed in further detail. Reported foodborne disease outbreaks in Africa show that the majority are caused by *Salmonella* spp. (**Box 1**), *Shigella flexneri*, *Shigella sonnei*, and *Shigella dysenteriae*; *Bacillus cereus*, *Staphylococcus aureus*, and *Clostridium perfringens*. Those reported in South Africa between 2010 and 2012 indicate that most outbreaks involved catering at mass gatherings, which may or may not be similar to other countries in Africa. Less frequent foodborne diseases are:

- Botulism (*Clostridium botulinum* Type E) from consuming traditionally salted fish in Egypt in 1991;
- Bloody diarrhea (*Escherichia coli* O157) from consuming beef and untreated water in Swaziland in 1992;
- Botulism (*C. botulinum* Type A) from consuming canned fish from discarded, corroded cans in South Africa in 2002;
- Typhoid fever (*Salmonella* Typhi) in Zimbabwe in 2011/2012 and in Zambia in 2012;
- Anthrax (*Bacillus anthracis*) from consuming undercooked meat from infected animals in Zimbabwe in 2011 and Lesotho in 2012.

Although brucellosis cases have been reported, as perhaps consumption of milk, is not very widespread, they have not been directly linked to contaminated food consumption, but rather to handling of infected animals.

Pathogenic bacteria and groups of bacteria that indicate poor hygiene or fecal contamination have been isolated from a wide range of foods obtainable on the continent. Besides the ones listed above that have also been isolated from foods not implicated in outbreaks, others include *Yersinia enterocolitica*, *Campylobacter jejuni*, *Listeria monocytogenes*, *Cronobacter*, *Vibrio alginolyticus*, *Vibrio parahaemolyticus*, *Brucella* spp., *E. coli*, enterococci. Foods from which these bacteria have been isolated range from raw, cooked to preserved (e.g., salted, cured, and smoked) meats including poultry, game/bush meat and fish; raw and cooked vegetables; raw and

pasteurized milk from cattle, sheep, goats and camels, and associated dairy products; a variety of indigenous foods; infant foods including commercially available powdered infant formula as well as weaning foods made in the home; food at retail level including delicatessens; food from restaurants, hotels, and other catering establishments including street foods. Studies have been conducted on food handling and hand hygiene practices in both formal and informal settings. Much data on the prevalence of pathogenic bacteria in foods produced, prepared and sold in Africa is therefore available. However, the precise significance of this data in terms of foodborne disease is largely unknown, even though levels of pathogens found were often at a level high enough to cause disease.

Cholera

Cholera is an acute diarrheal infection caused by ingestion of food or water contaminated with *Vibrio cholerae*. Of the estimated 3–5 million cases that occur globally every year, approximately 100 000–120 000 die. The WHO estimates that the officially reported cases represent only 5–10% of the actual number occurring annually worldwide indicating widespread underreporting of cholera. This may be due to weak surveillance systems and weak laboratory capacity as is the case in many African countries. The actual estimated number of people at risk of contracting cholera is approximately 1.4 billion, with children under the age of 5 years being the most vulnerable, together with immunocompromised people, i.e., the undernourished and those with HIV/AIDS, the numbers of which are collectively significant in Africa (see Section Introduction).

Cholera remains one of the most serious water- and foodborne diseases in Africa and affects hundreds of thousands of people, with thousands of deaths every year. It is viewed as the 'disease of the poor' as it occurs in places with poor sanitation, poor hygiene, crowding, unplanned human settlement, war, and famine, all of which lead to millions of displaced people annually in Africa, thereby contributing to the occurrence and spread of the disease.

Africa was free of cholera until 1971, after which it spread and became endemic to most countries on the continent. Of the numerous cholera outbreaks notified with the WHO since 2000, the majority are from African countries. Between 2001 and 2009, cases from Africa represented 93–98% of total cases worldwide. In 2003, there were 108 000 cases and 1884 deaths, whereas in 2004, the numbers were 71 600 cases and 1663 deaths, with Mozambique having the highest count of cases at 20 000. Even though cases in 2004 showed a marginal decline, this is no indication that the situation has improved. In fact, cholera cases have increased alarmingly and the disease is a reemerging threat, due to new strains of *V. cholerae*, increasing antimicrobial resistance and an ever-increasing size of vulnerable populations living in unsanitary conditions. These factors have resulted in some of the worst outbreaks of cholera experienced on the continent. In 2008 and 2009, 98 424 cases and 4276 deaths occurred in Zimbabwe alone, during which practically the entire country was affected.

More recently, in 2011, cholera cases reported globally increased by 16%. Of the 58 countries reporting cholera outbreaks, 27 countries were in Africa resulting in 188 678 cases, which is a massive 64% increase compared with 2010 during which 115 106 cases were reported. In 2011, 4183 deaths occurred on the African continent, which represents more than half of the 7816 deaths globally. Somalia had the highest number of cases and deaths, i.e., 77 636 and 1130, respectively, accounting for 27% of the deaths reported for the continent that year. Cameroon, Chad, Democratic Republic of Congo (DRC), Ghana, and Nigeria collectively reported 95 405 cases with 2672 deaths, i.e., 64% of the total number of deaths on the continent.

The most recent outbreak in Sierra Leone in 2012 is the worst experienced by that country in 15 years. As of October 2012, there were 20 736 cases with 280 deaths.

Access rates to water and sanitation in West and Central Africa are among the lowest in the world. Out of 24 countries in the region, not a single one is on track to meet the MDG target for sanitation. This is the underlying cause for cholera outbreaks in West and Central Africa. Although measures for cholera response can help contain the spread of the disease and reduce the number of fatalities, it would undoubtedly be much more effective if the underlying cause of this disease is tackled. This need was recognized at the 64th World Health Assembly (WHA) meeting held in 2011, where Resolution WHA64.15 was introduced, which calls for a revitalized focus on cholera. It defines a range of actions required of the WHO and its Member States toward creating an integrated, comprehensive strategy for cholera prevention and control. Most importantly, the strategy calls urgently for tackling the underlying cause of cholera, i.e., provision of adequate sanitation and safe disposal of human waste together with ensuring safe drinking water. Education and constant reinforcement in the use of proper hygiene measures to prevent contamination of food with *V. cholerae* is also essential. Strengthening surveillance and reporting of cholera together with building local capacities for collecting and analyzing data as well as emergency preparedness for unforeseen natural disasters is included. A point worth mentioning is a multipartner initiative aimed at establishing a stockpile of oral cholera vaccine for use in outbreak response. Importantly, it was emphasized that a vaccine should be used as an adjunct to established prevention and control measures as they provide a short-term benefit. The long-term solution is to improve water and sanitation, which is how the developed world successfully controlled cholera. It is clear therefore that cholera is not only a treatable disease but also more importantly, a preventable one.

Parasites

Food parasitology is an emerging discipline as it has been largely underestimated and therefore neglected. FAO and WHO recently convened a Joint Expert Meeting on foodborne parasites, during which it was acknowledged that infectious diseases caused by foodborne parasites have not received the same level of attention as other foodborne biological and chemical hazards. They nevertheless, cause a high burden of

disease in humans and warrant closer attention. Infections may have prolonged, severe, and sometimes, fatal outcomes, and result in considerable hardship in terms of food safety, food security, quality of life, and negative impacts on livelihoods. Notification of public health authorities in many countries, particularly in Africa, is not compulsory for most parasitic diseases, and therefore, official reports do not reflect the true prevalence/incidence of the disease. Many enteric parasites are readily transmitted on food and it is known that foodborne parasitic infections affect many millions of people worldwide. The WHO Foodborne Disease Epidemiology Reference Group (FERG) has assessed the global burden of human foodborne trematodiasis with data for the year 2005. It estimated that 56.2 million people were infected by foodborne trematodes alone, of which 7.8 million suffered from severe sequelae and 7158 died worldwide. Although many publications include data relating to parasites and countries in Africa, they do not provide specific information on food-related sources of such infections as cases of foodborne transmission have been difficult to determine, and linking infection to a contaminated food source remains so for the majority of scenarios, worldwide.

Food normally becomes a potential source of human infection by contamination, during production, collection, transportation, and preparation or during processing, and the sources of zoonotic contamination are usually feces, fecally contaminated soil or water. In many countries in Africa, certain farming, agricultural, and cultural practices positively enhance transmission. These include the use of human waste for fertilization, the use of contaminated water for irrigation, or washing of, particularly, vegetables which may be eaten raw or undercooked to retain the natural taste and preserve the heat-labile nutrients, the consumption of raw or undercooked meat (often as a cultural practice) originating from infected animals, as well as inefficient or absent pasteurization. Indirect transmission also occurs and the majority arises from infected foodhandlers and poor hygiene, often resulting from overcrowded living conditions where clean running water is scarce –this is particularly so in many African countries, where infrastructure in urban areas may be inadequate to accommodate the rapid urbanization occurring in Africa. Hence, services such as proper provision of sanitation and clean running water for personal hygiene and also for preparing food are not necessarily available. In addition, children and adults with little or no health education are also a risk factor in the spread of parasitic diseases – this is more often the case for the rural poor.

Although much literature originating from the developed world offers opinions on food- and waterborne parasites that are regarded as more important, this list may not be relevant from an African perspective. Examples of those that are perhaps of greater direct importance to Africa are *Entamoeba*, *Cryptosporidium*, *Taenia*, and *Echinococcus*. More recently, FAO/WHO have developed a list of parasites based on global ranking and the parasites mentioned above, rank among the eight most important parasites that have already been singled out by FAO/WHO as neglected tropical diseases and identified by FERG as priorities for further burden of illness studies. This does not suggest that other parasites such as *Toxoplasma*, *Trichinella*, *and Ascaris* are of lesser importance to Africa. In fact, **Table 1** provides data that has recently been published on the seroprevalence of *Toxoplasma* in a number of African countries. Focus was placed on pregnant women, HIV-positive individuals, and school children, i.e., the more vulnerable sectors of the population.

In addition to **Table 1**, Abu-Madi *et al*. (2008) also found 29.8% of subjects tested in Qatar were positive for *Toxoplasma*,

Table 1 Recent data on the seroprevalence of *Toxoplasma* in selected African countries

Country	*Population sector*	*Prevalence (%)*	*Reference*
Tunisia	General	58.4	Bouratbine *et al.* (2001)
Egypt	General	57.9	Hussein *et al.* (2001)
	Pregnant women	58.1	
	Pregnant women (rural)	57.6	El-Gozamy *et al.* (2009)
	Pregnant women (urban)	46.5	
Mali	AIDS patients	60	Maiga *et al.* (2001)
	HIV-seropositive blood donors	22.6	
	HIV-seronegative blood donors	21	
	General	27	Ouologuem *et al.* (2012)
Sudan	Pregnant women	34.1	Elnahas *et al.* (2003)
Nigeria	Healthy individuals	20.8	Uneke *et al.* (2005)
	HIV-positive	38.8	
	Pregnant women	40.8	Akinbami *et al.* (2010)
Tanzania	General	46	Swai and Schoonman (2009)
Ghana	Pregnant women	92.5	Ayi *et al.* (2009)
Swaziland	Children	8	Liao *et al.* (2009)
Morocco	Pregnant women	44.3	Barkat *et al.* (2010)
South Africa	HIV-positive individuals	9.8	Kristiah *et al.* (2011)
	HIV-negative pregnant women (Gauteng province)	12.8	
	General pregnant women	6.4	
Mozambique	HIV-positive pregnant women	31.3	Sitoe *et al.* (2010)
	HIV-negative pregnant women	10.9	
Cameroon	Pregnant women	70	Njunda *et al.* (2011)
São Tomé and Principe	Children	63.1	Fan *et al.* (2012)

with the highest prevalence of positives among subjects of African origin who had immigrated to Qatar – the African countries being Algeria, Egypt, Eritrea, Ethiopia, Kenya, Libya, Mauritania, Morocco, Senegal, Somalia, South Africa, Sudan, and Tunisia.

Human and society behavior plays a fundamental role in the epidemiology, emergence and spread of parasitic zoonoses and there are multiple drivers that contribute to changing trends in foodborne parasitic diseases, many of which are also applicable to Africa. These drivers are summarized below:

- Changing eating habits, such as the consumption of raw or lightly cooked food, particularly vegetables in order to preserve heat-labile nutrients and maintain the taste and crispy texture of the food; this includes the demand for exotic foods, such as bush meat. As more Africans become economically active due to current rapid economic growth in Africa, more disposable income is available in many societies and there is a consequential demand for better goods, including healthier foods. This can be seen by the vast array of products on supermarket shelves in many African countries and rapid expansion of retailers from South Africa, Europe, and America into these growing markets.
- Rapid population growth and more rapid urbanization. In this regard, Africa's population growth, estimated to be 1.5 billion people by the year 2020 as well as rapid urbanization, with 40% of Africans currently living in urban areas and this figure estimated to rise to 60% by 2050 is extremely relevant. This rapid pace of urbanization has resulted in an increasing burden on an infrastructure that may already have been weak for some time, due to decades of underinvestment. Current spend on infrastructure in Africa is in the region of US$45 billion per year, whereas US$90–100 billion a year is needed. This has led to inadequate sanitation, inadequate safe drinking water, and inadequate garbage collection disposal services and facilities, resulting in more breeding sites for vectors of parasites.
- An increasingly global food trade and particularly an increasing market in vegetables, fruit, meat, ethnic foods, and even farm animals, some of which originate from countries (developing countries in particular) without appropriate food safety procedures.
- Improved transport logistics and conditions, enabling agents to survive on food products and reach the consumer in a viable form.
- An increasingly transient human population carrying parasitic fauna worldwide and into geographical areas where such parasites may not have been an important consideration before. In Africa, political conflict and drought has resulted in the displacement of millions of people, not only into completely different countries but also into different areas within a country. This has most likely had an effect on movement of such parasitic fauna, of which the extent is unknown.
- The shift from low- to high-protein food consumption in the next 20 years. This is particularly relevant to Africa, where emerging nations are developing economically with a growing middle class demanding more diverse products, resulting in a concomitant greater dependency on meat and fish products.
- A higher proportion of immunologically compromised individuals either as a consequence of increasing elderly populations or the generation of highly susceptible groups with immunosuppressive diseases or treatments. In the African context, the two main groups affected are undernourished people and those living with HIV/AIDS, both of which result in compromised immune systems (see Section Introduction). These groups are far more susceptible to food- and waterborne infections, including parasites. Data in Table 1 attests this fact.
- Changing farming practices, for example, intensification to produce cheaper food or a shift to free-range/organic animal production to respond to consumer welfare concerns.
- Social and political upheavals, both of which are prevalent in Africa, leading to a decrease in veterinary control and a disturbance in modes of production.
- The impact of climate change on, for example, parasite–host habitats, which may present a greater likelihood of contamination due to extreme weather events and create increased pressure on the safety of some food sources. Climate change may also favor the distribution of intermediate hosts, bringing novel vectors into temperate regions or temperature-associated changes in contamination levels.

In addition to the above drivers, poverty plays a significant role in the prevalence of zoonotic parasitic infections. The World Bank estimated that over a third of the world's population resides and lives on less than US$2 per day, a great proportion of which is found in Africa. Limited access to diagnosis and treatment means that most emerging or reemerging zoonoses go unrecognized. This leads to a greater morbidity and mortality from such infections and the lack of treatment and control results in a greater prevalence of such zoonoses.

The issue of coinfections or polyparasitism has been raised and is certainly prevalent in Africa. Data shows that single infections are rare, with polyparasitism being more likely, due to multiple factors, including inadequate sanitation, lack of potable water, poor hygiene, lack of maternal education where children are involved, as well as close proximity to companion animals and livestock. A number of authors in African countries have reported polyparasitism in both adults and children, with children being at most risk, of which some examples are presented below:

- Chunge *et al.* (1991) found that 72.7% of people tested in Kenya in 1985 and 1986 had mixed infections and in a study conducted by Thiong'O *et al.* (2001) also in Kenya, polyparasitism was reported;
- Curtale *et al.* (2005) and Hussein and Khalifa (2010) suggested coexistence between *Fasciola* and *Schistosoma* in two separate studies conducted in Egypt;
- Ouattara *et al.* (2008) reported the coexistence of at least two species of parasites in 80.2% of pupils who were tested in Côte d'Ivoire;
- Samie *et al.* (2009) found that polyparasitism was more common in hospital patients (39.6%) than among school children (23%) tested in South Africa. Almost half (49%) of all individuals tested were infected with many parasites;

- Abu-Madi *et al.* (2010) established polyparasitism in a study conducted on 1299 African immigrants to Qatar originating from Algeria, Egypt, Eritrea, Ethiopia, Gambia, Ghana, Somalia, Sudan, and Tunisia;
- Tomlinson *et al.* (2010) reported on 80% of children tested across 24 schools in Angola, being infected with one or a combination of parasites;
- Ayalew *et al.* (2011) found a prevalence of 66.2% mixed infections in school children in Ethiopia;
- Damen *et al.* (2011) reported polyparasitism among rural pupils tested in Nigeria, albeit to a lesser degree than single infections.

Although chronic helminth infections could have a significant influence over the immune response, the impact on health of such polyparasitism in the context of enteric protozoan infections on African populations is unknown. There is also a need to understand the relative impact of single and coinfections on the susceptibility to HIV transmission and child education and welfare in Africa.

It is estimated that SSA has 60% of the world's available and unexploited arable land and is touted to become a future global supplier of food, together with Latin America and Asia, as emerging economies. Regarding the domestic population on the continent, the high incidence of HIV-positive individuals and undernourished people, both with compromised immune systems, as well as poverty and related factors such as poor hygiene, lack of sanitation, lack of education, and inadequate clean water sources, will most likely exacerbate the impact of food- and waterborne parasites. The added issue of polyparasitism and impact this may have on the African population generally and more specifically on the approximate 263 million immunocompromised individuals due to undernourishment and HIV, is however unknown.

Viruses

Foodborne diseases caused by viruses are not well-documented in Africa. More attention has been placed on waterborne viruses such as the rotavirus (ROV), which affects millions of children on the African continent. Hepatitis A virus (HAV) and Hepatitis E virus (HEV) are endemic in most African countries; however, the true burden of disease is unknown. Both of these viruses are associated with inadequate water supplies and poor sanitation and hygiene, leading to infection and inflammation of the liver. Although norovirus (NOV) is present on the continent, its exact prevalence and circulating genotypes is unknown. Where outbreaks are reported, there is not necessarily a link to a food source but rather, person-to-person contact as was the case in 2010 in South Africa where six premature babies died in a neonatal ward in a hospital in Johannesburg, from an NOV infection. The true number and impact of NOV infections in Africa is therefore underestimated as is the case with all other foodborne viral diseases. The Ebola virus is a most unlikely foodborne virus, but was nevertheless responsible for 37 cases and 21 deaths in Gabon in 1996, when raw chimpanzee meat carrying the Ebola virus was consumed. This section will therefore focus on ROV, HAV, and HEV in Africa.

ROV

ROV is the most common viral cause of severe diarrhea among infants and young children. An estimated 527 000 deaths occur each year with more than 85% of these deaths occurring in low-income countries mainly in south Asia and SSA, and over two million are hospitalized each year with pronounced dehydration. The primary mode of transmission is via the fecal–oral route. Because the virus is stable in the environment, transmission occurs through ingestion of contaminated water or food and contact with contaminated surfaces or objects. However, in most African countries, transmission is mainly through contaminated water. Since 2006, a number of African countries have participated in a WHO ROV surveillance program, that aimed to identify the genotypes in circulation, to gather information as to the prevalence of the disease in Africa and introduce vaccination programs to protect children from ROV infections. This surveillance program has generated much useful information and where vaccinations are used, the incidence of ROV infection has dropped. Sudan, Ghana, and Rwanda introduced vaccines for the first time in 2011; however, there are many countries where vaccination programs have not yet begun. To have a significant impact on preventing ROV infections and associated disease and deaths on the continent, vaccinations are essential for all African countries.

HAV

Globally, there are an estimated 1.4 million cases of hepatitis A every year. Epidemics can be explosive in growth and cause significant economic losses as it can take weeks or months for people recovering from the illness to return to normal daily activities. The impact on formal food establishments identified with the virus, and local productivity in general, can be substantial, but is largely unknown for Africa. HAV is transmitted via the fecal–oral route, most often through contaminated water and from person-to-person. It is also transmitted via food contaminated by infected foodhandlers, uncooked foods, inadequately cooked foods, i.e., if the temperature during food preparation is inadequate to kill the virus (85 °C for 1 min is required to kill HAV), or foods handled after cooking. It is particularly frequent in countries with poor sanitary and hygienic conditions as in many African and other developing countries. Generally, mortality rate is low but in Africa, among undernourished and immunocompromised people as well as those with hepatitis B or C or underlying liver disease (such as aflatoxicosis), superinfection with HAV can cause a considerable increase in mortality rate.

In most African countries with very poor sanitary conditions and poor hygienic practices, most children (90%) have been infected with the HAV before the age of 10 years. Those infected in childhood do not experience any noticeable symptoms. Older children and adults have thus built up immunity against the virus and epidemics and outbreaks are rare. However, as socioeconomic groups vary in many African countries, an associated variation in infection rate can be expected, with a higher percentage of children in lower socioeconomic groups being seropositive. What is being observed is a higher incidence rate of hepatitis A in those higher socioeconomic groups who

have escaped childhood infection thus making them susceptible in adulthood to HAV. An effective vaccine exists which is available in some African countries, particularly in regions where sanitary and hygienic conditions are good.

As no treatment for hepatitis A exists, prevention is the most effective approach against HAV infections. Improved sanitation, food safety, and immunization are the most effective ways to prevent hepatitis A. Other important interventions include providing:

- education on good sanitation and personal hygiene, especially hand washing;
- adequate and clean water supplies; and
- proper waste and sewage disposal.

HEV

Every year there are 20 million HEV infections, over three million acute cases of hepatitis E, and 70 000 hepatitis E-related deaths, many of which occur in parts of Africa, where large hepatitis E epidemics have been reported. Displaced people living in refugee camps due to wars, political, and economical strife as well as those living in overcrowded temporary housing after natural disasters, are particularly at risk. The most common source of infection is fecally contaminated drinking water and most outbreaks occur following monsoon rains, heavy flooding, contamination of well water, or massive uptake of untreated sewage into city water treatment plants. The ingestion of raw or uncooked shellfish has also been identified as the source of sporadic cases in endemic areas, which include a number of countries in Africa. The symptoms of HEV infection are much the same as for HAV infection. Most people recover completely; however, in contrast to HAV, HEV holds a significant risk for pregnant women with a fatality rate of 10–30% among pregnant women in their third trimester of pregnancy. HEV during pregnancy has also been associated with prematurity, low birth weight and an increased risk of perinatal mortality. HEV could also be serious among persons with preexisting chronic liver disease resulting in decompensation and mortality. Chronic HEV infections have been reported in immunosuppressed people as well. The question therefore arises as to a possible synergistic effect between aflatoxicosis and HEV infections (as for hepatitis B) and the impact this may have on human health in Africa, including the impact HEV may have on the immunocompromised HIV/AIDS and undernourished population in SSA. A vaccine has been developed but is not yet available globally. Outbreaks have been reported in a number of countries in Africa with significant numbers of fatalities (Table 2). For people with liver disease and healthy people, a seroprevalence of HEV of between 2% and 60% is indicated, with higher levels found in endemic areas. In yet other cases, HEV has been suspected, but not confirmed, mainly due to insufficient investigation. Therefore, in Africa, it is possible that HEV is responsible for more outbreaks than what are reported and it may have a more significant impact on human health, than what is believed.

Similarly to HAV, there is no treatment for HEV and prevention is indicated as the best approach, with the same prevention measures being effective, with one major difference, i.e., that currently there is no immunization possible against HEV.

Mycotoxins

Mycotoxins are toxic secondary metabolites produced by toxigenic fungi that contaminate various agricultural commodities either before harvest or under postharvest conditions. They are produced mainly by three genera, i.e., *Aspergillus*, *Penicillium*, and *Fusarium*. Foodborne illnesses due to consumption of foods contaminated with mycotoxins are difficult to detect as most often mycotoxicoses are chronic conditions that manifest themselves over a period of time. It is mainly in acute cases, where death occurs rather rapidly that a mycotoxicosis is more readily identified.

Although there are many toxigenic molds, only a few mycotoxins, particularly those affecting cereal grains and groundnuts are considered dangerous to human health. For Africa, these are mainly aflatoxins and fumonisins, where aflatoxins are associated with groundnuts and cereal grains, whereas fumonisins are mainly associated with maize. However, others such as deoxynivalenol, ochratoxin A, and zearalenone have also been found in commodities in some African countries. As aflatoxins are prevalent in cereal grains and groundnuts, they are also found in animal feed, from where they can enter the human food chain, through contaminated animal-derived foods (milk and meat) as aflatoxin M_1 (AFM_1). Any processed food or beverage commodity that is produced from mycotoxin-contaminated raw materials will most likely remain contaminated as most mycotoxins are not destroyed by heat or food processing. Traditionally fermented beers, which are very popular in Africa, are commonly made from maize, wheat, sorghum, and barley, and may contain mycotoxins if contaminated grains are used as fermentable substrates.

Tropical and subtropical conditions are found in most African countries, therefore high temperatures and moisture, monsoons, unseasonal rains during harvest and flash floods can lead to fungal proliferation and production of mycotoxins. These conditions together with poor harvesting practices, improper storage, and less than optimal conditions during transportation, marketing, and processing, contribute to fungal growth and increase the risk of mycotoxin production.

The FAO has estimated that up to 25% of the world's food crops are significantly contaminated with mycotoxins. It is also claimed that 60% of Africa's grain supplies are at risk due to fungal contamination and mycotoxin production. In most countries in Africa, the presence of mycotoxins in food is often overlooked. This is due to public ignorance and lack of knowledge, lack of enforcement of regulations where they exist, absence of monitoring programs, lack of technological capacity and infrastructure, dumping of contaminated food and/or feed onto the continent, and the introduction of contaminated commodities into the human food chain, especially during food shortages, which are common in Africa. This is mainly due to drought, wars, and political and economic instability. Other contributing factors are:

- Many people in Africa have more uniform diets than their counterparts in the developed world, with little diversity; staple diets consist of maize or other cereal crops, all of which are highly susceptible to mycotoxin contamination.
- Food is often bought from local markets with less attention to quality issues.

Table 2 Outbreaks of HEV in Africa

Country	*Year*	*Number of reported cases*	*Number of reported deaths*	*Source*
Botswana	1985	273	4 (HAV and HBV excluded; no seroprevalence for HEV conducted)	Contaminated water suspected
Central African Republic	2002	222	4	Contaminated drinking water suspected
	2004	213	Not reported	Use of untreated water suspected
Chad	1983/1984	38 French soldiers	None	Not reported
	2004	1442	46	Refugee camps – contaminated river water
	2005	Not reported	>50	Refugee camps – contaminated river water
Côte d'Ivoire	1983/1984	623 cases presumed HEV	Not reported	Not reported
Democratic Republic of Congo	2006	341	13	Contaminated water suspected
Djibouti	1993	Mixed HAV and HEV; numbers not reported	Not reported	Contaminated water
Ethiopia	1988/1989	423	None	Military camps – contaminated water
Namibia	1983	201	7 (6 pregnant women)	Settlements – no potable water; many Angolan refugees
	1995/1996	600	Not reported	Contaminated water supply
Nigeria	1997/1998	10	None	Not reported
Somalia	1985/1986	>2000	87 (46% pregnant women)	Refugee camps – not reported
	1989	11 413	346 (fatality rate 13.8% among pregnant women)	Use of contaminated river water
Sudan	2004	6861	90	Contaminated water suspected
	2012	1050	26	Refugee camps –poor water quality and sanitation
Uganda (Kitgum)	2008	>10 196	169	Poor sanitation
(Pader)	2008	'thousands'	'scores'	Internally displaced people most affected – poor sanitation
(Kaabong)	2009	210	12	Internally displaced people most affected – poor sanitation
(Karamoja)	2011	908	Not reported	Inappropriate disposal of fecal matter and inadequate access to safe water

Abbreviations: HAV, hepatitis A virus; HBV, hepatitis B virus; HEV, hepatitis E virus.

- Food insecurity – the need to satisfy hunger often overrides quality aspects, offering people little choice but to consume food that is contaminated with fungi and that may contain mycotoxins.
- Much of the African population relies on subsistence farming, where improper storage conditions often prevail, which are conducive to fungal growth and mycotoxin production.

Aflatoxins

Aflatoxins are the most studied group of mycotoxins in the African context and often cause acute aflatoxicosis, which is a toxic hepatitis leading to jaundice, and in severe cases, death. Acute aflatoxicosis is an underrecognized and underreported cause of liver damage. Aflatoxin B_1 (AFB_1) is the most common type of aflatoxin found in maize and groundnuts in Africa and has been linked to human primary liver cancer. It is synergistic with hepatitis B virus infection, which is common in SSA, where the risk of liver cancer is then increased tenfold. Developing countries have a higher liver cancer incidence rate and approximately 82% of the 600 000 new cases each year occur in developing countries. Although there have been reported outbreaks of aflatoxicosis in Africa, one of the most well documented and most severe outbreaks of acute aflatoxicosis worldwide, occurred in rural Kenya in 2004. The

outbreak implicated more than seven districts and resulted in 317 case-patients and 125 deaths, due to acute hepatotoxicity. Other outbreaks occurred in 2005 and in 2006, with 30 and 9 deaths reported, respectively. The source of the 2004 outbreak was aflatoxin-contaminated home-grown maize, which was bought from local farms in the affected area and which entered the distribution system, resulting in widespread aflatoxin contamination of market maize. Children and young adults were mostly affected and there were relapses after treatment due to continued exposure to contaminated food. Major challenges that were identified for the management of the cases included inadequately equipped and poorly staffed health care facilities, inadequate logistics, and unavailability of clean food for replacement of contaminated food.

There is increasing evidence linking aflatoxins to stunting and underweight in children, resulting in cognitive impairment and increased mortality risks, both of which can lead to lower human capital with long-term economic consequences. This is of concern, considering that children may be exposed to high aflatoxin levels early in life, i.e., *in utero*, via breast milk and weaning foods commonly used in Africa. Weaning foods consist mainly of maize, but other cereal grains and in some cases, groundnuts are also used, all of which are susceptible to aflatoxin and other mycotoxin contamination. Chronic aflatoxin exposure may result in immunosuppression as well, which could interact with malaria and HIV/AIDS. The health effects of aflatoxins are complicated further by possible exposure to multiple mycotoxins, which can coexist in the same commodity, for example, aflatoxins and fumonisins in maize. Therefore, individuals may be exposed to various combinations of mycotoxins.

There are a number of countries in Africa where a strong, formal agriculture and food industry exists. This is accompanied by legislation for maximum levels of, particularly, aflatoxins in various commodities including feed, a formal infrastructure as well as good farming, storage, and distribution practices. This results in a very low prevalence of aflatoxin contamination in relevant commodities. Industry associations in these countries play a significant role in ensuring that maximum legislated mycotoxin levels are not exceeded. However, even in these countries, there are challenges, for example, ensuring that groundnuts rejected by the formal food industry do not land up in lesser-known processing facilities where peanut butter is manufactured from contaminated peanuts and sold cheaply to unsuspecting institutions and enters into the informal distribution sector. Such peanut butter contaminated with high levels of AFB_1 has been found in rural school feeding programs, with potentially disastrous effects on the health of those children.

Fumonisins

Although the focus is mostly on aflatoxins, fumonisins are problematic in Africa as well, even though they are not as well-researched on the continent. The International Agency for Research on Cancer (IARC) has classified fumonisins as class 2B carcinogens, i.e., possibly carcinogenic to humans and the Joint FAO/WHO Expert Committee on Food Additives has recommended a tolerable daily intake for FB1, FB2, and FB3, alone or in combination, of 2 μg per kg bodyweight per day. There have been no documented fumonisin-related outbreaks in Africa and no country in Africa has fumonisin standards for food. Fumonisin has been associated with human esophageal cancer in parts of South Africa, where subsistence farming of maize occurs. It also reduces the uptake of folate and has therefore been implicated in a high incidence of neural tube defects in rural populations known to consume contaminated maize. Some studies on various local grain-based commodities in Africa have shown very high levels of fumonisin, up to 1830 μg kg^{-1}.

Mycotoxin contamination is not only a burden in Africa and other developing nations but it also significantly affects agricultural products in the developed world. It is estimated to cost the USA's grain industry an annual loss of US$2 billion. However, the application of modern agricultural practices including optimal drying and storage practices and the establishment of a legislatively regulated food processing and marketing system, have greatly reduced mycotoxin exposure in these populations. At the mycotoxin contamination levels, generally found in food products traded in these market economies, adverse human health effects have largely been overcome.

Some countries in Africa have addressed the regulation of mycotoxins in food and feed. In 2003, FAO listed 15 out of 54 countries having specific mycotoxin regulations. These countries cover approximately 59% of the inhabitants of the continent and most of the mycotoxin regulations concern aflatoxins. The fact that countries have no specific regulatory limit for mycotoxins does not mean that the problem is ignored. Several of these countries recognized that they have problems due to mycotoxins and that regulations should be developed. However, the establishment of mycotoxin regulations alone, in the absence of a supporting structure and associated activities will have limited effects in enhancing food safety and health protection, especially in countries where farmers grow agricultural produce for their own consumption via subsistence farming, which is the case in many African countries.

A multidisciplinary approach is key to a sustainable solution for the mycotoxin issue in Africa and needs to be viewed, in the overall context of local food safety, health, and agricultural issues. Collaborative efforts between farmers, researchers, and governments are required to prevent or at least significantly reduce the occurrence of mycotoxins in foods. Farmers should participate in research programs and governments should strengthen their food control and health care systems and provide a legislative environment in which farmers can operate. This legislative environment should include educating farmers and consumers as well as creating awareness, conducting surveillance, and regular monitoring of commodities and enforcing regulations. Novel, simple, cheap, yet accurate methods for detecting the presence of mycotoxins in foods, in particular aflatoxins and fumonisins in cereal grains and groundnuts, at levels detrimental to human health, are needed for Africa. Typical educational programs for farmers should focus on implementing good pre- and post-harvest practices including proper drying techniques, maintaining correct storage facilities, and ensuring that grains and oilseeds are not exposed to moisture during transport and

marketing. Promotion of the Hazard Analysis and Critical Control Point (HACCP) System, where feasible, should also be promoted. In this regard, the South African government has made HACCP mandatory for all processors of groundnuts, i.e., peanut sorting and grading facilities as well as peanut butter manufacturers, since November 2010 due to the aflatoxin problems associated with peanuts in South Africa.

The use of physical methods, including cleaning, separation of screenings, winnowing, washing, aqueous extraction, crushing, dehulling, and milling, has been shown to be effective in reducing mycotoxins in cereals. One of the most effective ways of minimizing aflatoxin contamination in peanuts is physical separation of contaminated, moldy, shriveled, discolored, or insect-infested seeds from sound kernels. Effective and simple drying and storage methods include drying on mats and sun drying and subsequent storage of bags elevated off the ground together with pest control. At preharvest level, the time of planting, the use of varieties less susceptible to mycotoxin contamination and the timing of the harvest are all useful interventions. Other interventions include enterosorption and chemoprotection, both of which are expensive and therefore difficult to implement in developing countries. There is also uncertainty as to the efficacy and safety of these two interventions. It is important to keep in mind that the appropriate intervention will depend on the crop and especially the country. Because of this, before implementing an intervention method, consideration is needed toward the sustainability, cultural acceptability, economic feasibility, ethical implication, and overall effectiveness of the proposed method(s).

Awareness campaigns have proven to be highly effective, even more so when organizations such as FAO and WHO work together with countries' governments to raise awareness and educate people on the issues and prevention methods. To be as effective as possible, multiple means of spreading the information must be used to ensure that it gets to all people, even those in remote rural areas.

Mycotoxins are clearly one of the more important issues in Africa. It is therefore evident that proper control of mycotoxin contamination is dependent on the concerted efforts of all role-players along the food production and distribution chain.

Street Foods

Street foods or street-vended foods are foods and beverages prepared and/or sold by vendors in streets and other public places for immediate or later consumption without any further processing or preparation. This definition includes fresh fruits and vegetables that are sold outside authorized market areas for immediate consumption. Street foods hold many benefits:

- Socioeconomically, they form a major component of the informal food distribution sector, providing economic support to small farmers as an outlet for rural produce, providing income and employment for a large number of people, especially women in poverty in Africa and providing an opportunity for development of business skills with very little capital investment.
- They offer a most affordable way of obtaining a nutritionally balanced meal outside the home for many people with limited means, thereby contributing to food security and possibly even to micronutrient supplementation, provided the street foods are safe.
- They are easily accessible.
- They are a source of attractive and different food for tourists.

Consumers of street foods have cited a number of reasons, besides affordability, for purchasing street foods in Africa. These include tastiness, nutritional value, convenience, cleanliness, and interpersonal trust between vendor and consumer. Even though cleanliness was included in consumer considerations in purchasing street foods, specific matters regarding hygienic practices and food safety were not included. Street foods account for a significant proportion of economic employment, daily urban food consumption of millions of low- and middle-income consumers, and for generating millions of US dollars per annum for this industry across Africa.

Even though street foods offer tremendous benefits, they are also a potential health risk as street-food vendors are often poor, uneducated, and untrained in food hygiene and sanitation. The global food crisis has worsened an already problematic food situation in many African countries and as a result, satisfying hunger often overrides the consideration of food safety and quality. The affordability of food security then extends into the affordability of food safety, i.e., how much food safety can be bought by a consumer who has less than US$1 per day to spend on food?

Other contributing factors to the questionable safety of street foods include lack of infrastructure such as clean, running water, unhygienic environment, lack of toilet and handwashing (with soap) facilities, inadequate waste facilities, improper waste management where facilities do exist, undercooking of food, cross-contamination due to bad hygiene practices, lack of refrigeration and other hygienic storage facilities for raw and cooked foods, lack of protection of food from insects and flies, dirty/improperly washed utensils, and insufficient resources for inspection and laboratory analysis. This general lack of hygiene can result in contamination with a variety of microbial pathogens, including fecal–orally transmissible parasites, viruses, and bacteria.

The prevalence of foodborne pathogens in street-vended foods of a country affects not only the local population but also potentially the cross-border traveler which could lead to spread of the pathogen once the visitor returns home.

The types of street foods that are prepared and sold in different African countries are as diverse as the prevailing climate, cultures, and religions themselves. Each of these foods may hold a variety of risks, not all of them necessarily microbiological in nature, although microbiological hazards are the most common ones identified. Foods range from different cereal-based porridges and traditionally fermented beers, all of which pose a potential risk for the presence of mycotoxins; a variety of cheeses often made from unpasteurized milk originating from nonstate veterinary inspected herds of cattle, sheep, goats, and camels thereby posing potential microbiological risks; various meat (including bush meat) and

poultry dishes often originating from animals infected with parasites and bacteria and/or slaughtered under unhygienic conditions or in nonapproved facilities; vegetables and fruits consumed either cooked or raw, with raw vegetables (and sometimes certain fruits) posing a microbiological risk if irrigated or washed with contaminated water; fish dishes where the fish may be infected with parasites or contaminated with high levels of histamine (where relevant) and bacterial pathogens; fruits and vegetables that may contain excessive levels of registered pesticides (above the accepted maximum residue limit) or the use of nonregistered or illegal (banned) pesticides; nuts of which their origin is either unknown or known and not well-understood and could therefore pose a mycotoxin risk; herbs and spices that may be contaminated with bacterial pathogens, thereby becoming a potential source of contamination in the final product, particularly if not cooked well or eaten raw; the reuse of cooking oil (particularly polyunsaturated oils such as sunflower seed oil which are easily oxidized by repetitive and prolonged use at high heat) when deep frying foods, which may result in diarrhea and other health problems in some individuals; extruded snacks which are often sourced from dubious suppliers, who usually sell these cheaply, with consequent potential risk of the presence of either illegal colorants or permitted colorants in excess of maximum regulated levels. Extruded snacks attract mainly children who are at higher risk of suffering ill-effects from such practices.

Finally, natural toxins associated with specific crops may be sold as street food and thus pose a significant health risk in some African countries. A case in point is the consumption of insufficiently processed bitter cassava root, which can cause konzo, an irreversible paralysis of the legs and leaves people unable or struggling to walk. It is caused by the ingestion of cyanide-containing compounds from the bitter cassava root when it is insufficiently processed, combined with a protein-deficient diet, especially proteins that provide sulfur-containing amino acids that clear the body of cyanide. Drought conditions cause an increase in cyanide to high levels, leading to the disease. Displaced people, because of war, are also at high risk of ingesting such cassava. Six countries in Africa, as far as is known, are affected by konzo, particularly the DRC and more recently, Angola. The true incidence of konzo in Africa is unknown and is believed to be underestimated, with unofficial estimates at 100 000 people affected in the DRC in 2000 due to the civil war in that country, with many affected refugees in the Central African Republic.

The presence of pathogenic bacteria in street foods in Africa is a well-researched topic. This is not the case for foodborne parasites and even less so, for foodborne viruses (see Sections Parasites and Viruses). Common bacteria and bacterial groups found include *L. monocytogenes*, *Listeria innocua*, *B. cereus*, *Salmonella* including *Salmonella arizonae*, *Salmonella.* Typhimurium, *Salmonella biafra*, *Salmonella braenderup*, and *Salmonella* Weltevreden, *Sh. flexneri*, *Sh. sonnei*, *Citrobacter freundii*, and other *Citrobacter* spp., *Enterobacter cloacae*, *Cronobacter sakazakii*, *St. aureus* including presence of enterotoxin where tested for, *Aeromonas hydrophila*, *E. coli*, *Cl. perfringens*, *Vibrio metschnikovii*, *Campylobacter* spp., *Alcaligenes* spp., *Klebsiella* spp., *Pseudomonas aeruginosa*, coliforms, micrococci, coagulase-negative staphylococci, streptococci.

Regardless of the numerous pathogens that have been isolated from street foods in Africa, very few foodborne outbreaks have been specifically linked to street foods. The main reasons for this are a severe underreporting of foodborne disease outbreaks; lack of laboratory capacity in identifying responsible pathogens and/or their toxins; inadequate resources in the responsible ministries to conduct inspections and monitoring programs; lack of appropriate guidelines, knowledge and practices in obtaining and transporting samples of food and clinical specimens in the correct manner to maintain the integrity of the samples; lack of capacity and knowledge in conducting a full epidemiological analysis.

The abovementioned is, however, not unique to street-vended foods.

One very important, but often overlooked fact is that street food vendors are quite capable of producing safe food. Studies have shown that regardless of a visibly unhygienic environment in certain African countries and regions within those countries, no significant pathogens have been isolated from selected foods. The main reasons for this are:

- the practice of basic hygiene – more so among women than men;
- the purchase of fresh raw food for the day's needs, every morning from a local, formally registered retailer close to the vendor, cooked and consumed the same day;
- the low amount of leftovers at the end of the day, which are taken home and consumed by the family, avoiding the practice of returning the following day with cooked food that has stood unrefrigerated for many hours at warm temperatures and being resold without adequate reheating; and
- access to toilets and potable water.

It is therefore clear that basic hygienic and other good practices are essential to provide safe street foods and are possible in Africa. Such good practices should, however, be supported by targeted training programs to improve the safety of street-vended foods. An example of a successful integration of the two above-mentioned components to improve the microbiological safety of street foods is provided below:

An FAO funded project on the microbiological safety of street foods in the Gauteng Province, South Africa was conducted in 1999–2000, after which three workshops were held in three main provinces to provide the local health authorities with results of the project. Shortly afterwards, the National Department of Health developed a training manual on safe practices for street food vendors for use by local health authorities. A number of these authorities in different provinces subsequently developed specific programmes for street food vending in their jurisdictions. The Ethekwini Metropolitan Council (in Kwa-Zulu Natal Province) decided to integrate the informal economy into its long-term plan to promote its economic development. Street food vendors now operate in allocated areas, thus minimizing the problem of public nuisance in Durban City and surrounding towns. The Metro ensures that prior to them being permitted to operate a food establishment, street food vendors receive essential food hygiene training, which enables them to comply with minimum hygiene regulations. A certificate of acceptability is then issued according to national food hygiene regulations, which allows for better control and coordination of the sector within the Metro. A similar success story applies to the Ehlanzeni District Municipality in the Mpumalanga Province. Here, local health authorities provided basic

services such as structures, cleaning services, running water, wash basins, storage facilities and toilets for the vendors, leading to safer foods and improved regulation. Most other provinces have since followed suit.

Improving the safety of street-vended foods in Africa poses great challenges, but the risk factors are well-identified and the solutions are clear. It is important for countries to share results of any studies conducted with all relevant stakeholders to develop appropriate strategies for improving the safety of street foods and to continue promoting the sale of street-vended foods. A successful transition from street-food vending being perceived as a nuisance and as unsafe by national health authorities is possible, when these authorities instead promote, support, and improve the safety of street-food vending. Experiences in South Africa have shown that success is possible provided food control authorities, street-food vendors and all other stakeholders, such as consumer groups and academic structures, collaborate to improve the sector.

Conclusion

The true prevalence of food- and waterborne disease in Africa is unknown and severe underreporting occurs. The continent undoubtedly faces numerous challenges in improving the health status of its population. Food and water are not only two essential requirements for life but access to safe and nutritious food is a basic human right. Although not all health-related matters on the continent are caused directly by unsafe food and water, a significant number are. Exacerbating the situation, are a very young population with millions of children under the age of 5 years and more than one quarter of 1 billion people on the continent immunocompromised due to HIV/AIDS and undernourishment.

Whose responsibility is food and water safety in Africa and what needs to be done? Resolving these matters is not an easy task and will involve a multidisciplinary and multiagency approach. The problem is political, economical, social, educational, and scientific and all of these aspects need to be addressed simultaneously and in a coordinated fashion to make a real and sustainable difference in Africa.

International agencies continue to support many projects in Africa, however, Africa needs to take responsibility for improving the lives of its own people. In this regard, the African Union (AU) has undertaken a number of initiatives to act on hunger, poverty alleviation, animal diseases and zoonoses, aflatoxicosis, enhanced and more coordinated responses to Codex Alimentarius Commission meetings, particularly in the areas of pesticides, food hygiene, and food contaminants. Of particular importance is the meeting held by the AU in Rwanda in November 2012, where the groundwork for an African food safety authority was laid. At country level, food safety capacities in all respects need to be strengthened. Political will is essential as this will drive allocation of resources to important areas addressing food and water safety in countries. An event occurred in 2010 in South Africa, i.e., the World Cup Soccer, which had a most remarkable outcome. A heightened awareness of foodborne illness was created and enhanced surveillance and numerous awareness campaigns were conducted by public and private entities, which included the country's health facilities, prior and during the event. This awareness has remained 2 years after the event and currently 2–12 foodborne diseases are being reported monthly in the country. In addition, a website has been developed by health agencies where the public can report a suspected foodborne illness. It acts as a nationwide foodborne disease portal and forms part of a national database registry that can help determine if the reported illness is part of a larger foodborne disease outbreak. To underscore the escalation of importance of food safety and foodborne disease in South Africa, the National Department of Health published guidelines for the management and control of infectious foodborne diseases in the country in 2011. The guidelines are aimed at assisting health care workers with practical, user friendly, and concise information on the diagnosis, treatment, and reporting of foodborne diseases with the ultimate goal of prevention, control, and obtaining accurate estimations of disease burden in communities.

Africa should use the momentum brought by international events being increasingly hosted on the continent to heighten awareness and implement systems to improve relevant infrastructure and the management of foodborne diseases.

FOODBORNE DISEASES

Prevalence of Foodborne Diseases in North America

P Sockett, University of Guelph, Guelph, ON, Canada

Glossary

Cost-of-illness An approach toward the economic evaluation of the burden of illness that collates, evaluates, and assesses the individual cost elements of illness. For foodborne diseases this usually includes healthcare-related costs, lost production, and value-of-life estimates.

Disease notification Regular reporting by physicians of new illnesses due to an agreed list of infections. Reporting is usually done to a senior public health official at the jurisdictional or national level.

Emerging disease Any infection or toxin that is becoming recognized as a cause of human illness. This includes agents that are newly identified as causing human illness, such as prions, or agents that are recently recognized as being significant pathogens as they become more common or laboratory technology advances make it easier to identify them in human specimens, such as *Campylobacter*.

Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of food or water.

Phage type A subdivision of a species of bacteria that depends on whether the bacterial cell is killed by certain bacterial viruses (bacteriophages). Individual strains or phage types will reflect the susceptibility of a particular bacteria to a set panel of bacteriophages.

Surveillance The systematic, ongoing collection, collation, and analysis of data, and the dissemination of information based on that data, usually for public health purposes when done in the context of human disease.

Toxin A naturally occurring poison produced by microbes, or naturally occurring in fungi, plants, and animals. Some microbial toxins, such as botulinum toxin, are preformed in the food under certain conditions; other microbial toxins, such as those produced by enterohemorrhagic *Escherichia coli* (EHEC), are formed in the intestine after the bacteria have been introduced. A number of toxins linked to seafood are produced by phytoplankton and are concentrated in the flesh of the shellfish (paralytic shellfish poisoning) or fish (ciguatoxin) during feeding. A common fish toxin, scombrotoxin, is a histamine-like chemical produced by the action of naturally occurring bacteria in poorly temperature-controlled caught fish.

Introduction

In Canada and the United States (US), foodborne diseases are important causes of morbidity and of potential economic loss. The importance of food safety and security is indicated by government and commercial infrastructures for regulating and protecting food and international trade in food animals, their feedstuffs and products, produce, and food products. Historically, each country has developed legislative requirements, beginning in the US, for example, in 1906 with the Federal Food and Drug Act, and monitoring and enforcement agencies including the US Food and Drug Administration (FDA), and the Canadian Food Inspection Agency. The evolution of legislative approaches to regulate food safety and establish standards for quality, signaled recognition of national government responsibility for safety and quality, and paved the way for the establishment of mechanisms for monitoring food quality and foodborne illness. These national structures work with international frameworks, including trade agreements and the international disease reporting requirements of the World Health Organization.

Although over 200 agents of foodborne disease are recognized, this article focuses on microbiological agents, the most commonly identified cause of foodborne human illness in North America. The significance of individual microbiological pathogens varies over time, with season and geography, and this article pays attention to those most commonly reported or which have emerged as important causes of morbidity or mortality since the 1960s. A relatively small number of microbes are responsible for most cases of reported illnesses including historically recognized pathogens such as *Salmonella*, *Staphyloccocus*, *Streptococcus*, *Clostridium*, and *Bacillus* as well as microorganisms more recently recognized as important including *Campylobacter*, enterohemorrhagic *Escherichia coli* (EHEC), and *Listeria*; protozoal parasites such as *Cyclospora*; and viruses, including norovirus.

Information on Foodborne Diseases

Collection of data on foodborne diseases has, until relatively recently, depended on mainly passive systems for collating

 doi:10.1016/B978-0-12-378612-8.00076-7

information on individual cases or outbreaks using jurisdictional and national notification and laboratory reporting systems. Data on foodborne disease at the national level in the US and Canada originated in the early decades of the twentieth century. Reporting in the US was initiated in 1923 to monitor the impact of contaminated milk. Reporting by the US on outbreaks of foodborne and waterborne diseases was added in 1938, and the Salmonella Surveillance Activity was established in 1962 to collate information from States, the US Department of Agriculture and the FDA.

In 1924 national notification was initiated in Canada for a limited number of diseases including typhoid and paratyphoid fever, shigellosis, and poliomyelitis. Subsequently, amebiasis and hepatitis A (1927), brucellosis (1928), trichinosis (1929), botulism (1933), salmonellosis (1958), cholera (1974), giardiasis (1983), listeriosis (1990), and verrotoxigenic *E. coli* (1990) were added. National data for Canada, including case and outbreak information and, from 1973, reports on foodborne, waterborne, and enteric disease incidents, summarized reporting incidence and documented reporting trends. Supplementary morbidity and mortality information is based on passive, national, or jurisdictional information systems for collecting data on hospitalizations and deaths.

These historical approaches to surveillance of foodborne diseases have inherent methodological issues that lead to underreporting and late reporting of the actual cases of disease; and removal and addition of pathogens from lists of notifiable diseases interrupt reporting trends. For most foodborne infections and intoxications, only a small proportion of cases are reflected in national statistics, although this varies with the microorganism. This low proportion reflects issues around seeking of medical care, physician testing and reporting, laboratory technology, and reporting policy.

Evolution of active approaches to foodborne disease surveillance is driven by the public health imperative to protect consumers and to reduce the burden of illness. This requires early recognition of, and response to, outbreaks and the need to improve understanding of foodborne disease risks. This itself is a response to changing trends in foodborne diseases and emergence of new pathogens that reflect a number of underlying factors (Table 1). During the 1990s, it was realized that the US and Canada needed to restructure their foodborne disease surveillance systems to address these new and emerging issues. Two areas of innovation have enabled the development of more active surveillance systems. First, developments in diagnostic technologies, which provide rapid results that can be easily digitized, and information technology that facilitates rapid networking of data. Second, evolution of surveillance from a linear process for analysis of reporting trends to an integrated process for linking reporting trends with identification and assessment of risk (Table 2).

Burden of Disease

Recognition that the incidence of foodborne diseases is significantly higher than indicated by national statistics, and a shift to a risk-assessment approach to identifying risks and priorities has led to efforts to more accurately estimate the burden of these diseases. Estimates in the 1980s suggested 2 million cases annually in Canada with associated costs-of-illness of over CAN$1 billion for health care, lost production and value of life. Estimated cases and costs in the US during the same period ranged between 6.0 million cases with costs of US$ 5.8 billion and 12.6 million cases with costs of US$ 10.6 billion. Further estimates for the US have varied as high as 24 to 81 million cases annually and showed notable variation in estimated hospitalizations and deaths (Table 3).

In 1999 it was estimated that 76 million cases of foodborne disease occurred in the US annually, 13.8 million due to known pathogens (Table 3), with 325 000 hospitalizations and 5000 deaths. Noroviruses (previously Norwalk-like viruses), *Salmonella*, and *Campylobacter* species were identified as the most common foodborne illnesses, accounting for 91% of cases due to known pathogens. These estimates reflect several years' data on reported infections and explained, and largely conservative, extrapolations to give national figures. Data for the US were extrapolated to provide estimates of the economic burden of disease and estimates for acute gastroenteritis which suggested 195 million episodes of illness annually in the US (Table 4). Similar estimates for *Salmonella*-related illness indicated 1.4 million cases annually.

An equivalent study for foodborne diseases has not been published for Canada since the 1980s, but estimates for three pathogens were published in 2006. Based on underreporting rates derived from studies of acute gastroenteritis, conservative estimates for annual cases of verotoxigenic *E. coli* (21 000), *Salmonella* (75 000), and *Campylobacter* (283 000) were calculated. Extrapolating results from studies in two Canadian

Table 1 Underlying factors influencing reported trends in foodborne diseases

- Increased scale of production and distribution from local to mass production at centralized facilities and mass transport and distribution networks.
- Changing husbandry practices to include industrialization of cattle, swine, and poultry production at one end of the spectrum, to production using 'organic' or traditional approaches to maintain produce or livestock free of contaminants such as antibiotics and pesticides at the other end.
- Changes in consumer preferences and food consumption patterns.
- A changing global food economy with, for example, access to fresh produce and fruit year-round via global markets.
- Advertising, and nutritional and dietary pressures on consumers to eat certain specific foods or commodities because they are cheap, easy to access, socially enabling, address obesity, imply health benefits, etc.
- Changes in food processing and packaging technologies and changes in demand for novel products.
- Improvements in technologies for the detection of pathogenic microorganisms, e.g. PCR PFGE and DNA sequencing, and sharing of information.

Abbreviations: PCR, Polymerase chain reaction; PFGE, pulsed field gel electrophoresis.

Table 2 National foodborne disease surveillance systems: USA and Canada

USA and Canada pre1990	
Notifiable disease reporting	Passive state (USA) or provincial/territorial (Canada)
Laboratory based surveillance	Reporting
USA since 1990	
FoodNet	Active sentinel – surveillance (10 sites)
PulseNet	National (and international) sub typing network for bacterial pathogens
eFORS[a]	Internet-based national outbreak reporting
NARMS[b]	Monitors for antimicrobial resistance (national)
Canada since 1990	
NESP[c]	Active laboratory reporting of key enteric pathogens
CIOSC[d]	Active internet-based national reporting of suspect or known outbreaks
CIPARS[e]	Monitors for antimicrobial resistance in selected pathogens
C-EnterNet	Active sentinel surveillance (1 site)
PulseNet	As above and linked with the US system

[e]Thomas *et al.*, 2006b.
[f]The range of estimates may include diarrhea with or without vomiting and may include a downward adjustment for cases with concomitant respiratory symptoms.

Provinces indicated approximately 40 million episodes of acute gastroenteritis annually (Table 4) of which a third was estimated to be foodborne. These estimates suggested slightly higher rates for *E. coli* and *Campylobacter* in Canada compared with the US, although the differences may simply reflect the approaches used.

National Trends

Human exposure to foodborne diseases is multifactored. Reported trends are driven by intrinsic factors relating to the microbiological quality of the food, and extrinsic factors, such as ambient temperature and preparation standards that act to amplify the microbiological load. Age and gender factors suggest that the highest incidence of foodborne disease occurs in the very young and elderly. This pattern may be influenced by the association of a specific agent and food preferences linked to age or the individuals' immune status. Thus, in an analysis of *Salmonella*, *Campylobacter*, *E. coli*, and *Shigella*, in Canada, young children and the elderly were more often reported, except for *Shigella* where cases declined in the elderly. An increase observed in 20–40 year olds for *Salmonella*, *Shigella*, and particularly *Campylobacter* infections, was linked to young adults leaving home for the first time and likely less aware of food handling and purchasing issues. For pathogens such as *Vibrio parahaemolyticus* or *Vibrio vulnificus*, cases are more likely in adults consuming seafood, whereas more children have severe symptoms with EHEC infections due to the pathogenesis of the organism. In this section, recent trends

are discussed in the context of factors that have influenced reported incidence.

Historically Established Foodborne Diseases and Preparation Practices

A relatively small number of foodborne diseases are responsible for the majority of reported illnesses (Table 5). Historically established causes include *Bacillus cereus*, *Botulism*, *Clostridium perfringens*, *Staphylococcus aureus*, *Shigella*, and *Streptococcus*. Trends in reporting of *B. cereus*, *C. perfringens*, *S. aureus*, and streptococcal infection are based primarily on cases identified in association with reported outbreaks in Canada and the US and likely underestimate disease incidence. The researchers compensated for this by using a multiplication factor of 10 in the 1999 estimates for the US. No recent comparable estimates exist for Canada. These pathogens are associated with food preparation practices including handling, storage, and temperature control. Declining reporting trends for these diseases possibly reflects the impact of improved food safety awareness, particularly in the catering industry.

Table 5 Estimated annual foodborne illnesses due to known pathogens in the USA

Disease or agent	*Estimated illnesses*
Bacteria

Source: Adapted from Mead PS, Slutsker L, Dietz V, *et al.* (1999) Food-related illness and death in the United States. *Emerging Infectious Diseases* 5: 607–625.

Reported cases of botulism since the 1980s (mainly toxin types A, B, and E) have rarely exceeded 50 cases annually in the US, with the highest incidence in Alaska, and 20 cases annually in Canada. Although sporadic cases and outbreaks associated with home food preparation and traditional aboriginal peoples' food account for a significant proportion, a number of outbreaks were associated with commercial or restaurant food items since the 1970s including: baked potatoes (skordalia), bean dip, bottled mushrooms, burrito, canned cheese sauce, chili sauce, clam chowder, garlic in oil, salsa, sauteed onions, and seafood products.

Historically Established Foodborne Diseases and Specific Interventions

The targeted elimination of tuberculosis (TB), due to *Mycobacterium bovis*, and brucellosis (*Brucella melitensis*) in cattle has significantly reduced their incidence in humans in the US and Canada over the last 40 years. An estimate of 1554 cases of brucellosis annually in the US has been made; currently less than 150 human cases are reported each year although increased incidence is noted since the late 1990s. TB infection linked to milk is now rare in both countries and when TB or brucellosis are recorded they are usually associated with travel to countries where the diseases are endemic in cattle, sheep, and goats, or the importation of raw milk products from these sources. The widespread adoption of milk pasteurization, in addition to contributing to the decline in human brucellosis and *Mycobacterium bovis* infection, helped to reduce milkborne typhoid, nontyphoidal *Salmonella* and streptococcal infections following its widespread adoption in the US and Canada by the middle of the twentieth century.

Improved Sanitation

The decline in typhoid and cholera during the early twentieth century reflected improvements in sanitation and reduced exposure to human feces via food and water. The US rate for typhoid declined from approximately 35 (per 100 000 population) in the 1920s to an insignificant rate today. Similarly, an average of over 3000 cases a year notified between 1924 and 1929 in Canada dropped to under a 100 cases a year from the 1970s. Most typhoid cases currently recorded are associated with travel to countries where typhoid remains endemic.

Exposure to human feces continues to play an important role in the transmission of enteric viruses, many of which are foodborne. Most enteric viruses are obligate human pathogens, and over 100 different types can be identified in human sewage including enteroviruses, hepatitis viruses, and gastroenteritis viruses. Noroviruses (Norwalk-like viruses) and hepatitis A are most commonly associated with reported human infection. Researchers have attributed 80% of the estimated 38.6 million foodborne illnesses annually in the US to viral causes, mostly noroviruses. Previously these infections would have been recorded as "unknown cause" and the apparent emergence of these viruses largely reflects improvements in diagnostic approaches in the 1990s.

Industrialization of Meat and Poultry Production

Meat production over the last four decades has seen unprecedented levels of intensive farming and centralized processing and distribution. This has significantly contributed to trends in the incidence of key foodborne diseases (*Salmonella*) and may have mitigated for the emergence of others (*Campylobacter, E. coli*). Intensive farming of cattle, swine, and poultry (both meat and egg production) have presented the farming industry with significant challenges to maintaining the health of livestock and the safety of products derived from them.

Feeding the demand for relatively cheap food has arguably moved the control of pricing from the farmer to the retailer and encouraged practices to maximize gain by the producer, including prophylactic use of antibiotics and recycling of nonuseable offal products into feed for the next generation. This later issue is specifically associated with the emergence of BSE in cattle and the human form of this prion disease, vCJD, in the UK in the late 1980s and early 1990s. The US and Canada have been relatively untouched to date with only 21 cases of BSE and 3 cases of vCJD. The emergence of BSE had profound impacts on cattle feed production, on the movement of cattle across borders, and on public scrutiny of the food supply.

Centralized processing and distribution has resulted in the potential for outbreaks to affect huge numbers of consumers. Probably the largest ever documented outbreak of foodborne illness in the US affected an estimated 197 000 people with *Salmonella* infection in 1995. The illness was linked to widely distributed, improperly pasteurized milk from a dairy in Illinois, USA.

The link between intensive meat and poultry production and increased human health risk is arguably supported by a polarization in *Salmonella* reporting trends. The decline of typhoid in the last century was followed by an increase in reported nontyphoidal *Salmonella* infection. Human cases based on laboratory identifications rose significantly from the 1960s to the 1980s. Nontyphoidal *Salmonella* infections are currently one of the most commonly reported foodborne diseases, and annual trends have remained within 40 000 to 45 000 laboratory confirmed cases in the US and 5000 to 7000 in Canada since the mid-1990s (Figure 1). Although *Salmonella* are ubiquitous in the intestinal tracts of animals, and over 2400 serotypes are described, only a handful are associated with most human illnesses.

Annually, several hundred *Salmonella* serotypes are identified from human cases, but only four or five account for upwards of 50% of reported infections. *Salmonella enteritidis* and *Salmonella typhimurium* are the most frequently reported, whereas *Salmonella heidelberg* and *Salmonella newport* were also in the top four serotypes in most years since 1995 in the US. Canada shows a similar pattern except that *Salmonella hadar* replaces *S. newport* in the four common types in most years. A summary of Canadian *Salmonella* isolates from 1996 to 1999 showed that the serotypes most common in humans were also common in cattle and poultry. Nonhuman isolates of *S. typhimurium* were predominantly from bovines, whereas *S. enteritidis*, *S. heidelberg,* and *S. hadar* were predominantly from poultry and *S. enteritidis* almost entirely from chicken and egg.

The increase in *S. enteritidis* in the US since the early 1970s, described as a "national epidemic," is one of the most important trends in *Salmonella* reporting in recent decades, reflecting international spread of a single serotype in chickens. Unlike cattle, where transmission of *Salmonella* is likely from animal to animal in crowded and stressful conditions, the spread of *S. enteritidis* in the late 1980s and early 1990s, was associated with transovarian transmission via infected eggs, possibly from limited breeding stock to poultry flocks and then by bird to bird transmission. Human infection at the same time was linked to infected eggs and poultry meat. The implication of infected breeding stock is further supported by the limited number of strains involved, suggesting a narrow genetic lineage. Declining reporting of *S. enteritidis* infection in the US from 1996 may reflect efforts to reduce infection of flocks as well as advice on reducing amplification and spread during retailing, storage, and food preparation.

Salmonella serotypes of human importance have multiple subtypes useful in epidemiological research, outbreak investigations and in tracking the evolution of characteristics such as antimicrobial resistance. These are demonstrated

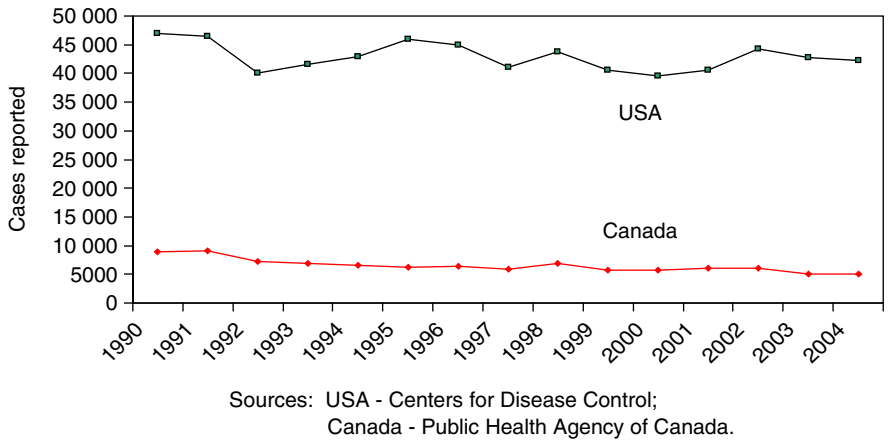

Figure 1 *Salmonella* reports by year for USA and Canada: Notifiable diseases data. *Source*: US Centers for Disease Control; Public Health Agency of Canada.

by traditional subtyping methods (phage typing (PT)) and recent molecular methods (pulsed field gel electophoresis (PFGE)). PT studies of *S. enteritidis* indicate that predominant phage types exhibit some geographic variation: phage types 8, 13, and 13a (and more recently PT4) in the US and Canada; PT4 in the UK; PT4 and PT8 in other parts of Europe. In Canada *S. enteritidis* phage types show similarities between human and poultry sources; PT4, PT8, and PT13 accounting for 40% to 80% of all types from both sources in recent years.

Industrialization of meat and poultry production has influenced the emergence of *Campylobacter* and EHEC since the 1970s. Despite identification as a potential pathogen in the late nineteenth century, *Campylobacter* was not fully recognized as a human pathogen until the 1970s when the development of selective growth media enabled laboratories to routinely test for the bacterium. *Campylobacter* infections, particularly *Campylobacter jejuni*, are now recognized as one of the most common foodborne illnesses. Although the early increase in *Campylobacter* was due to improved laboratory diagnosis, consumption of poultry with high contamination rates has contributed to recent trends. Researchers have estimated 2.4 million *Campylobacter* cases yearly in the US, a million more for *Salmonella* infection. Notifications of *Campylobacter* in Canada have consistently exceeded *Salmonella* for the last 15 years, ranging annually between 10 000 and 16 000 reports. A gradual decline in annual reports since 1994 may reflect improved awareness and food hygiene, although the actual reason is not known.

Although *Campylobacter* is widely found in the intestinal tract of domestic and wild animals and birds, most human illness is linked to meat, poultry and raw milk. Poultry appear susceptible to infection by low numbers of bacteria, and studies in the 1990s indicated that by 4 weeks of age most commercially produced chickens were colonized, probably from environmental sources such as nonchlorinated natural water. Rearing and processing practices contribute to further amplification and spread of the bacterium and a high (but variable) proportion of retail chicken meat is contaminated by the time it reaches the shop shelf. Bacterial counts may increase during transport, slaughter, and processing, although counts on carcasses can be reduced by chilling, by attention to processing plant hygiene and by processes which directly reduce carcass contamination (e.g., irradiation). Canada's C-EnterNet sentinel site studies, however, continued to show retail poultry meat samples ranging from 29% to 43% positive from 2006 to 2008, whereas contamination of other meats (beef and pork) was negligible.

In 1982, a new EHEC strain was linked to separate outbreaks of bloody diarrhea in two US states. The infection was associated with eating beef from a fast-food restaurant chain and *E. coli* O157:H7 was identified from nine cases. A new foodborne disease, described as "hamburger disease" in the press, had been recognized. Interestingly, Canadian researchers had described several *E. coli* strains with similar toxic effects in 1977. These verrotoxin-producing *E. coli* or shigatoxin-producing *E. coli* (STEC) infections were associated with bloody diarrhea (hemorrhagic colitis) and, in a small proportion of cases, hemolytic uremic syndrome (HUS), particularly in young children. HUS is of particular concern because of the life-threatening symptoms and the potentially severe impact on the long-term renal health of the individual, and is recognized as a major cause of renal failure in children.

E. coli outbreaks associated with ground beef products and milk reflects the link to cattle as a major source of EHEC infections. Approximately 3% of calves and up to 80% of adult cattle are positive for *E. coli* O157:H7. Although the organism does not cause symptoms in adult cattle, the spread may be facilitated by feedlot conditions. The seriousness of human illness and high levels of infection in adult cattle, which increases the potential for carcass contamination during slaughter, has resulted in closer scrutiny of ground beef, leading to multiple large recalls of these products. Although a variety of foods are linked to *E. coli* O157:H7 infection, including salad, fruit, vegetables, apple cider, raw milk, yoghurt, sausage, and deer meat jerky, many link to contamination with cattle manure. Current trends in laboratory-confirmed human cases indicate a gradual upward trend in reporting since the mid-1990s in the US, whereas Canadian data suggests a slight decline (Figure 2). Canada's C-EnterNet site

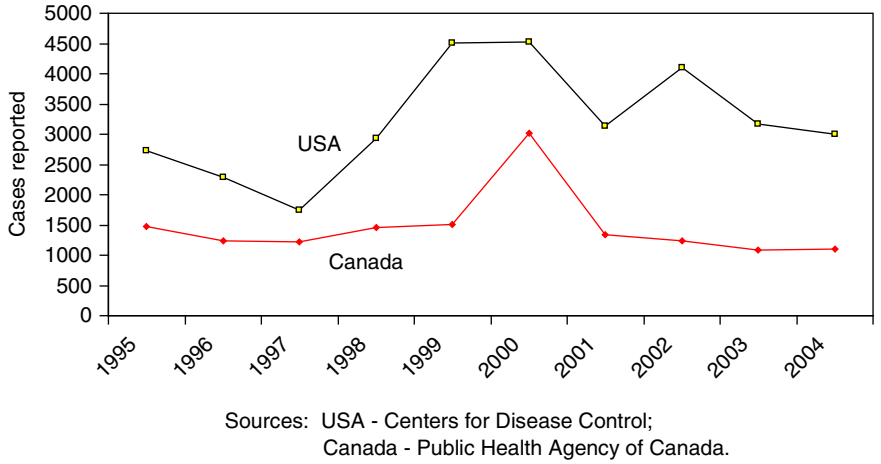

Figure 2 *E. coli* reports by year for USA and Canada: Notifiable diseases data. *Source*: US Centers for Disease Control; Public Health Agency of Canada.

showed significant levels of *E. coli* O157:H7 in dairy and beef cattle manure and farm samples but negligible levels in retail beef samples between 2006 and 2008, suggesting possible successes in minimizing contamination during processing.

Changes in Consumer Demand

What we eat and how we eat it has changed significantly in recent decades, and the increase in eating out, consumption of fast-food and ready-to-eat foods, demand for fresh produce is, to some extent, reflected in foodborne diseases trends. Two pathogens of growing interest, *Yersinia enterocolitica* and *Listeria monocytogenes* are relatively unusual compared to *Salmonella*, *Campylobacter* and EHEC, although their true incidence is unknown. Swine appear to be an important source of *Y. enterocolitica* although a sentinel study in Canada found low and declining levels of the pathogen in pig manure (8–4% of samples) and retail pork (13–3% of samples) between 2006 and 2008 respectively.

Researchers have estimated under 100 000 cases of *Y. enterocolitica* and 2500 cases of *L. monocytogenes* annually in the US. Counts in Canada averaged 624 laboratory confirmed cases (range: 767 to 495) of *Y. enterocolitica* from 1998 to 2004; under 100 cases of listeriosis were recorded annually in Canada through 1995–2004 (average 67.0 notified and 74 laboratory confirmed cases annually. Annual totals have since increased in Canada, including a peak of over 200 cases in 2008 partially linked to a major outbreak of 57 cases and 22 deaths linked to deli meats. Their importance is associated with the relative severity of infection, particularly with *Listeria*. In 1981, the first *Listeria monocytogenes* outbreak fully documenting a food vehicle was linked to coleslaw made from cabbage fertilized with composted sheep manure on a Canadian farm where two sheep had died of *L. monocytogenes* infection. Cold storage of much of the crop may have allowed the bacterium to proliferate, contributing to the outbreak affecting 41 human cases, including 17 deaths (9 were stillbirths or spontaneous abortions) (Sewell and Farber, 2001). *Listeria* and *Yersinia* are psychotrophs, and cold storage is ineffective in limiting growth, and outbreaks associated with products such as soft cheeses, raw and cold meats, and coleslaw requiring cold storage is not unexpected. *Listeria* contamination has been recently demonstrated on retail pork, beef, and chicken, with the highest levels on chicken and beef.

The current choice and year round availability of fresh fruit and vegetable products in US and Canadian supermarkets is likely a response to factors including:

- improved consumer awareness about the benefits of fresh fruit and vegetables through nutrition-education programs and interest in vegetarian lifestyles;
- availability of fresh produce year round from global markets reflecting rapid transport, new preservation technologies, increasing culturally diverse populations; and
- demand for ready-to-eat foods, including prepacked prepared vegetables and fruit, resulting from lifestyle choices and persuasive marketing.

These factors have contributed to increased foodborne illness from fresh produce and derivative products such as juices. Data from US suggest that the proportion of outbreaks linking a known pathogen and fresh produce rose from under 1% in the 1970s to 6% in the 1990s. This trend was more marked for *Salmonella* infections: An analysis of the 73 produce-related outbreaks in the US between 1950 and 2008, found only 7 outbreaks recorded before 1991. New technologies, such as modified atmosphere packaging, not only increase shelf life of fresh produce but may also allow some pathogens to grow faster than spoilage organisms under some circumstances; sourcing of fresh fruit and vegetable from countries with higher risk from fecal contamination; and a trend to eat produce raw have contributed to increased exposure.

Although food handler contamination during preparation was described for some outbreaks, mainly due to *B. cereus*, *S. aureus*, and hepatitis A virus, most implicate animal or human fecal contamination during growth, harvesting, and processing. The link to fecal contamination is further supported by the variation in enteric pathogens linked to produce (Table 6). *Salmonella* is the most common pathogen linked to produce, however, unlike meat-related outbreaks, there is more variation in the serotypes recorded, supporting the implication of

fecal contamination from multiple animal sources. The analysis of 73 produce-related *Salmonella* outbreaks, mentioned earlier, recorded 28 serotypes; some due to unusual serotypes associated with animals such as reptiles. Animal and bird feces appears to have been an important contributor in the outbreaks (mostly *Salmonella*) associated with sprouts, either due to contaminated seeds or contaminated irrigation water, with the added impact that the conditions required for sprouting support bacterial multiplication.

The arrival of a new coccidian parasite, *Cyclospora cayetanensis*, was associated with raspberries and blackberries from Guatemala in the US and Canada in the mid-1990s, and later with mesclun lettuce from the US and Peru. *Cyclospora* oocysts in soil contaminated by human feces was the most likely source of contamination, this corresponds with findings that oocysts originating from human feces that are found in soil show higher infectivity than oocysts recovered directly from human feces.

Environmental and Lifestyle Factors

Environmental factors affect foodborne disease trends directly via ambient temperature, or indirectly by influencing human activity. The seasonal trends of *Salmonella*, *Campylobacter,* and EHEC are well documented: the highest incidence occurring during the warmer months, reflecting the potential for greater microbial loading in the environment and in food stored at too high temperature, and people engaging in risky practices. These include, leaving food in the car too long when shopping, and activities including camping, picnicking, and barbequing, where temperature control of food is difficult to maintain. Other climate factors include heavy rainfall causing land run off carrying animal or human feces into irrigation and process water and resulting in surface contamination of vegetable and salad crops or fruit grown on the ground. Outbreaks linked to hanging fruit may be associated with contaminated irrigation, washing or cooling water, or in the use or consumption of contaminated dropped fruit. For example, the juice outbreaks due to *Salmonella*, *E. coli* O157:H7, and *Cryptosporidium* identified in **Table 6** followed the use of dropped apples and oranges.

It is difficult to quantify the impacts of climate change on disease trends; however, modeling ambient temperatures against foodborne illness, and *Salmonella* incidence specifically, indicates a relationship. Descriptive approaches suggest that aboriginal Americans, and northern people in particular, are experiencing effects of climate and environmental change. However, the extent to which environmental change is affecting factors such as lifestyle and disease prevalence in wildlife compared to other factors relating to, for example, socially driven cultural change, is unclear. Some reliance on country foods (game, fish, and sea mammals) anyway results in increased risk from parasitic diseases such as *Trichinella spiralis* and tapeworms compared with the general population. For example, all seven outbreaks of *Trichinella* infection in a Canadian review were associated with meat from wild animals, and there is indication that changes to traditional food practices carry increased risk of botulism.

Botulism is an interesting case study: a disproportionate number of incidents are recorded in Alaskan and Canadian Inuit. Most Canadian cases since the 1970s involved northern people and the US data indicates that 36% of events and 38% of cases recorded between 1990 and 2000 occurred among the relatively small Alaskan population. This compares with botulism in Canada between 1917 and 1973 when most cases were of European descent and linked to home-canned foods. This reflects a decline in home canning by Europeans as commercial availability of nonseasonal products increased, and the influence of environmental and lifestyle factors on aboriginal people resulting in the consumption of improperly preserved sea products or game eaten raw, dried, or fermented. Traditional approaches to fermentation of fish-heads, fish eggs, whale fins, seal flippers, and beaver tails relied on prolonged cold fermentation by burial in permafrost cooled ground. Investigation of outbreaks in Alaskan and Canadian native people since the late 1940s found that introduction of new country foods to a community and modified fermentation practices, including the use of sealed glass jars and plastic containers were the contributing factors. Whale and seal meat have occasionally been associated with *Salmonella* outbreaks in aboriginal people, and although it is unclear whether the animal had *Salmonella* infection or presence of the pathogen resulted from contamination by seagulls.

Fish and shellfish-associated illness has a long history and is caused by diverse agents including bacteria, parasites, and viruses as well as toxins produced by algae, diatoms, and bacteria naturally occurring in the environment, particularly *Vibrio* species. Although reported numbers of cases and outbreaks related to seafood are relatively low (a few hundred cases annually in the US and Canada combined) the popularity of seafood, their importation from many countries, and the serious illness caused by some agents identifies these products as potentially risky. Some seafoodborne agents, including fish and shellfish toxins and *Vibrio* bacteria, are recognized as emerging causes of illness that are potentially influenced by environmental conditions including ambient temperature and marine pollution from coastal land run off of nutrients. These conditions contribute to toxic algal blooms (red tides) producing neurotoxins (neurotoxic shellfish poisoning, paralytic shellfish poisoning, and amnesic shellfish poisoning) and diarrhoetic toxins (diarrhoetic shellfish poisoning). Although many illnesses are mild and under reported, occasional deaths are linked to several toxins and neurotoxic illness may have long-term health impacts; an outbreak of amnesic shellfish poisoning in Canada in 1987 resulted in 107 cases, some with persistent memory loss.

Outbreaks associated with fish in the US are mostly linked to scombrotoxin (57% of fish associated outbreaks: 1983 to 1992) and ciguatoxin (19%). Scombrotoxin, which induces histamine accumulation due to naturally occurring bacteria, is linked to poor temperature control post harvesting. Ciguatera poisoning is related to dinoflagellate toxins accumulating up the food chain, and human illness is primarily linked to higher carnivores. Puffer fish poisoning, resulting from toxins produced by naturally occurring bacteria, is rare in the US and Canada and cases are usually linked to imported fish.

Historically typhoid was the most important shellfish-associated illness, but since the mid-1950s such outbreaks have virtually disappeared. Introduction of purification procedures (depuration) in the 1930s, declining typhoid in the

population and introduction of stringent microbiological criteria for shellfish growing waters, along with monitoring programs, have reduced sewage-related illness. The exception is viral pathogens present in human feces, principally noroviruses, hepatitis A, and non-A, and non-B hepatitis. Introduction of rapid molecular methods to identify noroviruses has contributed to an increase in reported incidents, and indicates that they caused many gastroenteritis outbreaks (up to 50%) previously described as unknown etiology. Currently, noroviruses are estimated to account for two-thirds of all foodborne illnesses (Table 5), although the proportion linked to seafood is unknown. Interestingly, the description of self-limiting gastroenteritis 1 to 2 days after eating oysters in documented typhoid (about 2 weeks incubation) outbreaks in the nineteenth century in the US suggests viral gastroenteritis may have been common then, and was even considered a possible prodrome of typhoid.

Naturally occurring bacteria of the family Vibrionacaea, which include *Vibrio*, *Aeromonas*, and *Plesiomonas* species, account for most bacterial illnesses linked to seafood. Most cases are due to *Vibrio* species associated with filter feeding bivalve molusks such as oysters (usually eaten raw). An estimated 5000 foodborne *Vibrio* infections occur annually in the US (Table 5); in Canada, less than 50 isolates are reported annually, including nonfoodborne infections and infections acquired abroad. Laboratory reported *Vibrio* infections include toxigenic *Vibrio cholerae* (types O1, O139, and recently O141), and more commonly *V. vulnificus* (Gulf coast) and *V. parahaemolyticus* (commonly on the Pacific coast). Unlike toxigenic *V. cholerae* O1 and *V. parahaemolyticus*, *V. vulnificus* rarely causes diarrhea and is of concern because of the high mortality associated with septicemic infection in vulnerable groups. In one report of cases linked to oyster consumption in Florida between 1991 and 1994, the mortality rate was 60%. Concerns about *Vibrio* infections, particularly in the US Gulf States led to the development of the Cholera and Other Vibrios Surveillance System (COVISS), maintained by the Centres for Disease Control and Prevention (CDC) since the late 1980s.

The *Vibrios* primarily associated with human illness share tolerance for salinity (greater in the noncholera *Vibrios*) and are common in warm seawater including estuaries. Their reservoirs include fish, shellfish, plankton and sediment, and their complex ecology affects their persistence in the marine environment and increased prevalence in warmer months. There is potential for introduction of species into new environments via ship ballast water, the likely route for the introduction of *V. cholerae* O1 El Tor (Latin American biotype) into the northern Gulf of Mexico during the Latin American epidemic in the early 1990s. A similar mechanism may also play a role in the dispersal of toxic algae.

Conclusions

Historically, laboratory based and notified diseases reporting has tended to underestimate the incidence of individual disease agents. However, an important characteristic of these approaches is the tracking of specific pathogens over extended time periods permitting the detection of changes in reporting trends, provided there is some consistency in what is reported and how it is reported. Centralized collation of laboratory reports plays an essential role in the detection of emerging pathogens and the identification of outbreaks. Result from outbreak and epidemiological investigations provides valuable information on both the vehicle of infection and characteristics of the population infected. Recent approaches to surveillance have incorporated monitoring for risk factors at the community level and are contributing to improved understanding of the complex dynamics of foodborne diseases as well as helping to quantify levels of risk associated with specific products.

Variations in national foodborne disease statistics reflect differences in methodological approaches to collating or estimating burden, risk, and economic impact of disease as well as differences in the agents included in analyses, and approaches for estimating the proportion of illnesses and deaths due to known and unknown causes. Since the early 1990s a number of countries have attempted to better delineate the national burden of foodborne diseases. The results are used to estimate disease burden, the impact of specific pathogens, and the association of specific foods or food groups with human illness, as well as to assist countries in developing surveillance capacity.

The increasing prominence of foodborne diseases reflects greater public scrutiny of food safety; evolving public expectations of the safety, quality, and benefits of food; food producer and manufacturer response to consumer concerns; and the public health response to the burden, cost, and severity of the illnesses they cause. Changes in animal husbandry, eradication of diseases in economically important food animals, improved sanitation, global expansion of markets for food sources, introduction of new storage and preservation technologies, and development of laboratory diagnostic technologies have contributed to the evolving epidemiology of foodborne diseases. This includes both the emergence of new pathogens and recognition of the role of specific risk factors in human illness. Many factors that influence disease trends are amenable to preventive approaches aimed at reducing infection in animals, poultry, and produce on the one hand, or improved food storage, transport, handling, and food safety awareness on the other.

Glossary

Food Any substance, whether processed, semiprocessed, or raw, that is intended for human consumption, and includes drink, chewing gum, and any substance that has been used in the manufacture, preparation or treatment of 'food', but does not include cosmetics, tobacco, or substances used only as drugs. (In the context of this topic level contribution, drinking water is food.)

Food safety Assurance that food will not cause harm to the consumer when it is prepared and/or eaten according to its intended use.

Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of food or water.

Incidence Number of new cases in a specified population in a defined period of time, divided by the population at risk.

Infection A condition in which the body is invaded by an infectious organism (e.g., bacteria, virus, fungus).

Monitoring Continuous or repeated observation, measurement and evaluation of health and/or environmental or technical data for defined purposes, according to prearranged schedules in space and time, using comparable methods for sensing and data collection.

Outbreak The occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time.

Pathogen An organism capable of causing disease.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to hazard(s) in food.

Surveillance The systematic collection, analysis, interpretation and dissemination of health data on an ongoing basis, to gain knowledge of the pattern of disease occurrence and potential in a community, in order to control and prevent disease in the community.

Introduction

Foodborne disease is a worldwide problem despite of various efforts for water, sanitation, and food safety improvement. The global burden of nontyphoid salmonellosis around the world is estimated as 2.8 billion cases and 2.1 million people die from diarrheal disease every year. In 2000 alone, typhoid fever accounted for 2.16 million cases and resulted in 216 000 deaths with 90% of the morbidity and mortality occurred in Asia.

Bacterial pathogens, viruses, and parasites have been etiologically associated with foodborne illnesses outbreaks around the world. *Salmonella* is considered a pathogen of continuing concern while enterohemorrhagic *Escherichia coli* emerged as a foodborne pathogen in the 1980s. Although most foodborne illnesses are self-limiting, some can be life threatening, for example, renal failure (enterohemorrhagic *E. coli*), miscarriage and or stillbirth (*Listeria monocytogenes*), meningitis (*Cronobacter sakazakii*), etc. *Salmonella* serotypes commonly found in the regions seem to be different from those reported in North America and Europe, except for *Salmonella enteritidis* and *Salmonella* Typhimurium.

This article summarizes foodborne diseases prevalent in South East Asia and Central Asia. The two regions consist of mostly developing countries, some of them are still struggling with basic hygiene programs. South East Asia consists of Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Vietnam. Meanwhile, Central Asia includes Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, and Uzbekistan. Knowledge on pathogens prevalent in South East and Central Asia is mostly derived from reports from clinical isolates of diarrheal patients. *Shigella* is the major causative agent for diarrhea shared in the two regions. In addition to nontyphoid *Salmonella* typhoid and paratyphoid fever also still exist at different levels in some countries. Brucellosis caused by *Brucella* sp. and botulism intoxication due to *Clostridium botulinum* seems to occur more frequently in Central Asia than that in South East Asia, whereas limited report on parasites is available from Central Asia. In many countries, antibiotic-resistant strains of bacterial enteric pathogen are reported, possibly due to unrestricted use of antibiotics.

Food associated with the outbreaks is rarely confirmed during investigation. Given the possibility of unhygienic practices as the most important reason, most of the time no specific food could be etiologically linked to the outbreaks.

Foodborne disease outbreaks in South East and Central Asia are generally underreported. Typically, the number is extrapolated from the limited data because records and or monitoring of foodborne diseases are inadequate. This

article does not discuss foodborne intoxication resulted from chemical hazards such as natural toxicant, seafood toxins, mycotoxins, or environmental pollutant. Sporadic cases of these types of intoxication were still reported in the regions involving local meal such as cassava poisoning, bongkrek acid poisoning, toad poisoning, etc.

South East Asia

Review of foodborne pathogens in this region included data from 10 countries. However, due to the limited data, the extent of discussion of each country may vary. Characteristics shared within the region are unhygienic practices, unsafe water, cultural habit of consumption of raw or undercooked food in some regions, and the presence of inadequately monitored street vendors. All of the above-mentioned factors results in the persistence of enteric pathogens: bacteria, viruses, protozoa, and helminthic parasites.

Shigella, *Vibrio cholerae* O1, and *Salmonella* spp. are most commonly associated with diarrheal diseases in Cambodia, Indonesia, Thailand, Lao PDR, Malaysia, Myanmar, the Philippines, and Vietnam. Cholera in South East Asia, with *V. cholerae* O1 as the predominant strain, contributes to 7% of cholera cases in the world. Typhoid fever persists in some countries even though there is evidence for decreases worldwide. *S. enteritidis* was the most frequently isolated nontyphoid *Salmonella* serotype, whereas rotavirus was the virus most often associated with diarrhea in the region.

Consumption of raw or undercooked food, unhygienic practices such as open defecation, i.e., defecating outside and not in the toilet, and use of night soil for fertilization of fish ponds are risk factors for helminthic parasite infection. Freshwater and brackish water fish, freshwater and brackish water snails, amphibians, terrestrial snakes, aquatic insects, and aquatic plants are the usual vehicles. Various flukes, nematodes, and trematodes have been reported. Echinostomiasis due to *Echinostoma* is believed to be underreported. Echinostomiasis occurs in the Philippines, northern part of Thailand, Indonesia, Malaysia, and Singapore.

Street food vendors and schools have been linked with outbreaks in Brunei, Cambodia, Malaysia, Thailand, etc. With increased awareness on food safety, intervention programs have been developed in many countries and were reported to reduce the numbers of foodborne outbreaks. However, improved awareness of food safety has also prompted countries to conduct more surveys and/or investigations; thus, more outbreaks are reported.

Foreigners traveling in the South East Asia region have been reported as a factor linked to foodborne illnesses. A study of Swedish travelers stated that Thailand and Indonesia were among the 10 countries most often reported for travelers' infections. Eating local food and consuming nonpotable water are likely the reason for illnesses. These two countries together with Brunei, Cambodia, Myanmar, China, Hong Kong, Japan, Laos, Malaysia, Mongolia, North Korea, South Korea, the Philippines, Singapore, Taiwan, Thailand, Tibet, and Vietnam were grouped as East Asia. This group has a risk of nontyphoid salmonellosis in travelers of 270/100 000 and the serotype most commonly found in the group was *S. enteritidis* (15.1%). This was similar to the risk of traveling in West Africa (279/100 000) but lower than that in India and its neighbors (474/100 000), and East Africa (471/100 000). Another source of travelers' diarrhea was reported from a cruise ship traveling in the South East Asia region in which six out of 630 passengers were infected by *V. cholerae* O139 due to consumption of yellow rice in Bangkok.

Brunei

Brunei, the gross domestic product (GDP) per capita of which is the fifth highest in the world, has one of the best health services in Asia. The WHO report in 1999 suggested that cholera was no longer reported there since 1982. Previously the pathogen caused the largest outbreak in 1965 and another one with 24 cases in 1970. In 1999, however, an outbreak involving 72 confirmed and 29 suspect cases happened in schools. Another foodborne outbreak due to consumption of rice–chicken was reported in a seminar but no pathogen was identified.

Cambodia

Diarrhea was found to be the leading cause for morbidity and mortality in this country. It was reported that the illness was generally linked to an inadequate water and sanitation program. The access to drinking water for rural and urban communities was 29% and 69.55%, respectively, whereas access to hygienic facilities was only enjoyed by 8.6% in rural and 49% in urban areas. The number of diarrhea and dysentery cases in the age groups 0–4 years, 5–14 years, >15 years were 17.5% and 4%, 8.3% and 3.3%, 2.8%, and 1.2% of total illnesses, respectively.

Salmonella typhi was isolated from 0.9% the samples of diarrheal patients. Of the isolates, 56% were resistant to multiple antibiotics including ampicillin (56%), chloramphenicol (56%), and trimethoprim-sulfamethoxazole (81%). A couple of outbreaks in 2001 were reported, i.e., a school-related outbreak and an outbreak due to toxic fish.

Indonesia

A study of patients with diarrhea suggested that four major bacterial pathogens were *V. cholerae*, *Shigella flexneri*, *Salmonella* spp., and *Campylobacter jejuni*. The study also showed that 11% of the patients had parasites, consisting of *Blastocystis hominis* (5.7%), *Trichuris trichuria* (2.1%), *Ascaris lumbricoides* (1.5%), *Giardia lamblia* (0.8%), and *Endolimax nana*. Rotavirus, Norwalk-like virus, and adenovirus were also found in 37.5%, 17.6, and 3.3%, respectively. Rectal swabs of people suggested that 18% carried enterotoxigenic *E. coli*, 1% had enterohemorrhagic *E. coli* and 1% harbored *Clostridium difficile*.

The work of Tjaniadi et al. in 2003 confirmed the above findings and concluded that *V. cholerae* O1 was most often isolated (37.1%), followed by *S. flexneri* (27.3%) and *Salmonella* (17.7%). Other pathogens were also isolated at a lower rate, i.e., *Vibrio parahaemolyticus* (7.3%), *S. typhi* (3.9%), *C. jejuni* (3.6%), *V. cholerae* non-O1 (2.4%), and *Salmonella paratyphi* (0.7%). Some of the *V. cholerae*, *S. flexneri*, and *Salmonella* were resistant to various antibiotics, although *S. typhi* and *S. paratyphi* remained sensitive to all antibiotics tested. The absence of

antibiotic-resistant *S. typhi* was confirmed by a survey in five Asian countries published by WHO in 2008.

The endemic area in North district of Jakarta had 180.3 typhoid fever cases per 100 000 per year among the 5–15-year age group whereas cases of diarrhea in infant in this area were reported as high as 759/1000 per year. Cholera was common in infant (4/1000 per year) and was mainly caused by *V. cholerae* El Tor Ogawa (58%) and El Tor Inaba (42%). Children of 1–2 years mostly had shigellosis (32/1000 per year) due to *S. flexneri*. The study also suggested that 75–95% of the *Shigella* was resistant to ampicillin, trimethoprim-sulfamethoxazole, chloramphenicol, and tetracyclin but sensitive to nalidixic acid, ciprofloxacine, and ceftriaxone.

E. coli resistant to ampicillin, gentamicin, cefotaxine, ciprofloxacine, and trimethoprim-sulfamethoxazole was isolated from carriers in hospital and community. The recent use of antibiotics and having medical insurance were directly related to the increase in *E. coli* resistance to antibiotics.

Protozoa and helminthic parasites were linked to gastroenteritis and chronic diarrhea in the country. The *Cyclospora cayetanensis* isolation rate from expatriates with diarrhea in three independent studies were 8.6%–15.1%, 9.1%, and 13.6%. *Entamoeba hystolitica*, *G. lamblia*, *B. hominis*, *T. trichuria*, and *A. lumbricoides* were found at isolation rates of 6.3%, 2.8%, 15%, 3.5%, and 0.8%, respectively. A survey of Indonesian children aged 8–10 years showed that infection by helminthic parasites and protozoa were 84% and 77%, respectively, with asymptomatic children carrying *C. cayetanensis* accounting for 0.6% of the surveyed population. No *Cyclospora* was isolated for both expatriate and Indonesian children under 3 years, and this was attributed to several factors including no exposure to fresh fruits, vegetables, and garnish.

Street food vendors are more likely to cause infection from *S. pratyphi* based on two separate studies conducted in Semarang and Jakarta. While paratyphoid fever is more likely to be foodborne, typhoid fever is associated with a recent typhoid fever case in the home, no washing before eating, and recent consumption of ice cubes. Street food vendors were characterized by poor hand washing practices/facilities, direct contact between food and hands, male workers, and low education. Street food vendors serve various foods, from deep fried foods, soups, grilled satay, or fresh fruit salad. In relation to these vendors, 65% of water, 91% dishwashing water, and 100% of ice were contaminated with fecal coliforms. The risk factors for typhoid fever after two geographically different disasters were different. The absence of clean water and nonavailability of drugs were the main risk factors for typhoid fever following the 2008 tsunami in Aceh, Sumatra, while contact with typhoid patients and lack of hygiene education emerged as the risk factor following 2006 earthquake in Yogyakarta in Java.

Although food produced by the industry is rarely implicated in outbreaks, in 2004 processed milk caused 14 outbreaks in seven cities in six provinces in Java, Sumatera, and Nusa Tenggara islands. The milk was consumed by 2251 school children causing 469 students to become ill and one to die. Processed milk (pasteurized, powdered and commercially sterilized) was thought to be etiologically linked to the outbreaks. Poor hygienic practices, poor handling after processing, as well as poor preparation of milk were concluded as factors contributing to the outbreaks; however, no particular etiologic agent was announced.

Studies of the foodborne outbreaks were rarely published. Cooking methods commonly applied to Indonesian ready-to-eat traditional foods are sufficient to eliminate large number of *S. aureus* and other nonsporeforming bacterial pathogens. Therefore, postcooking handling was thought to be critical and the possible cause of many outbreaks. Between 2001 and 2009 there was an increase in the number of foodborne disease outbreak reported, but it was probably due to a better monitoring and/or reporting system (**Table 1**).

The Indonesia National Agency for Food and Drug Control (NADFC) suggested that pathogenic microorganisms were the major causative agent of the outbreaks, accounted for 37% of the outbreaks, although no specific pathogen was mentioned. Food prepared by street food vendors, together with homemade food and food from food service industries were responsible for most (83%) of the outbreak (**Figure 1**), which was consistent with epidemiological studies of Vollaard et al. in 2004a.

Food safety in Indonesia can be evaluated based on the performance of exported food. Export rejection by the US FDA, for example, was mainly due to *Salmonella* and filth. Dewanti-Hariyadi et al. in 2005 reported that shrimp collected from the ocean and ponds of the northern shore of Java were frequently contaminated with *Salmonella* with isolation rates of 6.25% and 12.5%, respectively. The data suggest that *Salmonella* is an important microbiological contaminant in food and this is in line with data suggesting that *Salmonella* was responsible for 17.7% of diarrheal cases.

Lao People's Democratic Republic (Lao PDR)

Diarrhea is a very important health problem in Lao PDR and 16% of death in children can be attributed to this illness. Investigation of the etiologic agent of diarrheal patients between 1996 and 1997 concluded that *Shigella* and diarrheagenic *E. coli* were the major pathogens, which were responsible for 16.8% and 17.2% of the cases, respectively. Almost all of *Shigella* and diarhegenic *E. coli* were reported to be resistant to ampicillin, tetracycline, and erythromycin. Rotavirus also contributed to 6.1%, whereas *C. jejuni*

Table 1 Number of reported outbreaks and reported cases of foodborne disease in Indonesia 2001–2009[a]

[a]Thong, 2006.

accounted for 4.4% of the cases. *Salmonella* and *Vibro* cases were considered low.

Between January and August of 2007, there was an average of seven diarrheal cases per 100 000 population. An investigation during a cholera epidemic in Sekong Province suggested that 58.6% of stool samples were positive for *V. cholerae* O1 Ogawa. Water was concluded to be the vehicle of the outbreak.

A human trichinellosis outbreak due to *Trichinella* species was reported in 2004. Pork meals, i.e., uncooked minced pork with mint and fermented pork were the implicated vehicles for of the nematodes.

Malaysia

The prevalence of enteropathogens in humans was reported from stool samples of diarrheal patients that had been previously estimated at a rate of 26.3 incidence per 100 people. The report suggested that of the stool samples examined, 11% had enteropathogenic bacteria, but viruses were not examined. The five most significant pathogens and their rate of isolation in stools are as follows: nontyphoid *Salmonella* 57%, enteropathogenic *E. coli* 14%, *Shigella* 11%, *Campylobacter* 5%, and *Aeromonas* 5%. The four most frequently isolated Salmonella serotypes from 2003 to 2005 were, in order, *S. enteritidis*, *weltervreden*, *corvallis*, and *typhimurium* (Table 2). This finding is consistent with *S. enteritidis* being the most frequently isolated serotype in much of Asia. In addition, where protozoa such as *Cryptosporidium* and *Giardia* have been isolated from humans, they are assumed to be from waterborne sources. Pathogenic bacteria resistant to multiple antibiotics were also reported in Malaysia. *S. typhi* was found to be resistant to ampicillin and chloramphenicol, whereas nontyphoid *Salmonella* were resistant to ampicillin, chloramphenicol, and cotrimoxazole. All *S. flexneri* were resistant to ampicillin and cotrimoxazole, while 80% were resistant to chloramphenicol. Frederick in 2011 also reported that 61.2% of *E. coli* strains

were resistant to multiple antibiotics, such as kanamycin, tetracyclin, chloramphenicol, gentamicin, ampicillin, nalidixic acid, trimethoprim-sulfamethoxazole, cefetoxin, norfloxacin, and ciprofloxacin.

Foodborne disease outbreaks have received more attention in the past few years and have been recognized as important infectious diseases. Soon et al. in 2010 suggested that the number of outbreaks that had been apparently steadily declining between 1999 and 2005 was attributed to food handlers' training programs. However, this optimistic conclusion was confounded by a significant increase in the number of outbreaks since then, and this increase was really an artifact of better investigation. Most foodborne disease outbreaks seemed to occur in schools, although the authors acknowledged there was likely underreporting for outbreaks outside schools. Various foods were implicated in the outbreaks, for example, rice in coconut milk (*nasi lemak*), chicken, beef broth, fish, and starch-based snacks.

Several studies of foodborne pathogens in specific foods have been reported. *E. coli* O157:H7 was isolated from 36% of beef samples, *L. monocytogenes* from 74% of imported beef, 43.5% of local beef and 56% of fermented fish, and *Campylobacter* in 3–18.8% of fresh vegetables. It was also established that *V. cholerae* is carried by shellfish that has been implicated in the cholera outbreaks.

Myanmar

Although data regarding foodborne illness in Myanmar are very limited, it was estimated that 70% of diarrheal diseases was due to food contamination. Diarrheal diseases, foodborne intoxication, typhoid, and paratyphoid were the most frequently encountered illnesses.

In September 2000, a typhoid fever outbreak was reported and a case-control study was established. The risk factors identified were drinking unboiled river water, contact with other patients before illness and failing to wash hands with soap after defecation.

A survey to evaluate indicator bacteria in a popular ready-to-eat food called *mohinga*, i.e., rice noodle served with fish soup, has been conducted ($n=50$). The survey suggested that 100% of the noodle was tested positive for coliform, 80% contained fecal coliform, and 2% contaminated with enteropathogenic *E. coli* or *S. typhi*. Twenty percent of the soup samples had coliform, but fecal coliform or pathogen was absent. Mixing noodles with very hot (90–100 °C) soup decreased the number of bacteria by 1/1000 as compared to that mixed with warm (60–70 °C) soup. Addition of ingredients (chili powder, etc.) increased the total bacterial content in *mohinga* by 2–3 logs more than that prepared without any ingredients.

The Philippines

A survey of 2908 patients with diarrhea during 1983–1984 found that 58.4% had one or more enteric pathogen and rotavirus was the most frequently isolated pathogen (30.6%). The three pathogenic bacteria most often associated with the diarrhea were *Shigella* (11.6%), *Salmonella* (9.2%), and enterotoxigenic *E. coli* (7.8%). Of the samples collected, 302 had multiple pathogens. However, *Salmonella*, enterotoxigenic *E. coli*, and *C. jejuni* were also isolated from healthy patients.

Table 3 Parasites detected in Katipunan, Zamboanga del Norte, the Philippines, February 2008[a]

Parasite	*No. (%)*
Trichuris trichuria	64 (31.1)
Entamoeba coli	49 (23.8)
Ascaris lumbricoides	46 (22.3)
Endolimax naan	14 (19.9)
Hookworm	34 (16.5)
Blastocystis hominis	21 (10.2)
Giardia lamblia	19 (0.2)
Entamoeba hystolytica	14 (6.8)
Cappilaria philippinensis	10 (4.9)

[a]Belizario et al. (2010).

Foodborne nematodes causing severe diarrhea is also a problem in this country. Of the 205 stool samples from people with diarrhea, 73.3% contained parasites: 32% with one parasite and 41% with more than one parasite. Table 3 shows the type of parasites isolated from this study.

Singapore

Cholera cases in Singapore have been declining from 17 cases in 1992 to seven cases a year in 2007. During 1992–2007, a total of 210 cholera cases were reported and *V. cholerae* O1 biotype El Tor as well as serotype Ogawa was reported in 83.8% of the cases. Food associated with the outbreaks included partially cooked green mussels (1993), iced banana-flavored drink with contaminated crushed ice (1999) and imported seafood items (2004). The study concluded that 24% of cholera cases were caused by imported foods.

Salmonellae continue to cause foodborne illnesses and an outbreak in 2000 was predominated by a few strains such as *S. enteritidis*, *S. stanley*, *S. weltervreden*, and *S. typhimurium*. Multiple antibiotic-resistant strains of *S. typhimurium* DT104L were isolated from stool samples and in some foods, particularly ground anchovy. In 2007, *S. enteritidis* has emerged as the most important foodborne pathogen and was responsible for 62.2% of nontyphoid salmonellosis. During an outbreak involving 216 gastroenteritis cases, cream cake was concluded as the food associated and *S. enteritidis* was confirmed as the causative agent.

Thailand

A comprehensive review by Pitisuttithum in 2003 suggested an average of 1493 cases of diarrhea per 100 000 people per year was recorded between 1990 and 1995 in Thailand. During the period, an average of 110 cases of foodborne intoxication, 140 cases of dysentery, 20 cases of enteric fever, and 26 cases of hepatitis were reported each year. *V. cholerae*, *S. flexneri* or *S. dysenteriae*, and *Salmonella* were associated with severe diarrhea, dysentery, and salmonellosis, respectively.

Table 4 Reported foodborne illness in Thailand 2003

Foodborne diseases	*No. of cases*	*Death*	*Morbidity rate*	*Mortality rate*
Acute diarrhea	956 313	146	541.26	0.05
Dysentery	23 113	3	12.44	0
Foodborne intoxications	12 685	11	67.79	0
Enteric fever	9 633	3	3.57	0

In a report made during the Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) regional conference on food safety for Asia and the Pacific in Seremban, Malaysia, Thailand stated that the number of acute diarrhea cases in the country started to decrease in 2003. Unsafe drinking water, lack of personal hygiene, and consumption behavior, for example eating raw or underprocessed food products, were considered as the factors influencing the number of cases. *Shigella*, *Salmonella*, and *E. coli* were reported as the bacterial pathogens most commonly associated with the reported outbreaks during the period. In addition, shigellosis was also linked to poverty. A summary of nationwide foodborne illness is presented in Table 4.

An increase in isolation rate of *Salmonella rissen* from humans, uncooked foods, and ready-to-eat foods was reported in 2008. The isolates that were similar to those isolated in Sweden were entirely tetracycline resistant. The number of foodborne infections doubled in the past 10 years and *Salmonella* as well as *Campylobacter* were the most frequently isolated pathogens from the outbreaks. Table 5 shows the prevalence of *Salmonella* isolated from various foods, food sources, and humans. Of the isolated *Salmonella*, 59% were tetracyclin-resistant, 28% were ampicillin-resistant, 5% were azithromycin-resistant, and 0.5% were ciprofloxacin-resistant. Meanwhile *Campylobacter* (*C. jejuni* and *C. coli)* was isolated at a frequency of 72%, 23%, 64%, and 47% from pigs, pork, chickens, and chicken meat, respectively.

Foodborne disease outbreaks were often linked to school meals. A large outbreak in school causing 1598 students to become ill was reported in 2005. The outbreak was associated with mixed chicken–rice dish with an attack rate of 37% and *Shigella sonnei* as well as *Salmonella* group C were etiologically linked to the outbreak.

A very rare outbreak of botulism was reported in Thailand in 2006. Although no fatalities were reported, the outbreak involved 91 victims, of which 42 needed mechanical ventilators due to respiratory failure. Improperly home-canned bamboo shoots were the source of the intoxication.

As an effort to improve food safety, an intervention program was established by the Department of Health, Bangkok. Pitisuttithum in 2003 evaluated the impact of the intervention and found that compliance of street foods, ready-to-cook, and cooked food to their respective standards had improved from 56.5% to 80.3%, 30.5% to 56.5%, and 82.5% to 90.1%, respectively. Survey at a year postintervention also showed that the number of street foods contaminated by *Salmonella*, *S. aureus*, *C. perfringens*, and *V. cholerae* non-O1 had decreased from 5.5% to 2.1%, 2.6% to 0.7%, 4.5% to 2.8%, and 2.2% to 0.7%, respectively. Similar results were also observed in ready-to-cook and cooked food.

Table 5 *Salmonella* serotypes most commonly isolated in Thailand

Source	Salmonella *serotype*
Pig	Rissen, Derby
Pork	Weltervreden, Rissen, Anatum, Emek
Chicken	Emek, Rissen, Enteritidis
Chicken meat	Weltervreden, Emek, Hadar
Human	Weltervreden, Rissen, Stanley, Enteritidis, Anatum

Vietnam

A study was conducted in Hanoi of 587 children with diarrhea and 249 age-matched healthy controls. Sixty percent of children with diarrhea harbored pathogenic bacteria. In children under 2-years-old, group A rotavirus was predominant (46.7%), followed by diarrheagenic *E. coli* (22.5%). In children over 2 years, enterotoxigenic *Bacteroides fragilis* and *Shigella* were found at the rate of 7.3% and 4.7%, respectively. *E. coli* and *Shigella* isolated from diarrheal children were resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole. Children with diarrhea are usually associated with poor families, houses lacking potable water and latrines, mothers who do not wash their hands, as well as mothers with low education and or little information on appropriate hygienic habits. Hien et al. in 2008 further identified the diarrheagenic *E. coli* isolated from the diarrheal children. They found attaching and effacing *E. coli* as the predominant strains (9.2%), followed by enteroaggregative *E. coli* (8.8%), enterotoxigenic *E. coli* (4%), enteropathogenic *E. coli* (2.8%), and enteroinvasive *E. coli* (0.8%).

Typhoid fever is still a problem in Vietnam, although a recent report suggested that the number of typhoid fever cases in Vietnam is relatively low, i.e., 24.2/100 000 per year. Infection due to flukes was generally linked to consumption of raw freshwater fish or crabs, and aquatic plants. *Procerovum varium* and *Heterophysopsis contina*, two zoonotic trematode metacercariae, were the most prevalent parasites in farmed grouper fish, and present a risk to fish consumers if the groupers are not adequately cooked.

Central Asia

Similar to South East Asia, acute diarrhea because of *Salmonella* infections was commonly reported in Central Asia. Additionally, typhoid fever is still being reported. *Salmonella* involved in the outbreaks were also reported as resistant to multiple antibiotics. Brucellosis and botulism, which were

rarely reported in South East Asia, have been linked to a few outbreaks in this region. However, not much information is available on the prevalence of helminthic illness in this region. As compared to data obtained from the South East Asia, data on foodborne pathogens in this region is even less available.

Kazakhstan

During 1999–2000, it was reported that 9.5% of the acute intestinal infection cases were caused by *Salmonella* sp. was responsible for 7.5% of the foodborne disease cases in children under 14 during the above-mentioned period. However, the number of *Salmonella* cases constantly declined from 1993 to 2000.

Two examples of rarely reported outbreaks from this country give some details as to the food, the agent, and its cause. In March 2010, 25 patients came down with gastroenteritis, of which 20 were hospitalized. All had been invited to dinner on March 25 in a local restaurant in Kapchigai city, Kazakhstan. Investigation of the outbreak suggested that *S. enteritidis* was the causative agent and pastry with meat was implicated in the outbreak. *S. enteritidis* was isolated from 10 patients and also the leftover pastry. Further investigation revealed that the home-made pastry was prepared in a house with poor sanitary conditions. Another foodborne illness outbreak in Atyrau in Western Kazakhstan reported that 32 patients were hospitalized with diarrhea. All were workers who lived in a company hostel and ate in the same cafeteria. Olivier salad (potato, meat, and mayonnaise) was concluded as the food epidemiologically associated with the illnesses. The outbreak itself was probably caused by improper food preparation practices.

Kyrgyzstan

Foodborne and waterborne diseases, such as bacillary dysentery and other types of diarrhea as well as typhoid fever, are more common in the summer and autumn months and high incidences occurred in the southeastern and southwestern parts of the country. Brucellosis was reported in the extreme southwest and southeast while echinococcosis (hydatid disease) from the southeast part of the country. *Fasciola hepatica* infection has also been reported from different regions of the country.

The WHO Surveillance Programme for Control of Foodborne Infections and Intoxications in Europe 8th Report notified a total foodborne outbreak of 16 765 in 1999 and 14 440 in 2000. In 29–32% of the cases, the causative agent was known. The most frequently notified disease was shigellosis, accounting for 24% of all notified cases in 1999 and 29% of cases in 2000.

Brucellosis was responsible for 6% of illness in 1999 and 8% of the cases in 2000, while botulism accounted for less than 1% of the cases in the 2 years. *Salmonella* was responsible for 2% of the cases in the same years and *S. typhimurium* contributed for 56–68% of the salmonellosis. *S. enteritidis* was also isolated at a lower rate (0.3–2.4%).

Tajikistan

Surveillance on typhoid fever in Dushanbe, Tajikistan, in 1997 reported 8901 cases of typhoid fever and 95 associated deaths. Of the 29 *S. typhi* isolated, 27 (93%) were resistant to ampicillin, chloramphenicol, nalidixic acid, streptomycin, sulfisoxazole, tetracycline, and trimethoprim-sulfamethoxazole. In a case-control study of 45 patients and 123 controls, *S. typhi* infection was associated with drinking unboiled water. Ninety seven percent of the tap water samples were found to be contaminated with fecal coliforms, and samples from the water treatment plants revealed that fecal coliforms were present in the water before and after treatment. There were multiple reasons for this finding: lack of adequate chlorination, equipment failure, and back-siphonage in the water distribution system. After chlorination and coagulation were applied at the treatment plants and a water conservation campaign was initiated to improve water pressure, the incidence of typhoid fever declined dramatically.

The WHO Surveillance Programme for Control of Foodborne Infections and Intoxications in Europe 8th Report 1999–2000 suggested that during 1996–2000, a total of eight foodborne intoxication or infection outbreaks were reported. However, no specific agent was identified following the investigation of these outbreaks involving a total of 106 cases. The WHO report indicated that the most frequently reported disease was acute intestinal infections, i.e., 74 318 cases or 1190.8 incidence per 100 000 population in 1999 and 85 212 cases or 1366 incidence per 100 000 population in 2000. Typhoid fever, bacterial dysentery, and brucellosis were responsible for 7335, 3702, and 337 cases per 100 000 population, respectively, in 1999 and 4415, 2645, and 851 cases per 100 000 population, respectively, in 2000. Brucellosis has been on the rise in Tajikistan and in the bordering country Kyrgyzstan since the mid-1990s. Brucellosis is transmitted mainly through consumption of unpasteurized goat and sheep milk.

Turkmenistan

WHO Surveillance Programme for Control of Foodborne Infections and Intoxications in Europe 7th Report 1993–1998 reported that a total of 33 foodborne disease outbreaks occurred in this country. The outbreaks were comprised of 22 botulism outbreaks involving 55 cases and 11 other bacterial infection outbreaks involving 614 cases. Both outbreaks were derived from improperly home-preserved food such as fish and eggplant. Cryptosporidiosis is also frequently found in children.

Uzbekistan

During 1999–2000, a total of 59 outbreaks of foodborne diseases were reported. Some fatalities occurred during food poisoning incidents in 1999 and 2000; botulism and chemicals accounted for the mortality. Unfortunately, no further details are given.

An investigation of 97 patients with typhoid fever in the Samarkand region of Uzbekistan in 2002 suggested that the endemic typhoid fever was transmitted by contaminated water. The cases of typhoid fever in Samarkand appeared to follow a seasonal pattern, with the majority of infections occurring during dry hot summer months. The study also reported that the use of antimicrobials in the 2 weeks preceding illness onset was also independently associated with illness.

The study also concluded that 15% of *S. typhi* were multiple drug resistant. They were resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole.

Prevalence of Foodborne Diseases in Australia and New Zealand

MD Kirk, The Australian National University, Canberra, ACT, Australia
RJ Lake, Institute of Environmental Science and Research Ltd, Christchurch, New Zealand

Glossary

Food vehicle A specific food responsible for an outbreak of foodborne illness or cases of disease.
Foodborne outbreak Two or more cases of illness resulting from a common food or meal.
Gastroenteritis Illness characterized by vomiting, diarrhea, and other symptoms. Gastroenteritis is often defined as three or more loose stools and/or two episodes of vomiting in 24 h.
Incidence The number of persons falling ill with foodborne illnesses during a given period in a specified population.
Notifiable disease A disease that must be reported to health departments under public health laws; where the onus may be on doctors, laboratories, or other specified persons to report cases.
Pathogen An organism that can cause disease in humans or animals.
Prevalence A measure of the occurrence of foodborne disease, indicating the total number of people who have a specific foodborne illness at a given point in time in a specified population.
Rate A measure of the frequency of occurrence of disease, where incidence or prevalence are expressed in terms of a rate or the number of cases per 100 000 or million persons in a given population in a certain time period, such as a year.
Surveillance The systematic collection, collation, analysis, and interpretation of data on cases of foodborne illness, and dissemination to those who have the power to act and prevent further disease.

Introduction

Diseases caused by microbial pathogens and transmitted by food affect all the countries of the world. There are in excess of 200 diseases that may be transmitted by food, although many of these are rare and do not occur in developed countries. Public health agencies invest considerable effort in ensuring safe food supplies. One important component of ensuring that the food supply is safe is surveillance for human cases of foodborne disease, to detect outbreaks, monitor trends, and provide evidence for public health action. One challenge for public health surveillance is that many foodborne illnesses result in mild symptoms that resolve spontaneously and do not require a visit to the doctor. This means that for every reported foodborne infection, there will be many more in the community. One implication of this is that surveillance data alone do not indicate the true magnitude of foodborne disease affecting a community.

In Australia and New Zealand, the most common potentially foodborne diseases are enteric infections, including campylobacteriosis, salmonellosis, listeriosis, shiga-toxin producing *Escherichia coli* (STEC) infection, and norovirus infection. As each of these diseases is caused by different pathogens with different characteristics, the prevention measures are subtly different for each of them.

Humans represent an important sentinel for contaminants in foods. Contamination can enter the food supply at several points in the chain of production and preparation, from: where the food is grown, processed or sold, or during preparation and consumption in domestic or foodservice kitchens. It can be very difficult to identify exactly where the contamination has occurred, except during epidemiological and food safety investigations. Generic food safety advice to cook food properly, keep cold food cold and hot food hot covers the main means of preventing foodborne infections in the home. For industrial sources of foodborne pathogens affecting the food supply, prevention is far more complex requiring intensive quality assurance and risk-based regulatory controls.

Many countries have assessed the prevalence of diseases that may be foodborne, as it is important for policy development. Collaborative groups attempting to estimate the burden of disease and compare findings from country-to-country have been established. Assessing the prevalence of foodborne diseases is a complex exercise; as there are many different etiological agents and many have multiple routes of transmission. In this article, the prevalence and major causes of foodborne diseases in Australia and New Zealand were reviewed.

Description of Surveillance Systems

Australia and New Zealand both have sophisticated systems for surveillance of diseases potentially transmitted by food. A

list of specified diseases are considered 'notifiable,' and cases that come to the attention of the health care system are reported via either general practitioners or laboratories which test for pathogens. Some infections and intoxications caused by food are not specifically notifiable, but may be reportable under public health law when they manifest in outbreaks of disease. In New Zealand and Australia, public health legislation has a requirement for notification of 'food- or waterborne disease outbreaks.' The main reasons for public health surveillance of enteric diseases include: assessment of trends, characterizing risk factors for infection, and detection and investigation of outbreaks. Proper investigation of outbreaks and characterization of risk factors can lead to immediate prevention of further cases, along with system-wide interventions to prevent future cases.

In New Zealand, the Institute of Environmental Science and Research Limited (ESR) collates reported cases of notified diseases through a database called EpiSurv, on behalf of the Ministry of Health. Infected cases who have an occupation that may put the public at risk, for example, foodhandlers and childcare workers, are followed up to ensure they are excluded from work until clear of infection. Information on risk factors and potential sources of infection may also be collected from cases. EpiSurv includes a dedicated module for the reporting of outbreaks. Key data fields collected include case demographics, clinical features and risk factors, and the results of outbreak investigations and analysis, for example, potential outbreak sources and the level of evidence for these sources. Information can be viewed via customizable local and national reports and maps. Data from case notifications and outbreak investigations are monitored to detect related cases both in New Zealand and overseas, and summaries are published in regular surveillance reports.

An annual report on foodborne disease has been published on their website by the New Zealand Ministry for Primary Industries since 2006, and incorporates surveillance data and attribution estimates. The reports also compare rates of reported foodborne disease against 5-year targets for reduction or control. In terms of attribution for foodborne transmission, the primary source for New Zealand is an expert elicitation conducted in 2005. More up to date estimates for poultry-associated campylobacteriosis have been derived from typing data of isolates from human cases and sources in a sentinel site study in the Manawatu region of New Zealand.

In Australia, six States and two Territories have primary public health powers to conduct public health surveillance of infectious diseases and investigate disease outbreaks. State and Territory health departments collect data on notifiable diseases in databases, which are aggregated into the National Notifiable Disease Surveillance System (NNDSS). At the national level, the Office of Health Protection (OHP) in the Department of Health and Ageing manages NNDSS, coordinates national action in response to communicable disease outbreaks and develops public health policy. OHP manages OzFoodNet – a national network of epidemiologists for the investigation of foodborne disease. Under the OzFoodNet program, each State and Territory health department employs one or more epidemiologists to investigate foodborne disease and improve multistate outbreak response. The OzFoodNet program of work is conducted in conjunction with other government agencies, and public health laboratories. OzFoodNet conducts surveillance for foodborne outbreaks and prepares regular reports on foodborne diseases in Australia.

Good microbiological laboratory services are the key to robust foodborne disease surveillance, as there is a need to identify common strains of foodborne pathogens infecting people from contaminated foods. Both New Zealand and Australia have extremely high-quality pathology laboratories, including public health reference laboratories. In New Zealand, ESR provides reference laboratory services to characterize viral and bacterial pathogens, such as *Salmonella*, toxigenic *E. coli*, and noroviruses. In Australia, most States and Territories have jurisdictional reference laboratories that conduct specialized testing for enteric pathogens. In Australia, the Microbiological Diagnostic Unit (MDU) Public Health Laboratory at the University of Melbourne conducts national characterization of a range of different pathogens, particularly *Salmonella*, *Listeria*, and toxigenic *E. coli* that are important for public health. MDU has conducted national surveillance for human and animal pathogens, particularly *Salmonella*, for many years. Similarly, the Institute of Medical and Veterinary Science in South Australia has housed the Australian *Salmonella* Reference Laboratory, which has a role in national surveillance. These laboratory services are critical to identifying and controlling foodborne diseases.

Diseases due to Foodborne Pathogens in Australia and New Zealand

Compared with other developed countries, Australia and New Zealand have higher rates of many illnesses due to potentially foodborne enteric pathogens. For example, the rate of campylobacteriosis in Australia is 10 times higher when compared with the US. There may be several reasons for this, including:

1. better ascertainment of cases of foodborne disease by surveillance in Australia and New Zealand,
2. higher rates of detection of foodborne pathogens in microbiology laboratories in Australia and New Zealand, and
3. differences in the risk factors for foodborne illness in Australia and New Zealand compared with other countries, giving rise to a truly greater incidence of foodborne illness.

Surveillance for foodborne infections differs in New Zealand and Australia, but we can learn from comparing data in the two countries. In particular, notification rates for *Campylobacter* infection have declined dramatically in New Zealand after a concerted risk management program was undertaken by the New Zealand poultry industry and government in 2006–07. Because of the intervention in New Zealand, the reported rate of infection is approaching that of Australia, but both countries are higher than most other countries in the world (**Figure 1**). Although poultry remains an important transmission vehicle for campylobacteriosis, in New Zealand increasing attention is being paid to other transmission routes. Nonfood transmission is likely to be more important in rural areas, including contaminated water and direct contact with livestock.

Figure 1 Rates of notification for campylobacteriosis in Australia and New Zealand, 2002–11. Reproduced from Data for Australia from NNDSS, available at: http://www9.health.gov.au/cda/Source/CDA-index.cfm (accessed on 18 January 2013) and Data for New Zealand from EpiSurv, available at: http://www.surv.esr.cri.nz/surveillance/annual_surveillance.php (accessed on 18 January 2013).

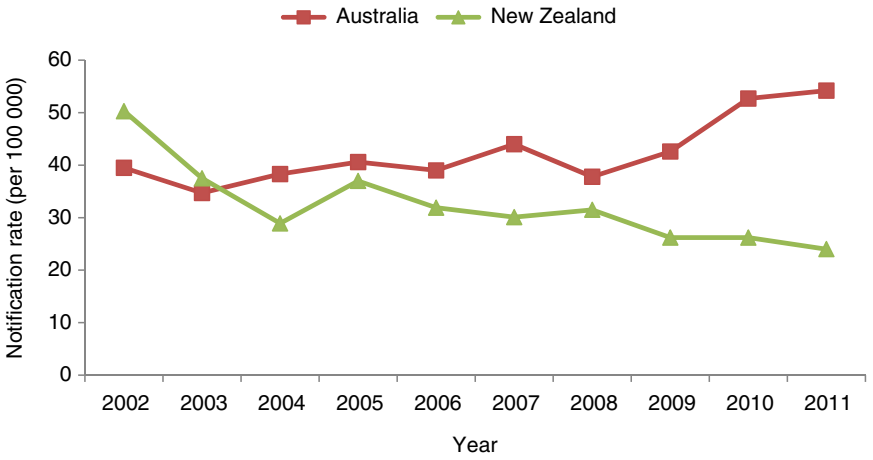

Figure 2 Rates of notification for salmonellosis in Australia and New Zealand, 2002–11. Reproduced from Data for Australia from NNDSS, available at: http://www9.health.gov.au/cda/Source/CDA-index.cfm (accessed on 18 January 2013) and Data for New Zealand from EpiSurv, available at: http://www.surv.esr.cri.nz/surveillance/annual_surveillance.php (accessed on 18 January 2013).

The rates of reported salmonellosis in New Zealand have been generally declining over the past decade (**Figure 2**). In New Zealand the prevalence of *Salmonella* in poultry and eggs is very low compared with other developed countries, largely due to industry control efforts in the 1990s. An analysis of *Salmonella* outbreak data from 2000 to 2009 found that food and foodhandler-associated outbreaks were the most commonly identified transmission routes, but specific foods common to multiple outbreaks were not able to be identified. In contrast, investigation of individual *Salmonella* outbreaks provides important information on sources of infection and preventive measures. A large outbreak of *Salmonella* Typhimurium 42 in New Zealand in 2008 was linked to contaminated flour, which is a novel food vehicle and highlighted that *Salmonella* can be transmitted by many different vehicles.

The rates of salmonellosis in Australia have increased steadily over the last 10 years, particularly since 2008. Much of the increase is thought to be related to *S.* Typhimurium infections associated with raw or minimally cooked egg dishes, as shown by sharp increases in egg-associated outbreaks at this time. Each year, Australian health departments investigate approximately 50–60 outbreaks of salmonellosis that are associated with a wide variety of foods. The OzFoodNet network has assisted with detecting and investigating outbreaks that are wide-spread geographically. Some of these outbreak investigations have identified novel food vehicles, such as dried peanuts, sesame seed products (halva and tahini), and rockmelons.

The highest rates of salmonellosis in both countries occur in young children. Many cases of salmonellosis are acquired in residents while traveling overseas. In Australia, rates of infection are highest in northern Australian populations,

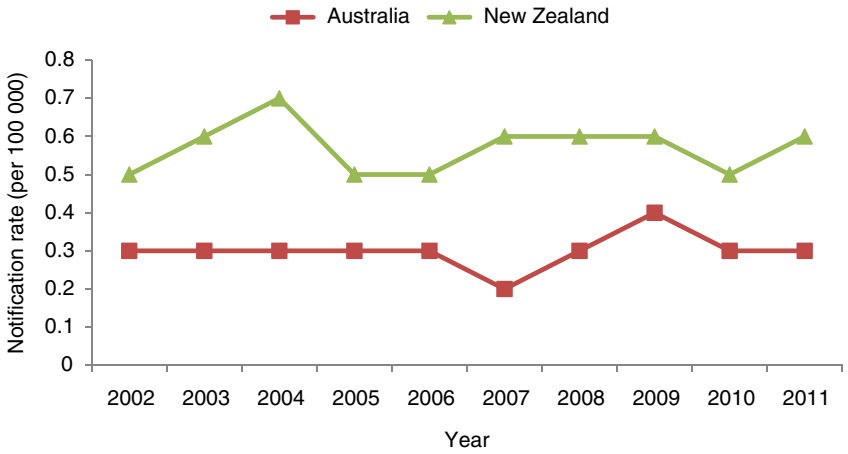

Figure 3 Rates of notification for listeriosis in Australia and New Zealand, 2002–11. Reproduced from Data for Australia from NNDSS, available at: http://www9.health.gov.au/cda/Source/CDA-index.cfm (accessed on 18 January 2013) and Data for New Zealand from EpiSurv, available at: http://www.surv.esr.cri.nz/surveillance/annual_surveillance.php (accessed on 18 January 2013).

particularly in people of indigenous origin. In contrast, higher rates of reported salmonellosis in New Zealand occur in the cooler South Island, and in the European ethnic group.

In New Zealand and Australia, the most common serotype of *Salmonella* is Typhimurium. Neither country has *Salmonella* Enteritidis endemic in egg-laying flocks. The distribution of *Salmonella* strains probably reflects local zoonotic reservoirs. For example, in the southernmost Australian State of Tasmania, the predominant strain of *Salmonella* is serotype Mississippi, which is thought to be acquired from native Australian animals in environmental settings. *Salmonella* Mississippi infections are uncommon in residents of mainland Australia. In New Zealand, *S.* Typhimurium 160 was the predominant strain from 2008 to 2010, and is largely not foodborne, but due to an epizootic in sparrows.

Listeriosis is a serious foodborne infection that results in meningitis, septicemia, pneumonia, and gastroenteritis, although only invasive infections are notifiable under public health legislation. Listeriosis usually affects two main risk groups: unborn babies, and people who are immunocompromised or elderly. The rates of reported *Listeria* infection in New Zealand are higher than in Australia (**Figure 3**). The ratio of perinatal infections to nonpregnancy-related infections appears higher also, with New Zealand in 2010 reporting 26.1% of infections as perinatal compared with 1.4% in Australia for the same year. This may indicate different risk factors for infection affecting the two populations, or may be an artifact of differences in the policies for testing for listeriosis. The majority of infections in both countries occur in people over the age of 65 , or who are on immunosuppressive medications.

STEC is another important foodborne pathogen under surveillance in both Australia and New Zealand. In the Australian State of South Australia in 1995, a major outbreak of *E. coli* O111:H-from contaminated mettwurst (fermented dried sausage) resulted in 23 cases of hemolytic uremic syndrome, one of whom died. This severe outbreak resulted in South Australia initiating robust surveillance for both *E. coli* O157 serogroup and non-O157 serogroups using polymerase chain reaction testing of all diarrheal stools containing blood for genes encoding for production of Shiga toxins. As a result, surveillance for STEC in South Australia is much better than the rest of the country. The rates of disease are lower in other jurisdictions, as STEC are not routinely tested for and usually only when requested. The overall rates of STEC are comparable in both New Zealand (3.5 per 100 000 persons in 2011) and South Australia (3.0 per 100 000), although there are differences in the main serogroups causing disease. In New Zealand, more than 90% of reported cases are infections with *E. coli* O157:H7, whereas in Australia it accounts for approximately 50% of cases.

Other Foodborne Diseases

Several other diseases that are notifiable may also be transmitted by food, but are not discussed in detail here. Examples include shigellosis, typhoid, cholera, botulism, and hepatitis A, which have caused foodborne outbreaks in both countries, but are relatively rare causes of foodborne disease most of the time. In 2009, Australia experienced a large and serious outbreak of hepatitis A due to imported semidried tomatoes, whereas New Zealand experienced an outbreak of hepatitis A due to contaminated blueberries in 2002.

Yersiniosis is a potentially foodborne disease, and is notifiable in New Zealand, where it is the third most commonly reported enteric infection. In contrast, in Australia the incidence was so low that surveillance ceased in 2001. Although outbreaks of norovirus infection are often reported as part of routine surveillance, sporadic cases are not notifiable.

Chemical hazards in food are outside the scope of this article. However, it is worth noting that in New Zealand, illness caused by toxins found in marine species (particularly shellfish) are notifiable (as 'Poisoning arising from chemical contamination of the environment'), whereas outbreaks of histamine intoxication from fish are also reported. Similarly, in some Australian States and Territories it is mandatory to report foodborne diseases of chemical origin, such as ciguatera.

Incidence (episodes per person per year)	0.80	0.77	0.97	0.74	1.11

Gastroenteritis in Australia and New Zealand

In Australia and New Zealand, there have been several studies examining the incidence of gastroenteritis. Gastroenteritis is the most common outcome of infection from several pathogens that are potentially transmitted by food. The incidence of gastroenteritis in Australia and New Zealand is similar regardless of study design and time of study (Table 1). In general, people experience approximately one episode of gastroenteritis each year.

Attribution

It is very difficult to estimate the proportion of gastroenteritis that is foodborne, as pathogens with different infectious and transmission characteristics result in the same outcome. Some pathogens, such as norovirus, are more commonly spread by one infectious person to another, whereas others are more commonly spread by contaminated food or water. To estimate the proportion of disease due to different pathogens that is transmitted by contaminated food, many international investigators have used expert elicitation, where experts were asked their opinion was about the proportion of each pathogen is foodborne.

For example, OzFoodNet in Australia conducted an expert elicitation, which estimated that 87% of *Salmonella* infections were spread by contaminated food. When the proportion of different etiological agents was considered for all 16 pathogens considered important for foodborne transmission of gastroenteritis, it was estimated that approximately 32% of gastroenteritis was foodborne. Using a similar expert elicitation approach for New Zealand, it was estimated in 2005 that a high proportion of enteric diseases are foodborne, including: norovirus and STEC infection where approximately 40% of infections were foodborne; yersiniosis, campylobacteriosis, and salmonellosis were approximately 60%; and listeriosis at 85%.

Policy Implications

The burden of foodborne disease caused by six microbial pathogens (*Campylobacter*, *Listeria*, *Salmonella*, STEC, norovirus, and *Yersinia*) in New Zealand was estimated as 1510 disability adjusted life years (DALYs) based on data up to 2005. Of the total, 880 DALYs were attributed to campylobacteriosis, with norovirus infection being the second greatest contributor (210 DALYs). The estimate for *Campylobacter* infections, along with other analyses typing investigations that attributed the majority of cases to poultry-associated types, added to the impetus to pursue risk management measures for this disease.

These burden estimates were made before the recent reduction in the incidence of campylobacteriosis over the period 2006–08. More recent data was used to provide a 2009 estimate of the total economic cost of these six diseases. The costs of government and business activity, medical treatment, and lost productivity were estimated as NZ$62.2 million, whereas personal and lifestyle costs (pain, suffering, and disruption) were estimated as NZ$99.7 million. Of the total cost of NZ$162 million, the largest proportion (NZ$50 million) was attributed to infection with norovirus, followed by campylobacteriosis (NZ$36 million).

In Australia, an estimate of costs based on data from 2001 found that 5.4 million cases of foodborne illness were estimated to cost AUS$1.2 billion annually. A separate estimate for the costs of STEC infection in South Australia found that the mean cost per case was AUS$3132, equating to AUS$2.6 million for STEC infections annually each year in Australia.

Apart from the estimates of the value of pain and suffering (which may be made in monetary or DALY metrics), estimates of cost in both countries found that the main contributor was lost productivity from a person not being able to work due to their own illness, or having to look after someone else who was ill. The main reason for the difference in costs between the two countries was that the Australian costing included cases of disease where there was no pathogen identified, but was likely to be foodborne. Foodborne disease of unknown etiology is likely to be extremely common based on efforts to estimate foodborne disease from other countries.

The burden of disease due to *Campylobacter* is high, due to the high number of cases, the severity of resulting gastroenteritis, and serious sequelae of infection such as Guillain–Barré syndrome, reactive arthritis, and irritable bowel syndrome. Poultry meat that is contaminated with *Campylobacter* has been identified as the key risk factor for infection in both countries through case–control studies and source attribution of molecular subtypes. In Australia, chicken meat contaminated with *Campylobacter* has been estimated to result in 50 500 cases of campylobacteriosis each year. The spectacular success of New Zealand in controlling foodborne disease has shown that governments and industry can enter into productive partnerships to prevent foodborne disease. In New Zealand, reported cases and hospitalizations for campylobacteriosis and Guillain–Barré syndrome declined following the regulatory measures, which has resulted in significant economic savings and reduced burden on individuals.

The generally good control of microbial hazards in the food supply of both countries may contribute to changes in the management of higher risk foods, as suggested by the current pressure to relax controls over raw milk consumption. It is important that countries maintain vigilance with foods that may be higher risk for causing foodborne disease. Efforts to improve our understanding about the occurrence and causes of foodborne disease are vital to maintaining a safe food supply.

Conclusion

Each year in Australia and New Zealand, people experience approximately one episode of acute gastrointestinal disease per person per year. It is difficult to estimate the proportion of these that are due to foodborne transmission, partly because even if a case presents to the health system and provides a stool sample, a pathogen may not be detected. Consequently the etiology of a large proportion of these cases is unknown. Nevertheless, for many of the most frequently reported enteric diseases, a high proportion is due to foodborne transmission. The prevalence of foodborne disease in Australia and New Zealand is similar to most developed countries. Both countries have invested substantial resources in investigating

and controlling foodborne diseases. This has resulted in major improvements in identifying the causes of foodborne disease outbreaks. New Zealand has experienced great success in reducing the incidence of campylobacteriosis. The interventions have had a substantial effect in reducing acute and chronic disease, and should serve as a model for other countries.

Prevalence of Foodborne Diseases in Europe

SJ O'Brien, University of Liverpool, Liverpool, UK

Glossary

Disability-adjusted life years It provides a measure of overall disease burden, expressed as the number of years lost due to ill health, disability, or early death.

Foodborne source attribution Refers to the process of partitioning foodborne infections by specific sources, where the term 'source' can include the animal reservoirs or food vehicles.

Meta-analysis Refers to the process of estimating the true effect size from pooled results of, for example, case–control studies, as opposed to the less precise result obtained from a single study under a given single set of assumptions and conditions.

Reservoir Refers to the animal hosts (including humans) from which foodborne pathogens originate. The reservoir can include diseased or asymptomatic carriers/shedders.

Systematic review Refers to a literature review, which is driven by a research question. The process involves identifying, appraising, selecting, and synthesizing all high-quality research evidence relevant to the research question.

Vehicles These are inanimate objects that enable contact between pathogen reservoir and people and include water, food, animals, soil, manure, compost, and other people.

Introduction

Foodborne disease kills people. Reminders of this chastening fact include the devastating outbreak of *Escherichia coli* O104:H4 in Germany in 2011, in which 54 people died and 22% of the 3186 cases of *E. coli* O104 developed the severe complication, hemolytic uremic syndrome (HUS). Outbreaks are striking events, yet the percentage of all cases of foodborne disease that occur as part of outbreaks is fairly small. The first port of call when seeking to understand the prevalence of foodborne disease is the official bodies that have responsibility for monitoring illness in the population. However, the datasets amassed by these organizations tend to underestimate the population burden of illness so, in the past decade or so, there has been a proliferation of new methods across Europe in an attempt to overcome this deficiency and develop better estimates of the true population burden of illness.

The Prevalence of Foodborne Disease in Europe: The Official Estimates

The major sources of collated data on the prevalence of foodborne disease in Europe are the World Health Organization (WHO) Regional Office in Europe and the European Center for Disease Prevention and Control (ECDC). The WHO program covers 53 countries that make up the WHO European Region – from the Republic of Ireland in the West to the Russian Federation in the East, and Israel to the South. The ECDC compiles data from the 27 Member States of the European Union (EU) and three European Economic Association/European Free Trade Association countries. In addition, the European Food Safety Authority (EFSA) is responsible for analyzing data on zoonoses, antimicrobial resistance, and foodborne outbreaks submitted by EU Member States for preparing the EU Summary Report. This is undertaken in collaboration with the ECDC.

The View from the WHO Regional Office in Europe

In 2002, World Health Assembly mandated WHO to develop a global strategy for reducing the burden of foodborne disease. In this strategy, it is recognized that preventing foodborne disease and responding to food safety challenges need a timely, holistic, risk-based approach.

Information about the prevalence of foodborne disease in the WHO European Region is available from the Centralized Information System for Infectious Diseases (CISID). The CISID dataset, compiled from national reports, is underpinned by accurate and up-to-date population data for the WHO European Region and information collected by WHO is useful for risk assessment.

The CISID dataset covers a wide range of foodborne pathogens. In the WHO European Region, salmonellosis and campylobacteriosis are the most commonly reported foodborne diseases. Between 2000 and 2010 the highest incidence of campylobacteriosis was consistently reported from the

 doi:10.1016/B978-0-12-378612-8.00077-9

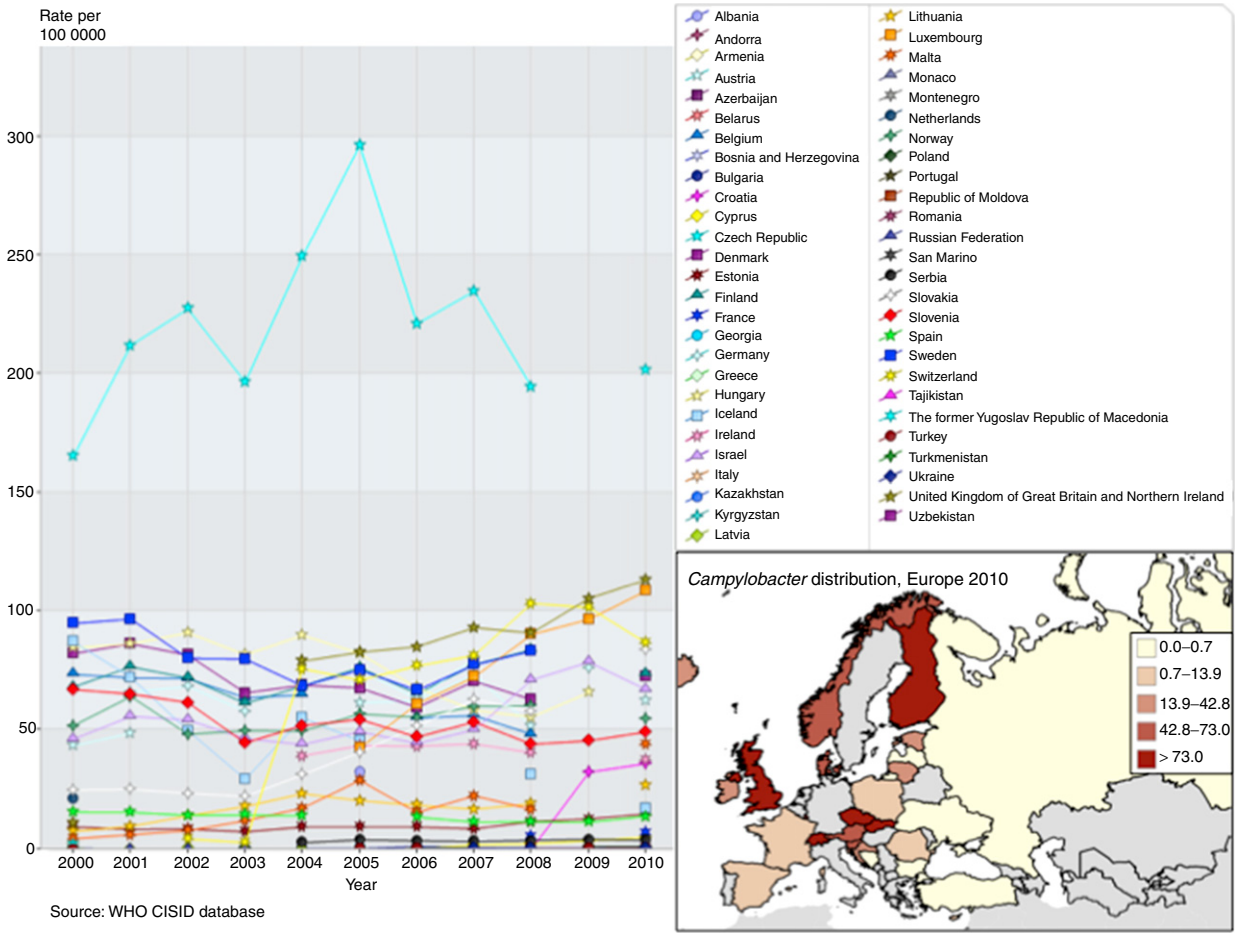

Figure 1 Trend in campylobacteriosis in the WHO European Region, 2000–10.

Former Yugoslav Republic of Macedonia, where rates were almost three times as high as elsewhere in the region (Figure 1).

The incidence of salmonellosis declined over the decades 2000–10 in several countries although *Salmonella* was still a frequent cause of the foodborne outbreaks (Figure 2).

The trend in listeriosis remained relatively stable over the decades 2000–10 (Figure 3), but reporting of enterohemorrhagic *E. coli* (EHEC) was mainly from Western European countries (Figure 4).

Brucellosis remained a significant public health problem in the Central Asian republics. Trichinellosis in the Balkan countries and echinococcosis in both the Central Asian republics and the Balkan countries were causes for concern. Botulism remained relatively frequent in Eastern Europe and is mainly related to traditional ways of preserving foods at home.

The View from the ECDC

Established in 2005, the ECDC is a EU agency that aims to strengthen Europe's defenses against infectious diseases. The Programme on Food- and Waterborne Diseases and Zoonoses was instituted in 2006, and covers a comprehensive range of pathogens. Early priorities included consolidating surveillance for salmonellosis, campylobacteriosis, verocytotoxin-producing *E. coli*/shiga toxin-producing *E. coli* (STEC) infection, listeriosis, shigellosis and yersiniosis; publication of an annual zoonosis report jointly with the EFSA; and developing novel methodology to estimate population exposure to salmonellosis and campylobacteriosis using seroepidemiology. In its 2011 annual epidemiological report, ECDC reported that *Campylobacter* rates are high and it remains the most commonly reported gastrointestinal illness across the EU. In 2009, there were over 201 000 confirmed cases (rate = 53 cases per 100 000 population). The highest rates were reported from the Czech Republic (193 cases per 100 000) and the UK (106 cases per 100 000).

By contrast, the incidence of *Salmonella* infection has decreased progressively since 2004 and this has been linked, at least partly, to effective programs to control infection in the poultry industry. There were over 111 000 cases reported in 2009 (rate = 23 cases per 100 000 population) and *Salmonella* continues to be a common source of outbreaks. *Salmonella* Enteritidis and *Salmonella* Typhimurium remain the most frequently identified serotypes but rates of *S.* Enteriditis infection were 24% lower in 2009 than in 2008 and rates of *S.* Typhimurium had also declined by 12%. Even in the higher incidence countries like the Czech Republic, Slovakia, Hungary, and Lithuania rates have also decreased markedly.

Reported cases of EHEC increased significantly between 2005 and 2009 to just over 3600 cases (rate = 0.86 per 100 000

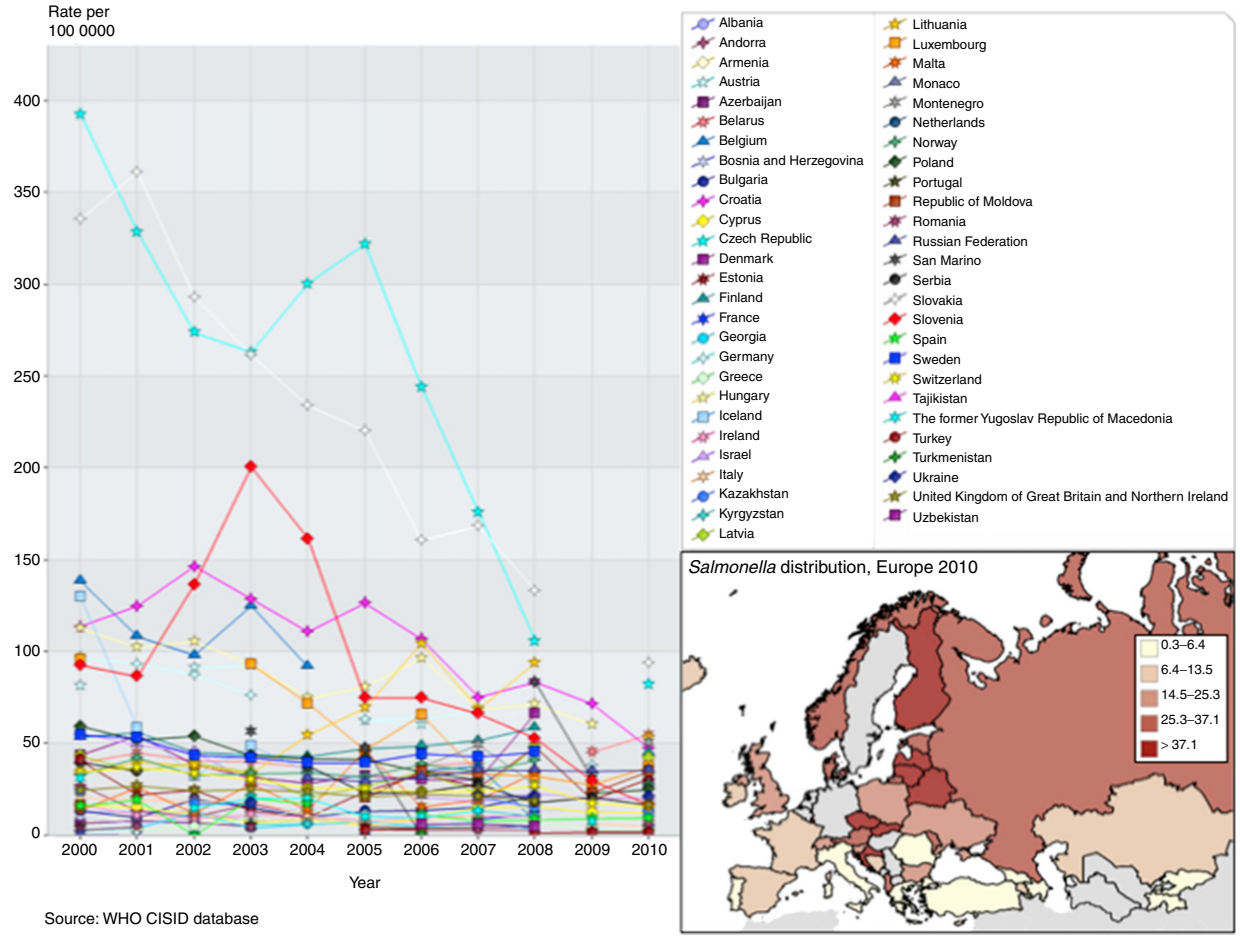

Figure 2 Trend in salmonellosis in the WHO European Region, 2000–10.

population). More than half of the cases were due to STEC O157. There were 242 confirmed STEC cases that developed HUS – a 66% increase in HUS cases compared with 2008. This large increase was, in part, explained by two sizable outbreaks of STEC – one in the UK linked to an open farm and a nationwide outbreak in the Netherlands associated with the consumption of STEC-contaminated beef steak tartare.

The ECDC report shows that some rare or uncommon gastrointestinal infections EU-wide can, nevertheless, affect particular subregions and countries. Brucellosis is reported mainly from Portugal, Spain, and Greece, where it is associated with goat farming. The majority of trichinellosis cases occurred in Bulgaria, Romania, and Lithuania, where it is likely to be associated with eating domestically reared pork and wild boar, and most confirmed echinococcosis cases were from Bulgaria, where increasing proportions of *Echinococcus*-positive cattle and sheep are also being reported. Overall, yersiniosis rates were decreasing but remain high in the Nordic states, Germany, the Czech Republic, and Slovakia, where infection is often associated with pork consumption. Confirmed case rates for listeriosis were highest in 2009 in Denmark (rate = 1.8 cases per 100 000 population), which has experienced a marked increase in cases, especially in people over 70 years of age. The increase was attributed, at least in part, to a surge in consumption of ready-to-eat (RTE) products in Denmark, especially in older people. A similar pattern was witnessed in the UK, where a doubling in cases of listeriosis in people aged more than 60 since 2001 was attributed to a combination of greater consumption of RTE products like sandwiches coupled with an increase in underlying medical conditions like cancer, requiring complex, immunosuppressive treatment.

The View from the EFSA

The EFSA, in collaboration with the ECDC, produces an annual 'European Union Summary Report on Trends and Sources of Zoonoses, Zoonotic Agents and Foodborne Outbreaks.' In 2010, there were 5262 foodborne outbreaks reported in the EU – similar to the level reported in 2009. These outbreaks involved nearly 43 500 people, of whom approximately 4600 were hospitalized and there were 25 deaths. The evidence implicating a food vehicle was considered to be strong in 698 outbreaks.

Salmonella was the most frequently reported pathogen (30.5% of all outbreaks), followed by viruses (15.0%) and *Campylobacter* (8.9%) (Figure 5). However, there was a considerable proportion of outbreaks in which the causative

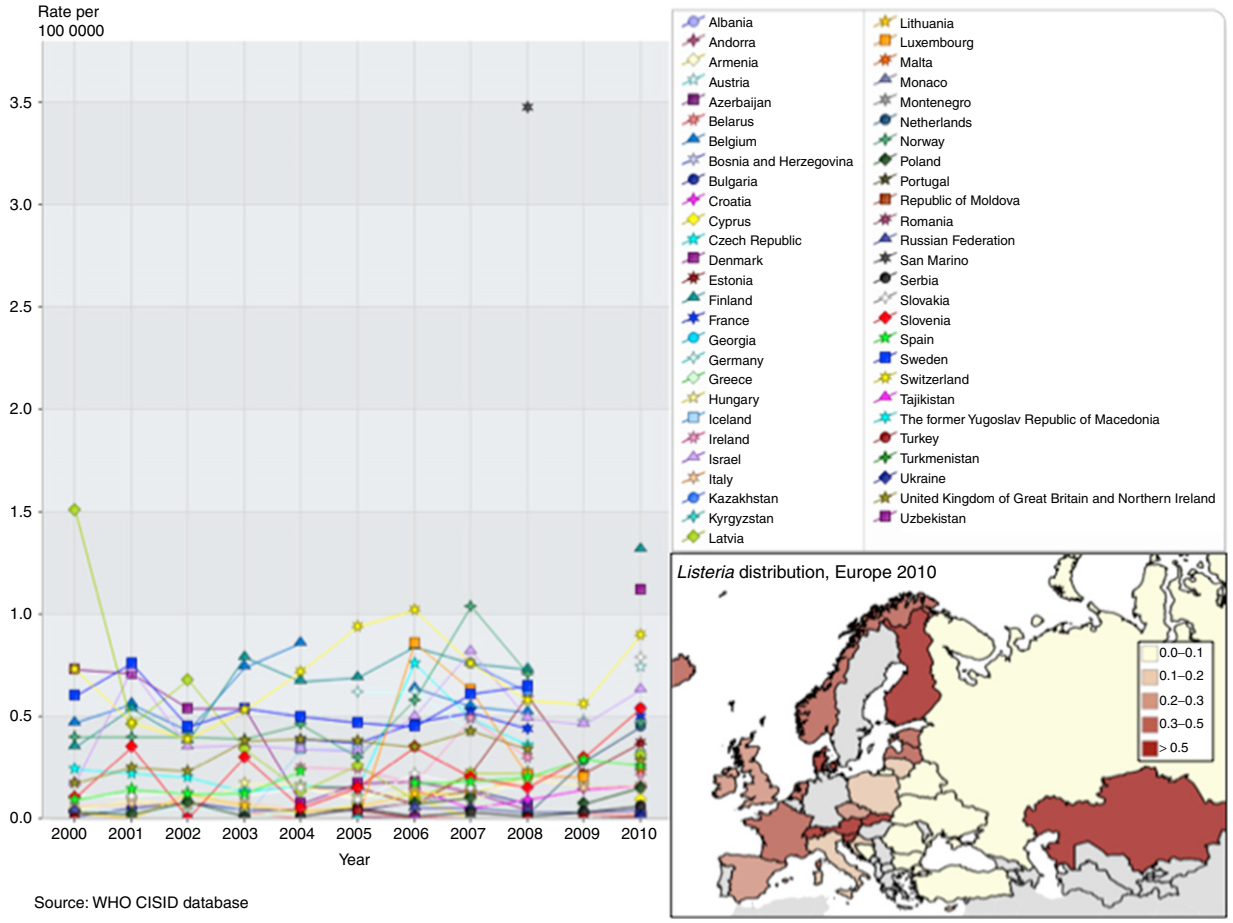

Figure 3 Trend in listeriosis in the WHO European Region, 2000–10.

organism was unknown and a large percentage of *Campylobacter* outbreaks in which the evidence implicating a food vehicle was considered to be weak.

The most frequently reported food vehicles were eggs and egg products (22.1%); mixed or buffet meals (13.9%); vegetables, juices, and vegetable/juice products (8.7%); and crustaceans, shellfish, molluscs, and shellfish products (8.5%). An increase in the numbers of reported outbreaks caused by vegetables and vegetable products was attributed mainly to contamination with viruses.

The View from 'NoroNet'

It is becoming increasingly apparent that norovirus (NoV) is an important foodborne pathogen. Contamination can occur either at primary production, for example, shellfish, salad vegetables, and soft fruits at source or, at retail, for example, through inadequate practises by infected food handlers. Funded initially through a research grant, 'NoroNet' now comprises a voluntary collaboration between virologists and epidemiologists from 13 European countries who have been sharing surveillance and research data on enteric virus infections, mainly NoV, since 1999. There are international partners from North America, Australia, China, India, and New Zealand. The objectives of NoroNet include providing better estimates for the proportion of foodborne NoV infections and determining the high-risk foods associated with illness. Several publicly available analytical tools have been developed including a 'transmission mode tool' to increase the chances of identifying a foodborne source of infection. Using this tool to analyze 1254 outbreaks from nine countries reported between 2002 and 2006 showed that the proportion of NoV outbreaks that were likely to be foodborne was 22%. 'NoroNet' was also instrumental in identifying the latest pandemic strain – the Sydney 2012 virus, which has recently overtaken all others to become the dominant strain worldwide.

Gaps in Our Knowledge

A major drawback of all surveillance systems, be they local, national, or international, is that they underestimate the true population burden of acute gastroenteritis and, in turn therefore, the true burden of foodborne disease. Surveillance systems eavesdrop on the clinical process. The greatest potential loss of information about illness in the population occurs when people do not access the healthcare system. In most countries, an episode of illness has no chance of being included in surveillance statistics unless the patient consults a doctor or nurse. Similarly, information on pathogens is only available if the doctor or nurse requests, and the patient provides, a sample for laboratory testing.

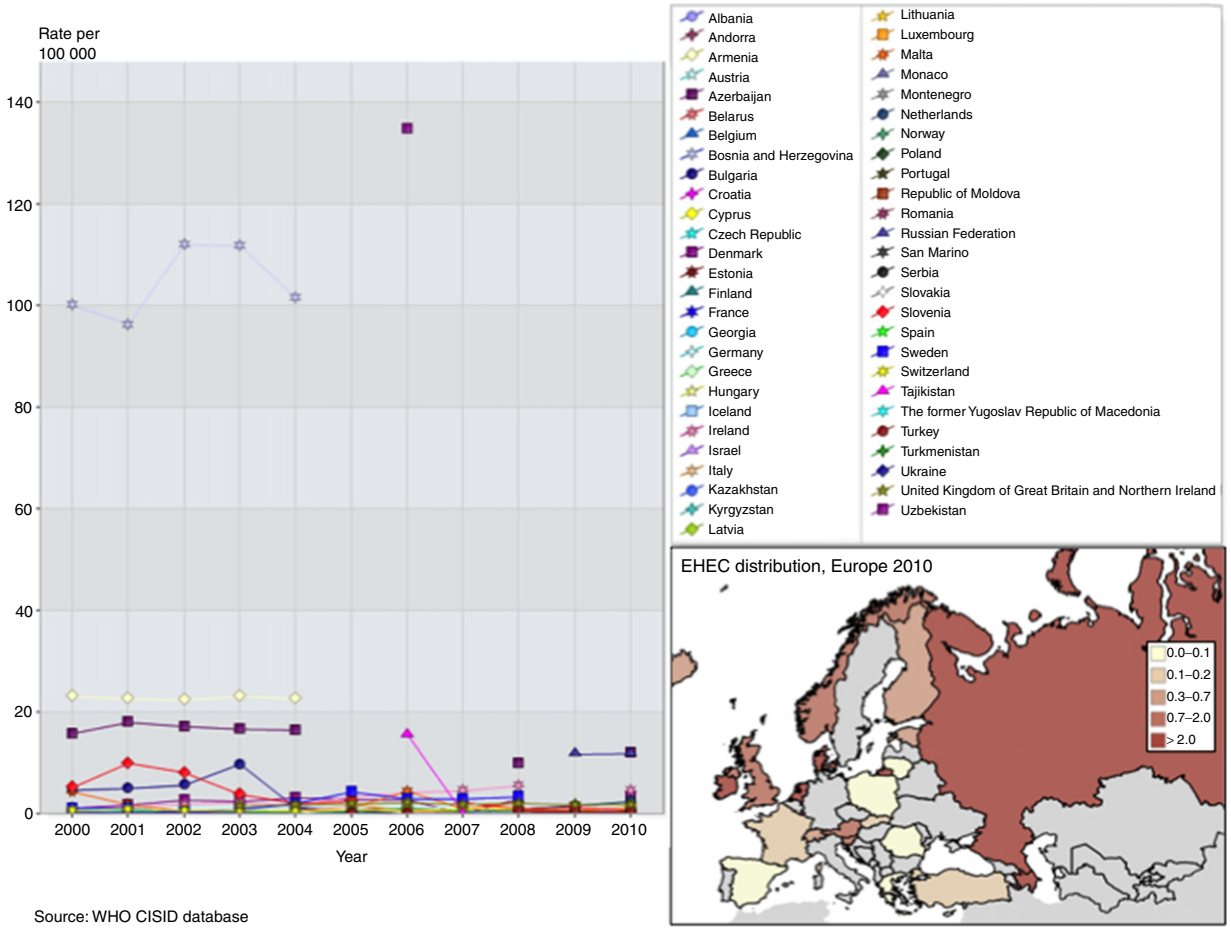

Figure 4 Trend in EHEC infections in the WHO European Region, 2000–10.

National surveillance systems for foodborne disease in Europe operate in different ways. Some are sentinel, symptom-based systems that collect little information on etiology. Others are based on laboratory-confirmed cases of infection. Laboratory testing protocols vary between laboratories within the same country, let alone between laboratories in different countries. Some cover the total population, while others include only a proportion of the total population. Most routine programs are passive, voluntary systems. The degree of underascertainment in many of the systems has not been measured, and all these factors conspire to make meaningful comparisons of disease rates between countries very difficult to accomplish.

The key to determining the real impact of foodborne disease on the population is to understand, first of all, the 'true' population burden of acute gastroenteritis.

Burden of Acute Gastroenteritis

There are several methodological approaches for estimating the incidence of acute gastroenteritis including retrospective cross-sectional surveys (telephone surveys of self-reported illness, door-to-door or postal questionnaire surveys) or prospective, population-based cohort studies (Table 1).

Telephone Surveys

Seven retrospective telephone surveys of self-reported illness have recently been completely performed in the WHO European Region (Table 1). These have the advantage that large samples of the population can be contacted and interviews are relatively short so that participation rates tend to be good. The major disadvantage of telephone surveys and other types of surveys seeking information on symptoms is that the etiology of symptoms is not captured. They are also prone to inaccurate recall, especially if the recall period is fairly long.

Rates of self-reported illness in the general population ranged between 1.4 cases per person per year in Denmark and 0.33 cases per person per year in France. Comparing rates across nations can be difficult. Differences in case definitions, study designs, periods of recall symptoms, and the populations studied can all hamper incidence rate comparisons. For example, one of the studies highlighted in

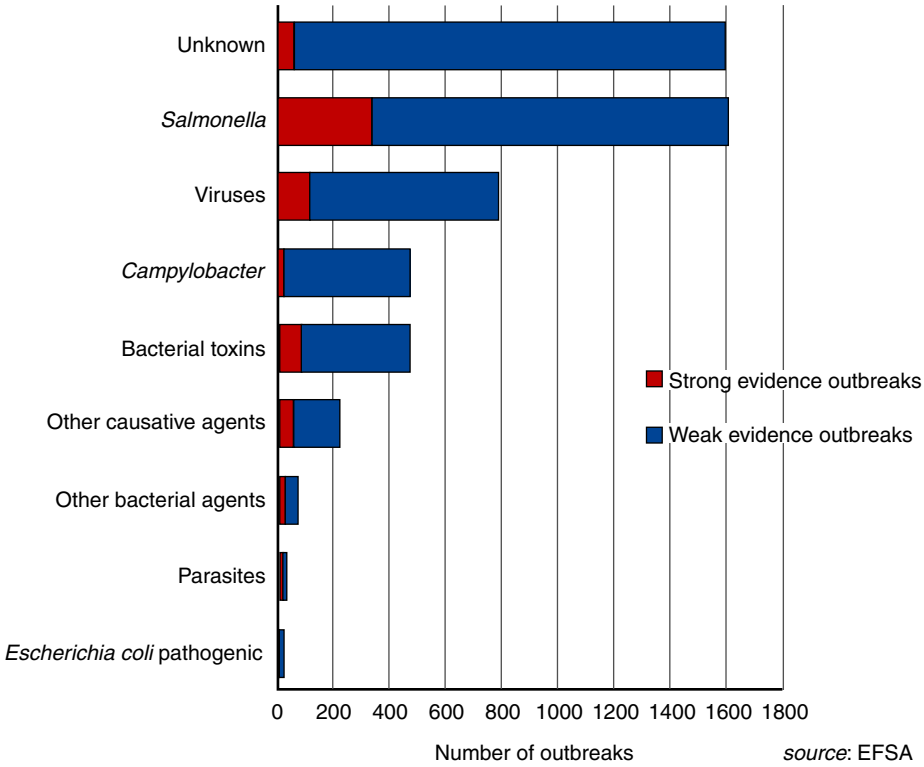

Figure 5 Etiology of foodborne disease outbreaks in the European Union, 2010.

Table 1 Recent population-based studies of the incidence of acute gastroenteritis in Europe

Country	*Study design*	*Study duration*	*Incidence estimate, expressed as rate per person per year (95% CI)*	*Lead author (publication date)*
Poland	Telephone survey	2008–09	0.9 (0.8–1.0)	Baumann-Popczyk *et al.* (2012)
The Netherlands	Questionnaire survey	2009–10	0.96 (0.81–1.11)	Doorduyn *et al.* (2012)
Hesse, Germany	Telephone survey	2004–06	0.86 (0.72–1.03) (children aged ≤15 years) 0.46 (0.37–0.51) (adults aged ≥16 years)	Hauri *et al.* (2011)
Italy	Telephone survey	2008–09	1.08 (0.90–1.14)	Scavia *et al.* (2012)
France	Telephone survey	2009–10	0.33 (0.28–0.37)	Van Cauteren *et al.* (2012)
Israel	Telephone survey	2005	1.49 (not reported) (children aged <17 years)	Ziv *et al.* (2011)
Denmark	Telephone survey	2009	1.4 (1.2–1.6)	Müller *et al.* (2012)
UK	Prospective cohort study	2008–09	0.27 (0.25–0.3) in the community	Tam *et al.* (2012a)

Table 1 only involved children. Nevertheless, using a standardized, symptom-based case definition enabled better comparison of rates between countries, and as the use of this case definition becomes more widespread some of these difficulties in interpreting rates between studies should diminish.

As well as determining disease rates information on healthcare usage in this series of coordinated, cross-sectional telephone surveys of self-reported illness was used to estimate under-reporting and underdiagnosis in the national surveillance systems of the countries taking part. Overall, underreporting and underdiagnosis were estimated to be lowest for Germany and Sweden, followed by Denmark, the Netherlands, UK, Italy, and Poland. Across all countries, the incidence rate was highest for *Campylobacter* spp. and *Salmonella* spp. Adjusting incidence estimates for biases inherent in different surveillance systems provides a better basis for international comparisons than relying on reported data.

Prospective, Population-Based Cohort Study

Prospective studies are uncommon, perhaps because of their expense. Three such studies have been conducted in Europe – one in the Netherlands and two in the UK. The major advantage of cohort studies is the ability to obtain samples from patients with infectious intestinal disease (IID) to confirm etiology, which is important if one of the aims is to calibrate national surveillance systems. A major drawback is that participation rates can be low and losses to follow-up may be high, but there are several strategies to try to overcome both of these important limitations.

In the UK, illness burden has been estimated in a population-based prospective cohort study and prospective study of presentations to primary care (the Second Study of Infectious Intestinal Disease in the Community (IID2 Study)). Up to 17 million people (approximately one in four) in the community were found to be suffering from IID in a year (annual incidence = 0.27 cases of IID per person per year). There were approximately 3 million cases of NoV infection and 500 000 cases of campylobacteriosis. The estimated time taken off from work or school because of IID was nearly 19 million days. Approximately 1 million people presented to their primary healthcare team and the leading causes were NoV infection (130 000 cases) and campylobacteriosis (80 000 cases).

As well as defining illness burden, a secondary objective of the IID2 Study was to recalibrate national surveillance systems, i.e., to estimate the number by which laboratory reports of specified pathogens need to be multiplied to establish the actual number of infections in the community. So, for every case of IID reported to national surveillance centers in the UK, 147 cases had occurred in the community. For *Campylobacter* the ratio of disease in the community to reports to national surveillance was approximately 9 to 1, for *Salmonella* the ratio was approximately 5 to 1, and for NoV the ratio was almost 300 to 1.

Health Economics Assessments

A very powerful way to win the interest of politicians and policy makers is to be able to attach a monetary value to food-related illness. In developed countries, diarrheal disease can be belittled as inconvenient and unimportant alongside noncommunicable diseases like diabetes, heart disease, and stroke. Nevertheless, there can be considerable disruption to society and the economy. For example, the estimated costs of diarrheal disease are in the region of 345 million EUR in the Netherlands, 270 million EUR in Australia, and 2.8 billion EUR in Canada.

Disability-Adjusted Life Years

In the Netherlands, in 2009, the burden of NoV infection alone was estimated to be 1622 (95% confidence interval (CI) 966–2650) disability-adjusted life years (DALYs) in a population of 16.5 million, which is a large amount for what is generally held to be a very mild and self-limiting illness.

Burden of Food-Related Illness

Having worked out the burden of acute gastroenteritis, the next rational step is to apportion illness burden by transmission route, namely foodborne transmission. Once again, several methodologic approaches are available, including epidemiologic and microbiologic approaches, intervention studies, expert elicitation, health economics assessments, and systematic reviews.

Source Attribution Using Outbreak Data

Outbreaks that have been meticulously investigated, i.e., where the evidence linking the outbreak to a food vehicle is strong, can provide useful information for subdividing diarrheal disease by transmission route. However, there are several limitations when interpreting the results. The first is the robustness of evidence incriminating a food vehicle in an outbreak in the first place. For example, in the EFSA Report published in 2010 only 698 of 5262 outbreaks were considered to provide strong evidence of a link to a food vehicle. Second, it has to be accepted that the distribution of food vehicles implicated in outbreaks is the same as the distribution of food vehicles responsible for sporadic cases of infection and this is a major assumption.

In the UK, in an attempt to estimate the impact of disease risks associated with eating different foods, over 1.7 million cases of UK-acquired foodborne disease per year resulted in almost 22 000 people being admitted to hospital and nearly 700 deaths. *Campylobacter* infection caused the greatest impact on the healthcare sector (nearly 161 000 primary care visits and 16 000 hospital admissions) although *Salmonella* infection resulted in the most deaths (more than 200).

In France, it has been estimated that foodborne pathogens cause between 10 000 and 20 000 hospital admissions per year. *Salmonella* is the most frequent cause of hospital admissions, followed by *Campylobacter* and *Listeria*.

Health Economics Assessments

The UK's Food Standards Agency estimates the cost of foodborne illness in England and Wales annually by assessing the resource and welfare losses attributable to foodborne pathogens. The overall estimated cost of foodborne illness annually in England and Wales has remained relatively constant since 2005 at approximately GBP 1.5 billion. For comparison, in New Zealand and the USA the costs are 216 million NZD and 152 billion USD, respectively.

Disability-Adjusted Life Years

In the Netherlands, the foodborne disease burden due to 14 food-related pathogens has been estimated using DALYs. This method for determining disease burden includes estimates of duration and takes into account disability weights for nonfatal cases and loss of statistical life expectancy for fatal cases. In total, there were an estimated 1.8 million cases of diarrheal disease and 233 deaths, of which approximately 680 000 cases and 78 deaths were allocated to foodborne transmission. The total burden was 13 500 DALYs. At a population level, *Toxoplasma gondii*, thermophilic *Campylobacter* spp., rotaviruses, NoVs, and *Salmonella* spp. accounted for the highest disease burden.

Similarly, the public health effects of illness caused by foodborne pathogens in Greece during 1996–2006 have been calculated. Approximately 370 000 illnesses per million people were judged to have occurred because of eating contaminated food. A total of 900 illnesses were found to be severe and three were fatal. The corresponding DALY estimate was 896 per million population. Brucellosis, echinococcosis, salmonellosis, and toxoplasmosis were the most common known causes of foodborne disease and accounted for 70% of the DALY estimate of 896 DALYs per million people.

Expert Elicitation

Expert elicitation employs expert opinion to apportion pathogens according to foodborne transmission or transmission via other routes. An example of this is the Delphi method, which usually involves experts answering questionnaires in two or more rounds. After each round, a facilitator provides an anonymous summary of the experts' forecasts from the previous round as well as the reasons they provided for their judgments. The experts can then modify their earlier answers in response to the replies of other members of their panel. The range of the answers in each round tends to decrease so that the panel will converge toward a 'correct' answer. The Delphi technique is predicated on the basis that forecasts (or decisions) from a structured panel of people are more accurate than those from unstructured groups. Panels do not need to meet in person for the method to work.

Using structured expert elicitation, almost half of the total burden of diarrheal disease in the Netherlands was attributed to food. *Toxoplasma gondii* and *Campylobacter* spp. were identified as key targets for additional intervention efforts, focusing on food and environmental pathways. Not surprisingly, perhaps, a very high proportion of toxin-producing bacteria (*Bacillus cereus*, *Clostridium perfringens*, and *Staphylococcus aureus*) were considered to be predominantly foodborne. By contrast, multiple transmission routes were assigned to the zoonotic bacterial pathogens and protozoan parasite *T. gondii* although the food pathway was considered to be the most important.

Seroepidemiology

An alternative way to assess the incidence of foodborne pathogens is to investigate exposure to them. Pioneered in Denmark and the Netherlands, an approach to studying infection pressure has been developed using serum antibodies to *Campylobacter* and *Salmonella* as biomarkers to estimate seroconversion rates. This shows that infections are much more common than clinical disease, probably because the majority of infections are asymptomatic. A great advantage of this method is that the assessment of incidence is independent of surveillance artifacts. The method confirms that comparing reported incidence between countries can lead to a totally false impression, even within the EU.

Food-Related Illness by Food Commodity

To pinpoint and then prioritize food safety interventions, the burden of food-related illness needs to be allocated to food commodities. Again, several methodologies exist.

Interventions

The most persuasive evidence for the role of contaminated food items probably comes from studies that demonstrate the impact of interventions on human disease burden. For example, in the UK, where two population-based prospective cohort studies have taken place 15 years apart, there has been a marked fall in nontyphoidal salmonellosis in the community. The fall in incidence coincides closely with voluntary vaccination programs in broiler-breeder and laying flocks, and suggests that these programs have made a major contribution in improving public health, demonstrating the success of such concerted, industry-led action.

Natural experiments also illustrate the importance of poultry contamination as a major source of human *Campylobacter* infection. For example, in the Netherlands widespread culling of poultry that took place because of an avian influenza outbreak was followed by a decrease in *Campylobacter* infection in people, particularly in the areas where culling had taken place. Similarly, when contamination with dioxins caused poultry to be pulled from the supermarket shelves in Belgium the incidence of laboratory-confirmed *Campylobacter* infection in people fell.

Microbiological Source Attribution

The main applications of source or reservoir attribution using microbial subtyping have been to *Salmonella* and *Listeria*. Sero- and phagetyping data tend to be used for this purpose. The underlying philosophy is controlling pathogens in the source or reservoir will avert subsequent human exposure, whatever transmission route or vehicle. Comparing results from animal and human surveillance programs provides insights about the major sources of disease in people.

In Denmark, a source attribution model has been developed to quantify the contribution of major animal-food sources to human salmonellosis. This showed that domestic food products accounted for over half of all cases, with over one-third of cases being attributable to table eggs. Nearly a fifth of cases were travel related, and in a similar proportion no source could be pinpointed. Nearly 10% of cases were attributed to imported food products and the most important source was imported chicken. Multidrug- and quinolone-resistant infections were rare in Danish-acquired infection and were caused more frequently by imported food products and traveling abroad.

Source Attribution Using Outbreak Data

Information from well-conducted outbreak investigations can be very useful for the so-called point of consumption attribution as they are gathered at the public health endpoint and can, therefore, be considered to be a direct measure of attribution at the point of exposure. One of the difficulties in using outbreak data, however, is that foods implicated in reported outbreaks are often complex foods, containing several ingredients or food items, any one of which might be the specific source of the pathogen. The method works best for pathogens where outbreaks are relatively common. So, for example, it is more robust for STEC and *Salmonella* than it is for

Campylobacter, because *Campylobacter* outbreaks are rarely recognized. Using EU outbreak data, 58% of *Salmonella* cases that could be allocated to a source were attributed to contaminated eggs and 29% of *Campylobacter* cases that could be allocated to a source were attributed to contaminated poultry. However, for both pathogens the majority of cases could not be attributed to a source, illustrating another limitation of using outbreak data for these purposes.

In the UK, using outbreak data for point of consumption attribution showed that the most important cause of UK-acquired foodborne disease was contaminated chicken and that red meat (beef, lamb, and pork) contributed heavily to deaths. The prioritization exercise that this type of analysis allowed showed that reducing the impact of UK-acquired foodborne disease was mainly dependent on preventing contamination of chicken.

Systematic Review and Meta-Analysis

Several case–control studies of sporadic salmonellosis and sporadic campylobacteriosis have been published, often using different methodologies and conducted in different settings. Systematic reviews consist of a formal process for literature review focused on a specific research question. In a systematic review of case–control studies and meta-analysis of 35 case–control studies of sporadic salmonellosis, traveling abroad, underlying medical conditions, eating raw eggs, and eating in restaurants were the most important risk factors for salmonellosis in the meta-analysis. Similarly, in a systematic review and meta-analysis of 38 case–control studies of sporadic campylobacteriosis, foreign travel, undercooked chicken, consumption of environmental sources, and direct contact with farm animals were all significant risk factors.

In a systematic review and meta-analysis of hepatitis E virus, occupational exposure to swine was found to be a more important route of transmission to humans than eating contaminated pork. This is an important finding requiring further exploration before any public health policy action in relation to food is implemented.

Investigating the Unknown

Most surveillance systems that capture information on etiology elicit information on known pathogens. Yet in the IID2 Study in the UK a known pathogen was assigned to 40% of community cases and 50% of the cases presenting to primary care. In the remainder of the stool samples submitted no pathogen was detected. So what about the rest? There is a number of possible reasons for the high percentage of cases with unknown etiology. First, it is possible that people reported transient changes in bowel habit not caused by IID. Second, these cases might have been caused by organisms not included in the diagnostic algorithms, like enteropathogenic or enterotoxigenic *E. coli*. Third, the cases might have been caused by putative pathogens like enterotoxigenic *Bacteroides fragilis* or *Laribacter hongkongensis*. Several coronaviruses, picobirnaviruses, pestiviruses, and toroviruses have recently been proposed as causes of IID, particularly in children. Whole-genome sequencing techniques, though not yet enabled for widespread use, create enormous prospects for identifying novel pathogens that might be transmitted through the food chain.

Conclusion

Foodborne illness in Europe is an important public health problem no matter what method is used to measure its impact. If success in public health is defined by illness prevented, there is still a long way to go in controlling foodborne disease in Europe.

FOODBORNE DISEASES

Prevalence of Foodborne Diseases in Western Pacific Region

H Toyofuku, National Institute of Public Health, Saitama, Japan

Glossary

Agent A factor (microorganism, chemical substances, etc.) whose presence or excessive presence is essential for the occurrence of the disease.
Case An occurrence of illness as defined by investigators.
Food Any substance, whether processed, semiprocessed, or raw, which is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation, or treatment of 'food' but does not include cosmetics, tobacco, or substances used only as drugs.
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by the consumption of food.
Foodborne disease outbreaks The occurrence of two or more cases of a similar foodborne disease resulting from the ingestion of the same food.
Global Foodborne Infections Network (GFN) It is a capacity-building program that promotes integrated, laboratory-based surveillance and intersectoral collaboration among human health, veterinary, and food-related disciplines. GFN is part of World Health Organization's endeavors to strengthen the capacities of its Member States in the surveillance and control of major foodborne diseases and to contribute to the global effort of containment of antimicrobial resistance in foodborne pathogens.
Notifiable disease A disease that must, by law or by ministerial decree, be reported to a government authority.
Surveillance The systematic collection, analysis, interpretation, and dissemination of health data on an ongoing basis, to gain knowledge of the pattern of disease occurrence and potential in a community, in order to control and prevent disease in the community.
Vehicle An inanimate intermediary (e.g., food) in the indirect transmission of an agent that carries the agent from a reservoir to a susceptible host.

Introduction

In the Western Pacific region, most countries are yet to recognize the true health, social, and economic costs of foodborne disease. As a result of the general lack of understanding of the burden imposed by these diseases, inadequate attention has been paid to developing effective national food safety programs.

According to the World Health Organization (WHO)-Western Pacific Region Office (WPRO), the region stretches over a vast area, from China in the north and west, to New Zealand in the south, and French Polynesia in the east. One of the most diverse of the WHO regions, the Western Pacific constitutes some of the world's least developed countries as well as the most rapidly emerging economies. It includes highly developed countries such as Australia, Japan, New Zealand, the Republic of Korea and Singapore, and fast growing economies such as China and Vietnam. There are 37 countries and areas in the Western Pacific region.

Even though Brunei, Lao People's Democratic Republic, Malaysia, Philippines, Singapore, and Vietnam belong to the WPRO, foodborne diseases in these countries are not addressed in this article. Similarly, foodborne diseases in Australia and New Zealand is covered by article 413, In this article, foodborne diseases reported in Japan, Republic of Korea, China, Taiwan, Hong Kong, Guam, and other countries are discussed.

It is important to note that foodborne outbreak investigation and reporting systems at the national level are not similar among countries in this region. Therefore the differences in the numbers reporting outbreaks and the causative agents may not necessarily reflect the levels of food safety situations among countries.

General

Because of large fish consumption in this region, the fishborne disease, especially had *Vibrio parahaemolyticus* as a leading etiological agent. However, in most of the countries, especially Japan and Korea, both numbers and cases of *V. parahaemolyticus* outbreaks decreased. In contrast, virus, especially foodborne norovirus infection increased in these countries.

Country Specific

Japan

Population: 128 million (2011).

The reporting of investigated foodborne outbreaks has been mandatory for Japan since 1948.

During 2001–11, a total of 16 088 outbreaks of foodborne disease were reported (Table 1). These outbreaks caused a reported 302 683 persons to become ill. Among 15 224 (94.6%) outbreaks for which the etiology was determined, bacterial pathogens cause the largest percentage of outbreaks (66.4%) and the largest percentage of cases (48.6%).

Among bacterial pathogens, *Campylobacter jejuni/coli* accounted for the largest number of outbreaks and *Salmonella* accounted for the largest number of outbreak-related cases. Viral pathogens, predominantly norovirus, caused 23.1% of outbreaks and 48.9% of cases; the proportion of outbreaks attributed to viral agents increased from 14.7% in 2001 to 35% in 2006, and kept over 30% since then. Natural toxins caused 9.3% of outbreaks and 2.6% of cases.

During the period 2001–11, there was a continuation in the decline of the total number of *Salmonella* outbreaks from 465 outbreaks in 2002 to 67 outbreaks in 2011. Also, the total number of outbreaks caused by *V. parahaemolyticus* decreased to 9 outbreaks in 2011 after an increase to 205 in 2004. The total number of outbreaks caused by *Campylobacter* increased from 428 outbreaks in 2002 to 645 outbreaks in 2005, then afterward decreased to 337 outbreaks in 2011. The total number of outbreaks caused by norovirus increased from 268 outbreaks in 2002 to 499 outbreaks in 2006, then afterward decreased to 297 outbreaks in 2011.

The average number of foodborne outbreaks were 1462.8 per year, (95% confidence interval (CI) 1267.9–1657.8) and the number of affected patients were 27 515 per year (95% CI 23 990.5–31 040.4). The number of outbreaks in 2001 and 2002 (1928 and 1850, respectively) were significantly higher than the average, due to higher numbers of both *Salmonella* and *V. parahaemolyticus* outbreaks. The number of affected patients in 2006 and 2007 (39 026 and 33 477, respectively) were significantly higher than the average, due to higher number of norovirus patients.

In a study using the active surveillance method in Miyagi Prefecture from April 2005 to March 2006, the estimated incidence of foodborne infections per 100 000 per year in that region was 237 cases for *Campylobacter*, 32 cases for *Salmonella*, and 15 cases for *V. parahaemolyticus*, whereas the reported number of cases caused by these three pathogens in the foodborne outbreak-reporting system in Miyagi were 6.06, 0.51, and 1.36 per year per 100 000 population. The authors emphasized the need for a complementary system, such as a laboratory-based active surveillance in Japan, to the present passive surveillance of foodborne illnesses in Japan to identify and prioritize food safety issues more precisely, to validate the results of relevant microbiological risk assessments, and to monitor the effectiveness of risk management options.

The two most frequently isolated *Salmonella* serotypes during 2008–11 were, in order, *Salmonella* Enteritidis and *Salmonella* Infantis (Table 2). This finding is consistent with *S.* Enteritidis being the most frequently isolated serotype in much of Asia.

Regarding enterohemorrhagic *Escherichia coli* (EHEC) serotypes, nearly all the EHEC foodborne outbreaks were associated with O157, followed by O26 since 2000 (Table 3).

The most common single foodstuff category reported as food vehicle in 2011 was fish and shellfish, responsible for 137 (10.9%) outbreaks. Meat and meat products were the next most common category (6.1%), followed by combined food (5.8%), and fruits and vegetables and their products (3.9%).

Regarding a source attribution of *Salmonella* foodborne diseases, based on the outbreak investigation results, 45–60% of the *Salmonella* foodborne outbreak incidences were considered to be associated with eggs between 1998 and 2002, however, the percentage dropped to 24.2% in 2003. The number of *Salmonella* foodborne outbreak incidences associated with beef, pork and poultry meat, and raw vegetables, which have been frequently reported in other countries, were very limited.

In 2011, eating out at restaurants was the most important setting reported for foodborne outbreaks (51%), followed by households (7%) and Japanese-style inns (4.5%).

Regarding foodborne trematode infection, 150 000 infections of *Metagonimus yokogawai* and 50–100 infections of *Paragonimus* spp. were presented at the WHO/FAO Workshop in Hanoi in 2002.

Korea

Population: 50 004 441 (2012).

In Korea, foodborne disease must be reported to the local public health center.

During 2002–11, a total of 2357 outbreaks of foodborne disease were reported (Table 4). These outbreaks caused a reported 75 275 persons to become ill. Among 1436 (60.9%) outbreaks for which the etiology was determined, bacterial pathogens cause the largest percentage of outbreaks (71.6%) and the largest percentage of cases (72.6%). The total number of outbreaks decreased to 249 in 2011 after an increase to 510 in 2007 from 77 in 2002. The total number of patients decreased to 7105 in 2011 after an increase to 10 833 in 2006 from 2939 in 2002.

In 2011, enteropathogenic *E. coli* (EPEC) caused the most poisoning incidents, and the rest were like the following – Norovirus > *Salmonella* > *Campylobacter* > *Staphylococcus aureus* > *V. parahaemolyticus*.

Viral pathogens, predominantly norovirus, caused 24.9% of outbreaks and 26.0% of cases; the proportion of outbreaks attributed to viral agents increased from 2% in 2001 to 37.7% in 2008, and kept over 20% since then. Among bacterial pathogens, EPEC accounted for the largest number of outbreaks and outbreak-related cases. Natural toxins caused 2.1% of outbreaks and 0.5% of cases.

According to the 2010 trend of food poisoning outbreak by month and location, 51% of outbreaks and 55% of patient occurred in the summer (June to September). 49.6% out of whole food poisoning incidents occurred in restaurants when sorted by locations, and 58.5% out of whole patients were found in group catering services (2011 KFDA Report).

Regarding facilities that caused EPEC outbreaks, schools (1220 patients, 63% of all the EPEC patients) were the most important setting, followed by restaurants (333 patients, 17%), and business (250 cases, 13%). Norovirus outbreaks occurred more frequently at schools (66% of the norovirus patients) and *Salmonella* outbreaks occurred more frequently at restaurants (66% of the *Salmonella* patients).

The most frequently isolated *Salmonella* serotypes during 2006–09 was *S.* Enteritidis, followed by Typhi and Typhimurium (37 isolates each) and Infantis and Typhi (in 2007), and Typhimurium and Typhi (2008 and 2009) (Table 5). This finding is consistent with *S.* Enteritidis being the most frequently isolated serotype in much of Asia.

In addition, the Korea Center for Disease Control and Prevention published cases of notifiable diseases. Among the data, Table 6 indicated cases of which a certain percentage was considered as foodborne. Cholera cases decreased to 3 in 2011 after an increase to 16 in 2006 from 10 in 2004. Typhoid fever cases also decreased to 167 in 2011 after an increase to 233 in 2007 from 174 in 2004. Paratyphoid fever cases and *Vibrio vulnificus* cases were reported as approximately 50 during this period. *Shigella* cases decreased to 117 in 2011 from 280 in 2004. EHEC cases decreased to 37 in 2006, then increased to 71 in 2011. Brucellosis cases decreased to 22 in 2011 after an increase to 215 in 2006 from 47 in 2004.

Parasite

Clonorchiasis is still highly prevalent among inhabitants in the riverside areas of southern Korea. A study in villages along the four major rivers, Nakdong-gang, Seomjin-gang, Youngsan-gang, and Guem-gang in southern Korea, from January to December 2006, with a total of 24 075 stool samples found 2661 infected people (11.1%) for *Clonorchis sinensis*, 431 (1.8%) for heterophyids, 226 (0.9%) for *Entamoeba* spp., 57 (0.2%), for *Giardia lamblia*, 30 (0.1%) for *Trichuris trichiura*, and 18 (0.07%) for echinostomes.

In all, 700 000 infections of *Clonorchis sinensis*, 300 000 infections of *M. yokogawai*, 1000 infections of *Paragonimus* spp., and 257 infections of other species of intestinal foodborne trematode infection were presented at the WHO/FAO Workshop in Hanoi in 2002.

China

Population: 1 307 593 000 (2010).

Bacteria

In China, the number of outbreaks of foodborne disease and the number of patients affected has increased in the past decades. During 1994–2005, 12 687 outbreaks of foodborne diseases were reported, resulting in 280 380 persons becoming ill and 2297 persons dying. Among events for which the etiology was determined, microbial pathogens were responsible for 4515 events (28.25%), resulting in 146 852 persons becoming ill (42.75%) and 349 dying.

Wang *et al*. identified 1082 foodborne outbreaks, with 57 612 illnesses and 51 deaths through literature review in China during 1994 and 2005. Among the 1082 outbreaks for which the etiology was determined, *V. parahaemolyticus* caused the greatest number of outbreaks (19.50%), followed by *Salmonella* (16.73%), *Bacillus cereus* (13.40%), *Proteus* (11.46%), and *S. aureus* (7.76%). Of the 57 612 cases, *Salmonella* was the most important agent, accounting for 22.16% of illness, followed by *Proteus* (11.56%), a mixture of bacteria (11.2%) and *B. cereus* (9.97%). *Clostridium botulinum* caused the most death (62.75%) and the highest mortality rate (32 deaths in 254 cases).

Among the 181 *Salmonella* foodborne outbreaks, *S.* Enteritidis accounted for the majority (28.73%), followed by Typhimurium (14.36%), Dublin (5.5%), and Blegdam (4.4%). Of the 72 events of *E. coli* foodborne outbreaks, EPEC was the most common classes (70.83%) and other classes of *E. coli* only occupied a small portion. There was no data about EHEC-related infections.

Of the 1082 bacterial foodborne disease events, 31.05% (336 events) occurred in food services units and 26.25% (283 events) took place at home. *Vibrio parahaemolyticus* and *E. coli* outbreaks occurred more commonly in food services (55.45% and 47.22%, respectively). *Salmonella* and *Clostridium botulinum* outbreaks occurred more commonly at home (50.83% and 86.67%, respectively). *Bacillus cereus* and *Shigella* outbreaks occurred more frequently at school (35.86% and 58.33%, respectively).

Cui *et al*. reported the incidence of hepatitis A. In China, hepatitis cases have been reported as part of the National Notifiable Disease Reporting System since 1959, and have been reported separately by serotypes since 1990. The incidence of hepatitis A has declined by 90% since 1991, from 55.7 per 10 000 population in 1991 to 5.9 in 2007.

Li *et al*. reported the proportion of hemorrhagic colitis caused by *E. coli* O157:H7 as 0.97–5.89% in Xuzhou in Jiangsu in June, 2007.

According to the WHO Global Foodborne Infections Network country databank, Typhimurium (26.2%) is the most common *Salmonella* serotype isolated from humans in 2006, followed by Enteritidis (17%), Senftenberg (9.5%), and Derby (9%).

Ran *et al*. conducted a multiprovince (Shanghai, Beijing, and Guangxi) laboratory confirmed nontyphoidal *Salmonella* infections survey in China and found that the *Salmonella* isolation rate was low (of the 39 172 patients with diarrhea evaluated, 662 (2.7%) grew nontyphoidal *Salmonella*).

Cholera incidence rate decreased and stayed at the rate of 0.01 cases per 100 000 population since 2006 after an increase to 0.07 per 100 000 population in 2005. The incidence rate of dysentery decreased to 18.9 per 100 000 in 2010 from 63.04 per 100 000 population in 2000. The death rate also decreased to 0.003 per 100 000 population in 2010 from 0.04 per 100 000 population in 2000. The incidence rate of typhoid and paratyphoid fever was reported only in 2009 at 1.28 per 100 000 population. The incidence rate of Brucellosis increased to 2.7 per 100 000 in 2009 from 0.41 per 100 000 in 2002 (Table 7).

Parasite

The foodborne parasitic zoonoses (FBPZ) causes death and serious diseases in mainland China, where approximately 150 million people are suffering from FBPZ problem.

Clonorchiasis caused by the oriental liver fluke *Clonorchis sinensis* is one of the major parasite zoonosis and 12.5–15 million people are estimated to be infected in China, and the southern province Guangdong has the largest number of infected people (nearly 5.5 million).The increased prevalence of clonorchiasis in humans could be related to factors such as unhygienic practice, poor knowledge, inappropriate farming/fish practices, and eating raw fish.

Approximately 400 angiostrongyliasis cases have been reported in China since 1984, and those predominantly between 1979 and 2008. Humans become infected by ingesting freshwater and terrestrial snails and slugs.

Human paragonimiasis is caused by the consumption of raw or undercooked stream crabs that are infected with *Paragonimus westermani* or drinking water contaminated by metacercaria. This disease is prevalent in 24 provinces and less than 1 million infections were estimated countrywide. People in Shanghai and Chongqing have the highest prevalence, at 5.1% and 4.1%, respectively.

Echinococcosis, including cystic echinococcosis caused by the cestode *Echinococcus granulosus* and alveolar echinococcosis caused by *Echinococcus multilocularis*, is one of the most serious parasitic zoonoses in China. It was estimated that 380 000 people were infected with echinococcosis and 50 million people were at risk of infection.

Human trichinellosis is caused by *Trichinella spiralis* and *Trichinella nativa*, and the infection occurs through the consumption of raw or undercooked meat. Twenty million people were estimated to be infected in China. Yunnan and Inner Mongolia have a serious high mean prevalence of 8.3% and 6.3%, respectively.

Human cysticercosis caused by the larval stage of *Taenia solium* occurred and approximately 7 million people were infected in China.

Human infection with *Toxoplasma gondii* has been reported nationwide with a mean infection rate of 7.9%, approximately 100 million people were estimated as being infected.

Human cases of cryptosporidiosis have been recorded in 14 provinces, with young children being more susceptible to infection than adults (infection rate = 2.1% in children). For example, *Cryptosporidium* oocysts were found in 57 of 548 children with diarrhea (10.4%) in the Zhejiang province.

Human infection with *G. lamblia* has been documented all around China, and was estimated to be approximately 30 million infections.

China, Hong Kong Special Administrative Region

Population: 7 053 000 (2010).

Food poisoning is one of the statutory notifiable diseases in Hong Kong. A total of 6955 food poisoning outbreaks were notified from 2001 to 2011. The number of food poisoning outbreaks increased steadily from 2003 to 2006 and then decreased afterward.

Among the outbreaks, 78.3% were caused by bacteria, followed by viruses (10.1%), mostly norovirus and natural toxins (7.6%). Ciguatera poisoning, a locally notifiable disease, is commonly reported in Hong Kong, and there was an average of 26 ciguatera incidents affecting more than 10 persons annually. In 2004, only 65 incidents (7.9%) affecting 247 patients (7.8%) were attributed to ciguatera poisoning (Table 8).

Taiwan

Population: 22 805 547 (2006).

In Taiwan, data from incidences of foodborne disease outbreaks have been collected by the Department of Health (DoH) since 1981, and detailed epidemiological data were systemically collected only after 1986. The DoH established Taiwan's Food and Drug Administration in January 2010.

During 1986–95, 852 outbreaks of foodborne illness, including 26 173 cases, were reported in Taiwan, of which 555 (65%) were caused by bacterial infection. Bacterial pathogens, particularly *V. parahaemolyticus* (35.5%), *S. aureus* (30.5%), *B. cereus* (18.7%), *E. coli* (6.5%), and *Salmonella* spp. (5.6%) were the main etiologic agents.

In 1994, 102 outbreaks of foodborne disease involving 4726 cases were reported to the Taiwan DoH. Of these outbreaks, 72.5% (74/102) were caused by bacterial pathogens, with *V. parahaemolyticus* responsible for 56.7% (42/74), *S. aureus* 20.3% (15/74), *B. cereus* 14.9% (11/74) and *Salmonella* spp. other than *Salmonella* Typhi and *Salmonella* Paratyphi 8.1% (6/74).

In Taiwan, the average prevalence of reported foodborne illness from 1995 to 2001 was 6.86 per 100 000 population. During this period, 1171 outbreaks of foodborne illness, including 109 884 cases, were reported in northern Taiwan, of which 735 (62.8%) were caused by bacterial infection. Bacterial pathogens, particularly *V. parahaemolyticus* (86.0%), *S. aureus* (7.6%), and *Salmonella* spp. (4.9%) were the main etiologic agents. *Vibrio parahaemolyticus* has been a leading cause of problems in Taiwan for many years.

During 2002–11, 3088 outbreaks of foodborne illness, including 46 259 cases, were reported in Taiwan, of which 1167 (97%) out of 1203 etiology-identified outbreaks were caused by bacterial infection. Bacterial pathogens, particularly *V. parahaemolyticus* (48.7%), *S. aureus* (6.3%), *B. cerius* (4.9%), and *Salmonella* spp. (4%) were the main etiologic agents. *Vibrio parahaemolyticus* has been a leading cause of problems in Taiwan for this decade, however, both the number of outbreaks and patients decreased to 52 outbreaks with 596 cases in 2011 from 86 outbreaks with 2014 cases in 2002.

Cases of *B. cereus* outbreaks were the largest in 2010 and 2011. Interestingly no *Campylobacter* outbreaks were recorded during this period; however, Wang *et al*. reviewed 104 *Campylobacter enteritis* infection at National Taiwan University hospital in Taipei from January 2000 to December 2006, and found *C. coli* and *C. jejuni* from 24% and 80% of the patients, respectively.

Among food poisoning of which incriminated food was identified in 2009, fresh vegetables and fruits and their products was the most important food (48 out of 53 (90.6%) incriminated food identified known outbreaks and 1172 cases out of 1276 (91.8%) cases from those outbreaks), followed by mixing prepared foods (29 outbreaks with 525 cases).

In 2010, mixing prepared foods was the most important food (39 out of 83 (47.0%) incriminated food identified outbreaks and 2026 cases out of 3480 (58.2%) cases from those outbreaks), followed by meal box (17 outbreaks with 1118 cases) (Table 9).

Among the notifiable diseases, the following number of cases were reported in 2009 and 2010, respectively: typhoid fever 80, 33; paratyphoid fever 6, 12; acute hepatitis A 234, 110; EHEC infection 0, 0; cholera 3, 5; botulism 1, 11; and toxoplasmosis 7, 5.

[a]Diseases infected outside of Guam.

Taiwan Centers for Disease Control in 2002 began routine subtyping and building a deoxyribonucleic acid (DNA) fingerprint database of bacterial pathogens. After a 4 year practice, PulseNet Taiwan, the National Molecular Subtyping Network for Infectious Disease Surveillance, was formally inaugurated by the DoH, Taiwan.

According to the PulseNet Taiwan, till date, 10 238 *Salmonella* spp., 2048 *Shigella* spp., 89 *V. parahaemolyticus* isolates were included in the DNA fingerprint database. Salmonellosis is estimated to be the most prevalent foodborne disease. More than 2000 *Salmonella* isolates were collected each year from the collaborative hospitals for the determination of serotypes, PFGE fingerprints and traits of antimicrobial susceptibility. *Vibrio parahaemolyticus* is the leading causal agent for foodborne disease outbreaks in Taiwan, however, because most of the outbreaks of *V. parahaemolyticus* infections are easily identified, routine PFGE analysis is not applied to this organism.

In Taiwan, EHEC is a notifiable disease. Taiwan has no indigenous case of *E. coli* O157:H7 infection; only an imported case was identified in 2001. *Vibrio cholerae* infection was rare for the past 40 years. Listeriosis is not in the list of notifiable diseases in Taiwan. Although the incidence rate is unknown, *Listeria monocytogenes* is infrequently identified from patients in Taiwan.

Guam

Total population (mid-year): 168 564 (2005).

According to the annual notifiable disease report from 1996 to 2009, *Salmonella* was the leading agent of potential foodborne infections, followed by *Shigella* and *Campylobacter* (520, 484, and 231 cases, respectively in 14 years). Diseases caused by these pathogens were reported constantly during this period. Cases caused by *V. parahaemolyticus* decreased from 22 cases in 1998 to 1 case in 2007. Even though cases are limited, fish poisoning caused by ciguatera and scombroid are also constantly reported (Table 10).

Marshall Islands

Population: 54 000 (2010).

No systematic surveillance data is available. On 25 March 2009, the largest outbreak in the tiny island of Ebye in the Republic of the Marshall Islands was reported in 174 cases among 187 attendees at a local funeral. Even though the etiology of this outbreak could not be conclusively determined as no causal organism or toxin was identified, however, from clinical epidemiological investigations, the most likely agent of this outbreak could be either enterotoxins of *S. aureus* or *B. cereus*.

Fiji

Population: 861 000 (2010).

To enhance public health capacity in Fiji for foodborne disease surveillance, *Salmonella* Surveillance Project was developed. In 2004–05, 86 non-Typhi *Salmonella* and 275 *S.* Typhi laboratory-confirmed infections were reported. *Salmonella enterica* serotype I 3,10:r:– and *S. enterica* serotype Weltevreden were the most commonly isolated non-Typhi serotype.

See also: Bacteria: *Brucella*; *Campylobacter*; *Clostridium botulinum*; *Clostridium perfringens*; *Listeria monocytogenes*; *Plesiomonas shigelloides*; *Salmonella* Non-Typhi; *Salmonella* Typhi and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli* and Other Pathogenic *Escherichia coli*; *Shigella*; *Staphylococcus aureus*; *Vibrio cholerae*; *Vibrio parahaemolyticus*; *Vibrio vulnificus*.

Foodborne Diseases: Foodborne Diseases in Travelers; Overview of Biological Hazards and Foodborne Diseases; Overview of Chemical, Physical, and Other Significant Hazards; Prevalence of Foodborne Diseases in Australia and New Zealand; Prevalence of Foodborne Diseases in South East and Central Asia. **Helminth-Trematode:** *Echinostoma*. **Natural Toxicants:** Tetrodotoxin. **Public Health Measures:** Challenges of Developing Countries in Management of Food Safety. **Viruses:** Hepatitis A Virus; Norovirus

Glossary

Adaptive immunity (or specific immunity) Is composed of highly specialized systemic cells and processes that eliminate or prevent pathogenic growth. It is acquired during life. The immunity is produced by exposure to antigens, by infection or vaccination (active immunity), or by the transfer of antibody or lymphocytes from an immune donor (passive immunity). Responses are designed to maximally eliminate specific pathogens or pathogen-infected cells. It generates an immunological memory and subsequent responses to a previously encountered antigen are more effective and more rapid than those generated by innate immunity.

Immune memory Greatly speeds up the response to pathogens that have been previously encountered (primary response); if the body is reinfected with a previously encountered pathogen, an adapted cell subpopulation will provide a very specific, efficient, and rapid secondary response.

Immune tolerance Is the process by which the immune system does not attack an antigen. Immune tolerance in pregnancy is the absence of a maternal immune response against the fetus and placenta.

Immunosuppression (or immunodepression) Lowers the body's normal immune response to invasion by foreign substances; may result from certain diseases, such as acquired immune deficiency syndrome or lymphoma. Immunosuppression may also be deliberately induced with drugs (e.g., to prevent the rejection of an organ transplantation) or incidental (e.g., as a side effect of radiotherapy or chemotherapy for cancer).

Innate immunity (or nonspecific immunity) Is the first line of defense. It comprises the cells and mechanisms that defend the host from infection by other organisms in a nonspecific manner. It does not confer long-lasting or protective immunity to the host.

Introduction

The development and outcome of foodborne diseases result from a close interrelationship between the virulence of the pathogen, the number of organisms the person is exposed to at a given time, the quality of the host's anatomical and functional barriers, and the immune competency of the person. The latter, in turn, is affected by age, pregnancy, genetic factors, certain diseases (human immunodeficiency virus (HIV) infection and cancer), use of certain medications, and nutritional status.

Most infectious foodborne illnesses are characterized by acute symptoms that are limited to the gastrointestinal tract, including vomiting and diarrhea. These illnesses are generally limited in both duration and severity, and most patients without underlying illnesses or malnutrition recover without medical treatment or require only modest supportive care. However, some individuals are at increased risk of higher incidence, developing more severe outcomes and higher mortality rates; they are classically defined as the very young, the elderly, pregnant women, and the immunocompromised, often referred to as 'YOPI' (young, old, pregnant women, and immunocompromised). Through local and systemic responses, the immune system is a key element in modifying the establishment of infection, controlling disease once it is established, limiting the severity and dissemination of the disease, and assisting in the control of the pathogen. In addition to the physiological impairment of the immune system, there is a great diversity of diseases and therapeutics generating long-term or permanent immunosuppression making people more vulnerable to foodborne disease: primary immunodeficiencies, immunosuppressive therapy following organ transplantation or for treatment of other diseases, HIV infection, cancer, defects of iron metabolism, and cirrhosis or other liver diseases. Immunocompromised people vary in their degree of immunosuppression and susceptibility to foodborne infection and this is clearly demonstrated by the dose–response model used for the risk assessment on *Listeria monocytogenes* in ready-to-eat foods developed by the World Health Organization (WHO)/Food and Agriculture Organization of the United Nations.

To the author's knowledge, no attempt has been undertaken to estimate the global burden of foodborne diseases in vulnerable populations, because of a number of difficulties, which include:

1. Insufficient data from surveillance in countries where such programs exist: In addition to underreporting, information

on underlying health conditions of patients is rarely collected.
2. Estimation for each pathogen of the percentage of illness attributable to foodborne transmission: These percentages have been evaluated in a small number of countries on the basis of various data such as, outbreak investigation, consumption patterns, specific surveys. Using these estimates for countries with different levels of sanitation and hygiene and different consumption patterns would be questionable.
3. A substantial number of foodborne diseases is caused by unspecified agents. (This paper focuses on pathogens; some chemicals are also of particular concern for the vulnerable groups of the population, such as methylmercury, lead, marine biotoxins, etc.) These include known agents with insufficient data to estimate agent-specific illness, known agents not yet recognized as causing foodborne illness and agents known to be in food but of unproven pathogenicity, and very few data are presently available in this field.

However, an abundant international scientific and medical literature, including case reports, surveys, and reviews, has been published on foodborne diseases in these sensitive populations which provides insight on this growing public health problem affecting both developed and underdeveloped countries.

Age-Related Physical or Physiological Susceptibility

Neonates, Infants, and Children

Increased Susceptibility to Foodborne Pathogens: Relative Immaturity of the Immune System and the Vicious Cycle of Malnutrition–Diarrhea

Although partially protected by maternal antibodies during the first months of life (depending on the mother's immunity), neonates and infants are potentially sensitive to a range of pathogens because their immune system is not fully developed. Developmental immaturity, insufficient proliferative responses and dysregulation of cytokine networks (immature cells are unable to make cytokines critical to mounting effective immune responses and of generating a population of memory cells), and reduced antibactericidal properties are major contributing factors. Neonatal innate immunity is also associated with reduced production of immunoglobulin, mucus, and acid, and deficient gut motility necessary for appropriate local responses to pathogens.

In this context, breast-feeding deserves special attention. Breast milk contains large quantities of secretory immunoglobulin A (IgA), lysozyme secreting macrophages, both T and B lymphocytes that release interferon-γ (IFN-γ), migration inhibition factors, and monocyte chemotactic factors, and impacts the initial bacterial colonization of the newborn gut, thus strengthening the various immune responses; in addition, breast milk supplies the ideal mix, density, and physiological form of nutrients to promote adequate infant growth and development. Unlike bottle-feeding, breast-feeding protects from diarrhea by its antibacterial and antiviral properties and, when exclusive, by avoiding exposure to foodborne pathogens. Because antiretroviral (ARV) interventions to either the HIV-infected mother or HIV-exposed infant can significantly reduce the risk of transmission of HIV through breastfeeding, WHO recommends that national au-thorities in each country decide which infant-feeding practice, i.e. breastfeeding with an ARV intervention to reduce transmission or avoidance of all breastfeeding, will be primarily promoted and supported by maternal and child health services. As soon as breast-feeding is no longer adequate as the sole source of food – between 4 and 6 months of age according to the nutritional status of the mother – breast milk needs to be supplemented, and later on (>2 years) substituted by appropriate foods until the child is gradually introduced to family food. Two major risk factors for foodborne diseases may occur at this stage: ingestion of weaning foods contaminated with pathogens and undernutrition.

Acquired immunity develops with exposure to various antigens, building a defense that is antigen specific. Unlike innate immune responses, the adaptive responses are highly specific to the particular pathogen that induces them and provide long-lasting protection. For the child's immune system to develop normally, exposure to foreign antigens is necessary. Acquired immunity takes time to develop after initial exposure to a new antigen. As children age and encounter more and more pathogens, the immune system becomes more responsive against these microorganisms and can better protect against them because an immune memory is formed. The peak isolation rate of diarrhea in infants and children is partly attributed to the increased susceptibility on the first exposure and partly because medical care is quickly sought for infants and incidents are more often reported.

Evaluating children's susceptibility to foodborne diseases involves raising the issue of malnutrition because children have less nutritional reserve than adults, making them particularly at risk for undernutrition and consequently, to diarrhea. In resource-poor countries, malnutrition appears early as a major problem. A small rise in the prevalence of malnutrition between 3 and 6 months indicates early introduction of milk substitutes, a further rise in the malnutrition rate between 6 and 12 months corresponds to late introduction or inadequate amount of complementary feeds, and further increase between 12 and 23 months is likely to be due to low energy intake, because children are not fed enough with household food. Moderately malnourished children have a 30–70% greater rate of diarrhea, 2- to 3-fold increase in the duration of their episodes than better nourished children in the same settings and the risk of death increases gradually with the deterioration of the nutritional status. A vicious cycle between diarrhea and malnutrition appears quickly. Malnutrition leads to weight loss, lowered immunity, higher susceptibility to pathogens, and impaired growth and development in children; this is further aggravated by diarrhea, malabsorption, loss of appetite, and diversion of nutrients for the immune response; as a consequence, this situation generates reduced dietary intake. In addition, fever increases both energy and micronutrient requirements. Protein energy malnutrition impairs cell-mediated immunity (significant decrease in functional T lymphocytes and an increase in null cells), phagocytic function, and the complement system. It also diminishes Ig concentrations and cytokine production. Micronutrient deficiencies (vitamin A which maintains the

integrity of the epithelium in the gastrointestinal tract, zinc and copper) also adversely affect the immune response. Infection induces protein catabolism and negative nitrogen balance, depletion of carbohydrate stores and increased gluconeogenesis, affects lipid metabolism, and redistributes minerals between nutrient compartments. These factors further increase the vicious cycle between malnutrition and infection. Diarrhea is a major cause of complication in children with severe acute malnutrition and increases their odds of death substantially irrespective of other factors. For example, a review of the medical files of children with severe malnutrition admitted at New Halfa Hospital, Sudan, indicated that among the 1097 children admitted during 2007–09, 73% were children <2 years and 71% had diarrhea; of the 61 children who died, 18% had septicemia following diarrhea and respiratory tract infections. Currently, malnutrition is responsible for more than one-half of all deaths of children worldwide, primarily deaths caused by infectious diseases.

Impact of Increased Susceptibility to Foodborne Pathogens on Health

Despite the efforts of the international community, diarrheal diseases still pose a major threat to children. For example, a study of 79 067 deaths of children <5 years from 25 countries in sub-Saharan Africa and Southeast Asia in 1998 to estimate causes of death in high child-mortality countries demonstrated that diarrhea ranked second (after pneumonia) with 25% of cases. The estimated incidence rates in developing countries ranged from 3.5 to 7.0 cases per child per year during the first 2 years of life, and from 2 to 5 cases per child per year for the first 5 years.

In a number of countries in Asia and Africa, weaning foods prepared under unhygienic conditions are frequently heavily contaminated with pathogens and the incidence of diarrheal diseases starts increasing soon after weaning is initiated. Gastroenteritis is usually expressed as a mild diarrhea, but it can be seen as a severe clinical form with enhanced symptoms (nausea and vomiting), possibly leading to dehydration and death in children. Major bacterial pathogens include *Escherichia coli*, *Salmonella*, *Campylobacter*, and *Shigella*. Two pathogens deserve special mention regarding neonates and infants in spite of low disease incidence: *Cronobacter* spp. and *Clostridium botulinum*. Although *Cronobacter* spp. causes invasive infections in all age groups, neonates and infants <2 months are likely to experience higher disease rates, with those born prematurely or with low birth weight being at higher risk for severe infection (necrotizing enterocolitis, bacteremia, and meningitis), with high case-fatality rates (50–80%). In England, over the period 1997–2003, the annual incidence rate for neonates, infants aged 1–11 months, children 1–4 years, and children 5–9 years were respectively 17, 2, 0.7, and 0.2 cases per million population. Outbreaks have been detected most commonly among newborns and very young infants in hospital nurseries and neonatal intensive care units. Contaminated powdered infant formula has been epidemiologically linked with infections. Unlike most adults, infants are susceptible to infection by spores of *C. botulinum*, which, after ingestion, can germinate and then colonize the infant colon producing botulinum neurotoxin in the digestive tract, which then induces a rare but life-threatening disease. In healthy adults, the intestinal microflora prevents growth from ingested *C. botulinum* spores, but in infants the microflora is unable to stem growth. Honey is a well-recognized vehicle.

Diarrheagenic *E. coli*, and more especially enteropathogenic *E. coli* and enterotoxigenic *E. coli* (ETEC), are a leading cause of infantile bacterial diarrhea in developing countries: ETEC causes approximately 210 million cases and 380 000 deaths, each year mostly in children. The diverse range of *E. coli* pathotypes and antigens means that children may be subject to repeated infections by different subtypes without immune protection. A special pathovar of *E. coli*, enterohemorrhagic *E. coli* (EHEC) can result in hemorrhagic colitis with a small percentage of cases developing hemolytic uremic syndrome (HUS), a life-threatening complication characterized by hemolytic anemia, thrombocytopenia, and renal insufficiency. Young children are at the highest risk of developing HUS: In the USA, in 2000–06, the median age of patients who developed HUS was 4 years. Compared with persons who did not develop HUS, those with HUS were younger, more likely to be hospitalized, had a longer length of hospital stay, and were more likely to die. Death occurs in approximately 12% of patients with diarrhea-associated HUS, and 25% of survivors demonstrate long-term renal sequelae.

Besides diarrhea, several nonTyphi serotypes of *Salmonella* Enterica (NTS) are an important cause of childhood bacteremia. Although infection of healthy adults usually results in self-limiting gastroenteritis of short duration that does not require antibiotic therapy, the very young are at increased risk, with higher incidence of disease, of complications, and of death. Invasive NTS has emerged as a leading cause of bloodstream infection in children, with an associated case fatality of 20–25%, especially in Africa. The clinical presentation of invasive NTS disease is often close to that of *Salmonella typhi*. In former Zaire, for example, the case-fatality rate for NTS and *Salmonella* Typhi infections were 22.7% and 29.4%, respectively; infants under 6 months had a higher case-fatality rate than older children (relative risk = 1.7) and death occurred significantly more often when children fell ill with *Salmonella* bacteremia in the late rainy season, coinciding with the peak of malnutrition, than in the dry season. In comparison to NTS, *S. typhi* is a highly adapted, invasive, and human-restricted pathogen that in the nineteenth century caused considerable illness and death in the USA and Europe but now has the greatest impact in developing countries where school-age children, especially those from resource-poor settings with inadequate water and sanitation systems, are disproportionately affected. It is estimated that a total of 400 000 cases occur annually in Africa, with a significant morbidity between 1 and 5 years of age. Additionally, the emergence and spread of *S.* Typhi strains having multiple resistance to nearly all commonly available antibiotics in most developing countries is another major challenge to health care systems by reducing the effective treatment options, increasing treatment costs, and increasing the risk of complications and death.

Campylobacter (*Campylobacter jejuni* and *Campylobacter coli*) is one of the most common causes of bacterial acute gastroenteritis worldwide and an important cause of childhood morbidity. In developed countries, the disease is found mainly in children <5 years and in young adults; in the USA in 1996–2000, the highest incidence was observed among

infants <1 year (56 cases per 100 000 population), followed by 41 cases per 100 000 population among children aged 1–4 years. Bacteremia is detected in less than 1% of patients and is most likely to occur among the very young or very old or in immunocompromised patients. Serious systemic illness caused by *Campylobacter* infection rarely occurs but can lead to sepsis and death.

Shigella is the most important cause of bloody diarrhea worldwide. Review of the English-language literature between 1984 and 2005 indicated a global incidence of shigellosis at 80–165 million cases annually, with 99% of episodes occurring in the developing world; case-fatality rates ranged from 0% to 21% according to studies; *Shigella* was isolated from diarrheal or dysenteric stools with similar frequency in Asia and Africa and with lower frequency in Latin America and the Caribbean. During a prospective population-based study in six Asian countries conducted between 2000 and 2004, over 600 000 persons of all ages residing in Bangladesh, China, Pakistan, Indonesia, Vietnam, and Thailand, *Shigella* was isolated from 2927 (5%) of 56 958 diarrhea episodes. The incidence for children <5 was 13 episodes per 1000 residents per year whereas the overall incidence was 2 per 1000 per year.

Viral gastroenteritis occurs with two epidemiologic patterns, endemic sporadic cases in children and outbreaks that affect people of all ages and are caused by two main agents: rotavirus and norovirus. The illness affects all children worldwide during the first years of life regardless of their level of sanitation, hygiene, quality of water and food, or type of behavior. The incidence of rotavirus diarrhea is high, accounting for approximately 12% of severe gastroenteritis among children <5 years and 80% of recognized viral etiologies. A multicenter study in Europe (Belgium, France, Germany, Italy, Spain, Sweden, and the UK) indicated that 86% of rotavirus diarrhea occurred in children aged between 3 months and 3 years. Cases were more severe than the acute gastroenteritis in general with dehydration, vomiting, fever, and lethargy, resulting in more emergency department consultations and hospitalizations. Rotavirus is one of the main causes of seasonal peaks in pediatric hospitalizations, and contributes significantly to periodic high bed-capacity pressures and associated adverse consequences. In a 2009–10 survey in Burkina-Faso, acute malnutrition was significantly associated with more severe symptoms and a prolonged duration of diarrheal episodes in children. Norovirus is the leading cause of foodborne outbreaks worldwide, especially in closed and crowded environments, such as hospitals, nursing homes, and cruise ships and, as child rotavirus immunization programs are developed, may soon eclipse rotavirus as the most common source of pediatric gastroenteritis: For example, norovirus was the second most common cause of community-acquired acute gastroenteritis in children in Greece in 2008–09, following rotavirus, and the commonest cause in hospitalized children <5 years in Spain in 2006–07. Compared with rotavirus enteritis, norovirus infection is slightly less severe and fever was less frequent. Immunity against norovirus appears to be strain specific, and, given the genetic variability in circulating viruses, individuals are likely to be repeatedly infected during their lifetime.

Hepatitis A and hepatitis E viruses are associated with inadequate water supplies and poor sanitation and hygiene, and spread by close personal contact, with occasional foodborne outbreaks. Hepatitis A is highly endemic in developing nations where infection often occurs in children who are likely to be asymptomatic; only 30% of children <6 years develop symptoms, which usually are nonspecific and flu-like without jaundice. In industrialized countries, the introduction of hepatitis A vaccines led to a sharp decline in the number of reported cases in children and a shift to a higher percentage of cases occurring in older age groups.

Intestinal parasitic infections contribute significantly to the enteric disease burden experienced by children. The two most frequent parasites identified in children diarrhea are *Giardia lamblia and Cryptosporidium (Cryptosporidium hominis* and *Cryptosporidium parvum)*. Although an important percentage of cases may be asymptomatic, cryptosporidiosis in children is most frequently associated with diarrhea, nausea, vomiting, fever, and abdominal discomfort that usually resolves within 2 weeks. Although cryptosporidiosis and giardiasis affect persons in all age groups, the highest incidence is observed for children 1–9 years as illustrated by data from the USA, various countries in Europe, Africa, and Asia. Multiple symptomatic *Cryptosporidium* infections associated with prolonged oocyst shedding occur frequently in countries where the disease is endemic (40% of infected children in a study in India) and may contribute to the long-term effects of cryptosporidiosis on the physical growth of children. Low birth weight, malnutrition, stunting, and lack of breast-feeding have been reported to predispose children to cryptosporidiosis and other various foodborne parasitic diseases as well. Data worldwide, and more especially from Asia and Africa, indicate that *Cyclospora*, *Entamoeba histolytica*, *Microsporidium*, *Blastocystis hominis*, and *Ascaris lumbricoides* are also frequently isolated from feces of children with diarrhea.

Pregnant Women

Because of the changes in hormonal and immunological parameters that take place during pregnancy, pregnant women are especially vulnerable to a number of infections including those caused by foodborne pathogens. More importantly, these foodborne infections may be transmitted to their fetus.

Because the fetus has genetic traits partially maternal and partially paternal and is antigenically different from the mother, the maternal immunological system becomes tolerant of the foreign tissue antigens present in the fetus. To prevent the rejection of such a 'semi-allogenic graft' by the maternal immune system, cell-mediated immunity, which plays a major role in foreign tissue graft rejection, must be downregulated during pregnancy. A number of immunological and hormonal changes (increase in progesterone production) therefore take place in the woman's body for a successful pregnancy. The immunological relationship between the mother and the fetus is a bidirectional communication determined by fetal antigen presentation and by recognition of and reaction to these antigens by the maternal immune system (e.g., cytokines of maternal origin operate on placental development and antigen expression on the placenta determines the maternal cytokine pattern). Placental immune response and its tropism for specific pathogens affect the pregnant woman's susceptibility to

certain pathogens and impact the severity of the disease. Consequently, there is a modulation of the immune system which leads to differential responses depending not only on the microorganisms, but also on the stages of the pregnancy. Pregnant women and their fetuses are especially susceptible to two pathogens: *L. monocytogenes* and *Toxoplasma gondii*. They are intracellular microorganisms and therefore, cell-mediated immunity plays a key role in the control of the disease.

Listeria monocytogenes: Although the infection of the mother may be asymptomatic or characterized by a self-limited, nonspecific flu-like illness of the third trimester, the transplacental transmission may have more serious consequences for the fetus and newborn and may lead to subsequent intrauterine infection causing spontaneous abortion, stillbirth, and severe neonatal septicemia. All kinds of industrially processed ready-to-eat foods which support *L. monocytogenes* growth during extended refrigerated storage are typical food vehicles of listeriosis and this explains why it is mainly reported from industrialized countries. The incidence in France in 2001–08 was 5.6 cases per 100 000 pregnancies, ranking pregnant women among the highest risk groups for listeriosis. In the USA in 2004–09, pregnant women had a markedly higher listeriosis risk (relative risk: 114) than nonpregnant women.

Toxoplasma gondii: When a seronegative pregnant woman is infected by *T. gondii*, the disease is similar to that of any adult infected by the parasite and is not recognized in most cases. However, congenital infection leads to miscarriage, stillbirth, and preterm birth, or to neurological disorders in the infant (mental retardation and visual impairment) although the majority of infected newborns are asymptomatic at birth. The fetus is presumed to be at risk only if the mother has a primary, active infection during pregnancy. Transplacental infection of the fetus is estimated to occur in approximately 45% of infected pregnant women. The birth prevalence of congenital toxoplasmosis throughout the world ranges from less than 1 to 10 per 10 000 live births. A recent review of the literature published during the last decade on toxoplasmosis seroprevalence in women who were pregnant or of childbearing age indicated that foci of high prevalence were present in Latin America, parts of Eastern/Central Europe, the Middle East, parts of Southeast Asia, and Africa. A trend toward lower seroprevalence was noted in many European countries and the USA.

In addition to these particular two pathogens, transplacental infection of the fetus, preterm delivery, or low birth weight were also reported for *S.* Typhi, *C. jejuni*, *Brucella* species (generally *Brucella melitensis*), *Coxiella burnetii* (causing Q fever), and hepatitis A and E viruses. In the case of hepatitis E, although the mortality rate is usually low (0.07–0.6%), the illness may be severe among pregnant women (fulminant hepatic failure), with mortality rates reaching 25% as seen in large outbreaks in China, Southeast and Central Asia, the Middle East, and in Africa.

The Elderly

The elderly constitute a very heterogenous population in terms of physiological functions, health, and lifestyle. All these changes increase susceptibility to a number of foodborne diseases and the elderly people experience more frequently invasive infection, prolonged convalescence, serious sequelae, and higher case-fatality rates. In the USA, the highest morbidity rates were in older adults (>65 years) for all foodborne pathogens except *Shigella*; overall, most deaths (58%) occurred in persons >65 years old. *Listeria* had the highest case-fatality rate (16.9%), followed by *Vibrio* (5.8%), EHEC (0.8%), *Salmonella* (0.5%), *Campylobacter* (0.1%), and *Shigella* (0.1%).

Immune Senescence

With advancing age appear progressive decline and dysfunction of the immune system, in both peripheral and gut-associated immune response. In contrast to the relative immaturity of immune system cells in the neonates, the immune system in the elderly is characterized by a general decrease in cell function, rather than major changes in the number of cells; both qualitative and quantitative changes in the efficiency of humoral and cell-mediated immune responses are observed (such as delayed-type hypersensitivity reactions, T cell-dependent antibody production, response of memory cells, production of interleukin-2, antibody production to new antigens, etc.). Innate immunity is also compromised. Impairment in mucosal immune system contributes significantly to the increased risk of severe illness and mortality. The effect of a weakened immune response often manifests most clearly during periods of important stress (surgery, sepsis, multiple organ failure, malnutrition, dehydration, etc.). In addition to senescence, the alteration of the immune system by treatments that deeply affect its functions such as chemotherapy with cancers and immunosuppressive drugs used with solid organ transplantation is one of the leading causes of death in the elderly.

Physiological Changes in the Gastrointestinal Tract

The gastrointestinal tract changes during aging. Inflammation and shrinkage of the gastric mucosa increase with age, leading to low gastric acidity and a decreased role in limiting the number of microorganisms that enter the small intestine. A reduction of peristalsis delays the clearance of the pathogen from the intestinal tract, giving some pathogens more time to grow and form toxins in the gut, contributing substantially to the increased prevalence and severity of foodborne infections. In addition to these well-known factors, a recent genomic analysis of fecal bacteria showed that significant structural changes occur in the microbiota with aging, especially regarding protective bifidobacteria; reductions in these organisms in the large bowel may be related to greater disease risk.

The presence of underlying conditions also contribute significantly to the morbidity and mortality of foodborne diseases in the elderly. Diabetes exposes people >65 years to a higher risk of foodborne diseases if in insufficient control through persistent hyperglycemia. Prolonged use of antibiotics may stimulate overgrowth of pathogens and the loss of competitive inhibition provided by the natural gut microflora. Many elderly people are malnourished (various degrees of malnutrition and micronutrient deficiencies), which reduces cell-mediated immunity; a number of reasons explain this malnutrition: taking medication, digestive disorders, chronic illnesses, physical disabilities, dental problems, altered senses of smell and taste, early satiety, decrease in pleasure, social isolation, and depression may lead to appetite loss and financial constraints may decrease resources allocated to food.

In addition to health-related underlying conditions, the lifestyles of the elderly may generate additional risk factors for both acquiring and transmitting foodborne diseases. In western countries, retired persons use their increased leisure time to travel which put elderly travelers at a higher risk for diarrheal disease when visiting places where poor hygiene, improper food handling, or storage at inappropriate temperatures may result in increased exposure to food contamination. Conversely, a large proportion of the geriatric population, who require nursing care and related medical or psychosocial services, live in long-term care facilities (LTCFs); characteristics of this environment and its residents facilitate the acquisition and transmission of gastrointestinal infection.

Impact on Health

NTS infection more often presents as a primary bacteremia and is associated with significantly more frequent extraintestinal organ involvement and a high mortality rate (up to 40% in some studies). Among persons with no underlying disease, incidence rates of listeriosis increased with age, from 0.05 cases per 100 000 persons <65 years to 0.98 cases per 100 000 persons >75 years in France in 2001–08; an unexplained increase in the number of listeriosis cases has been observed with the elderly from the UK, EU, and USA for a few years. In the USA in 2000–06, a survey of patients with EHEC infections without HUS showed that, the case-fatality rate was highest among persons aged >60 years; also, among EHEC cases with the HUS symptoms, the case-fatality rate of persons aged >60 years was 33.3%, i.e., 11-fold higher than of the case-fatality rate of children aged <5 years. Thirty percent of deaths of the elderly occur in nursing home residents in the USA. In Australia in 2007, 1010 (54%) of the 1882 reported outbreaks of gastroenteritis occurred in LTCFs. Main bacterial pathogens were *Salmonella*, *Clostridium perfringens* (pseudomembranous colitis), and *Staphylococcus aureus*; the incidence of *Salmonella* infections was higher in LTCF residents than in community residents. In recent years, noroviruses have emerged as a major cause of gastroenteritis outbreaks in LTCFs. Using a modeling approach, 228 deaths associated with norovirus were estimated in England and Wales between 2001 and 2006, which represented 20% of deaths from infectious intestinal disease in patients >65 years. Although food may become contaminated outside the facility, many outbreaks originate from contamination occurring within the facility during food handling, storage, and preparation. In the Western countries where the elderly are a quickly growing segment of the population, deaths related to bacterial gastroenteritis are increasing at a greater rate than in any other age category. This suggests that foodborne diseases will be an expanding burden on the health care system unless better prevention and control measures are implemented.

Diseases and Therapeutics Generating Long-Term or Permanent Immunosuppression

The frequency of community and hospitalized patients with compromised host defenses has increased dramatically over recent decades worldwide. The origin of this trend is multifactorial and includes: (1) the emergence of HIV infection since the early 1980s; (2) the increasing use of solid and hematologic transplantation strategies; (3) patients with cancer treated with chemotherapy; and (4) the use of immunosuppressive medication for conditions such as Crohn's disease, rheumatoid arthritis, and other conditions which can be successfully controlled with iatrogenic immunosuppression. This makes a composite of multiple compromised host defenses including anatomic breeches, cell-mediated, and humoral immunodeficiencies. Because of diminished or absent immune responses, the expected local clinical signs of infection may not be present or detectable; atypical presentations caused by opportunistic pathogens are more prevalent, making the detection and management of infections in such patients more difficult. Despite significant progress in the prevention, diagnosis, and treatment of foodborne infection in the immunocompromised host, it remains an important cause of morbidity, increased length of hospitalization, increased total costs, and mortality.

HIV Infection

HIV infection is the most common immunodeficiency state worldwide. Numerical and functional deficiencies in $CD4^+$ T lymphocytes and deficiencies of other cells of the immune system is followed by an increased susceptibility to opportunistic and common pathogens. The development of malnutrition in HIV/acquired immune deficiency syndrome (AIDS) includes disorders of food intake, nutrient absorption, and intermediary metabolism. Interactions between HIV, immunity, and nutrition are complex and related to each other: HIV causes immune impairment leading to malnutrition which leads to further immune deficiency, then contributing to rapid progression of HIV infection to AIDS. In addition, coinfection with HIV and malaria is very common in sub-Saharan Africa, HIV and malaria being among the leading causes of morbidity and mortality in this region. HIV-associated immunosuppression contributes to more frequent and more severe malaria episodes. Malnutrition, immune system, malaria, and diarrhea are interconnected in a complex negative cascade which expands the burden of diarrheal disease.

HIV-infected subjects have a predilection for chronic diarrhea, which is most pronounced in those with lowest CD4 cell counts. A wide range of etiologic agents are responsible for acute and chronic diarrheal disease, and the prevalence of such agents varies greatly by geographic region, season, patient age, immune status, the use of cotrimoxazole for opportunistic infection prophylaxis and of highly active antiretroviral therapy (HAART), and socioeconomic conditions. Gastroenteritis secondary to *Salmonella*, *Campylobacter*, and a variety of enteric viruses can result in persistent infection, with more severe and prolonged diarrheal disease and an increased risk of bloodstream invasion and metastatic infection. Invasive strains of NTS have emerged as an important cause of bloodstream infection in HIV-infected adults and children, often associated with multiple recurrences, and with high case-fatality rates (20–25% in Africa). The increasing prevalence of antibiotic resistance complicates the management of this disease. Protozoa infections are more common than helminth infections. Cerebral toxoplasmosis was one of the first opportunistic infections to be described in HIV-infected patients. After acute infection, *T. gondii* continues to exist in tissue in

humans; in people with immunodeficiencies such as AIDS, rupture of cysts results in disease reactivation, including encephalitis or disseminated toxoplasmosis. Toxoplasmosis remains one of the main causes of early death among HIV/AIDS patients in some countries. Cryptosporidiosis remains the most common opportunistic enteric protozoal disease in HIV-infected patients. Although the first case of human cryptosporidiosis was reported in 1976, full recognition of cryptosporidiosis as a human disease originated from its association with AIDS patients in the late 1970s. The prevalence of intestinal colonization due to *Cryptosporidium* is significantly higher among HIV-infected persons presenting with diarrhea and low CD4 lymphocyte count <200 cells μl^{-1}. Chronic diarrheal cases were frequently found to have polyparasitic infection. Other parasites frequently identified in HIV/AIDS patients include *Isopsora belli*, *Cyclospora*, *Blastocystosis*, *Entamoeba*. A number of studies (e.g., in Germany, Spain, Italy, and Puerto Rico) demonstrated that HAART has resulted in a reduction of bacterial and parasitic infections by a restoration of the cell-mediated immunity and also by a direct inhibitory effect on the proteases of parasites.

Cancer and Organ Transplantation

Several bacterial and viral foodborne infections pose a threat to cancer patients. Patients are immunocompromised because of their disease or their medical therapy. Similarly, patients with solid organ transplants can become immunosuppressed from a pharmacological regimen used to prevent rejection of a transplanted organ and thus susceptible to foodborne infections. Multiple studies have identified malignancy and organ transplantation as a risk factor for NTS or *Campylobacte*r bacteremia, causing prolonged duration, atypical localization, and higher mortality. In Saudi Arabia, *Cryptosporidium* infection rates of 84% and 74.3% were observed in patients receiving immunosuppressive drugs for organ transplantation and malignancy, respectively. Norovirus infections are increasingly being recognized as important causes of diarrhea in hematopoietic stem cell transplant recipients. A study in France on the incidence rates of listeriosis among people with the same underlying condition during the period 2001–08 indicated they varied widely according to the nature of cancer, ranging from 0.19 cases per 100 000 cases of kidney cancer to 55 cases per100 000 cases of chronic lymphocytic leukemia. Decreasing risk ranking of patients with cancer was the following: chronic lymphocytic leukemia, liver cancer, myeoloproliferative disorder, multiple myeloma, esophageal, stomach, pancreas, lung, and brain cancer. Organ transplantation belonged to the group of underlying conditions with the highest incidence (>5 cases per 100 000). These patients had a >100-fold increased risk of listeriosis compared with persons <65 years with no underlying conditions. The case-fatality rate of listeriosis ranged from 20% to 40%, with the highest for cases with lung and pancreatic cancer.

Other Underlying Conditions

In contrast to this population of patients with acquired immunodeficiencies which is rapidly increasing, patients with hereditary immunodeficiencies, which may affect any part of the immune defenses, including humoral, cell-mediated, and innate immunity, constitute a small but relatively constant proportion of the population for which few foodborne infection cases have been reported. More cases are reported for underlying conditions such as cirrhosis and liver diseases, hemodialysis, and diabetes. Patients with cirrhosis, bacterial peritonitis, bacteremia, and extraintestinal localizations with high in-hospital mortality rates have been associated with *Salmonella*, *Campylobacter*, *Cryptosporidium*, and *Vibrio vulnificus*.

The role of immunosuppressive medication in the increased susceptibility to foodborne disease has been demonstrated in several studies; for example, in a retrospective study in Israel, 80 episodes of NTS bacteremia in children were compared with 55 episodes in adults over a 10-year period; adults were more likely than children to have predisposing diseases and to receive prior immunosuppressive agent medications. In a 13-year retrospective cohort study to describe nonperinatal listeriosis mortality in Los Angeles County (USA) during the period 1992–2004, steroid medication was found to be a statistically significant risk factor for mortality. In addition to treatment of cancer and of organ transplant rejection as illustrated in the previous paragraph, immunosuppressive agents are prescribed in patients suffering from chronic cold hemagglutinin disease, rheumatoid arthritis, the nephrotic syndrome, systemic lupus erythematosus, Crohn's disease, multiple sclerosis, or psoriasis, making these people more vulnerable to foodborne infections.

Acid-suppressing medications, which inhibit secretion of gastric acid, heal the lesions and suppress the symptoms of diseases like peptic ulcer and reflux esophagitis and, as a consequence, interfere with the antibacterial action of gastric secretions. During outbreaks as well as sporadic cases, antacids have been identified as a risk factor for listeriosis, salmonellosis, and campylobacteriosis.

It is well established that chronic psychological factors produce low to moderate degrees of immunosuppression and increase infectious disease incidence. Whether this affects foodborne disease, especially during extreme conditions such as household food insecurity, maternal distress, refugees, or displaced population camps requires further investigations because such situations usually correlate with deficient hygiene and sanitation related to food handling, preparation, and storage.

Prevention of Foodborne Disease in Vulnerable Populations

In addition to 'the five keys to safer food' promoted by WHO, which explains the basic principles that each individual should know all over the world to ensure safe food handling practices and prevent foodborne diseases ('keep clean, separate raw and cooked, cook thoroughly, keep food at safe temperatures, and use safe water and raw materials'), more specific recommendations to vulnerable population according to their health status and/or their potential exposure to foodborne pathogens should be considered to ensure an appropriate level of foodborne disease prevention.

The national food safety/public health agencies of a number of countries have developed recommendations for

such population at increased risk. For example, The US Department of Agriculture's (USDA) Food Safety and Inspection Service and the US Department of Health and Human Services' Food and Drug Administration have prepared 'Guides for People at Risk of Foodborne Illness' to provide practical guidance on how to reduce risk of foodborne illness (http://www.fda.gov/Food/ResourcesForYou/Consumers/SelectedHealthTopics/default.htm). These brochures include:

- Food Safety for People with Cancer
- Food Safety for Transplant Recipients
- Food Safety for People with HIV/AIDS
- Food Safety for Pregnant Women
- Food Safety for Older Adults
- Food Safety for People with Diabetes

and they inform on foodborne pathogens and symptoms of major illnesses, and advice on eating at home or out, on selecting lower risk foods and on safe handling, preparation, storage, and transportation of food. Several organizations – for example, WHO, USDA, the Food Standards Agency of the UK – have issued guidelines to ensure product safety, including information on safe infant formula preparation, storage, and handling (http://www.nal.usda.gov/wicworks/WIC_Learning_Online/support/job_aids/formula.pdf, http://www.food.gov.uk/multimedia/pdfs/formulaguidance.pdf, http://www.who.int/foodsafety/publications/micro/pif2007/en/).

In addition to ensuring the microbiological safety of food for vulnerable groups and providing advice on high-risk foods and food safety, strengthening foodborne disease surveillance is also an essential component to minimize foodborne infections in these populations, especially in hospitals and in aged-care facilities where foodborne outbreaks are becoming a major issue in spite of being preventable.

Conclusion

Many factors can influence the susceptibility to foodborne infection, including increases in diseases that cause immunosuppression, increased use of immunosuppressive agents, and malnutrition. Both the developed and developing countries suffer to various degrees the consequences of foodborne illness.

On a global scale, the leading cause of increased host susceptibility to infection is probably malnutrition. There are 925 million undernourished people in the world today. In the developing world, an estimated 230 million (39%) children <5 years are chronically undernourished and approximately 54% of deaths among children of this age are associated with malnutrition. The prevalence of child malnutrition in the year 2020 is projected to remain high. In sub-Saharan Africa, the number of child deaths is increasing while food insecurity and absolute poverty are expected to increase. Since 1999, the year in which it is thought that the HIV epidemic peaked, the number of new infections has fallen by 19% globally; however, of the estimated 15 million people living with HIV in low- and middle-income countries who presently need treatment, only 5.2 million have access. In spite of growing understanding of cancer cell biology which is gradually leading to better treatments, cancer remains one of the major causes of morbidity and mortality worldwide. As the world's population continues to grow and age, the burden of cancer will inevitably increase; even if current incidence rates remain the same, it is estimated that by 2020, the number of new cases of cancer in the world will increase to more than 15 million (with deaths increasing to 12 million). The predicted sharp increase in new cases will mainly be due to progressively aging populations in both developed and developing countries.

The world's population is aging significantly and rapidly because of age dynamics, declining fertility, and longer life expectancy. From 1950 to 2050, the total global population is projected to grow by 3.5 times; during this period, the number of people >60 years is projected to grow by 10 times and the number of people >80 years is projected to grow by 30 times. The development of shanty towns without sanitation around the megalopolis cities of Asia, Africa, and South America generate overpopulation with poor economic and social conditions. 1.2 billion people are living on less than a dollar a day. Poverty and poor living conditions, including lack of sanitation and infrastructure for wastewater and solid waste management, lack of health education, increase the opportunities for food contamination and resulting disease. Moreover, scientists predict substantial impacts from climate change on the incidence of diarrhea and poor people are most likely to be the first victims and the greatest sufferers of environmental degradation following these changes.

If current trends continue, the number of people vulnerable to foodborne disease will continue to grow globally, making diarrheal diseases an even more important public health problem, especially in the developing world. It is clear that diarrhea is a major obstacle in the realization of Millennium Development Goal no. 4 ('Reduce child mortality'), in spite of being a preventable disease.

Foodborne Diseases in Travelers

R Steffen, University of Zurich, Zurich, Switzerland

Glossary

Dysentery Pragmatically defined as travelers' diarrhea, which invades the intestinal mucosa resulting in systemic disease with fever and blood admixed to the stools.

Enterotoxigenic *E. coli* The most frequent pathogen associated with travelers' diarrhea in any low-income parts of the world.

Hazard analysis and critical control points (HACCP) A preventive system that identifies, evaluates, and controls hazards that are significant for food safety.

High-risk destinations Countries with a two-week incidence rate of travelers' diarrhea exceeding 20%.

Travelers' diarrhea Three or more unformed stools per 24 h with at least one accompanying symptom, such as fecal urgency, abdominal cramps, nausea, vomiting, or fever.

Foodborne diseases are the most frequent health problem among travelers from industrialized countries visiting low-income destinations. Predominantly this is described as travelers' diarrhea (TD), although more serious gastrointestinal infections, such as typhoid fever or cholera, may also occur. Also hepatitis A, hepatitis E, and lastly poliomyelitis are essentially transmitted by the fecal–oral route. Food intoxication has only rarely been described in recent years in this population, but historically incidents have become known, for example, on a jumbo jet.

TD is usually defined as three or more unformed stools per 24 h with at least one accompanying symptom, such as fecal urgency, abdominal cramps, nausea, vomiting, fever, etc. However, milder forms of TD may also result in incapacitation, as the patients cannot predict how the illness will evolve. In this population, dysentery is usually pragmatically defined as TD which invades the intestinal mucosa resulting in systemic disease with fever and blood admixed to the stools.

Epidemiology

Similarly to children in the developing world, travelers face pathogens unprotected, they are nonimmunes. The most recent attack rates on tourists and business people having visited different parts of the world are shown in Figure 1. Also other populations, for example, military, may be affected. Developing countries are high-risk regions with rates of TD of 20 to more than 60% per 2-week stay. In contrast, visitors to low-risk areas experience TD in less than 8%. However, for travel within Europe or North America the rate is not nil. From comparing rates over time it becomes obvious that there has been a dramatic reduction of TD rates in southern Europe. It also appears that Tunisia and Jamaica through systematic efforts of their authorities, mainly the ministries of health and tourism, have been able to reduce the risk of the illness. In contrast, over the past decades hardly any risk reduction has been observed in most of the other destinations when returning travelers were investigated.

Environmental and Behavioral Factors

Seasonality may have a limited relevance: Among British tourists in Monastir, Tunisia, the rates varied from 16–18% in May–July to 20–23% in August–October and also in Mexico and Jamaica lower rates are observed in winter; in contrast, there are no relevant differences observed in the tropics.

On a specific destination, there are highly significant differences in TD incidence rates in different risk groups. Probably most important is the selection of hotel. As demonstrated in Jamaica, the incidence rates in 18 hotels visited by at least 40 clients for 1 week varied between 0 and 33% ($p < .001$). Experts while visiting these places realize that these rates mirror the hygienic conditions. Five star-rated hotels tend to have a slightly higher TD incidence rate as compared to many three or four star-rated hotels. This is plausible, considering that elaborate food in the more refined places more frequently needs to be touched by fingers.

As expected, duration of exposure is relevant. TD usually occurs during the first week abroad. Although there is still a risk of illness in the subsequent weeks and up to 2 years, it appears that some immunity is gradually developed.

Whether or not avoidance of potentially contaminated food and beverages play a role, is still debated. Although various retrospective studies, probably biased, showed no effect, the only follow-up survey demonstrated a linear increase

 doi:10.1016/B978-0-12-378612-8.00082-2

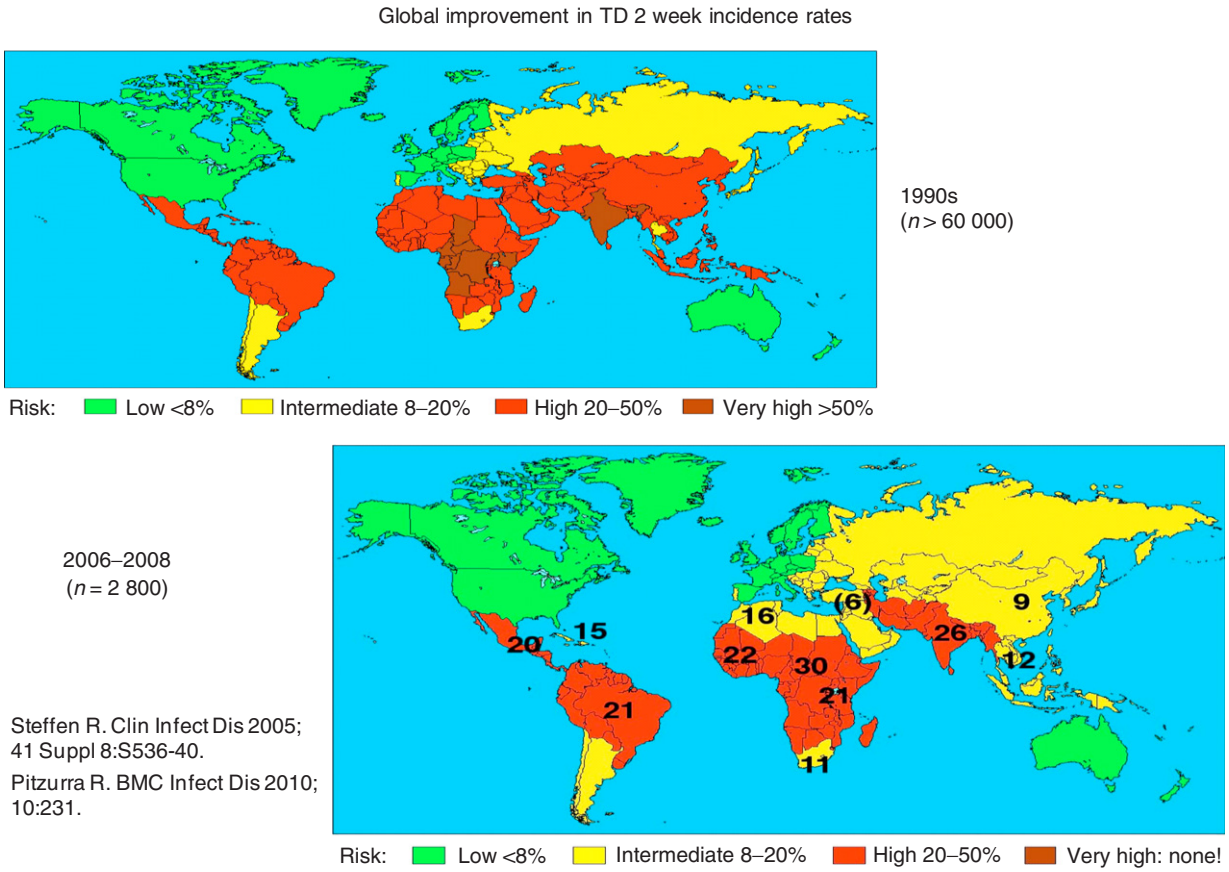

Figure 1 Two-week incidence rates of travelers' diarrhea at various destinations in Swiss travelers, 2006 to 2008. In Turkey and the Arabian Peninsula the color for intermediate risk is deliberate despite the rate of 6%, as this region was high risk in the 1990s and as the sample was very small. Reproduced from Pitzurra R, Fried M, Rogler G, Rammert C, Tschopp A, and Hatz C (2011) Irritable bowel syndrome among a cohort of European travellers to resource-limited destinations. *Journal of Travel Medicine* 18: 250–256.

of TD incidence with increasing numbers of dietary mistakes. Additional behavioral risk factors may be bathing in seawater or having meals in cafeterias or from street vendors. Also, consumption of unpasteurized milk resulted in an excessive odds ratio (OR) of 6.2; similarly, Mexican sauces were identified as often being contaminated. Excessive beer consumption resulted in a significant higher TD rate, whereas there is indication that wine may have some protective effect.

Host Factors

The origin of the traveler is the most relevant host factor. Owing to acquired immunity, the risk of illness is far lower in those living in areas with high endemicity when visiting other developing countries; this has been demonstrated in delegates to conventions, students, and military populations. Similarly, various studies have demonstrated that travelers who recently visited the tropics have a diminished incidence rate of TD, probably because of some developed immunity.

Various studies have demonstrated younger age to be a risk factor. Particularly prone to suffer from TD are infants, toddlers, and those between 15 and 30 years of age. We can imagine that small children are at a particularly high risk because their fingers indiscriminately touch floors and other contaminated materials before being licked, whereas in young adults a greater appetite may result in consumption of a larger inoculum of pathogens. In most studies no significant, or at least no clinically relevant, difference of TD incidence rates has been observed by gender, a recent account illustrating a higher proportion of females consulting Geosentinel sites was most likely biased. A more adventurous travel style of young adults is not the only explanation for the higher risk, because the significant difference is demonstrated even when the population is stratified by hotel and only all inclusive travelers are analyzed who do not consume any meals outside the hotel.

A genetic susceptibility to TD has been demonstrated. At least enteroaggregative *Escherichia coli*-associated diarrhea occurs significantly more often in AA genotype-251 (OR 209, 95% confidence interval (CI) 28–1525), as compared to a T genotype (OR 14, 95% CI 2–105) or event TT genotypes (OR 1). It is unknown whether a higher incidence rate of TD among British travelers is associated with genetic differences or different dietary habits.

Additionally, lack of gastric acidity subsequent to operation or associated with medication such as omeprazole or magnesium hydroxide aluminum hydroxide has been identified as a risk factor. Increasingly the gastric acid barrier is compromised by long-term medication in travelers.

Clinical Picture and Impact

TD usually is not a severe illness. Slightly less than one in four patients voids six or more unformed stools per day. The proportion of patients with classic TD is less than 40% at intermediate risk destinations, but clearly exceeds 55% at typical high-risk destinations. TD is hardly a life-threatening condition, although a few fatalities have been anecdotally reported, hospitalizations are particularly often indicated in small children. The average duration of untreated TD is approximately 4 days; 50% are free of symptoms within 48 h. Patients with fever, other symptoms suggesting severe TD, and those in whom pathogens are identified tend to have a longer duration of illness.

More important is the incapacitation due to TD, which may lead to extreme frustration at times of highest expectations. Approximately one-third of all patients are unable to pursue planned activities, which means that at typical high-risk destinations such as India or Kenya 30 and 20%, respectively, of all travelers will be incapacitated by TD. The duration of incapacitation is usually limited to 12–24 h, which is considerable, if we assume that many trips last only for a week. Additional time is lost when health professionals need to be consulted.

There is a growing interest in sequelae: Already early studies indicated that TD persists in 1% for 4 months or longer. Recently, several studies have indicated that irritable bowel syndrome (IBS) may be associated with TD. Although rates of up to 11% were documented in small initial studies, only 1.5% among 2800 Swiss travelers reported such problems.

Etiology

There has been a consensus for some time that diarrheagenic *E. coli* is the most important cause of TD, but for decades some 20–40% of all TD cases remained without a definable cause. Recently, stool samples from TD patients in Mexico, Guatemala, and India have been analyzed more thoroughly, including assessments in 20 instead of just 5 *E. coli* colonies, evaluation as to whether *Bacteroides fragilis* secrete an enterotoxigenic proinflammatory zinc-dependent metalloprotease toxin (ETBF), and also determination of various *Arcobacter* species. Particularly in Goa, India, bacterial pathogens were detected in 94% of TD stool samples, whereas the overall pathogen detection rate at all sites was 84% (Table 1). This confirms that the vast majority of TD is caused by fecal contamination of food and beverages.

Another recent study has demonstrated that between 10 and almost 20% of patients with gastrointestinal infections abroad may be infected or coinfected by noroviruses. Parasites such as *Entamoeba histolytica* or *Giardia lamblia* are the cause of TD in less than 5%, but they may persist for a longer period on returning home and thus higher rates may be detected in returning travelers. Often multiple pathogens are detected in these thorough scientific TD stool assessments, whereas in routine stool bacteriology far fewer pathogens are detected. In outbreaks in hotels or on cruise ships, often a single pathogen can be identified. In contrast, it appears the airline catering has an effective quality control, as hardly any post-flight outbreaks has been reported in the recent decade.

Table 1 Etiology of travelers' diarrhea – bacterial pathogens[a]

Enterotoxigenic *E. coli* (ETEC)	76%
Heat stabile enterotoxigenic *E. coli* (ETEC-ST)	51%
Campylobacter spp.	9%
Arcobacter spp.	8%
Enterotoxigenic *Bacteriodes fragilis* (EBTF)	7%
Shigella spp.	4%
Salmonella spp.	2%
Aeromonas spp.	2%
Plesiomonas spp.	2%
Vibrio spp.	1%

[a]Based on 201 TD stool samples collected 2007/08 in Guatemala, Mexico, and India (JIA).

Pathogens associated with TD may be resistant to any antimicrobials, although this appears to be less frequent among patients with TD as compared to locals in the same country. It is of concern that pathogens detected in stools of TD patients show increasing rates of resistance not only to quinolones, but also to azithromycin. Most assume that travelers using antimicrobials against TD for a variety of reasons contribute far less to resistance as compared to the local population.

Prevention

Essentially we can consider five different strategies for prevention. The first would be to reduce the risk for the visitors in the host countries. This can be achieved by implementation of the principles of hazard analysis and critical control points (HACCP) in hotels and restaurants, as demonstrated in Jamaica by Ashley *et al.*, 2004. Also, improvement of the infrastructure to provide safe water supplies, safe sewage collection, and disposal may drastically reduce the risk of TD.

The second option is to abandon travel plans to any high-risk country. Anecdotally it appears that some people are afraid to travel, among other reasons, because of the risk of TD. But travel health professionals should probably consider only advising against travel to a developing country for persons at high risk of complications of TD while abroad, be they immunosuppressed or infants and very small children, who often need to be hospitalized in case of such illness.

The third option is the avoidance of potentially contaminated food and beverages. The rule 'boil it, cook it, peel it – or forget it' has been shown to drastically reduce the risk of TD in one prospective study, whereas all retrospective surveys failed to show such a benefit. Anyhow, less than 5% of tourists strictly adhere to this recommendation, the majority of travelers select, for instance, salads from attractive buffets or accept ice cubes in the drinks. Organisms in contaminated ice will survive concentrations of alcohol found in drinks mixed with tequila and whisky. However, almost all enteropathogens are killed at 70 °C and most food items served at 60 °C are safe.

The fourth option is prophylactic medication, and a variety of drugs have been considered. These include probiotics, bismuth subsalicylate (available in the US), and antimicrobials. Only antibiotics offer a satisfactory protection, reducing the incidence of TD by 80% or more. Quinolones, azithromycin, and rifaximine (a nonabsorbed antibiotic, which therefore has

a profile of adverse events similar to placebo) are those most often considered. This is controversial: although in North America such prophylaxis is sometimes prescribed, European doctors are extremely reluctant to prescribe prophylactic antibiotics. This might be exceptionally considered for high-risk groups, such as for patients with preexisting illness in whom dehydration subsequent to TD may be dangerous (e.g., those with a history of stroke or transient ischemic attacks, inflammatory bowel disease, insulin-dependent diabetes mellitus, chronic renal failure, or AIDS), or persons who are particularly prone to suffer from TD, be that for genetic reasons (rare) or due to a lack of the gastric acid barrier. Such prophylaxis may also be considered for very important persons (VIPs) during very short trips.

Currently no vaccine offers satisfactory protection against TD. Typhoid vaccines are specific against typhoid, which is not characterized by diarrhea. The only cholera vaccine available in a limited number of countries (e.g., not in the US) offers some limited cross-protection against enterotoxigenic *E. coli* (ETEC), but the estimated efficacy against TD of all causes is limited to 5–23%. A skin-patch vaccine against ETEC is currently being tested.

Therapeutic Options

As discussed in the section on Prevention, there is no practical way to prevent TD. Thus, therapy – and while abroad often self-treatment – plays an important role. As diagnostic capabilities at many of the favorite tourist destinations worldwide are virtually inexistant, one will select therapeutic agents on the basis of scientific studies, some of which dating back many years.

The leading principle in the management of TD is to avoid dehydration. In healthy adults, an adequate fluid and electrolyte balance can be maintained with tea with sugar (fluids without sugar are not well absorbed by the infected gastrointestinal tract), bottled soft drinks (no cola, as that contains caffeine, which increases intestinal motility and thus diarrhea), juices, and soups, crackers, etc., to replace electrolytes. Electrolyte-containing oral-rehydration solutions such as those formulated by World Health Organization (WHO) will neither diminish the amount or duration of diarrhea, but they are paramount in infants, children, or also in elderly TD patients in whom dehydration may much more rapidly have devastating effects. Because of damage to the intestinal lactase-producing cells by enteric pathogens, dairy products should be avoided during illness, otherwise no diet is indicated.

Most experts agree that travelers to TD risk destinations should carry a travel-kit. Purchase of often cheaper medication at the destination is no longer recommended, because it is known that a substantial proportion may be falsified and ineffective; also storage at adequate temperatures may be a problem in many pharmacies in a tropical climate. It is paramount to give the travelers detailed verbal and written instructions on how the medications in the travel-kit should be used.

For self-treatment of TD, this ought to include an antimotility agent (usually loperamide) and an antibiotic. Many studies have shown that both these medications lead to rapid symptomatic improvement. The most dramatic reduction in the duration of illness is achieved by a combination therapy: two-thirds of the patients are free of symptoms within 4 h. In adult TD patients loperamide up to 16 mg 24 h^{-1} may be used, but such high doses often subsequently result in constipation. Loperamide is contraindicated during bouts of dysentery as defined in the introduction, unless used in combination with an antibiotic. Quinolones, and in Southeast Asia azithromycin, have become the antibiotics of choice for self-treatment. Studies have shown single-dose therapy and 3- to 5-day courses to be equally effective in most situations. It appears that early therapy is slightly more effective.

In contrast, therapy with lactobacilli or other probiotics has not been shown to be effective in modifying the course of TD. Also charcoal has been shown to be ineffective.

Some with concerns about self-therapy have recommended that TD patients should consult a local doctor. A recent study conducted in Phuket (Thailand), Goa (India), and Mombasa (Kenya) illustrated that some physicians caring for patients at tourist hotels use obsolete antimicrobials or combinations, that are not recommended in industrialized nations. Additionally, many have now set up their private clinics in vicinity of the hotels and increasingly hospitalize TD patients (some 80% of the TD consultations) overnight for antimicrobial infusion therapy. This results in costs amounting to several hundred US dollars, which the patients try to get reimbursed from their insurance on return. In some remote areas there is concern about nosocomial transmission mainly of the hepatitis B virus, occasionally also of other pathogens.

Rather often TD symptoms may have their onset only on return, or they may persist. Although state-of-the-art laboratory facilities are usually available in the country of residence, it is generally not practical to perform bacteriological stool examinations, first, because most patients will be cured by empiric therapy as described above before the results of the assessment are available, and second, because most laboratories do not routinely perform all the examinations listed in Table 1. Whenever symptoms are not cured by antibiotics, a stool analysis for parasites is indicated. If the results are negative or targeted therapy does not relieve the symptoms, ultimately colonoscopy may be indicated, as rarely TD symptoms may be the expression of a yet undetected malignancy in the gastrointestinal tract.

BACTERIA

Contents

Acinetobacter

E Bergogne-Bérézin, University Bichat-Claude Bernard, Paris, France

History, Background, and Taxonomy

After years of erratic taxonomy of Gram-negative diploid organisms with same morphology, expert microbiologists established these bacteria in the 1970s in several genera: *Moraxella* spp., *Branhamella* sp., *Achromobacter* spp., with further studies identifying the genus *Acinetobacter* spp. These strictly aerobic bacteria grow easily on common media, at temperatures 20–30 °C, (optimum: 33–35 °C). Growth at 41 and 44 °C is a phenotypic character. Phenotypic identification of *Acinetobacter* spp. was based on oxidase–indole–nitrate-negative tests, catalase-positive tests, and oxidative production (or not) of acid from D-glucose, D-ribose, D-xylose, and L-arabinose. Phenotypic studies recognized two species in 1980 (Approved Lists of Bacterial Names), based on sugar use: *Acinetobacter calcoaceticus* and *Acinetobacter lwoffii* (nonacid

producing). Both species names have been used for two decades until application of DNA–DNA hybridization in 1986, discriminating genomic groups. 6 given species names were added to 12 initial genomic species, in 2008, 31 named genomic species and 12 unnamed species, and in 2009 were added *Acinetobacter berezinae* sp.nov. and *Acinetobacter guillouiae* sp.nov. in this evolving taxonomy of the genus.

Epidemiology and Habitat

Acinetobacter spp. are ubiquitous Gram-negative coccobacilli and nonmotile (displaying a 'twitching motility' presumably due to polar fimbriae). *Acinetobacter* spp. are widely distributed in nature, in soil and water, as free-living saprophytes. They are found in virtually 100% of soil and fresh-water samples (less than $1–7.9 \times 10^4$ cfu 100 ml^{-1}). They utilize a wide variety of substrates as sole carbon source in nature, plants, food, and foodstuffs (source for human carriage).

Acinetobacter spp. are recovered from human specimens, interstitial areas, axillae, toe webs, throat, and various secretions of healthy people. They form a small part of the human skin flora in approximately 25% of normal people. Digestive tract colonization has been documented in infants and adults in a prospective study (77% of 73 patients). Rectal colonization of *Acinetobacter* comprises the risk of 'translocation' phenomenon (transfer from gut to form infected sites in lungs or other organs).

Acinetobacter genospecies roles vary: *Acinetobacter baumannii* or *Aci. calcoaceticus* is more common in pathological conditions, whereas *Acinetobacter johnsonii*, *Acinetobacter junii*, and *Aci. lwoffii*, predominate in the environment. In animals, various *Acinetobacter* spp. have been isolated, but they were only occasionally found as agents of animal infections.

Clinical Profile of *Acinetobacter* Infections

"You've heard of MRSA, but what about *Acinetobacter*?" Los-Angeles Times Health, (24 December 2009).

Carriage of *Acinetobacter* spp.

Carriage of *Acinetobacter* spp. by personnel hands, patients, and materials in hospitals contributes to dissemination and outbreaks of nosocomial infections.

Acinetobacter Respiratory Tract Infections

Acinetobacter respiratory tract infections (RTIs) are severe Gram-negative pneumonias with fever, neutrophilia, purulent sputum, and infiltrates on radiograph or computed tomography scan. Bacteria are isolated from bronchial aspirations, brushings, or bronchoalveolar lavage. RTIs occur in mechanically ventilated patients, elderly, and patients with various risk factors.

Community-Acquired Pneumonia

Rare cases have been found in patients with chronic pulmonary diseases, diabetes mellitus, and renal and hepatic insufficiencies, with high mortality rates.

Bacteremic Pneumonia

It is the most severe infection, associated with shock and sepsis in patients with severe underlying pathologies. Mortality rates range from 30% to 75% when sources of the pathogens are trauma, surgical procedures, presence of catheters, intravenous (IV) lines, dialysis, and burns. Respiratory failure at admission increases the risk of bacteremia by threefold in case of malignancies, intracranial hemorrhage, and central venous catheters. Clinical signs of true bacteremic episodes are fever, leukocytosis, and blood cultures positive with the same genotypic isolate of *Acinetobacter*. Incidence of *Acinetobacter* bacteremia ranks second after pneumonias, its prognosis depends on the underlying condition of patients.

Urinary Tract Infections

From 2% to 61% of nosocomial UTIs have been attributed to *Acinetobacter* spp. with mean incidence of 30.5%, occurring in patients with risk factors like indwelling urinary catheter. Removal of the catheter is recommended to control bacteriuria.

Skin and Soft Tissue Infections

Infections of skin structures such as decubitus ulcers, leg ulcers, and onychodystrophy of the hands occurring 2 months after *Acinetobacter* peritonitis have been early identified. Colonization of burns, postoperative wounds with *Acinetobacter* spp. are seen in specific units, competing with *Pseudomonas aeruginosa* in most burned patients.

Meningitis

Nosocomial meningitis is infrequent manifestation of *Acinetobacter* infection after neurosurgical procedures. Cases of primary meningitis occur especially in children. *Acinetobacter* meningitis may result from the introduction of the organism directly into the central nervous system following intracranial surgery, myelography, ventriculography, lumbar puncture, or transnasal aspiration of craniopharyngioma. Relatively indolent, *Acinetobacter* meningitis is identified by meningeal signs, high fever, lethargy, or headache. An exceptional outbreak of *Acinetobacter* meningitis was described in a group of children with leukemia, after administration of intrathecal methotrexate.

Pediatric *Acinetobacter* Infections

Pediatric *Acinetobacter* infections occur by acquisition of the organism in infants with peripheral IV catheters. Environmental cultures revealed that air conditioners increased the incidence of cases by airborne dissemination of the bacteria. *Aci. baumannii* infection was related to mechanical ventilation in 15 preterm infants. In Japan, *Acinetobacter* septicemia was

seen in intensive care unit (ICU) neonates during 30 months (mortality rate 11%): Strains were isolated from the hands of staff, sinks, and fecal samples.

Miscellaneous

Rare infections such as suppurative thyroiditis, necrotizing enterocolitis, *Acinetobacter* pericarditis with tamponade (in a patient with systemic lupus erythematosus), and septic pericarditis. Rare cases of *Acinetobacter* infections have been recognized by genotypic identification of strains, as seen after earthquake (Turkey, 1999) and in war zones (Vietnam conflict, Gulf war soldiers, 2003–2004).

Therapeutic Problems

Antibiotic Resistance

The earliest problem has been the 'natural' resistance of the bacteria to few antibiotics existing in the 1970s (ampicillin, carbenicillin, cephalothin, tetracyclines, and chloramphenicol). As new antibiotics were developing in 1980s (second- and third-generation cephalosporins, aminoglycosides, and fluoroquinolones), *Acinetobacter* acquired mechanisms of resistance to the major antibiotic classes: They can produce a wide variety of β-lactamases: plasmid-mediated (TEM, SHV-type, and CARB-5 hydrolyzing penicillins), chromosomally mediated (cephalosporinases, extended spectrum β-lactamases (ELSB, CTX-M), emerging carbapenemases: (VIM, KPC, OXA-24–26–40–58….).

Imipenem Resistance

Spread of carbapenem-resistant strains constitutes a major threat for treatments of multidrug-resistant (MDR) *Acinetobacter*. Other mechanisms like alteration of drug targets (penicillin-binding proteins), efflux pumps, and permeability problems are growing. *Acinetobacter* developed resistance to initially active aminoglycosides, inactivated by production of a series of aminoglycoside-modifying enzymes. Fluoroquinolones, used to treat *Acinetobacter* infections, underwent chromosomal mutations in the *gyr*A and *par*C genes and are fluoroquinolone resistant in patients in admitted ICUs. Few therapeutic alternatives, combinations include sulbactam and fosfomycin, and rifampicin and colistin.

Pathogenesis and Virulence Factors

Seen as relatively low-grade pathogens, in fact *Acinetobacter* spp. exhibit significant pathogenic importance. Virulence mechanisms of *Acinetobacter* strains include: (1) presence of a polymer (slime), a polysaccharidic capsule, formed of L-rhamnose, D-glucuronic acid, and D-mannose, found mainly in *Aci. baumannii* isolated from catheters and tracheal devices. Polysaccharidic structure protects bacteria from phagocytosis; (2) adhesiveness to human epithelial cells mediated by the capsule in relation to presence of polar thick fimbriae (5 nm), correlated with twitching motility; (3) lipopolysaccharide component of cell wall and presence of lipid A are major virulence factors in the pathogenicity of *Acinetobacter*; (4) outer membrane proteins can stimulate inflammatory response; (5) extracellular enzymes (lipases, esterases, amylase, and collagenase), periplasmic enzymes (butyrate and esterase), and membrane-bound enzymes (proteases, leucine, and alanine aminopeptidases) damage tissue lipids and proteins; and (6) iron regulation and role of siderophores are other factors associated with virulence (*Acinetobacter* spp. are able to grow under iron-deficient conditions).

Sources and Food Origins of *Acinetobacter* spp. Relation with Human Contamination

Intestinal Carriage: Potential Sources of Contamination of Food

Intestinal flora of neonates has been shown as a reservoir of the organism and risk factor for bacterial carriage. Bacterial overgrowth in the stomach of ICU patients due to diminished acid secretions can allow *Acinetobacter* to multiply and reach intestinal areas (carriage and contamination). Mouse gastritis due to *Aci. lwoffii*, by means of urease activity and fimbriae helping to adhere to gastric epithelial cells result in gastric acid suppression favoring *Acinetobacter* gut colonization.

Acinetobacter Presence in Food

Some data are available on the contamination and spoilage of food due to *Acinetobacter*, and also its possible role in human infection.

Meats

As psychrophilic-like *Pseudomonas*, *Acinetobacter* can multiply at low temperatures on surfaces of dry carcasses. Owing to their composition, muscles are sensitive to microbial alteration. In chicken carcasses and other poultry meats, it has been shown that *Acinetobacter* spp. contribute to the spoilage process of refrigerated meat, economically important spoilage of bacon and chickens. Preparations containing mince meats can have high microbial load, contaminating equipments and fresh pork sausages (Sulzbacher *et al.*). A survey in the University of Nebraska has identified *Acinetobacter* spp., as contaminants of beef and occurrence in radurized product.

Milk Products

In raw milk and cheese, even stored in refrigerated conditions, microbial development in tubular heat exchanger (pasteurizing milk) has been shown through ascending temperature ($\sim$20–90 °C), with change of dominant microbiota formed of *Acinetobacter* to thermophilic bacilli. The lipolytic activity of *Acinetobacter* in milk and dairy products results in different alterations of smell and taste. Among recently designated *Aci. berezinae* sp. and *Aci. guillouiae* sp., food origin of few strains was raw milk.

A positive application of *Acinetobacter* as lipase producers has been described as they are capable of efficient degradation of fats and oil in kitchen wastewater treatment.

Fishes

Among the microorganisms found on surfaces and in the intestine of fresh fishes, when caught in warm waters, *Acinetobacter* is common. Dominant microflora in molluscs consists of Gram-negative bacteria (*Pseudomonas*, *Acinetobacter*, and *Flavobacterium*). Taken in waters of northern areas, Gram-negative bacilli predominates, including *Acinetobacter*.

Vegetables

Acinetobacter strains have been found in vegetables. In tropical climates like in Hong Kong, 51% of local vegetables are colonized with *Aci. baumannii*. In raw sewage effluent, 10^6 cfu 100 msl^{-1} have been found, and in vegetables 30 isolates out of 177 vegetables. Fresh water (with sediment), sewage, soil (barley field), and activated sludge (from Sweden, Australia, Portugal, and Moravia) were colonized with *Aci. baumannii*.

Food-Animal Transport

Food-animal transport and use of antimicrobial agents may produce selection of drug resistance among aerobic bacteria such as *Acinetobacter*. Industrial food animal production includes concentrated animal-feeding operation, as a source of bacterial transmission.

Transmisison to Humans

Acinetobacter spp. most frequently isolated in food are *Aci. johnsonii*, *Aci. junii*, *and Aci. lwoffi*. Contaminations from food may occur during industrial preparation, under poor hygienic conditions. Home food preparation could be a potential source of occasional infection of skin, gut, and throat, but rare cases are found in the literature, knowing that *Acinetobacter* spp. are bacteria of low virulence. Conditions which allow the agent to express its pathogenicity are hospitals where patients are at the high risk of infection. In Korean food, an *Aci. baumannii* producing a PER-1 enzyme (ELSB) has been isolated, responsible for a nosocomial outbreak in an ICU In 1000 autochthonous strains from fresh and fermented artisanal products (Piemond area), 98 were bacteriocin-producing strains with hypothetic presence of *Acinetobacter* as a bacteriocin producer. (In genetically modified foods prepared for fragile new born babies, contamination risks by *Acinetobacter* spp. remain potential).

Other Aspects in Relation to Food and Other Conditions

Unusual and Special Situations

Sludge Cigarettes

Environmental species (*Acinetobacter baylyi*, *Acinetobacter towneri*, and *Acinetobacter tandorii)* were recently isolated from activated sludge. *Acinetobacter* strains isolated from wounded soldiers of Iraq were sent to France and analyzed for the presence of pathogens in tobacco and persistence in cigarettes: Identifying DNA of *Acinetobacter* spp. in cigarettes confirmed their role for fulminant epidemics of pneumonia in a surgical ICU.

Oysters

Microbial flora of pacific oysters (*Crassostrea gigas*) has been shown as containing *Acinetobacter* in treated sea water. Microbial potential presence in oysters subject to ultraviolet radiation-treated water remained comparable to levels held in untreated sea water.

Body Lice

Occasionally, *Aci. baumannii* has been found in infected animals and insects: *Aci. baumannii* strains have been isolated from 22% of body lice, fleas, or ticks, contaminated by biting homeless people having silent bacteremia, or as in tropical countries with high and humid temperature where biting insects contribute to contaminations.

Military Environmental Conditions

During Operation Iraqi Freedom, significant numbers of MDR *Aci. baumannii* infections occurred. Search for potential sources of contamination from foods resulted in isolation of several strains in soil bags (from 31 locations in field hospital soil), one strain in drinking water source, and one strain isolated from soil outside a field nutrition care section. These data demonstrate that despite practice of strict hygiene and controlled food (from the US), sparse isolates in military zone were responsible for outbreaks of *Acinetobacter* infections. Thirty-seven *Acinetobacter* isolates were obtained from equipment room, operating room, heater/air conditioners, sinks, tent walls, and most instruments. Other studies have been carried out with *Aci. baumannii* isolates from Iraq soldiers (Naval Medical Center) including molecular genetics.

Acinetobacter Metabolism

Enzymatic Activities

The high metabolic power of these bacteria expresses enzymatic activities, either destructive or active in assimilation, or dispersion of metabolites in the environment. From these activities, food spoilage, and/or persistence of *Acinetobacter* in industrial foods can occur but is not yet studied enough. Destructive enzymatic activities in *Acinetobacter* by lipases: The strain *Acinetobacter* BD413 expressed in high levels an extracellular lipase in early stationary phase, but rapidly degraded by an endogenous protease.

Proteases

Recognized for food bacterial spoilage, protease activities are based on the ability to utilize different proteins: *Acinetobacter* exhibits powerful proteolytic activities, hydrolyzing all test-proteins (gelatin, casein, and water-soluble proteins of beef muscle), among 122 tested bacteria.

Degradation of Aromatic Compounds

Acinetobacter radioresistens S13, able to grow on phenol or benzoate as sole carbon and energy sources, has been capable to produce biodegradation kinetics for mixtures of acetate,

benzoate, and phenol: the substrate utilization benzoate > acetate > phenol, showed that benzoate was the preferred substrate.

Inhibitory Effects of Radiolytic Products Have Been Carried Out Against Multidrug Resistant Organisms

Acinetobacter could not grow when incubated at 5% on the surface of fresh meat irradiated to 1500 krad.

Beneficial Aspects of *Acinetobacter*

Positive properties were found in its industrial applications: (1) production of surface polysaccharide-containing biopolymers of industrial importance (emulsan®); (2) ability of *Acinetobacter* spp. to sequester inorganic phosphate (intracellular polyphosphate) with application in phosphate removal from wastewater environments; and (3) degradation by *Acinetobacter* of ochratoxin A produced by *Aspergillus ochraceus* and other fungi. (Ochratoxin, a carcinogenetic toxin, in rats and mice is involved in Balkan endemic nephropathy).

Conclusion

Acinetobacter is a bacteria of low virulence. It is a major risk for vulnerable people, for example, patients in hospitals. It is found in a variety of food; however, it has been rarely associated with foodborne disease. Therefore, its role as a foodborne pathogen is undefined. However, *Acinetobacter* is a promising beneficial 'cleaning bacteria' as it has application in a number of areas such as phosphate removal, aromatic wastes, spillages, scraps, and degradation of ochratoxin.

BACTERIA

Aeromonas

AJ Rodriguez-Morales, Universidad Tecnológica de Pereira and Office of Scientific Research, Pereira, Risaralda, Colombia
DM Castañeda-Hernández, Fundación Universitaria del Área Andina, Pereira, Colombia

Glossary

Anthroponosis An infectious disease in which the etiological agent is carried by humans and is transferred to other humans and animals.
Foodborne disease Any disease resulting from the consumption of contaminated food, pathogenic bacteria, fungus, viruses, or parasites that contaminate food, as well as chemical or natural toxins such as poisonous mushrooms.
Organism life cycle A period involving all different generations of a species succeeding each other through means of reproduction, whether through asexual reproduction or sexual reproduction (a period from one generation of organisms to the same point in the next).
Taxonomy The science of classification, in microbiology the arrangement of microorganisms into a classification.
Zoonosis Any infectious disease that can be transmitted between species (by various ways, by a vector or by their products, and food) from animals to humans or from humans to animals (less common).

Introduction

Aeromonas is a Gram-negative, facultative anaerobic rod that morphologically resembles members of the family *Enterobacteriaceae*. Diseases produced by some species of this genus are called aeromoniasis (ICD-10 A05.8).

The Pathogen

In taxonomy bank of the NCBI 29 species of *Aeromonas* have been described (Table 1), many of them associated with human diseases. The most important pathogens are *Aeromonas hydrophila*, *Aeromonas caviae*, and *Aeromonas veronii* biovar *sobria* (Table 1). The organisms are ubiquitous in fresh and brackish water. *Aeromonads* are estuarine bacteria and are ubiquitous in fish and shellfish, meats, and fresh vegetables. They group with the gamma subclass of the Proteobacteria (g-proteobacteria).

Aeromonas hydrophila, the most clinically important species of the genus, is a widespread representative of *Aeromonas* found in water, water habitants, domestic animals, and foods (fish, shellfish, poultry, and raw meat). The microorganism has the potential to be a foodborne pathogen, especially strains from hybridization group (HG1), associated with clinical cases of illness. *Aeromonas* species have been recognized as potential or emerging foodborne pathogens for more than 20 years. Additionally, as it affects fish, amphibians, and reptiles, *Aeromonas* is also considered a zoonotic bacteria. Aeromoniasis is rare in wild or domestic mammals and birds.

Table 1 Main species included in the genus *Aeromonas*, characterized and reported in the National Center for Biotechnology Information (NCBI) Taxonomy Browser (2012) (http://www.ncbi.nlm.nih.gov/taxonomy)

Aeromonas allosaccharophila	*Aeromonas media*
Aeromonas aquariorum	*Aeromonas molluscorum*
Aeromonas bestiarum	*Aeromonas piscicola*
Aeromonas bivalvium	*Aeromonas popoffii*
Aeromonas cavernicola	*Aeromonas rivuli*
Aeromonas caviae	*Aeromonas salmonicida*
Aeromonas cf. bestiarum/salmonicida	*Aeromonas sanarellii*
Aeromonas diversa	*Aeromonas schubertii*
Aeromonas encheleia	*Aeromonas sharmana*
Aeromonas enteropelogenes	*Aeromonas simiae*
Aeromonas eucrenophila	*Aeromonas sobria*
Aeromonas fluvialis	*Aeromonas taiwanensis*
Aeromonas guangheii	*Aeromonas tecta*
Aeromonas hydrophila	*Aeromonas veronii*
Aeromonas jandaei	

Clinical Presentation

Two major diseases have been associated with *Aeromonas*: gastroenteritis and wound infections, with or without bacteremia or sepsis. Gastroenteritis typically occurs after the ingestion of contaminated water or food (aeromoniasis is a foodborne disease), usually presenting with selflimiting diarrhea, with children being the most susceptible population, whereas wound infections result from exposure to contaminated water. Although some potential virulence factors (e.g., endotoxins, hemolysins, enterotoxins, and adherence factors)

 doi:10.1016/B978-0-12-378612-8.00405-4

have been identified, their precise role is still unknown. Aeromonas species cause: Opportunistic systemic disease in immunocompromized patients (although still few reports have enoughly support this), diarrheal disease in otherwise healthy individuals, and wound infections.

The pathogen produces different virulence factors including exotoxins, cytotoxins, adhesions, and others which are considered responsible for intestinal and extraintestinal infections in human beings and also for a wide variety of infections in animals, but the exact role of each, particularly in human disease has not been fully elucidated. As a psychrotroph, *A. hydrophila* grow in foods during refrigeration. Aeromonads are not resistant to food processing regimes and are readily killed by heat treatment. The disease spectrum associated with this microorganism includes gastroenteritis, septicemia, traumatic and aquatic wound infections, and infections after medical leech therapy. Multiple resistance of the bacterium to many antimicrobials is a fact of high significance.

Importance as Food Pathogen

Aeromonas has become increasingly recognized as human enteropathogen. This foodborne bacteria has been cultured from fish, pigs, broilers, eggs, milk, and vegetables, among other food products. *Aeromonas* sp. also multiply rapidly at $+4\ ^{\circ}C$ which is a significant risk in food storage. Furthermore, *Aeromonas* sp. have been recovered from fresh water sources, and some isolates are resistant to chlorination which makes it a further risk factor. No large food- or waterborne outbreaks have been reported so far with *Aeromonas* sp., but human isolated cases are commonly reported in the literature in association to water and food contamination. In 1995, in Sweden, a foodborne outbreak involving *A. hydrophila* was reported. A group of 27 people consumed a typical Swedish food 'landgång' which is a type of 'smörgåsbord' containing shrimps with mayonnaise, liver paté, ham, sausage, and legume salad which was purchased from a food store. A total of 22 of the 27 persons became ill within 20–34 h of consumption of the food and reported the symptoms ranging from severe acute diarrhea, abdominal pain, headache, fever, and vomiting.

Prevention and Control

Many scientific studies are done to assess the influence of different factors on survival of *A. hydrophila* and other species of the genus. The ability of the pathogen to grow at refrigeration temperatures may have great impact on refrigerator stored foods. Many factors for control of growth of *A. hydrophila* have been studied. Current strategies of control include: Hurdle technology (temperature, pH, NaCl, and $NaNO_2$), washing, oxidizing, smoking, modified atmosphere, use of probiotics, polyphosphates/NaCl, heating, use of plant extracts, high hydrostatic pressure, cooling/chilling, chlorine treatment, and alcohol treatment, among many others.

BACTERIA

Arcobacter

HI Atabay, İzmir Institute of Technology, İzmir, Turkey, and University of Sifa, İzmir, Turkey
JEL Corry, University of Bristol, Bristol, UK
C Ceylan, İzmir Institute of Technology, İzmir, Turkey

Glossary

Foodborne pathogens Microorganisms that are transmitted to humans via foods and cause diseases in humans.
Gastroenteritis Inflammation of stomach and intestinal tissues.
Identification Differentiation of bacteria at the species and/or subspecies level by characterizing by phenotypic and/or genotypic methods.
Isolation The growth of bacteria in/on a suitable growth medium to obtain the desired bacterial species.
Plating medium A solid growth medium solidified by addition of agar, that includes essential nutrients for bacterial growth.
Selective supplement Combinations of antimicrobial agents used to inhibit the unwanted bacteria in an isolation medium.

Background

The first isolation of an *Arcobacter* species was from bovine fetuses in the late 1970s. It was identified as an aerotolerant *Campylobacter* sp. (*Campylobacter cryaerophila*) because of its DNA base composition and general morphology, differing from other *Campylobacter* spp. because of its aerotolerance and its ability to grow at temperatures down to 15 °C. Similar bacteria were soon isolated from sources such as aborted bovine and porcine fetuses, cow's milk and bovine preputial sheath washings. *Campylobacter nitrofigilis* was isolated from a salt marsh, and appeared to be a nonpathogenic free-living species. After a comprehensive taxonomic study, the name *Arcobacter* was proposed in 1991 for this group, as a second genus in the family Campylobacteraceae. Consequently, the aerotolerant campylobacters became *Arcobacter cryaerophilus* and *Arcobacter nitrofigilis*, respectively. The genus *Arcobacter* later expanded to include two more members, *Arcobacter butzleri* and *Arcobacter skirrowii* isolated from various sources such as from human and animal diarrhea, aborted fetuses of animals, human blood, and from preputial fluids of bulls. Recently, another species, *Arcobacter cibarius*, was isolated from the skin of broiler carcasses and the same year, an obligately halophilic strain, called *Arcobacter halophilus*, was isolated from a hypersaline lagoon, indicating the ubiquitous distribution of *Arcobacter* spp. and a tendency to adapt to diverse environmental conditions. Three more species have been identified in the past few years: *Arcobacter mytili* has been isolated from mussels and brackish water; *Arcobacter thereius* from the liver and kidney of aborted pig fetuses and the cloaca of duck; and *Arcobacter marinus* from the marine environment. An unclassified organism, '*Candidatus* Arcobacter sulfidicus' producing filamentous sulfur has also been isolated from coastal seawater.

Characteristics of the Organisms

Like *Campylobacter* spp., *Arcobacter* spp. are Gram-negative, slightly curved, S-shaped, or helical rods 0.2–0.9 μm wide and 1–3 μm long. A characteristic darting or corkscrew-like motility is provided by a single polar, unsheathed flagellum. Arcobacters produce whitish or grayish smooth-rounded colonies varying in size, depending on the species. They produce oxidase and catalase and some strains are α-hemolytic. They can multiply at 15 and at 37 °C, but many are unable to multiply at 41.5 °C. Arcobacters can grow in aerobic conditions, but the best growth is observed under microaerobic conditions with 3–10% O_2, 5–10% CO_2, although *A. skirrowii* grows better when hydrogen is also present. They are unable to ferment carbohydrate but utilize organic acids and amino acids as carbon sources. Their most important distinctive features compared to *Campylobacter* spp. are their ability to grow in air at 30 °C and their growth at temperatures down to 15 °C.

Pathogenicity, Clinical Manifestations, and Virulence Factors

Three species of *Arcobacter*, *A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*, are associated with various diseases in humans and animals. *Arcobacter butzleri* is the species most commonly reported as a cause of gastroenteritis and bacteremia in humans, with *A. cryaerophilus* and *A. skirowii* less frequent. Diarrhea is the most common symptom reported. They have been found particularly as a cause of diarrhea in malnourished children in developing countries. Although *Arcobacter* spp. and *Campylobacter jejuni* cause diarrhea with similar symptoms, *A. butzleri* infections are more frequently associated with a persistent,

 doi:10.1016/B978-0-12-378612-8.00083-4

watery diarrhea, whereas *C. jejuni* more commonly causes bloody diarrhea. *Arcobacter butzleri* infections are also associated with abdominal pain with and without diarrhea, nausea and vomiting, or fever. However, some patients may remain asymptomatic. *Arcobacter skirrowii* has been implicated as a cause of chronic diarrhea.

Arcobacter butzleri, *A. cryaerophilus*, and *A. skirrowii* are associated with diseases in cattle, sheep, and pigs, such as enteritis, mastitis, and reproductive disorders, including abortions. *Arcobacter butzleri* is also associated with diarrhea in nonhuman primates, such as macaques.

Although arcobacters are associated with various diseases in humans and animals understanding of the mechanism(s) of pathogenicity of these microorganisms and their toxin production is still limited. Some strains have cytotoxins and cytolethal distending factors, some hemagglutinate human and animal erythrocytes, and some can adhere to cell lines and have invasive potential.

Epidemiology of *Arcobacter* spp.

The transmission of *Arcobacter* spp. to humans is considered to occur mainly through contaminated food and drinking water; close contact with pets; and perhaps through person-to-person-transmission. *Arcobacter* spp. have been isolated from the intestinal tract of healthy mammals including cattle, pigs, sheep, dogs, and horses, and also from pork, beef, lamb, poultry meat, and shellfish. Like campylobacters, arcobacters are more prevalent on poultry meat than red meat and thus, poultry carcasses may be a major reservoir of these bacteria. Four species of *Arcobacter*, *A. butzleri*, *A. cryaerophilus*, *A. cibarius*, and *A. skirrowii* have so far been recovered from poultry carcasses. Although arcobacters are common on chicken carcasses, in contrast to *Campylobacter* spp., they are rarely isolated from the intestinal contents of these birds probably because birds have a relatively high body temperature ($\geq 41\ ^{\circ}C$). However, *Arcobacter* spp. have been isolated from the cloacal swabs taken from various types of poultry, including chickens, turkeys, ducks, and geese. Eggs are not regarded as a source of arcobacters.

In contrast to the situation with campylobacters, contamination of poultry carcasses with arcobacters is considered to occur from the processing and slaughterhouse environment rather than the intestinal tract of the birds. Arcobacters are able to survive and multiply in the warm and wet environment of processing plants, and form biofilm on processing lines and surfaces. They have also been detected in piggery effluent, and effluent-irrigated soils, and in farm environments including surface water. Whether or not arcobacters have been detected in animals and from different farms could be affected by a number of factors, including the isolation/identification methods used and sample size. *Arcobacter* spp. are also found in various aqueous environments, including drinking water reservoirs, canal waters, river or surface water, ground water, and sewage. *Arcobacter butzleri* is sensitive to chlorine, so consumption of so nonchlorinated drinking water or contact with contaminated water sources may be a source of infection with these bacteria. *Arcobacter* infection may be more common in developing countries with poor water supplies.

Isolation, Identification, and Detection of *Arcobacter* spp.

Isolation

Arcobacter spp. were initially isolated from bovine fetuses using a semisolid *Leptospira* medium (Ellinghause–McClullough–Johnson–Harris) containing 5-fluorouracil. There is still no standard isolation method, but a number of isolation media and protocols have been devised in order to detect the three most common arcobacters (*A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*) in various types of sample. These methods generally exploit the ability of arcobacters to grow at lower temperatures ($\leq 30\ ^{\circ}C$) and in aerobic conditions in order to avoid isolating camplyobacters. Prolonging incubation of plating media up to 7 days aids detection of less robust species such as *A. cryaerophilus* and *A. skirrowi*, for which inclusion of hydrogen in the incubation atmosphere may be helpful. Basal media originally developed for other bacterial pathogens such as cefsulodin–irgasan–novobiocin agar base, and modified campylobacter cefoperazone deoxycholate agar base have been used in combination with different selective agents, for example, cefoperazone, amphotericin B, and teicoplainin (CAT) and 5-fluorouracil with some success for the isolation of arcobacters. They can also be recovered from various types of samples by using different isolation strategies that depend on their high motility and small size. In this context, arcobacters can be recovered by dispensing a small volume of a suspension of the samples, either before or after enrichment, onto a 0.45 or 0.65 μm pore size membrane filter laid on a plate of selective and/or nonselective agar medium for about 30 min before removing the filter and spreading the liquid remaining evenly over the agar. This allows the highly motile arcobacters and campylobacters to penetrate though the filter, whereas leaving other bacteria behind, and also allows detection of strains of *Arcobacter* more sensitive than most to selective agents. For instance, Atabay and Corry in 1997 were able to recover three species of *Arcobacter*, *A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*, the latter two for the first time, from chicken carcasses using blood agar and this isolation protocol after enrichment. At present, a commercially marketed arcobacter enrichment broth (Oxoid), which incorporates peptone, yeast extract, and sodium chloride and CAT supplement as selective agents, is available. A number of other media and protocols have been devised to recover arcobacters by using different combinations of antibacterial agents and/or incorporating indicators such as color change and swarming on a semisolid medium. For instance, Johnson and Murano in 1999 developed an enrichment and plating medium (JM) to isolate *A. butzleri*, *A. cryaerophilus*, and *A. nitrofigilis* from poultry. They used cefoperazone, thioglycollate, bile salts, and pyruvate in both media. In addition the liquid broth contained 5-fluorouracil., and activated charcoal in enrichment broth and sheep blood in plating agar were used as detoxifying agents. A deep red color around colonies, possibly due to the thioglycollate, was observed with JM plating medium. Houf *et al.* in 2001 described a new liquid and a similar solid medium, both incorporating amphotericin B, cefoperazone, 5-fluorouracil, novobiocin, and trimethoprim as selective agents, with Oxoid arcobacter enrichment broth as basal medium. Their media were less effective for isolating *A. skirrowii* than *A. butzleri* and *A. cryaerophilus* from poultry

samples. The review articles written by Philips in 2001 and Corry *et al.* in 2003 provide more detailed information regarding the isolation media and methods used for arcobacters.

Identification

Arcobacters are not easy to culture, and they are unable to ferment or utilize carbohydrates, so that only a few biochemical tests are available for characterization and speciation, so identification of *Arcobacter* species using phenotypic tests is difficult. In addition, their close resemblance to campylobacters can lead to misidentification in routine laboratories. Catalase activity, indoxyl acetate hydrolysis, cadmium chloride susceptibility, nitrate reduction, α-hemolysis, growth on MacConkey agar and in the presence of 3.5% NaCl and 1% glycine are the most useful tests to differentiate *Arcobacter* spp. phenotypically. Whole-cell protein profiling using sodium dodecyl sulfate polyacryamide gel electrophoresis or whole-cell fatty acid profiling has also been used successfully. In addition, there is a phenotypic identification scheme based on the probabilistic identification of campylobacters and arcobacters, but these are difficult to perform for a routine laboratory and aberrant results can be encountered. Therefore, several nucleic acid-based methods such as multiplex-polymerase chain reaction (PCR), and real-time PCR, 16S rDNA sequencing and microarray techniques can be utilized accurately and definitively for the differentiation of *Arcobacter* to the species level. The primers and oligonucleotide probes used for the identification and detection of arcobacters are mainly based on a part of the 16S rRNA and/or 23S rRNA genes. A species-specific multiplex-PCR assay is widely used, which involves five primers targeting for simultaneous detection and identification of *A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*. Because this m-PCR enables differentiation of only three species of arcobacters, a new 16S rDNA-restriction fragment length polymorphism method has been developed to differentiate the six species of *Arcobacter* of interest in human and/or animal health.

Molecular Detection

Although cultural methods are a well-established way of isolating pure cultures of living bacteria, the methods available for *Arcobacter* spp. are slow and labor-intensive, and not as sensitive as those used, for example, for *Salmonella* spp. Therefore, PCR-based detection–identification of *Arcobacter* spp. is often used after enrichment culture, instead of or as well as selective plating. The current PCR protocols generally target 16S or 23S rDNA sequences.

Two TaqMan-based real-time PCR methods have recently been developed using primer-probe sets developed for the *rpoB/C* and 23S rDNA sequences of *A. butzleri* and *A. cryaerophilus*, respectively. These have been used for detecting arcobacters from environmental samples, without the need for prior enrichment, with a detection sensitivity of 5–7 CFU per reaction. Use of several different real-time PCR assays with different genomic DNA targets will enable the development of better detection–identification schemes for a wider range of *Arcobacter* spp.

Control/Preventive Measures for *Arcobacter* spp.

As previously mentioned, *Arcobacter* spp. are similar to *Campylobacter* spp. except that (like *Salmonella*) they are able to multiply at lower temperatures and in air, and thus might multiply in domestic and catering kitchens, or after cross-contamination onto ready-to-eat foods. Campylobacters sometimes cause outbreaks of infection from contaminated water or milk, and a significant proportion of human cases are linked to contaminated raw poultry. Although arcobacters are common in untreated water and on raw poultry meat, human infection from these sources does not seem to be very common and the authors have very little information concerning any other sources of human infection with *Arcobacter* spp. Consumers probably do not need to be educated specifically with respect to the risks of infection with arcobacters, as they are a relatively rare infection compared to *Campylobacter* and *Salmonella*, and precautions to avoid these two more common infections should be effective against arcobacters.

In general, *Arcobacter* spp. are susceptible to various treatments including heating and food preservatives such as nisin, and lactic and citric acids, although they are somewhat more resistant than *Campylobacter* spp. to freezing, desiccation, irradiation, and disinfectants. Therefore, they do not seem likely either to survive well, or multiply in chilled processed foods. However, some field isolates of *Arcobacter* are resistant to antibiotics commonly used for the treatment of bacterial diseases in humans and animals (e.g., chloramphenicol, vancomycin, methicillin, sulfamethoxazole-trimethoprim, erythromycin, ciprofloxacin, and ampicillin) so *Arcobacter* infections might be difficult to treat.

Bacteria in biofilms or attached to surfaces are well known to be more difficult to inactivate using disinfection or heat than planktonic bacteria. The ability of *Arcobacter* spp. to colonize food processing environments indicates that they are more likely than campylobacters to contaminate foods from this source. For this reason, and their tendency to be resistant to antibiotics, they should not be ignored as possible emerging pathogens.

Research Needs

Reliable, standardized, and optimal methods are required to recover all species of *Arcobacter* including sublethally damaged strains from food, environmental, and clinical samples in addition to faster and more reliable detection methods. Currently few countries monitor human clinical samples for arcobacters, and their significance as human pathogens is not known. More information is needed concerning their antimicrobial resistance mechanisms. Studies concerning their mechanisms of pathogenicity are also needed. In addition, the ecology and epidemiology of *Arcobacter* spp. needs to be elucidated in more detail.

BACTERIA

Bacillus anthracis

L Baillie, Cardiff University, Cardiff, UK
TG Huwar, Battelle, Aberdeen, MD, USA

Glossary

Ascites Excess fluid in the space between the tissues lining the abdomen and abdominal organs (the peritoneal cavity).
Cyanosis Blue or purple coloration of the skin or mucous membranes due to the tissues near the skin surface being low on oxygen.
Dysphagia Difficulty in swallowing.
Dyspnea Difficulty in breathing caused by interactions among multiple physiological, psychological, social, and environmental factors, and may induce secondary physiological and behavioral responses.
Edema A condition of abnormally large fluid volume in the circulatory system or in tissues between the body's cells (interstitial spaces).
Hematemesis Vomiting of blood.
Obligate pathogen An organism that must cause disease in order to be transmitted from one host to another.
Stridor Abnormal, high-pitched, musical breathing sound caused by a blockage in the throat or voice box (larynx).

Background

The bacterium *Bacillus anthracis* is the causative agent of the rapidly lethal zoonotic disease anthrax. Written accounts of anthrax as a scourge of man and livestock date back to the first and second millennium BC. Because of its agricultural impact, *B. anthracis* was the subject of seminal nineteenth-century microbiological studies, enabling Koch to establish his postulates in 1877 by proving *B. anthracis* (named by Cohn in 1875) was the cause of anthrax. Subsequent researchers, such as Greenfield and Pasteur, in the early 1880s demonstrated the feasibility of using attenuated live vaccines to protect livestock, establishing history's second bacterial vaccine. At the turn of twentieth century, Metchnikoff employed *B. anthracis* to characterize the ability of macrophages to kill microbes and helped establish the field of immunology.

Characteristics of Organism

Bacillus anthracis is the only obligate pathogen within the genus *Bacillus*, which is comprised of gram-positive, aerobic or facultatively anaerobic, spore-forming, and rod-shaped bacteria. The ability to form spores accounts for its reported longevity and resistance to physical and chemical disinfectants (Figure 1). Fortunately, spores are susceptible to agents, such as formaldehyde, which have historically been used to decontaminate animal hides.

To initiate infection, spores must undergo germination, a process where they transform from an inactive spore into a biologically active bacterium. The factors that trigger germination are not well characterized, but are influenced by temperature, pH, moisture, and the presence of oxygen and carbon dioxide. *In vitro* studies have demonstrated that *B. anthracis* spores will germinate at 8–45 °C, pH 5–9, relative humidity >95%, and with adequate nutrition. Optimum germination conditions for the Vollum strain of *B. anthracis* have been shown to be 22 °C in the presence of the amino acid L-alanine. Although spores germinate poorly in serum, the process is considerably more efficient within professional phagocytic cells, such as alveolar macrophages. Indeed, studies suggest that exposure to antibacterial free radicals generated within the phagolysosome triggers germination.

The *Bacillus* genus includes the genetically closely related '*Bacillus cereus* group' and comprises *B. cereus*, *B. anthracis*, *Bacillus thuringiensis*, *Bacillus mycoides*, *Bacillus pseudomycoides*, and *Bacillus weihenstephanensis*. *B. anthracis* can be clearly distinguished from the other members at the genetic level by using a range of deoxyribonucleic acid (DNA)-based approaches, including multilocus sequence typing. Although these techniques enable rapid assessment of relationships between large numbers of isolates, it is now economically feasible to determine the complete genetic sequence of a bacterium. Analysis of the genome of *B. anthracis Ames* revealed a 5.23-megabase chromosome with considerable sequence homology to *B. cereus* and *B. thuringiensis*, suggesting a common insect pathogen ancestor, which acquired additional plasmid-borne virulence factors.

The phenotypic diversity within the *B. cereus* group is often mediated by plasmid-encoded factors; and in the case of *B. anthracis*, these consist of two plasmids, pXO1 (182 kb) and pXO2 (96 kb), both encoding major virulence factors. The ability of these virulence plasmids to be transferred to other members of the *B. cereus* group has been reported. An example of this is *B. cereus* G9241, which was isolated from individuals presenting with an infection clinically indistinguishable from inhalational anthrax. Genetic analysis revealed the presence of a

 doi:10.1016/B978-0-12-378612-8.00086-X

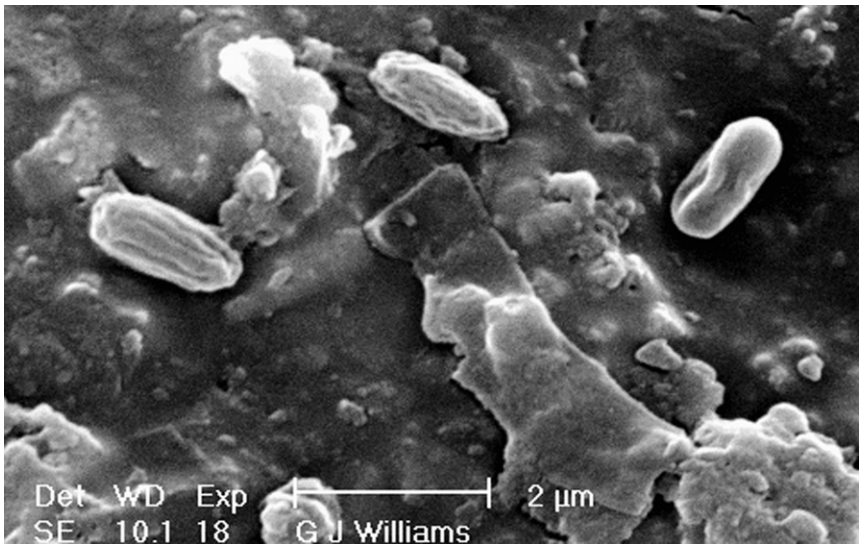

Figure 1 Scanning electron microscopy image of *B. anthracis* spores on a metal surface.

homolog to pXO1 and a second plasmid, which although genetically distinct from pXO2, encoded a phenotypically similar antiphagocytic capsule. Given the central role of virulence plasmids in pathogenicity and their ability to move between closely related strains, we should take care in dismissing all clinical isolates of *B. cereus* as environmental contaminants.

Clinical Manifestations

Although primarily a disease of herbivores, particularly human food animals, the organism can infect humans, frequently with fatal consequences if left untreated. In herbivores, the disease usually follows a hyperacute course in which the signs of illness are absent until shortly before death. At death, the blood of the animal exudes from the nose, mouth, or anus and contains $>10^8$ bacilli per milliliter. It is thought that the release of bacteria from infected animals in the form of resistant spores plays an important role in the infective cycle; the spores contaminate the soil, healthy animals that graze on contaminated land are exposed to the spores and subsequently develop an infection, which leads to the death of the animal and the release of more bacteria.

The institution of mass animal vaccination programs and the maintenance of stringent veterinary control measures have drastically reduced the incidence of the disease in the first-world countries. In other parts of the world, where vaccination is not routinely available, the organism remains a significant cause of animal mortality and human disease.

The sudden death of a food animal in UK would be routinely investigated by veterinary authorities, and, if due to anthrax, the animal and its products would be destroyed. In countries with less well-developed public health systems, the meat of an infected animal may be considered too valuable to 'waste' and subsequently the flesh is likely to be consumed or sold. In Zambia, custom dictates that an animal that dies from unknown causes cannot be disposed of, but must be butchered and shared among relatives and friends to be eaten. Efforts to advise local communities on the dangers of such behavior encounter resistance due to the economic loss caused by burying or burning.

Although most human cases arise as a consequence of contact with contaminated animal products, it should be noted that infections can also occur as a result of illicit activity (i.e., contaminated heroin) and intentional exposure such as the 2001 US anthrax bioterrorist mail attacks. Although both events are extremely rare, the potential use of *B. anthracis* as a biological weapon is a cause for considerable concern.

The disease presents in four forms in humans: cutaneous, injectional, inhalational, and gastrointestinal with meningitis developing as a possible complication. The injected, gastrointestinal tract and inhalational forms are regarded as being most frequently fatal as they can go unrecognized until it is too late to instigate effective treatment.

Of all the forms, cutaneous infection accounts for most human cases ($>95\%$). It is generally believed that *B. anthracis* is noninvasive and thus requires a break in the skin to gain access to the body. Workers who carry contaminated hides or carcasses on their shoulders are liable to infection on the back of their necks and handlers of other food materials or products tend to be infected on the hands, arms, or wrists.

Entry of infecting spores occurs via a lesion in the skin resulting in the formation of a small pimple within 3–5 days, the center of which ulcerates to form a dry, black, firmly adherent scab, surrounded by a ring of vesicles, the typical anthrax eschar. Despite its deadly appearance, there is little pain; pain and pus develop only if there is a secondary infection. Lesions vary greatly in size from approximately 2 cm to several centimeters across and are accompanied by pronounced edema, which can become life threatening if located on the face or neck. In uncomplicated cases, the eschar begins to resolve in approximately 10 days after the appearance of the initial papule; resolution takes 2–6 weeks, regardless of treatment, leaving little trace. Complications arise when the organism spreads to the bloodstream, resulting in an overwhelming infection in approximately 20% of untreated cutaneous cases.

A new clinical form of anthrax (injectional) has been reported in drug users with cases occurring in Norway and UK

due to the injection of contaminated heroin. This novel route of infection presents considerable diagnostic challenges as it results in a clinical picture that differs markedly from that encountered during more traditional infections. In 2009, an outbreak of anthrax occurred amongst heroin users in Scotland, which resulted in 31 cases. The route of transmission in most of these cases was assumed to be through the use of contaminated needles, although smoking and snorting the drug may also have acted as a route of transmission.

The early stages of infection are characterized by a severe, painless, soft tissue focus at the site of injection, which leads to abscess formation. Examination of surgically removed material reveals the presence of capillary bleeding, superficial necrosis, extensive edema, but not fasciolysis and necrotic material along the length of the needle track. Systemic symptoms include sepsis, organ dysfunctions, and shock ultimately leading to death.

In contrast, inhalation anthrax is caused by aerosolized spores produced either during processing of contaminated animal products, such as hides, wool, and hair, or as a consequence of a bioterrorist attack. The illness has an incubation period of 1–6 days, during which nonspecific symptoms of fever, sweats, fatigue, dyspnea, nonproductive cough, and nausea can occur. These symptoms persist for 2 or 3 days; and in some cases, there is a short period of clinical improvement. This is followed by the sudden onset of increasing respiratory distress with dyspnea, stridor, cyanosis, increased chest pain, and sweating. Respiratory distress is typically followed by rapid onset of shock and death within 24–36 h. The recent bioterrorist attack in USA in 2001 resulted in 22 cases of laboratory-confirmed anthrax, half of which were inhalational and resulted in 5 fatalities.

Gastrointestinal anthrax is extremely rare in industrialized countries and occurs mainly in Africa, the Middle East and Central and South Asia. Where the disease is infrequent or rare in livestock, it is hardly seen in humans. Most cases of intestinal anthrax result from eating insufficiently cooked meat from anthrax-infected animals.

Historically, it is estimated that there is one cutaneous case for every 10 infected carcasses butchered and one enteric outbreak for every 30–60 animals eaten. Owing to the rareness of the conditions, there are no figures for the number of organisms that need to be ingested to cause disease. Although usually fatal, there are serological and epidemiological data to suggest that low-grade infection may occur.

There are two clinical forms of gastrointestinal anthrax, which may occur following ingestion of contaminated food or drink:

- Intestinal anthrax: The symptoms include nausea, vomiting, fever, abdominal pain, hematemesis, bloody diarrhea, and massive ascites. Toxemia and shock develop and results in death.
- Oropharyngeal anthrax: The main clinical features are sore throat, dysphagia, fever, regional lymphadenopathy in the neck, and toxemia. Even with treatment, the mortality is approximately 50%.

It is extremely important that effective treatment is started early as the prognosis is often death. Suspicion of the case being anthrax depends greatly on awareness and alertness on the part of the physician to the patient's history and the likelihood that he/she had consumed contaminated food and drink.

Pathogenesis and Virulence Factors

The organism adopts a range of strategies to evade and subvert the immune defenses of the infected individual. The pathogen gains entry to the host as a spore, either as the consequence of some form of trauma or by ingestion or inhalation. Once internalized, the spore is taken up by phagocytic cells, such as macrophages, and germination is triggered by a yet-to-be-determined process. Subsequent growth and replication within the macrophage serves two functions; it neutralizes a key component of the innate immune system and provides a safe environment for the bacteria to increase in numbers. The infected macrophage ultimately lyses to release biologically active bacteria, which go on to establish extracellular infection. The organism is aided in this process by two major virulence factors, a tripartite AB toxin and an antiphagocytic capsule. The toxin encoded on plasmid pXO1 accounts for most of the organism's pathology, whereas the antiphagocytic acid capsule encoded by pXO2 aids the replicating organism in evading uptake by immune effector cells. The loss of either of these plasmids leads to significant attenuation.

Plasmid pXO1 encodes the genes for calmodulin-sensitive adenyl cyclase (*cya*), lethal factor (*lef*), and protective antigen (*pagA*) and the combined products of these genes result in the production of anthrax toxin (ATx). ATx is comprised of three nontoxic proteins; lethal factor (LF, 90 kDa), edema factor (EF, 89 kDa), and protective antigen (PA, 83 kDa), which combine on eukaryotic host cell surfaces to make noncovalent, toxic complexes. ATx follows the AB model with the A moiety composed of two alternative catalytic subunits LF and EF, whereas the B moiety, PA, translocates EF or LF into the cytosol. A schematic representation of ATx endocytosis and cytoplasmic delivery is shown in **Figure 2**.

PA is so named due to its role as the key protective immunogen in the current human vaccines. PA binds to one of at least two identified ubiquitous cell surface receptors; ATx receptor I/tumor endothelial marker 8 (ANTXR1/TEM8) or ATx receptor 2/capillary morphogenesis protein 2 (ANTXR2/CMG2), and to a coreceptor identified as the low-density lipoprotein receptor-related protein 6. On binding, PA is cleaved into two fragments by a cell surface furin-like protease, producing a 20 kDa peptide (PA_{20}) cleaved from the *N*-terminus and the 63 kDa A moiety binding site (PA_{63}). Spontaneous generation of the membrane-inserting ring-shaped heptameric $(PA_{63})_7$ or octameric $(PA_{63})_8$ prepore complex creates binding sites for up to three (heptamer) or four (octamer) molecules of LF and/or EF. Once the prepore has bound LF or EF, creating anthrax lethal toxin (LeTx) or anthrax edema toxin (EdTx), respectively, the complex is endocytosed. The acidic pH of the early endosome triggers major conformational changes, resulting in the formation of the transmembrane structure of the pore. The complex is transported through the early endosome in intraluminal vesicles and delivered to the late endosome. At the low pH of the late endosome ($\sim$pH 5–6), the intraluminal vesicles undergo back

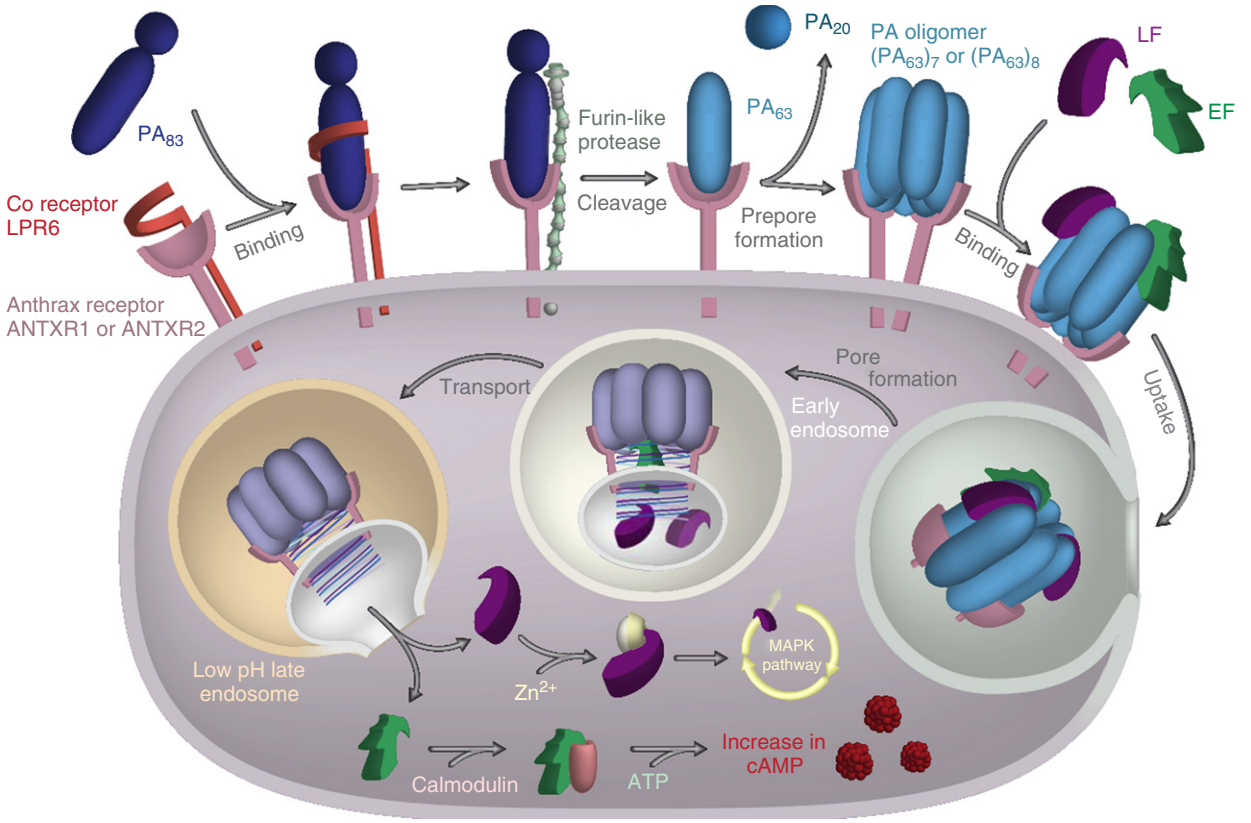

Figure 2 A schematic representation of ATx endocytosis and cytoplasmic delivery.

fusion with the endosomal membrane resulting in translocation of LF and EF, in an unfolded state, through the pore into the cell cytosol, where they catalyze reactions that disrupt the host cell.

LeTx, the combination of LF and PA, is considered to be the central effector of death. LF contains a thermolysin-like active site and zinc-binding consensus motif HExxH, which acts as a Zn^{2+} metalloprotease, specifically cleaving most isoforms of mitogen-activated protein kinase (MAPK) kinases (MEKs). MEKs are functional components of three-component phosphorylation cascades and these signals lead to the upstream activation of MAPKs. The MAPK cascade is essential for full induction of the oxidative burst and proinflammatory cytokine expression, and its disruption by LeTx neutralizes macrophage activation favoring bacterial escape from lymph nodes during the initial phase of infection.

The combination of EF and PA results in EdTx causing edema through elevation of cellular cyclic adenosine monophosphate (cAMP) concentrations in affected tissues. EF is an inactive adenyl cyclase when transported into the target cell by PA. Once located in the cytosol, the binding of calmodulin (a eukaryotic calcium-binding protein) induces conformational transition, which activates the EF adenyl cyclase catalytic site. The activity of EF leads to overproduction of cAMP from adenosine triphosphate (ATP), which in turn leads to various disruptions of cytokine secretion and an increase in ANTXR expression that culminates in an increased rate of toxin internalization. The resulting effects of EdTx are the same as those caused by cholera toxin with the affected cells secreting large amounts of fluid.

The toxins are employed as a means to impair host defense and immunity in the establishment of infection. Almost all cells of the immune system utilize MAPK pathways for proper function and phagocytic cells of the innate immune system, macrophages and neutrophils, are the first line of defense against microbial infection before the induction of the adaptive immune response. LeTx is able to induce the proinflammatory programmed cell death pathway in macrophages and dendritic cells, block neutrophil chemotaxis, and inhibit superoxide and nitric oxide production, thus suppressing the immune response and crippling host defenses. Death resulting from administration of LeTx in murine studies is associated with shock, vascular collapse, and generalized hypoxia, exhibiting some of the symptoms and pathology seen in human inhalational anthrax patients.

Like LeTx, a major role for EdTx appears to be disabling of host defense by impairing the function of phagocytic cells. However, in contrast to LeTx, the overall contribution to the pathological process is ill defined. Increased intracellular cAMP induced by EF or other means inhibits neutrophil chemotaxis, phagocytosis, superoxide production, and microbiocidal activity. Interestingly, intravenous administration of EdTx in murine studies have demonstrated that death occurs at lower doses and with a more rapid onset that with LeTx. EdTx causes widespread tissue damage and multiorgan failure accompanied by hemorrhage and hypotension, features that are also observed in

human patients. These observations support the idea that the two toxins synergistically impair cellular function.

Although toxins play a major role in the virulence of *B. anthracis,* to be fully pathogenic, the infecting strain must also produce a capsule. The structure is composed of a polypeptide (γ-polyglutamic acid (γ-PGA)), which inhibits phagocytosis and opsonization of the bacilli by virtue of its negative charge. The genes controlling capsule synthesis, *capA*, *capB*, and *capC* are organized in an operon (*capBCADE*) located on the plasmid, pXO2. In a murine model of pulmonary anthrax, encapsulation of the bacilli was essential for dissemination from the lungs and for persistence and survival within the host. Virulence appears to be associated with the antiphagocytic properties of the capsule, and degradation of the capsule by γ-PGA depolymerase enhances both *in vitro* macrophage phagocytosis and neutrophil killing. Capsule expression is, in part, subject to regulation by serum, temperature, CO_2, and bicarbonate via an, as yet, unclear mechanism involving the *atxA* and *acpA* genes. These regulators also control the level of expression of the ATx genes.

Bacillus anthracis also expresses a number of other plasmid and chromosome encoded factors that contribute to the overall pathogenesis of the organism. Differential expression of any or all of these 'minor factors' could account for the difference in virulence between wild-type strains. Candidate virulence factors include chromosomally encoded extracellular proteases; phospholipases, such as cereolysin; and S-layer proteins. Interestingly PlcR, a global transcription regulator of a virulence regulon thought to play a major role in insect virulence, is defective in *B. anthracis*, possibly due to the acquisition of pXO1.

Epidemiology

Bacillus anthracis is an organism that is widely distributed around the globe and the mechanism of its continued existence in the ecosystem has been a topic of debate for decades. Currently, it is considered to be an obligate pathogen whose environmental presence is dependent on the continued infection of susceptible animals. During infection episodes, the spore form of the organism is able to persist in the soil in a dormant state for many years.

Although cases of the disease are rare in western countries, relatively high incidence of the disease occurs in sub-Saharan Africa, the Indian subcontinent and Indonesia, certain provinces of China, parts of Turkey, and various countries of the former USSR. The disease was largely eradicated from the western world by the implementation of mass animal vaccination programs, maintenance of stringent veterinary control measures, and an increase in the use of man-made alternatives to animal products. Nevertheless, specialized leather and woolen industries continue to depend on hides and wool from particular species or breeds raised in countries where anthrax is still endemic.

Anthrax epidemics occurring in livestock herds are of the point source type with animals acquiring infection as a consequence of grazing on spore-contaminated soil. Animal-to-animal transmission appears to be a rare event and when it does occur, it is usually a result of contact with contaminated bodily fluid from an infected carcass or dispersion mediated by necrophilic blow flies or hemophagic biting flies. Outbreaks have been linked to environmental changes, particularly flooding, which may result in the redistribution and concentration of anthrax spores in particular areas.

Analytical Methods

Given the scarcity of anthrax in the developed world, it is unlikely that many routine diagnostic laboratories would have the experience, or access to the materials required, to identify the organism correctly. The main problem is the differentiation of *B. anthracis* from the phenotypically similar *B. cereus* or *B. thuringiensis* group, which may also be present in many of the samples examined for anthrax.

Direct detection of the organism in the field is relatively simple in animals that have died suddenly of the disease. At death, the blood of an animal generally contains $>10^8$ bacilli per milliliter. Blood films are dried, fixed immediately by heat or immersion for 1 min in absolute alcohol, and stained with polychrome methylene blue, which after 20 s is washed off. When the slide is dry, it is examined for characteristic deep blue, square-ended bacilli surrounded by a well-demarcated pink capsule (McFadyean's reaction). It should be noted that in some animal species, such as pigs, the terminal bacteremia is limited and the bacilli are unlikely to be seen in McFadyean-stained blood smears.

If available, antibody and DNA-based assays can also be used; these target unique signatures, such as major virulence factors (toxins and capsule), and are considerably more sensitive than staining. Indeed, although a plethora of rapid assays have been developed, which claim to be able to directly detect and confirm the presence of *B. anthracis* in clinical and environmental samples, there has as yet been no independent validation of the veracity of these claims.

The antigen-based methods, which have been developed, focus mainly on detecting the presence of PA. One such immunochromatographic assay based on a specific monoclonal capture antibody can detect as little as 25 ng ml^{-1} of PA and can be performed in a few minutes without the need for special reagents. It has thus been proposed that this test could be used in addition to staining to screen animal blood and tissue and confirm the presence, or absence, of the organism. DNA-based detection based on processes, such as the polymerase chain reaction (PCR) methodologies, has also been used successfully to detect the presence of *B. anthracis* in animal-derived and environmental samples.

The somewhat surprising experience of the 2001 anthrax postal attacks was that traditional culture, although relatively time consuming compared with rapid PCR or antibody-based assays, was more sensitive, required less technical training, and was able to detect viable organisms unlike the other assays.

Indeed, unless there is an index of suspicion, it is unlikely that animal products would be routinely cultured for the presence of *B. anthracis.* In cases where contamination with *B. anthracis* is suspected, the isolation protocol shown in **Figure 3** is conducted. The sensitivity limit of this technique is approximately 5 spores per gram of starting material. It should be borne in mind that the number of bacteria isolated very

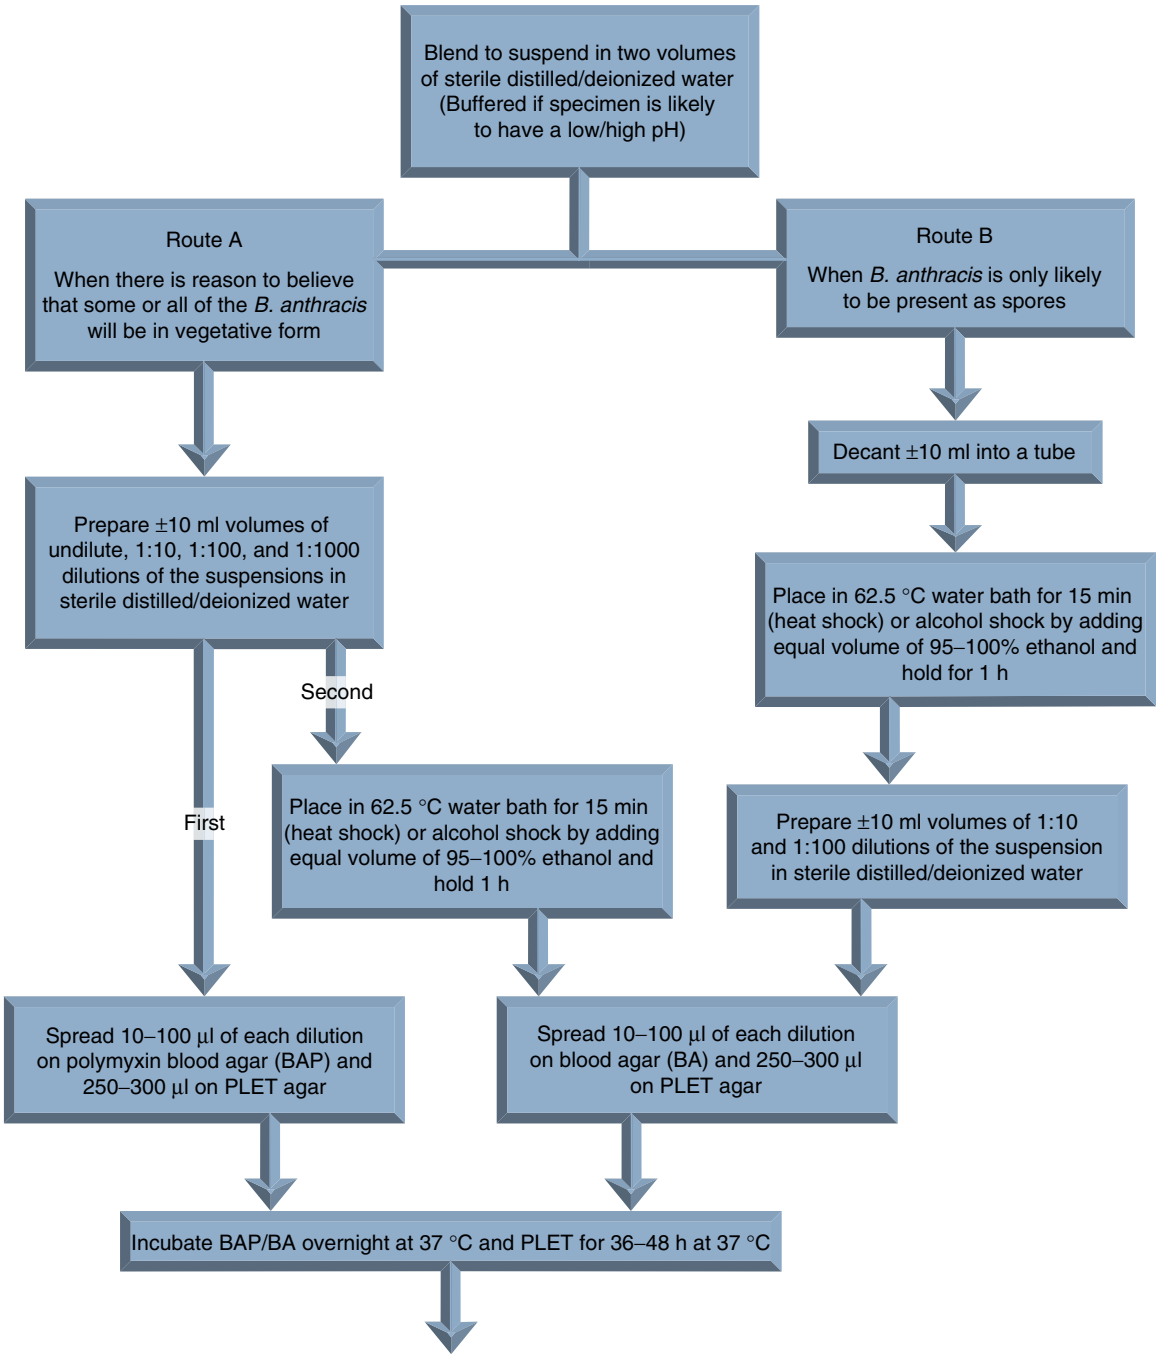

Figure 3 WHO protocol for the isolation of anthrax.

much depends on the distribution of the organism within the sample.

The polymyxin B–lysozyme–ethylenediaminetetraacetic acid (EDTA)–thallous acetate agar (PLET agar) described in the method is a semiselective medium for *B. anthracis*, which contains polymyxin (30 000 units l^{-1}), lysozyme (300 000 units l^{-1}), EDTA (0.3 g l^{-1}), and thallous acetate (0.04 g l^{-1}). The bacterium grows well on a variety of culture media and produces characteristic colonies when grown on sheep blood agar, which appear rough, gray, and nonhemolytic when incubated aerobically and often show a classic 'medusa edge' (Figure 4). When incubated in the presence of 5% CO_2, fully virulent isolates of *B. anthracis* produce mucoid, wet-looking colonies as a consequence of capsule formation. Thus, culture from clinical samples is relatively simple given the ability of the organism to grow on routine laboratory media and the likely absence of other members of the closely related *B. cereus* group, which are ubiquitous in the environment and can be misidentified as *B. anthracis* based on these morphological criteria.

Once colonies have been isolated, further testing is required to confirm their identity. Many saprobic species of

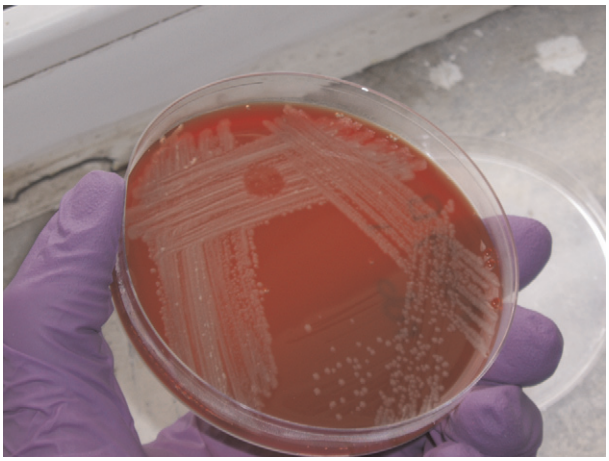

Figure 4 An environmental isolate of *B. anthracis* cultured on a blood agar plate. The zone of inhibition is due to lysis by diagnostic γ-phage.

Table 1 Detection and identification methods for *B. anthracis*

Direct tests
Microscopy (McFadyean's stain)
Antigen detection
PCR
Preliminary tests
Lack of motility
Lack of hemolysis
Sensitivity to diagnostic γ-phage
Sensitivity to penicillin
Commercial biochemical kits: API 50CHB, Biolog
Confirmatory tests (specialist labs)
Virulence in animals – guinea pig
Capsule formation – McFadyean's stain
Toxin detection – immunoassays
Virulence gene detection – PCR

aerobic spore-forming bacilli are hard to distinguish from *B. anthracis* except on the basis of pathogenicity. The most commonly encountered are *B. cereus*, or *B. thuringiensis*, or *B. mycoides*; *Bacillus subtilis*; and *Bacillus licheniformis*.

The preliminary tests shown in Table 1 allow the presumptive identification of an isolate as *B. anthracis*. Commercially available biochemical screening systems such as API 50CHB (bioMerieux, France) and Biolog (Biolog Inc., Hayward, CA, USA) have been developed, which provide a simple, first-line, one-step screen test for the presumptive identification of *B. anthracis*.
